	EM	F_1	EM	F_1	EM	F_1
gold only	65.87	74.67	59.76	90.41	41.54	68.15
distractor	60.88	68.99	30.99	74.67	20.06	52.37
Human	83.60	91.40	61.50	90.04	52.30	82.55
Human UB	96.80	98.77	87.40	97.56	84.60	96.37

Table 8: Comparing baseline model performance with human performance on 1,000 random samples. "Human UB" stands for the upper bound on annotator performance on HOTPOTQA. For details please refer to the main body.

As can be seen in Table 8, the original crowd worker achieves very high performance in both finding supporting facts, and answering the question correctly. If the baseline model were provided with the correct supporting paragraphs to begin with, it achieves parity with the crowd worker in finding supporting facts, but still falls short at finding the actual answer. When distractor paragraphs are present, the performance gap between the baseline model and the crowd worker on both tasks is enlarged to ∼30% for both EM and F_1.

We further establish the upper bound of human performance in HOTPOTQA, by taking the maximum EM and F_1 for each example. Here, we use each Turker's answer in turn as the prediction, and evaluate it against all other workers' answers. As can be seen in Table 8, most of the metrics are close to 100%, illustrating that on most examples, at least a subset of Turkers agree with each other, showing high inter-annotator agreement. We also note that crowd workers agree less on supporting facts, which could reflect that this task is inherently more subjective than answering the question.

6 Related Work

Various recently-proposed large-scale QA datasets can be categorized in four categories.

Single-document datasets. SQuAD (Rajpurkar et al., 2016, 2018) questions that are relatively simple because they usually require no more than one sentence in the paragraph to answer.

Multi-document datasets. TriviaQA (Joshi et al., 2017) and SearchQA (Dunn et al., 2017) contain question answer pairs that are accompanied with more than one document as the context. This further challenges QA systems' ability to accommodate longer contexts. However, since the supporting documents are collected after the question answer pairs with information retrieval, the questions are not guaranteed to involve interesting reasoning between multiple documents.

KB-based multi-hop datasets. Recent datasets like QAngaroo (Welbl et al., 2018) and COMPLEXWEBQUESTIONS (Talmor and Berant, 2018) explore different approaches of using pre-existing knowledge bases (KB) with pre-defined logic rules to generate valid QA pairs, to test QA models' capability of performing multi-hop reasoning. The diversity of questions and answers is largely limited by the fixed KB schemas or logical forms. Furthermore, some of the questions might be answerable by one text sentence due to the incompleteness of KBs.

Free-form answer-generation datasets. MS MARCO (Nguyen et al., 2016) contains 100k user queries from Bing Search with human generated answers. Systems generate free-form answers and are evaluated by automatic metrics such as ROUGE-L and BLEU-1. However, the reliability of these metrics is questionable because they have been shown to correlate poorly with human judgement (Novikova et al., 2017).

7 Conclusions

We present HOTPOTQA, a large-scale question answering dataset aimed at facilitating the development of QA systems capable of performing explainable, multi-hop reasoning over diverse natural language. We also offer a new type of factoid comparison questions to test systems' ability to extract and compare various entity properties in text.

A Data Collection Details

A.1 Data Preprocessing

We downloaded the dump of English Wikipedia of October 1, 2017, and extracted text and hyperlinks with WikiExtractor.[8] We use Stanford CoreNLP 3.8.0 (Manning et al., 2014) for word and sentence tokenization. We use the resulting sentence boundaries for collection of supporting facts, and use token boundaries to check whether Turkers are providing answers that cover spans of entire tokens to avoid nonsensical partial-word answers.

A.2 Further Data Collection Details

Details on Curating Wikipedia Pages. To make sure the sampled candidate paragraph pairs are intuitive for crowd workers to ask high-quality multi-hop questions about, we manually curate 591 categories from the lists of popular pages by WikiProject.[9] For each category, we sample (a, b) pairs from the graph G where b is in the considered category, and manually check whether a multi-hop question can be asked given the pair (a, b). Those categories with a high probability of permitting multi-hop questions are selected.

Bonus Structures. To incentivize crowd workers to produce higher-quality data more efficiently, we follow Yang et al. (2018), and employ bonus structures. We mix two settings in our data collection process. In the first setting, we reward the top (in terms of numbers of examples) workers every 200 examples. In the second setting, the workers get bonuses based on their productivity (measured as the number of examples per hour).

A.3 Crowd Worker Interface

Our crowd worker interface is based on ParlAI (Miller et al., 2017), an open-source project that facilitates the development of dialog systems and data collection with a dialog interface. We adapt ParlAI for collecting question answer pairs by converting the collection workflow into a system-oriented dialog. This allows us to have more control over the turkers input, as well as provide turkers with in-the-loop feedbacks or helpful hints to help Turkers finish the task, and therefore speed up the collection process.

Please see Figure 4 for an example of the worker interface during data collection.

Paragraph A, 2015 Miami Dolphins season:

[1] The 2015 Miami Dolphins season was the franchise's 46th season in the National Football League and the 50th overall. [2] The Dolphins look to improve on their 8-8 record from 2014 and return to the playoffs for the first time in seven seasons. [3] However Miami failed to clinch a playoff berth for the seventh consecutive season after a Week 14 loss to the Giants.

Paragraph B, 2008 Miami Dolphins season:

[4] The 2008 Miami Dolphins season was the organization's 39th season in the National Football League and 43rd overall. [5] During the regular season the Dolphins completed the greatest single-season turnaround in NFL history, going from a 1–15 regular season record in 2007 to an 11–5 record in 2008. [6] The previous record for most improved team one year after a 1–15 season belonged to the 1992 Indianapolis Colts, who went 9–7. [7] The 1999 Indianapolis Colts were the only other team to accomplish a 10-game turnaround, winning 13 games after winning 3 in 1998. [8] Additionally, Miami won the AFC East, becoming the first team in NFL history to win their division after only having one win the previous season.

Please type a question given the two paragraphs above, you have 10 min(s) (**0**/1 examples finished so far).

HINT: Maybe ask a question where the answer is 2008 Miami Dolphins season. It should require pie information from both paragraphs.
Example from Tutorial: Which movie starring Ed Harris is based on a French novel? (Info A: starring Harris, Info B: based on a French novel)

Algorithm 2 Inverted Index Filtering Strategy

```
Input: question text $q$, control threshold $N$, ngram-to-Wikidoc inverted index $\mathcal{D}$
Inintialize:
Extract unigram + bigram set $r_q$ from $q$
$N_{cand} = +\infty$
$C_{gram} = 0$
while $N_{cands} > N$ do
    $C_{gram} = C_{gram} + 1$
    Set $S_{overlap}$ to be an empty dictionary
    for $w \in r_q$ do
        for $d \in \mathcal{D}[w]$ do
            if $d$ not in $S_{overlap}$ then
                $S_{overlap}[d] = 1$
            else
                $S_{overlap}[d] = S_{overlap}[d] + 1$
            end if
        end for
    end for
    $S_{cand} = \emptyset$
    for $d$ in $S_{overlap}$ do
        if $S_{overlap}[d] \geq C_{gram}$ then
            $S_{cand} = S_{cand} \cup \{d\}$
        end if
    end for
    $N_{cands} = |S_{cand}|$
end while
return $S_{cand}$
```

graphs may not be included in the output candidate pool S_{cand}, we set such missing gold paragraph's rank as $|S_{cand}| + 1$ during the evaluation, so MAP and Mean Rank reported in this paper are upper bounds of their true values.

C.2 Compare *train-medium* Split to Hard Ones

Table 9 shows the comparison between *train-medium* split and hard examples like *dev* and *test* under retrieval metrics in full wiki setting. As we can see, the performance gap between *train-medium* split and its *dev*/*test* is close, which implies that *train-medium* split has a similar level of difficulty as hard examples under the full wiki setting in which a retrieval model is necessary as the first processing step.

Set	MAP	Mean Rank	CorAns Rank
train-medium	41.89	288.19	82.76
dev	42.79	304.30	97.93
test	45.92	286.20	74.85

Table 9: Retrieval performance comparison on full wiki setting for *train-medium*, *dev* and *test* with 1,000 random samples each. MAP and are in %. Mean Rank averages over retrieval ranks of two gold paragraphs. CorAns Rank refers to the rank of the gold paragraph containing the answer.

Can a Suit of Armor Conduct Electricity?
A New Dataset for Open Book Question Answering

Abstract

We present a new kind of question answering dataset, OpenBookQA, modeled after open book exams for assessing human understanding of a subject. The open book that comes with our questions is a set of 1326 elementary level science facts. Roughly 6000 questions probe an understanding of these facts and their application to novel situations. This requires combining an open book fact (e.g., metals conduct electricity) with broad common knowledge (e.g., a suit of armor is made of metal) obtained from other sources. While existing QA datasets over documents or knowledge bases, being generally self-contained, focus on linguistic understanding, OpenBookQA probes a deeper understanding of both the topic—in the context of common knowledge—and the language it is expressed in. Human performance on OpenBookQA is close to 92%, but many state-of-the-art pre-trained QA methods perform surprisingly poorly, worse than several simple neural baselines we develop. Our oracle experiments designed to circumvent the knowledge retrieval bottleneck demonstrate the value of both the open book and additional facts. We leave it as a challenge to solve the retrieval problem in this multi-hop setting and to close the large gap to human performance.

1 Introduction

Open book exams are a common mechanism for assessing human understanding of a subject, where test takers are allowed free access to a relevant book, study guide, or class notes when answering questions. In this context, the goal is not to evaluate memorization but a deeper understanding of the material and its application to new situations (Jenkins, 1995; Landsberger, 1996). The application, in turn, often requires combining a fact in the book (e.g., *metals conduct electricity*) with additional common knowledge the test taker is expected to have acquired by this stage (e.g., *a suit of armor is made of metal*).

Question:
Which of these would let the most heat travel through?
A) a new pair of jeans.
B) a steel spoon in a cafeteria.
C) a cotton candy at a store.
D) a calvin klein cotton hat.

Science Fact:
Metal is a thermal conductor.

Common Knowledge:
Steel is made of metal.
Heat travels through a thermal conductor.

Figure 1: An example for a question with a given set of choices and supporting facts.

Motivated by this setting, we present a new kind of question answering dataset, OpenBookQA,[1] that consists of two parts: $\mathcal{Q}$, a set of 5957 multiple-choice questions, and $\mathcal{F}$, a set of 1326 diverse facts about elementary level science. $\mathcal{F}$ has three key characteristics of an 'open book': (a) it forms the basis for generating $\mathcal{Q}$; (b) it has been deemed central to scientific explanations (Jansen et al., 2018); and (c) by itself, $\mathcal{F}$ is generally insufficient to answer questions in $\mathcal{Q}$. Faced with a question $q \in \mathcal{Q}$, a student or system S is expected retrieve a relevant fact $f \in \mathcal{F}$, and appeal to their own common knowledge, $\mathcal{K}_S$, when applying f to answer q.

Figure 1 provides an example. Here, *metals are thermal conductors* is a core scientific fact available in $\mathcal{F}$. One way to apply this fact to decide whether *a steel spoon* would let the *most heat travel through* is to appeal to common knowledge that steel is metallic and heat travels through thermal conductors. In general, the expected common knowledge is relatively simple (taxonomic facts,

---

[1] The dataset and the code for the models are available at `http://data.allenai.org/OpenBookQA`.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2381–2391
Brussels, Belgium, October 31 - November 4, 2018.

definitions, object properties, etc.); the difficulty lies in identifying it and meaningfully combining it with a core fact from $\mathcal{F}$ to answer the question.

OpenBookQA questions are challenging as they require *multi-hop reasoning with partial context* provided by $\mathcal{F}$. Specifically, unlike existing datasets for reading comprehension (RC), answering questions on the back of a textbook (TQA),[2] as well as question answering over structured knowledge-bases (KBQA), the open book $\mathcal{F}$ that comes with OpenBookQA is not self-contained. A successful system must therefore go beyond the typical challenges such as paraphrase matching and coreference resolution, without benefiting from the canonicalized and complete information in KBQA.

Generating interesting open book questions is a difficult task. We used a multi-stage process starting with $\mathcal{F}$, using crowd-sourcing to generate (noisy) questions based on $\mathcal{F}$ that probe novel situations, using an automatic filter to ensure hardness for retrieval and association based systems, using a crowd filter to ensure answerability by a lay person, and further using an expert filter to ensure higher quality in Dev and Test sets.

We evaluate a number of existing QA systems for science (without retraining) on OpenBookQA, finding that they perform surprisingly close to the random guessing baseline of 25%. Human performance, on the other hand, is close to 92%.[3]

Motivated by recent findings of gameability of NLP datasets (Gururangan et al., 2018), we also develop and evaluate simple, attention-based, neural baselines including a *plausible answer detector* (which ignores the question text completely) and an *odd-one-out solver*. These highlight inevitable human bias in any crowdsourced dataset, increasing performance on OpenBookQA to 48%.

Building upon a recent neural model for incorporating external knowledge in the story cloze setting (Mihaylov and Frank, 2018), we propose a knowledge-aware neural baseline that can utilize both the open book $\mathcal{F}$ and common knowledge retrieved from sources such as ConceptNet (Speer et al., 2017). While retrieving the most useful pieces of knowledge remains an open challenge, our 'oracle' experiments with the fact f used while generating a question q and an interpretation (by the question author) of the additional knowledge k needed for q, provides valuable insight into the nature of this dataset: Facts from the open book $\mathcal{F}$ are valuable (5% improvement) but not sufficient. Using both f and k increases the accuracy to 76%, but is still far from human level performance, suggesting the need for non-trivial reasoning to combine these facts.

To encourage further research on this new task, for each Train and Dev question q, OpenBookQA also includes f as intermediate supervision signal, which may be viewed as a partial *explanation* for q. We leave closing the large gap to human performance as a challenge for the NLP community.

2 Related Work

By construction, answering OpenBookQA questions requires (i) some base science facts from a provided 'open book', (ii) broader understanding about the world (common or commonsense knowledge), and (iii) an ability to combine these facts (reasoning). This setup differs from several existing QA tasks, as summarized below.

Reading Comprehension (RC) datasets have been proposed as benchmarks to evaluate the ability of systems to understand a document by answering factoid-style questions over this document. These datasets have taken various forms: multiple-choice (Richardson et al., 2013), cloze-style (Hermann et al., 2015; Onishi et al., 2016; Hill et al., 2016), and span prediction (Rajpurkar et al., 2016; Trischler et al., 2017; Joshi et al., 2017) However, analysis (Chen et al., 2016; Sugawara et al., 2017) of these datasets has shown that many of the questions can be solved with context token matching (Chen et al., 2017a; Weissenborn et al., 2017) or relatively simple paraphrasing.

To focus on the more challenging problem of reasoning across sentences, new datasets have been proposed for multi-step RC. **QAngaroo** (Welbl et al., 2018) have used a knowledge-base to identify entity pairs (s, o) with a known relation, r, which is also supported by a multi-hop path in a set of documents. They use structured tuple queries (s, r, ?) and use all the documents along the path as the input passage. **NarrativeQA** (Kociský et al., 2017) is an RC dataset that has been shown to require an iterative reasoning about the narrative of a story. Similar to OpenBookQA, the questions were generated to ensure that the answer is not a direct match or paraphrase

---

[2] Only ∼5% of the TQA questions of Kembhavi et al. (2017) require additional common knowledge.

[3] To avoid ambiguity in the term 'human performance', Section 3.2 describes the specific randomized model we use.

that can be retrieved with an IR approach. Most recently, Khashabi et al. (2018) proposed **MultiRC**, a multiple-choice RC dataset that is designed to require multi-sentence reasoning and can have multiple correct answers. Again, like most RC datasets, it is self-contained.

Tasks with external knowledge. While many of the RC datasets could benefit from commonsense or background knowledge, they are designed to be self-contained, i.e., solvable by the document context alone. Datasets such as the **Story Cloze Test** (Mostafazadeh et al., 2016), **MCScript**,[4] and **ProPara** (Mishra et al., 2018) do require additional domain knowledge about everyday events, scripts, and processes, respectively. However, these datasets need domain-specific modeling of events, whereas OpenBookQA appeals to broad common knowledge cutting across a variety of types and topics.

Stasaski and Hearst (2017) explore the creation of multi-hop questions and propose generating stronger distractors for the multiple-choice setting. Their work, however, starts with structured knowledge, specifically a Biology ontology.

Lastly, many **Science Question Answering** datasets (e.g. Clark et al., 2016, 2018) have been released that need broad external knowledge to answer the questions. However, these questions are not associated with a core set of facts, i.e., an "open book" used to define these questions. As a result, the questions vary widely in style and complexity (Clark et al., 2018). In contrast, OpenBookQA focuses on a more well-defined subset of science QA, appealing to one core fact from the open book and one (or few) relatively simple commonly known supporting facts.

3 OpenBookQA Dataset

The OpenBookQA dataset consists of about 6,000 4-way multiple-choice questions, each associated with one core fact from a "book" $\mathcal{F}$ of 1326 such facts, and an auxiliary set $\mathcal{K}$ of about 6000 additional facts. The questions were created via a multi-stage crowdsourcing and partial expert filtering process, discussed in Section 3.1.

The small "book" $\mathcal{F}$ consists of recurring science themes and principles, each of which can be (and here is) instantiated into multiple questions. For $\mathcal{F}$, we use a subset of the WorldTree corpus which Jansen et al. (2018) have analyzed for sufficiency for elementary level science. The subset we use is taken from the 2287 WorldTree facts that were marked as "central" by the original authors in at least one explanation. We further filter them down to 1326 that appear general enough to be applicable to multiple situations.

OpenBookQA additionally requires broad common knowledge, which is expected to come from large corpora, such as ConceptNet, Wikipedia, or a corpus with 14M science-related sentences used by some existing baselines. The crowdsourcing process below also asks workers to mark a second fact, k, needed for each question q, in addition to f. These second facts, unfortunately, were often incomplete, over-complete, or only distantly related to q. We thus include in OpenBookQA the set $\mathcal{K}$ of such second facts only as *auxiliary data* for optional use. We emphasize that $\mathcal{K}$ should not be viewed as 'gold' additional facts, or as a substitute for broad common knowledge.

3.1 Crowdsourcing Process

The overall question generation and filtering pipeline is summarized in Figure 2. Given the "book" $\mathcal{F}$ of core facts, the process proceeds as follows, starting with an empty question set Qs and an empty 'second facts' set $\mathcal{K}$:

1. A crowd-worker[5] w is shown a random science fact f from the set $\mathcal{F}$.

2. w is asked to think of a second common fact, k, that may be combined with f to derive a new, valid assertion s.

3. w then converts s into a question-answer pair and extends this into a 4-way multiple choice question by adding 3 incorrect answer choices, $q_{\text{mc}} = (q, \{c_1, c_2, c_3, c_4\})$, where one of the c_i's is the unique correct answer.

4. The system verifies q_{mc} passes basic checks such as uniformity of answer choices.[6]

5. w then feeds the multiple-choice question q_{mc} to an information retrieval solver (Clark et al.,

---

[4] SemEval-2018 Task 11: Machine Comprehension using Commonsense Knowledge `https://competitions.codalab.org/competitions/17184`

[5] We used Amazon Mechnical Turk, with workers from North America and with a 'masters' level qualification.

[6] Specifically, it looks for: 1) exactly 4 answer choices; 2) no negation words to trivially fool baselines (no, none, not, isn't, doesn't, aren't, don't, won't, except, can't, shouldn't, wouldn't, couldn't, mustn't); 3) uniform answer choice length: all with at most 3 or at least 4 words.

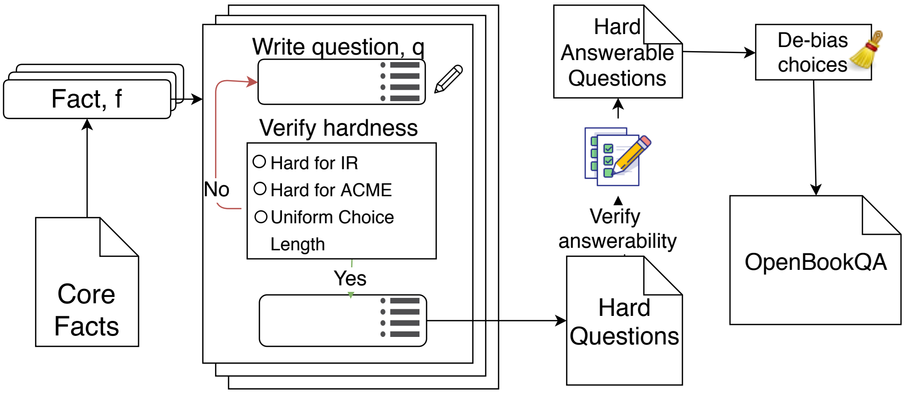

Figure 2: OpenBookQA question generation pipeline

2016) and a word association based solver (Turney, 2017), and verifies that (a) neither of them answers q_{mc} correctly and (b) the top 3 IR retrieved sentences are insufficient to answer q_{mc}; if not, the question is edited and re-tried.

6. Question q_{mc} is then shown to 5 new crowd-workers, who are asked to answer it.

7. If at least 4 out of 5 workers answer q_{mc} correctly, it is deemed answerable and the process continues. If not, q_{mc} is discarded.

8. The answer choices of q_{mc} are randomly shuffled to avoid unintended bias.[7]

9. q_{mc} is associated with f as the core science fact and added to the question set $\mathcal{Q}$. k is added to the set $\mathcal{K}$ of additional (noisy) facts.

The Dev and Test splits were further filtered by an in-house expert to ensure higher quality.

3.2 Human Performance

To assess human accuracy on this dataset, we consider the following model: Each question $q \in \mathcal{Q}$ has some (unknown) human accuracy p_q, defined as the probability that a random human subject, chosen uniformly from a large pool $\mathcal{H}$, would answer q correctly. Thus, we can think of this as defining a Bernoulli random variable, $X_q \sim B(p_q)$, whose mean is (unknown) p_q. The average human accuracy on $\mathcal{Q}$ under this model is:

$$H(\mathcal{Q}) = \frac{1}{|\mathcal{Q}|} \sum_{q \in \mathcal{Q}} p_q$$

where $\{p_q \mid q \in \mathcal{Q}\}$ are unknown.

With $\mathcal{H}$ as the set of crowd-workers (cf. Footnote 5), step 6 of the above question generation process is equivalent to obtaining 5 independent samples, $X_{q,i}, i \in I, |I| = 5$, from $B(p_q)$. We must, however, be careful when using this data to estimate p_q, as the same 5 samples were used to decide whether q makes it into the question set $\mathcal{Q}$ or not. For instance, if we had kept only those questions that all 5 workers answered correctly, it would clearly be inaccurate to claim that the human accuracy on $\mathcal{Q}$ is 100%. Nevertheless, it is possible to re-use the judgments from Step 6 to approximate $H(\mathcal{Q})$ with high confidence, without posing the questions to new workers.

Intuitively, if all questions in $\mathcal{Q}$ were difficult to answer (i.e., all p_q were small), it would be unlikely that all $|\mathcal{Q}|$ questions would pass the test in Step 6. We can use the contrapositive of this observation to conclude that p_q, on average, must have been high for $q \in \mathcal{Q}$.

Formally, aggregating across all questions gives the following empirical estimate of $H(\mathcal{Q})$:

$$\begin{aligned}\tilde{H}(\mathcal{Q}) &= \frac{1}{|\mathcal{Q}|} \sum_{q \in \mathcal{Q}} \frac{1}{|I|} \sum_{i \in I} X_{q,i} \\ &= \frac{1}{|\mathcal{Q}||I|} \sum_{q \in \mathcal{Q}, i \in |I|} X_{q,i}\end{aligned}$$

For analysis, we assume all samples $X_{q,i}$ are independent, i.e., every answer is obtained independently.[8] An application of Hoeffding's Inequality (Hoeffding, 1963) shows that $\tilde{H}(\mathcal{Q})$ converges to $H(\mathcal{Q})$ very rapidly as $n = |\mathcal{Q}||I|$ grows; specifically, $\tilde{H}(\mathcal{Q}) \leq H(\mathcal{Q}) + t$ with probability at least $1 - \exp(-2nt^2)$; similarly for $\tilde{H}(\mathcal{Q}) \geq H(\mathcal{Q}) - t$. In our Dev and Test sets, where $|\mathcal{Q}| = 500$ and $|I| = 5$, this translates into $H(Q)$ being at least

---

[7] Choice 'A' was the correct answer in 69% of the questions at the end of Step 4.

[8] Realistically, there is some dependence across questions as a single worker may answer multiple questions. We leave a formal analysis of this setting as future work.

OpenBookQA Statistics	
# of questions	5957
# of choices per question	4
Avg. question sentences	1.08 (6)
Avg. question tokens	11.46 (76)
Avg. choice tokens	2.89 (23)
Avg. science fact tokens	9.38 (28)
Vocabulary size (q+c)	11855
Vocabulary size (q+c+f)	12839
Answer is the longest choice	1108 (18.6%)
Answer is the shortest choice	216 (3.6%)

Table 1: Statistics for full OpenBookQA dataset. Parenthetical numbers next to each average are the *max*.

$\tilde{H}(Q) - 3\%$ with probability over 98.8% and at least $\tilde{H}(Q) - 2.5\%$ with prob 95.6%; we report the former as our conservative estimate on human performance.

3.3 Question Set Analysis

OpenBookQA consists of 5957 questions, with 4957/500/500 in the Train/Dev/Test splits.[9] Table 1 summarizes some statistics about the full dataset. Each question has exactly four answer choices and one associated fact used in the creation process. We report the average length of questions, candidate choices, and associated facts, as well as how often is the longest/shortest choice the correct one.

We analyzed 100 questions in the Train set to capture the kind of common knowledge and reasoning needed. For each, we wrote down the additional common knowledge needed to answer this question *in addition* to the original science fact. In 21% of the cases, the crowdsourced question actually tests for a fact that doesn't necessarily need the original science fact. For example, the question: "On a rainy day the clouds are (A) low (B) white (C) small (D) gray" was written based on the science fact "clouds produce rain" but doesn't need this fact to answer it. We ignore such questions in our analysis. For the remaining questions, we categorized the additional facts into five high-level categories (and collapsed the remaining facts into a catch-all OTHERS category) based on previous approaches on similar science questions (Clark et al., 2018; Jansen et al., 2016):

1. ISA: Basic taxonomic facts such as isa(tree, living thing), isa(granite, rock).
2. PROPERTY: Properties of objects such as madeof(belt buckle, metal), has(mammals, four legs), contains(lemon juice, citric acid).
3. DEFINITION: Definitions of objects that may be based on their appearance (tape is a plastic with markings), working mechanism (telescope is a device that uses mirrors to view objects), etc.
4. CAUSAL: Causal facts such as causes(adding lemon juice to milk, milk to break down).
5. BASIC: General scientific fact that did not fit above, e.g. squirrels eat nuts for food.

Fact Type	% Questions	% Facts
PROPERTY	29.11%	25.81%
ISA	20.25%	17.20%
BASIC	17.72%	19.35%
DEFINITION	17.72%	15.05%
CAUSAL	11.39%	9.68%
OTHERS	13.92%	12.90%

Table 2: Percentage of questions and facts for the five most common type of additional facts. Note that % Questions does not add up to 100% since we count the percentage of questions where at least one such fact is needed.

Table 2 presents the proportions of these facts in our analyzed question set. For each type of fact, we calculate the percentage of questions that need at least one such fact (shown as % Questions). We also calculate the overall percentage of each fact type across all the common knowledge facts (shown as % Facts). Most of our questions need simple facts such as *isa* knowledge and properties of objects, further confirming the need for simple reasoning with common knowledge. Apart from these five major categories of facts, the catch-all OTHERS category contains commonsense facts (e.g., it is dark at night), world knowledge (e.g., Japan is often hit by earthquakes) and lexical rewrites[10] (e.g., *ad infinitum* means over and over).

Most of our questions need simple facts that should be easily retrievable from any knowledge-base/textual corpora. On an average, each question needed 1.16 additional facts ignoring any linguistic variations. Despite the simplicity of the knowledge needed for these questions, as we show

---

[9] Overall, 8140 questions were collected, of which 2183 were discarded in crowdsourcing Step 7.

[10] Of course, every question had lexical variations. We marked it when this was the *only* change to the core fact.

empirically, most baseline approaches achieve a relatively low score on this dataset (even when the core fact is provided). We claim that this is due to the fact that the reasoning needed to answer these questions is non-trivial. Table 3 shows few questions with the associated facts and high-level reasoning needed to answer these questions. Assuming a model can extract the described relations (e.g. defn, contains), the QA system still needs to be able to chain these facts together, identify the resulting relation and verify its expression for each choice. In the extreme case (as shown in the last example), even though only one additional fact is needed to answer the question, it needs a system to *apply* the core "general" science fact to a "specific" situation.

4 Baseline Models

We evaluate the performance of several baselines systems on the Dev and Test subsets of OpenBookQA. For each question, a solver receives 1 point towards this score if it chooses the correct answer, and $1/k$ if it reports a k-way tie that includes the correct answer. The "Guess All" baseline, which always outputs a 4-way tie, thus achieves a score of 25%, same as the expected performance of a uniform random baseline.

4.1 No Training, External Knowledge Only

Since OpenBookQA is a set of elementary level science questions, one natural baseline category is existing systems that have proven to be effective on elementary- and middle-school level science exams. These pre-trained systems, however, rely only on their background knowledge and do not take the set $\mathcal{F}$ of core facts into account. Further, their knowledge sources and retrieval mechanism are close to those used by the IR solver that, by design, is guaranteed to fail on OpenBookQA. These two aspects place a natural limit on the effectiveness of these solvers on OpenBookQA, despite their excellent fit for the domain of multiple-choice science questions. We consider four such solvers.

PMI (Clark et al., 2016) uses pointwise mutual information (PMI) to score each answer choice using statistics based on a corpus of 280 GB of plain text. It extracts unigrams, bigrams, trigrams, and skip-bigrams from the question q and each answer choice c_i. Each answer choice is scored based on the average PMI across all pairs of question and answer n-grams.

TableILP (Khashabi et al., 2016) is an Integer Linear Programming (ILP) based reasoning system designed for science questions. It operates over semi-structured relational tables of knowledge. It scores each answer choice based on the optimal (as defined by the ILP objective) "support graph" connecting the question to that answer through table rows. The small set of these knowledge tables, however, often results in missing knowledge, making TableILP not answer 24% of the OpenBookQA questions at all.

TupleInference (Khot et al., 2017), also an ILP-based QA system, uses Open IE tuples (Banko et al., 2007) as its semi-structured representation. It builds these subject-verb-object tuples *on-the-fly* by retrieving text for each question from a large corpus. It then defines an ILP program to combine evidence from multiple tuples.

DGEM (Khot et al., 2018) is a neural entailment model that also uses Open IE to produce a semi-structured representation. We use the adaptation of this model to multiple-choice question answering proposed by Clark et al. (2018), which works as follows: (1) convert q and each c_i into a hypothesis, h_i, and each retrieved fact into a premise p_j; and (2) return the answer choice with the highest entailment score, $\arg\max_i e(p_j, h_i)$.

4.2 No Training; $\mathcal{F}$ and Extr. Knowledge

We also consider providing the set $\mathcal{F}$ of core facts to two existing solvers: the **IR** solver of Clark et al. (2016) (to assess how far simple word-overlap can get), and the **TupleInference** solver.

4.3 Trained Models, No Knowledge

We consider several neural baseline models that are trained using Train set of OpenBookQA. For ease of explanation, we first define the notation used in our models. For a given question $q_{\mathrm{mc}} = (q, \{c_1, c_2, c_3, c_4\})$, we define the set of token sequences , $\mathcal{S} = \{q, c_1, c_2, c_3, c_4\}$. For each token sequence $s \in \mathcal{S}$, w^s_j is the j^{th} and $e^s_j = \mathrm{Emb}(w^s_j)$ is the embedding for this token. We use n_s to indicate the number of tokens in s and d for the dimensionality of the embeddings.[11] We model multiple-choice QA as multi-class classification: Given q_{mc}, predict one of four class labels $L =$

---

[11] For all experiments we use $d = 300$ *GloVe* (Pennington et al., 2014) embeddings pre-trained on 840B tokens from *Common Crawl* (https://nlp.stanford.edu/projects/glove/).

Question	Science Fact	Common Knowledge (Type)	Reasoning Challenge
What is the most likely to be an effect of acid rain on an aquatic environment? (A) increase in plant growth (B) increase in fish population **(C) decrease in plant life** (D) cleaner and clearer water	acid rain has a negative impact on water quality	decrease in water quality leads to a decrease in aquatic life (CAUSAL)	causes(x, y) ∧ causes(y, z) ⇒ causes(x, z)
The moon's surface (A) is smooth on the entire surface (B) contains an internal core of cheese (C) is filled with lakes **(D) contains large cavities cause by explosions**	the moon's surface contains many craters	Craters are large cavities caused by explosions (DEFINITION)	contains(x, y) ∧ defn(y, z) ⇒ contains(x, z)
As a car approaches you in the night (A) the headlights remain at a constant (B) the headlights turn off **(C) the headlights become more intense** (D) the headlights recede into the dark	as a source of light becomes closer, that source will appear brighter	Headlights of a car are source of light (PROPERTY)	[lhs ⇒ rhs] ⇒ [ground(lhs) ⇒ ground(rhs)]

Table 3: Example training questions (with their correct choices **marked**) along with the facts and reasoning needed. In the last example, the science fact states that lhs="source of light becomes closer" implies rhs="source will appear brighter". Grounding this rule based on the common-knowledge fact, produces a new rule: "As headlights of the car come closer, headlights will appear brighter"

$\{1, 2, 3, 4\}$, where the true label is the correct answer index.

Embeddings + Similarities as Features. We first experiment with a simple logistic regression model (Mihaylov and Nakov, 2016; Mihaylov and Frank, 2016, 2017) that uses centroid vectors r_s^{emb} of the word embeddings of tokens in s, and then computes the cosine similarities between the question and each answer choice, $r_{q,c_i}^{\cos}$:

$$r_s^{\text{emb}} = \frac{1}{n_s}\sum_{j=1}^{n_s} e_{s_j} \in \mathbb{R}^d$$

$$r_{q,c_i}^{\cos} = \cos(r_q^{\text{emb}}, r_{c_i}^{\text{emb}}) \in \mathbb{R}^1$$

For each training instance, we build a feature representations $\vec{f}$ by concatenating these vectors and train an $L2$ logistic regression classifier:

$$\vec{f} = [r_q^{\text{emb}}; r_{c_{1..4}}^{\text{emb}}; r_{q,c_{1..4}}^{\cos}] \in \mathbb{R}^{5d+4}$$

BiLSTM Max-Out Baselines. As a simple neural baseline, we adapt *BiLSTM max-out* model (Conneau et al., 2017) to our QA task. That is, we first encode the question tokens and choice tokens $w_{1 \ldots n_s}^s$, independently with a bi-directional context encoder (LSTM) to obtain a context (ctx) representation $h_{s_{1\ldots n_s}}^{\text{ctx}} = \text{BiLSTM}(e_{1\ldots n_s}^s) \in \mathbb{R}^{n_s \times 2h}$ Next, we perform an element-wise aggregation operation max on the encoded representations $h_{s_{1..n_s}}^{\text{ctx}}$ to construct a single vector:

$$r_s^{\text{ctx}} = \max(h_{s_{1..n_s}}^{\text{ctx}}) \in \mathbb{R}^{2h}. \qquad (1)$$

Given the contextual representations for each token sequence, we experiment with three configurations for using these representations for QA:

(a) Plausible Answer Detector. This baseline goes to the extreme of completely ignoring q and trying to learn how plausible it is for c_i to be the correct answer to *some* question in this domain. This captures the fact that certain choices like 'a magical place' or 'flying cats' are highly unlikely to be the correct answer to a science question without negation (which is the case for OpenBookQA).

We implement a plausible answer detector using a *choice-only* model for predicting the answer by obtaining a score α_{c_i} as: $\alpha_{c_i} = W_c^T r_{c_i}^{\text{ctx}} \in \mathbb{R}^1$, where $W_c^T \in \mathbb{R}^{2h}$ is a weights vector optimized during training, $i = \{1..4\}$ is the index of the choice. To obtain the answer choice from the set of choice scores $\alpha_{c_{1..4}}$ using $\arg\max(\text{softmax}(\alpha_{c_{1..4}}))$, where $\text{softmax}(\alpha_{c_i}) = \frac{\exp(\alpha_{c_i})}{\sum_{j=1}^{4}\exp(\alpha_{c_j})}$ as usual.

(b) Odd-One-Out Solver. It considers all 4 answer options jointly and selects the one that is least similar to the others. This captures bias in human authored questions arising from the fact that creating good quality incorrect answers is difficult. Workers generally start with the correct answer, and then come up with three incorrect ones. The latter often tend to be homogeneous or share other common properties (e.g., non-scientific terms) uncharacteristic of the correct answer.

We implement this using a *choice-to-choices* attention model. For each choice c_i, we calculate the attention to the other choices as α_{c_i,c_j}. We then sum these attention values to compute the attention for c_i to the rest of the choices, $\alpha_{c_i 2 c_{r(est)}}$, and return the choice with the lowest sum. The attention is computed as $\alpha_{c_i,c_j} = \mathrm{Att}(r^{\mathrm{ctx}}_{c_i}, r^{\mathrm{ctx}}_{c_j})$ where

$$\mathrm{Att}(u, v) = W^T([u; v; u \cdot v; |u - v|]) \in \mathbb{R}^1$$

is a linear attention function and $W \in \mathbb{R}^{8h}$ is a weight vector. We then compute $\alpha_{c_i 2c_{r(est)}} = \sum_{j=1}^{4} \alpha_{c_i,c_j}$ $(j \neq i)$ and select the answer with the index $a_{c2c_r} = \arg\min(\mathrm{softmax}(\alpha_{c_{1..4}2c_r}))$.

(c) Question Match. This solver tries to predict which choice best matches the question (Nakov et al., 2016), without relying on external knowledge. To achieve that, we compute an attention score α_{q,c_i} between q and each of the choices q_i as $\alpha_{q,c_i} = \mathrm{Att}(r^{\mathrm{ctx}}_{q}, r^{\mathrm{ctx}}_{c_i})$, and select the one with the highest score. We also experiment with a model where r^{ctx}_{q} and $r^{\mathrm{ctx}}_{c_i}$ are obtained using token-wise interaction proposed in ESIM (Chen et al., 2017b).

4.4 Trained Model with External Knowledge

Lastly, we implement a two stage model for incorporating external common knowledge, K. The first module performs information retrieval on K to select a fixed size subset of potentially relevant facts $K_{Q,C}$ for each instance in the dataset (see Appendix A). The second module is a neural network that takes (Q, C, $K_{Q,C}$) as input to predict the answer $a_{q,c}$ to a question Q from the set of choices C.

Knowledge-Enhanced Reader. As a base knowledge-aware model, we use a variant of the model of Mihaylov and Frank (2018), implemented by extending our **BiLSTM max-out question-match baseline (c)**. For each instance the model reads the question q and answers $c_{1..4}$ independently and attends to the set of retrieved external knowledge facts $\mathrm{K}_{Q,C}$. We encode each fact k_j from $\mathrm{K}_{Q,C} = k_{1..N_k}$ (N_k is the number of facts) with same BiLSTM as used for q and $c_{1..4}$ and construct a single vector $r^{\mathrm{ctx}}_{k_j} \in \mathbb{R}^{2h}$ using Eq. 1. Having such representations for each k_j results in knowledge memory matrix $M_k = r^{\mathrm{ctx}}_{k_{1..N_k}} \in \mathbb{R}^{N_k \times 2h}$. Note that M_k is dynamic memory, specific for each instance in the batch and is encoded in each step during training. This memory is used to calculate a knowledge-aware representation, $r^{\mathrm{kn}}_{s} = \sum((M_k^T r^{\mathrm{ctx}}_{s}).M_k) \in \mathbb{R}^{2h}$. Each context (ctx) representation r^{ctx}_{s} $(s \in \mathcal{S})$ is combined with r^{kn}_{s} to obtain a knowledge-enhanced representation $r^{\mathrm{ctx+kn}}_{s} = (r^{\mathrm{ctx}}_{s} + r^{\mathrm{kn}}_{s})/2$. We then model the knowledge-enhanced attention $\alpha^{\mathrm{kn}}_{q,c_i}$ between q and c_i as a linear combination of the ctx, kn and ctx + kn representations as

$$\begin{aligned}\alpha_{q,c_i} = W^T[&\mathrm{Att}(r^{\mathrm{ctx}}_{s}, r^{\mathrm{ctx}}_{c_i}); \mathrm{Att}(r^{\mathrm{kn}}_{s}, r^{\mathrm{kn}}_{c_i});\\ &\mathrm{Att}(r^{\mathrm{ctx+kn}}_{s}, r^{\mathrm{ctx}}_{c_i}); \mathrm{Att}(r^{\mathrm{ctx}}_{s}, r^{\mathrm{ctx+kn}}_{c_i});\\ &\mathrm{Att}(r^{\mathrm{ctx}}_{s}, r^{\mathrm{kn}}_{c_i}); \mathrm{Att}(r^{\mathrm{kn}}_{s}, r^{\mathrm{ctx}}_{c_i});\\ &\mathrm{Att}(r^{\mathrm{ctx+kn}}_{s}, r^{\mathrm{kn}}_{c_i}); \mathrm{Att}(r^{\mathrm{kn}}_{s}, r^{\mathrm{ctx+kn}}_{c_i});\\ &\mathrm{Att}(r^{\mathrm{ctx+kn}}_{s}, r^{\mathrm{ctx+kn}}_{c_i})],\end{aligned}$$

where $W \in \mathbb{R}^9$ is a weight vector initialized with the *ones* vector and optimized during training. We then select the answer c_i with the highest score.

Solver	Dev	Test
Human solver	89.3*	91.7*
Guess All ("random")	25.0	25.0

Table 4: Scores obtained by various solvers on OpenBookQA, reported as a percentage ± the standard deviation across 5 runs with different random seeds. Other baselines are described in the corresponding referenced section. For oracle evaluation, we use the gold science fact f associated with each question, and optionally the additional fact k provided by the question author. Bold denotes the best Test score in each category.

5 Baseline Performance

The results for various baseline models are summarized in Table 4, grouped by method category. We make a few observations:

First, the task is **largely solvable by a lay-person**, as evidenced by the 92% score of crowd-workers. This is measured as described in Section 3.2. We use annotations from Step 6 of the question generation process and report $\tilde{H}(Q) - 3\%$ as a conservative lower estimate. As an additional assessment, we also obtained 5 *new* annotations for 100 randomly chosen questions from each of Train, Dev, and Test sets. The performance remained similar at 88.6%, 90.2%, and 91.6%, resp.

The **second group** shows that pre-trained state-of-the-art solvers for multiple-choice science questions perform poorly. One explanation is their correlation with the the IR method used for question filtering, as mentioned in Section 4.1.

The **third group** of results suggests that adding $\mathcal{F}$ to pre-trained models has a mixed effect, improving TupleInference by 8.7% but not changing DGEM.[12] Unlike DGEM, TupleInference relies on brittle word-overlap similarity measures very similar to the ones used by IR. Since IR (KB) gets 0% by design, TupleInference (KB) also has poor performance and adding $\mathcal{F}$ helps it find better support despite the brittle measures.

The **fourth group** demonstrates that carefully designed trainable neural models—even if simplistic and knowledge-free—can be surprisingly powerful. For example, the "plausible answer detector" can predict the correct answer with 49.6% accuracy without even looking at the question. The "odd-one-out" solver, by considering other answer choices, raises this to 50.2%. The "question match" solver, which simply compares the BiLSTM max-out encoding of the question with that of various answer choices, also achieves 50.2%.[13] Similar findings have been reported for several recent datasets (Gururangan et al., 2018), making it imperative to perform such tests early.

Interestingly, all of these neural knowledge-free baselines simultaneously succeed on 34.4% of the Dev questions, and simultaneously fail on 23.6%. For **Question Match** and **ESIM** we also experiment with ElMo (Peters et al., 2018) which improved their score on Test with 0.4% and 1.8%.

The **final group** demonstrates the need for external knowledge and deeper reasoning. When the "oracle" science fact f used by the question author is provided to the knowledge-enhanced reader, it improves over the knowledge-less models by about 5%. However, there is still a large gap, showing that the core fact is insufficient to answer the question. When we also include facts retrieved from WordNet (Miller et al., 1990), the score improves by about 0.5%. Unlike the WordNet gain, adding ConceptNet (Speer et al., 2017) introduces a distraction and reduces the score. This suggests that ConceptNet is either not a good source of knowledge for our task, or only a subset of its relations should be considered. Overall, external knowledge helps, although retrieving the right bits of knowledge remains difficult. In the last row of Table 4, we use the oracle core fact along with question author's interpretation of the additional fact k. This increases the scores substantially, to about 76%. This big jump shows that improved knowledge retrieval should help on this task. At the same time, we are still not close to the human performance level of 92% due to various reasons: (a) the additional fact needed can be subjective, as hinted at by our earlier analysis; (b) the authored facts $\mathcal{K}$ tend to be noisy (incomplete, over-complete, or only distantly related), also as mentioned earlier; and (b) even given the true gold facts, performing reliable "reasoning" to link them properly remains a challenge.

Sample predictions and analysis of questions from Dev are provided in Appendix D.

6 Conclusion

We present a new dataset, OpenBookQA, of about 6000 questions for open book question answering. The task focuses on the challenge of combining a corpus of provided science facts (open book) with external broad common knowledge. We show that this dataset requires simple common knowledge beyond the provided core facts, as well as multi-hop reasoning combining the two. While simple neural methods are able to achieve an accuracy of about 50%, this is still far from the human performance of 92% on this task. We leave closing this gap for future research, and illustrate, via oracle-style experiments, the potential of better retrieval and reasoning on this task.

Acknowledgments

The authors would like to thank Lane Aasen for helping develop the infrastructure for the crowdsourcing task, and Madeleine van Zuylen for providing expert annotation for the Dev and Test questions.

---

[12] By design, IR with its default corpus gets 0% on OpenBookQA. Hence we don't consider the effect of adding $\mathcal{F}$, which appears artificially magnified.

[13] This model also achieves the current best score, 33.87%, on the ARC Reasoning Challenge (Clark et al., 2018). When adapted for the textual entailment task by comparing BiLSTM max-out encodings of premise and hypothesis, it achieves 85% on the SciTail dataset (Khot et al., 2018).

Abstract

We propose a new dataset for evaluating question answering models with respect to their capacity to reason about beliefs. Our tasks are inspired by theory-of-mind experiments that examine whether children are able to reason about the beliefs of others, in particular when those beliefs differ from reality. We evaluate a number of recent neural models with memory augmentation. We find that all fail on our tasks, which require keeping track of inconsistent states of the world; moreover, the models' accuracy decreases notably when random sentences are introduced to the tasks at test.[1]

1 Reasoning About Beliefs

Possessing a capacity similar to human reasoning has been argued to be necessary for the success of artificial intelligence systems (*e.g.*, Levesque et al., 2011). One well-studied domain that requires reasoning is question answering, where simply memorizing and looking up information is often not enough to correctly answer a question. For example, given the very simple scenario in Table 1, searching for the word "Mary" and returning a nearby word is not a correct strategy; instead, a model needs to recognize that Mary is currently at the second location (office and not the bathroom).

Recent research has focused on developing neural models that succeed in such scenarios (Sukhbaatar et al., 2015; Henaff et al., 2017). As a benchmark to evaluate these models, Weston et al. (2016) released a dataset – Facebook bAbi – that provides a set of toy tasks, each examining a specific type of reasoning. For example, the scenario in Table 1 evaluates the capacity to reason using a single supporting fact. However, the bAbi tasks are already too simple for the current models. Only a few years after their release, existing models fail at only one or two (out of 20) tasks (Rae et al., 2016; Santoro et al., 2017). Moreover, all except two of the reasoning tasks in this dataset only require transitive inference (Lee et al., 2016).

Mary went to the bathroom.
John moved to the hallway.
Mary travelled to the office.
Where is Mary? A: office

Table 1: A task from the bAbi dataset (Weston et al., 2016).

People reason not just about their own observations and beliefs but also about others' mental states (such as beliefs and intentions). The capacity to recognize that others can have mental states different than one's own – *theory of mind* – marks an important milestone in the development of children and has been extensively studied by psychologists (for a review, see Flavell, 2004). Artificial intelligence (AI) systems will also require a similar reasoning capacity about mental states as they are expected to be able to interact with people (*e.g.*, Chandrasekaran et al., 2017; Grant et al., 2017; Rabinowitz et al., 2018).

However, the bAbi dataset does not include tasks that evaluate a model's ability to reason about beliefs. Grant et al. (2017) created a bAbi-style dataset inspired by an influential experiment on the theory of mind called the Sally-Anne task (*e.g.* Baron-Cohen et al., 1985). Their goal was to examine whether the end-to-end memory network (Sukhbaatar et al., 2015) can answer questions such as "where does Sally think the milk is?" in situations that Sally's belief about the location of milk does not match the reality. For example, Sally thinks that the milk is in the fridge but the milk is actually on the table.

The dataset of Grant et al. (2017) provides a first step in designing benchmarks to evaluate the mental-state reasoning capacity of question-answering models, but it is still limited in the types of reasoning it probes. For example, it

only considered first-order beliefs (*e.g.*, Sally's belief about the location of milk). People also reason about second-order (and higher-order) beliefs (*e.g.*, Anne's belief about Sally's belief about the location of the milk). More importantly, similarly to the bAbi dataset, success in each task is defined as correctly answering one question. This does not guarantee that a model has an understanding of the state of the world; in fact, even in developmental theory-of-mind experiments, children are asked a few questions (*e.g.*, "where is milk really?") to ensure that their correct answer reflects their understanding and is not simply due to chance.

In this paper, we address these shortcomings by designing a new dataset that enables us to evaluate a model's capacity to reason about different types of beliefs as well as whether it maintains a correct understanding of the world. To this end, we evaluate a number of different models that perform well on the bAbi tasks: the end-to-end memory network (Sukhbaatar et al., 2015), the multiple observer model (Grant et al., 2017), the recurrent entity network (Henaff et al., 2017), and Relation-Network (Santoro et al., 2017). We find that none of these models succeed at our tasks, suggesting that they are not able to keep track of inconsistent states of the world, in particular when someone's belief does not match the history or reality of a situation.

2 Theory of Mind Experiments

Behavioral research shows that children gradually develop a theory of mind (for a review, see Gopnik and Astington, 1988). At the age of two, most children have an understanding of others' desires and perceptions – if someone wants something, they will try to get it and if something is in their sight, they can see it. Children begin to understand others' beliefs around the age of three, but this understanding is still limited. For example, they might not be able to reason that someone's actions are a result of their beliefs. By the age of five, most children have a unified theory of mind and are able to represent and reason about others' desires, perceptions, and beliefs. Developmental psychologists have designed various experimental paradigms to examine to what extent children are able to reason about others' mental states. We use these experiments as guidelines for designing tasks to evaluate the reasoning capacity of question-answering models. We first explain these experiments.

2.1 The Sally-Anne Experiment

The Sally-Anne false-belief experiment, proposed by Baron-Cohen et al. (1985), examines children's ability to reason about others' *false beliefs*, *i.e.*, when someone's belief does not match the reality. In this experiment, the participants observe two agents, Sally and Anne, with their containers, a basket and a box. After putting a marble in her basket, Sally leaves the room (and is not able to observe the events anymore). After Sally's departure, Anne moves the marble to her box. Then, Sally returns to the room (see Figure 1). The participants are asked the following questions:

- "Where will Sally look for her marble?" *(belief question)*
- "Where is the marble really?" *(reality question)*
- "Where was the marble in the beginning?" *(memory question)*

The first question tests the participants' ability to reason about Sally's belief about the location of her marble. Interestingly, most children before the age of 3 answer this question incorrectly and say that Sally will look at the box (where the marble really is) instead of the basket (where Sally thinks the marble is). These children are not able to reason about Sally's belief which is different from the reality of the world. The reality and memory questions are used to confirm that children's correct answer to the belief question is not due to chance; but because they have a correct understanding of the state of world and others' beliefs.

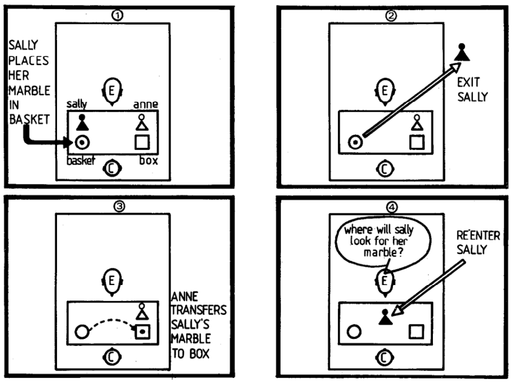

Figure 1: The Sally-Anne experiment setup from Baron-Cohen et al. (1985).

2.2 The Icecream Van Experiment

The Sally-Anne experiment examines the ability to reason about another person's belief or a *first-order belief*. People are also able to reason about beliefs about beliefs, for example, Anne thinks that Sally believes that the marble is in basket. Perner and Wimmer (1985) performed a set of experiments to examine children's reasoning capacity about such higher-order beliefs. In their set-up Mary and John together see an ice cream van in the park, and the icecream man tells them that he will be in the park until later in the afternoon. Mary leaves the park and goes home. A bit after she leaves, the icecream man decides to leave the park and tells John that he is going to the church. On his way to the church he runs into Mary and informs her that he will be selling icecreams close to the church all afternoon. The participants are then asked the following second-order question: "Where does John think Mary goes to get icecream?" Note that John does not know that Mary has been told about the new location of the icecream van; he has a *second-order false belief* about Mary's belief. The participants are also asked a few control questions (*e.g.*, "does Mary know that the van is in the church?") to ensure that they do not correctly answer the second-order question by chance. Perner and Wimmer (1985) found that 6- and 7-year old children are able to answer the second-order questions, suggesting that reasoning about higher-order beliefs (as compared to a first-order belief) is a harder cognitive task.

3 The Theory of Mind Task Dataset

Inspired by the theory-of-mind experiments explained in Section 2 and building on the work of Grant et al. (2017), we created a dataset based on three tasks designed to capture increasingly complex theory-of-mind reasoning: *true-*, *false-*, and *second-order false-belief* tasks. Examples of each task type are given in Figure 2. In the true-belief task, Sally observes the world and as a result she has a first-order *true belief* about the location of the milk – her belief matches reality. In the false-belief task, Sally's first-order belief differs from reality (*i.e.*, she has a *false belief*) because she was absent when the state of the world changed. In the second-order false-belief task, Sally observes the new location of the milk; thus, she has a *true belief* about the milk's location. However, Anne's belief about Sally's mental state does not match reality because Anne does not know that Sally has observed the change in the environment. As a result, Anne has a *false belief* about Sally's beliefs. These tasks are more challenging than the bAbI scenarios, because a model needs to learn whether each agent has a true or false belief about a given world state to succeed, where the world state now includes the mental states of each agent.

Note that we assume all containers are transparent in the underlying world; whenever an agent enters a location, they become aware of the objects true location. We made this decision to keep the tasks as structurally similar as possible. This prevents models from simply learning to produce a specific answer for a task type when a sentence like "Sally looks inside the pantry" is present in the story. The container-transparency property is consistent throughout all task-question pairs.

Question types. To examine the reasoning capacity of each model about beliefs and second-order beliefs, we employ four question types inspired by theory-of-mind experiments discussed in Section 2; see Table 2 for examples of these question types. These questions enable us to test whether a model can reason about first-order and second-order beliefs, and at the same time, knows the initial and current correct location of an object; thus, we can distinguish between when a model answers a question by chance and when it actually understands the entire state of the world.

Table 3 gives the answers for the 12 combinations of task type and question. Given a *true-belief* or *false-belief* task, the answers to the first-order and second-order questions are the same (*e.g.*, "pantry" in the *true-belief* condition and "fridge" in the *false-belief* condition for the tasks in Figure 2). However, they are different in the *second-order false belief* task because Anne has a false belief about Sally's belief.

Dataset variants. We use these tasks to generate two datasets: *ToM* and *ToM-easy*. The primary difference between these two datasets is that, in *ToM-easy*, each story has only one task, while *ToM* can have multiple tasks within a single story. Each dataset contains a training set with 10 000 examples with each of the 12 combinations of task and question types.

In *ToM*, the tasks are randomly grouped into sets of 5 to form stories, which is the same number used in the bAbI dataset. In the test set for *ToM*, each story contains 4 tasks, but there is only one question present at the end. Because questions that come closer to the beginning of a story have

True Belief	**False Belief**	**Second-order False Belief**
Anne entered the kitchen.	Anne entered the kitchen.	Anne entered the kitchen.
Sally entered the kitchen.	Sally entered the kitchen.	Sally entered the kitchen.
The milk is in the fridge.	The milk is in the fridge.	The milk is in the fridge.
Anne moved the milk to the pantry.	*Sally exited the kitchen.*	*Sally exited the kitchen.*
	Anne moved the milk to the pantry.	Anne moved the milk to the pantry.
		Anne exited the kitchen.
		Sally entered the kitchen.

Figure 2: An example story from each of the three task types.

Memory	Where was the milk at the beginning?
Reality	Where is the milk really?
First-order	Where will Sally look for the milk?
Second-order	Where does Anne think that Sally searches for the milk?

Table 2: Examples of the four question types.

	TB	**FB**	**SOFB**
Memory	first	first	first
Reality	second	second	second
First-order	second	first	second
Second-order	second	first	first

Table 3: The correct answer to each question for *true-belief* (TB), *false-belief* (FB), and *second-order false-belief* (SOFB) tasks. Here, “first” and “second” are the initial and actual locations of the object of interest, respectively (*e.g.*, fridge and pantry in Figure 2).

fewer distracting sentences (*i.e.*, potential answer words) that may confound a model, they are easier to answer. We found that this testing procedure gave us a more precise understanding of the performance of the model by separating the difficulty of a question due to its position in a story from the inherent difficulty of the question itself.

Generating the data. Each reasoning task in Weston et al. (2016) can be formalized with a grammar. The training and test data are then the derivations of this grammar. We refer to each derivation as a story (*e.g.*, Figure 2). We follow Grant et al. (2017) in writing grammars for our new tasks. In particular, all the task grammars consist of a set of *entities* (people and objects in the stories) and *predicates* that take entities as subject or object. The grammars also specify the *properties* of entities – which predicates take them as subjects or objects. A predicate can include *actions* that are ways an agent interact with the world (*e.g.*, *place, move, enter, exit*) and *beliefs* that are mental state terms (*e.g.*, *believe, think*). As an example, *Sally* with the property *is agent* can perform the action *displace* on *apple* with the property *is object*. Similar to the previous work, we use a restricted set of *action* and *belief* predicates.

4 The Models

We briefly describe the models that we evaluate in this paper. We chose these models based on the novelty in their architecture or their near state-of-the-art results in the bAbi tasks. More specifically, given 10k examples and joint-training on the bAbi tasks, the best end-to-end memory network (Sukhbaatar et al., 2015) and relation network (Santoro et al., 2017) fail at 6 and 2 tasks, respectively. Given the same training dataset and per-task training, the recurrent entity network succeed at all tasks (but the authors do not report the results of joint-training). Recall that the bAbi tasks are structured as a set of sentences followed by a question about them (*e.g.*, a story from Figure 2 followed by a question from Table 2).

The End-to-End Memory Network. Sukhbaatar et al. (2015) proposed a neural memory-augmented model, the end-to-end memory network (MemN2N), that extends the memory network architecture (Weston et al., 2014). Similarly to its predecessor, MemN2N has a memory component in which sentences are embedded and an attention function that weights the embedded sentences based on their similarity to a given question. The MemN2N model introduces multiple layers of memory (hops) by stacking memory components such that the question embedding at layer $k+1$ is the sum of the output and question embedding of layer k.

The Multiple Observer Model. To perform well on the *false-belief* and *second-order false-belief* conditions, a model needs to identify that agents have experienced different events, and, as a result, have differing knowledge about the state of the world. Although having multiple layers of memory in the MemN2N model enables it to combine attention to different memory slots (*i.e.*, embedded sentences) at each layer, the model does not have access to each agent’s unique perspective. For example, the model is not explicitly told that Sally does not observe the change of the location of the milk in the *false-belief* condition. To address this, Grant et al. (2017) propose the Multiple Observer model that integrates MemN2N with individual memory modules for each agent in the story. An agent's memory only receives the sentences for which the agent is present and observes the world. Their model has an additional attention function that weighs the memory modules based on their relevance to the question. The model is expected to learn to attend to Sally's memory module if the question is about her belief about a state of the world.

The Recurrent Entity Network. Henaff et al. (2017) propose a memory-augmented architecture, EntNet, with two interesting properties; first, their model is a recurrent neural network and thus can capture the sequential nature of the events in a story. Second, instead of keeping a whole sentence embedding in a memory slot, their model can learn the important entities of a story (*e.g.*, a person) and their properties (*e.g.*, location) through a set of gated recurrent units and two weight matrices.

The Relation Network. Santoro et al. (2017) propose a neural model for relational reasoning. Their model consider the possibility of a relation among each two possible pairs of objects. To model the bAbi tasks, they consider each pair of sentences together with the question as inputs to their relation network.

5 Experimental Results

Experiment set-up We train all models jointly over all task types without noise, but evaluate them independently on different task and question pairs. We choose the best-performing models by selecting hyperparameters on the validation set. Similarly to Sukhbaatar et al. (2015), we consider a model successful only when its accuracy exceeds 95% across the entire task suite.

MemN2N and Multiple Observer Models. We first examine how each model performs across a range of parameter and initialization values. MemN2N models are very sensitive to the network initialization and for each set of parameters, the best result out of 10 runs is reported (Sukhbaatar et al., 2015). We first visualize the accuracy of all runs as a box plot to identify how sensitive each model is to random initialization (of parameters and internal states) and thus difficult to train. We also report the results for the best run in each experiment. We use a memory size of 50, the same as experiments of Sukhbaatar et al. (2015), to ensure that the memory contains all sentences of a given story.

EntNet. We report results averaged over 3 initializations because we observed little randomness due to initialization. We selected the learning rate on a held out validation set separately for *ToM-easy* and *ToM*; all otehr the same hyperparameters as Henaff et al. (2017): 20 memory slots and an embedding size of 100 We trained until the training error hit zero, which occurred around 50 epochs for both datasets. .

RelNet. We report results using a single seed because we saw little randomness due to initialization; this is in accordance with the authors' findings (Santoro et al., 2017). We selected model hyperparameters on a held-out validation set separately for each of the *ToM* and *ToM-easy* datasets.

5.1 Overall Performance on *ToM-easy*

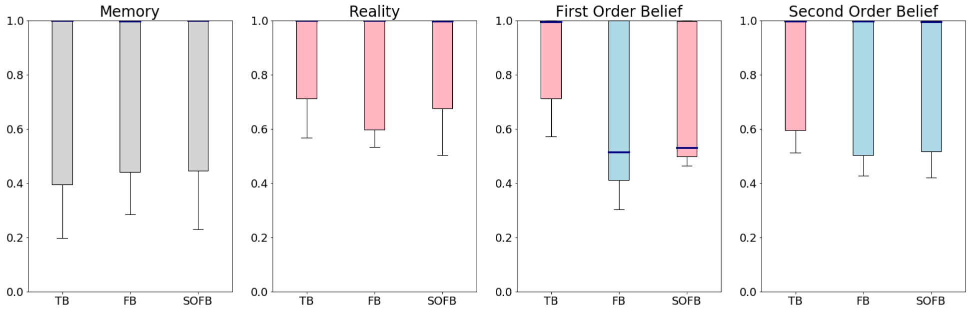
We expect the models perform well on this dataset, given that there is only one task in the memory during both training and test and as a result unrelated events do not interfere with a model's reasoning in this condition.

Despite the large variance in accuracy across runs, the MemN2N models often succeed at the memory, reality, and second-order questions (Figure 3a). Note that the median accuracy (the dark blue line in box) is close to 1 for these questions. However, the model often fails (median accuracy around 0.5) given the first-order question ("where will Sally look for the milk") and the *false-belief* and *second-order false-belief* tasks. This pattern is different from the empirical findings on people; the second-order question is harder than the first order one for people. We observe that the performance of the Multiple Observer model is similar to the MemNet for most question-task pairs (expect one) but there is less variation in the accuracy values. Interestingly, the median accuracy is close to one for the first-order question and the *second-order false-belief* task but the Multiple Observer model still performs poorly for this question on the *false-belief* task.

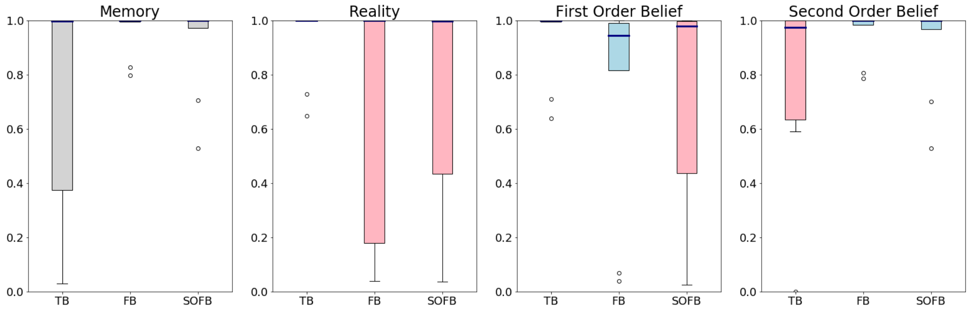
Why is the first-order question harder for the MemN2N model? To investigate this, we look more closely at our task-question pairs. As shown in Table 3, the answers to the first-order question are different for the *false-belief* and *second-order false-belief* tasks but are the same for the

Figure 3: Memory Network and Multiple Observer Model Performance Across Task and Question Types. Pink indicates that the answer to the question is the first container that contained the object in that task. Blue indicates that the answer is the last container that contained the object before the question was asked. Grey indicates that the answer was the first container that contained the object in the entire story which may or may not be the same as the pink.

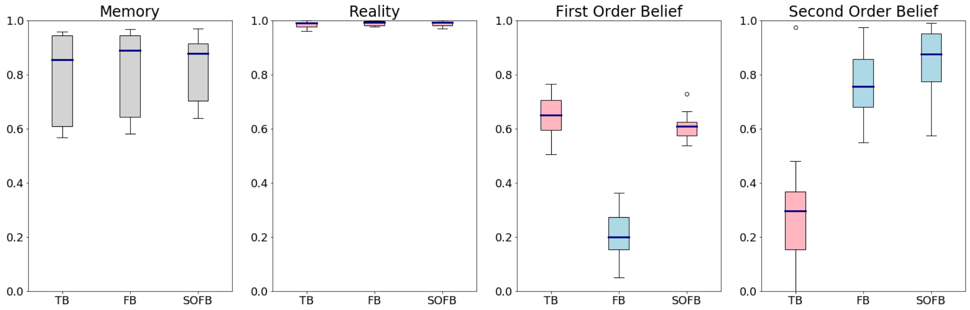
(a) Memory Network with memory size 50 evaluated on the *ToM-easy* dataset.



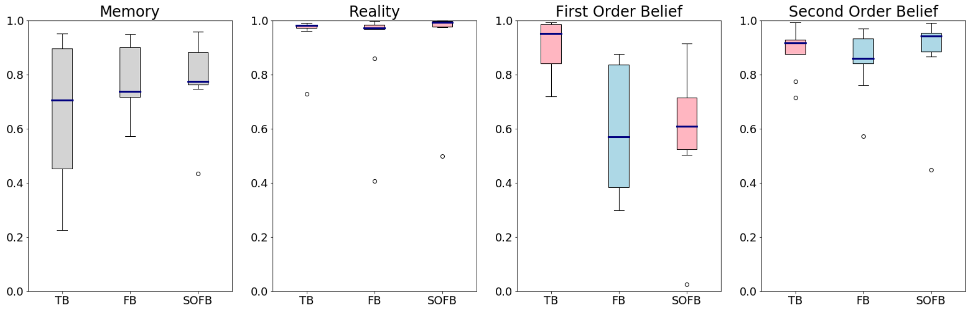
(b) Multiple Observer Model with memory size 50 evaluated on the *ToM-easy* dataset.



(c) Memory Network with memory size 50 evaluated on the *ToM* dataset.



(d) Multiple Observer Model with memory size 50 evaluated on the *ToM* dataset.



second-order one. We suspect that it is harder for the MemN2N model to learn two distinct answers for the same question given the the similarities of the two false-belief tasks. To test this hypothesis, we altered the data such that the answers to first-order question are (incorrectly) the same for both *false-belief* and *second-order false-belief* tasks (and also the second-order question). We observe that the median accuracy is close to 1 for all conditions suggesting that the model can learn the distinction between two of the tasks but not all three.

We observe that EntNet and RelNet models are not too sensitive to the initialization value, and thus just report the result on best-performing models. Both EntNet and RelNet best models succeed at the *ToM-easy* tasks; their mean error is 0.

5.2 Overall Performance on *ToM*

This dataset is more similar to the bAbi dataset in that, during both training and test, the memory contains a story with multiple tasks; as a result, it is harder for the model to identify the entities relevant to a given question.

As shown in Figure 3c, the MemN2N performs worse on all the questions with the exception of the reality question, where performance is slightly worse but has lower variance. (*cf.* the *ToM-easy* dataset). The first- and second-order questions are, overall, harder for the model. The performance of the Multiple Observer model is better for most of the questions (see Figure 3d), especially the second-order, but it is slightly worse for the memory question. This suggests that adding agent-specific memory modules is not enough to succeed on all the *ToM* tasks, and that the increased complexity of inference with multiple memory modules harms performance on another task.

We also look at the best-performing MemN2N and Multiple Observer models over all question-task pairs. These models are selected based on their performance on the validation dataset. We observe that none of these models succeed on the *ToM* tasks, but, interestingly, the Multiple Observer model performs better overall as compared to the original MemN2N model (see Table 4).

***ToM* and bAbi.** How are *ToM* and bAbi tasks similar? The combination of our *true-belief* task and the reality question is very similar to bAbi task 1 (single supporting fact). To correctly answer the reality question ("where is the milk really?", a model need to use a single fact from the story ("Anne moved the milk to the pantry."). The MemN2N model succeeds at both bAbi task 1 and the reality question given the *true-belief* task. However, the correct answer to the memory question ("where was the milk at the beginning?") for the *true-belief* task also requires a single fact ("the milk is in the fridge."). Interestingly, the error of MemN2N on the memory question is much higher than the reality question. The model (unlike people) cannot learn two representations (initial and current location) for an object. This result demonstrates the importance of representing alternative states of the world, whether it be past states of reality (*i.e.*, where the "milk" used to be) or mental states about the world (*i.e.*, where an agent believes the "milk" to be).

EntNet and RelNet. We also report results of two relevant memory-augmented neural network models on our tasks, EntNet (Henaff et al., 2017) and RelNet (Santoro et al., 2017), in Table 4. Again, because we did not observe sensitivity to initialization for these models, only average performance of their best-performing model is reported. We see that even though these models succeed on the *ToM-easy* dataset, they fail on the *ToM* tasks, suggesting that these models cannot simultaneously deal with inconsistent (*i.e.*, past, present, and mental) states of the world.

We further investigate which questions are the hardest for each best model; see Table 5. We observe that each of the MemN2N, Multiple Observer and RelNet models perform poorly on some combination of the first- and second-order questions, but are successful at answering the reality question. We hypothesize that this phenomenon occurs because the reality question is the most similar to the bAbi tasks. In addition, all models fail the memory question for each task type. While this is to be expected for EntNet due to its recurrent nature and therefore bias towards recency, it is surprising that the other models, which exhibit only a small positional bias, cannot correctly represent a past state of the world in order to answer the memory question correctly.

5.3 Experimenting with Noise

We examine to what extent each model's architecture is sensitive to the position of sentences in each story. We do so by adding a novel sentence at random locations in each story at test time. For any setting of the noise, p, there is a $p\%$ probability of a noise sentence occurring before each sentence in the story. Noise sentences cannot follow other noise sentences in the story. In this paper, we report results with $p = .1$. We observe that the accuracy of all best models decreases notably in the

Model	*ToM-easy*	*ToM-easy* (noised)	*ToM*	*ToM* (noised)
MemN2N (Sukhbaatar et al., 2015)	100.00%	90.28%	82.38%	77.00%
Multiple Observer (Grant et al., 2017)	100.00%	**95.81**%	91.11%	87.43%
EntNet (Henaff et al., 2017)	100.00%	94.61%	93.67%	**88.63**%
RelNet (Santoro et al., 2017)	100.00%	87.82%	**94.31**%	76.84%

Table 4: A comparison of model performance. All models succeed on the *ToM-easy* dataset without noise. Multiple Observer model performs best on *ToM-easy* with noise, RelNet performs best on *ToM*, and EntNet performs best on *ToM* with noise.

Model	**True-belief**	**False-belief**	**Second-order False-belief**
MemN2N (Sukhbaatar et al., 2015)	M (94.4); FOB (78.2); SOB (42.9)	M (94.3); FOB (17.3)	M (92.8); FOB (56.4)
Multiple Observer (Grant et al., 2017)	M (93.2)	M (90.5); FOB (56.4); SOB (92.5)	M (93.0); FOB (90.3); SOB (90.3)
EntNet (Henaff et al., 2017)	M (74.0)	M (76.1)	M (74.25)
RelNet (Santoro et al., 2017)	M (39.7%); FOB (71.37%)	M (78.5%)	M (34.9%); FOB (81.8%)

Table 5: Model accuracy on failed questions given the *ToM* task (without noise); M, R, FOB, and SOB are the memory, reality, first- and second-order questions, respectively. The number in the parentheses is the accuracy for that question on that task.

presence of noise (see Table 4). This result is particularly interesting as it shows that none of the models are able to use the semantics of the sentences in a story in their reasoning – they are all sensitive to the presence of distractor sentences.

Interestingly, the RelNet model is the best performer amongst the models we considered on the *ToM* dataset, yet it is also the most sensitive to noise. Moreover, the Multiple Observer model – with explicit memories for each agent – is the most robust to noise; it has the minimum decrease in accuracy between each dataset and its noised version.

5.4 Experimenting with Memory

In the experiments of Sukhbaatar et al. (2015) the memory size is fixed to 50, which is necessary to capture the entire story in memory (e.g. the answer to the memory question in *ToM* may rely on information at the beginning of a story). We observed that smaller memory sizes artificially improved the performance of the MemN2N and Multiple Observer model on *ToM* tasks. For example, using a memory size of 10, our best MemN2N model performance boosts on the hardest task of *ToM* (FB task with first order belief question) from 5.1% to 97.5% and on the easiest task from 98.3% to 100.0% (SOFB task with reality question). This result is not surprising because given a small memory size, *ToM* and *ToM-easy* are very similar tasks; the memory size of 10 allows for at most two full tasks in memory.

6 Related Work

Recent research has emphasized the importance of modeling and understanding people's mental states for AI systems. Eysenbach et al. (2016) created a dataset of scene-description pairs where each scene is a set of visual frames and some frames include people with mistaken beliefs.[2] The authors build a regression model for identifying a mistaken belief and the person who has such a belief in a given frame. Our work differs with theirs in that we are interested in understanding whether a model can reason about people's true and false beliefs to correctly answer questions as opposed to identifying mistaken beliefs.

Grant et al. (2017) studied whether the end-to-end memory network of Sukhbaatar et al. (2015) can pass a false-belief test – correctly answer where Sally would search for an object in false- and true-belief situations. They created a dataset inspired by the bAbi dataset to examine whether the model can reason about interaction of beliefs and actions in these situations – how actions cause beliefs and vice versa. They show that MemN2N fails at the false-belief test, and their extension of that model with separate memories for each agent and an observer outperforms MemN2N.

Rabinowitz et al. (2018) formulate the capacity to reason about others' beliefs as a meta-learning problem. They propose a neural network, ToMnet, that learns to predict the behavior of different agents given their past and current trajectory. Similarly to Grant et al. (2017), in addition to individual agents, they model an "observer" that has access to states and actions of all agents (though this information can be noisy and partial). Interestingly, their model successfully predicts an agent's behavior in a false-belief situation – the agent's behavior reflects its false-belief as opposed to the reality of the world.

Finally, Chandrasekaran et al. (2017) take a dif-

---

[2] For example, a scene where a person gets sick eating mushrooms is paired with the sentence "the couple mistakenly thinks it's ok to eat the mushrooms".

ferent approach by studying whether people can understand the "beliefs" of a visual-question answering system. More specifically, they examine whether the participants can predict when the model would fail in answering a question as well as if they can predict the model's answer. They find that even with a few examples, people get better at answering these questions.

7 Discussion

We propose a dataset for evaluating question-answering models. Our dataset – inspired by seminal theory-of-mind experiments in children – measures to what extent recently introduced neural models can reason about beliefs and states of the world that are potentially mututally inconsistent. We evaluate three of the recent neural question answering models (and an extension of one) on our tasks. We find that none of the models are able to succeed fully on a suite of tasks that requires keeping track of inconsistent beliefs or states of the world. These inconsistencies arise from differences between the past and the present, as well as the mental states of agents who may have false beliefs about the world or about the mental states of other agents.

The purpose of the dataset introduced in this work is not to test advanced language fluency; instead, consistency in the linguistic structure of the tasks allows us to isolate the performance of the models' reasoning capabilities. Even though the language is simple, the models struggle to achieve good performance. Furthermore, we note that the proposed dataset should be treated as a diagnostic tool and that good performance on similar toy tasks is not sufficient for reasoning capabilities.

Abstract

Semantic role labeling (SRL) aims to recognize the predicate-argument structure of a sentence. Syntactic information has been paid a great attention over the role of enhancing SRL. However, the latest advance shows that syntax would not be so important for SRL with the emerging much smaller gap between syntax-aware and syntax-agnostic SRL. To comprehensively explore the role of syntax for SRL task, we extend existing models and propose a unified framework to investigate more effective and more diverse ways of incorporating syntax into sequential neural networks. Exploring the effect of syntactic input quality on SRL performance, we confirm that high-quality syntactic parse could still effectively enhance syntactically-driven SRL. Using empirically optimized integration strategy, we even enlarge the gap between syntax-aware and syntax-agnostic SRL. Our framework achieves state-of-the-art results on CoNLL-2009 benchmarks both for English and Chinese, substantially outperforming all previous models.

1 Introduction

The purpose of semantic role labeling (SRL) is to derive the predicate-argument structure of each predicate in a sentence. A popular formalism to represent the semantic predicate-argument structure is based on dependencies, namely dependency SRL, which annotates the heads of arguments rather than phrasal arguments. Given a sentence (in Figure 1), SRL is generally decomposed into multiple subtasks in pipeline framework, consisting of predicate identification (*makes*), predicate disambiguation (*make.02*), argument identification (e.g., *Someone*) and argument classification (*Someone* is A0 for the predicate *makes*). SRL is beneficial to a wide range of natural language processing (NLP) tasks, including machine translation (Shi et al., 2016) and question answering (Berant et al., 2013; Yih et al., 2016).

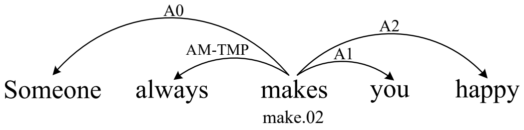

Figure 1: An example of dependency-based SRL.

Most traditional SRL methods rely heavily on feature templates that struggle to capture sufficient discriminative information, while neural models are capable of extracting features automatically. In particular, recent works (Zhou and Xu, 2015; He et al., 2017; Marcheggiani et al., 2017) propose syntax-agnostic models for SRL and achieve favorable results, which seems to be in conflict with the belief that syntactic information is an absolutely necessary prerequisite for high-performance SRL (Gildea and Palmer, 2002). Despite the success of these models, the main reasons for putting syntax aside are two-fold. First, it is still challenging to effectively incorporate syntactic information into neural SRL models, due to the sophisticated tree structure of syntactic relation. Second, the syntactic parsers are unreliable on account of the risk of erroneous syntactic input, which may lead to error propagation and an unsatisfactory SRL performance.

However, syntactic information is considered closely related to semantic relation and plays an essential role in SRL task (Punyakanok et al., 2008). Recently, Marcheggiani and Titov (2017)

proposed a syntactic graph convolutional networks (GCNs) based SRL model and further improved the SRL performance with relatively better syntactic parser as input. Since syntax can provide rich structure and information for SRL, we seek to effectively model complex syntactic tree structure for incorporating syntax into neural SRL.

In this paper, we present a general framework[1] for SRL, which enables us to integrate syntax into SRL in diverse ways. Following Marcheggiani and Titov (2017), we focus on argument labeling and formulate SRL as sequence labeling problem. However, we differ by (1) leveraging enhanced word representation, (2) applying recent advances in recurrent neural networks (RNNs), such as highway connections (Srivastava et al., 2015), (3) using deep encoder with residual connections (He et al., 2016), (4) further extending Syntax Aware Long Short-Term Memory (SA-LSTM) (Qian et al., 2017) for SRL, and (5) introducing the Tree-Structured Long Short-Term Memory (Tree-LSTM) (Tai et al., 2015) to model syntactic information for SRL.

In addition, as pointed out by He et al. (2017) for span SRL, the worse syntactic input will hurt performance if the syntactically-driven SRL model trusts syntactic information too much, and high-quality syntax can still make a large impact on SRL, which motivates us to investigate the effect of syntactic quality on dependency SRL. In summary, our major contributions are as follows:

- We propose a unified neural framework for dependency SRL to more effectively integrate syntactic information with multiple methods.
- Our SRL framework incorporated with syntax achieves the new state-of-the-art results on both English and Chinese CoNLL-2009 benchmarks.
- We explore the impact of different quality of syntactic input on SRL performance, showing that high quality syntactic parse may indeed improve syntax-aware SRL.

2 A Unified SRL Framework

In order to explore the effectiveness of the syntactic feature from various perspectives, we propose a unified neural framework that is capable of optionally accommodating various types of syntactic encoders for syntax-based SRL.

Since the CoNLL-2009 shared task (Hajič et al., 2009) have beforehand indicated the predicate positions, we need to identify and label all arguments for each predicate, which is a typical sequence tagging problem. In this work, we construct a general SRL framework for argument labeling. As shown in Figure 2, our SRL framework includes three main modules, (1) BiLSTM encoder that directly takes sequential inputs, (2) MLP with highway connections for softmax output layer, and (3) an optional syntactic encoder that receives the outputs of the BiLSTM encoder and then let its own outputs integrate with the BiLSTM outputs through residual connections.

Note that when the syntactic encoder is completely removed, MLP only takes inputs directly from the BiLSTM encoder, which let our framework become a syntax-agnostic labeler.

2.1 Sentence Encoder

Word representation Given a sentence and known predicate, we consider predicate-specific word representation, following previous work (Marcheggiani and Titov, 2017). Specifically, each word embedding representation e_i of input sentence is the concatenation of several features, a randomly initialized word embedding e_i^r, a pre-trained word embedding e_i^p, a randomly initialized lemma embedding e_i^l, a randomly initialized POS tag embedding e_i^{pos}, and a predicate-specific feature e_i^f, which is a binary flag set 0 or 1 indicating whether the current word is the given predicate.

To further enhance the word representation, we leverage an external embedding ELMo (Embeddings from Language Models) proposed by Peters et al. (2018). ELMo is obtained by deep bidirectional language model that takes characters as input, enriching subword information and contextual information, which has expressive representation power. Eventually, the resulting word representation is concatenated as $e_i = [e_i^r, e_i^p, e_i^l, e_i^{pos}, e_i^f, \text{ELMo}_i]$.

BiLSTM encoder We use bi-directional Long Short-term Memory neural network (BiLSTM) (Hochreiter and Schmidhuber, 1997) as the sentence encoder to model sequential inputs. Given an input sequence $(e_1, \ldots, e_n)$, the BiLSTM processes these embedding vectors sequentially from both directions to obtain two separated hidden states, $\overrightarrow{h}_i$ and $\overleftarrow{h}_i$ respectively. By concatenating the two states, we get a contextual representation $h_i = [\overrightarrow{h}_i, \overleftarrow{h}_i]$, which will be taken by the next

---

[1] Our code is available here: `https://github.com/bcmi220/unified_syn_srl`.

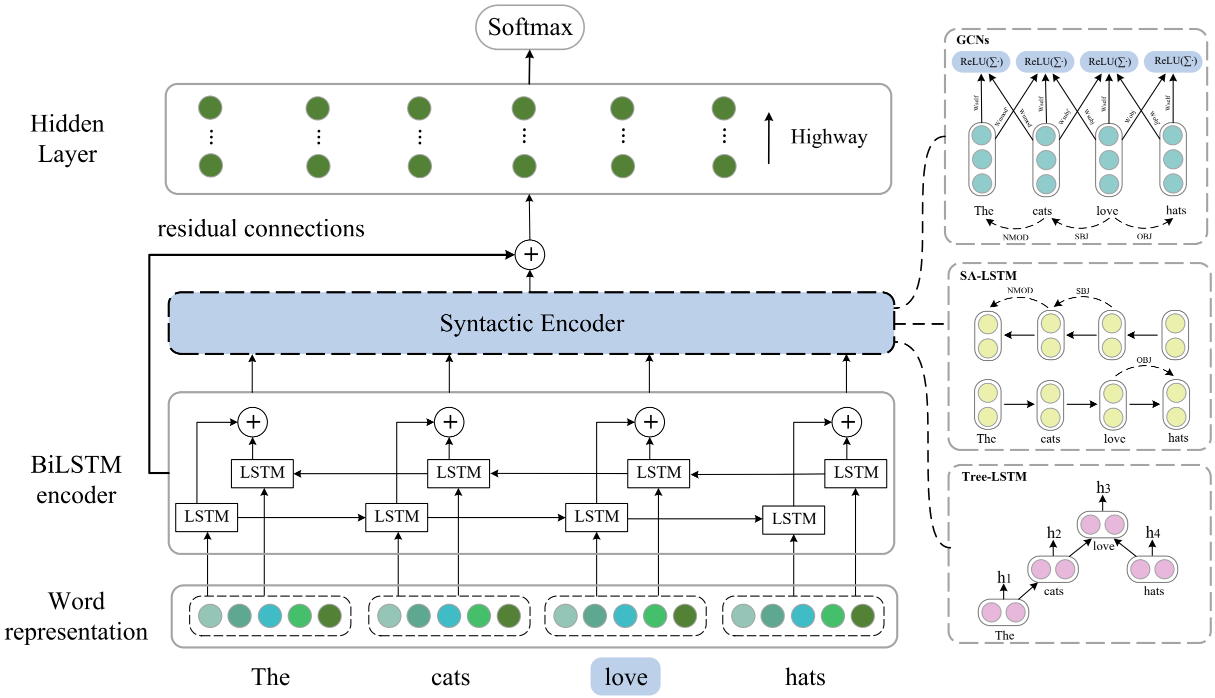

Figure 2: The unified syntax-based SRL framework

BiLSTM layer as input. In this work, we stack four layers of BiLSTM.

2.2 Role Labeler

We adopt a Multi-Layer Perceptron (MLP) with highway connections (Srivastava et al., 2015) on the top of our deep encoder, which takesthe concatenated representation as input. The MLP consists of 10 layers and we employ *ReLU* activations for the hidden layer. To get the final predicted semantic roles, we use a softmax layer over the outputs to maximize the likelihood of labels. The MLP part takes inputs from both the BiLSTM encoder and syntactic encoder, which are joint through a residual connection (He et al., 2016) as shown in Figure 2. It is worth noting that our deep encoder is different from the one of Marcheggiani and Titov (2017), which directly applies a softmax transformation over the syntactic representation and predicts the role label for each word. That is, their syntactic encoder outputs are directly taken as the input of hidden layer.

3 Syntactic Encoder

To integrate the syntactic information into sequential neural networks, we employ a syntactic encoder on top of the BiLSTM encoder.

Specifically, given a syntactic dependency tree T, for each node n_k in T, let $C(k)$ denote the syntactic children set of n_k, $H(k)$ denote the syntactic head of n_k, and $L(k,\cdot)$ be the dependency relation between node n_k and those have a direct arc from or to n_k. Then we formulate the syntactic encoder as a transformation f^{τ} over the node n_k, which may take some of $C(k)$, $H(k)$, or $L(k,\cdot)$ as input, and compute a syntactic representation v_k for node n_k, namely, $v_k = f^{\tau}(C(k), H(k), L(k,\cdot), x_k)$. When not otherwise specified, x_k denotes the input feature representation of n_k which may be either the word representation e_k or the output of BiLSTM h_k, σ denotes the logistic sigmoid function, and $\odot$ denotes the element-wise multiplication.

In practice, the transformation f^{τ} can be any syntax encoding method. In this paper, we will consider three types of syntactic encoders, syntactic graph convolutional network (Syntactic GCN) (in Section 3.1), syntax aware LSTM (SA-LSTM) (in Section 3.2), tree-structured LSTM (Tree-LSTM) (in Section 3.3). Then, we will provide a brief introduction in subsequent subsections.

3.1 Syntactic GCN

GCN (Kipf and Welling, 2017) is proposed to induce the representations of nodes in a graph based on the properties of their neighbors. Given its effectiveness, Marcheggiani and Titov (2017) introduce a generalized version for the SRL task, namely syntactic GCN, and shows that syntactic GCN is effective in incorporating syntactic information into neural models.

Syntactic GCN captures syntactic information flows in two directions, one from heads to dependents (along), the other from dependents to heads (opposite). Besides, it also models the information flows from a node to itself, namely, it assumes that a syntactic graph contains self-loop for each node. Thus, the syntactic GCN transformation of a node n_k is defined on its neighborhood $N(k) = C(k) \cup H(k) \cup \{n_k\}$. For each edge connects n_k and its neighbor n_j, we can compute a vector representation for it,

$$u_{k,j} = W^{dir(k,j)} x_j + b^{L(k,j)},$$

where $dir(k, j)$ denotes the direction type (along, opposite or self-loop) of the edge from n_k to n_j, $W^{dir(k,j)}$ is direction type specific parameter, $b^{L(k,j)}$ is label specific parameter. Considering that syntactic information from all the neighboring nodes may make different contribution to semantic role labeling, syntactic GCN introduces an additional edge-wise gating for each node pair (n_k, n_j) as

$$g_{k,j} = \sigma(W_g^{dir(k,j)} x_k + b_g^{L(k,j)}).$$

The syntactic representation v_k for a node n_k can be then computed as:

$$v_k = \mathit{ReLU}(\sum_{j \in N(k)} g_{k,j} \odot u_{k,j}).$$

3.2 SA-LSTM

SA-LSTM (Qian et al., 2017) is an extension of the standard BiLSTM architecture, which aims to simultaneously encode the syntactic and contextual information for a given word as shown in Figure 2. On one hand, the SA-LSTM calculates the hidden state in sequence timestep order like the standard LSTM,

$$\begin{aligned} i_g &= \sigma(W^{(i)} x_k + U^{(i)} h_{k-1} + b^{(i)}), \\ f_g &= \sigma(W^{(f)} x_k + U^{(f)} h_{k-1} + b^{(f)}), \\ o_g &= \sigma(W^{(o)} x_k + U^{(o)} h_{k-1} + b^{(o)}), \\ u &= f(W^{(u)} x_k + U^{(u)} h_{k-1} + b^{(u)}), \\ c_k &= i_g \odot u + f_g \odot c_{k-1}. \end{aligned}$$

On the other hand, it further incorporates the syntactic information into the representation of each word by introducing an additional gate,

$$\begin{aligned} s_g &= \sigma(W^{(s)} x_k + U^{(s)} h_{k-1} + b^{(s)}), \\ h_k &= o_g \odot f(c_k) + s_g \odot \tilde{h}_k. \end{aligned}$$

where $\tilde{h}_k = f(\sum_{t_j < t_k} \alpha_j \times h_j)$ is the weighted sum of all hidden state vectors h_j which come from previous node (word) n_j, the weight factor α_j is actually a trainable weight related to the dependency relation $L(k, \cdot)$ when there exists a directed edge from n_j to n_k.

Note that $\tilde{h}_k$ is always the hidden state vector of the syntactic head of n_k according to the definition of α_j. Since a word will be assigned a single syntactic head, such a strict constraint prevents the SA-LSTM from incorporating complex syntactic structures. Inspire by the idea of GCN, we relax the directed constraint of α_j, whenever there is an edge between n_j and n_k.

After the SA-LSTM transformation, the outputs of the SA-LSTM layer from both directions are concatenated and taken as the syntactic representation of each word n_k, i.e., $v_k = [\overrightarrow{h_k}, \overleftarrow{h_k}]$. Different from the syntactic GCN, SA-LSTM encoding both syntactic and contextual information in a single vector v_k.

3.3 Tree-LSTM

Tree-LSTM (Tai et al., 2015) can be considered as an extension of the standard LSTM, which aims to model the tree-structured topologies. At each timestep, it composes an input vector and the hidden states from arbitrarily many child units. Specifically, the main difference between Tree-LSTM unit and the standard one is that the memory cell updating and the calculation of gating vectors are depended on multiple child units. A Tree-LSTM unit can be connected to arbitrary number of child units and assigns a single forget gate for each child unit. This provides Tree-LSTM the flexibility to incorporate or drop the information from each child unit.

Given a syntactic tree, the Tree-LSTM transformation is defined on node n_k and its children set $C(k)$, which can be formulated as follows (Tai et al., 2015):

$$\tilde{h}_k = \sum_{j \in C(k)} h_k, \tag{1}$$

$$\begin{aligned} i_g &= \sigma(W^{(i)} x_k + U^{(i)} \tilde{h}_k + b^{(i)}), \\ f_g^{k,j} &= \sigma(W^{(f)} x_k + U^{(f)} h_j + b^{(f)}), \\ o_g &= \sigma(W^{(o)} x_k + U^{(o)} \tilde{h}_k + b^{(o)}), \\ u &= \tanh(W^{(u)} x_k + U^{(u)} \tilde{h}_k + b^{(u)}), \\ c_k &= i_g \odot u + \sum_{j \in C(k)} f_g^{k,j} \odot c_j, \\ h_k &= o_g \odot \tanh(c_k). \end{aligned} \tag{2}$$

where $j \in C(k)$, h_j is the hidden state of the j-th child node, c_k is the memory cell of the head node k, and h_k is the hidden state of node k. Note that in Eq.(2), a single forget gate $f_g^{k,j}$ is computed for each hidden state h_j.

However, the primitive form of Tree-LSTM does not take the dependency relations into consideration. Given the importance of dependency relations in SRL task, we further extend the Tree-LSTM by adding an additional gate r_g and reformulate the Eq. (1),

$$\begin{aligned} r_g^{k,j} &= \sigma(W^{(r)} x_k + U^{(r)} h_j + b^{L(k,j)}), \\ \tilde{h}_k &= \sum_{j \in C(k)} r_g^{k,j} \odot h_j. \end{aligned}$$

where $b^{L(k,j)}$ is a relation label specific bias term. After the Tree-LSTM transformation, the hidden state of each node in dependency tree is taken as its syntactic representation, i.e., $v_k = h_k$.

4 Experiments

We evaluate our models performance of syntactic GCN (henceforth Syn-GCN), SA-LSTM and Tree-LSTM on CoNLL-2009 datasets both for English and Chinese with standard training, development and test splits. For predicate disambiguation, we follow previous work (Marcheggiani and Titov, 2017), using the off-the-shelf disambiguator from Roth and Lapata (2016). For syntactic dependency tree, we parse the corpus with Biaffine Parser (Dozat and Manning, 2017).

4.1 Experimental Settings

In our experiments, the pre-trained word embeddings for English are 100-dimensional GloVe vectors (Pennington et al., 2014). For Chinese, we exploit Wikipedia documents to train the same dimensional Word2Vec embeddings (Mikolov et al., 2013). All other vectors are randomly initialized, the dimension of lemma embeddings is 100, and the dimension of POS tag embedding is 32. In addition, we use 300-dimensional ELMo embedding for English[2].

Table 1: Results on the English in-domain test set.

During training, we use the categorical cross-entropy as objective, with Adam optimizer (Kingma and Ba, 2015) the learning rate 0.001, and the batch size is set to 64. The BiLSTM encoder consists of 4-layer BiLSTM with 512-dimensional hidden units. We apply dropout for BiLSTM with a 90% keeping probability between time-steps and layers. We train models for a maximum of 20 epochs and obtain the nearly best model based on English development results.

4.2 Results

We compare our models of Syn-GCN, SA-LSTM and Tree-LSTM with previous approaches for dependency SRL on both English and Chinese. Noteworthily, our model is local (argument identification and classification decisions are conditionally independent) and single without reranking, which neither includes global inference nor com-

---

[2] For Chinese, we do not use pre-trained ELMo whose weights are only available for English.

Table 2: Results on the Chinese test set.

bines multiple models. The experimental results on the in-domain English and Chinese test sets are summarized in Tables 1 and 2, respectively.

For English, our models of Syn-GCN, SA-LSTM and Tree-LSTM overwhelmingly surpass most previously published single models, achieving state-of-the-art results of 89.8%, 89.7% and 89.4% in F_1 scores respectively. In comparison to ensemble models, our Syn-GCN even performs better than the previous model (Marcheggiani and Titov, 2017) with a margin of 0.7% F_1.

From Table 1, we also see that our Syn-GCN model provides the best recall and F_1 score, while our SA-LSTM model yields the competitive performance with higher precision at the expense of recall, which shows that SA-LSTM is better at classifying arguments. Overall, the Tree-LSTM gives slightly weaker performance, which may be attributed to tree-structured network topology. More specifically, Tree-LSTM only considers information from arbitrary child units so that each node lacks of the information from parent. However, our Syn-GCN and SA-LSTM combine bidirectional information, both head-to-dependent and dependent-to-head.

For Chinese (Table 2), even though we use the same parameters as for English, our models are still comparable with the best reported results.

Table 3 presents the results on English out-of-domain test set. Our models outperform the highest records achieved by He et al. (2018), with absolute improvements of 0.2-0.5% in F_1 scores. These favorable results on both in-domain and out-of-domain data demonstrate the effectiveness and robustness of our proposed unified framework.

4.3 Ablation and Analysis

To investigate the contributions of word representation and deep encoder in our method, we conduct a series of ablation studies on the English development set, unless otherwise stated.

Effect of word representation In order to better understand how the enhanced word representation influences our model performance, we train our Syn-GCN model with different settings in input word embeddings. Table 4 shows results for our system when we remove POS tag and ELMo embedding respectively. Interestingly, the impact of POS tag embedding (about 0.4% F_1) is less compared to the previous works, which allows us to build an accuracy model even when the POS tag is unavailable. We also observe that effect of ELMo embedding is somewhat surprising (1.2% F_1 performance degradation). Experimental results indicate that a combination of these features could enhance the word representation, leading to SRL performance improvement.

System	syntax-agnostic	syntax-aware	Δ F$_1$
M&T (2017)	87.7	88.0	0.3
He et al. (2018)	88.7	89.5	0.8
Cai et al. (2018)	89.6	89.6	$\approx$0.0
Our model	88.7	89.8	1.1

Table 5: Comparison of our Syn-GCN model with (Marcheggiani and Titov, 2017), (He et al., 2018) and (Cai et al., 2018) on the English test set. Δ F$_1$ shows the absolute performance gap between syntax-agnostic and syntax-aware settings.

Effect of deep encoder Table 5 reports F$_1$ scores of our Syn-GCN model, Marcheggiani and Titov (2017), He et al. (2018) and Cai et al. (2018) on English test set in both syntax-agnostic and syntax-aware settings. The comparison shows that our framework is more effective for incorporating syntactic information by giving more performance improvement through introducing syntax over syntax-agnostic SRL than previous state-of-the-art systems did.

To further investigate the impact of deep encoder, we perform our Syn-GCN, SA-LSTM and Tree-LSTM models with another alternative configuration, using the same encoder as (Marcheggiani and Titov, 2017) (M&T encoder for short), which removes the residual connections from our framework. The corresponding results of our models are also summarized in Table 6 for comparison. Note that the first row is the results of our syntax-agnostic model. Surprisingly, we observe a dramatical performance decline of 1.2% F$_1$ for our Syn-GCN model with M&T encoder. A less significant performance loss for our SA-LSTM (-0.4%) and Tree-LSTM (-0.5%) models shows that the Syn-GCN is more sensitive to contextual information. Nevertheless, the overall results show that applying deep encoder could receive higher gains.

4.4 Syntactic Role

As mentioned before, syntactic parsers are unreliable due to the risk of erroneous syntactic input, especially on out-of-domain data. This section thus attempts to explore the impact of different quality of syntactic input on SRL performance. To this end, we further carry out experiments on English test data with different syntactic inputs based on our Syn-GCN model.

Our system	P	R	F$_1$
Baseline (syntax-agnostic)	89.5	87.9	88.7
Syn-GCN	90.3	89.3	**89.8**
SA-LSTM	90.8	88.6	89.7
Tree-LSTM	90.0	88.8	89.4
Syn-GCN (M&T encoder)	89.2	88.0	88.6
SA-LSTM (M&T encoder)	89.8	88.8	**89.3**
Tree-LSTM (M&T encoder)	90.0	87.8	88.9

Table 6: Comparison of models with deep encoder and M&T encoder (Marcheggiani and Titov, 2017) on the English test set.

Syntactic Input

Four types of syntactic inputs are used to explore the role of syntax in our unified framework, (1) the automatically predicted parse provided by CoNLL-2009 shared task, (2) the parsing results of the CoNLL-2009 data by state-of-the-art syntactic parser, the Biaffine Parser (used in our previous experiments), (3) corresponding results from another parser, the BIST Parser (Kiperwasser and Goldberg, 2016), which is also adopted by Marcheggiani and Titov (2017), (4) the gold syntax available from the official data set.

Evaluation Metric

It is worth noting that for SRL task, the standard evaluation metric is the semantic labeled F$_1$ score (Sem-F$_1$), and we use the labeled attachment score (LAS) to quantify the quality of syntactic input. In addition, the ratio between labeled F$_1$ score for semantic dependencies and the LAS for syntactic dependencies (Sem-F$_1$/LAS) proposed by CoNLL-2008 shared task[3] (Surdeanu et al., 2008), are also given for reference. To a certain extent, the ratio Sem-F$_1$/LAS could normalize the semantic score relative to syntactic parse, impartially estimating the true performance of SRL, independent of the performance of the input syntactic parser.

Comparison and Discussion

Table 7 presents the comprehensive results of our Syn-GCN model on the four syntactic inputs aforementioned of different quality together with previous SRL models. A number of observations can be made from these results. First, our model gives quite stable SRL performance no matter the syntactic input quality varies in a broad range, ob-

---

[3] CoNLL-2008 is an English-only task, while CoNLL-2009 extends to a multilingual one. Their main difference is that predicates have been pre-identified for the latter.

System	LAS	P	R	Sem-F_1	Sem-F_1/LAS
Zhao et al. (2009c) [SRL-only]	86.0	–	–	85.4	99.3
Zhao et al. (2009a) [Joint]	89.2	–	–	86.2	96.6

He et al. (2018) [Gold syntax]	100	91.0	89.7	90.3	90.3
Our Syn-GCN (CoNLL-2009 predicted)	86.0	90.5	88.5	89.5	104.07
Our Syn-GCN (Biaffine Parser)	90.22	90.3	89.3	89.8	99.53
Our Syn-GCN (BIST Parser)	90.05	90.3	89.1	89.7	99.61
Our Syn-GCN (Gold syntax)	100.0	91.0	90.0	90.5	90.50

Table 7: Results on English test set, in terms of labeled attachment score for syntactic dependencies (LAS), semantic precision (P), semantic recall (R), semantic labeled F_1 score (Sem-F_1), the ratio Sem-F_1/LAS. All numbers are in percent. A superscript * indicates LAS results from our personal communication with the authors.

taining overall higher scores compared to previous state-of-the-arts. Second, It is interesting to note that the Sem-F_1/LAS score of our model becomes relatively smaller as the syntactic input becomes better. Though not so surprised, these results show that our SRL component is even relatively stronger. Third, when we adopt a syntactic parser with higher parsing accuracy, our SRL system will achieve a better performance. Notably, our model yields a Sem-F_1 of 90.5% taking gold syntax as input. It suggests that high-quality syntactic parse may indeed enhance SRL, which is consistent with the conclusion in (He et al., 2017).

5 Related Work

Semantic role labeling was pioneered by Gildea and Jurafsky (2002), also known as shallow semantic parsing. In early works of SRL, considerable attention has been paid to feature engineering (Pradhan et al., 2005; Zhao and Kit, 2008; Zhao et al., 2009a,b,c; Li et al., 2009; Björkelund et al., 2009; Zhao et al., 2013). Along with the the impressive success of deep neural networks (Zhang et al., 2016; Cai and Zhao, 2016; Qin et al., 2016; Wang et al., 2016b,a; Zhang et al., 2018; Li et al., 2018; Huang et al., 2018), a series of neural SRL systems have been proposed. For instance, Foland and Martin (2015) presented a semantic role labeler using convolutional and time-domain neural networks. FitzGerald et al. (2015) exploited neural network to jointly embed arguments and semantic roles, akin to the work (Lei et al., 2015), which induced a compact feature representation applying tensor-based approach.

Recently, people have attempted to build end-to-end systems for span SRL without syntactic input (Zhou and Xu, 2015; He et al., 2017; Tan et al., 2018). Similarly, Marcheggiani et al. (2017) also proposed a syntax-agnostic model for dependency SRL and obtained favorable results. Despite the success of syntax-agnostic models, there are several works focus on leveraging the advantages of syntax. Roth and Lapata (2016) employed dependency path embedding to model syntactic information and exhibited a notable success. Marcheggiani and Titov (2017) leveraged the graph convolutional network to incorporate syntax into a neural SRL model. Qian et al. (2017) proposed SA-LSTM to model the whole tree structure of dependency relation in an architecture engineering way.

Besides, syntax encoding has also successfully promoted other NLP tasks. Tree-LSTM (Tai et al., 2015) is a variant of the standard LSTM that can encode a dependency tree with arbitrary branching factors, which has shown effectiveness on semantic relatedness and the sentiment classification tasks. In this work, we extend the Tree-LSTM with a relation specific gate and employ it to recursively encode the syntactic dependency tree for SRL. RCNN (Zhu et al., 2015) is an extension of the recursive neural network (Socher et al., 2010) which has been popularly used to encode trees with fixed branching factors. The RCNN is able to encode a tree structure with arbitrary number of factors and is useful in a re-ranking model for dependency parsing (Zhu et al., 2015).

In our experiments, we simplify and reformulate the RCNN model. However, the simplified model performs poorly on the development and the test sets. The reason might be that the RCNN model with a single global composition parameter is too simple to cover all types of syntactic relation in a dependency tree. Because of the poor performance of the modified RCNN, we do not include it in this work. Considering there might be other approach to incorporate the recursive network in SRL model, we leave it as our future work and just provide a brief discussion here.

In this work, we extend existing methods and introduce Tree-LSTM for incorporating syntax into SRL. Rather than proposing completely new model, we synthesize these techniques and present a unified framework to take genuine superiority of syntactic information.

6 Conclusion

This paper presents a unified neural framework for dependency-based SRL, effectively incorporating syntactic information by directly modeling syntax based on syntactic parse tree. Rather than proposing completely new model, we extend existing models and apply tree-structured LSTM for SRL. Our approach significantly outperforms all previous models, achieving state-of-the-art results on the CoNLL-2009 benchmarks for both English and Chinese.

Our experiments specially show that giving an enlarged performance gap from syntax-agnostic to syntax-aware setting, SRL can be further promoted with the help of deep enhanced representation and effective methods of integrating syntax. Furthermore, we explore the impact of the quality of syntactic input. The relevant results indicate that high-quality syntactic parse is more favorable to semantic role labeling.

Abstract

We propose a novel approach to semantic dependency parsing (SDP) by casting the task as an instance of multi-lingual machine translation, where each semantic representation is a different foreign dialect. To that end, we first generalize syntactic linearization techniques to account for the richer semantic dependency graph structure. Following, we design a neural sequence-to-sequence framework which can effectively recover our graph linearizations, performing almost on-par with previous SDP state-of-the-art while requiring less parallel training annotations. Beyond SDP, our linearization technique opens the door to integration of graph-based semantic representations as features in neural models for downstream applications.

1 Introduction

Many sentence-level representations were developed with the goal of capturing the sentence's proposition structure and making it accessible for downstream applications (Montague, 1973; Carreras and Màrquez, 2005; Banarescu et al., 2013; Abend and Rappoport, 2013). See Abend and Rappoport (2017), for a recent survey.

While syntactic grammars (Marcus et al., 1993; Nivre, 2005) induce a rooted tree structure over the sentence by connecting verbal predicates to their arguments, these semantic representations often take the form of the more general labeled graph structure, and aim to capture a wider notion of propositions (e.g, nominalizations, adjectivals, or appositives). In particular, we will focus on the three graph-based semantic representations collected in the Broad-Coverage Semantic Dependency Parsing SemEval shared task (SDP) (Oepen et al., 2015): (1) DELPH-IN Bi-Lexical Dependencies (DM) (Flickinger, 2000),[1] (2) Enju Predicate-Argument Structures (PAS) (Miyao et al., 2014), and (3) Prague Semantic Dependencies (PSD) (Hajic et al., 2012). These annotations have garnered recent attention (e.g., (Buys and Blunsom, 2017; Peng et al., 2017a)), and were consistently annotated in parallel on over more than 30K sentences of the Wall Street Journal corpus (Charniak et al., 2000).

In this work we take a novel approach to graph parsing, casting sentence-level semantic parsing as a multilingual machine-translation task (MT). We deviate from current graph-parsing approaches to SDP (Peng et al., 2017a) by treating the different semantic formalisms as foreign target dialects, while having English a as a common source language (Section 3). Subsequently, we devise a neural MT sequence-to-sequence framework that is suited for the task.

In order to apply sequence-to-sequence models for structured prediction, a linearization function is required to interpret the model's sequential input and output. Initial work on structured prediction sequence-to-sequence modeling has focused on tree structures (Vinyals et al., 2015; Aharoni and Goldberg, 2017), as these are quite easy to linearize using the bracketed representation (as employed in the Penn TreeBank (Marcus et al., 1993)). Following, various efforts were made to port the attractiveness of sequence-to-sequence modeling to the more general graph structure of semantic representations, such as AMR or MRS (Peng et al., 2017b; Barzdins and Gosko, 2016; Konstas et al., 2017; Buys and Blunsom, 2017). However, to the best of our knowledge, all such current methods actually sidestep the challenge of graph linearization – they reduce the input graph to a tree using lossy heuristics, which are specifi-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2412–2421
Brussels, Belgium, October 31 - November 4, 2018.

cally tailored for their target representation.

In contrast, we design a novel deterministic and lossless linearization (Section 4), which is applicable to any graph with ordered nodes (e.g., sentence word order). To that end, we devise solutions for the various obstacles for linearizing a graph structure, such as reentrancies (or multiple heads), non-connected components, and non-projective relations. This lineariztion allows us to follow the spirit of Johnson et al. (2017) in training all source-target combinations in a multi-task approach (Section 5). These combinations include the three traditional text to semantic parsing tasks, as well as six additional inter-representation translation tasks, constituting of all binary combinations of the target representations (e.g., PSD to PAS, or DM to PSD).

Following, we design an encoder-decoder model which has two shared encoders, one for raw English sentences and another for linearized graphs, and a single global graph decoder. Interestingly, we show that training on the auxiliary inter-representation translation tasks greatly improves the performance on the original SDP tasks, without requiring any additional manual annotation effort (Section 6).

Our contributions are two-fold. First, we show that novel sequence-to-sequence models are able to effectively capture and recover general graph structures, making them a viable and easily extensible approach towards the SDP task. Second, beyond SDP, as the inclusion of syntactic linearization was shown beneficial in various tasks (Aharoni and Goldberg, 2017; Le et al., 2017) so does our approach prompt easy integration of graph-based representations as complementary semantic signal in various downstream applications.

2 Background

We begin this section by presenting the corpus we use to train and test our model (the SDP corpus) and the current state-of-the-art in predicting semantic dependencies. Then, we discuss previous work on sequence-to-sequence models for tree prediction, which this work extends to general graph structures. Finally, we briefly describe the multilingual translation approach, which we borrow and adapt to the semantic parsing task.

	DM	**PAS**	**PSD**
#Train sentences	35,657	35,657	35,657
#Test sentences	1,410	1,410	1,410
#Labels	59	42	91
%Trees	2.30	1.22	42.19
%Projective	2.91	1.64	41.92

Table 1: SDP corpus statistics. Numbers taken from Oepen et al. (2015).

2.1 Semantic Dependencies

In general, the development of most semantic formalisms was carried out by disjoint and independent efforts. However, the 2014 and 2015 SemEval shared tasks (Oepen et al., 2014, 2015) have culminated in the Semantic Dependency Parsing (SDP) resource, a consistent and large corpus (roughly 39K sentences), annotated in parallel with three well-established formalisms: DELPH-IN MRS-Derived Bi-Lexical Dependencies (DM) (Flickinger, 2000), Enju Predicate-Argument Structures (PAS) (Miyao et al., 2014), and Prague Semantic Dependencies (PSD) (Hajic et al., 2012). While varying in their labels and annotation guidelines, all three representations induce a graph structure, where each node corresponds to a single word in the sentence. See Table 1 for more details on this corpus, and Figure 1 for examples of the three SDP formalisms. SDP has enabled the application of machine learning models for the task. Peng et al. (2017a) have set the state-of-the-art results on all three tasks, using techniques inspired by graph-based dependency parsing models (Kiperwasser and Goldberg, 2016; Dozat and Manning, 2016; Kuncoro et al., 2016). Their best results were obtained by leveraging the fact that SDP was annotated on parallel texts. They reached 88% average labeled F1 score across the SDP representations on an in-domain test set, via joint prediction of the three representations using higher-order cross-representation features. The first row in Table 4 summarizes their performance for the three prediction tasks.

In this work we will take a different approach to structured prediction of the SDP corpus. We will design a novel sequence-to-sequence model, not necessitating parallel annotations, which are often unavailable for multi-task learning.

Figure 1: Example of gold annotations for the three sentence-level representations in the SDP corpus (DM, PAS, and PSD) on the same sentence, which was slightly shortened for presentation. Arcs in each of the representations appear above the sentence. Our "SHIFT" edges, which appear dashed below it, were introduced in Section 4 to ensure that all nodes are reachable from the first word.

2.2 Structured Prediction using Sequence-to-Sequence Models

In contrast to the graph-parsing algorithms discussed in Section 2.1, a recent line of work has explored the usage of more general sequence-to-sequence models to perform structured prediction, focusing specifically on predicting tree structures. These approaches devise a task-specific linearization function which converts the structured representation to a sequential string, which is then used to train the recurrent neural network. During inference, the inverted linearization function is applied to the output to recover the desired structure.

Vinyals et al. (2015) showed that sequence-to-sequence phrase-based constituency parsing can be achieved using a tree depth-first search (DFS) traversal as a linearization function.[2] Following this work, several recent efforts have employed a similar DFS approach to AMR and MRS parsing (Barzdins and Gosko, 2016; Konstas et al., 2017; Peng et al., 2017b; Buys and Blunsom, 2017), after reducing AMR to trees by removing re-entrencies.

Several recent works have found syntactic linearization useful outside of neural parsers. For example, in neural machine translation, Aharoni and Goldberg (2017) showed that predicting target-side linearized syntactic trees can improve the quality and grammatically of the predicted translations. In Section 4, we show for the first time that the DFS approach is a viable linearization function also for semantic dependencies, by extending it to account for the challenges introduced by the richer graph structures in SDP.

2.3 Multi-lingual Machine Translation

Multi-Task Learning (MTL) is a modeling approach which shares and tunes the model parameters across several tasks. In some instances of MTL, a subset of the tasks may be defined as the "main tasks", while the other tasks are treated as auxiliaries which improve performance on the main tasks by contributing to their training signal. MTL had regained popularity in recent years thanks to its easy and wide-spread applicability in neural networks (Collobert et al., 2011; Sogaard

---

[2] DFS for rooted trees is equivalent to the bracketed notation of the Penn Treebank.

and Goldberg, 2016).

Perhaps most relevant to this work is Google's neural machine translation system by Johnson et al. (2017), which trained a single sequence-to-sequence model to translate between multiple languages. They introduced the usage of a special tag in the source sentence to specify the desired target language. For example, <*2es*> indicates that the model should translate the input sentence to Spanish.

In Section 4, we adapt the MTL strategy to train a single model for all SDP formalisms. We use a similar "to" and "from" tags to indicate source and desired target representations, and show that introducing auxiliary inter-task translations can improve performance on the main target tasks, namely parsing semantic representations for raw input text.

3 Task Definition

We define the task of **semantic translation**, as converting to, and between, different sentence-level semantic representations. Formally, a sentence-level semantic representation according to formalism R is a tuple, $\mathcal{M}_\mathcal{R} = (S, G)$, where $S = \{w_1, ..., w_n\}$ is a raw sentence, and $G = (V, E \mid V = \{v_1, ..., v_n\}, E \subseteq V^2)$ is a labeled graph whose vertices have a one-to-one correspondence with the words in S,[3] while its edges represent binary semantic relations, adhering to R's specifications.

Using these notations, our input is defined as a triplet $(source, target, \mathcal{M}_{source})$. Preceding the input semantic representation are identifiers for source and target representation schemes (e.g., "PAS", "DM" or "PSD"). The semantic translation task is then to produce $\mathcal{M}_{target}$. I.e., the sentence's representation under the $target$ formalism.

This definition is broad enough to encapsulate many sentence-level representations, and in this work we will use the three SDP representations, as well as an empty "RAW" representation (where $E(G) = \emptyset$ for all sentences) to allow for translations from raw input sentences. We note that future work may extend this framework with other graph-based sentence representations.

4 Graph Linearization

As discussed in Section 2, structured prediction in a sequence-to-sequence framework requires a linearization function, from the desired structure to a linear sequence, and vice versa.

Oftentimes, such linearization consists of node traversal along the edges of the input graph. While previous work have had certain structural constraints on their input (e.g., imposing tree or non-cyclic constructions), in this work, we construct a *lossless* function which allows us to feed the sequence-to-sequence network with a linearized *general* graph representation and expect a linearized graph in its output.

In this section, we describe our linearization traversal order, which generalizes the DFS traversal applied previously only for trees. We do this by converting an SDP graph such that all nodes are reachable from node v_1. We then outline the challenging aspects of graph properties (which do not exist in trees), show that they are prevalent in the SDP corpus, and describe our proposed solutions. To the best of our knowledge, this is the first work which tackles the task of general graph linearization.

While our linearization can be predicted with good accuracy (as we show in following sections), there is ample room to experiment with representational variations, which we start exploring in Section 6. Our conversion code is made publicly available,[4] allowing further experimentation with general graph linearization for SDP and other related tasks.

4.1 Traversing Graphs with Non-Connected Components

The DFS approach is an applicable linearization of trees since a recursive traversal, which starts at the root and explores all outgoing edges, is guaranteed to visit all of the graph's nodes. However, DFS linearization is not directly applicable to SDP, as its graphs often consist of several non-connected components.

For such graphs, there exists no starting node from which all of the nodes are reachable via DFS traversal, and certain nodes are bound to be left out of the traditional DFS encoding. For example, the words "can" and "greatest" in Figure 1a reside in different components, and therefore no single path

---

[3] The one-to-one node-to-word correspondence follows SDP's formulation, but can be relaxed to adjust for other graph structures.

[4] `https://github.com/gabrielStanovsky/semantics-as-foreign-language`

(which traverses along the graph's edge direction) will discover both of them.

To overcome this limitation, we make sure that all nodes are reachable from node v_1, corresponding to the first word in the sentence, from which we start our traversal. This is achieved by introducing an artificial `SHIFT` edge between any two consecutive nodes v_i, v_{i+1} for which there is no directed path already connecting them. Following, it is easy to see, by induction, that all nodes are reachable from v_1, as for every node v_i there exists a directed path $(v_1, v_2, ..., v_{i-1}, v_i)$. For example, revisit the previously mentioned "can" and "greatest" nodes in Figure 1a, which are connected using "SHIFT" edges.

4.2 Linearizing a DFS Graph Traversal

Intuitively, our linearization is a pre-order DFS, generalizing Vinyals et al. (2015)'s approach to syntactic linearization. We start from v_1 and explore all paths from it, in a depth-first manner. Once a path is exhausted, either by reaching a node with no outgoing edges[5] or by reaching an already visited node, we use special backtracking edges to form a path backwards "up" the graph, until we hit a node which still has unexplored outgoing edges.

Formally, our linearization of a given DFS traversal is composed of 3 types of elements (see Figure 2 for example):

First, a **Node reference** identifies a node in the graph, which in turn corresponds to word in the SDP formalism. We identify nodes using two tokens: (1) Their position in the sentence, relative to the previous node in the path (while the first position in the linearization is written in absolute terms, as "0"), and (2) Explicitly writing the word corresponding to the node.

For example, in Figure 2, traversing the *ARG1* edge from "easy" lands at "`ind/2` **`understand`**", whose outgoing *ARG2* edge arrives at "`ind/-4` **`success`**".

Second, an **Edge reference**, identifies an edge label. These are denoted by a single token, composed of 2 parts: (1) The edge's formalism (in our case, the SDP representation to which it pertains), and (2) The edge label. Traversing an edge (u, v) with label L will be encoded by placing the edge reference between the node references of u and v. For instance, in Figure 2, moving from node 0 to node 1 through the edge labeled "poss" is encoded with the following string: "`ind/0` **`Their`** `PAS/poss ind/1` **`success`**".

Finally, **Backtracking edges**, signify a step "backward" in the traversal. These are denoted with a single token, similarly to edge references, with the addition of a "BACK" suffix. For example, in Figure 2, we backtrack from the already visited node "understand" by writing: "*`PAS/ARG1/BACK`*".

This linearization can be deterministically and efficiently inverted back to the graph structure. This is done by building the graph while reading the linearization, adding to it nodes and edges when they first appear, and omitting possible node recurrences in the linearization (due to cycles or backtracking edges), such as "success", which appears twice in the Figure 2.

Redundancy in encoding We note that certain items in our proposed linearization are redundant. First, writing down the explicit word in the traversal is not necessary, as the positional index is sufficient to uniquely identify a node. Second, a single backtracking tag would have been enough to identify the specific edge which is currently being backtracked (e.g., `BACK` instead of `PAS/verb_ARG1/BACK`). The latter is similar to the redundancy in the syntactic linearization of Vinyals et al. (2015), who specify the type of closing bracket, e.g., `NP(...)NP` instead of `NP(...)`.

In Section 6 we show empirically that our model benefits from explicitly generating these redundancies during decoding.

4.3 DFS Traversal Order

A graph DFS traversal does not dictate an order in which to explore the different outgoing paths at each branching point. Consider, as a recurring example, the branching point at the word "vote" in Figure 1c, in which we need to choose an order amongst its four neighbors.

While syntactic linearization conveniently follows the ordering of the words in the sentence, Konstas et al. (2017) have noted that different child visiting linearization orders affect the performance of text generation from AMR. In particular, they found that following the order of annotation of a human expert worked best.

Intuitively, since different graph traversals affect the sequence of encoded nodes during train-

---

[5] Note that after introducing the artificial "SHIFT" edges, only v_n may have no outgoing edges.

DFS order type	Example (*vote*'s PSD neighbors)
Random permutation	*(play, for, jocks, now)**
Sentence order Neighbor's index in the sentence	*(jocks, now, for, play)*
Closest words Neighbor's absolute distance	*(now, for, play, jocks)*
Smaller-first # nodes reachable from the neighbor	*(now, play, for, jocks)*

Table 2: Different neighbor exploration orders. Under the name of each order type, we list the key by which we sort each node's neighbors. The "Example" column shows the corresponding ordering of "vote"'s neighbors in Figure 1c. *An example of one possible random permutation.

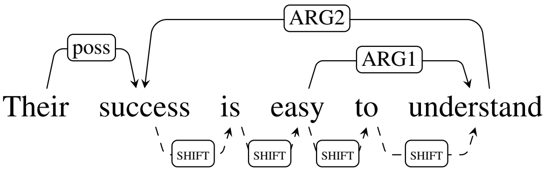
ing, the network will inevitably have to learn different weights and attention when presented with different orderings. Therefore, some traversal orderings may be easier to learn than others, leading to better (hopefully more semantic) abstractions.

To the best of our knowledge, the human annotation order is not available for the SDP annotations, and there is no clear a priori optimal ordering. We therefore experiment with several visiting orders, as described in Table 2. Notably, **Sentence order** is equivalent to the ordering used by Vinyals et al. (2015) for syntactic linearization, while **Closest words** orders child nodes from short to longer range-dependencies (commonly associated with syntactic versus semantic relations), and **Smaller first** is motivated by the easy-first approach (Goldberg and Elhadad, 2010), first encoding paths which are shorter (and easier to memorize), before longer, more complicated sequences.

In Section 6 we evaluate the effect of these variations on the SDP parsing task.

5 Model

We start by describing our model architecture, inspired by recent MT architectures, while allowing for different types of inputs, namely English sentences and linearized graphs. Following, we present our methods for training and testing, and specific hyper-parameter configuration and implementation details.



(a) Gold PAS representation from the SDP corpus. Original gold edges appear above the words, while our introduced edges appear below them.

```
ind/0 Their PAS/poss ind/1 success
SHIFT ind/1 is SHIFT ind/1 easy
PAS/ARG1 ind/2 understand PAS/ARG2
ind/-4 success PAS/ARG2/BACK ind/4
understand PAS/ARG1/BACK ind/-2 easy
SHIFT ind/1 to SHIFT ind/1 understand
```

(b) Our linearization scheme for the sentence in 2a. Each node is represented by its relative index and surface form. Backwards traversing edges (marked with *BACK*) appear in italics.

Figure 2: Example of gold PAS representation from the development partition of the SDP corpus (top), and our corresponding linearization (bottom).

5.1 Architecture

Our architecture, depicted in Figure 3, consists of a sequence-to-sequence model using a bi-LSTM encoder-decoder with attention on input and output tokens, similar to that used by Johnson et al. (2017) for multi-lingual MT. As described in Section 3, it is trained on 9 translation tasks in parallel. We split these into two groups, consisting of 3 primary tasks and 6 auxiliary tasks, as follows:

$$\begin{aligned}\texttt{PRIMARY} &= \{(\text{RAW}, tgt) \mid \\ &\qquad tgt \in (\text{DM, PAS, PSD})\} \\ \texttt{AUXILIARY} &= \{(src, tgt) \in \{\text{DM, PAS, PSD}\}^2 \mid \\ &\qquad src \neq tgt\}\end{aligned}$$

The `PRIMARY` tasks deal with converting raw sentences to linearized graph structures, which we can compare to previous published baselines and are therefore our main interest. Conversely, while the `AUXILIARY` tasks provide additional training signal to tune our model, they are also interesting from an analytic point-of-view, which we examine in depth in Section 6.

To allow the model to differentiate between the different tasks, we prefix each input sample with two tags (see example in Figure 3). First, similarly to Johnson et al. (2017), we add a tag indicating the desired target representation, e.g., `<to:DM>`. Second, In contrast to multi-lingual MT which omits the source language (to allow for

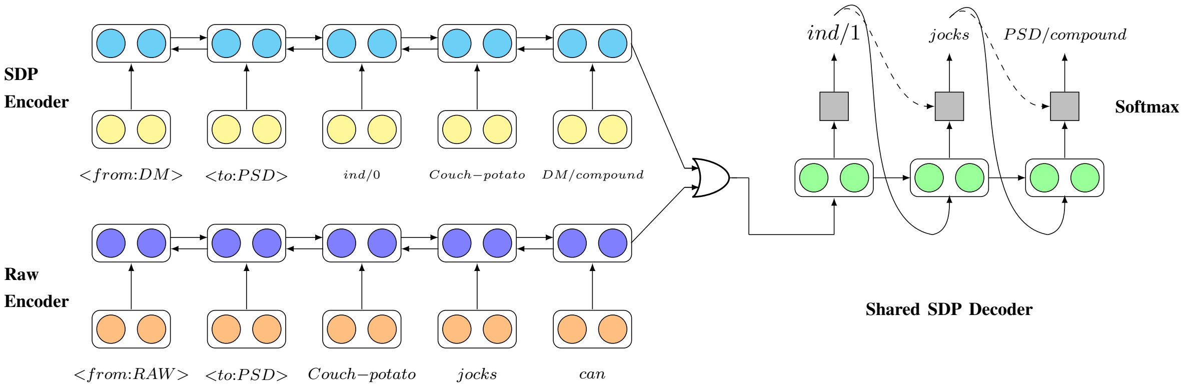


Figure 3: **Simplified sketch of our sequence-to-sequence architecture.** The figure depicts encoding and decoding of two input training samples, one from raw text to PSD (lower left), and the other from DM to PSD (top left). The OR gate denotes choosing only one sample to encode at each training step. While the two samples use different encoders, they share a single global SDP decoder (right) which outputs a the graph structure. As denoted by dashed edges, at every decode step we can deterministically interject and override the softmax probabilities for redundant elements, based on previous predictions. For simplicity sake, a small number of units is showed for encoders and decoder and the attention and deep encoder-decoder layers are omitted.

code switching), we explicitly denote the source representation, e.g., `<from:PSD>`. This addition further strengthens the correlation between inputs from the same representation.[6]

Further deviating from the current practice in MT, our architecture uses two encoders and a single decoder (while common MT regards the encoder-decoder as a single unit). The first shared encoder specializes in encoding raw text for all `PRIMARY` tasks, while a second encodes linearized graph structures for the `AUXILIARY` tasks. Both encoders are linked to a single decoder which converts their output representations to a linearized graph.

Intuitively, the two encoders correspond to the different nature of input to the `PRIMARY` tasks (an English sentence) versus that of the `AUXILIARY` tasks (a linearized graph), while a single decoder allows for a common linearized graphs output format. Since the decoder is trained across all 9 tasks, both encoders are optimized to arrive at similar latent representations which are geared towards graph prediction.

5.2 Training and Inference

The overall size of multi-task training data is $320,913$ samples. This constitutes a 9-fold increase over a single-model for SDP ($35,657$ sentences in the SDP corpus) and a 3-fold increase over a standard MTL approach to SDP (without the `AUXILIARY` tasks). During training, we penalize the model on all predicted elements, including the redundant elements discussed in Section 4.2. During inference, however, these redundancies may cause contradictions leading to incoherent sequences. Namely, a word may not conform to the previous word index, and a backtracking edge may point to a different relation. To overcome this we artificially increase the softmax probabilities (dashed edges in Figure 3) so that they reflect the DFS path decoded up until that point. Specifically, we override the predicted word according to the previous index, and backtrack "up" the corresponding edge.

5.3 Implementation Details

All of our hyper-parameters were tuned on a held out partition of 1000 sentences in the training set. In particular, we use 3 hidden layers for both of the encoders, and 2 hidden layers for the decoder. English word embeddings were fixed with 300-dimensional GloVe embeddings (Pennington et al., 2014), while the graph elements, which consist of a lexicon of roughly 400 tokens across three representations, were randomly initialized. We trained the model until convergence, roughly 20

---

[6] Moreover, "code-switching" between semantic representations is inherently undesired.

	DM	PAS	PSD	Avg.
Random	86.1	87.7	78.4	84.1
Sentence order	87.2	90.3	79.9	85.8
Closest words	87.5	89.8	79.7	85.8
Smaller-first	**87.9**	**90.9**	**80.3**	**86.2**

Table 3: Evaluation of different DFS orderings, in labeled F1 score, across the different tasks.

epochs, in about 12 hours on a GPU (NVIDIA GeForce GTX 1080 Ti), in batches of 50 sentences. All of these sentences belong to the same task, which is chosen at random before each batch.

Finally, our models were developed using the OpenNMT-py library (Klein et al., 2017), and are made available.[7]

6 Evaluation

We perform several evaluations, testing the impact of alternative configurations, including the different DFS traversal orders and MTL versus single-task approach, as well as our model's performance against current state-of-the-art on each of the `PRIMARY` tasks.

6.1 Results

The results of our different analyses are reported in Tables 3-6, as elaborated below. For all evaluations, we use the in-domain test partition of the SDP corpus, containing $1,410$ sentences. Following Peng et al. (2017a) we report performance using labeled F1 scores as well as average scores across representations. We compare the produced graphs, after applying the inverted linearization function, rather than comparing the DFS path directly, as there may be several DFS graph traversals encoding the same relations.

DFS order matters - Table 3 depicts our model's performance when linearizing the graphs according to the different traversal orders discussed and exemplified in Table 2. Overall, we find that the "smaller-first" approach performs best across all datasets, and that imposing one of our orders is always preferable over random permutations. Intuitively, the "smaller-first" approach presents shorter, and likely easier, paths first, thus minimizing the amount of error-propagation for following decoding steps. Due to its better performance, we will report only the smaller-first's performance in all following evaluations.

From English to SDP - Table 4 presents the performance of our complete model ("MTL PRIMARY+AUX") versus Peng et al. (2017a). On average, our model performs within 1% F1 point from the state-of-the art (outperforming it on the harder PSD task), despite using the more general sequence-to-sequence approach instead of a dedicated graph-parsing algorithm. In addition, an ablation study shows that multi-tasking the `PRIMARY` tasks is beneficial over a single task setting, which in turn is outperformed by the inclusion of the `AUXILIARY` tasks.

Simulating disjoint annotations - In contrast with SDP's complete overlap of annotated sentences, multi-task learning often deals with disjoint training data. To simulate such scenario, we retrained the models on a randomly selected set of 33% of the train sentences for each representation ($11,886$ sentences), such that the three representations overlap on only 10% ($3,565$ sentences). The results in Table 5 show that our approach is more resilient to the decrease in annotation overlap, outperforming the state-of-the-art model on the DM and PSD task, as well as on the average score. We hypothesize that this is in part thanks to our ability to use the inter-task translations, even when these exist only for part of the annotations.

6.2 Translating Between Representations

As a byproduct of training on the `AUXILIARY` tasks, our model can also be tested on translating *between* the different representations. This is done by presenting it with a linearized graph of one representation and asking it to translate it to another. To the best of our knowledge, this is the first work which tries to accomplish this.

We report the performance of all source-target combinations in Table 6. These evaluations provide several interesting comparisons between the representations: (1) For all representations, translating from any of the other two is easier than parsing from raw text, (2) The PAS and DM representations can be converted between them with high accuracy (95.7% and 96.1%, respectively). This can be due to their structural resemblance, noted in previous work (Peng et al., 2017a; Oepen et al., 2015), and (3) While PSD serves as a viable input for conversion to DM and PAS (92.1% F1 on

average), it is relatively harder to convert either of them to PSD (88.6%). This might indicate that PSD subsumes some of the information in DM and PAS.

7 Conclusions and Future Work

We presented a novel sequence-to-sequence approach to the task of semantic dependency parsing, by casting the problem as multi-lingual machine translation. To that end, we introduced a DFS-based graph linearization function which generalizes several previous works on tree linearization. Following, we showed that our model, inspired by neural MT, benefits from the inter-task training signal, reaching performance almost on-par with current state of the art in several scenarios.

Future work can employ this linearization function within downstream applications, as was done with syntactic linearization, or extend this framework with other graph-based representations, such as universal dependencies (Nivre et al., 2016) or AMR (Banarescu et al., 2013).

Abstract

In this paper, we propose a new rich resource enhanced AMR aligner which produces multiple alignments and a new transition system for AMR parsing along with its oracle parser. Our aligner is further tuned by our oracle parser via picking the alignment that leads to the highest-scored achievable AMR graph. Experimental results show that our aligner outperforms the rule-based aligner in previous work by achieving higher alignment F1 score and consistently improving two open-sourced AMR parsers. Based on our aligner and transition system, we develop a transition-based AMR parser that parses a sentence into its AMR graph directly. An ensemble of our parsers with only words and POS tags as input leads to 68.4 Smatch F1 score, which outperforms the parser of Wang and Xue (2017).

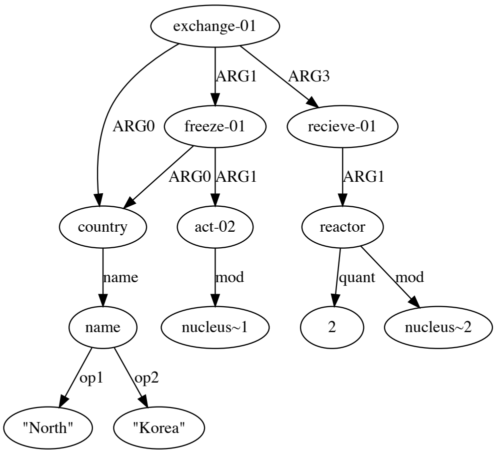

Figure 1: AMR graph for the sentence *"North Korea froze its nuclear actions in exchange for two nuclear reactors."*

1 Introduction

Abstract Meaning Representation (AMR) (Banarescu et al., 2013) is a semantic representation which encodes the meaning of a sentence in a rooted and directed graph, whose nodes are abstract semantic concepts and edges are semantic relations between concepts (see Figure 1 for an example). Parsing a sentence into its AMR graph has drawn a lot of research attention in recent years with a number of parsers being developed (Flanigan et al., 2014; Wang et al., 2015b; Pust et al., 2015; Artzi et al., 2015; Peng et al., 2015; Zhou et al., 2016; Goodman et al., 2016; Damonte et al., 2017; Ballesteros and Al-Onaizan, 2017; Foland and Martin, 2017; Konstas et al., 2017).

The nature of abstracting away the association between a concept and a span of words complicates the training of the AMR parser. A word-concept aligner is required to derive such association from the sentence-AMR-graph pair and the alignment output is then used as reference to train the AMR parser. In previous works, such alignment is extracted by either greedily applying a set of heuristic rules (Flanigan et al., 2014) or adopting the unsupervised word alignment technique from machine translation (Pourdamghani et al., 2014; Wang and Xue, 2017).

The rule-based aligner – JAMR aligner proposed by Flanigan et al. (2014) is widely used in previous works thanks to its flexibility of incorporating additional linguistic resources like WordNet. However, achieving good alignments with the JAMR aligner still faces some difficult challenges. The first challenge is deriving an optimal alignment in ambiguous situations. Taking the sentence-AMR-graph pair in Figure 1 for example, the JAMR aligner doesn't distinguish between the two "*nuclear*"s in the sentence and can yield sub-optimal alignment in which the first "*nuclear*" is aligned to the `nucleus~2` concept. The second challenge is recalling more semantically matched word-concept pair without harming the

Brussels, Belgium, October 31 - November 4, 2018.

alignment precision. The JAMR aligner adopts a rule that aligns the word-concept pair which at least have a common longest prefix of 4 characters, but omitting the shorter cases like aligning the word "*actions*" to the concept `act-01` and the semantically matched cases like aligning the word "*example*" to the concept `exemplify-01`. The final challenge which is faced by both the rule-based and unsupervised aligners is tuning the alignment with downstream parser learning. Previous works treated the alignment as a fixed input. Its quality is never evaluated and its alternatives are never explored. All these challenges make the JAMR aligner achieve only an alignment F1 score of about 90% and influence the performance of the trained AMR parsers.

In this paper, we propose a novel method to solve these challenges and improve the word-to-concept alignment, which further improves the AMR parsing performance. A rule-based aligner and a transition-based oracle AMR parser lie in the core of our method. For the aligner part, we incorporate rich semantic resources into the JAMR aligner to recall more word-concept pairs and cancel its greedily aligning process. This leads to multiple alignment outputs with higher recall but lower precision. For the parser part, we propose a new transition system that can parse the raw sentence into AMR graph directly. Meanwhile, a new oracle algorithm is proposed which produces the best achievable AMR graph from an alignment. Our aligner is tuned by our oracle parser by feeding the alignments to the oracle parser and picking the one which leads to the highest Smatch F1 score (Cai and Knight, 2013). The chosen alignment is used in downstream training of the AMR parser. Based on the newly proposed aligner and transition system, we develop a transition-based parser that directly parses a sentence into its AMR graph and it can be easily improved through ensemble thanks to its simplicity.

We conduct experiments on LDC2014T12 dataset.[1] Both intrinsic and extrinsic evaluations are performed on our aligner. In the intrinsic evaluation, our aligner achieves an alignment F1 score of 95.2%. In the extrinsic evaluation, we replace the JAMR aligner with ours in two open-sourced AMR parsers, which leads to consistent improvements on both parsers. We also evaluate our transition-based parser on the same dataset. Using both our aligner and ensemble, a score of 68.1 Smatch F1 is achieved without any additional resources, which is comparable to the parser of Wang and Xue (2017). With additional part-of-speech (POS) tags, our ensemble parser achieves 68.4 Smatch F1 score and outperforms that of Wang and Xue (2017).

The contributions of this paper come in two folds:

- We propose a new AMR aligner (§3) which recalls more semantically matched pairs and produces multiple alignments. We also propose a new transition system for AMR parsing (§4.1) and use its oracle (§4.2) to pick the alignment that leads to the highest-scored achievable AMR graph (§4.3). Both intrinsic and extrinsic evaluations (§5) show the effectiveness of our aligner by achieving higher F1 score and consistently improving two open-sourced AMR parsers.
- We build a new transition-based parser (§4.4) upon our aligner and transition system which directly parses a raw sentence into its AMR graph. Through simple ensemble, our parser achieves 68.4 Smatch F1 score with only words and POS tags as input (§6) and outperforms the parser of Wang and Xue (2017).

Our code and the alignments for LDC2014T12 dataset are publicly available at `https://github.com/Oneplus/tamr`

2 Related Work

AMR Parsers. AMR parsing maps a natural language sentence into its AMR graph. Most current parsers construct the AMR graph in a two-staged manner which first identifies concepts (nodes in the graph) from the input sentence, then identifies relations (edges in the graph) between the identified concepts. Flanigan et al. (2014) and their follow-up works (Flanigan et al., 2016; Zhou et al., 2016) model the parsing problem as finding the maximum spanning connected graph. Wang et al. (2015b) proposes to greedily transduce the dependency tree into AMR graph and a bunch of works (Wang et al., 2015a; Goodman et al., 2016; Wang and Xue, 2017) further improve the transducer's performance with rich features and imitation learning.[2] Transition-based methods

---

[1] `catalog.ldc.upenn.edu/ldc2014t12`

[2] Wang et al. (2015b) and the follow-up works refer their transducing process as "transition-based". However, to dis-

that directly parse an input sentence into its AMR graph have also been studied (Ballesteros and Al-Onaizan, 2017; Damonte et al., 2017). In these works, the concept identification and relation identification are performed jointly.

An aligner which maps a span of words into its concept serves to the generation of training data for the concept identifier, thus is important to the parser training. Missing or incorrect alignments lead to poor concept identification, which then hurt the overall AMR parsing performance. Besides the typical two-staged methods, the aligner also works in some other AMR parsing algorithms like that using syntax-based machine translation (Pust et al., 2015), sequence-to-sequence (Peng et al., 2017; Konstas et al., 2017), Hyperedge Replacement Grammar (Peng et al., 2015) and Combinatory Category Grammar (Artzi et al., 2015).

Previous aligner works solve the alignment problem in two different ways. The rule-based aligner (Flanigan et al., 2014) defines a set of heuristic rules which align a span of words to the graph fragment and greedily applies these rules. The unsupervised aligner (Pourdamghani et al., 2014; Wang and Xue, 2017) uncovers the word-to-concept alignment from the linearized AMR graph through EM. All these approaches yield a single alignment for one sentence and its effect on the downstream parsing is not considered.

JAMR Aligner (Flanigan et al., 2014). Two components exist in the JAMR aligner: 1) a set of heuristic rules and 2) a greedy search process.

The heuristic rules in the JAMR aligner are a set of indicator functions $\rho(c, w_{s,e})$ which take a concept c and a span of words $w_{s,e}$ starting from s and ending with e as input and return whether they should be aligned. These rules can be categorized into *matching rules* and *updating rules*. The matching rules directly compare c with $w_{s,e}$ and determine if they should be aligned. The updating rules first retrieve the concept c' that $w_{s,e}$ aligns, then determine if c and $w_{s,e}$ should be aligned by checking whether c and c' meet some conditions. Here, we illustrate how *update rules* work by applying a rule named **Entity Type** on the AMR graph in Figure 1 as an example. When determining if the entity type concept `country` should be aligned to "*North Korea*", the **Entity Type** rule first retrieve that this span is aligned to the fragment `(name :op1 "North" :op2 "Korea")`, then determine if they are aligned by checking if `name` is the tail concept of `country`.

The greedy search process applies rules in a manually defined order. The results are mutually exclusive which means once a graph fragment is aligned by one rule, it cannot be realigned. By doing so, conflicts between the alignments produced by different rules are resolved. Flanigan et al. (2014) didn't talk about the principle of orders but it generally follows the principle that 1) the matching rules have higher priorities than the updating rules, and 2) exact matching rules have higher priorities than the fuzzy matching rules.

3 Enhanced Rule-based Aligner

3.1 Enhancing Aligner with Rich Semantic Resources

Error propagates in the greedy search process. An alignment error can lead to future errors because of the dependencies and mutual exclusions between rules. In the JAMR aligner, rules that recall more alignments but introduce errors are carefully opted out and it influences the aligner's performance. Our motivation is to use rich semantic resources to recall more alignments. Instead of resolving the resulted conflicts and errors by greedy search, we keep the multiple alignments produced by the aligner and let a parser decide the best alignment.

In this paper, we use two kinds of semantic resources to recall more alignments, which include the similarity drawn from *Glove embedding* (Pennington et al., 2014)[3] and the *morphosemantic* database (Fellbaum et al., 2009) in the WordNet project[4]. Two additional matching schemes **semantic match** and **morphological match** are proposed as:

Semantic Match. *Glove embedding* encodes a word into its vector representation. We define *semantic match* of a concept as a word in the sentence that has a cosine similarity greater than 0.7 in the embedding space with the concept striping off trailing number (e.g. `run-01` → `run`).

Morphological Match. *Morphosemantic* is a database that contains links among derivational

---

tinguish their work with that of Damonte et al. (2017) and Ballesteros and Al-Onaizan (2017), we use the term "transduce" instead.

[3] `nlp.stanford.edu/projects/glove/`

[4] `wordnet.princeton.edu/wordnet/download/standoff/`

(Semantic Named Entity) Applies to `name` concepts and their `opn` children. Matches a span that matches the semantic match of each child in numerical order.

(Morphological Named Entity) Applies to `name` concepts and their `opn` children. Matches a span that matches the morphological match of each child in numerical order.

(Semantic Concept) Applies to any concept. Strips off trailing '-[0-9]+' from the concept, and matches any semantic matching word.

(Morphological Concept) Applies to any concept. Strips off trailing '-[0-9]+' from the concept, and matches any morphological matching word or WordNet lemma.

Table 1: The extended rules.

links connecting noun and verb senses (e.g., "*example*" and `exemplify`). We define morphological match of a concept as a word in the sentence having the (*word*, `concept`) link in the database.

By defining the **semantic match** and **morphological match**, we extend the rules in Flanigan et al. (2014) with four additional matching rules as shown in Table 1. These rules are intended to recall the concepts or entities which either semantically resemble a span of words but differ in the surface form, or match a span of words in their morphological derivation.

3.2 Producing Multiple Alignments

Using the rules in the JAMR aligner along with our four extended matching rules, we propose an algorithm to draw multiple alignments from a pair of sentence and AMR graph and it is shown in Algorithm 1. In this algorithm, A_c denotes the set of candidate alignments for a graph fragment c, in which each alignment is represented as a tuple (s, e, c') where s denotes the starting position, e denotes the ending position, and c' denotes the concept that lead to this alignment. At the beginning, A_c is initialized as an empty set (line 1 to 2). Then all the matching rules are tried to align a span of words to that fragment (line 3 to 7). After applying all the matching rules, all the updating rules are repeatedly applied until no new alignment is generated in one iteration (line 8 to 16). During applying the updating rules, we keep track of the dependencies between fragments. Finally, all the possible combination of the alignments are enumerated without considering the one that violates the fragment dependencies (line 17 to 26).

Algorithm 1: Our alignment algorithm.

```
Input: An AMR graph with a set of graph fragments $C$;
       a sentence $W$; a set of matching rules $\mathrm{P}_M$; and
       a set of updating rules $\mathrm{P}_U$.
Output: a set of alignments $\mathcal{A}$.
1  for $c \in C$ do
2      $A_c \leftarrow \emptyset$;
3  for $\rho_M \in \mathrm{P}_M$ do
4      for $w_{s,e} \leftarrow spans(W)$ do
5          for $c \in C$ do
6              if $\rho_M(c, w_{s,e})$ then
7                  $A_c \leftarrow A_c \cup (s, e, \mathsf{nil})$;
8  updated $\leftarrow$ true ;
9  while updated is true do
10     updated $\leftarrow$ false;
11     for $\rho_U \in \mathrm{P}_U$ do
12         for $c, c' \in C \times C$ do
13             for $(s, e, d) \in A'_c$ do
14                 if $\rho_U(c, w_{s,e}) \wedge (s, e, c') \notin A_c$ then
15                     $A_c \leftarrow A_c \cup (s, e, c')$;
16                     updated $\leftarrow$ true;
17 $\mathcal{A} \leftarrow \emptyset$ ;
18 for $(a_1, ..., a_c) \in CartesianProduct(A_1, ..., A_{|C|})$ do
19     legal $\leftarrow$ true;
20     for $a \in (a_1, ..., a_c)$ do
21         $(s, e, c') \leftarrow a$;
22         $(s', e', d) \leftarrow a_{c'}$;
23         if $s \neq s' \wedge e \neq e'$ then
24             legal $\leftarrow$ false ;
25     if legal then
26         $\mathcal{A} \leftarrow \mathcal{A} \cup (a_1, ..., a_c)$;
```

4 Transition-based AMR Parser

Our enhanced rule-based aligner produces multiple alignments, and we would like to use our parser to evaluate their qualities. A parameterized parser does not accomplish such goal because training its parameters depends on the aligner's outputs. A deterministic parser works in this situation but is required to consider the association between concepts and spans. This stops the deterministic parsers which build AMR graph only from the derived concepts[5] from being used because they do not distinguish alignments that yields to the same set of concepts.[6]

This discussion shows that to evaluate the quality of an alignment, we need a deterministic (oracle) parser which builds the AMR graph from the raw sentence. Ballesteros and Al-Onaizan (2017) presented a transition-based parser that directly parses a sentence into its AMR graph. A transition system which extends the swap-based dependency parsing system to handle AMR non-projectivities (Damonte et al., 2017) was proposed in their work.

---

[5] e.g. the reference relation identifier in Flanigan et al. (2014) and the oracle transducer in Wang et al. (2015b).

[6] recall the "*nuclear*" example in Section 1.

Transition	Current State	Resulting State	Description
Drop	$[\sigma\|\mathtt{s}_0,\ \delta,\ b_0\|\beta,\ A]$	$[\sigma\|\mathtt{s}_0,\ \delta,\ \beta,\ A]$	pops out the word that doesn't convey any semantics (e.g., function words and punctuations).
Merge	$[\sigma\|\mathtt{s}_0,\ \delta,\ b_0\|b_1\|\beta,\ A]$	$[\sigma\|\mathtt{s}_0,\ \delta,\ b_0\_b_1\|\beta,\ A]$	concatenates a sequence of words into a span, which can be derived as a named entity (`name`) or `date-entity`.
Confirm(`c`)	$[\sigma\|\mathtt{s}_0,\ \delta,\ b_0\|\beta,\ A]$	$[\sigma\|\mathtt{s}_0,\ \delta,\ \mathtt{c}\|\beta,\ A]$	derives the first element of the buffer (a word or span) into a concept `c`.
Entity(`c`)	$[\sigma\|\mathtt{s}_0,\ \delta,\ b_0\|\beta,\ A]$	$[\sigma\|\mathtt{s}_0,\ \delta,\ \mathtt{c}\|\beta,\ A \cup \mathrm{relations}(c)]$	a special form of Confirm that derives the first element into an entity and builds the internal entity AMR fragment.
New(`c`)	$[\sigma\|\mathtt{s}_0,\ \delta,\ \mathtt{b}_0\|\beta,\ A]$	$[\sigma\|\mathtt{s}_0,\ \delta,\ \mathtt{c}\|\mathrm{b}_0\|\beta,\ A]$	generates a new concept `c` and pushes it to the front of the buffer.
Left(`r`)	$[\sigma\|\mathtt{s}_0,\ \delta,\ \mathtt{b}_0\|\beta,\ A]$	$[\sigma\|\mathtt{s}_0,\ \delta,\ \mathtt{b}_0\|\beta,\ A \cup \{\mathtt{s}_0 \xleftarrow{\mathtt{r}} \mathtt{b}_0\}]$	links a relation `r` between the top concepts on the stack and the buffer.
Right(`r`)	$[\sigma\|\mathtt{s}_0,\ \delta,\ \mathtt{b}_0\|\beta,\ A]$	$[\sigma\|\mathtt{s}_0,\ \delta,\ \mathtt{b}_0\|\beta,\ A \cup \{\mathtt{s}_0 \xrightarrow{\mathtt{r}} \mathtt{b}_0\}]$	
Cache	$[\sigma\|\mathtt{s}_0,\ \delta,\ \mathrm{b}_0\|\beta,\ A]$	$[\sigma,\ \mathtt{s}_0\|\delta,\ \mathrm{b}_0\|\beta,\ A]$	passes the top concept of the stack onto the deque.
Shift	$[\sigma\|\mathtt{s}_0,\ \delta,\ \mathtt{b}_0\|\beta,\ A]$	$[\sigma\|\mathtt{s}_0\|\delta\|\mathtt{b}_0,\ [\,],\ \beta,\ A]$	shifts the first concept of the buffer onto the stack along with those on the deque.
Reduce	$[\sigma\|\mathtt{s}_0,\ \delta,\ \mathrm{b}_0\|\beta,\ A]$	$[\sigma,\ \delta,\ \mathrm{b}_0\|\beta,\ A]$	pops the top concept of the stack.

Table 2: The transition system. The letters in `monospace` font represent the concepts, the *italic* letters represent the word, and the letters in normal font are either concepts or words.

Their work presented the possibility for the oracle parser, but their oracle parser was not touched explicitly. What's more, in the non-projective dependency parsing, Choi and McCallum (2013)'s extension to the list-based system (Nivre, 2008) with caching mechanism achieves expected linear time complexity and requires fewer actions to parse a non-projective tree than the swap-based system. Their extension to transition-based AMR parsing is worth studying.

In this paper, we propose to extend Choi and McCallum (2013)'s transition system to AMR parsing and present the corresponding oracle parser. The oracle parser is used for tuning our aligner and training our parser. We also present a comprehensive comparison of our system with that of Ballesteros and Al-Onaizan (2017) in Section 6.3.

4.1 List-based Extension for AMR Parsing

We follow Choi and McCallum (2013) and define a state in our transition system as a quadruple $s = (\sigma, \delta, \beta, A)$, where σ is a stack holding processed words, δ is a deque holding words popped out of σ that will be pushed back in the future, and β is a buffer holding unprocessed words. A is a set of labeled relations. A set of actions is defined to parse sentence into AMR graph. Table 2 gives a formal illustration of these actions and how they work. The first five actions in Table 2 are our extended actions, and they are used to deriving concepts from the input sentence.

4.2 Oracle Parser

Given an alignment and the gold standard AMR graph, we can build the best AMR graph by repeatedly applying one of these actions and this is what we called *oracle* parser. Before running the oracle parser, we first remove the concepts which aren't aligned with any span of words from the AMR graph. During running the oracle parser, for a state $s = (\sigma|\mathtt{s}_0,\ \delta,\ \mathrm{b}_0|\mathrm{b}_1|\beta,\ A)$, our oracle parser decides which action to apply by checking the following conditions one by one.

1. If b_0 is a word and it doesn't align to any concept, perform Drop.
2. If b_1 is within a span in the alignment, perform Merge.
3. If b_0 is a word or span and it only aligns to one entity concept `c`, perform Entity(`c`).
4. If b_0 is a word or span and it aligns to one or more concepts, perform Confirm(`c`) where `c` is the concept b_0 aligns and has the longest graph distance to the root.
5. If b_0 is a concept and its head concept c has the same alignment as b_0, perform New(`c`).
6. If b_0 is a concept and there is an unprocessed edge `r` between $\mathtt{s}_0$ and $\mathtt{t}_0$, perform Left(`r`) or Right(`r`) according to `r`'s direction.

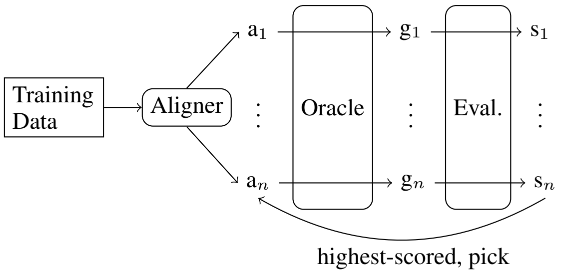

Figure 2: The workflow of tuning the aligner with the oracle parser. a_i denotes the i-th alignment, g_i denotes the i-th AMR graph, and s_i denotes the score of the i-th AMR graph.

7. If s_0 has unprocessed edge, perform CACHE.
8. If s_0 doesn't have unprocessed edge, perform REDUCE.
9. perform SHIFT.

We test our oracle parser on the *hand-align* data created by Flanigan et al. (2014) and it achieves 97.4 Smatch F1 score.[7] Besides the errors resulted from incorrect manual alignments, entity errors made by the limitation of our ENTITY(`c`) action count a lot. Since our ENTITY action directly converts the surface form of a word span into an entity. It cannot correctly generate entity names when they require derivation,[8] or where tokenization errors exist.[9]

4.3 Tune the Aligner with Oracle Parser

Using our oracle parser, we tune the aligner by picking the alignment which leads to the highest-scored AMR graph from the set of candidates (see Figure 2 for the workflow). When more than one alignment achieve the highest score, we choose the one with the smallest number of actions. Intuitively, choosing the one with the smallest number of actions will encourage structurally coherent alignment[10] because coherent alignment requires fewer CACHE actions.

4.4 Parsing Model

Based on our aligner and transition system, we propose a transition-based parser which parse the raw sentence directly into its AMR graph. In this paper, we follow Ballesteros and Al-Onaizan (2017) and use StackLSTM (Dyer et al., 2015) to model the states. The score of a transition action a on state s is calculated as

$$p(a|s) = \frac{\exp\{g_a \cdot \textsc{StackLSTM}(s) + b_a\}}{\sum_{a'} \exp\{g_{a'} \cdot \textsc{StackLSTM}(s) + b_{a'}\}},$$

where $\textsc{StackLSTM}(s)$ encodes the state s into a vector and g_a is the embedding vector of action a. We encourage the reader to refer Ballesteros and Al-Onaizan (2017) for more details.

Ensemble. Ensemble has been shown as an effective way of improving the neural model's performance (He et al., 2017). Since the transition-based parser directly parse a sentence into its AMR graph, ensemble of several parsers is easier compared to the two-staged AMR parsers. In this paper, we ensemble the parsers trained with different initialization by averaging their probability distribution over the actions.

5 Alignment Experiments

5.1 Settings

We evaluate our aligner on the LDC2014T12 dataset. Two kinds of evaluations are carried out including the *intrinsic* and *extrinsic* evaluations.

For the *intrinsic* evaluation, we follow Flanigan et al. (2014) and evaluate the F1 score of the alignments produced by our aligner against the manually aligned data created in their work (*hand-align*). We also use our oracle parser's performance as an *intrinsic* evaluation assuming that better alignment leads to higher scored oracle parser.

For the *extrinsic* evaluation, we plug our alignment into two open-sourced AMR parsers: 1) JAMR (Flanigan et al., 2014, 2016) and 2) CAMR (Wang et al., 2015b,a) and evaluate the final performances of the AMR parsers on both the newswire proportion and the entire dataset of LDC2014T12. We use the configuration in Flanigan et al. (2016) for JAMR and the configuration in Wang et al. (2015a) without semantic role labeling (SRL) features for CAMR.

5.2 Results

Intrinsic Evaluation. Table 3 shows the intrinsic evaluation results, in which our alignment intrinsically outperforms JAMR aligner by achieving better alignment F1 score and leading to a higher scored oracle parser.

---

[7] Since some alignments in *hand-align* were created on incorrect AMR annotations, we filter out them and only use the correct subset which has 136 pairs of alignment and AMR graph. This data is also used in our intrinsic evaluation.

[8] e.g., "*North Koreans*" cannot be parsed into `(name :op1 "North" :op2 "Korea")`

[9] e.g., "*Wi Sung - lac*" cannot be parsed into `(name :op1 "Wi" :op2 "Sung-lac")`

[10] e.g. the first "*nuclear*" aligned to `nucleus~1` in Fig. 1

Aligner	Alignment F1 (on hand-align)	Oracle's Smatch (on dev. dataset)
JAMR	90.6	91.7
Our	95.2	94.7

Table 3: The intrinsic evaluation results.

model	newswire	all
JAMR parser: Word, POS, NER, DEP

CAMR parser: Word, POS, NER, DEP		
+ JAMR aligner	68.4	64.6
+ Our aligner	68.8	65.1

Table 4: The parsing results.

Extrinsic Evaluation. Table 4 shows the results. From this table, we can see that our alignment consistently improves all the parsers by a margin ranging from 0.5 to 1.7. Both the intrinsic and the extrinsic evaluations show the effectiveness our aligner.

5.3 Ablation

To have a better understanding of our aligner, we conduct ablation test by removing the *semantic matching* and *oracle parser tuning* respectively and retrain the JAMR parser on the newswire proportion. The results are shown in Table 5. From this table, we can see that removing either of these components harms the performance. Removing *oracle parser tuning* leads to severe performance drop and the score is even lower than that with JAMR aligner. We address this observation to that alignment noise is introduced by the semantic matching especially by the word embedding similarity component. Without filtering the noise by our oracle parser, just introducing more matching rules will harm the performance.

6 Parsing Experiments

6.1 Settings

We use the same settings in our aligner extrinsic evaluation for the experiments on our transition-based parser. For the input to the parser, we tried two settings: 1) using only words as input, and 2) using words and POS tags as input. Automatic POS tags are assigned with Stanford POS tagger (Manning et al., 2014). Word embedding from Ling et al. (2015) is used in the same way with Ballesteros and Al-Onaizan (2017). To opt out the effect of different initialization in training the neural network, we run 10 differently seeded runs and report their average performance following Reimers and Gurevych (2017).

- Oracle Parser Tuning	67.6
JAMR parser + JAMR aligner	71.3

Table 5: The ablation test results.

6.2 Results

Table 6 shows the performance of our transition-based parser along with comparison to the parsers in the previous works. When compared with our transition-based counterpart (Ballesteros and Al-Onaizan, 2017), our word-only model outperforms theirs using the same JAMR alignment. The same trend is witnessed using words and POS tags as input. When replacing the JAMR alignments with ours, the parsing performances are improved in the same way as in Table 4, which further confirms the effectiveness of our aligner.

The second block in Table 6 shows the results of our ensemble parser, in which ensemble significantly improves the performance and more parsers ensembled, more improvements are achieved. An ensemble of 10 parsers with only words as input achieves 68.1 Smatch F1 score which is comparable to the AMR parser of Wang and Xue (2017). Using the minimal amount of additional syntactic information – POS tags, the performance of the ensemble of 10 parsers is further pushed to 68.4, which surpasses that of Wang and Xue (2017) which relied on named entity recognition (NER) and dependency parsing (DEP).

A further study on the speed shows that our 10 parser ensemble can parse 43 tokens per second which is faster than JAMR (7 tokens/sec.) and CAMR (24 tokens/sec.) thanks to the simplicity of our model and independence of preprocessing, like NER and DEP.[11]

6.3 Comparison to Ballesteros and Al-Onaizan (2017)

To explain the improved performance against Ballesteros and Al-Onaizan (2017) in Table 6, we

give a comprehensive comparison between our transition system and that of Ballesteros and Al-Onaizan (2017).

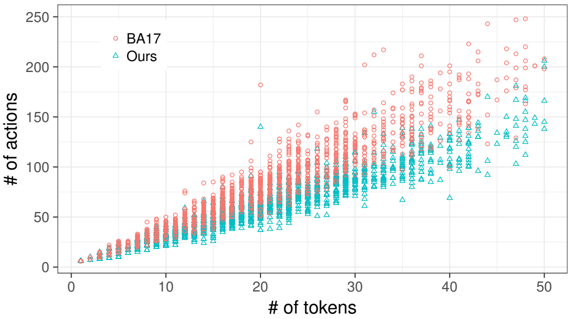

Figure 3: Number of actions required to parse the development set by two systems.

Capability. In both these two systems, a span of words can only be derived into concept for one time. "Patch" actions are required to generate new concepts from the one that is aligned to the same span.[12] Ballesteros and Al-Onaizan (2017) uses a DEPENDENT action to generate one tail concept for one hop and cannot deal with the cases which have a chain of more than two concepts aligned to the same span. Our list-based system differs theirs by using a NEW action to deal these cases. Since the new concept is pushed onto the buffer, NEW action can be repeatedly applied and used to generate arbitrary concepts that aligned to the same span. On the development set of LDC2014T12, our oracle achieves 91.7 Smatch F1 score over the JAMR alignment, which outperforms Ballesteros and Al-Onaizan (2017)'s oracle (89.5 in their paper) on the same alignment. This result confirms that our list-based system is more powerful.

Number of Actions. Our list-based system also differs theirs in the number of oracle actions required to parse the same AMR graphs. We use the oracles from two systems to parse the development set of LDC2014T12 on the same JAMR alignments. Figure 3 shows the comparison in which our system clearly uses fewer actions (the average number of our system is 63.7 and that of Ballesteros and Al-Onaizan (2017) is 86.4). Using fewer actions makes the parser learned from the oracle less prone to error propagation. We attribute the improved performance in Table 6 to this advantage of transition system.

7 Conclusion

In this paper, we propose a new AMR aligner which is tuned by a novel transition-based AMR oracle parser. Our aligner is also enhanced by rich semantic resource and recalls more alignments. Both the intrinsic and extrinsic evaluations show the effectiveness of our aligner by achieving higher alignment F1 score and consistently improving two open-sourced AMR parsers. We also develop transition-based AMR parser based on our aligner and transition system and it achieves a performance of 68.4 Smatch F1 score via ensemble with only words and POS tags as input.

Abstract

We propose a novel *dependency-based hybrid tree* model for semantic parsing, which converts natural language utterance into machine interpretable meaning representations. Unlike previous state-of-the-art models, the semantic information is interpreted as the latent dependency between the natural language words in our joint representation. Such dependency information can capture the interactions between the semantics and natural language words. We integrate a neural component into our model and propose an efficient dynamic-programming algorithm to perform tractable inference. Through extensive experiments on the standard multilingual GeoQuery dataset with eight languages, we demonstrate that our proposed approach is able to achieve state-of-the-art performance across several languages. Analysis also justifies the effectiveness of using our new dependency-based representation.[1]

1 Introduction

Semantic parsing is a fundamental task within the field of natural language processing (NLP). Consider a natural language (NL) sentence and its corresponding meaning representation (MR) as illustrated in Figure 1. Semantic parsing aims to transform the natural language sentences into machine interpretable meaning representations automatically. The task has been popular for decades and keeps receiving significant attention from the NLP community. Various systems (Zelle and Mooney, 1996; Kate et al., 2005; Zettlemoyer and Collins, 2005; Liang et al., 2011) were proposed over the years to deal with different types of semantic representations. Such models include structure-based models (Wong and Mooney, 2006; Lu et al., 2008; Kwiatkowski et al., 2010; Jones et al., 2012) and neural network based models (Dong and Lapata, 2016; Cheng et al., 2017).

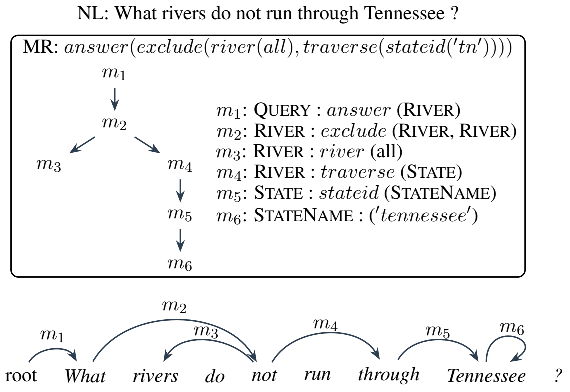

Figure 1: Top: natural language (NL) sentence; middle: meaning representation (MR); bottom: dependency-based hybrid tree representation.

Following various previous research efforts (Wong and Mooney, 2006; Lu et al., 2008; Jones et al., 2012), in this work, we adopt a popular class of semantic formalism – logical forms that can be equivalently represented as tree structures. The tree representation of an example MR is shown in the middle of Figure 1. One challenge associated with building a semantic parser is that the exact correspondence between the words and atomic semantic units are not explicitly given during the training phase. The key to the building of a successful semantic parsing model lies in the identification of a good *joint* latent representation of both the sentence and its corresponding semantics. Example joint representations proposed in the literature include a chart used in phrase-based translation (Wong and Mooney, 2006), a constituency tree-like representation known as *hybrid tree* (Lu et al., 2008), and a CCG-based derivation tree (Kwiatkowski et al., 2010).

Previous research efforts have shown the effec-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2431–2441
Brussels, Belgium, October 31 - November 4, 2018.

tiveness of using dependency structures to extract semantic representations (Debusmann et al., 2004; Cimiano, 2009; Bédaride and Gardent, 2011; Stanovsky et al., 2016). Recently, Reddy et al. (2016, 2017) proposed a model to construct logical representations from sentences that are parsed into dependency structures. Their work demonstrates the connection between the dependency structures of a sentence and its underlying semantics. Although their setup and objectives are different from ours where externally trained dependency parsers are assumed available and their system was trained to use the semantics for a specific down-stream task, the success of their work motivates us to propose a novel joint representation that can explicitly capture dependency structures among words for the semantic parsing task.

In this work, we propose a new joint representation for both semantics and words, presenting a new model for semantic parsing. Our main contributions can be summarized as follows:

- We present a novel *dependency-based hybrid tree* representation that captures both words and semantics in a joint manner. Such a dependency tree reveals semantic dependencies between words which are easily interpretable.
- We show that exact dynamic programming algorithms for inference can be designed on top of our new representation. We further show that the model can be integrated with neural networks for improved effectiveness.
- Extensive experiments conducted on the standard multilingual GeoQuery dataset show that our model outperforms the state-of-the-art models on 7 out of 8 languages. Further analysis confirms the effectiveness of our dependency-based representation.

To the best of our knowledge, this is the first work that models the semantics as latent dependencies between words for semantic parsing.

2 Related Work

The literature on semantic parsing has focused on various types of semantic formalisms. The λ-calculus expressions (Zettlemoyer and Collins, 2005) have been popular and widely used in semantic parsing tasks over recent years (Dong and Lapata, 2016; Gardner and Krishnamurthy, 2017; Reddy et al., 2016, 2017; Susanto and Lu, 2017a; Cheng et al., 2017). Dependency-based compositional semantics (DCS)[2] was introduced by Liang et al. (2011), whose extension, λ-DCS, was later proposed by Liang (2013). Various models (Berant et al., 2013; Wang et al., 2015; Jia and Liang, 2016) on semantic parsing with the λ-DCS formalism were proposed. In this work, we focus on the tree-structured semantic formalism which has been examined by various research efforts (Wong and Mooney, 2006; Kate and Mooney, 2006; Lu et al., 2008; Kwiatkowski et al., 2010; Jones et al., 2012; Lu, 2014; Zou and Lu, 2018).

Wong and Mooney (2006) proposed the WASP semantic parser that regards the task as a phrase-based machine translation problem. Lu et al. (2008) proposed a generative process to generate natural language words and semantic units in a joint model. The resulting representation is called *hybrid tree* where both natural language words and semantics are encoded into a joint representation. The UBL-s (Kwiatkowski et al., 2010) parser applied the CCG grammar (Steedman, 1996) to model the joint representation of both semantic units and contiguous word sequences which do not overlap with one another. Jones et al. (2012) applied a generative process with Bayesian tree transducer and their model also simultaneously generates the meaning representations and natural language words. Lu (2014, 2015) proposed a discriminative version of the hybrid tree model of (Lu et al., 2008) where richer features can be captured. Dong and Lapata (2016) proposed a sequence-to-tree model using recurrent neural networks where the decoder can branch out to produce tree structures. Susanto and Lu (2017b) augmented the discriminative hybrid tree model with multilayer perceptron and achieved state-of-the-art performance.

There exists another line of work that applies given syntactic dependency information to semantic parsing. Titov and Klementiev (2011) decomposed a syntactic dependency tree into fragments and modeled the semantics as relations between the fragments. Poon (2013) learned to derive semantic structures based on syntactic dependency trees predicted by the Stanford dependency parser. Reddy et al. (2016, 2017) proposed a linguistically motivated procedure to transform syntactic dependencies into logical forms. Their semantic parsing performance relies on the quality of the syntactic dependencies. Unlike such efforts, we do not re-

---

[2] Unlike ours, their work captures dependencies between semantic units but not natural language words.

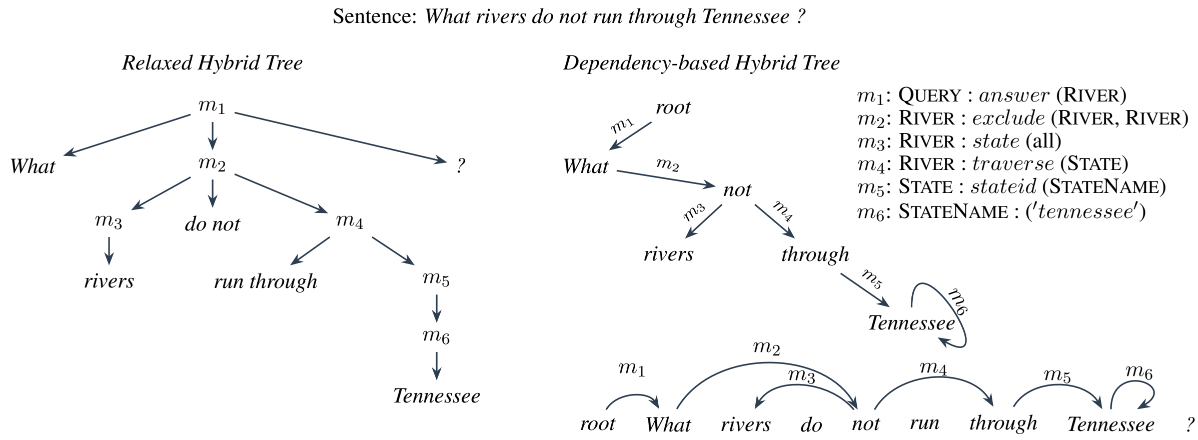

Figure 2: The *relaxed hybrid tree* (left) (Lu, 2014) and our *dependency-based hybrid tree* (right) as well as the flat representation (bottom right) of the example in Figure 1.

quire external syntactic dependencies, but model the semantic units as latent dependencies between natural language words.

3 Approach

3.1 Variable-free Semantics

The variable-free semantic representations in the form of FunQL (Kate et al., 2005) used by the defacto GeoQuery dataset (Zelle and Mooney, 1996) encode semantic compositionality of the logical forms (Cheng et al., 2017). In the tree-structured semantic representations as illustrated in Figure 1, each tree node is a semantic unit of the following form:

$$m_i \equiv \tau_\alpha : p_\alpha(\tau_\beta^*)$$

where m_i denotes the complete semantic unit, which consists of semantic type τ_α, function symbol p_α and an argument list of semantic types τ_β^* (here $*$ denotes that there can be 0, 1, or 2 semantic types in the argument list. This number is known as the *arity* of m_i). Each semantic unit can be regarded as a function that takes in other (partial) semantic representations of certain types as arguments and returns a semantic representation of a specific type. For example in Figure 1, the root unit is represented by m_1, the type of this unit is QUERY, the function name is $answer$ and it has a single argument RIVER which is a semantic type. With recursive function composition, we can obtain a complete MR as shown in Figure 1.

3.2 Dependency-based Hybrid Trees

To jointly encode the tree-structured semantics $\boldsymbol{m}$ and a natural language sentence $\boldsymbol{n}$, we introduce our novel *dependency-based hybrid tree*. Figure 2 (right) shows the two equivalent ways of visualizing the dependency-based hybrid tree based on the example given in Figure 1. In this example, $\boldsymbol{m}$ is the tree-structured semantics $m_1(m_2(m_3, m_4(m_5(m_6))))$ and $\boldsymbol{n}$ is the sentence $\{w_1, w_2, \cdots, w_8\}$[3]. Our dependency-based hybrid tree $\boldsymbol{t}$ consists of a set of dependencies between the natural language words, each of which is labeled with a semantic unit. Formally, a dependency arc is represented as (w_p, w_c, m_i), where w_p is the *parent* of this dependency, w_c is the *child*, and m_i is the semantic unit that serves as the *label* for the dependency arc. A valid dependency-based hybrid tree (with respect to a given semantic representation) allows one to recover the correct semantics from it. Thus, one constraint is that for any two adjacent dependencies (w_p, w_c, m_i) and (w'_p, w'_c, m_j), where $w_c \equiv w'_p$, m_i must be the parent of m_j in the tree-structured representation $\boldsymbol{m}$. For example, in Figure 2, the dependencies (*not*, *through*, m_4) and (*through*, *Tennessee*, m_5) satisfy the above condition. However, we cannot replace (*through*, *Tennessee*, m_5) with, for example, (*through*, *Tennessee*, m_6), since m_6 is not the child of m_4. Furthermore, the number of children for a word in the dependency tree should be consistent with the arity of the corresponding semantic unit that points to it. For example, "*not*" has 2 children in our dependency-based hybrid tree representation because the semantic unit m_2 (i.e., RIVER : $exclude$ (RIVER, RIVER)) has arity 2. Also, "*rivers*" is the leaf as m_3, which points to it, has arity 0. We will discuss in Section 3.3

---

[3] We also introduce a special token "*root*" as w_0.

Abstract Semantic Unit	Arity	Dependency Pattern

C	2	**XY**, **YX**

Table 1: List of dependency patterns.

on how to derive the set of allowable dependency-based hybrid trees for a given $(\boldsymbol{m}, \boldsymbol{n})$ pair.

To understand the potential advantages of our new joint representation, we compare it with the *relaxed hybrid tree* representation (Lu, 2014), which is illustrated on the left of Figure 2. We highlight some similarities and differences between the two representations from the *span level* and *word level* perspectives.

In a relaxed hybrid tree representation, words and semantic units jointly form a constituency tree-like structure, where the former are leaves and the latter are internal nodes of such a joint representation. Such a representation is able to capture alignment between the natural language words and semantics at the span level.[4] For example, m_2 covers the span from "*rivers*" to "*Tennessee*", which allows the interactions between the semantic unit and the span to be captured. Similarly, in our dependency-based hybrid tree, such span level word-semantics correspondence can also be captured. For example, the arc between "*not*" and "*through*" is labeled by the semantic unit m_4. This also allows the interactions between m_4 and words within the span from "*not*" to "*through*" to be captured.

While both models are able to capture the span-level correspondence between words and semantics, we can observe that in the relaxed hybrid tree, some words within the span are more directly related to the semantic unit (e.g., "*do not*" are more related to m_2) and some are not. Specifically, in their representation, the span level information assigned to the parent semantic unit always contains the span level information assigned to all its child semantic units. This may not always be desirable and may lead to irrelevant features. In fact, Lu (2014) also empirically showed that the span-level features may not always be helpful in their representation. In contrast, in our dependency-based hybrid tree, the span covered by m_2 is from "*What*" to "*not*", which only consists of the span level information associated with its first child semantic units. Therefore, our representation is more flexible in capturing the correspondence between words and semantics at the span level, allowing the model to choose the relevant span for features.

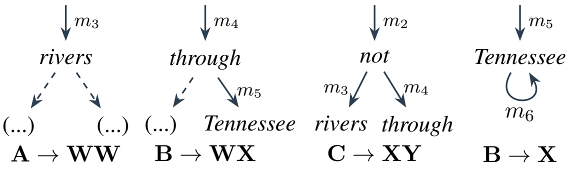

Figure 3: Example dependency patterns used in the dependency-based hybrid tree of Figure 2.

Furthermore, our representation can also capture precise interactions between words through dependency arcs labeled with semantic units. For example, the semantic unit m_4 on the dependency arc from "*not*" to "*through*" in our representation can be used to capture their interactions. However, such information could not be straightforwardly captured in a relaxed hybrid tree, which is essentially a constituency tree-like representation. In the same example, consider the word "*not*" that bridges two arcs labeled by m_2 and m_4. Lexical features defined over such arcs can be used to indirectly capture the interactions between semantic units and guide the tree construction process. We believe such properties can be beneficial in practice, especially for certain languages. We will examine their significance in our experiments later.

3.3 Dependency Patterns

To define the set of allowable dependency-based hybrid tree representation so as to allow us to perform exact inference later, we introduce the *dependency patterns* as shown in Table 1. We use **A**, **B** or **C** to denote the abstract semantic units with arity 0, 1, and 2, respectively. We use **W** to denote a contiguous word span, and **X** and **Y** to denote the first and second child semantic unit, respectively.

We explain these patterns with concrete cases in Figure 3 based on the example in Figure 2. For the first case, the semantic unit m_3 has arity 0, the pattern involved is **WW**, indicating both the left-hand and right-hand sides of "*rivers*" (under the dependency arc with semantic unit m_3) are just word spans (**W**, whose length could be zero). In the second case, the semantic unit m_4 has arity 1, the pattern involved is **WX**, indicating the left-hand side of "*through*" (under the arc of semantic unit m_4) is a word span and the right-hand side should be handled by the first child of m_4 in the

---

[4] We refer readers to (Lu, 2014) for more details.

semantic tree, which is m_5 in this case. In the third case, the semantic unit m_2 has two arguments, and the pattern involved in the example is $\mathbf{XY}$, meaning the left-hand and right-hand sides should be handled by the first and second child semantic units (i.e., m_3 and m_4), respectively.[5] The final case illustrates that we also allow self-loops on our dependency-based hybrid trees, where an arc can be attached to a single word.[6] To avoid an infinite number of self-loops over a word, we set a maximum depth c to restrict the maximum number of recurrences, which is similar to the method introduced in (Lu, 2015).

Based on the dependency patterns, we are able to define the set of all possible allowable *dependency-based hybrid tree* representations. Each representation essentially belongs to a class of *projective* dependency trees where semantic units appear on the dependency arcs and (some of the) words are selected as nodes. The semantic tree can be constructed by following the arcs while referring to the dependency patterns involved.

3.4 Model

Given the natural language words $\boldsymbol{n}$, our task is to predict $\boldsymbol{m}$, which is a tree-structured meaning representation, consisting of a set of semantic units as the nodes in the semantic tree. We use $\boldsymbol{t}$ to denote a dependency-based hybrid tree (as shown in Figure 2), which jointly encodes both natural language words and the gold meaning representation. Let $\mathcal{T}(\boldsymbol{n}, \boldsymbol{m})$ denote all the possible dependency-based hybrid trees that contain the natural language words $\boldsymbol{n}$ and the meaning representation $\boldsymbol{m}$. We adopt the widely-used structured prediction model conditional random fields (CRF) (Lafferty et al., 2001). The probability of a possible meaning representation $\boldsymbol{m}$ and dependency-based hybrid tree $\boldsymbol{t}$ for a sentence $\boldsymbol{n}$ is given by:

$$P_{\mathbf{w}}(\boldsymbol{m}, \boldsymbol{t}|\boldsymbol{n}) = \frac{e^{\mathbf{w}\cdot\mathbf{f}(\boldsymbol{n},\boldsymbol{m},\boldsymbol{t})}}{\sum_{\boldsymbol{m}',\boldsymbol{t}' \in \mathcal{T}(\boldsymbol{n},\boldsymbol{m}')} e^{\mathbf{w}\cdot\mathbf{f}(\boldsymbol{n},\boldsymbol{m}',\boldsymbol{t}')}}$$

where $\mathbf{f}(\boldsymbol{n}, \boldsymbol{m}, \boldsymbol{t})$ is the feature vector defined over the $(\boldsymbol{n}, \boldsymbol{m}, \boldsymbol{t})$ tuple, and $\mathbf{w}$ is the parameter vector. Since we do not have the knowledge of the "true" dependencies during training, $\boldsymbol{t}$ is regarded as a latent-variable in our model. We marginalize $\boldsymbol{t}$ in the above equation and the resulting model is a latent-variable CRF (Quattoni et al., 2005):

$$\begin{aligned} P_{\mathbf{w}}(\boldsymbol{m}|\boldsymbol{n}) &= \sum_{\boldsymbol{t}\in\mathcal{T}(\boldsymbol{n},\boldsymbol{m})} P_{\mathbf{w}}(\boldsymbol{m}, \boldsymbol{t}|\boldsymbol{n}) \\ &= \frac{\sum_{\boldsymbol{t}\in\mathcal{T}(\boldsymbol{n},\boldsymbol{m})} e^{\mathbf{w}\cdot\mathbf{f}(\boldsymbol{n},\boldsymbol{m},\boldsymbol{t})}}{\sum_{\boldsymbol{m}',\boldsymbol{t}' \in \mathcal{T}(\boldsymbol{n},\boldsymbol{m}')} e^{\mathbf{w}\cdot\mathbf{f}(\boldsymbol{n},\boldsymbol{m}',\boldsymbol{t}')}} \end{aligned} \tag{1}$$

Given a dataset $\mathcal{D}$ of $(\boldsymbol{n}, \boldsymbol{m})$ pairs, our objective is to minimize the negative log-likelihood:[7]

$$\mathcal{L}(\mathbf{w}) = -\sum_{(\boldsymbol{n},\boldsymbol{m})\in\mathcal{D}} \log \sum_{\boldsymbol{t}\in\mathcal{T}(\boldsymbol{n},\boldsymbol{m})} P_{\mathbf{w}}(\boldsymbol{m}, \boldsymbol{t}|\boldsymbol{n}) \tag{2}$$

The gradient for model parameter w_k is:

$$\begin{aligned} \frac{\partial\mathcal{L}(\mathbf{w})}{\partial w_k} =& \sum_{(\boldsymbol{n},\boldsymbol{m})\in\mathcal{D}} \sum_{\boldsymbol{m}',\boldsymbol{t}} \mathbf{E}_{P_{\mathbf{w}}(\mathbf{m}',\boldsymbol{t}|\boldsymbol{n})}[f_k(\boldsymbol{n}, \boldsymbol{m}, \boldsymbol{t})] \\ &- \sum_{(\boldsymbol{n},\boldsymbol{m})\in\mathcal{D}} \sum_{\boldsymbol{t}} \mathbf{E}_{P_{\mathbf{w}}(\boldsymbol{t}|\boldsymbol{n},\boldsymbol{m})}[f_k(\boldsymbol{n}, \boldsymbol{m}, \boldsymbol{t})] \end{aligned}$$

where $f_k(\boldsymbol{n}, \boldsymbol{m}, \boldsymbol{t})$ represents the number of occurrences of the k-th feature. With both the objective and gradient above, we can minimize the objective function with standard optimizers, such as L-BFGS (Liu and Nocedal, 1989) and stochastic gradient descent. Calculation of these expectations involves all possible dependency-based hybrid trees. As there are exponentially many such trees, an efficient inference procedure is required. We will present our efficient algorithm to perform exact inference for learning and decoding in the next section.

3.5 Learning and Decoding

We propose dynamic-programming algorithms to perform efficient and exact inference, which will be used for calculating the objective and gradients discussed in the previous section. The algorithms are inspired by the inside-outside style algorithm (Baker, 1979), graph-based dependency parsing (Eisner, 2000; Koo and Collins, 2010; Shi et al., 2017), and the *relaxed hybrid tree* model (Lu, 2014, 2015). As discussed in Section 3.3, our latent dependency trees are projective as in traditional dependency parsing (Eisner, 1996; Nivre and Scholz, 2004; McDonald et al., 2005) – the dependencies are non-crossing with respect to the word order (see bottom of Figure 1).

---

[5] Analogously, the pattern $\mathbf{YX}$ would mean m_4 handles the left-hand side and m_3 right-hand side.

[6] The limitations associated with disallowing such a pattern have been discussed in the previous work of (Lu, 2015).

[7] We ignore the L_2 regularization term for brevity.

The objective function in Equation 2 can be further decomposed into the following form[8]:

$$\mathcal{L}(\mathbf{w}) = -\sum_{(\boldsymbol{n},\boldsymbol{m})\in\mathcal{D}} \log \sum_{\boldsymbol{t}\in\mathcal{T}(\boldsymbol{n},\boldsymbol{m})} e^{\mathbf{w}\cdot\mathbf{f}(\boldsymbol{n},\boldsymbol{m},\boldsymbol{t})} + \sum_{(\boldsymbol{n},\boldsymbol{m})\in\mathcal{D}} \log \sum_{\boldsymbol{m}',\boldsymbol{t}'\in\mathcal{T}(\boldsymbol{n},\boldsymbol{m}')} e^{\mathbf{w}\cdot\mathbf{f}(\boldsymbol{n},\boldsymbol{m}',\boldsymbol{t}')}$$

We can see the first term is essentially the combined score of all the possible latent structures containing the pair $(\boldsymbol{n}, \boldsymbol{m})$. The second term is the combined score for all the possible latent structures containing $\boldsymbol{n}$. We show how such scores can be calculated in a factorized manner, based on the fact that we can recursively decompose a dependency-based hybrid tree based on the dependency patterns we introduced.

Formally, we introduce two interrelated dynamic-programming structures that are similar to those used in graph-based dependency parsing (Eisner, 2000; Koo and Collins, 2010; Shi et al., 2017), namely *complete span* and *complete arc span*. Figure 4a shows an example of *complete span* (left) and *complete arc span* (right). The *complete span* (over $[i, j]$) consists of a headword (at i) and its descendants on one side (they altogether form a subtree), a dependency pattern and a semantic unit. The *complete arc span* is a span (over $[i, j]$) with a dependency between the headword (at i) and the modifier (at k). We use $C_{i,j,p,m}$ to denote a complete span, where i and j represent the indices of the headword and endpoint, p is the dependency pattern and m is the semantic unit. Analogously, we use $A_{i,k,j,p,m}$ to denote a complete arc span where i and k are used to denote the additional dependency from the word at the i-th position as headword to the word at the k-th position as modifier.

As we can see from the derivation in Figure 4, each type of span can be constructed from smaller spans in a bottom-up manner. Figure 4a shows that a complete span is constructed from a complete arc span following the dependency patterns in Table 1. Figure 4b shows a complete arc span can be simply constructed from two smaller complete spans based on the dependency pattern. In Figure 4c and 4d, we further show how such two complete spans with pattern $\mathbf{X}$ (or $\mathbf{Y}$) and $\mathbf{W}$ can be constructed. Figure 4c illustrates how to model a transition from one semantic unit to another where the parent is m_1 and the child is m_2 in the semantic tree. If m_2 has arity 1, then the pattern is $\mathbf{B}$ following the dependency patterns in Table 1. For spans with a single word, we use the lowercase $\mathbf{w}$ as the pattern to indicate this fact, as shown in Figure 4d. They are the atomic spans used for building larger spans. As the complete span in Figure 4d is associated with pattern $\mathbf{W}$, which means the words within this span are under the semantic unit m_1, we can incrementally construct this span with atomic spans. We illustrate the construction of a complete dependency-based hybrid tree in the supplementary material.

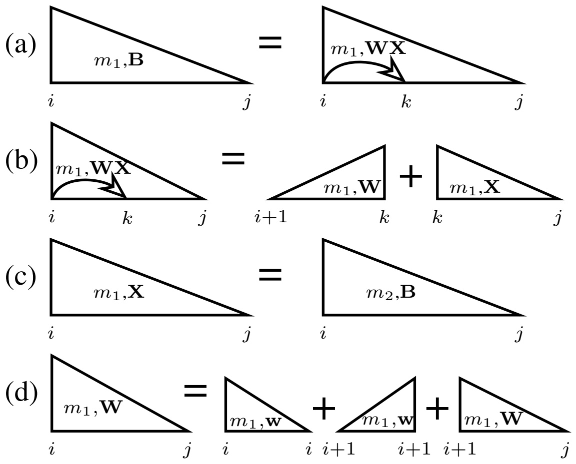

Figure 4: The dynamic-programing structures and derivation of our model. The other direction is symmetric. See supplementary material for the complete structures.

Our final goal during training for a sentence $\boldsymbol{n} = \{w_0, w_1, \cdots, w_N\}$ is to construct all the possible *complete spans* that cover the interval $[0, N]$, which can be represented as $C_{0,N,\cdot,\cdot}$. Similar to the chart-based dependency parsing algorithms (Eisner, 1996, 2000; Koo and Collins, 2010), we can obtain the *inside* and *outside* scores using our dynamic-programming derivation in Figure 4 during the inference process, which can then be used to calculate the objective and feature expectations. Since the spans are defined by at most three free indices, the dependency pattern and the semantic unit, our dynamic-programming algorithm requires $\mathcal{O}(N^3 M)$ time[9] where M is the number of semantic units. The resulting complexity is the same as the relaxed hybrid tree model (Lu, 2014).

During decoding, we can find the optimal (tree-structured) meaning representation $\boldsymbol{m}^*$ for a given

---

[8] Regularization term is excluded for brevity.

[9] We omit a small constant factor associated with patterns.

Feature Type	Examples
Word	"m_4 & *run*", "m_4 & *through*"
Pattern	"m_2 & **XY**", "m_4 & **WX**"
Transition	"m_2 & m_3", "m_2 & m_4"
Head word	"m_2 & *What*", "m_4 & *not*"
Modifier word	"m_2 & *not*", "m_4 & *through*"
Bag of words	"m_4 & *not*", "m_4 & *run*", "m_4 & *through*"

Table 2: Features for the example in Figure 2.

input sentence $\boldsymbol{n}$ by the Viterbi algorithm. This step can also be done efficiently with our dynamic-programming approach, where we switch from marginal inference to MAP inference:

$$\boldsymbol{m}^*, \boldsymbol{t}^* = \underset{\boldsymbol{m},\boldsymbol{t} \in \mathcal{T}(\boldsymbol{n},\boldsymbol{m})}{\arg\max} \; e^{\mathbf{w}\cdot\mathbf{f}(\boldsymbol{n},\boldsymbol{m},\boldsymbol{t})}$$

A similar decoding procedure has been used in previous work (Lu, 2014; Durrett and Klein, 2015) with CKY-based parsing algorithm.

3.6 Features

As shown in Equation 1, the features are defined on the tuple $(\boldsymbol{n}, \boldsymbol{m}, \boldsymbol{t})$. With the dynamic-programming procedure, we can define the features over the structures in Figure 2. Our feature design is inspired by the hybrid tree model (Lu, 2015) and graph-based dependency parsing (McDonald et al., 2005). Table 2 shows the feature templates for the example in Figure 2. Specifically, we define simple unigram features (concatenation of a semantic unit and a word that directly appears under the unit), pattern features (concatenation of the semantic unit and the child pattern) and transition features (concatenation of the parent and child semantic units). They form our basic feature set.

Additionally, with the structured properties of dependencies, we can define dependency-related features (McDonald et al., 2005). We use the parent (head) and child (modifier) words of the dependency as features. We also use the bag-of-words covered under a dependency as features. The dependency features are useful in helping improve the performance as we can see in the experiments section.

3.7 Neural Component

Following the approach used in Susanto and Lu (2017b), we could further incorporate neural networks into our latent-variable graphical model. The integration is analogous to the approaches described in the neural CRF models (Do and Artieres, 2010; Durrett and Klein, 2015; Gormley, 2015; Lample et al., 2016), where we use neural networks to learn distributed feature representations within our graphical model.

We employ a neural architecture to calculate the score associated with each dependency arc (w_p, w_c, m) (here w_p and w_c are the parent and child words in the dependency and m is the semantic unit over the arc), where the input to the neural network consists of words (i.e., (w_p, w_c)) associated with this dependency and the neural network will calculate a score for each possible semantic unit, including m. The two words are first mapped to word embeddings $\mathbf{e}_p$ and $\mathbf{e}_c$ (both of dimension d). Next, we use a bilinear layer[10] (Socher et al., 2013; Chen et al., 2016) to capture the interaction between the parent and the child in a dependency:

$$r_i = \mathbf{e}_p^{\mathbf{T}} \mathbf{U}_i \mathbf{e}_c$$

where r_i represents the score for the i-th semantic unit and $\mathbf{U}_i \in \mathbb{R}^{d \times d}$. The scores are then incorporated into the probability expression in Equation 1 during learning and decoding. As a comparison, we also implemented a variant where our model directly takes in the average embedding of $\mathbf{e}_p$ and $\mathbf{e}_c$ as additional features, without using our neural component.

4 Experiments

Data and evaluation methodology We conduct experiments on the publicly available variable-free version of the GeoQuery dataset, which has been widely used for semantic parsing (Wong and Mooney, 2006; Lu et al., 2008; Jones et al., 2012). The dataset consists of 880 pairs of natural language sentences and the corresponding tree-structured semantic representations. This dataset is annotated with eight languages. The original annotation of this dataset is English (Zelle and Mooney, 1996) and Jones et al. (2012) annotated the dataset with three more languages: German, Greek and Thai. Lu and Ng (2011) released the Chinese annotation and Susanto and Lu (2017b) annotated the corpus with three additional languages: Indonesian, Swedish and Farsi. In order to compare with previous work (Jones et al., 2012; Lu, 2015), we follow the standard splits with 600 instances for training and 280 instances for testing. To evaluate the performance, we follow the

Table 3: Performance comparison with state-of-the-art models on GeoQuery dataset. († represents the system is using lambda-calculus expressions as meaning representations.)

standard evaluation procedure used in various previous works (Wong and Mooney, 2006; Lu et al., 2008; Jones et al., 2012; Lu, 2015) to construct the Prolog query from the tree-structured semantic representation using a standard and publicly available script. The queries are then used to retrieve the answers from the GeoQuery database, and we report accuracy and F_1 scores.

Hyperparameters We set the maximum depth c of the semantic tree to 20, following Lu (2015). The L_2 regularization coefficient is tuned from 0.01 to 0.05 using 5-fold cross-validation on the training set. The Polyglot (Al-Rfou et al., 2013) multilingual word embeddings[11] (with 64 dimensions) are used for all languages. We use L-BFGS (Liu and Nocedal, 1989) to optimize the DEPHT model until convergence and stochastic gradient descent (SGD) with a learning rate of 0.05 to optimize the neural DEPHT model. We implemented our neural component with the Torch7 library (Collobert et al., 2011). Our complete implementation is based on the StatNLP[12] structured prediction framework (Lu, 2017).

4.1 Baseline Systems

We run the released systems of several state-of-the-art semantic parsers, namely the WASP parser (Wong and Mooney, 2006), HYBRIDTREE model (Lu et al., 2008), UBL system (Kwiatkowski et al., 2010), *relaxed hybrid tree* (RHT) (Lu, 2015)[13], the sequence-to-tree (SEQ2TREE) model (Dong and Lapata, 2016), the *neural hybrid tree* (NEURAL HT) model (Susanto and Lu, 2017b), and the multilingual semantic parser (Susanto and Lu, 2017a) with single language (MSP-SINGLE) as input. The results for TREETRANS (Jones et al., 2012) are taken from their paper.

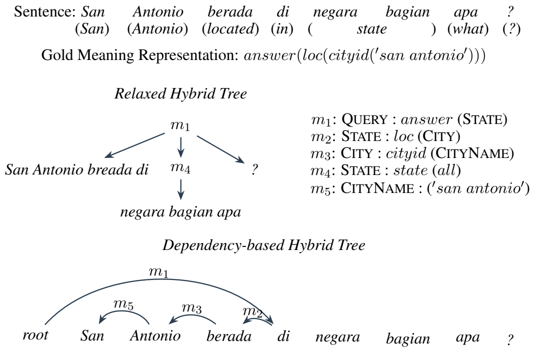

Figure 5: Example results from DEPHT and RHT on Indonesian.

4.2 Results and Discussion

Table 3 (top) shows the results of our dependency-based hybrid tree model compared with non-neural models which achieve state-of-the-art performance on the GeoQuery dataset. Our model DEPHT achieves competitive performance and outperforms the previous best system RHT on 6 languages. Improvements on the Indonesian dataset are particularly striking (+11.8 absolute points in F_1). We further investigated the outputs from both systems on Indonesian by doing error analysis. We found 40 instances that are incorrectly predicted by RHT are correctly predicted by DEPHT. We found that 77.5% of the errors are due to incorrect alignment between words and semantic units. Figure 5 shows an example of such errors where the relaxed hybrid tree fails to capture the correct alignment. We can see the question is asking "*What state is San Antonio located in?*". However, the natural language word order in Indone-

sian is different from English, where the phrase "*berada di*" that corresponds to m_2 (i.e., loc) appears between "*San Antonio*" (which corresponds to $m_5 - 'san\ antonio'$) and "*what*" (which corresponds to m_1 – $answer$). Such a structural non isomorphism issue between the sentence and the semantic tree makes the relaxed hybrid tree parser unable to produce a joint representation with valid word-semantics alignment. This issue makes the RHT model unable to predict the semantic unit m_2 (i.e., loc) as RHT has to align the words "*San Antonio*" which should be aligned to m_5 before aligning "*berada di*". However, m_5 has arity 0 and cannot have m_2 as its child. Thus, it would be impossible for the RHT model to predict such a meaning representation as output. In contrast, we can see that our dependency-based hybrid tree representation appears to be more flexible in handling such cases. The dependency between the two words "*di*" (*in*) and "*berada*" (*located*) is also well captured by the arc between them that is labeled with m_2. The error analysis reveals the flexibility of our joint representation in different languages in terms of the word ordering, indicating that the novel dependency-based joint representation is more robust and suffers less from language-specific characteristics associated with the data.

Effectiveness of dependency To investigate the helpfulness of the features defined over latent dependencies, we conduct ablation tests by removing the dependency-related features. Table 4 shows the performance of augmenting different dependency features in our DepHT model with basic features. Specifically, we investigate the performance of head word and modifier word features (HM) and also the bag-of-words features (BOW) that can be extracted based on dependencies. It can be observed that dependency features associated with the words are crucial for all languages, especially the BOW features.

Effectiveness of neural component The bottom part of Table 3 shows the performance comparison among models that involve neural networks. Our DepHT model with embeddings as features can outperform neural baselines across several languages (i.e., Chinese, Indonesian and Swedish). From the table, we can see the neural component is effective, which consistently gives better results than DepHT and the approach that uses word embedding features only. Susanto and Lu (2017b) presented the Neural HT model with different window size J for their multilayer perceptron. Their performance will differ with different window sizes, which need to be tuned for each language. In our neural component, we do not require such a language-specific hyperparameter, yet our neural approach consistently achieves the highest performance on 7 out of 8 languages compared with all previous approaches. As both the embeddings and the neural component are defined on the dependency arcs, the superior results also reveal the effectiveness of our dependency-based hybrid tree representation.

5 Conclusions and Future Work

In this work, we present a novel *dependency-based hybrid tree* model for semantic parsing. The model captures the underlying semantic information of a sentence as latent dependencies between the natural language words. We develop an efficient algorithm for exact inference based on dynamic-programming. Extensive experiments on benchmark dataset across 8 different languages demonstrate the effectiveness of our newly proposed representation for semantic parsing.

Future work includes exploring alternative approaches such as transition-based methods (Nivre et al., 2006; Chen and Manning, 2014) for semantic parsing with latent dependencies, applying our dependency-based hybrid trees on other types of logical representations (e.g., lambda calculus expressions and SQL (Finegan-Dollak et al., 2018)) as well as multilingual semantic parsing (Jie and Lu, 2014; Susanto and Lu, 2017a).

Acknowledgments

We would like to thank the anonymous reviewers for their constructive comments on this work. We would also like to thank Yanyan Zou for helping us with running the experiments for baseline systems. This work is supported by Singapore Ministry of Education Academic Research Fund (AcRF) Tier 2 Project MOE2017-T2-1-156, and is partially supported by project 61472191 under the National Natural Science Foundation of China.

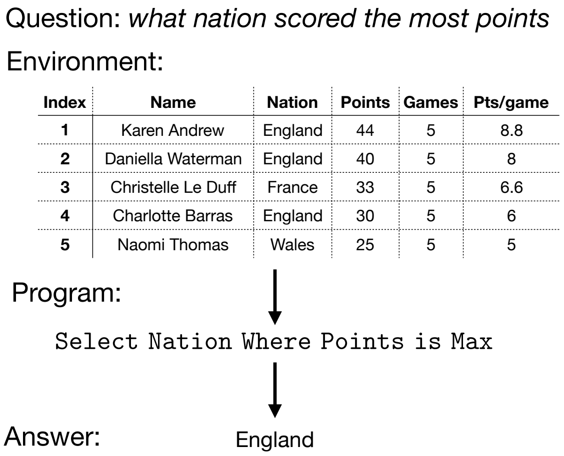
Abstract

Semantic parsing from denotations faces two key challenges in model training: (1) given only the denotations (e.g., answers), search for good candidate semantic parses, and (2) choose the best model update algorithm. We propose effective and general solutions to each of them. Using *policy shaping*, we bias the search procedure towards semantic parses that are more compatible to the text, which provide better supervision signals for training. In addition, we propose an update equation that generalizes three different families of learning algorithms, which enables fast model exploration. When experimented on a recently proposed sequential question answering dataset, our framework leads to a new state-of-the-art model that outperforms previous work by 5.0% absolute on exact match accuracy.

1 Introduction

Semantic parsing from denotations (SpFD) is the problem of mapping text to executable formal representations (or *program*) in a situated environment and executing them to generate denotations (or *answer*), in the absence of access to correct representations. Several problems have been handled within this framework, including question answering (Berant et al., 2013; Iyyer et al., 2017) and instructions for robots (Artzi and Zettlemoyer, 2013; Misra et al., 2015).

Consider the example in Figure 1. Given the question and a table environment, a semantic parser maps the question to an executable program, in this case a SQL query, and then executes the query on the environment to generate the answer *England*. In the SpFD setting, the training data does not contain the correct programs. Thus, the existing learning approaches for SpFD perform two steps for every training example, a search step that explores the space of programs and finds suitable candidates, and an update step that uses these programs to update the model. Figure 2 shows the two step training procedure for the above example.



Question: *what nation scored the most points*

Environment:

Index	Name	Nation	Points	Games	Pts/game
1	Karen Andrew	England	44	5	8.8
2	Daniella Waterman	England	40	5	8
3	Christelle Le Duff	France	33	5	6.6
4	Charlotte Barras	England	30	5	6
5	Naomi Thomas	Wales	25	5	5

Program:

`Select Nation Where Points is Max`

Answer: England

Figure 1: An example of semantic parsing from denotations. Given the table environment, map the question to an executable program that evaluates to the answer.

In this paper, we address two key challenges in model training for SpFD by proposing a novel learning framework, improving both the *search* and *update* steps. The first challenge, the existence of *spurious programs*, lies in the search step. More specifically, while the success of the search step relies on its ability to find programs that are semantically correct, we can only verify if the program can generate correct answers, given that no gold programs are presented. The search step is complicated by *spurious programs*, which happen to evaluate to the correct answer but do not represent accurately the meaning of the natural language question. For example, for the environment in Figure 1, the program `Select Nation Where Name = Karen Andrew` is spurious. Selecting spurious programs as positive examples can greatly affect the performance of semantic parsers as these programs generally do not gen-

5	Naomi Thomas	Wales	25	5	5

Figure 2: An example of semantic parsing from denotation. Given the question and the table environment, there are several programs which are spurious.

eralize to unseen questions and environments.

The second challenge, *choosing a learning algorithm*, lies in the update step. Because of the unique *indirect supervision* setting of SpFD, the quality of the learned semantic parser is dictated by the choice of how to update the model parameters, often determined empirically. As a result, several families of learning methods, including maximum marginal likelihood, reinforcement learning and margin based methods have been used. How to effectively explore different model choices could be crucial in practice.

Our contributions in this work are twofold. To address the first challenge, we propose a policy shaping (Griffith et al., 2013) method that incorporates simple, lightweight domain knowledge, such as a small set of lexical pairs of tokens in the question and program, in the form of a *critique policy* (§ 3). This helps bias the search towards the correct program, an important step to improve supervision signals, which benefits learning regardless of the choice of algorithm. To address the second challenge, we prove that the parameter update step in several algorithms are similar and can be viewed as special cases of a generalized update equation (§ 4). The equation contains two variable terms that govern the update behavior. Changing these two terms effectively defines an infinite class of learning algorithms where different values lead to significantly different results. We study this effect and propose a novel learning framework that improves over existing methods.

We evaluate our methods using the sequential question answering (SQA) dataset (Iyyer et al., 2017), and show that our proposed improvements to the search and update steps consistently enhance existing approaches. The proposed algorithm achieves new state-of-the-art and outperforms existing parsers by 5.0%.

2 Background

We give a formal problem definition of the semantic parsing task, followed by the general learning framework for solving it.

2.1 The Semantic Parsing Task

The problem discussed in this paper can be formally defined as follows. Let $\mathcal{X}$ be the set of all possible questions, $\mathcal{Y}$ programs (e.g., SQL-like queries), $\mathcal{T}$ tables (i.e., the structured data in this work) and $\mathcal{Z}$ answers. We further assume access to an executor $\Phi : \mathcal{Y} \times \mathcal{T} \to \mathcal{Z}$, that given a program $y \in \mathcal{Y}$ and a table $t \in \mathcal{T}$, generates an answer $\Phi(y, t) \in \mathcal{Z}$. We assume that the executor and all tables are deterministic and the executor can be called as many times as possible. To facilitate discussion in the following sections, we define an environment function $e_t : \mathcal{Y} \to \mathcal{Z}$, by applying the executor to the program as $e_t(y) = \Phi(y, t)$.

Given a question x and an environment e_t, our aim is to *generate* a program $y^* \in \mathcal{Y}$ and then execute it to produce the answer $e_t(y^*)$. Assume that for any $y \in \mathcal{Y}$, the score of y being a correct program for x is $\texttt{score}_\theta(y, x, t)$, parameterized by θ. The *inference* task is thus:

$$y^* = \arg\max_{y \in \mathcal{Y}} \texttt{score}_\theta(y, x, t) \tag{1}$$

As the size of $\mathcal{Y}$ is exponential to the length of the program, a generic *search* procedure is typically employed for Eq. (1), as efficient dynamic algorithms typically do not exist. These search procedures generally maintain a beam of program states sorted according to some scoring function, where each program state represents an incomplete program. The search then generates a new program state from an existing state by performing an action. Each action adds a set of tokens (e.g., `Nation`) and keyword (e.g., `Select`) to a program state. For example, in order to generate the program in Figure 1, the DynSP parser (Iyyer et al., 2017) will take the first action as adding the SQL expression `Select Nation`. Notice that $\texttt{score}_\theta$ can be used in either probabilistic or non-probabilistic models. For probabilistic models, we assume that it is a Boltzmann policy, meaning that $p_\theta(y \mid x, t) \propto \exp\{\texttt{score}_\theta(y, x, t)\}$.

2.2 Learning

Learning a semantic parser is equivalent to learning the parameters θ in the scoring function, which is a structured learning problem, due to the large, structured output space $\mathcal{Y}$. Structured learning algorithms generally consist of two major components: *search* and *update*. When the gold programs are available during training, the search procedure finds a set of high-scoring incorrect programs. These programs are used by the update step to derive loss for updating parameters. For example, these programs are used for approximating the partition-function in maximum-likelihood objective (Liang et al., 2011) and finding set of programs causing margin violation in margin based methods (Daumé III and Marcu, 2005). Depending on the exact algorithm being used, these two components are not necessarily separated into isolated steps. For instance, parameters can be updated in the middle of search (e.g., Huang et al., 2012).

For learning semantic parsers from denotations, where we assume only answers are available in a training set $\{(x_i, t_i, z_i)\}_{i=1}^{N}$ of N examples, the basic construction of the learning algorithms remains the same. However, the problems that search needs to handle in SpFD is more challenging. In addition to finding a set of high-scoring incorrect programs, the search procedure also needs to *guess* the correct program(s) evaluating to the gold answer z_i. This problem is further complicated by the presence of spurious programs, which generate the correct answer but are semantically incompatible with the question. For example, although all programs in Figure 2 evaluate to the same answer, only one of them is correct. The issue of the spurious programs also affects the design of model update. For instance, maximum marginal likelihood methods treat all the programs that evaluate to the gold answer equally, while maximum margin reward networks use model score to break tie and pick one of the programs as the correct reference.

3 Addressing Spurious Programs: Policy Shaping

Given a training example (x, t, z), the aim of the search step is to find a set $\mathcal{K}(\mathtt{x}, \mathtt{t}, \mathtt{z})$ of programs consisting of correct programs that evaluate to z and high-scoring incorrect programs. The search step should avoid picking up spurious programs for learning since such programs typically do not generalize. For example, in Figure 2, the spurious program `Select Nation Where Index is Min` will evaluate to an incorrect answer if the indices of the first two rows are swapped[1]. This problem is challenging since among the programs that evaluate to the correct answer, most of them are spurious.

The search step can be viewed as following an exploration policy $b_\theta(y|x, t, z)$ to explore the set of programs $\mathcal{Y}$. This exploration is often performed by beam search and at each step, we either sample from b_θ or take the top scoring programs. The set $\mathcal{K}(\mathtt{x}, \mathtt{t}, \mathtt{z})$ is then used by the update step for parameter update. Most search strategies use an exploration policy which is based on the score function, for example $b_\theta(y|x, t, z) \propto \exp\{\texttt{score}_\theta(y, t)\}$. However, this approach can suffer from a *divergence* phenomenon whereby the score of spurious programs picked up by the search in the first epoch increases, making it more likely for the search to pick them up in the future. Such *divergence* issues are common with latent-variable learning and often require careful initialization to overcome (Rose, 1998). Unfortunately such initialization schemes are not applicable for deep neural networks which form the model of most successful semantic parsers today (Jia and Liang, 2016; Misra and Artzi, 2016; Iyyer et al., 2017). Prior work, such as ϵ-greedy exploration (Guu et al., 2017), has reduced the severity of this problem by introducing random noise in the search procedure to avoid saturating the search on high-scoring spurious programs. However, random noise need not bias the search towards the correct program(s). In this paper, we introduce a simple policy-shaping method to guide the search. This approach allows incorporating prior knowledge in the exploration policy and can bias the search away from spurious programs.

---

[1] This transformation preserves the answer of the question.

Algorithm 1 Learning a semantic parser from denotation using generalized updates.

```
Input: Training set $\{(x_i, t_i, z_i\}_{i=1}^{N}$ (see Section 2), learning
    rate $\mu$ and stopping epoch $\tilde{T}$(see Section 4).
Definitions: $\texttt{score}_\theta(y, x, t)$ is a semantic parsing model
    parameterized by $\theta$. $p_s(y \mid x, t)$ is the policy used for
    exploration and search$(\theta, x, t, z, p_s)$ generates candi-
    date programs for updating parameters (see Section 3).
    $\Delta$ is the generalized update (see Section 4).
Output: Model parameters $\theta$.
1: » Iterate over the training data.
2: for $t = 1$ to $T$, $i = 1$ to $N$ do
3:     » Find candidate programs using the shaped policy.
4:     $\mathcal{K} = \text{search}(\theta, x_i, t_i, z_i, p_s)$
5:     » Compute generalized gradient updates
6:     $\theta = \theta + \mu\Delta(\mathcal{K})$
7: return $\theta$
```

Policy Shaping Policy shaping is a method to introduce prior knowledge into a policy (Griffith et al., 2013). Formally, let the current behavior policy be $b_\theta(y|x, t, z)$ and a predefined critique policy, the prior knowledge, be $p_c(y|x, t)$. Policy shaping defines a new *shaped behavior policy* $p_b(y|x, t)$ given by:

$$p_b(y|x, t) = \frac{b_\theta(y|x, t, z)p_c(y|x, t)}{\sum_{y' \in \mathcal{Y}} b_\theta(y'|x, t, z)p_c(y'|x, t)}. \quad (2)$$

Using the shaped policy for exploration biases the search towards the critique policy's preference. We next describe a simple critique policy that we use in this paper.

Lexical Policy Shaping We qualitatively observed that correct programs often contains tokens which are also present in the question. For example, the correct program in Figure 2 contains the token *Points*, which is also present in the question. We therefore, define a simple surface form similarity feature $\texttt{match}(x, y)$ that computes the ratio of number of non-keyword tokens in the program y that are also present in the question x.

However, surface-form similarity is often not enough. For example, both the first and fourth program in Figure 2 contain the token *Points* but only the fourth program is correct. Therefore, we also use a simple co-occurrence feature that triggers on frequently co-occurring pairs of tokens in the program and instruction. For example, the token *most* is highly likely to co-occur with a correct program containing the keyword `Max`. This happens for the example in Figure 2. Similarly the token *not* may co-occur with the keyword `NotEqual`. We assume access to a lexicon $\Lambda = \{(w_j, \omega_j)\}_{j=1}^{k}$ containing k lexical pairs of tokens and keywords. Each lexical pair (w, ω) maps the token w in a text to a keyword ω in a program. For a given program y and question x, we define a co-occurrence score as $\texttt{co\_occur}(y, x) = \sum_{(w,\omega)\in\Lambda} \mathbb{1}\{w \in x \wedge \omega \in y\}\}$. We define critique score $\texttt{critique}(y, x)$ as the sum of the `match` and `co_occur` scores. The critique policy is given by:

$$p_c(y|x, t) \propto \exp\left(\eta * \texttt{critique}(y, x)\right), \quad (3)$$

where η is a single scalar hyper-parameter denoting the confidence in the critique policy.

4 Addressing Update Strategy Selection: Generalized Update Equation

Given the set of programs generated by the search step, one can use many objectives to update the parameters. For example, previous work have utilized maximum marginal likelihood (Krishnamurthy et al., 2017; Guu et al., 2017), reinforcement learning (Zhong et al., 2017; Guu et al., 2017) and margin based methods (Iyyer et al., 2017). It could be difficult to choose the suitable algorithm from these options.

In this section, we propose a principle and general update equation such that previous update algorithms can be considered as special cases to this equation. Having a general update is important for the following reasons. First, it allows us to understand existing algorithms better by examining their basic properties. Second, the generalized update equation also makes it easy to implement and experiment with various different algorithms. Moreover, it provides a framework that enables the development of new variations or extensions of existing learning methods.

In the following, we describe how the commonly used algorithms are in fact very similar – their update rules can all be viewed as special cases of the proposed generalized update equation. Algorithm 1 shows the meta-learning framework. For every training example, we first find a set of candidates using an exploration policy (line 4). We use the program candidates to update the parameters (line 6).

4.1 Commonly Used Learning Algorithms

We briefly describe three algorithms: *maximum marginalized likelihood*, *policy gradient* and *maximum margin reward*.

Maximum Marginalized Likelihood The maximum marginalized likelihood method maximizes the log-likelihood of the training data by marginalizing over the set of programs.

$$\begin{aligned} J_{MML} &= \log p(z_i|x_i, t_i) \\ &= \log \sum_{y \in \mathcal{Y}} p(z_i|y, t_i) p(y|x_i, t_i) \end{aligned} \quad (4)$$

Because an answer is deterministically computed given a program and a table, we define $p(z \mid y, t)$ as 1 or 0 depending upon whether the y evaluates to z given t, or not. Let $\texttt{Gen(z,t)} \subseteq \mathcal{Y}$ be the set of compatible programs that evaluate to z given the table t. The objective can then be expressed as:

$$J_{MML} = \log \sum_{y \in \texttt{Gen}(\texttt{z}_\texttt{i}, \texttt{t}_\texttt{i})} p(y|x_i, t_i) \quad (5)$$

In practice, the summation over $\texttt{Gen}(.)$ is approximated by only using the compatible programs in the set $\mathcal{K}$ generated by the search step.

Policy Gradient Methods Most reinforcement learning approaches for semantic parsing assume access to a reward function $R : \mathcal{Y} \times \mathcal{X} \times \mathcal{Z} \rightarrow \mathbb{R}$, giving a scalar reward $R(y, z)$ for a given program y and the correct answer z.[2] We can further assume without loss of generality that the reward is always in $[0, 1]$. Reinforcement learning approaches maximize the expected reward J_{RL}:

$$J_{RL} = \sum_{y \in \mathcal{Y}} p(y|x_i, t_i) R(y, z_i) \quad (6)$$

J_{RL} is hard to approximate using numerical integration since the reward for all programs may not be known a priori. Policy gradient methods solve this by approximating the derivative using a sample from the policy. When the search space is large, the policy may fail to sample a correct program, which can greatly slow down the learning. Therefore, off-policy methods are sometimes introduced to bias the sampling towards high-reward yielding programs. In those methods, an additional exploration policy $u(y|x_i, t_i, z_i)$ is used to improve sampling. Importance weights are used to make the gradient unbiased (see Appendix for derivation).

Maximum Margin Reward For every training example (x_i, t_i, z_i), the maximum margin reward method finds the highest scoring program y_i that evaluates to z_i, as the *reference* program, from the set $\mathcal{K}$ of programs generated by the search. With a margin function $\delta : \mathcal{Y} \times \mathcal{Y} \times \mathcal{Z} \rightarrow \mathbb{R}$ and reference program y, the set of programs $\mathcal{V}$ that violate the margin constraint can thus be defined as:

$$\begin{aligned} \mathcal{V} = \{y' \mid y' \in \mathcal{Y} \textbf{ and } \texttt{score}_\theta(y, x, t) \\ \leq \texttt{score}_\theta(y', x, t) + \delta(y, y', z)\}, \end{aligned} \quad (7)$$

where $\delta(y, y', z) = R(y, z) - R(y', z)$. Similarly, the program that most violates the constraint can be written as:

$$\begin{aligned} \bar{y} = \arg\max_{y' \in \mathcal{Y}} \{\texttt{score}_\theta(y', x, t) + \delta(y, y', z) \\ -\texttt{score}_\theta(y, x, t)\} \end{aligned} \quad (8)$$

The most-violation margin objective (negative margin loss) is thus defined as:

$$\begin{aligned} J_{MMR} = & -\max\{0, \texttt{score}_\theta(\bar{y}, x_i, t_i) \\ & -\texttt{score}_\theta(y_i, x_i, t_i) + \delta(y_i, \bar{y}, z_i)\} \end{aligned}$$

Unlike the previous two learning algorithms, margin methods only update the score of the reference program and the program that violates the margin.

4.2 Generalized Update Equation

Although the algorithms described in §4.1 seem very different on the surface, the gradients of their loss functions can in fact be described in the same generalized form, given in Eq. (9)[3]. In addition to the gradient of the model scoring function, this equation has two variable terms, $w(\cdot)$, $q(\cdot)$. We call the first term $w(y, x, t, z)$ *intensity*, which is a positive scalar value and the second term $q(y|x, t)$ the *competing distribution*, which is a probability distribution over programs. Varying them makes the equation equivalent to the update rule of the algorithms we discussed, as shown in Table 1. We also consider meritocratic update policy which uses a hyperparameter β to sharpen or smooth the intensity of maximum marginal likelihood (Guu et al., 2017).

Intuitively, $w(y, x, t, z)$ defines the positive part of the update equation, which defines how aggressively the update favors program y. Likewise, $q(y|x, t)$ defines the negative part of the learning

---

[2] This is essentially a contextual bandit setting. Guu et al. (2017) also used this setting. A general reinforcement learning setting requires taking a sequence of actions and receiving a reward for each action. For example, a program can be viewed as a sequence of parsing actions, where each action can get a reward. We do not consider the general setting here.

[3] See Appendix for the detailed derivation.

Generalized Update Equation:

$$\Delta(\mathcal{K}) = \sum_{y \in \mathcal{K}} w(y, x, t, z) \left(\nabla_\theta \texttt{score}_\theta(y, x, t) - \sum_{y' \in \mathcal{Y}} q(y'|x, t) \nabla_\theta \texttt{score}_\theta(y', x, t) \right) \tag{9}$$

Learning Algorithm	**Intensity** $w(y, x, t, z)$	**Competing Distribution** $q(y\|x, t)$
Maximum Margin Likelihood	$\frac{p(z\|y)p(y\|x)}{\sum_{y'} p(z\|y')p(y'\|x)}$	$p(y\|x)$
Meritocratic(β)	$\frac{(p(z\|y)p(y\|x))^\beta}{\sum_{y'} (p(z\|y')p(y'\|x))^\beta}$	$p(y\|x)$
REINFORCE	$\mathbb{1}\{y = \hat{y}\}R(y, z)$	$p(y\|x)$
Off-Policy Policy Gradient	$\mathbb{1}\{y = \hat{y}\}\, R(y, z)\, \frac{p(y\|x)}{u(y\|x,z)}$	$p(y\|x)$
Maximum Margin Reward (MMR)	$\mathbb{1}\{y = y^*\}$	$\mathbb{1}\{y = \bar{y}\}$
Maximum Margin Avg. Violation Reward (MAVER)	$\mathbb{1}\{y = y^*\}$	$1/\|\mathcal{V}\|\mathbb{1}\{y \in \mathcal{V}\}$

Table 1: Parameter updates for various learning algorithms are special cases of Eq. (9), with different choices of intensity w and competing distribution q. We do not show dependence upon table t for brevity. For off-policy policy gradient, u is the exploration policy. For margin methods, y^* is the reference program (see §4.1), $\mathcal{V}$ is the set of programs that violate the margin constraint (cf. Eq. (7)) and $\bar{y}$ is the most violating program (cf. Eq. (8)). For REINFORCE, $\hat{y}$ is sampled from $\mathcal{K}$ using $p(.)$ whereas for Off-Policy Policy Gradient, $\hat{y}$ is sampled using $u(.)$.

algorithm, namely how aggressively the update penalizes the members of the program set.

The generalized update equation provides a tool for better understanding individual algorithm, and helps shed some light on when a particular method may perform better.

Intensity versus Search Quality In SpFD, the effectiveness of the algorithms for SpFD is closely related to the quality of the search results given that the gold program is not available. Intuitively, if the search quality is good, the update algorithm could be aggressive on updating the model parameters. When the search quality is poor, the algorithm should be conservative.

The intensity $w(\cdot)$ is closely related to the aggressiveness of the algorithm. For example, the maximum marginal likelihood is less aggressive given that it produces a non-zero intensity over all programs in the program set $\mathcal{K}$ that evaluate to the correct answer. The intensity for a particular correct program y is proportional to its probability $p(y|x, t)$. Further, meritocratic update becomes more aggressive as β becomes larger.

In contrast, REINFORCE and maximum margin reward both have a non-zero intensity only on a single program in $\mathcal{K}$. This value is 1.0 for maximum margin reward, while for reinforcement learning, this value is the reward. Maximum margin reward therefore updates most aggressively in favor of its selection while maximum marginal likelihood tends to hedge its bet. Therefore, the maximum margin methods should benefit the most when the search quality improves.

Stability The general equation also allows us to investigate the stability of a model update algorithm. In general, the variance of update direction can be high, hence less stable, if the model update algorithm has peaky competing distribution, or it puts all of its intensity on a single program. For example, REINFORCE only samples one program and puts non-zero intensity only on that program, so it could be unstable depending on the sampling results.

The competing distribution affects the stability of the algorithm. For example, maximum margin reward penalizes only the most violating program and is benign to other incorrect programs. Therefore, the MMR algorithm could be unstable during training.

New Model Update Algorithm The general equation provides a framework that enables the development of new variations or extensions of existing learning methods. For example, in order to improve the stability of the MMR algorithm, we propose a simple variant of maximum margin reward, which penalizes all violating programs instead of only the most violating one. We call this approach *maximum margin average violation reward* (MAVER), which is included in Table 1 as well. Given that MAVER effectively considers more negative examples during each update, we expect that it is more stable compared to the MMR algorithm.

5 Experiments

We describe the setup in §5.1 and results in §5.2.

5.1 Setup

Dataset We use the sequential question answering (SQA) dataset (Iyyer et al., 2017) for our experiments. SQA contains 6,066 sequences and each sequence contains up to 3 questions, with 17,553 questions in total. The data is partitioned into training (83%) and test (17%) splits. We use 4/5 of the original train split as our training set and the remaining 1/5 as the dev set. We evaluate using exact match on answer. Previous state-of-the-art result on the SQA dataset is 44.7% accuracy, using maximum margin reward learning.

Semantic Parser Our semantic parser is based on DynSP (Iyyer et al., 2017), which contains a set of SQL actions, such as adding a clause (e.g., `Select Column`) or adding an operator (e.g., `Max`). Each action has an associated neural network module that generates the score for the action based on the instruction, the table and the list of past actions. The score of the entire program is given by the sum of scores of all actions.

We modified DynSP to improve its representational capacity. We refer to the new parser as DynSP++. Most notably, we included new features and introduced two additional parser actions. See Appendix 8.2 for more details. While these improvements help us achieve state-of-the-art results, the majority of the gain comes from the learning contributions described in this paper.

Hyperparameters For each experiment, we train the model for 30 epochs. We find the optimal stopping epoch by evaluating the model on the dev set. We then train on train+dev set till the stopping epoch and evaluate the model on the held-out test set. Model parameters are trained using stochastic gradient descent with learning rate of 0.1. We set the hyperparameter η for policy shaping to 5. All hyperparameters were tuned on the dev set. We use 40 lexical pairs for defining the `co-occur` score. We used common English superlatives (e.g., *highest*, *most*) and comparators (e.g., *more*, *larger*) and did not fit the lexical pairs based on the dataset.

Given the model parameter θ, we use a base exploration policy defined in (Iyyer et al., 2017). This exploration policy is given by $b_\theta(y \mid x, t, z) \propto \exp(\lambda \cdot R(y, z) + \mathtt{score}_\theta(y, \theta, z))$. $R(y, z)$ is the reward function of the incomplete program y, given the answer z. We use a reward function $R(y, z)$ given by the Jaccard similarity of the gold answer z and the answer generated by the program y. The value of λ is set to infinity, which essentially is equivalent to sorting the programs based on the reward and using the current model score for tie breaking. Further, we prune all syntactically invalid programs. For more details, we refer the reader to (Iyyer et al., 2017).

5.2 Results

Table 2 contains the dev and test results when using our algorithm on the SQA dataset. We observe that margin based methods perform better than maximum likelihood methods and policy gradient in our experiment. Policy shaping in general improves the performance across different algorithms. Our best test results outperform previous SOTA by 5.0%.

Policy Gradient vs Off-Policy Gradient REINFORCE, a simple policy gradient method, achieved extremely poor performance. This likely due to the problem of exploration and having to sample from a large space of programs. This is further corroborated from observing the much superior performance of off-policy policy gradient methods. Thus, the sampling policy is an important factor to consider for policy gradient methods.

The Effect of Policy Shaping We observe that the improvement due to policy shaping is 6.0% on the SQA dataset for MAVER and only 1.3% for maximum marginal likelihood. We also observe that as β increases, the improvement due to policy shaping for meritocratic update increases. This supports our hypothesis that aggressive updates of margin based methods is beneficial when the search method is more accurate as compared to maximum marginal likelihood which hedges its bet between all programs that evaluate to the right answer.

Stability of MMR In Section 4, the general update equation helps us point out that MMR could be unstable due to the peaky competing distribution. MAVER was proposed to increase the stability of the algorithm. To measure stability, we cal-

Algorithm	Dev		Test	
	w.o. Shaping	w. Shaping	w.o. Shaping	w. Shaping
Maximum Margin Likelihood	33.2	32.5	31.0	32.3
Meritocratic ($\beta = 0$)	27.1	28.1	31.3	30.1
Meritocratic ($\beta = 0.5$)	28.3	28.7	31.7	32.0

MAVER	39.6	44.1	43.7	**49.7**

Table 2: Experimental results on different model update algorithms, with and without policy shaping.

w	q	Dev
MMR	MML	**41.9**
Off-Policy Policy Gradient	MMR	37.0
MMR	MMR	40.7

Table 3: The dev set results on the new variations of the update algorithms.

culate the mean absolute difference of the development set accuracy between successive epochs during training, as it indicates how much an algorithm's performance fluctuates during training. With this metric, we found mean difference for MAVER is 0.57% where the mean difference for MMR is 0.9%. This indicates that MAVER is in fact more stable than MMR.

Other variations We also analyze other possible novel learning algorithms that are made possible due to generalized update equations. Table 3 reports development results using these algorithms. By mixing different intensity scalars and competing distribution from different algorithms, we can create new variations of the model update algorithm. In Table 3, we show that by mixing the MMR's intensity and MML's competing distribution, we can create an algorithm that outperform MMR on the development set.

Policy Shaping helps against Spurious Programs In order to better understand if policy shaping helps bias the search away from spurious programs, we analyze 100 training examples. We look at the highest scoring program in the beam at the end of training using MAVER. Without policy shaping, we found that 53 programs were spurious while using policy shaping this number came down to 23. We list few examples of spurious program errors corrected by policy shaping in Table 4.

Policy Shaping vs Model Shaping Critique policy contains useful information that can bias the search away from spurious programs. Therefore, one can also consider making the critique policy as part of the model. We call this model shaping. We define our model to be the shaped policy and train and test using the new model. Using MAVER updates, we found that the dev accuracy dropped to 37.1%. We conjecture that the strong prior in the critique policy can hinder generalization in model shaping.

6 Related Work

Semantic Parsing from Denotation Mapping natural language text to formal meaning representation was first studied by Montague (1970). Early work on learning semantic parsers rely on labeled formal representations as the supervision signals (Zettlemoyer and Collins, 2005, 2007; Zelle and Mooney, 1993). However, because getting access to gold formal representation generally requires expensive annotations by an expert, distant supervision approaches, where semantic parsers are learned from denotation only, have become the main learning paradigm (e.g., Clarke et al., 2010; Liang et al., 2011; Artzi and Zettlemoyer, 2013; Berant et al., 2013; Iyyer et al., 2017; Krishnamurthy et al., 2017). Guu et al. (2017) studied the problem of spurious programs and considered adding noise to diversify the search procedure and introduced meritocratic updates.

Reinforcement Learning Algorithms Reinforcement learning algorithms have been applied to various NLP problems including dialogue (Li et al., 2016), text-based games (Narasimhan et al., 2015), information extraction (Narasimhan et al., 2016), coreference resolution (Clark and Man-

Question	without policy shaping	with policy shaping
"of these teams, which had more than 21 losses?"	`SELECT Club WHERE Losses = ROW 15`	`SELECT Club WHERE Losses > 21`
"of the remaining, which earned the most bronze medals?"	`SELECT Nation WHERE Rank = ROW 1`	`FollowUp WHERE Bronze is Max`
"of those competitors from germany, which was not paul sievert?"	`SELECT Name WHERE Time (hand) = ROW 3`	`FollowUp WHERE Name != ROW 5`

Table 4: Training examples and the highest ranked program in the beam search, scored according to the shaped policy, after training with MAVER. Using policy shaping, we can recover from failures due to spurious programs in the search step for these examples.

ning, 2016), semantic parsing (Guu et al., 2017) and instruction following (Misra et al., 2017). Guu et al. (2017) show that policy gradient methods underperform maximum marginal likelihood approaches. Our result on the SQA dataset supports their observation. However, we show that using off-policy sampling, policy gradient methods can provide superior performance to maximum marginal likelihood methods.

Margin-based Learning Margin-based methods have been considered in the context of SVM learning. In the NLP literature, margin based learning has been applied to parsing (Taskar et al., 2004; McDonald et al., 2005), text classification (Taskar et al., 2003), machine translation (Watanabe et al., 2007) and semantic parsing (Iyyer et al., 2017). Kummerfeld et al. (2015) found that max-margin based methods generally outperform likelihood maximization on a range of tasks. Previous work have studied connections between margin based method and likelihood maximization for supervised learning setting. We show them as special cases of our unified update equation for distant supervision learning. Similar to this work, Lee et al. (2016) also found that in the context of supervised learning, margin-based algorithms which update all violated examples perform better than the one that only updates the most violated example.

Latent Variable Modeling Learning semantic parsers from denotation can be viewed as a latent variable modeling problem, where the program is the latent variable. Probabilistic latent variable models have been studied using EM-algorithm and its variant (Dempster et al., 1977). The graphical model literature has studied latent variable learning on margin-based methods (Yu and Joachims, 2009) and probabilistic models (Quattoni et al., 2007). Samdani et al. (2012) studied various variants of EM algorithm and showed that all of them are special cases of a unified framework. Our generalized update framework is similar in spirit.

7 Conclusion

In this paper, we propose a general update equation from semantic parsing from denotation and propose a policy shaping method for addressing the spurious program challenge. For the future, we plan to apply the proposed learning framework to more semantic parsing tasks and consider new methods for policy shaping.

Sentence Compression for Arbitrary Languages via Multilingual Pivoting

Jonathan Mallinson, Rico Sennrich and **Mirella Lapata**

`J.Mallinson@ed.ac.uk, {rsennric,mlap}@inf.ed.ac.uk`

Abstract

In this paper we advocate the use of bilingual corpora which are abundantly available for training sentence compression models. Our approach borrows much of its machinery from neural machine translation and leverages bilingual pivoting: compressions are obtained by translating a source string into a foreign language and then back-translating it into the source while controlling the translation length. Our model can be trained for any language as long as a bilingual corpus is available and performs arbitrary rewrites without access to compression specific data. We release[1] MOSS, a new parallel **M**ultilingual C**o**mpre**ss**ion dataset for English, German, and French which can be used to evaluate compression models across languages and genres.

1 Introduction

Sentence compression aims to produce a summary of a single sentence that retains the most important information while preserving its fluency. The task has attracted much attention due to its potential for applications such as text summarization (Jing, 2000; Madnani et al., 2007; Woodsend and Lapata, 2010; Berg-Kirkpatrick et al., 2011), subtitle generation (Vandeghinste and Pan, 2004; Luotolahti and Ginter, 2015), and the display of text on small-screens (Corston-Oliver, 2001).

The bulk of research on sentence compression has focused on a simplification of the task involving exclusively word deletion (Knight and Marcu, 2002; Riezler et al., 2003; Turner and Charniak, 2005; McDonald, 2006; Clarke and Lapata, 2008; Cohn and Lapata, 2009), whereas a few approaches view sentence compression as a more general text rewriting problem (Galley and McKeown, 2007; Woodsend and Lapata, 2010; Cohn and Lapata, 2013). Irrespective of how the compression task is formulated, most previous work relies on syntactic information such as parse trees to help decide what to delete from a sentence or which rules to learn in order to rewrite a sentence using less words. More recently, there has been much interest in applying neural network models to natural language generation tasks, including sentence compression (Rush et al., 2015; Filippova et al., 2015; Chopra et al., 2016; Kikuchi et al., 2016). Filippova et al. (2015) focus on deletion-based sentence compression which they model as a sequence labeling problem using a recurrent neural network with long short-term memory units (LSTM; Hochreiter and Schmidhuber 1997). Rush et al. (2015) capture the full gamut of rewrite operations drawing insights from encoder-decoder models recently proposed for machine translation (Bahdanau et al., 2015).

Neural network-based approaches are data-driven, relying on the ability of recurrent architectures to learn continuous features without recourse to preprocessing tools or syntactic information (e.g., part-of-speech tags, parse trees). In order to achieve good performance, they require large amounts of training data, in the region of millions of long-short sentence pairs.[2] Existing compression datasets are several orders of magnitude smaller. For example, the Ziff-Davis corpus (Knight and Marcu, 2002) contains 1,067 sentences and originated from a collection of news articles on computer products. Clarke and Lapata (2008) create two manual corpora sampled from written (1,433 sentences) and spoken sources (1,370 sentences). Cohn and Lapata (2013) elicit manual compressions for 625 sentences taken from newspaper articles. More recently, Toutanova et al. (2016) crowdsource a larger corpus which contains manual compressions for single *and* multiple sentences (about 26,000 pairs of source and compressed texts).

[2] Rush et al. (2015) use approximately four million training instances and Filippova et al. (2015) two million.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2453–2464
Brussels, Belgium, October 31 - November 4, 2018.

Since large scale compression datasets do not occur naturally, they must be somehow approximated, e.g., by pairing headlines with the first sentence of a news article (Filippova and Altun, 2013; Rush et al., 2015). As a result, the training corpus construction process must be repeated and reconfigured for new languages and domains (e.g., many headline-first sentence pairs are spurious and need to be filtered using language and domain specific heuristics). And although it may be easy to automatically obtain large scale training data in the news domain, it is not clear how such data can be sourced for many other genres with different writing conventions.

Our work addresses the paucity of data for sentence compression models. We argue that *multilingual* corpora are a rich source for learning a variety of rewrite rules across languages and that existing neural machine translation (NMT) models (Sutskever et al. 2014; Bahdanau et al. 2015) can be easily adapted to the compression task through bilingual pivoting (Mallinson et al., 2017) coupled with methods which decode the output sequence to a desired length (e.g., subject to language and genre requirements). We obtain compressions by translating a source string into a foreign language and then back-translating it into the source while controlling the translation length (Kikuchi et al., 2016). Our model can be trained for any language as long as a bilingual corpus is available, and can perform arbitrary rewrites while taking advantage of multiple pivots if these exist.We also demonstrate that models trained on multilingual data perform well out-of-domain.

Although our approach does not employ compression corpora for training, for evaluation purposes, we create MOSS, a new **M**ultilingual C**o**mpre**ss**ion dataset for English, French, and German. MOSS is a *parallel* corpus containing documents from the European parliament proceedings, TED talks, news commentaries, and the EU bookshop. Each document is written in English, French, and German, and compressed by native speakers of the respective language who process a document at a time. We obtain five compressions per document leading to 2,000 long-short sentence pairs per language. Like previous related resources (Clarke and Lapata, 2008; Cohn and Lapata, 2013; de Loupy et al., 2010) our corpus is curated manually, however it differs from Toutanova et al. (2016) in that it contains compressions for individual sentences, not documents.

There has been relatively little interest in compressing languages other than English. A few models have been proposed for Japanese (Hori and Furui, 2004; Hirao et al., 2009; Harashima and Kurohashi, 2012), including a neural network model (Hasegawa et al., 2017) which repurposes Filippova and Altun's (2013) data construction method for Japanese. There is a compression corpus available for French (de Loupy et al., 2010), however, we are not aware of any modeling work on this language. Overall, there are no standardized datasets in languages other than English, either for training or testing.

Our contributions in this work are three-fold: a novel application of bilingual pivoting to sentence compression; corroborated by empirical results showing that our model scales across languages and text genres without additional supervision over and above what is available in the bilingual parallel data; and the release of a multilingual, multi-reference compression corpus which can be effectively used to gain insight in the compression task and facilitate further research in compression modeling.

2 Pivot-based Neural Compression

In our pivot-based sentence compression model an input sequence is first translated into a foreign language, and then back into the source language. Unlike previous paraphrasing pivoting models (Mallinson et al., 2017), we parameterize our translation models with a length feature, which allows us to produce compressed output. We define two models, performing compression in one step or alternatively in two steps which affords more flexibility in model output.

2.1 NMT Background

In the neural encoder-decoder framework for MT (Bahdanau et al., 2015; Sutskever et al., 2014), an encoder takes in a source $X = (x_1, \ldots, x_{T_x})$ of length T_x and the decoder generates a target sequence $(y_1, \ldots, y_{T_y})$ of length T_y. Let h_i be the hidden state of the source symbol at position i, obtained by concatenating the forward and backward encoder RNN hidden states, $h_i = [\overrightarrow{h_i}; \overleftarrow{h_i}]$. We deviate from previous work (Bahdanau et al., 2015; Sutskever et al., 2014) in that we initialize the decoder with the average of the hidden states, following Sennrich et al. (2017):

$$s_0 = tanh(W_{init} \frac{\sum_{i=1}^{T_x} h_i}{T_x}) \qquad (1)$$

where W_{init} is a learnt parameter. Our decoder is a conditional recurrent neural network, specifically a gated recurrent unit (GRU, Cho et al., 2014) with attention, which we denote as $cGRU_{att}$. $cGRU_{att}$ takes as input the previous hidden state s_{j-1}, the source annotations $C = h_1, ..., h_{T_x}$, and the previously decoded symbol y_{j-1} in order to update its hidden state s_j, which is used to decode symbol y_j at position j:

$$s_j = cGRU_{att}(s_{j-1}, y_{j-1}, C) \tag{2}$$

$cGRU_{att}$ consists of three components. The first combines the previously decoded symbol y_{j-1} and the previous hidden state s_{j-1} to generate an intermediate representation s'_j. The attention mechanism, ATT, inputs the entire context set C along with intermediate hidden state s'_j in order to compute the context vector c_j:

$$c_j = ATT(C, s'_j) = \sum_i^{T_x} \alpha_{ij} h_i \tag{3}$$

$$\alpha_{ij} = \frac{exp(e_{ij})}{\sum_{k=1}^{T_x} exp(e_{kj})} \tag{4}$$

$$e_{ij} = f(s'_j, h_i) \tag{5}$$

Where α_{ij} is the normalized alignment weight between the source symbol at position i and the target symbol at position j, and f is a feedfoward neural network.

Finally, we generate s_j, the hidden state of $cGRU_{att}$, by using the intermediate representation s'_j and the context vector c_j. Given s_j, y_{j-1}, and c_j the output probability $p(y_j | s_j, y_{j-1}, c_j)$ is computed using a feedforward neural network with a softmax activation. We define the probability of sequence y as:

$$P(y|x; \theta) = \prod_{j=1}^{T_y} p(y_j | s_j, y_{j-1}, c_j) \tag{6}$$

2.2 Length Control

To be able to produce compressed sentences, we parameterize our model with a length vector which allows to control the output length. Our approach is similar to the *LenInit* model of Kikuchi et al. (2016), however we use a GRU instead of an LSTM. The hidden state of the decoder consists of the average of the encoder's hidden states but also a length vector LV, a learnt parameter, which is scaled by the desired target length $T_{y'}$. We therefore rewrite Equation (1) as follows:

$$s'_0 = tanh\left(W_{init}\left[\frac{\sum_{i=1}^{T_x} h_i}{T_x}; LV \cdot T_{y'}\right]\right) \tag{7}$$

As such we now define our model as:

$$P(y|x, T_{y'}; \theta) \tag{8}$$

During training, the target length is set to $T_{y'} = T_y$. However, at test time, the target length generally varies according to the domain, genre, and language at hand. We determine the target length experimentally based on a small validation set.

2.3 Pivoting

Pivoting is often used in machine translation to overcome the shortage of parallel data, i,e., when there is no translation path from the source language to the target by taking advantage of paths through an intermediate language. The idea dates back at least to Kay (1997), who observed that ambiguities in translating from one language onto another may be resolved if a translation into some third language is available, and has met with success in phrase-based SMT (Wu and Wang, 2007; Utiyama and Isahara, 2007) and more recently in neural MT systems (Firat et al., 2016).

We use pivoting to provide a path from a source English sentence, via an intermediate foreign language, to English in a compressed form. We propose to extend Mallinson et al.'s (2017) approach to multi-pivoting, where a sentence x is translated to K-best foreign pivots, $F_x = \{f_1, ..., f_K\}$. The probability of generating compression $y = y_1...y_{T_y}$ is decomposed as:

$$P(y|x) = \sum_f^{F_x} P(y|f; \overrightarrow{\theta}) \cdot P(f|x; \overleftarrow{\theta}) \tag{9}$$

which we approximate as the tokenwise weighted average of the pivots:

$$P(y|x) \approx \prod_{j=1}^{T_y} \sum_f^{F_x} P(y_j | y_{<j}, f) P(f|x) \tag{10}$$

where $y_{<j} = y_1, ...y_j$. To ensure a probability distribution, we normalize the K-best list F_x, such that the translation probabilities sum to one. We use beam search to decode tokens by conditioning on multiple pivoting sentences. The results with the best decoding scores are considered candidate compressions.

To ensure the model produces compressed output, we extend the pivoting approach in two ways. In *single step* compression, one of the translation

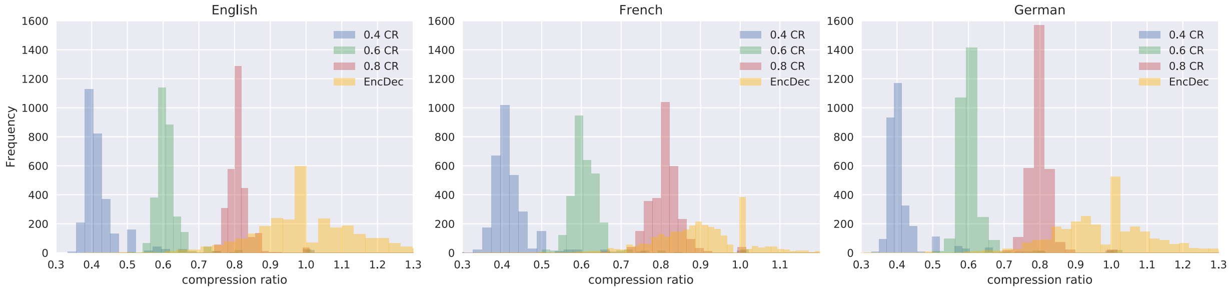

Figure 1: Histograms of output lengths at three compression rates (CR) compared to a vanilla encoder-decoder system which does not manipulate output length. German is used as pivot for English, and English as pivot for French and German.

models is parameterized with length information:

$$P(y|x,T_{y'}) \approx \sum_{f}^{F} P(y|f,T_{y'};\overrightarrow{\theta}) \cdot P(f|x;\overleftarrow{\theta})$$

In *dual-step* compression, we parameterize both translation models with length information:

$$P(y|x,T_{y'},T_{y''}) \approx \sum_{f}^{F} P(y|f,T_{y'};\overrightarrow{\theta}) \cdot P(f|x,T_{y''};\overleftarrow{\theta})$$

We find that dual-compression performs better when the system is expected to drastically compress the source sentence (e.g., in a headline generation task). Imposing a high compression ratio from the start tends to produce unintelligible text. The model attempts to reduce the length of the source at all costs, even at the expense of being semantically faithful to the input. Performing two moderate compressions in succession reduces both length and content conservatively and as a result produces more meaningful text.

In Figure 1 we illustrate how the pivot-based model sketched above can successfully control the output of the generated compressions. We show the output of a single-step compression model on three languages initialized with varying compression rates[3] (see Section 4 for details on how the models were trained and tested). The compression rate (CR) is used to determine length parameter of Equation (8):

$$T_{y'} = T_x \cdot CR \tag{11}$$

The figure shows how the output length varies compared to a vanilla encoder-decoder system which uses pivoting to backtranslate the source language (Mallinson et al., 2017). We can see that the majority of sentences are generated with length close to the desired compression rate.

3 The Moss Dataset

For evaluation purposes, we created a multilingual sentence compression corpus in English, German, and French. The corpus was collated from existing document and sentence aligned multilingual datasets which vary both in terms of topic and genre. We sampled five documents each from:

1. Europarl, the European Parliament Proceedings Parallel Corpus (Koehn, 2005), has been used extensively in machine translation research; it contains the minutes of the European parliament and is a spoken corpus of formulaic nature; speakers take part in debating various issues concerning EU policy (e.g., taxation, environment).
2. The TED parallel Corpus (Cettolo et al., 2012) contains transcripts in multiple languages of short talks devoted to spreading powerful ideas on a variety of topics ranging from science to business and global issues.
3. The EU bookshop corpus (Skadiņš et al., 2014) contains publications from European institutions covering a variety of topics such as refugees, gender equality, and travel.
4. The News Commentary Parallel Corpus contains articles downloaded from Project Syndicate, an international media organization that publishes commentary on global topics (e.g., economics, world affairs).

We obtained compressions using the Crowdflower platform. Crowdworkers were given instructions that explained the task and defined sentence compression with the aid of examples. They

---

[3] The term refers to the percentage of words retained from the source sentence in the compression.

English	French	German
On the very day that the earthquake struck, the European Council asked the High Representative and the Commission to mobilise all appropriate assistance. *Assistance was mobilized on the very day of the earthquake.*	Le jour même du tremblement de terre, le Conseil européen a demandé à la haute représentante et à la Commission de mobiliser toute l'aide appropriée. *Le Conseil européen a demandé à la haute reprsentante et à la Commission de mobiliser l'aide.*	Am gleichen Tag, an dem das Erdbeben ausbrach, ersuchte der Europäische Rat die Hohe Vertreterin und die Kommission um die Mobilisierung aller angemessenen Hilfe. *Europa erbrachte Hilfe noch am selben Tag.*
We're at a tipping point in human history, a species poised between gaining the stars and losing the planet we call home. *We're at tipping point in human history, poised between gaining the stars and losing the Earth.*	L'histoire humaine est à un tournant. Notre espèce hésite à toucher les étoiles ou à perdre la planète qui est la sienne. *L'humanité est à un tourt. Notre espèce a envie des étoiles ou perdre sa planète.*	Wir stehen vor einem historischen Wendepunkt: zwischen dem Griff nach den Sternen und dem Verlust unseres Heimatplaneten. *Wir sind vor einem historischen Wendepunkt: zwischen dem Griff nach Sternen und Verlust unseres Planeten.*
Surveys undertaken by the World Bank in developing countries show that when poor people are asked to name the three most important concerns they face good health is always mentioned. *World Bank surveys in developing countries show poor people always name good health as an important concern.*	Les enquêtes menées par la Banque mondiale dans les pays en développement montrent que, quand on demande aux populations pauvres de nommer les trois défis les plus importants qu'ils rencontrent, leur "bonne santé" fait toujours partie de cette liste. *Quand on demande aux populations pauvres de nommer les trois défis les plus importants qu'ils rencontrent, leur "bonne santé" fait toujours partie de la liste.*	Umfragen der Weltbank in Entwicklungsländern zeigen, wenn man Arme nach den drei wichtigsten Anliegen fragt, die sie beschäftigen, wird "Gesundheit" immer genannt. *Umfragen in Entwicklungslndern zeigen, dass bei Armen das wichtigste Anliegen Gesundheit ist.*

Table 1: Examples of crowdsourced compressions (in italics) from the MOSS corpus. Sentences shown (in order of appearance) from Europarl, TED, and News Commentary corpora.

were asked to compress while preserving the most important information, ensuring the sentences remained grammatical and meaning preserving. Annotators were encouraged to use any rewriting operations that seemed appropriate, e.g., to delete words, add new words, substitute them, or reorder them. Annotation proceeded on a document-by-document basis, line-by-line. Crowdworkers compressed the first twenty lines of each document and we elicited five compression per document. Example compressions are shown in Table 1.

Table 2 presents various statistics on our corpus. As can be seen, Europarl contains the longest sentences across languages (see column SL), TED contains the shortest sentences, while the other two corpora are somewhere in-between. We also observe that crowdworkers compress the least when it comes to TED (see column CR), which is not surprising given the brevity of the utterances. Overall, French speakers seem more conservative when shortening sentences compared to English and German. In general, compression rates are genre dependent, they range from 0.58 (for English Europarl) to 0.84 (for German TED). We also examined the degree to which crowdworkers paraphrase the source sentence using Translation Edit Rate (TER; Snover et al., 2006), a measure commonly used to automatically evaluate the quality of machine translation output. We used TER to compute the (average) number of edits required to change a long sentence to shorter output. We also report the number of edits by type, i.e., the number of insertions, substitutions, deletions, and shifts needed (on average) to convert long to short sentences. We observe that crowdworkers perform a fair amount of rewriting across corpora and languages. The most frequent rewrite operations are deletions followed by substitutions, shifts, and insertions.

4 Experimental Setup

Neural Machine Translation Training Nematus (Sennrich et al., 2017) was used as the machine translation system for all our experiments. We generally used the default settings and training procedures as specified within Nematus. All networks have a hidden layer size of 1,000, and an embedding layer size of 512. In addition, layer normalization (Ba et al., 2016) was used. During training, we used ADAM (Kingma and Ba, 2014), a minibatch size of 80, and the training set was reshuffled between epochs. We also employed early stopping.

Table 2: MOSS statistics across corpora and languages: length of source (SL) and target sentence (TL), compression rate (CR), TER scores, and number of insertions (Ins), deletions (Del), substitutions (Sub), and shifts (Shft).

We used up to four encoder-decoder NMT models in our experiments (BLEU scores[4] shown in parentheses): English→French (27.03), French→English (29.14), English→German (28.3), and German→English (31.19). German training/test data was taken from the WMT16 shared task and French from the WMT14 shared task. The training data was 4.2 million and 39 million sentence pairs for en-de, and en-fr, respectively. We also used back-translated monolingual training data, from the news domain, (Sennrich et al., 2016a) in training for the German systems. The data was pre-processed using standard scripts found in MOSES (Koehn et al., 2007). Rare words were split into sub-word units, using byte pair encoding (BPE; Sennrich et al. 2016b). The BPE operations are shared between language directions.

We experimented with various model variants using one or multiple pivots. The compression rate (see Equation (8)) was tuned experimentally on the validation set which consists of one document from each domain (20 source sentences; 100 compression-pairs). Compression rates varied from 0.55 to 0.85 and were broadly comparable to those shown in Table 2.

Comparison Systems We compared our model against *ABS*, a sequence-to-sequence attention-based model, developed by Rush et al. (2015). This model was trained on a monolingual dataset extracted from the Annotated English Gigaword corpus (Napoles et al., 2011). The dataset consists of approximately 4 million pairs of the first sentence from each source document and its headline. We also trained *LenInit* (Kikuchi et al., 2016) on the same corpus which is conceptually similar to ABS but additionally controls the output length using a length embedding vector (as described in Section 2.2).[5] Unfortunately, we could not train these models for French or German, since there are no monolingual sentence compression datasets available at a similar scale. An obvious workaround is to translate Gigaword to French and German and then train compression models on the translated data. As the quality of the translation is relatively poor, we also translated German or French into English, compressed it with ABS and LenInit trained on the Gigaword corpus, and then translated the compressions back to French or German. Finally, we include a prefix (*Pfix*) baseline which does not perform any rewriting but simply truncates the source sentence so that it matches the compression ratio of the validation set.

5 Results

MOSS Evaluation We assessed model performance using three automatic metrics which represent different aspects of the compression task and have been found to correlate well with human judgments (Toutanova et al., 2016; Clarke and Lapata, 2006). These include a recall metric based on skip bi-grams, any pair of words in a sequence allowing for gaps of size four[6] (RS-R); a recall metric based on bi-grams of dependency tree triples (D2-R); and bi-gram ROUGE (R2-F1). We used the Stanford neural network parser (Chen and Manning, 2014) to obtain dependency triples.

Table 3(a) reports results on English with a model which controls the output length ($\mathcal{L}$) and uses either a single pivot (SP; $K = 1$) or multiple pivots (MP; $K = 10$). We experimented with French (fr) or German (de) as pivot languages. All pivot-based models perform compression in a single step (see Section 2.3). Dual-step compres-

---

[4] BLEU scores were calculated using mteval-v13a.pl.

[5] We used our own implementation of ABS and LenInit which on DUC-2004 obtained ROUGE scores similar to those published in Rush et al. (2015) and Kikuchi et al. (2016).

[6] We add a begin-of-sentence marker at the start of the candidate and reference sentences.

Wenn man die Armen nach den drei Hauptanliegen fragt, werden sie gefordert.

Table 4: System output for the example source sentences in Table 1.

sion obtained inferior results which we omit for the sake of brevity. As can be seen, models which use a single pivot are better than those using multiple ones (German is better than French; see SP$_{de}$ vs SP$_{fr}$). More pivots might introduce noise at the expense of translation quality.

Overall, pivot-based models outperform ABS and LenInit. This is perhaps to be expected since these models are tested on out of domain data with different vocabulary and writing conventions; MOSS does not contain any newspaper articles. Unfortunately, it is not possible to train ABS and LenInt on in-domain data as compression data only exists for the headlines-first sentences pairs. As an upper bound, we also report how well humans agree with each other, treating one (randomly selected) reference as system output and computing how it agrees with the rest (row Gold in Table 3). All models lag significantly behind human performance on this task.

Tables 3(b) and 3(c) report results on French and German, respectively. For these languages, we obtained best results with English as pivot, using a single-step compression model. ABS and LenInit perform poorly when trained directly on translations of Gigaword into French and German; their performance improves considerably when they are trained on the Gigaword and used to compress English translations of French or German (ABS$_{en}$, LenInit$_{en}$). Again, we observe that our models (SP$_{\mathcal{L},en}$, MP$_{\mathcal{L},en}$) outperform the comparison systems across all metrics and that using a single pivot yields better compressions. Example compressions are given in Table 4 where we show output produced by ABS and SP for each language (see the supplementary material for more examples). Finally, notice that automatic scores for the prefix baseline across languages are misleadingly high, since it simply repeats the source sentence up to a fixed length without performing any rewriting.

Table 6: Statistics of model output (SP$_{\mathcal{L}}$) on MOSS (aggregated across domains): length of source (SL) and target (TL), compression rate (CR), TER scores, and number of insertions (Ins), deletions (Del), substitutions (Sub), and shifts (Shft).

We also elicited human judgments through the Crowdflower platform. We asked crowdworkers to rate the grammaticality of the target compressions and whether they preserved the most important information from the source. In both cases, they used a five-point rating scale where a high number indicates better performance. We randomly selected 25 sentences from each corpus from the test portion of MOSS, i.e., 100 long-short sentence pairs per language. We compared compressions generated by our model (SP$_{\mathcal{L}}$), with ABS models for the three languages, the prefix baseline, and (randomly selected) gold-standard reference (Ref) compressions from MOSS. All systems used the length parameter to allow comparisons with approximately the *same* compression rates. We collected five ratings per compression. Our results are summarized in Table 5. We show mean ratings for grammaticality (Gram), importance (Imp) and their combination (column Avg). Across languages our model (SP$_{\mathcal{L}}$) significantly ($p < 0.05$) outperforms comparison systems (Pfix, ABS) on both dimensions of grammaticality and importance (significance tests were performed using a student t-test). All systems are significantly worse ($p < 0.05$) than the human reference compressions.

Models	RS-R	D2-R	R2-F1	R1-R	R2-R	RL-R

Table 7: DUC-2004 results (75 char length cap); results for comparison systems are taken from their respective papers.

Finally, in Table 6 we analyze the output of our best model (SP$_{\mathcal{L}}$) using the same statistics we applied to the human compressions (see Table 2). As can be seen, the model generally compressess more aggressively and applies more edits than the crowdworkers (both compression rates and TER scores are higher for all three languages). Although the rate of deletions is similar to humans, insertions, substitutions and shifts happen to a greater extent for our model, indicating that it performs a good amount of paraphrasing.

DUC-2004 Evaluation Besides MOSS, we evaluated our model on the benchmark DUC-2004 task-1 dataset. In this task, the aim is to create a very short summary (75 bytes) for a document. The evaluation set consists of 500 source documents (from the New York Times and Associated Press Wire services) each paired with four human-written (reference) summaries. We follow previous work (Rush et al., 2015; Chopra et al., 2016) in compressing the first sentence of the document and presenting this as the summary. To make the evaluation unbiased to length, the output of all systems is cut-off after 75-characters and no bonus is given for shorter summaries.

Our results are shown in Table 7. To compare with existing methods, we also report ROUGE (Lin, 2004) unigram and bigram overlap (Lin, 2004) and the longest common subsequence (ROUGE-L).[9] We employed a dual step compression model (see Section 2) as preliminary experiments showed that it was superior to single-stage variants. We compared single and multiple pivot models against existing ABS and ABS+ (Rush et al., 2015), two encoder-decoder models trained on the English Gigaword. ABS+ applies minimum error rate (MERT) training as a copy-

Table 8: System output for DUC-2004.

ing mechanism. LenEmb and LenInit include a length parameter (Kikuchi et al., 2016), whereas RAS uses a specialized recurrent neural network architecture (Elman, 1990). We also report how well DUC-2004 abstractors agree with each other (row Gold in Table 7). Example compressions are given in Table 8, where we show output produced by SP$_{\mathcal{L},de}$ and a human reference (see the supplementary material for further examples).

Using automatic metrics we see that our model generally performs worse compared to these systems and that German is the best pivot for English. Although the objective of this paper is not to obtain state-of-the-art scores on this evaluation set, it is interesting to see that our model is able to compress out-of-domain. We do not have access to headline-first sentence pairs, while all comparison systems do. We also elicited human judgments on the compressions of 100 lead sentences whose documents were randomly selected from the DUC-2004 test set. We compared the prefix baseline, our model (SP$_{\mathcal{L},de}$), ABS+ (Rush et al., 2015), LenEmb (Kikuchi et al., 2016), Topiary (Zajic et al., 2004), and a randomly selected reference. Topiary came top in almost all measures in the DUC-2004 evaluation; it first compresses the lead sentence using linguistically motivated heuristics and then enhances it with topic keywords. Crowdworkers rated grammaticality and importance, using a five-point scale; we collected five ratings per compression.

As shown in Table 9 ABS+ has the lead with our system following suit. In terms of grammaticality, ABS+ and SP$_{\mathcal{L},de}$ are not significantly different from the gold standard or from each other (Pfix, Topiary, and LenEmb are significantly worse than Gold; $p < 0.05$). In terms of importance, pairwise differences between systems and the gold standard are not significant. Overall, we observe that SP$_{\mathcal{L},de}$ performs comparably to ABS+ even though it was not trained on any compression specific data. Inspection of system output reveals that our model performs more paraphrasing than comparison systems (a conclusion also confirmed by the statistics in Table 6).

Models	Gram	Imp	Avg
Pfix	3.03	2.93	2.98
SP$_{\mathcal{L},de}$	3.37	3.22	3.29
Topiary	3.05	3.15	3.10
ABS+	**3.67**	**3.23**	**3.45**
LenEmb	3.14	3.08	3.11
Ref	3.62	3.27	3.45

Table 9: Mean ratings elicited by humans on DUC-2004; Avg is the average rating of grammaticality and importance.

6 Conclusions

In this paper we have shown that multilingual corpora can be used to bootstrap compression models across languages and text genres. Our approach adapts existing neural machine translation machinery to the compression task coupled with methods which decode the output to a desired length. An interesting direction for future work would be to train our model using reinforcement learning (Ranzato et al., 2016; Zhang and Lapata, 2017) in order to control the compression output more directly. Moreover, although we do not use any direct supervision in our experiments, it would be interesting to incorporate it as a means of domain adaptation (Cheng et al., 2016).

Unsupervised Cross-lingual Transfer of Word Embedding Spaces

Ruochen Xu, Yiming Yang, Naoki Otani, Yuexin Wu

{ruochenx, yiming, notani, yuexinw }@cs.cmu.edu

Abstract

Cross-lingual transfer of word embeddings aims to establish the semantic mappings among words in different languages by learning the transformation functions over the corresponding word embedding spaces. Successfully solving this problem would benefit many downstream tasks such as to translate text classification models from resource-rich languages (e.g. English) to low-resource languages. Supervised methods for this problem rely on the availability of cross-lingual supervision, either using parallel corpora or bilingual lexicons as the labeled data for training, which may not be available for many low resource languages. This paper proposes an unsupervised learning approach that does not require any cross-lingual labeled data. Given two monolingual word embedding spaces for any language pair, our algorithm optimizes the transformation functions in both directions simultaneously based on distributional matching as well as minimizing the back-translation losses. We use a neural network implementation to calculate the Sinkhorn distance, a well-defined distributional similarity measure, and optimize our objective through back-propagation. Our evaluation on benchmark datasets for bilingual lexicon induction and cross-lingual word similarity prediction shows stronger or competitive performance of the proposed method compared to other state-of-the-art supervised and unsupervised baseline methods over many language pairs.

1 Introduction

Word embeddings are well known to capture meaningful representations of words based on large text corpora (Mikolov et al., 2013; Pennington et al., 2014). Training word vectors using monolingual corpora is a common practice in various NLP tasks. However, how to establish cross-lingual semantic mapping among monolingual embeddings remain an open challenge as the availability of resources and benchmarks are highly imbalanced across languages.

Recently, increasing effort of research has been motivated to address this challenge. Successful cross-lingual word mapping will benefit many cross-lingual learning tasks, such as transforming text classification models trained in resource-rich languages to low-resource languages. Downstream applications include word alignment, text classification, named entity recognition, dependency parsing, POS-tagging, and more (Søgaard et al., 2015). Most methods for cross-lingual transfer of word embeddings are based on supervised or semi-supervised learning, i.e., they require cross-lingual supervision such as human-annotated bilingual lexicons and parallel corpora (Lu et al., 2015; Smith et al., 2017; Artetxe et al., 2016). Such a requirement may not be met for many language pairs in the real world.

This paper proposes an unsupervised approach to the cross-lingual transfer of monolingual word embeddings, which requires zero cross-lingual supervision. The key idea is to optimize the mapping in both directions for each language pair (say A and B), in the way that the word embedding translated from language A to language B will match the distribution of word embedding in language B. And when translated back from B to A, the word embedding after two steps of transfer will be maximally close to the original word embedding. A similar property holds for the other direction of the loop (from B to A and then from A back to B). Specifically, we use the Sinkhorn distance (Cuturi, 2013) to capture the distributional similarity between two set of embeddings after transformation, which we found empirically superior to the KL-divergence (Zhang et al., 2017a) and distance to nearest neighbor (Artetxe et al., 2017; Conneau et al., 2017) with regards to the quality of learned

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2465–2474
Brussels, Belgium, October 31 - November 4, 2018.

transformation as well as the robustness under different training conditions.

Our novel contributions in the proposed work include:

- We propose an unsupervised learning framework which incorporates the Sinkhorn distance as a distributional similarity measure in the back-translation loss function.
- We use a neural network to optimize our model, especially to implement the Sinkhorn distance whose calculation itself is an optimization problem.
- Unlike previous models which only consider cross-lingual transformation in a single direction, our model jointly learns the word embedding transfer in both directions for each language pair.
- We present an intensive comparative evaluation where our model achieved the state-of-the-art performance for many language pairs in cross-lingual tasks.

2 Related Work

We divide the related work into supervised and unsupervised categories. Representative methods in both categories are included in our comparative evaluation (Section 3.4). We also discuss some related work in unsupervised domain transfer in addition.

Supervised Methods: There is a rich body of supervised methods for learning cross-lingual transfer of word embeddings based on bilingual dictionaries (Mikolov et al., 2013; Faruqui and Dyer, 2014; Artetxe et al., 2016; Xing et al., 2015; Duong et al., 2016; Gouws and Søgaard, 2015), sentence-aligned corpora (Kočiskỳ et al., 2014; Hermann and Blunsom, 2014; Gouws et al., 2015) and document-aligned corpora (Vulić and Moens, 2016; Søgaard et al., 2015). The most relevant line of work is that by Mikolov et al. (2013) where they showed monolingual word embeddings are likely to share similar geometric properties across languages although they are trained separately and hence cross-lingual mapping can be captured by a linear transformation across embedding spaces. Several follow-up studies tried to improve the cross-lingual transformation in various ways (Faruqui and Dyer, 2014; Artetxe et al., 2016; Xing et al., 2015; Duong et al., 2016; Ammar et al., 2016; Artetxe et al., 2016; Zhang et al., 2016; Shigeto et al., 2015). Nevertheless, all these methods require bilingual lexicons for supervised learning. Vulić and Korhonen (2016) showed that 5000 high-quality bilingual lexicons are sufficient for learning a reasonable cross-lingual mapping.

Unsupervised Methods have been studied to establish cross-lingual mapping without any human-annotated supervision. Earlier work simply relied on word occurrence information only (Rapp, 1995; Fung, 1996) while later efforts have considered more sophisticated statistics in addition (Haghighi et al., 2008). The main difficulty in unsupervised learning of cross-lingual mapping is the formulation of the objective function, i.e., how to measure the goodness of an induced mapping without any supervision is a non-trivial question. Cao et al. (2016) tried to match the mean and standard deviation of the embedded word vectors in two different languages after mapping the words in the source language to the target language. However, such an approach has shown to be sub-optimal because the objective function only carries the first and second order statistics of the mapping. Artetxe et al. (2017) tried to impose an orthogonal constraint to their linear transformation model and minimize the distance between the transferred source-word embedding and its nearest neighbor in the target embedding space. Their method, however, requires a seed bilingual dictionary as the labeled training data and hence is not fully unsupervised. (Zhang et al., 2017a; Barone, 2016) adapted a generative adversarial network (GAN) to make the transferred embedding of each source-language word indistinguishable from its true translation in the target embedding space (Goodfellow et al., 2014). The adversarial model could be optimized in a purely unsupervised manner but is often suffered from unstable training, i.e. the adversarial learning does not always improve the performance over simpler baselines. Zhang et al. (2017b), Conneau et al. (2017) and Artetxe et al. (2017) also tried adversarial approaches for the induction of seed bilingual dictionaries, as a sub-problem in the cross-lingual transfer of word embedding.

Unsupervised Domain Transfer: Generally speaking, learning the cross-lingual transfer of word embedding can be viewed as a domain transfer problem, where the domains are word sets in different languages. Thus various work in the field of *unsupervised domain adaptation* or *unsupervised transfer learning* can shed light on our problem. For example, He et al. (2016) proposed a semi-supervised method for machine translation to utilize large monolingual corpora. Shen et al. (2017) used unsupervised learning to transfer sentences of different sentiments. Recent work in computer vision addresses the problem of image style transfer without any annotated training data (Zhu et al., 2017; Taigman et al., 2016; Yi et al., 2017). Among those, our work is mostly inspired by the work on CycleGAN (Zhu et al., 2017), and we adopt their cycled consistent loss over images into our back-translation loss. One key difference of our method from CycleGAN is that they used the training loss of an adversarial classifier as an indicator of the distributional distance, but instead, we introduce the Sinkhorn distance in our objective function and demonstrate its superiority over the representative method using adversarial loss (Zhang et al., 2017a).

3 Proposed Method

Our system takes two sets of monolingual word embeddings of dimension d as input, which are trained separately on two languages. We denote them as $X = \{x_i\}_{i=1}^n, Y = \{y_j\}_{j=1}^m, x_i, y_j \in \mathbb{R}^d$. During the training of monolingual word embedding for X and Y, we also have the access to the word frequencies, represented by vectors $r \in \mathbb{N}^n$ and $c \in \mathbb{N}^m$ for X and Y, respectively. Specifically, r_i is the frequency for word (embedding) x_i and similarly for c_j of y_j. As illustrated in Figure 3, our model has two mappings: $G : X \rightarrow Y$ and $F : Y \rightarrow X$. We further denote transferred embedding from X as $G(X) := \{G(x_i)\}_{i=1}^n$ and correspondingly for $F(Y)$.

In the unsupervised setting, the goal is to learn the mapping G and F without any paired word translation. To achieve this, our loss function consists of two parts: Sinkhorn distance (Cuturi, 2013) for matching the distribution of transferred embedding to its target embedding distribution; and a back-translation loss for preventing degenerated transformation.

3.1 Sinkhorn Distance

3.1.1 Definition

Sinkhorn distance is a recently proposed distance between probability distributions. We use the Sinkhorn distance to measure the closeness between $G(X)$ and Y, and also between $F(Y)$ and X. During the training, our model optimizes G and F for lower Sinkhorn distance to make the transferred embeddings match the distribution of the target embeddings. Here we only illustrate the Sinkhorn distance between $G(X)$ and Y, the derivation for $F(Y)$ and X is very similar. Although the vocabulary sizes of two languages could be different, we are able to sample mini-batches of equal size from $G(X)$ and Y. therefore we assume $n = m$ in the following derivation.

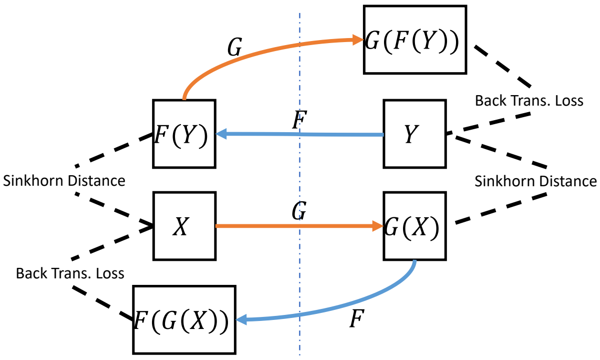

Figure 1: The model takes monolingual word embedding X and Y as input. G and F are embedding transfer functions parameterized by a neural network, which are represented by solid arrows. The dashed lines indicate the input for our objective losses, namely the Sinkhorn distance and back-translation loss

.

To compute Sinkhorn distance, we firstly compute a distance matrix $M^{(G)} \in \mathbb{R}^{n \times m}$ between $G(X)$ and Y where $M_{ij}^{(G)}$ is the distance measure between $G(x_i)$ and y_j. The superscript on $M^{(G)}$ indicates the distance that depends on a parameterized transformation G. For instance, if we choose Euclidean distance as a measure (see Section 3.1.3 for more discussions), we will have

$$M_{ij}^{(G)} = \|G(x_i) - y_j\|_2.$$

Given the distance matrix, the Sinkhorn distance between $P_{G(X)}$ and P_Y is defined as:

$$d_{sh}(G) := \min_{P \in U_\alpha(r,c)} \langle P, M^{(G)} \rangle \qquad (1)$$

where $\langle \cdot, \cdot \rangle$ is the Forbenius dot-product and $U_\alpha(r, c)$ is an entropy constrained transport poly-

Algorithm 1 Computation of Sinkhorn Distance $d_{sh}(G)$

```
procedure SINKHORN($M^{(G)}, r, c, \lambda, I$)
    $K^{(G)} := e^{-\lambda M^{(G)}}$
    $v = \mathbb{1}_m / m$            ▷ normalized one vector
    $i = 0$
    while $i < I$ do                  ▷ iterate for $I$ times
        $u = r./K^{(G)} v$
        $v = c./{K^{(G)}}^T u$
        $i = i + 1$
    $d_{sh}(G) = u^T((K^{(G)} \otimes M^{(G)})v)$
    return $d_{sh}(G)$                ▷ The Sinkhorn distance
```

tope, defined as

$$U_\alpha(r,c) = \{P \in {\mathbb{R}_+}^{n \times m} | P\mathbb{1}_m = r, P^T \mathbb{1}_n = c, \\ h(P) \le h(r) + h(c) - \alpha\} \qquad (2)$$

Note that P is non-negative and the first two constraints make its element-wise sum be 1. Therefore, P can be seen as a set of probability distributions. The same applies for r and c since they are frequencies. h is the entropy function defined on any probability distributions and α is a hyperparameter to choose. For any probabilistic matrix $P \in U_\alpha(r,c)$, it can be viewed as the joint probability of $(G(X), Y)$. The first two constraints ensure that P has marginal distribution on $G(X)$ as $P_{G(X)}$ and on Y as P_Y. We can also view P_{ij} as the evidence for establishing a translation between word vector x_i and word vector y_j.

An intuitive interpretation of equation (1) is that we are trying to find the optimal transport probability P under the entropy constraint such that the total distance to transport from $G(X)$ to Y is minimized.

3.1.2 Computing Sinkhorn Distance $d_{sh}(G)$

Cuturi (2013) showed that the optimal solution of formula (1) has the form $P^* = \mathbf{diag}(u) K \mathbf{diag}(v)$, where u and v are some non-negative vectors and $K^{(G)} := e^{-\lambda M^{(G)}}$; λ is the Lagrange multiplier for the entropic constraint in 2 and each α in Equation (1) has one corresponding λ. The Sinkhorn distance can be efficiently computed by a matrix scaling algorithm. We present the pseudo code in Algorithm 1. Note that the computation of $d_{sh}(G)$ only requires matrix-vector multiplication. Therefore, we can compute and back propagate the gradient of $d_{sh}(G)$ with regards to the parameters in G using standard deep learning libraries. We show our implementation details in Section 3.4 and supplementary material.

3.1.3 Choice of the Distance Metric

In Section 3.1.1, we used the Euclidean distance of vector pairs to define $M^{(G)}$ and Sinkhorn distance $d_{sh}(G)$. However, in our preliminary experiment, we found that Euclidean distance of unnormalized vectors gave poor performance. Therefore, following the common practice, we normalize all word embedding vectors to have a unit L2 norm in the construction of $M^{(G)}$.

As pointed out in Theorem 1 of Cuturi (2013), $M^{(G)}$ must be a valid metric in order to make $d_{sh}(G)$ a valid metric. For example, the commonly used cosine distance, which is defined as $CosDist(a,b) = 1 - cos(a,b)$, is not a valid metric because it does not satisfy triangle inequality [1]. Thus, for constructing $M^{(G)}$, we propose the square root cosine distance ($SqrtCosDist$) below:

$$SqrtCosDist(a,b) := \sqrt{2 - 2cos(a,b)} \qquad (3)$$

$$M_{ij}^{(G)} = SqrtCosDist(G(x_i), y_j) \qquad (4)$$

Theorem 1. *$SqrtCosDist$ is a valid metric.*

Proof. $\forall a, b \in \mathbb{R}^d$, let $\hat{a} = \frac{a}{\|a\|}$, $\hat{b} = \frac{b}{\|b\|}$. We have $cos(a,b) = \langle \hat{a}, \hat{b} \rangle$ and $\langle \hat{a}, \hat{a} \rangle = \langle \hat{b}, \hat{b} \rangle = 1$. Then

$$\begin{aligned} SqrtCosDist(a,b) &= \sqrt{2 - 2cos(a,b)} \\ &= \sqrt{\langle \hat{a}, \hat{a} \rangle + \langle \hat{b}, \hat{b} \rangle - 2\langle \hat{a}, \hat{b} \rangle} \\ &= \sqrt{\langle \hat{a} - \hat{b}, \hat{a} - \hat{b} \rangle} \\ &= \|\hat{a} - \hat{b}\| \end{aligned}$$

Obviously, the last term is the Euclidean distance between normalized input vectors $\hat{a}$ and $\hat{b}$. Since Euclidean distance is a valid metric, it follows that $SqrtCosDist$ satisfies all the axioms for a valid metric. $\square$

3.2 Objective Function

Given enough capacity, G is capable to transfer X to Y for arbitrary word-to-word mappings. To ensure that, we learn a meaningful translation and also to regularize the search space of possible transformations, we enforce the word embedding after the forward and the backward transformation

---

[1] If we select $a = [1,0], b = [\frac{\sqrt{2}}{2}, \frac{\sqrt{2}}{2}], c = [0,1]$ We have $CosDist(a,c) \geq CosDist(a,b) + CosDist(b,c)$, which violates the triangle inequality.

should not diverge much from its original direction. We simply choose the back-translation loss based on the cosine similarity:

$$d_{bt}(G, F) = \sum_i 1 - cos(x_i, F(G(x_i))) + \sum_j 1 - cos(y_i, G(F(y_i))) \quad (5)$$

where cos is the cosine similarity.

Putting everything together, we minimize the following objective function.

$$L_{X,Y,r,c}(G, F) = d_{sh}(G) + d_{sh}(F) + \beta d_{bt}(G, F) \quad (6)$$

where hyper-parameter β controls the relative weight of the last term against the first two terms in the objective function. By definition, computation of $d_{sh}(G)$ or $d_{sh}(F)$ involves another minimization problem as shown in Equation (1). We solve it using the matrix scaling algorithm in Section 3.1.2, and treat $d_{sh}(G)$ as a deterministic and differentiable function of parameters in G. The same holds for $d_{sh}(F)$ and F.

3.3 Wasserstein GAN Training for Good Initial Point

In preliminary experiments, we found that our objective 6 is sensitive to the initialization of the weight in G and F in the purely unsupervised setting. It requires a good initial setting of the parameters to avoid getting stuck in the poor local minimal. To address this sensitivity issue, we employed a similar approach as in (Zhang et al., 2017b; Aldarmaki et al., 2018) to firstly used an adversarial training approach to learn G and F and use them as the initial point for training our full objective 6. More specifically, we choose to minimize the optimal transport distance below.

$$d_{ot}(G) := \min_{P \in U(r,c)} \langle P, M^{(G)} \rangle \quad (7)$$

U is the transport polytope without entropy constraint, defined as follows.

$$U = \{P \in {\mathbb{R}_+}^{n \times m} | P\mathbb{1}_m = r, P^T\mathbb{1}_n = c\} \quad (8)$$

We optimize the distance above by its dual form and through adversarial training, which is also known as Wasserstein GAN (WGAN) (Arjovsky et al., 2017). We applied the optimization trick proposed by Gulrajani et al. (2017).

Although the first phase of adversarial training could be unstable, and the performance is lower than using the Sinkhorn distance, the adversarial training narrows down the search space of model parameters and boosting the training of our proposed model.

3.4 Implementation

We implemented transformation G and F by a linear transformation. The dimension of the input and output are the same with the word embedding dimension d.[2] For all the experiments in the subsequent section, the β in (6) was set to be 0.1. For hyper-parameters from the computation of Sinkhorn distance, we choose $\lambda = 10$ and run the matrix scaling algorithm for 20 iterations. Due to the space constraint, a detailed implementation description is presented in the supplementary material. The code of our implementation is publicly available [3].

4 Experiments

We conducted an evaluation of our approach in comparison with state-of-the-art supervised/unsupervised methods on several evaluation benchmarks for bilingual lexicon induction (Task 1) and word similarity prediction (Task 2). We include our main results in this section and report the ablation study in the supplementary material.

4.1 Data

4.1.1 Monolingual Word Embedding Data

All the methods being evaluated in both tasks take monolingual word embedding in each language as the input data. We use publicly available pretrained word embeddings trained on Wikipedia articles: (1) a smaller set of word embeddings of dimension 50 trained on comparable Wikipedia dump in five languages (Zhang et al., 2017a)[4] and (2) a larger set of word embeddings of dimension 300 trained on Wikipedia dump in 294 languages (Bojanowski et al., 2016)[5]. For conve-

---

[2] We tried more complex non-linear transformations for G and F. The performance is slightly worse than the linear case.

[3] Our implementation https://github.com/xrc10/unsup-cross-lingual-embedding-transfer

[4] Available at http://nlp.csai.tsinghua.edu.cn/~zm/UBiLexAT

[5] Available at https://github.com/facebookresearch/fastText/blob/master/pretrained-vectors.md

nience, we name the two sets **WE-Z** and **WE-C**, respectively.

4.1.2 Bilingual Lexicon Data

We need true translation pairs of words for evaluating methods in bilingual lexicon induction (Task 1). We followed previous studies and prepared two datasets below.

LEX-Z: Zhang et al. (2017a) constructed the bilingual lexicons from various resources. Since their ground truth word pairs are not released, we followed their procedure, crawled bilingual dictionaries and randomly separated them into the training and testing set of equal size.[6] Note that our proposed method did not utilize the training set. It was only used by supervised baseline methods described in Section 4.2. There are eight language pairs (order counted); the corresponding dataset statistics are summarized in Table 1. We use WE-Z embeddings in this dataset.

LEX-C: This lexicon was constructed by Conneau et al. (2017) and contains more translation pairs than LEX-Z. They divided them into training and testing set. We run our model and the baseline methods on 16 language pairs. For each language pair, the training set contains $5,000$ unique query words and the testing set has $1,500$ query words. We followed Conneau et al. (2017) and set the search space of candidate translations to be the $200,000$ most frequent words in each target language. We use WE-C embeddings in this dataset.

4.1.3 Bilingual Word Similarity Data

For bilingual word similarity prediction (Task 2) we need the true labels for evaluation. Following Conneau et al. (2017), we used the SemEval 2017 competition dataset, where human annotators measured the cross-lingual similarity of nominal word pairs according to the five-point Likert scale. This dataset contains word pairs across five languages: English (en), German (de), Spanish (es), Italian (it), and Farsi (fa). Each language pair has about 1,000 word pairs annotated with a real similarity score ranging from 0 to 4.

4.2 Baseline Methods

We evaluated the same set of supervised and unsupervised baselines for comparative evaluation in both Task 1 and Task 2. The supervised baselines include the methods of Shigeto et al. (2015); Zhang et al. (2016); Artetxe et al. (2016); Xing et al. (2015); Mikolov et al. (2013); Artetxe et al. (2017).[7] We fed all the supervised methods with the bilingual dictionaries in the training portions of the LEX-Z and LEX-C datasets, respectively.

		# tokens	vocab. size	bi. lex. size
tr-en	tr	6m	7,482	18,404
	en	28m	13,220	27,327
es-en	es	61m	4,774	3,482
	en	95m	6,637	10,772
zh-en	zh	21m	3,349	54,170
	en	53m	5,154	51,375
it-en	it	73m	8,490	4,999
	en	93m	6,597	11,812

Table 1: The statistics of LEX-Z. The languages are Spanish (es), French (fr), Chinese (zh), Turkish (tr) and English (en). Number of tokens is the size of training corpus of WE-Z. The bilingual lexicon size means the number of unique words of a language in the gold bilingual lexicons.

For unsupervised baselines we include the methods of Zhang et al. (2017a) and Conneau et al. (2017), whose source code is publicly available as provided by the authors.[8]

4.3 Results in Bilingual Lexicons Induction (Task 1)

Bilingual lexicon induction is a task to induce a translation in the target language for each query word in the source language. After the query word and the target-language words are represented in the same embedding space (or after our system maps the query word from the source embedding space to the target embedding space), the k nearest target words are retrieved based on their cosine similarity scores with respect to the query vector. If the k retrieved target words contain any valid translation according to the gold bilingual lexicon, the translation (retrieval) is considered successful. The fraction of the correctly translated source words in the test set is defined as $accuracy@k$,

---

[6] The bilingual dictionaries we crawled are submitted as supplementary material.

"-" means that during the training time, the model failed to converge to reasonable local minimal and hence the result is omitted in the table.

which is conventional metric in benchmark evaluations.

Table 2 shows the accuracy@1 for all the methods on LEX-Z in our evaluation. We can see that our method outperformed the other unsupervised baselines by a large margin on all the eight language pairs. Compared with the supervised methods, our method is still competitive (the best or the second-best scores on four out of eight language pairs), even ours does not require cross-lingual supervision. Also, we notice the performance variance over different language pairs. Our method outperforms all the methods (supervised and unsupervised combined) on the English-Spanish (en-es) pair, perhaps for the reasons that these two languages are most similar to each other, and that the monolingual word embeddings for this pair in the comparable corpus are better aligned than the other language pairs. On the other hand, all the methods including ours have the worst performance on the English-Turkish (en-tr) pair. Another observation is the performance differences in the two directions of the language pair. For example, the performance of it-en is better than en-it for all methods in table 2. A part of the reason is that there are more unique English words than non-English words in the evaluation set. This would cause direction "xx-en" to be easier than "en-xx" because there are often multiple valid ground truth English translations for each query in "xx". But the same may not hold for the opposite direction of "en-xx". Nevertheless, the relative performance of our method compared to others is quite robust over different language pairs and different directions of

Table 4: The accuracy@k scores of all methods in bilingual lexicon induction on **LEX-C**. The best score for each language pair is bold-faced for the supervised and unsupervised categories, respectively. Languages are paired among **English (en), German (de), Spanish (es), French (fr) and Italian (it)**. ”-” means that during the training time, the model failed to converge to reasonable local minimal and hence the result is omitted in the table.

translation.

Table 3 and Table 4 summarize the results of all the methods on the LEX-C dataset. Several points may be worth noticing. Firstly, the performance scores on LEX-C are not necessarily consistent with those on LEX-Z (Table 2) even if the methods and the language pairs are the same; this is not surprising as the two datasets differ in query words, word embedding quality, and training-set sizes. Secondly, the performance gap between the best supervised methods and the best unsupervised methods in both Table 3 and Table 4 are larger than that in Table 2. This is attributed to the large amount of good-quality supervision in LEX-C (5,000 human-annotated word pairs) and the larger candidate size in WE-C (200, 000 candidates). Thirdly, the average performance in Table 3 is lower than that in Table 4, indicating that the language pairs in the former are more difficult than that in the latter. Nevertheless, we can see that our method has much stronger performance than other unsupervised methods in Table 3, i.e., on the harder language pairs, and that it performed comparably with the model by Conneau et al. (2017) in Table 4 on the easier language pairs. Combining all these observations, we see that our method is highly robust for various language pairs and under different training conditions.

4.4 Results in Cross-lingual Word Similarity Prediction (Task 2)

We evaluate models on cross-lingual word similarity prediction (Task 2) to measure how much the predicted cross-language word similarities match the ground truth annotated by humans. Following the convention in benchmark evaluations for this task, we compute the Pearson correlation between the model-induced similarity scores and the human-annotated similarity scores over testing word pairs for each language pair. A higher correlation score with the ground truth represents the better quality of induced embeddings. All systems use the cosine similarity between the transformed embedding of each query and the word embedding of its paired translation as the predicted similarity score.

	Methods	de-en	es-en	fa-en	it-en
Supervised	Mikolov et al. (2013)	0.71	0.72	0.68	0.71

	Zhang et al. (2017a)	-	-	-	-
	Ours	**0.71**	**0.71**	0.67	**0.71**

Table 5: Performance (measured using Pearson correlation) of all the methods in cross-lingual semantic word similarity prediction on the benchmark data from Conneau et al. (2017). The best score in the supervised and unsupervised category is bold-faced, respectively. The languages include English (en), German (de), Spanish (es), Persian (fa) and Italian (it). ”-” means that the model failed to converge to reasonable local minimal during the training process.

Table 5 summarizes the performance of all the methods in cross-lingual word similarity prediction. We can see that the unsupervised methods, including ours, perform equally well as the supervised methods, which is highly encouraging.

5 Conclusion

In this paper, we presented a novel method for cross-lingual transformation of monolingual embeddings in an unsupervised manner. By simultaneously optimizing the bi-directional mappings w.r.t. Sinkhorn distances and back-translation losses on both ends, our model enjoys its prediction power as well as robustness, with the impressive performance on multiple evaluation benchmarks. For future work, we would like to extend this work in the semi-supervised setting where insufficient bilingual dictionaries are available.

Abstract

State-of-the-art natural language processing systems rely on supervision in the form of annotated data to learn competent models. These models are generally trained on data in a single language (usually English), and cannot be directly used beyond that language. Since collecting data in every language is not realistic, there has been a growing interest in cross-lingual language understanding (XLU) and low-resource cross-language transfer. In this work, we construct an evaluation set for XLU by extending the development and test sets of the Multi-Genre Natural Language Inference Corpus (MultiNLI) to 15 languages, including low-resource languages such as Swahili and Urdu. We hope that our dataset, dubbed XNLI, will catalyze research in cross-lingual sentence understanding by providing an informative standard evaluation task. In addition, we provide several baselines for multilingual sentence understanding, including two based on machine translation systems, and two that use parallel data to train aligned multilingual bag-of-words and LSTM encoders. We find that XNLI represents a practical and challenging evaluation suite, and that directly translating the test data yields the best performance among available baselines.

1 Introduction

Contemporary natural language processing systems typically rely on annotated data to learn how to perform a task (e.g., classification, sequence tagging, natural language inference). Most commonly the available training data is in a single language (e.g., English or Chinese) and the resulting system can perform the task only in the training language. In practice, however, systems used in major international products need to handle inputs in many languages. In these settings, it is nearly impossible to annotate data in all languages that a system might encounter during operation.

A scalable way to build multilingual systems is through cross-lingual language understanding (XLU), in which a system is trained primarily on data in one language and evaluated on data in others. While XLU shows promising results for tasks such as cross-lingual document classification (Klementiev et al., 2012; Schwenk and Li, 2018), there are very few, if any, XLU benchmarks for more difficult language understanding tasks like natural language inference. Large-scale natural language inference (NLI), also known as recognizing textual entailment (RTE), has emerged as a practical test bed for work on sentence understanding. In NLI, a system is tasked with reading two sentences and determining whether one entails the other, contradicts it, or neither (*neutral*). Recent crowdsourced annotation efforts have yielded datasets for NLI in English (Bowman et al., 2015; Williams et al., 2017) with nearly a million examples, and these have been widely used to evaluate neural network architectures and training strategies (Rocktäschel et al., 2016; Gong et al., 2018; Peters et al., 2018; Wang et al., 2018), as well as to train effective, reusable sentence representations (Conneau et al., 2017; Subramanian et al., 2018; Cer et al., 2018).

In this work, we introduce a benchmark that we call the Cross-lingual Natural Language Inference corpus, or XNLI, by extending these NLI corpora to 15 languages. XNLI consists of 7500 human-annotated development and test examples in NLI three-way classification format in English, French, Spanish, German, Greek, Bulgarian, Russian, Turkish, Arabic, Vietnamese, Thai, Chinese, Hindi, Swahili and Urdu, making a total of 112,500 annotated pairs. These languages span several language families, and with the inclusion of Swahili and Urdu, include two lower-resource languages as well.

Because of its focus on development and test

Table 1: Examples (premise and hypothesis) from various languages and genres from the XNLI corpus.

data, this corpus is designed to evaluate *cross-lingual* sentence understanding, where models have to be trained in one language and tested in different ones.

We evaluate several approaches to cross-lingual learning of natural language inference that leverage parallel data from publicly available corpora at training time. We show that parallel data can help align sentence encoders in multiple languages such that a classifier trained with English NLI data can correctly classify pairs of sentences in other languages. While outperformed by our machine translation baselines, we show that this alignment mechanism gives very competitive results.

A second practical use of XNLI is the evaluation of pretrained general-purpose language-universal sentence encoders. We hope that this benchmark will help the research community build multilingual text embedding spaces. Such embeddings spaces will facilitate the creation of multilingual systems that can transfer across languages with little or no extra supervision.

The paper is organized as follows: We next survey the related literature on cross-lingual language understanding. We then describe our data collection methods and the resulting corpus in Section 3. We describe our baselines in Section 4, and finally present and discuss results in Section 5.

2 Related Work

Multilingual Word Embeddings Much of the work on multilinguality in language understanding has been at the word level. Several approaches have been proposed to learn cross-lingual word representations, i.e., word representations where translations are close in the embedding space. Many of these methods require some form of supervision (typically in the form of a small bilingual lexicon) to align two sets of source and target embeddings to the same space (Mikolov et al., 2013a; Kociský et al., 2014; Faruqui and Dyer, 2014; Ammar et al., 2016). More recent studies have showed that cross-lingual word embeddings can be generated with no supervision whatsoever (Artetxe et al., 2017; Conneau et al., 2018).

Sentence Representation Learning Many approaches have been proposed to extend word embeddings to sentence or paragraph representations (Le and Mikolov, 2014; Wieting et al., 2016; Arora et al., 2017). The most straightforward way to generate sentence embeddings is to consider an average or weighted average of word representations, usually referred to as continuous bag-of-words (CBOW). Although naïve, this method often provides a strong baseline. More sophisticated approaches—such as the unsupervised SkipThought model of Kiros et al. (2015) that extends the skip-gram model of Mikolov et al. (2013b) to the sentence level—have been proposed to capture syntactic and semantic dependencies inside sentence representations. While these fixed-size sentence embedding methods have been outperformed by their supervised counterparts (Conneau et al., 2017; Subramanian et al., 2018), some recent developments have shown that pretrained language models can also transfer very well, either when the hidden states of the model are used as contextualized word vectors (Peters et al., 2018), or when the full model is fine-tuned on transfer tasks (Radford et al.; Howard and Ruder, 2018).

Multilingual Sentence Representations There has been some effort on developing multilingual sentence embeddings. For example, Chandar et al. (2013) train bilingual autoencoders with the objective of minimizing reconstruction error between two languages. Schwenk et al. (2017) and España-Bonet et al. (2017) jointly train a sequence-to-sequence MT system on multiple languages to learn a shared multilingual sentence embedding space. Hermann and Blunsom (2014) propose a compositional vector model involving unigrams and bigrams to learn document level representations. Pham et al. (2015) directly train embedding representations for sentences with no attempt at compositionality. Zhou et al. (2016) learn bilingual document representations by minimizing the Euclidean distance between document representations and their translations.

Cross-lingual Evaluation Benchmarks The lack of evaluation benchmark has hindered the development of such multilingual representations. Most previous approaches use the Reuters cross-lingual document classification corpus Klementiev et al. (2012) for evaluation. However, the classification in this corpus is done at document level, and, as there are many ways to aggregate sentence embeddings, the comparison between different sentence embeddings is difficult. Moreover, the distribution of classes in the Reuters corpus is highly unbalanced, and the dataset does not provide a development set in the target language, further complicating experimental comparisons.

In addition to the Reuters corpus, Cer et al. (2017) propose sentence-level multilingual training and evaluation datasets for semantic textual similarity in four languages. There have also been efforts to build multilingual RTE datasets, either through translating English data (Mehdad et al., 2011), or annotating sentences from a parallel corpora (Negri et al., 2011). More recently, Agic and Schluter (2017) provide a corpus, that is very complementary to our work, of human translations for 1332 pairs of the SNLI data into Arabic, French, Russian, and Spanish. Among all these benchmarks, XNLI is the first large-scale corpus for evaluating sentence-level representations on that many languages.

In practice, cross-lingual sentence understanding goes beyond translation. For instance, Mohammad et al. (2016) analyze the differences in human sentiment annotations of Arabic sentences and their English translations, and conclude that most of them come from cultural differences. Similarly, Smith et al. (2016) show that most of the degradation in performance when applying a classification model trained in English to Spanish data translated to English is due to cultural differences. One of the limitations of the XNLI corpus is that it does not capture these differences, since it was obtained by translation. We see the XNLI evaluation as a necessary step for multilingual NLP before tackling the even more complex problem of domain-adaptation that occurs when handling this the change in style from one language to another.

3 The XNLI Corpus

Because the test portion of the Multi-Genre NLI data is private, the Cross-lingual NLI Corpus (XNLI) is based on new English NLI data. To collect the core English portion, we follow precisely the same crowdsourcing-based procedure used for the existing Multi-Genre NLI corpus, and collect and validate 750 new examples from each of the ten text sources used in that corpus for a total of 7500 examples. With that portion in place, we create the full XNLI corpus by employing professional translators to translate it into our ten target languages. This section describes this process and the resulting corpus.

Translating, rather than generating new hypothesis sentences in each language separately, has multiple advantages. First, it ensures that the data distributions are maximally similar across languages. As speakers of different languages may have slightly different intuitions about how to fill in the supplied prompt, this allows us to avoid adding this unwanted degree of freedom. Second, it allows us to use the same trusted pool of workers as was used prior NLI crowdsourcing efforts, without the need for training a new pool of workers in each language. Third, for any premise, this process allows us to have a corresponding hypothesis in any language.

This translation approach carries with it the risk that the semantic relations between the two sentences in each pair might not be reliably preserved in translation, as Mohammad et al. (2016) observed for sentiment. We investigate this potential issue in our corpus and find that, while it does occur, it only concerns a negligible number of sentences (see Section 3.2).

3.1 Data Collection

The English Corpus Our collection procedure for the English portion of the XNLI corpus follows the same procedure as the MultiNLI corpus. We sample 250 sentences from each of the ten sources that were used in that corpus, ensuring that none of those selected sentences overlap with the distributed corpus. Nine of the ten text sources are drawn from the second release of the Open American National Corpus[1]: *Face-To-Face*, *Telephone*, *Government*, *9/11*, *Letters*, *Oxford University Press* (*OUP*), *Slate*, *Verbatim*, and *Government*. The tenth, *Fiction*, is drawn from the novel *Captain Blood* (Sabatini, 1922). We refer the reader to Williams et al. (2017) for more details on each genre.

Given these sentences, we ask the same MultiNLI worker pool from a crowdsourcing platform to produce three hypotheses for each premise, one for each possible label.

We present premise sentences to workers using the same templates as were used in MultiNLI. We also follow that work in pursuing a second validation phase of data collection in which each pair of sentences is relabeled by four other workers. For each validated sentence pair, we assign a gold label representing a majority vote between the initial label assigned to the pair by the original annotator, and the four additional labels assigned by validation annotators. We obtained a three-vote consensus for 93% of the data. In our experiments, we kept the 7% additional ones, but we mark these ones with a special label '-'.

Translating the Corpus Finally, we hire translators to translate the resulting sentences into 15 languages using the *One Hour Translation* platform. We translate the premises and hypotheses separately, to ensure that no context is added to the hypothesis that was not there originally, and simply copy the labels from the English source text. Some examples are shown in Table 1.

3.2 The Resulting Corpus

One main concern in studying the resulting corpus is to determine whether the gold label for some of the sentence pairs changes as a result of information added or removed in the translation process.

Investigating the data manually, we find an example in the Chinese translation where an entailment relation becomes a contradictory relation, while the entailment is preserved in other languages. Specifically, the term *upright* which was used in English as entailment of *standing*, was translated into Chinese as *sitting upright* thus creating a contradiction. However, the difficulty of finding such an example in the data suggests its rarity.

To quantify this observation, we recruit two bilingual annotators to re-annotate 100 examples each in both English and French following our standard validation procedure. The examples are drawn from two non-overlapping random subsets of the development data to prevent the annotators from seeing the source English text for any translated text they annotate. With no training or burn-in period, these annotators recover the English consensus label 85% of the time on the original English data and 83% of the time on the translated French, suggesting that the overall semantic relationship between the two languages has been preserved. As most sentences are relatively easy to translate, in particular the hypotheses generated by the workers, there seems to be little ambiguity added by the translator.

More broadly, we find that the resulting corpus has similar properties to the MultiNLI corpus. For all languages, on average, the premises are twice as long as the hypotheses (See Table 2). The top hypothesis words indicative of the class label – scored using the mutual information between each word and class in the corpus – are similar across languages, and overlap those of the MultiNLI corpus (Gururangan et al., 2018). For example, a translation of at least one of the words *no*, *not* or *never* is among the top two cues for contradiction in all languages.

As in the original MultiNLI corpus, we expect that cues like these ('artifacts', in Guru-

rangan's terms, also observed by Poliak et al., 2018; Tsuchiya, 2018) allow a baseline system to achieve better-than-random accuracy with access only to the premise sentences. We accept this as an unavoidable property of the NLI task over naturalistic sentence pairs, and see no reason to expect that this baseline would achieve better accuracy than the relatively poor 53% seen in Gururangan et al. (2018).

4 Cross-Lingual NLI

In this section we present results with XLU systems that can serve as baselines for future work.

4.1 Translation-Based Approaches

The most straightforward techniques for XLU rely on translation systems. There are two natural ways to use a translation system: TRANSLATE TRAIN, where the training data is translated into each target language to provide data to train each classifier, and TRANSLATE TEST, where a translation system is used at test time to translate input sentences to the training language. These two methods provide strong baselines, but both present practical challenges. The former requires training and maintaining as many classifiers as there are languages, while the latter relies on computationally-intensive translation at test time. Both approaches are limited by the quality of the translation system, which itself varies with the quantity of available training data and the similarity of the language pair involved.

4.2 Multilingual Sentence Encoders

An alternative to translation is to rely on language-universal embeddings of text and build multilingual classifiers on top of these representations. If an encoder produces an embedding of an English sentence close to the embedding of its translation in another language, then a classifier learned on top of English sentence embeddings will be able to classify sentences from different languages without needing a translation system at inference time.

We evaluate two types of cross-lingual sentence encoders: (i) pretrained universal multilingual sentence embeddings based on the average of word embeddings (X-CBOW), (ii) bidirectional-LSTM (BiLSTM) (Hochreiter and Schmidhuber, 1997) sentence encoders trained on the MultiNLI training data (X-BILSTM). The former evaluates transfer learning while the latter evaluates NLI-specific encoders trained on in-domain data. Both approaches use the same alignment loss for aligning sentence embedding spaces from multiple languages which is present below. We consider two ways of extracting feature vectors from the BiLSTM: either using the initial and final hidden states (Sutskever et al., 2014), or using the element-wise max over all states (Collobert and Weston, 2008).

The first approach is commonly used as a strong baseline for monolingual sentence embeddings (Arora et al., 2017; Conneau and Kiela, 2018; Gouews et al., 2014). Concretely, we consider the English fastText word embedding space as being fixed, and fine-tune embeddings in other languages so that the average of the word vectors in a sentence is close to the average of the word vectors in its English translation. The second approach consists in learning an English sentence encoder on the MultiNLI training data along with an encoder on the target language, with the objective that the representations of two translations are nearby in the embedding space. In both approaches, an English encoder is fixed, and we train target language encoders to match the output of this encoder. This allows us to build sentence representations that belong to the same space. Joint training of encoders and parameter sharing are also promising directions to improve and simplify the alignment of sentence embedding spaces. We leave this for future work.

In all experiments, we consider encoders that output a vector of fixed size as a sentence representation. While previous work shows that performance on the NLI task can be improved by using cross-sentence attention between the premise and hypothesis (Rocktäschel et al., 2016; Gong et al., 2018), we focus on methods with fixed-size sentence embeddings.

4.2.1 Aligning Word Embeddings

Multilingual word embeddings are an efficient way to transfer knowledge from one language to another. For instance, Zhang et al. (2016) show that cross-lingual embeddings can be used to extend an English part-of-speech tagger to the cross-lingual setting, and Xiao and Guo (2014) achieve similar results in dependency parsing. Cross-lingual embeddings also provide an efficient mechanism to bootstrap neural machine translation (NMT) systems for low-resource language pairs, which is critical in the case of unsupervised machine translation (Lample et al., 2018; Artetxe et al., 2018). In that case, the use cross-lingual embeddings directly helps the alignment of sentence-level encoders. Cross-lingual embeddings can be generated efficiently using a very small amount of supervision. By using a small parallel dictionary with $n = 5000$ word pairs, it is possible to learn a linear mapping to minimize

$$W^\star = \underset{W \in O_d(\mathbb{R})}{\operatorname{argmin}} \|WX - Y\|_{\mathrm{F}} = UV^T,$$

where d is the dimension of the embeddings, and X and Y are two matrices of shape (d, n) that correspond to the aligned word embeddings that appear in the parallel dictionary, $O_d(\mathbb{R})$ is the group of orthogonal matrices of dimension d, and U and V are obtained from the singular value decomposition (SVD) of YX^T: $U\Sigma V^T = \mathrm{SVD}(YX^T)$. Xing et al. (2015) show that enforcing the orthogonality constraint on the linear mapping leads to better results on the word translation task.

In this paper, we use common-crawl word embeddings (Grave et al., 2018) aligned with the MUSE library of Conneau et al. (2018).

4.2.2 Universal Multilingual Sentence Embeddings

Most of the successful recent approaches for learning universal sentence representations have relied on English (Kiros et al., 2015; Arora et al., 2017; Conneau et al., 2017; Subramanian et al., 2018; Cer et al., 2018). While notable recent approaches have considered building a shared sentence encoder for multiple languages using publicly available parallel corpora (Johnson et al., 2016; Schwenk et al., 2017; España-Bonet et al., 2017), the lack of a large-scale, sentence-level semantic evaluation has limited their adoption by the community. In particular, these works do not cover the scale of languages considered in XNLI, and are limited to high-resource languages. As a baseline for the evaluation of multilingual sentence representations in the 15 languages of XNLI, we consider state-of-the-art common-crawl embeddings with a CBOW encoder. Our approach, dubbed X-CBOW, consists in fixing the English pretrained word embeddings, and fine-tuning the target (e.g., French) word embeddings so that the CBOW representations of two translations are close in embedding space. In that case, we consider our multilingual sentence embeddings as being pretrained and only learn a classifier on top of them to evaluate their quality, similar to so-called "transfer" tasks in (Kiros et al., 2015; Conneau et al., 2017) but in the multilingual setting.

4.2.3 Aligning Sentence Embeddings

Training for similarity of source and target sentences in an embedding space is conceptually and computationally simpler than generating a translation in the target language from a source sentence. We propose a method for training for cross-lingual similarity and evaluate approaches based on the simpler task of aligning sentence representations. Under our objective, the embeddings of two parallel sentences need not be identical, but only close enough in the embedding space that the decision boundary of the English classifier captures the similarity.

We propose a simple alignment loss function to align the embedding spaces of two different languages. Specifically, we train an English encoder on NLI, and train a target encoder by minimizing the loss:

$$\mathcal{L}_{\text{align}}(x, y) = sim(x, y) - \lambda(sim(x_c, y) + sim(x, y_c))$$

where (x, y) corresponds to the source and target sentence embeddings, (x_c, y_c) is a contrastive term (i.e. negative sampling), λ controls the weight of the negative examples in the loss. For a similarity measure, we use the L2 norm with $sim(x, y) = -\|x - y\|_2$. We obtain similar results using the cosine similarity. A ranking loss (Weston et al., 2011) of the form

$$\begin{aligned}\mathcal{L}_{\text{rank}}(x, y) = &\max(0, \alpha - sim(x, y) + s(x, y_c)) \; + \\ &\max(0, \alpha - sim(x, y) + s(x_c, y))\end{aligned}$$

Table 3: BLEU scores of our translation models (XX-En) P@1 for multilingual word embeddings.

that pushes the sentence embeddings of a translation pair to be closer than the ones of negative pairs leads to very poor results in this particular case. As opposed to $\mathcal{L}_{\text{align}}$, $\mathcal{L}_{\text{rank}}$ does not encourage the embeddings of sentence pairs to be close enough so that the shared classifier can understand that these sentences have the same meaning.

We use $\mathcal{L}_{\text{align}}$ in the cross-lingual embeddings baselines X-CBOW, X-BILSTM-LAST and X-BILSTM-MAX. For X-CBOW, the encoder is pretrained (transfer-learning), while the English X-BiLSTMs are trained on NLI (in-domain). For the three methods, the English encoder is then fixed. Each of the 14 other languages have their own encoders with same architecture. These encoders are trained to "copy" the English encoder using the $\mathcal{L}_{\text{align}}$ loss and the parallel data described in section 5.2.

We only back-propagate through the target encoder when optimizing $\mathcal{L}_{\text{align}}$ such that all 14 encoders live in the same English embedding space. In these experiments, we initialize lookup tables of the LSTMs with pretrained cross-lingual embeddings discussed in Section 4.2.1.

5 Experiments and Results

5.1 Training details

We use internal translation systems to translate data between English and the 10 other languages. For TRANSLATE TEST (see Table 4), we translate each test set into English, while for the TRANSLATE TRAIN, we translate the English training data of MultiNLI[2]. To give an idea of the translation quality, we give BLEU scores of the automatic translation from the foreign language into English of the XNLI test set in Table 3.

We use pretrained 300D word embeddings and only consider the most 500,000 frequent words in the dictionary, which generally covers more than 98% of the words found in XNLI corpora. We set the number of hidden units of the BiLSTMs to 512, and use the Adam optimizer (Kingma and Ba, 2014) with default parameters. For the alignment loss, setting λ to 0.25 worked best in our experiments, and we found that the trade-off between the importance of the positive and the negative pairs was particularly important (see Table 5). When fitting the target BiLSTM encoder to the English encoder, we fine-tune the lookup table associated to the target encoder, but keep the source word embeddings fixed. The classifier is a feed-forward neural network with one hidden layer of 128 hidden units, regularized with dropout (Srivastava et al., 2014) at a rate of 0.1. For X-BiLSTMs, we perform model selection on the XNLI validation set in each target language. For X-CBOW, we keep a validation set of parallel sentences to evaluate our alignment loss. The alignment loss requires a parallel dataset of sentences for each pair of languages, which we describe next.

5.2 Parallel Datasets

We use publicly available parallel datasets to learn the alignment between English and target encoders. For French, Spanish, Russian, Arabic and Chinese, we use the United Nation corpora (Ziemski et al., 2016), for German, Greek and Bulgarian, the Europarl corpora (Koehn, 2005), for Turkish, Vietnamese and Thai, the OpenSubtitles 2018 corpus (Tiedemann, 2012), and for Hindi, the IIT Bombay corpus (Anoop et al., 2018). For all the above language pairs, we were able to gather more than 500,000 parallel sentences, and we set the maximum number of parallel sentences to 2 million. For the lower-resource languages Urdu and Swahili, the number of parallel sentences is an order of magnitude smaller than for the other languages we consider. For Urdu, we used the Bible and Quran transcriptions (Tiedemann, 2012), the OpenSubtitles 2016 and 2018 corpora (Tiedemann, 2012) and LDC2010T21, LDC2010T23 LDC corpora, and obtained a total of 64k parallel sentences. For Swahili, we were

only able to gather 42k sentences using the Global Voices corpus and the Tanzil Quran transcription corpus[3].

5.3 Analysis

Comparing in-language performance in Table 4, we observe that, when using BiLSTMs, results are consistently better when we take the dimension-wise maximum over all hidden states (BiLSTM-max) compared to taking the last hidden state (BiLSTM-last). Unsuprisingly, BiLSTM results are better than the pretrained CBOW approach for all languages. As in Bowman et al. (2015), we also observe the superiority of BiLSTM encoders over CBOW, even when fine-tuning the word embeddings of the latter on the MultiNLI training set, thereby again confirming that the NLI task requires more than just word information. Both of these findings confirm previously published results (Conneau et al., 2017).

Table 4 shows that translation offers a strong baseline for XLU. Within translation, TRANSLATE TEST appears to perform consistently better than TRANSLATE TRAIN for all languages. The best cross-lingual results in our evaluation are obtained by the TRANSLATE TEST approach for all cross-lingual directions. Within the translation approaches, as expected, we observe that cross-lingual performance depends on the quality of the translation system. In fact, translation-based results are very well-correlated with the BLEU scores for the translation systems; XNLI performance for three of the four languages with the best translation systems (comparing absolute BLEU, Table 3) is above 70%. This performance is still about three points below the English NLI performance of 73.7%. This slight drop in performance may be related to translation error, changes in style, or artifacts introduced by the machine translation systems that result in discrepancies between the training and test data.

For cross-lingual performance, we observe a healthy gap between the English results and the results obtained on other languages. For instance, for French, we obtain 67.7% accuracy when classifying French pairs using our English classifier and multilingual sentence encoder. When using our alignment process, our method is competitive with the TRANSLATE TRAIN baseline, suggesting that it might be possible to encode similarity between languages directly in the embedding spaces generated by the encoders. However, these methods are still below the other machine translation baseline TRANSLATE TEST, which significantly outperforms the multilingual sentence encoder approach by up to 6% (Swahili). These production systems have been trained on much larger training data than the ones used for the alignment loss (section 5.2), which can partly explain the superiority of this method over the baseline. Interestingly, the two points difference in accuracy between X-BiLSTM-last and X-BiLSTM-max is maintained across languages, which suggests that having a stronger encoder in English also positively impacts the transfer results on other languages.

In Table 5, we report the validation accuracy using BiLSTM-max on three languages with different training hyper-parameters. Fine-tuning the

embeddings does not significantly impact the results, suggesting that the LSTM alone is ensuring alignment of parallel sentence embeddings. We also observe that the negative term is not critical to the performance of the model, but can lead to slight improvement in Chinese (up to 1.6%).

6 Conclusion

A typical problem in industrial applications is the lack of supervised data for languages other than English, and particularly for low-resource languages. Since annotating data in every language is not a realistic approach, there has been a growing interest in cross-lingual understanding and low-resource transfer in multilingual scenarios. In this work, we extend the development and test sets of the Multi-Genre Natural Language Inference Corpus to 15 languages, including low-resource languages such as Swahili and Urdu. Our dataset, dubbed XNLI, is designed to address the lack of standardized evaluation protocols in cross-lingual understanding, and will hopefully help the community make further strides in this area. We present several approaches based on cross-lingual sentence encoders and machine translation systems. While machine translation baselines obtained the best results in our experiments, these approaches rely on computationally-intensive translation models either at training or at test time. We found that cross-lingual encoder baselines provide an encouraging and efficient alternative, and that further work is required to match the performance of translation based methods.

Abstract

Cross-lingual Entity Linking (XEL) aims to ground entity mentions written in *any* language to an English Knowledge Base (KB), such as Wikipedia. XEL for most languages is challenging, owing to limited availability of resources as supervision. We address this challenge by developing the first XEL approach that combines supervision from multiple languages *jointly*. This enables our approach to: **(a)** augment the limited supervision in the target language with additional supervision from a high-resource language (like English), and **(b)** train a *single* entity linking model for multiple languages, improving upon individually trained models for each language. Extensive evaluation on three benchmark datasets across 8 languages shows that our approach significantly improves over the current state-of-the-art. We also provide analyses in two limited resource settings: **(a)** *zero-shot setting*, when no supervision in the target language is available, and in **(b)** *low-resource setting*, when some supervision in the target language is available. Our analysis provides insights into the limitations of zero-shot XEL approaches in realistic scenarios, and shows the value of joint supervision in low-resource settings.[1]

1 Introduction

Entity Linking (EL) systems ground entity mentions in text to entries in Knowledge Bases (KB), such as Wikipedia (Mihalcea and Csomai, 2007). Recently, the task of Cross-lingual Entity Linking (XEL) has gained attention (McNamee et al., 2011; Ji et al., 2015; Tsai and Roth, 2016) with the goal of grounding entity mentions written in *any* language to the English Wikipedia. For instance, Figure 1 shows a Tamil (a language with >70 million speakers) and an English mention (shown [**enclosed**]) and their mention contexts. XEL involves grounding the Tamil mention (which translates to 'Liverpool') to the football club Liverpool_F.C., and not the city or the university. XEL enables knowledge acquisition directly from documents in any language, without resorting to machine translation.

சுரேஸ் **[லிவர்பூல்]** மற்றும் உருகுவே விளையாடுகிறார்.

Everton won against **[Liverpool]** in an FA Cup match.

Figure 1: Tamil and English mention contexts containing [**mentions**] of the entity Liverpool_F.C. from the respective Wikipedias. Tamil Wikipedia only has 9 mentions referring to Liverpool_F.C., whereas English Wikipedia has 5303 such mentions. Clearly, there is a need to augment the limited contextual evidence in low-resource languages with evidence from high-resource languages like English. Tamil sentence translates to "Suarez plays for [**Liverpool**] and Uruguay."

Training an EL model requires grounded mentions, i.e. mentions of entities that are grounded to a Knowledge Base (KB), as supervision (Figure 1). While millions of such mentions are available in English, by virtue of hyperlinks in the English Wikipedia, this is not the case for most languages. This makes learning XEL models challenging, especially for languages with limited resources (e.g., the Tamil Wikipedia is only 1% of the English Wikipedia in size). To overcome this challenge, it is desirable to augment the limited contextual evidence available in the target language with evidence from high-resource languages like English.

We propose XELMS (XEL with Multilingual Supervision) (§2), the first approach that fulfills the above desiderata by using multilingual supervision to train an XEL model. XELMS represents the mention contexts of the same entity from different languages in the same semantic space using a single context encoder (§2.1). Language-agnostic entity representations are jointly learned with the relevant mention context representations, so that an entity and its context share similar representations.

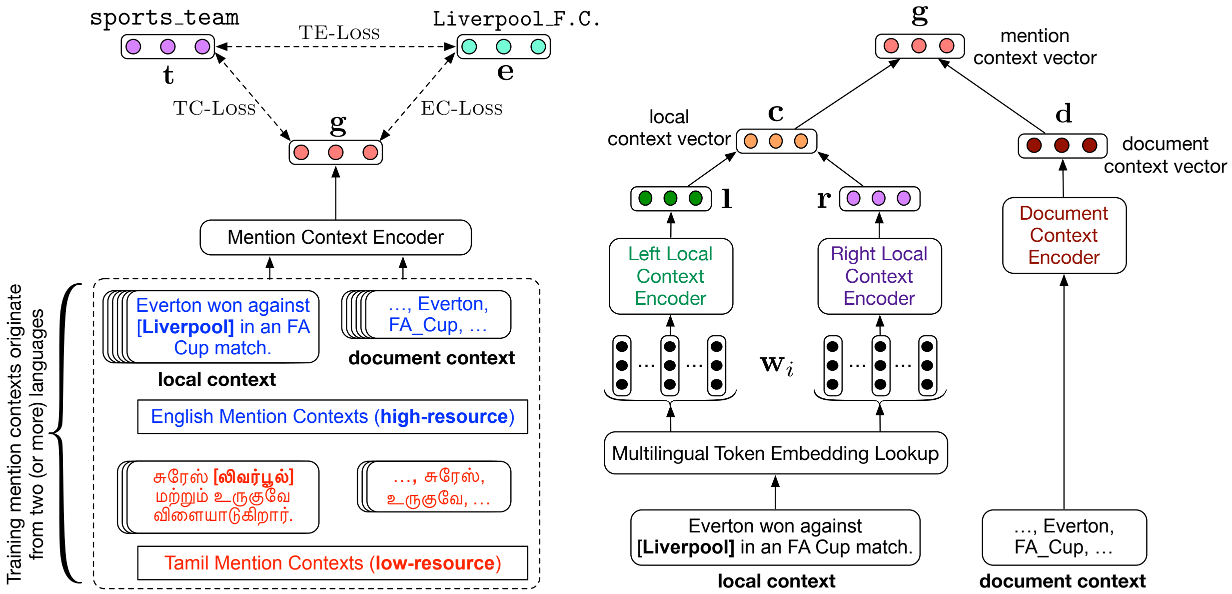
Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2486–2495
Brussels, Belgium, October 31 - November 4, 2018.



(a) Overview of XELMS. Mentions are shown [**enclosed**].

(b) Mention Context Encoder.

Figure 2: (**a**) Grounded mentions from two or more languages (English and Tamil shown) can be used to supervise XELMS. The context $\mathbf{g}$, entity $\mathbf{e}$ and type $\mathbf{t}$ vectors interact through Entity-Context loss (EC-LOSS), Type-Context loss (TC-LOSS) and Type-Entity loss (TE-LOSS). The Tamil sentence is the same as in Figure 1, and other mentions in it translate to [**Suarez**] and [**Uruguay**]. (**b**) The Mention Context Encoder (§2.1) encodes the local context (neighboring words) and the document context (surfaces of other mentions in the document) of the mention into $\mathbf{g}$. Internal view of local context encoder is in Figure 3.

Additionally, by encoding freely available structured knowledge, like fine-grained entity types, the entity and context representations can be further improved (§2.2).

The ability to use multilingual supervision enables XELMS to learn XEL models for target languages with limited resources by exploiting freely available supervision from high resource languages (like English). We show that XELMS outperforms existing state-of-the-art approaches that only use target language supervision, across 3 benchmark datasets in 8 languages (§5.1). Moreover, while previous XEL models (McNamee et al., 2011; Tsai and Roth, 2016) train separate models for different languages, XELMS can train a *single* model for performing XEL in multiple languages (§5.2).

One of the goals of XEL is to enable understanding of languages with limited resources. We provide experimental analyses in two such settings. In the *zero-shot setting* (§6.1), where *no* supervision is available in the target language, we show that the good performance of zero-shot XEL approaches (Sil et al., 2018) can be attributed to the use of prior probabilities. These probabilities are computed from large amount of grounded mentions, which are not available in realistic zero-shot settings. In the *low-resource setting* (§6.2), where some supervision is available in the target language, we show that even when only a fraction of the available supervision in the target language is provided, XELMS can achieve competitive performance by exploiting supervision from English.

The contributions of our work are,

- A new XEL approach, XELMS, that learns a XEL model for a language with limited resources by exploiting additional supervision from a high-resource language like English.
- XELMS can also train a *single* XEL model for multiple languages jointly, which we show improves on separately trained models.
- Analysis of XEL approaches in the zero-shot and low-resource settings. Our analysis reveals that in realistic scenarios, zero-shot XEL is not as effective as previously shown. We also show that in low-resource settings jointly training with English leads to better utilization of target language supervision.

2 Cross-lingual EL with XELMS

Given a mention m in a document $\mathcal{D}$ written in any language, XEL involves linking m to its gold entity e^* in a KB, $\mathcal{K} = \{e_1, \cdots, e_n\}$.

An overview of XELMS is shown in Figure 2a. XELMS computes the probability, $\mathrm{P}_{\text{context}}(e \mid m)$, of a mention m referring to entity $e \in \mathcal{K}$ using a mention context vector $\mathbf{g} \in \mathbb{R}^h$ representing

m's context, and an entity vector $\mathbf{e} \in \mathbb{R}^h$, representing the entity $e \in \mathcal{K}$ (one vector per entity). XELMS can also incorporate structured knowledge like fine-grained entity types (§2.2) using a multi-task learning approach (Caruana, 1998), by learning a type vector $\mathbf{t} \in \mathbb{R}^h$ for each possible type t (e.g., sports_team) associated with the entity e. The entity vector $\mathbf{e}$, context vector $\mathbf{g}$ and the type vector $\mathbf{t}$ are jointly trained, and interact through appropriately defined pairwise loss terms – an Entity-Context loss (EC-LOSS), Type-Entity loss (TE-LOSS) and a Type-Context loss (TC-LOSS).

The mention context vector $\mathbf{g}$ is generated by a mention context encoder (§2.1), shown in Figure 2b. The *mention context* of m in a document $\mathcal{D}$ consists of: **(a)** neighboring words around the mention, which we refer to as its *local context* and, **(b)** surfaces of other mentions appearing in $\mathcal{D}$, which we refer as its *document context*.

XELMS is trained using grounded mentions in multiple languages (English and Tamil in Figure 2a), which can be derived from Wikipedia (§4.1).

2.1 Mention Context Representation

To learn from mention contexts in multiple languages, we generate mention context representations using a language-agnostic mention context encoder. An overview of the mention context encoder is shown in Figure 2b. Below we describe the components of the mention context encoder, namely multilingual word embeddings and local and document context encoders.

Multilingual Word Embeddings (Ammar et al., 2016b; Smith et al., 2017; Duong et al., 2017) jointly encode words in multiple ($\geq$2) languages in the same vector space such that semantically similar words in the same language, and translationally equivalent words in different languages are close (per cosine similarity). Multilingual embeddings generalize bilingual embeddings, which do the same for two languages *only*.

We use FASTTEXT (Bojanowski et al., 2017; Smith et al., 2017), which aligns monolingual embeddings of multiple languages in the same space using a small dictionary (~2500 pairs) from each language to English. Both monolingual embeddings and the dictionary can be easily obtained for languages with limited resources. We denote the multilingual word embeddings for a set of tokens $\{w_1, w_2, \cdots, w_n\}$ by $\mathbf{w}_{1:n} = \{\mathbf{w}_1, \mathbf{w}_2, \cdots, \mathbf{w}_n\}$, where each $\mathbf{w}_i \in \mathbb{R}^d$.

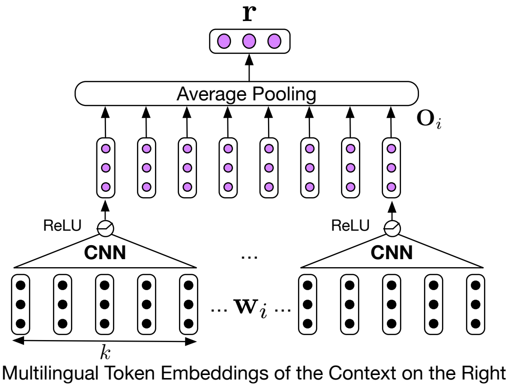


Figure 3: Local Context Encoder, for the right context. Figure 2b shows how it fits inside Mention Context Encoder.

Local Context Representation The local context of a mention m, spanning tokens i to j, consists of left context (tokens $i - W$ to j) and right context (tokens i to $j + W$). For example, for the mention [**Liverpool**] in Figure 2b, the left and right contexts are "Everton won against Liverpool" and "Liverpool in a FA Cup match" respectively. The local context encoder (Figure 3) encodes the left and the right contexts into vectors $\mathbf{l} \in \mathbb{R}^h$ and $\mathbf{r} \in \mathbb{R}^h$ using a convolutional neural network (CNN). These two vectors are then combined to generate the local context vector $\mathbf{c} \in \mathbb{R}^h$ (Figure 2b).

The CNN convolves continuous spans of k tokens using a filter matrix $\mathbf{F} \in \mathbb{R}^{kd \times h}$ to project the concatenation ($\oplus$ operator) of the token embeddings in the span. The resulting vector is passed through a ReLU unit to generate convolutional output $\mathbf{O}_i$. The outputs $\{\mathbf{O}_i\}$ are pooled by averaging,

$$\mathbf{O}_i = \text{RELU}(\mathbf{F}^T(\mathbf{w}_i \oplus \cdots \oplus \mathbf{w}_{i+k-1})) \quad (1)$$

$$\text{ENC}(\mathbf{w}_{1:n}) = \text{AVG}(\mathbf{O}_1, \cdots, \mathbf{O}_{n-k+1}) \quad (2)$$

Left and right context vectors $\mathbf{l}$ and $\mathbf{r}$ are computed using respective ENC(.) layers,

$$\mathbf{l} = \text{ENC}_{\text{left}}(\mathbf{w}_{i-W} \cdots \mathbf{w}_j) \quad (3)$$

$$\mathbf{r} = \text{ENC}_{\text{right}}(\mathbf{w}_i \cdots \mathbf{w}_{j+W}) \quad (4)$$

These vectors together generate the local context vector $\mathbf{c} = \mathcal{F}_{2h,h}(\mathbf{l} \oplus \mathbf{r})$. Here $\mathcal{F}_{d_i,d_o} : \mathbf{v}_i \rightarrow \mathbf{v}_o$ denotes a feed-forward layer that takes $\mathbf{v}_i \in \mathbb{R}^{d_i}$ as input, and outputs $\mathbf{v}_o \in \mathbb{R}^{d_o}$.

Document Context Representation Presence of certain mentions in a document can help disambiguate other mentions. For example, "Suarez", "Everton" in a document can help disambiguate "Liverpool". To incorporate this, we define the

document context d_m of a mention m appearing in document $\mathcal{D}$ to be the bag of all other mentions in $\mathcal{D}$. We encode d_m into a dense document context vector $\mathbf{d} \in \mathbb{R}^h$ by a feed-forward layer $\mathbf{d} = \mathcal{F}_{|V|,h}(d_m)$. Here V is the set containing all mention surfaces seen during training. When training jointly over multiple languages, V consists of mention surfaces seen in all languages (e.g. all English and Tamil mention surfaces) during training. This enables parameter sharing by embedding mention surfaces in different languages in the same low-dimensional space.
The local and document context vectors $\mathbf{c}$ and $\mathbf{d}$ are combined to get the mention context vector $\mathbf{g} = \mathcal{F}_{2h,h}(\mathbf{c} \oplus \mathbf{d})$.

Context Conditional Probability We compute the probability of a mention m linking to entity e using its context vector $\mathbf{g}$ and the entity vector $\mathbf{e}$,

$$\mathrm{P}_{\text{context}}(e \mid m) = \frac{\exp(\mathbf{g}^T\mathbf{e})}{\sum\limits_{e' \in C(m)} \exp(\mathbf{g}^T\mathbf{e}')} \quad (5)$$

where $C(m)$ denotes all candidate entities of the mention m (§3.1 explains how $C(m)$ is generated). We minimize the negative log-likelihood of $\mathrm{P}_{\text{context}}(e \mid m)$ with respect to the gold entity e^* against the candidate entities $C(m)$, and call it the Entity-Context loss (EC-LOSS),

$$\text{EC-LOSS} = -\log \frac{\mathrm{P}_{\text{context}}(e^* \mid m)}{\sum\limits_{e' \in C(m)} \mathrm{P}_{\text{context}}(e' \mid m)} \quad (6)$$

2.2 Including Type Information

Incorporating the fine-grained types of a mention m can help rank entities of the appropriate type higher than others (Ling et al., 2015; Gupta et al., 2017; Raiman and Raiman, 2018). For instance, knowing the correct type of mention **[Liverpool]** as sports_team and constraining linking to entities with the relevant type, encourages disambiguation to the correct entity.

To make the mention context representation $\mathbf{g}$ type-aware, we predict the set of fine-grained types of m, $\mathbf{T}(m) = \{t_1, ..., t_{|\mathbf{T}(m)|}\}$ using $\mathbf{g}$. Each t_i belongs to a pre-defined type vocabulary Γ.[2] The probability of a type t belonging to $\mathbf{T}(m)$ given the mention context is defined as $\mathrm{P}(t \mid m) = \sigma(\mathbf{t}^T\mathbf{g})$, where σ is the sigmoid function and $\mathbf{t}$ is the learnable embedding for type t.

We define a Type-Context loss (TC-LOSS) as,

$$\text{TC-LOSS} = \mathrm{BCE}(\mathbf{T}(m), \mathrm{P}(t \mid m)) \quad (7)$$

where BCE is the Binary Cross-Entropy Loss,

$$-\sum_{t \in \mathbf{T}(m)} \log \mathrm{P}(t \mid m) - \sum_{t \notin \mathbf{T}(m)} \log(1 - \mathrm{P}(t \mid m))$$

We also incorporate the entity-type information in the entity representations, and define a similar Type-Entity loss (TE-LOSS).

To identify the gold types $\mathbf{T}(m)$ of a mention m, we make the distant supervision assumption (same as Ling et al. (2015)) and assign the types of the gold entity e^* to be the types of the mention. Gold fine-grained types of the entities can be acquired from resources like Freebase (Bollacker et al., 2008) or YAGO (Hoffart et al., 2013).

3 Training and Inference

We explain how XELMS generates candidate entities, performs inference, and combines the different training losses.

3.1 Candidate Generation

Candidate generation identifies a small number of plausible entities for a mention m to avoid brute force comparison with all KB entities. Given m, candidate generation outputs a list of candidate entities $C(m) = \{e_1, e_2, \cdots, e_K\}$ of size at most K (we use K=20), each associated with a prior probability $\mathrm{P}_{\text{prior}}(e_i \mid m)$ indicating the probability of m referring to e_i, given only m's surface. $\mathrm{P}_{\text{prior}}$ is estimated from counts over the training mentions.

We adopt Tsai and Roth (2016)'s candidate generation strategy with some minor modifications (Appendix A). Using other approaches like CrossWikis (Spitkovsky and Chang, 2012), lead to consistently worse recall. We note that transliteration based candidate generation (McNamee et al., 2011; Pan et al., 2017; Tsai and Roth, 2018; Upadhyay et al., 2018) can further improve recall.

3.2 Inference

We combine the context conditional entity probability $\mathrm{P}_{\text{context}}(e \mid m)$ (eq. 5) and prior probability $\mathrm{P}_{\text{prior}}(e \mid m)$ by taking their union:

$$\begin{aligned}\mathrm{P}_{\text{model}}(e \mid m) &= \mathrm{P}_{\text{prior}}(e \mid m) + \mathrm{P}_{\text{context}}(e \mid m) \\ &\quad - \mathrm{P}_{\text{prior}}(e \mid m) \times \mathrm{P}_{\text{context}}(e \mid m)\end{aligned}$$

Inference for the mention m picks the entity,

$$\hat{e} = \underset{e \in C(m)}{\arg\max}\, \mathrm{P}_{\text{model}}(e \mid m) \quad (8)$$

---

[2] We use the type vocabulary Γ from Ling and Weld (2012), which contains 112 fine-grained types ($|\Gamma| = 112$)

3.3 Training Objective

When only training the mention context encoder and entity vectors, we minimize the EC-Loss averaged over all training mentions. When using the two type-aware losses, we minimize a weighted sum of EC-Loss, TE-Loss, and TC-Loss, using the weighing scheme of Kendall et al. (2018),

$$\frac{\text{EC-Loss}}{2\lambda_{\text{EC}}^2} + \frac{\text{TE-Loss}}{2\lambda_{\text{TE}}^2} + \frac{\text{TC-Loss}}{2\lambda_{\text{TC}}^2} \\ + \log \lambda_{\text{EC}}^2 + \log \lambda_{\text{TE}}^2 + \log \lambda_{\text{TC}}^2 \quad (9)$$

Here λ_i are learnable scalar weighing parameters, and the respective $\frac{1}{2\lambda_i^2}$ and $\log \lambda_i^2$ term ensure that λ_i^2 does not grow unboundedly. This way, the model learns the relative weight for each loss term.

During training, mentions from different languages are mixed using *inverse-ratio mini-batch mixing* strategy. That is, if two languages have training data sizes proportional to $\alpha : \beta$, at any time during training, mini-batches seen from them are in the ratio $\frac{1}{\alpha} : \frac{1}{\beta}$. This strategy prevents languages with more training data from overwhelming languages with less training data. Though simple, we found this strategy yielded good results.

4 Experimental Setup

We briefly describe the training and evaluation datasets, and the previous XEL approaches from the literature used in our comparison.

4.1 Training Mentions

Following previous work, we use hyperlinks from Wikipedia (dumps dated 05/20/2017) as our source of grounded mentions for supervision. Wikipedias in different languages have different pages for the same entity, which are resolved by using interlanguage links (e.g., page 利物浦 in Chinese Wikipedia resolves to Liverpool in English). Training mentions statistics are shown in Table 1.

Lang.	# Train Mentions	Size Relative to # English Mentions
German (de)	22.6M	43.7%
Spanish (es)	13.8M	26.7%
French (fr)	16.2M	31.3%
Italian (it)	11.5M	22.2%
Chinese (zh)	5.9M	11.4%
Arabic (ar)	3.1M	6.0%
Turkish (tr)	1.8M	3.5%
Tamil (ta)	473k	0.9%

Table 1: Number of train mentions (from Wikipedia) in each language, with % size relative to English (51.7M mentions). Train mentions from Wikipedias like Arabic, Turkish and Tamil are <10% the size of those from the English Wikipedia.

We evaluate on 8 languages – German (de), Spanish (es), Italian (it), French (fr), Chinese (zh), Arabic (ar), Turkish (tr) and Tamil (ta), each of which has varying amount of grounded mentions from the respective Wikipedia (Table 1). We note that our method is applicable to any of the 293 Wikipedia languages as a target language.

4.2 Evaluation Datasets

We evaluate XELMS on the following benchmark datasets, spanning 8 different languages, thus providing an extensive evaluation.

McN-Test dataset from (McNamee et al., 2011). The test set was collected by using parallel document collections, and then crowd-sourcing the ground truths. All the test mentions in this dataset consists of person-names only.

TH-Test A subset of the dataset used in (Tsai and Roth, 2016), derived from Wikipedia.[3] The mentions in the dataset fall in two categories – *easy* and *hard*, where hard mentions are those for which the most likely candidate according to the prior probability (i.e., $\arg\max \mathrm{P}_{\text{prior}}(e \mid m)$) is *not* the correct title. Indeed, most Wikipedia mentions can be correctly linked by selecting the most likely candidate (Ratinov et al., 2011). We use all the hard mentions from Tsai and Roth (2016)'s test splits for each language, and collectively call this subset TH-Test.

TAC15-Test TAC 2015 (Ji et al., 2015) dataset for Chinese and Spanish. It contains documents from discussion forum articles and news.

We evaluate all models using linking accuracy on gold mentions, and assume gold mentions are provided at test time. Table 2 summarizes the different domains of the evaluation datasets.

Tuning We avoid any dataset-specific tuning, instead tuning on a development set and applying the same parameters across all datasets. All tunable parameters were tuned on a development set containing the hard mentions from the train split released by Tsai and Roth (2016). We refer the reader to Appendix B for details on tuning.

---

[3] Pan et al. (2017) also created a dataset using Wikipedia, but did not categorize mentions like Tsai and Roth (2016). Preliminary experiments on their dataset showed XELMS consistently beat Pan et al. (2017)'s model. We chose TH-Test for more controlled experiments.

Dataset	Lang.	Source
TH-Test	de, es, fr, it, zh, ar, tr, ta	Wikipedia
McN-Test	de, es, fr, it, zh, ar, tr	News, Parliament Proceedings
TAC15-Test	es, zh	News, Discussion Forums

Table 2: Evaluation datasets used in our experiments.

4.3 Comparative Approaches

We compare against the following state-of-the-art (SoTA) approaches, described with the language from which they use mention contexts in **(.)**,

Tsai and Roth (2016) (Target Only) trains a separate XEL model for each language using mention contexts from the target language Wikipedia only. Current SoTA on TH-Test.

Pan et al. (2017) (English Only) uses entity coherence statistics from English Wikipedia and the document context of a mention for XEL. Current SoTA on McN-Test, except for Italian and Turkish, for which it's McNamee et al. (2011).

Sil et al. (2018) (English Only) uses multilingual embeddings to transfer a pre-trained English entity linking model to perform XEL for Spanish and Chinese. Prior probabilities P_{prior} are used as a feature. Current SoTA on TAC15-Test.

5 Experiments

We show that: **(a)** XELMS can train a better entity linking model for a target language on various benchmark datasets by exploiting additional data from a high resource language like English (§5.1). **(b)** XELMS can train a *single* XEL model for multiple related languages and improve upon separately trained models (§5.2). **(c)** Adding additional type information as multi-task loss to XELMS further improves performance (§5.3).

In all tables, we report the linking accuracy of XELMS, averaged over 5 different runs, and mark with * the statistical significance ($p < 0.01$) of the best result (shown **bold**) against the state-of-the-art (SoTA) using Student's one-sample t-test.

5.1 Monolingual and Joint Models

In Table 3 and 4 we compare XELMS(mono), which uses monolingual supervision in the target language only, and XELMS(joint), which uses supervision from English in addition to the monolingual supervision, with the state-of-the-art approaches.

Dataset →	TH-Test			McN-Test		
		XELMS			XELMS	
Lang ↓	SoTA	mono	joint	SoTA	mono	joint
de	53.3	53.7	**55.6***	89.7	90.9	**91.5**
es	54.5	54.9	**56.6***	**91.5**	91.2	91.4
fr	47.5	48.5	**49.9***	92.1	92.6	**92.7**
it	48.3	48.4	**51.9***	85.9	87.0	**87.8***
zh	57.6	58.1	**61.3***	**91.2***	87.4	88.2
ar	62.1	62.6	**63.8***	80.2	80.3	**83.1***
tr	60.2	61.0	**61.7***	**95.3***	91.0	91.9
ta	54.1	54.7	**59.7***	n/a	n/a	n/a
avg.	54.7	55.2	**57.6**	89.4	88.6	**89.5**

Table 3: XELMS(joint) improves upon XELMS(mono) and the current State-of-The-Art (SoTA) on TH-Test and McN-Test, showing the benefit of using additional supervision from English. The best score is shown **bold** and * marks statistical significance of best against SoTA. Refer §4.3 for details on SoTA.

	Model ↓ Lang. →	es	zh
	(Tsai and Roth, 2016)	82.4	85.1
	(Sil et al., 2018) (SoTA)	83.9	85.9
XELMS	mono	83.3	84.4
	mono$^{\text{+type}}$	83.5	84.8
	joint	84.1	85.5
	joint$^{\text{+type}}$	**84.4***	**86.0**
	multi	83.9	n/a
	multi$^{\text{+type}}$	**84.4***	n/a

Table 4: Linking accuracy on TAC15-Test. Numbers for Sil et al. (2018) from personal communication.

We see that XELMS(mono) achieves similar or slightly better scores than respective SoTA on all datasets. The SoTA for McN-Test in Turkish and Chinese enhances the model by using transliteration for candidate generation, explaining their superior performance. XELMS(joint) performs substantially better than XELMS(mono) on all datasets (Table 3 and 4), proving that using additional supervision from a high resource language like English leads to better linking performance. In particular, XELMS(joint) outperforms the SoTA on all languages in TH-Test, on Spanish in TAC15-Test, and on 4 of the 7 languages in McN-Test.

5.2 Multilingual Training

XELMS is the first approach that can train a *single* XEL model for multiple languages. To demonstrate this capability, we train a model, henceforth referred as XELMS(multi), *jointly* on 5 related languages – Spanish, German, French, Italian and En-

Dataset →	TH-TEST			MCN-TEST		
		XELMS			XELMS	
Lang ↓	SoTA	joint	multi	SoTA	joint	multi
de	53.3	**55.6***	55.2	89.7	**91.5**	91.4
es	54.5	56.6	**56.8***	**91.5**	91.4	91.4
fr	47.5	49.9	**51.0***	92.1	**92.7**	92.6
it	48.3	51.9	**52.3***	85.9	87.8	**87.9***
avg.	50.9	53.5	**53.8**	89.8	**90.8**	**90.8**

Table 5: Linking accuracy of a *single* XELMS(multi) model for four languages – German, Spanish, French and Italian. Individually trained XELMS(joint) scores are also shown. The best score is shown **bold** and * marks statistical significance of **best** against SoTA. Refer §4.3 for details on SoTA.

glish. We compare XELMS(multi) to the respective XELMS(joint) model for each language.

Table 4 and 5, show that XELMS(multi) is better (or at par) than XELMS(joint) on all datasets. This shows that XELMS(multi) can making more efficient use of available supervision in related languages than previous approaches which trained separate models per language.

5.3 Adding Fine-grained Type Information

To study the effect of adding fine-grained type information, in Table 4 we compare XELMS(mono) and XELMS(joint) to XELMS(mono^{+type}) and XELMS(joint^{+type}) respectively, which are versions of XELMS(mono) and XELMS(joint) trained using the two type-aware losses.

XELMS(mono^{+type}) and XELMS(joint^{+type}) both improve compared to XELMS(mono) and XELMS(joint) on MCN-TEST and TH-TEST (Table 6 vs Table 3), showing the benefit of using structured knowledge in the form of fine-grained types. Similar trends are also seen on TAC15-TEST (Table 4), where XELMS(joint^{+type}) improves on the SoTA for Spanish and Chinese.

6 Experiments with Limited Resources

The key motivation of XELMS is to exploit supervision from high-resource languages like English to aid XEL for languages with limited resources. In this section, we examine two such scenarios,
(a) *Zero-shot setting* i.e., no supervision available in the target language. Our analysis reveals the limitations of zero-shot XEL approaches and finds that the prior probabilities play an important role in achieving good performance (§6.1), which are unavailable in realistic zero-shot scenarios.
(b) *Low-resource setting* i.e., some supervision available in the target language. We show that by combining supervision from a high-resource language, like English, XELMS can achieve competitive performance with a fraction of available supervision in the target language (§6.2).

Dataset →	TH-TEST			MCN-TEST		
		XELMS			XELMS	
Lang ↓	SoTA	mono^{+type}	joint^{+type}	SoTA	mono^{+type}	joint^{+type}
de	53.3	54.0	**55.9***	89.7	91.2	**91.5**
es	54.5	55.1	**57.2***	**91.5**	91.0	91.2
fr	47.5	49.0	**50.6***	92.1	92.6	**92.7**
it	48.3	49.2	**52.2***	85.9	87.4	**87.9***
zh	57.6	58.9	**61.5***	**91.2***	87.6	88.4
ar	62.1	63.0	**64.0***	80.2	81.1	**84.0***
tr	60.2	61.5	**62.0***	**95.3***	91.2	92.1
ta	54.1	56.0	**59.9***	n/a	n/a	n/a
avg.	54.7	55.8	**57.9**	89.4	88.9	**89.7**

Table 6: Adding fine-grained type information further improves linking accuracy (compare to Table 3). The best score is shown **bold** and * marks statistical significance of best against SoTA. Refer §4.3 for details on SoTA.

6.1 Zero-shot Setting

We first explain how XELMS can perform zero-shot XEL, the implications of our zero-shot setting, and how it is more realistic than previous work.

Zero-shot XEL with XELMS XELMS performs zero-shot XEL by training a model using English supervision and multilingual embeddings for English, and directly applying it to the test data in another language using the respective multilingual word embedding instead of English embeddings.

No Prior Probabilities Prior probabilities (or prior), i.e., P_{prior} have been shown to be a reliable indicator of the correct disambiguation in entity linking (Ratinov et al., 2011; Tsai and Roth, 2016). These probabilities are estimated from counts over the training mentions in the target language. In the absence of training data for the target language, as in the zero-shot setting, these prior probabilities are not available to an XEL model.

Comparison to Previous Work The only other model capable of zero-shot XEL is that of Sil et al. (2018). However, Sil et al. (2018) use prior probabilities and coreference chains for the target language in their zero-shot experiments, both of which will not be available in a realistic zero-shot scenario. Compared to Sil et al. (2018), we evaluate the performance of zero-shot XEL in more realistic setting, and show it is adversely affected by absence of prior probabilities.

Dataset → **Approach** ↓	TAC15-Test (es)	(zh)	TH-Test (avg)	McN-Test (avg)
XELMS (Z-S w/ prior)	80.3	83.9	43.5	88.1
XELMS (Z-S w/o prior)	53.5	55.9	41.1	86.0
SoTA	83.9	85.9	54.7	89.4

Table 7: Linking accuracy of the zero-shot (Z-S) approach on different datasets. Zero-shot (w/ prior) is close to SoTA for datasets like TAC15-Test, but performance drops in the more realistic setting of zero-shot (w/o prior) (§6.1) on all datasets, indicating most of the performance can be attributed to the presence of prior probabilities. The slight drop in McN-Test is due to trivial mentions, which only have a single candidate.

Is zero-shot XEL really effective? To evaluate the effectiveness of the zero-shot XEL approach, we perform zero-shot XEL using XELMS on all datasets. Table 7 shows zero-shot XEL results on all datasets, both with and without using the prior during inference. Note that zero-shot XEL (with prior) is close to SoTA (Sil et al. (2018)) on TAC15-Test, which also uses the prior for zero-shot XEL. However, for zero-shot XEL (without prior) performance drops by more than 20% for TAC15-Test, 2.4% for TH-Test and by 2.1% for McN-Test. This indicates that zero-shot XEL is not effective in a realistic zero-shot setting (i.e., when the prior is unavailable for inference).

We found that the prior is indeed a strong indicator of the correct disambiguation. For instance, simply selecting the the most likely candidate using the prior for TAC15-Test achieved 77.2% and 78.8% for Spanish and Chinese respectively. It is interesting to note that both zero-shot XEL (with or without prior) perform worse than the best possible model on TH-Test, because TH-Test was constructed to ensure prior probabilities are not strong indicators (Tsai and Roth, 2016). On McN-Test, we found that an average of 75.9% mentions have only one (the correct) candidate, making them trivial to link, regardless of the absence of priors.

The results show that most of the XEL performance in zero-shot settings can be attributed to availability of prior probabilities for the candidates. It is evident that zero-shot XEL in a realistic setting (i.e., when prior probabilities are not available) is still a challenging problem.

6.2 Low-resource Setting

We analyze the behavior of XELMS in a low-resource setting, i.e. when some supervision is available in the target language. The aim of this setting is to estimate how much supervision from the target language is needed to get reasonable performance when using it jointly with supervision from English. To discount the effect of prior probabilities, we report all results without the prior.

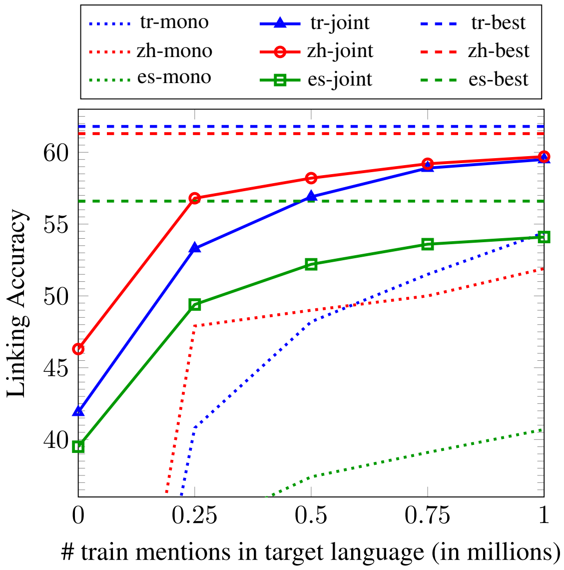

Figure 4: Linking accuracy vs. the number of train mentions in the target language L (= Turkish (tr), Chinese (zh) and Spanish (es)). We compare both XELMS(mono) and XELMS(joint) to the best results using all available supervision, denoted by L-best. To discount the effect of the prior, all results above are without it. For number of train mentions = 0, XELMS(joint) is equivalent to zero-shot without prior. Best viewed in color.

Figure 4 plots results on the TH-Test dataset when training a XELMS(joint) model by gradually increasing the number of mention contexts for target language L (= Spanish, Chinese and Turkish) that are available for supervision. Figure 4 also shows the best results achieved using all available target language supervision (denoted by L-best). For comparison with the mono-lingually supervised model, we also plot the performance of XELMS(mono), which only uses the target language supervision.

Figure 4 shows that after training on 0.75M mentions from Turkish and Chinese (and 1.0M mentions from Spanish), the XELMS(joint) model is within 2-3% of the respective L-best model which uses all training mentions in the target language, indicating that XELMS(joint) can reach competitive performance even with a fraction of the full target language supervision. For comparison, a XELMS(mono) model trained on the same number of training mentions is 5-10% behind the respective XELMS(joint) model, showing better utilization of target language supervision by XELMS(joint).

7 Related Work

Existing approaches have taken two main directions to obtain supervision for learning XEL models — **(a)** using mention contexts appearing in the target language (McNamee et al., 2011; Tsai and Roth, 2016), or **(b)** using mention contexts appearing only in English (Pan et al., 2017; Sil et al., 2018). We describe these directions and their limitations below, and explain how XELMS overcomes these limitations.

McNamee et al. (2011) use annotation projection via parallel corpora to generate mention contexts in the target language, while Tsai and Roth (2016) learns separate XEL models for each language and only use mention contexts in the target language. Both these approach have scalability issues for languages with limited resources. Another limitation of these approaches is that they train separate models for each language, which is inefficient when working with multiple languages. XELMS overcomes these limitations as it can use mention context from multiple languages simultaneously, and train a single model.

Other approaches only use mention contexts from English. While Pan et al. (2017) compute entity coherence statistics from English Wikipedia, Sil et al. (2018) perform zero-shot XEL for Chinese and Spanish by using multilingual embeddings to transfer a pre-trained English EL model. However, our work suggests that mention contexts in the target language should also be used, if available. Indeed, a recent study (Lewoniewski et al., 2017) found that for language sensitive topics, the quality of information can be better in the relevant language version of Wikipedia than the English version. Our analysis also shows that zero-shot XEL approaches like that of Sil et al. (2018) are not effective in realistic zero-shot scenarios where good prior probabilities are unlikely to be available. In such cases, we showed that combining supervision available in the target language with supervision from a high-resource language like English can yield significant performance improvements.

The architecture of XELMS is inspired by several monolingual entity linking systems (Francis-Landau et al., 2016; Nguyen et al., 2016; Gupta et al., 2017), approaches that use type information to aid entity linking (Ling et al., 2015; Gupta et al., 2017; Raiman and Raiman, 2018), and the recent success of multilingual embeddings for several tasks (Ammar et al., 2016a; Duong et al., 2017).

8 Conclusion

We introduced XELMS, an approach that can combine supervision from multiple languages to train an XEL model. We illustrate its benefits through extensive evaluation on different benchmarks. XELMS is also the first approach that can train a *single* model for multiple languages, making more efficient use of available supervision than previous approaches which trained separate models.

Our analysis sheds light on the poor performance of zero-shot XEL in realistic scenarios where the prior probabilities for candidates are unlikely to exist, in contrast to findings in previous work that focused on high-resource languages. We also show how in low-resource settings, XELMS makes it possible to achieve competitive performance even when only a fraction of the available supervision in the target language is provided.

Several future research directions remain open. For all XEL approaches, the task of candidate generation is currently limited by existence of a target language Wikipedia and remains a key challenge. A joint inference framework which enforces coherent predictions (Cheng and Roth, 2013; Globerson et al., 2016; Ganea and Hofmann, 2017) could also lead to further improvements for XEL. Similar techniques can be applied to other information extraction tasks like relation extraction to extend them to multilingual settings.

Abstract

This paper proposes to study fine-grained coordinated cross-lingual text stream alignment through a novel information network decipherment paradigm. We use Burst Information Networks as media to represent text streams and present a simple yet effective network decipherment algorithm with diverse clues to decipher the networks for accurate text stream alignment. Experiments on Chinese-English news streams show our approach not only outperforms previous approaches on bilingual lexicon extraction from coordinated text streams but also can harvest high-quality alignments from large amounts of streaming data for endless language knowledge mining, which makes it promising to be a new paradigm for automatic language knowledge acquisition.

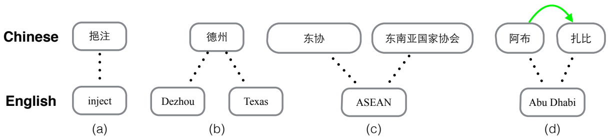

Figure 1: Knowledge derived from fine-grained cross-lingual text stream alignments: (a) word translations; (b) polysemy/multi-references; (c) synonym/co-reference; (d) entity phrases

1 Introduction

Coordinated text streams (Wang et al., 2007) refer to the text streams that are topically related and indexed by the same set of time points. Previous studies (Wang et al., 2007; Hu et al., 2012) on coordinated text stream focus on discovering and aligning common topic patterns across languages. Despite their contributions to applications like cross-lingual information retrieval and topic analysis, such a coarse-grained topic-level alignment framework inevitably overlooks many useful fine-grained alignment knowledge. For example, Figure 1 shows typical knowledge that can be derived from fine-grained Chinese-English text stream alignments. In addition to (a) bi-lingual word translations, we can also discover (b) polysemous and multi-referential words if one Chinese word is aligned to multiple English words, (c) synonymous and co-referential word pairs if two Chinese words are aligned to the same English word, and (d) entity phrases (e.g., 阿布扎比 in Figure 1) if adjacent Chinese words in text are aligned to the same English named entity.

In order to acquire language knowledge for Natural Language Processing (NLP) applications, we study fine-grained cross-lingual text stream alignment. Instead of directly turning massive, unstructured data streams into structured knowledge (D2K), we adopt a new Data-to-Network-to-Knowledge (D2N2K) paradigm, based on the following observations: (i) most information units are not independent, instead they are interconnected or interacting, forming massive networks; (ii) if information networks can be constructed across multiple languages, they may bring tremendous power to make knowledge mining algorithms more scalable and effective because we can employ the graph structures to acquire and propagate knowledge.

Based on the motivations, we employ a promising text stream representation – *Burst Information Networks (BINets)* (Ge et al., 2016a), which can be easily constructed without rich language resources, as media to display the most important information units and illustrate their connections in the text streams. With the BINet representation, we propose a simple yet effective network decipherment algorithm for aligning cross-lingual text streams, which can take advantage of the co-burst characteristic of cross-lingual text streams and easily incorporate prior knowledge and rich clues for fast and accurate network decipherment.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2496–2506
Brussels, Belgium, October 31 - November 4, 2018.

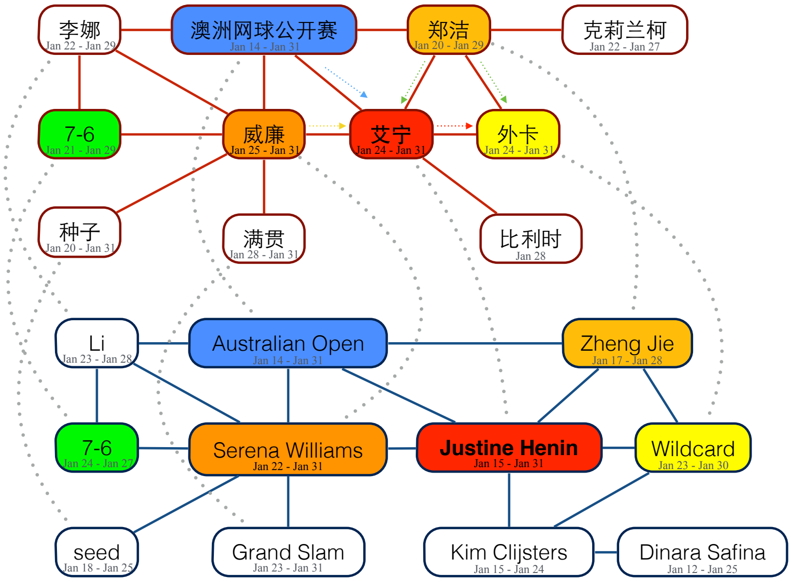

Figure 2: (A part of) Burst Information Networks built from Chinese and English news streams.

For example, in Figure 2, each node in a BINet is a bursty word with one of its burst periods, representing an important information unit in a text stream. To decipher the Chinese BINet, our approach first focuses on the nodes in the English BINet in Figure 2 as the candidates because they co-burst with the Chinese nodes. Then, we decipher some nodes based on prior knowledge (the green node), the pronunciation similarity clue (the orange nodes) or literal translation similarity clue (the blue node). These deciphered nodes will serve as neighbor clues to decipher their adjacent nodes (the red node) which will then be used for further decipherment (e.g., decipher the yellow node) through knowledge propagation across the network, as the dashed arrows in Figure 2 show.

Experiments on Chinese-English coordinated news streams show our approach can accurately align nodes across the cross-lingual BINets and derive various knowledge, and that with more streaming data provided, we can harvest more high-quality alignments and thus derive more knowledge. By aligning endless text streams, it is promising for never-ending language knowledge mining, which can not only complement language resources but also benefit some NLP applications.

The main contributions of this paper are:

- We propose a promising framework to mine knowledge from inexhaustible coordinated cross-lingual text streams through fine-grained alignment, exploring a paradigm for language knowledge acquisition.
- We propose a network decipherment approach for text stream alignment, which can work in both low and rich resource settings and outperform previous approaches.
- We release our data (annotations) and systems to guarantee the reproducibility and help future work improve on this task.

2 Burst Information Network

A Burst Information Network (BINet) is a graph-based text stream representation and has proven effective for multiple text stream mining tasks (Ge et al., 2016a,b,c). In contrast to many information networks (e.g., (Ji, 2009; Li et al., 2014)), BINets are specially for text streams. They focus on the burst information units which are usually related to important events or trending topics in text streams and illustrate their connections.

A BINet is originally defined as $G = \langle V, E, \boldsymbol{\omega} \rangle$ in (Ge et al., 2016a). Each node $v \in V$ is a burst element defined as a burst word[1] during one of its burst periods $\langle w, \mathcal{P} \rangle$ where w denotes a word and $\mathcal{P}$ denotes one consecutive burst period of w, as Figure 2 shows. Each edge $\epsilon \in E$ indicates the connection between two burst elements with the weight ω which is defined as the number of documents where these two burst elements co-occur in the text stream. In this paper, we extend the BINet definition to $G = \langle V, E, \boldsymbol{\omega}, \boldsymbol{\pi} \rangle$ by adding a binary

---

[1] Burst words and their corresponding burst periods can be detected based on Kleinberg burst detection algorithm (Kleinberg, 2003), as (Ge et al., 2016a) did.

indicator π to indicate if two nodes (i.e., burst elements) are frequently (more than 5 times) adjacent (as a bigram) in text, for mining knowledge such as entity phrases in Figure 1(d).

3 Decipherment

After constructing a BINet from a foreign language (we use Chinese as a foreign language in this paper), we can decipher it by consulting an Engish BINet constructed from its coordinated English text stream. We define $G_c = \langle V_c, E_c, \boldsymbol{\omega_c}, \boldsymbol{\pi_c} \rangle$ and $G_e = \langle V_e, E_e, \boldsymbol{\omega_e}, \boldsymbol{\pi_e} \rangle$ as the Chinese BINet and English BINet respectively. For people who do not know Chinese, G_c is a network of ciphers. We design a novel BINet decipherment procedure to decipher G_c by aligning as many nodes in G_c as possible to G_e. The decipherment process is defined to find $e \in V_e$ for a node $c \in V_c$ so that e is c's counterpart in the English text stream.[2]

3.1 Starting Point

To decipher the Chinese BINet, we need a few seeds based on prior knowledge as a starting point. Inspired by previous work on bi-lingual lexicon induction, decipherment and name translation mining, we utilize a few linguistic resources - a bilingual lexicon and language-universal representations such as time/calendar date, number, website URL, currency and emoticons to decipher a subset of Chinese nodes. For the example shown in Figure 2, we can decipher some nodes in the Chinese BINet such as “7-6” (to “7-6”) and “种子” (to “seed”).

3.2 Candidate Generation

For the nodes that cannot be deciphered by the prior knowledge, we first need to discover their possible candidates. For a node c in the Chinese BINet, its counterpart e can be any node in the English BINet or does not exist in the English BINet, resulting in an extremely large search space. Fortunately, burst information that refers to a hot topic usually co-bursts across languages. Based on this characteristic, for a node in the Chinese BINet, its counterpart is likely to be a node with the same burst period in the English BINet. For example, the node “威廉(Williams)” in the Chinese BINet in Figure 2 bursts between January 25 and January 31, 2010. We only need to look for its counterpart from the nodes in the English BINet whose burst period overlaps with this period. Formally, for a node $c \in V_c$ in the Chinese BINet, its candidate nodes in the English BINet can be derived as:

$$Cand(c) = \{e | \mathcal{P}(e) \cap \mathcal{P}(c) \neq \emptyset\}$$

where $e \in V_e$, and $\mathcal{P}(c)$ and $\mathcal{P}(e)$ are the burst periods of c and e respectively.

3.3 Candidate Verification

For the candidate list for c (i.e., $Cand(c)$), we need to verify each node $e \in Cand(c)$ and choose the most probable one as c's counterpart. Formally, we define $Score(c, e)$ as the credibility score of e being the correct counterpart of c and propose the following novel clues for verification.

Pronunciation

Inspired by previous work on name translation mining (e.g., (Schafer III, 2006; Sproat et al., 2006; Ji, 2009)), for a node $e \in Cand(c)$, if its pronunciation is similar to c, then e is likely to be the translation of c. For a Chinese node c and an English node e, we define S_p as its scaled pronunciation score to measure their pronunciation similarity whose range is $[0, 1]$:

$$S_p \in [0, 1] \propto \frac{1}{LD}$$

where LD is the normalized (by e's length) Levenshtein edit distance between c's pinyin[3] string and e's word string.

Translation

For a node $e \in Cand(c)$, it is possible that e's word exists or partially exists in the bi-lingual lexicon. We can exploit the translation clue to verify if e is c's counterpart. For example, “Australian Open” is a candidate of “澳洲网球公开赛(Australian Open)” as shown in Figure 2. Even though “澳洲网球公开赛(Australian Open)” is not in the bi-lingual lexicon, “Australian” and “open” are in the lexicon and their Chinese translations are “澳洲的(Australian)” and “公开(open)” respectively. If we literally translate “Australian Open” word by word, we will get “澳洲的公开” which has long common subsequences with the Chinese node “澳洲网球公开赛(Australian Open)”, inferring that “Australian Open” is likely to be the translation of “澳洲网球公开赛”.

---

[2] c and e are burst elements (i.e., nodes in the BINets). Sometimes, we also use c and e to denote the nodes' word if that does not lead to misunderstanding.

[3] Pinyin is the official romanization system for Chinese. We use pinyin instead of IPA because romanization is usually more easily available than IPA for a language.

Motivated by this observation, for a candidate $e \in Cand(c)$, we first extract its possible Chinese translations $C(e)$ from the bilingual lexicon. Note that if e is a multiword, we concatenate translations of its components. Then, for $\langle c, e \rangle$, we define S_t as its scaled translation similarity score whose range is $[0, 1]$:

$$S_t \in [0,1] \propto \max_{c' \in C(e)} LCS(c, c')$$

where $\max_{c' \in C(e)} LCS(c, c')$ is maximum length of the longest common subsequence between c and $c' \in C(e)$.

Neighbor

The graph topological structure of a BINet is also an important clue for decipherment. By analyzing a node's neighbors, we can learn useful topic-level knowledge to decipher the node. For the example in Figure 2, "艾宁(Henin)" in the Chinese BINet has neighbors such as "威廉(Williams)", "澳洲网球公开赛(Australian Open)" and "郑洁(Zheng Jie)" while "Justine Henin" in the English BINet is connected with "Serena Williams", "Australian Open" and "Zheng Jie". If we know "Serena Williams", "Australian Open" and "Zheng Jie" are the counterpart of '威廉", "澳洲网球公开赛" and "郑洁" respectively, we can infer "Justine Henin" is likely to be the counterpart of "艾宁", which can be further used as a clue to decipher its neighbors such as "外卡(wildcard)" through knowledge propagation.

We define $N(c)$ and $N(e)$ as the set of adjacent nodes of c in the Chinese BINet and the adjacent nodes of e in the English BINet respectively. The neighbor clue score S_n of $\langle c, e \rangle$ is defined as:

$$S_n = \sum_{c' \in N(c)} \hat{\omega}_{c,c'} \max_{e' \in N(e)} Score(c', e') \qquad (1)$$

where $Score(c', e')$ is the overall score of e' being the counterpart of c', as defined at the beginning of this section, $\hat{\omega}_{c,c'} = \frac{\omega_{c,c'}}{\sum_{c'' \in N(c')} \omega_{c',c''}}$ is the normalized weight of the edge between c and c'.

Correlation of burst

If the word of $e \in Cand(c)$ frequently co-bursts with the word of c, then e is likely to be the counterpart of c. For example, "Serena Williams" in the English stream usually co-bursts with "小威" in the Chinese stream, as shown in Figure 3, which is a useful clue to infer that "Serena Williams" is the counterpart of "小威".

We define S_b as the burst correlation score:

$$S_b = \frac{\boldsymbol{s}_{w(c)} \cdot \boldsymbol{s}_{w(e)}}{\|\boldsymbol{s}_{w(c)}\|_1 + \|\boldsymbol{s}_{w(e)}\|_1 - \boldsymbol{s}_{w(c)} \cdot \boldsymbol{s}_{w(e)}} \qquad (2)$$

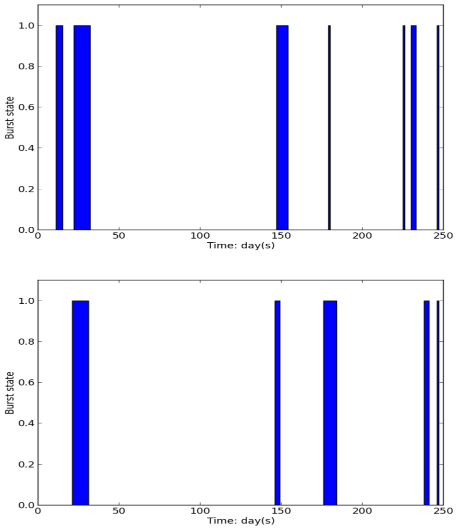

Figure 3: Burst states of "小威" (the upper) and "Serena Williams" (the lower) are correlated.

where $w(v)$ denotes the word of the node v and $\boldsymbol{s}_w$ denotes the burst sequence of the word w in which each entry is a binary variable indicating if w bursts at a moment throughout the time frame. Note that in the above equation, we regard $\boldsymbol{s}_{\boldsymbol{w}}$ as a vector. The numerator is the number of days when $w(c)$ and $w(e)$ co-burst and the denominator is the number of days when either $w(c)$ or $w(e)$ bursts.

3.4 Graph-based Decipherment

We define the overall (credibility) score as the linear combination of the clues introduced above:

$$Score(c, e) = \eta S_p + \lambda S_t + \gamma S_n + \delta S_b \qquad (3)$$

where S_p, S_t, S_n and S_b are the scores that measure the value/reliability of the pronunciation, translation, neighbor and burst correlation clues respectively, and η, λ, γ and δ are hyperparameters for adjusting their weights.

Based on Eq (3), we can now compute the score of any candidate pair $\langle c, e \rangle$. For pairs that are known to be correct alignments according to prior knowledge, their overall scores will be fixed to 1.0. For other possible candidate pairs, we simply initialize their scores as follows:

$$Score(c, e) = \frac{1.0}{|Cand(c)|} \qquad (4)$$

where $Cand(c)$ is the set of c's candidate nodes in the English BINet.

Given that $Score(c, e)$ is influenced by other pairs' scores, we design an iterative algorithm to compute and update the scores to decipher the entire Chinese BINet through propagation. This process is elaborated in Algorithm 1.

Algorithm 1 Graph-based Decipherment

```
1:  For the determined pair $\langle c, e\rangle$ based on the prior knowledge, $Score(c, e) \leftarrow 1.0$
2:  For other undermined pairs $\langle c, e\rangle$, initialize $Score(c, e)$ according to Eq (4);
3:  while $True$ (until $\Delta Conf(G_c, G_e) \leq 0.0001$) do
4:      for each undetermined pair $\langle c, e\rangle$ do
5:          Compute $new\_score$ according to Eq (3);
6:          $update(c, e) = \min(1.0, new\_score)$
7:      end for
8:      for each undetermined pair $\langle c, e\rangle$ do
9:          $Score(c, e) \leftarrow update(c, e)$
10:     end for
11: end while
```

$\Delta Conf(G_c, G_e)$ in the 3rd line of Algorithm 1 is the difference between the network decipherment confidence score at the current iteration and that at its previous iteration. $Conf(G_c, G_e)$ is defined as follows, reflecting how much confidence we have in our network decipherment result:

$$Conf(G_c, G_e) = \sum_{c \in V_c} \max_{e \in Cand(c)} Score(c, e) \qquad (5)$$

In practice, propagation of prior knowledge and clues makes the confidence score increase because it helps us know more about the network (as illustrated by Figure 2). When the confidence score stops increasing or increases marginally (≤ 0.0001) after several iterations, the algorithm terminates[4].

4 Experiments

We first evaluate our approach on aligning nodes in the cross-lingual BINets for fine-grained cross-lingual stream alignment in Section 4.1. Then, we show the value of derived alignments for endless language knowledge acquisition in Section 4.2.

4.1 Stream alignment

4.1.1 Data

We used the public 2010 Agence France Presse (AFP) news in Chinese (Graff and Chen, 2005) and English Gigaword (Graff et al., 2003) as our cross-lingual text streams. The Chinese stream has 17,327 while the English one contains 186,737 documents.

We removed stopwords, conducted lemmatization and name tagging for the English stream, and did word segmentation and name tagging for the Chinese stream using the Stanford CoreNLP toolkit (Manning et al., 2014).

We detected bursts and constructed the BINets[5] for the Chinese and English stream based on (Ge et al., 2016a). The constructed Chinese BINet has 7,360 nodes and 33,892 edges while the English one has 8,852 nodes and 85,125 edges. Our seed bi-lingual lexicon is released by (Zens and Ney, 2004), containing 81,990 Chinese word entries, each of which has an English translation. Among the 7,360 nodes in the Chinese BINet, 2,281 nodes need to be deciphered since their words are not in the bi-lingual lexicon.

4.1.2 Evaluation Setting

We evaluate our approach in an end-to-end fashion. For a node c in the Chinese BINet, we choose the node e^* which has the highest score as c's counterpart in the English BINet:

$$e^* = \arg \max_{e \in Cand(c)} Score(c, e)$$

We rank the aligned node pairs by the score and manually evaluate the quality of the top K pairs. A pair $\langle c,e \rangle$ is annotated as correct if e is a correct translation of c or e refers to an entity that c refers to. The annotation assignment is done by three human judges with 89.4% agreement. The disagreement mainly arises from the ambiguity of some named entities. In the evaluation, we consider $\langle c,e \rangle$ correct if more than two judges annotate it as correct.

We compare our approach to the following baselines that use various combinations of clues to verify candidates for decipherment as well as the state-of-the-art algorithm for language decipherment from non-parallel corpora:

- Pronunciation verification (*pv*): Use the pronunciation clue only
- Translation verification (*tv*): Use the translation clue only
- Neighbor verification (*nv*): Use the neighbor clue only to decipher the BINet through propagation.
- Correlation of burst verification: (*cv*): Use the burst correlation clue only
- *pv*+*tv* and *pv*+*tv*+*nv*
- *Bayesian Inference*: Bayesian inference based decipherment approach (Dou and Knight, 2012) based on the alignment of bigram language

---

[4] Due to the upper bound of $Conf(G_c, G_e)$, the algorithm must terminate after several iterations.

[5] We discarded the edges whose weight is smaller than a threshold (5 for Chinese and 20 for English BINet given the difference of their data size) for removing trivial connections.

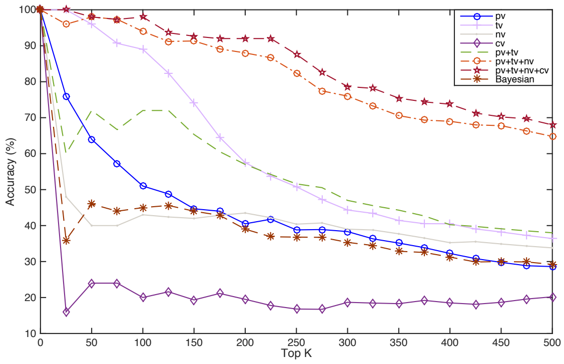

Figure 4: Accuracy curves of various approaches. Note that *pv+tv+nv+cv* is our final approach.

models across languages. We adapt it to our experiment setting by considering adjacent nodes in a BINet as bigrams for decipherment.

We used 2009 AFP Chinese/English news in Gigaword as our development set to tune hyperparameters. Since our approach has only 4 parameters (i.e., η, λ, γ, δ in Eq (3)), it is easy to tune the parameters using grid search (from 0.0 to 1.0 with a step 0.2) on the development set. For baselines except Bayesian inference, the score computation function is almost identical to Eq (3) except that the weights of the clues which are not used are set to 0.

4.1.3 Results

We present the results in Figure 4. Our approach outperforms all the baselines because it considers various clues for decipherment. Among the baselines, accuracy scores of *pv* and *tv* drop dramatically with K increasing because a single clue can only decipher a limited number of nodes effectively. *pv+tv* seems to alleviate the problem to some extent: its accuracy does not drop so drastically as *pv* or *tv* because multiple clues allow us to decipher more nodes but its accuracy is still not desirable. Among the clues, *cv* performs worst, demonstrating that the burst correlation clue alone is far from enough for decipherment. Compared with *pv*, *tv* and *cv*, *nv* deciphers the nodes in the Chinese BINet through propagation but the neighbor clue alone is not sufficient for accurate decipherment. It is notable that *nv* achieves comparable performance to the Bayesian inference method which uses similar clues, demonstrating the effectiveness of our decipherment framework despite its simplicity. Moreover, our graph-based decipherment approach is more flexible to incorporate a variety of clues. When it is combined with *pv+tv*, the performance shows a significant boost and achieves approximately 90% accuracy in the top 200 results though it is slightly inferior to our final approach due to the lack of awareness of burst correlation.

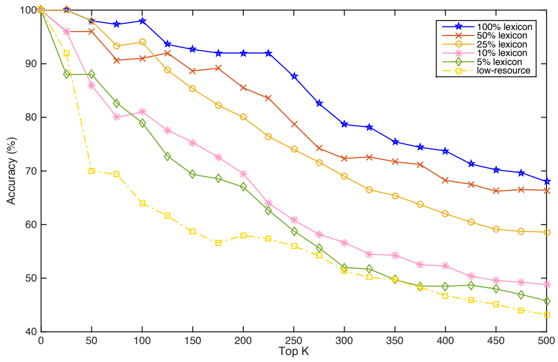

Figure 5: Accuracy curves of our approach with different resource settings.

Another interesting observation from Figure 4 is that our approach clearly know the confidence of its predictions. For top 100 mined pairs with the highest confidence scores (i.e., the score in Eq (3)), **the accuracy is 98%**. Therefore, it is easy to control the quality of mined pairs, which is important for a text mining algorithm.

We also study the effect of language resources on the performance. We first randomly sample different sizes of entries from the original bi-lingual lexicon as new bi-lingual lexicons. The results[6] in Figure 5 show the accuracy improves as the size of bi-lingual lexicon grows because more prior knowledge benefits deciphering the BINet. In addition, we test our approach in a low-resource setting where there is no knowledge of the romanization system (i.e., pinyin) and no pre-trained word segmentation and name tagging tools are available. The only available resource is a very small bi-lingual lexicon with 1,000 most common Chinese words[7] and their corresponding English translations. In this setting, we use an unsupervised Chinese word segmentation approach combining a Hierarchical Dirichlet Process (HDP) model with a Bayesian HMM model (Chen et al., 2014) to segment Chinese text instead of the preprocessing steps mentioned in Section 4.1.1. According to Figure 5, our approach still performs well in the low-resource setting although its accuracy curve is lower than that in rich-resource settings, demonstrating it can work in both rich- and low-resource settings.

---

[6] The sample processes are repeated for 3 times and the results are the averaged accuracy.

[7] We sample these Chinese words based on IDF.

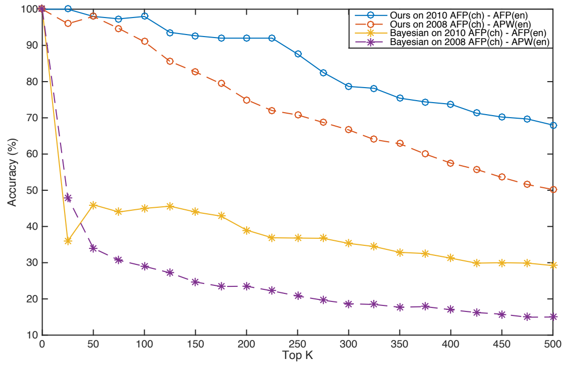

Figure 6: Accuracy curves on multiple datasets.

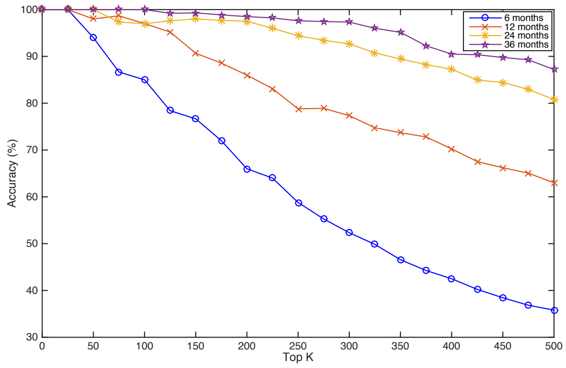

Figure 7: Stream alignments derived from 2008 on the Chinese and English AFP news streams. With more data (i.e., streams within a longer time frame) being aligned, our approach can harvest more high-quality alignments.

In order to test the generalization ability, we evaluate our approach using the same hyperparameters on another coordinated text streams – AFP Chinese and APW English news stream in 2008. The results in Figure 6 show that our decipherment approach consistently outperforms the other baseline and still deciphers the top 100 nodes in high accuracy even though the curve in 2008 is lower than that in 2010. The performance difference in 2008 and 2010 mainly arises from the difference on topic overlaps. In the streams of 2010, the Chinese and English news are from the same news agency (i.e., AFP). Therefore, the topic overlaps of the cross-lingual streams are larger than 2008, allowing more nodes to be deciphered correctly.

Finally, we investigated the performance of our approach under various sizes of data provided, as shown in Figure 7. As observed, when the data size is small (e.g., 6-month coordinated text streams), the approach works poorly because there are very few nodes in BINets that can be aligned. As the data size increases, our approach can efficiently[8] harvest a growing number of high-quality alignments, as reflected by the higher curves in Figure 7. Considering massive coordinated text streams generated every day, if the approach can be applied to the endless streams, it is possible to monitor the streaming data and derive countless alignments for never-ending language knowledge acquisition.

Node	Chinese (burst period)	English (burst period)
1	贝鲁斯柯尼 (346-348)	Berlusconi (344-348)

13	央行 (75-76)	Bank of Japan (73-76)
14	翁山 (310-311)	Aung San Suu Kyi (308-313)
15	苏姬 (310-311)	Aung San Suu Kyi (308-313)

Table 1: Alignment examples. The numbers of burst periods denote the number of days after Jan 1, 2010.

4.2 Endless language knowledge mining

Table 1 shows the stream alignment result of our approach. As demonstrated above, we can derive a variety of language knowledge from the fine-grained cross-lingual alignments.

Word/entity translations are the main knowledge that can be derived from our alignment results by extracting word pairs from the aligned cross-lingual node pairs. Formally, we find a Chinese word w's English translation w^* as follows:

$$w^* = w(e^*)$$

$$e^* = arg\,\max\nolimits_{e \in V_e} \max\nolimits_{c \in V_c(w)} Score(c, e)$$

where $V_c(w)$ is the set of Chinese nodes whose word is w, and $w(e)$ denotes the word of node e.

We evaluate our approach on mining translations of bursty Chinese words, based on the evaluation criteria of bilingual lexicon extraction. Specifically, we test how many out-of-vocabulary (OOV) words appearing in the Chinese BINet are correctly translated. The datasets used for evaluation are the 2010 and 2008 streams in Figure 6. In total, there are 1,226 and 1,082 distinct Chinese OOV words (excluding incorrectly segmented words) in the corresponding Chinese BINets. Accuracy is used to measure the proportion of the words being correctly translated, as (Tamura et al., 2012) did.

Table 2 compares our approach to representative bilingual lexicon extraction approaches. CONTEXT is one of the earliest approaches for extracting word translations from comparable cor-

---

[8] Efficiency is reported in the supplementary notes.

Model	Acc_1(2010)	Acc_1(2008)
Context (Fung and Yee, 1998)	0.32%	0.37%
CoLP (Tamura et al., 2012)	0.32%	0.46%
SimLP (Tamura et al., 2012)	0.49%	0.46%
Diverse (Schafer and Yarowsky, 2002)	5.22%	4.25%
DiverseSP (Sproat et al., 2006)	5.46%	4.44 %
Bayesian(LM) (Dou and Knight, 2012)	0.57%	0.55%
Bayesian(BINet)	11.17%	4.81%
Ours	**28.38%**	**19.78%**

Table 2: Performance of translating bursty words.

pora based on context similarity. CoLP and SimLP are label propagation models on word co-occurrence and similarity graphs for bilingual lexicon extraction. Diverse is a variant of Context by adding various information (e.g., pronunciation and temporality) and DiverseSP is the approach using phonetic and frequency correlation with a score propagation strategy. Bayesian is the Bayesian decipherment approach which has been introduced in the previous section, and it is evaluated in two settings (i.e., based on traditional bigram language models and BINets). According to Table 2, our approach substantially outperforms the other approaches on both datasets, showing its advantages for mining translation of bursty words in coordinated text streams. It is also notable that the BINet-based Bayesian improves the LM-based counterpart, demonstrating the advantage of burst-level alignment for this task.

In addition to the comparisons to the classical baselines, we also test the latest representative unsupervised bi-lingual lexicon extraction approaches (Zhang et al., 2017a,b) based on word embedding and generative adversarial nets (GANs). Unfortunately, these approaches do not perform well in our setting. For example, the approach in (Zhang et al., 2017a) achieved $<1\%$ accuracy[9]. One reason is that the topic overlap of coordinated cross-lingual text streams is not so significant as the Wikipedia data used for their experiments, and the other reason is that their approaches focus on common fundamental words like “城市(city)” while our targets are OOVs like “东协(ASEAN)” which do not frequently appear in a corpus. In contrast, our approach is more practical: it not only works well in easily available and endless coordinated text streams without high content overlap requirement, but also can accurately mine translations of many OOVs which do not appear frequently and really need mining their translations.

Knowledge	Derived	Correct	Acc
Word/entity translation pair	500	416	0.83
Polysemy/multi-referential word	11	8	0.73
Synonym/Co-referential word pair	72	49	0.68
Entity phrase	99	84	0.85

Table 3: Knowledge derived from top 500 alignments obtained by aligning AFP Chinese and English text streams from 2002 to 2010.

As illustrated in Figure 1, besides word/entity translations, various types of knowledge can also be derived from the BINet alignment results as by-products. For example, for node 9 in Table 1, deciphering the nickname “小威” into *Serena Williams* can benefit cross-lingual entity linking. Nodes 10-11 also demonstrate the potential effect on synonym detection, entity linking and coreference resolution, like the case of Figure 1(b). Nodes 12-13 show that the deciphered BINets can detect polysemous/multi-referential word like “央行(Central bank)” which may refer to different entities during different burst periods, like Figure 1(c). Moreover, the deciphered BINets can also help entity phrase extraction based on the idea of Figure 1(d). For example, in nodes 14-15, 翁山苏姬(Aung San Suu Kyi) is not recognized as a person name by the Chinese name tagger; instead, it is mistakenly separated into two words – 翁山(Aung San) and 苏姬(Suu Kyi). However, since 翁山(Aung San) and 苏姬(Suu Kyi) are deciphered into the same English named entity – Aung San Suu Kyi, we can merge them back to form the correct entity.

For evaluating our approach's performance on language knowledge acquisition, we align the AFP Chinese-English text streams from 2002 to 2010. The Chinese stream has 119,196 documents and the English one contains 1,608,636 documents. Our approach obtained 7,211 node alignments[10]. Among them, we focus on the top 500 alignments to guarantee their quality and use the aforementioned idea for deriving language knowledge.

Table 3 shows the result of deriving knowledge from the alignments. Among top 500 alignments, we derived 416 correct word/entity translation pairs with 83% accuracy. Also, we correctly derived 8 polysemous/multi-referential words, 49 synonymous/co-referential word pairs and 84 entity phrases as byproducts. It is notable that the data size of coordinated cross-lingual text streams available on the web is much larger than that used in our experiment and they are endlessly updated.

---

[9] We implement this approach using the codes released by the authors. Their reported accuracy for the common words with over 1,000 occurrences is 2.53% on Gigaword corpus.

[10] The alignments with a low score (< 0.05) are discarded.

That means it is promising to endlessly derive language knowledge by applying our approach to the huge size of endless cross-lingual text streams, which may benefit NLP applications like machine translation, entity linking and name tagging.

5 Related Work

Previous studies on cross-lingual text stream alignment tend to focus on coarse-grained (i.e., topic-level) alignment for finding common patterns (Wang et al., 2007; De Smet and Moens, 2009; Wang et al., 2009; Zhang et al., 2010; Hu et al., 2012) and discovering parallel sentences and documents (Munteanu and Marcu, 2005; Enright and Kondrak, 2007; Uszkoreit et al., 2010; Smith et al., 2010; Krstovski and Smith, 2011, 2016) across languages. Studies on fine-grained cross-lingual alignment are mainly for bilingual lexicon induction (e.g., (Fung and Yee, 1998; Rapp, 1999; Koehn and Knight, 2002; Schafer and Yarowsky, 2002; Shao and Ng, 2004; Schafer III, 2006; Hassan et al., 2007; Haghighi et al., 2008; Udupa et al., 2009; Klementiev and Callison-Burch, 2010; Tamura et al., 2012; Irvine and Callison-Burch, 2013, 2015b; Kiela et al., 2015; Irvine and Callison-Burch, 2015a; Vulic and Moens, 2015; Cao et al., 2016; Zhang et al., 2017b,a)) and name translation mining (e.g., (Sproat et al., 2006; Klementiev and Roth, 2006; Udupa et al., 2008; Ji, 2009; won You et al., 2010; Kotov et al., 2011; Lin et al., 2011; Sellami et al., 2014)) from non-parallel corpora. However, these approaches are mainly developed for general comparable corpora, not specially for cross-lingual text streams; thus many of them did not use the powerful stream-level information (e.g., co-burst across languages). In contrast to the word-level alignment methods, we attempt to mine burst-level alignment to largely narrow down candidates, and introduce powerful clues for improving accuracy and discovering various language knowledge.

In contrast to previous cross-lingual projection work like data transfer (Pado and Lapata, 2009) and model transfer (McDonald et al., 2011), we do not require any parallel data. Moreover, our BINets are cheap to construct, which can be easily extended to other languages. This is also the first attempt to apply the decipherment idea (e.g., (Ravi and Knight, 2011; Dou and Knight, 2012; Dou et al., 2014)) to graph structures instead of sequence data.

6 Conclusions and Future Work

This paper proposes an approach to deciphering the Burst Information Network constructed from foreign languages as a novel way to align cross-lingual text streams. For the first time we propose to model stream alignment as a network decipherment problem. By leveraging the network structures with stream-level burst features as well as various clues, our approach can accurately align the important information units across languages and derive a variety of knowledge. Given that our approach is unsupervised, effective, intuitive, interpretable, and easily implementable, it is promising to use it as a framework for never-ending language knowledge mining from big data, which might benefit NLP applications such as machine translation and cross-lingual information access.

For future work, we plan to 1) conduct more experiments and analyses following this preliminary study to verify our approach's effectiveness for more languages and domains (e.g., social stream VS news stream); 2) attempt to use word embedding (e.g., word2vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014) and ELMo (Peters et al., 2018)) for local context encoding and use it as a clue for decipherment; 3) apply our approach to real-time coordinated text streams for never-ending knowledge mining and use the mined knowledge to improve the downstream applications.

Abstract

Homographic puns have a long history in human writing, widely used in written and spoken literature, which usually occur in a certain syntactic or stylistic structure. How to recognize homographic puns is an important research. However, homographic pun recognition does not solve very well in existing work. In this work, we first use WordNet to understand and expand word embedding for settling the polysemy of homographic puns, and then propose a WordNet-Encoded Collocation-Attention network model (WECA) which combined with the context weights for recognizing the puns. Our experiments on the SemEval2017 Task7 and Pun of the Day demonstrate that the proposed model is able to distinguish between homographic pun and non-homographic pun texts. We show the effectiveness of the model to present the capability of choosing qualitatively informative words. The results show that our model achieves the state-of-the-art performance on homographic puns recognition.

1 Introduction

A pun is a writers use of a word in an ambiguous and inconsistent way in language, often to play on the different meanings of the word or utilize similarly pronounced sounds for a common humorous effect. Puns are widely used in written and spoken literature, which intended as jokes. For example, Tom Swifty by(Lippman and Dunn, 2000), in which puns usually occur in a certain syntactic or stylistic structure. From literature, speeches and oral storytelling, puns are also a standard rhetorical device, which also can be applied non-humorously. For instance, Shakespeare is well known for his puns, which continually appeared in his non-comedic works by (Tanaka, 1992). Both humorous and non-humorous puns have been the theme of extensive and attractive works that has led to discernment for the nature of puns with double meaning.

There are many relevant studies on pun recognition in natural language processing. Many scholars attempted to classify puns according to the similar relationship between the pronunciations and double meanings of the words. For example, (Pafford, 1987) categorizes pun into homophonic puns and homographic puns, which used homonyms and polysemy of words respectively. The research on pun recognition has carried out according to this classification system of Redfern. Our work also considers that puns consist of homophonic and homographic puns.

Type of Pun	Example	Pun Word
Homographic	I used to be a banker but I lost interest.	interest
Homophonic	When the church bought gas for their annual barbecue, proceeds went from sacred to the propane.	propane

Table 1: Pun Examples

Both homographic puns and homophonic puns have double meanings to increase deep impression in a certain environment. However, two types of puns have their own features, respectively. Homographic puns, as an important class of puns, which the words for two senses of puns share the same orthographic form. While homophonic puns have the similarity in pronunciations with double senses that distinguished from homographic puns. The former one mainly settles synonyms, while the latter one solves homonyms. Because of the difference, we can not use the unified model to distinguish. Table 1 illustrates the examples of homographic pun and homophonic pun.

In this study, we mainly focus on homographic

puns since they widely used everywhere (Miller, Tristan and Turković, Mladen, 2016) and easily obtain in existing corpus. However, homographic puns recognition in the current works does not solve very well because of their confused double meanings.

To solve the mentioned problem, we propose a computational WordNet-Encoded Collocation-Attention network model (WECA) to recognize homographic puns. Our model takes semantic word embedding and collocation into account for homographic puns recognition. Based on the experiments, the results show that our work will improve the performance of homographic puns recognition. This work is the first to recognize homographic puns with improved word representation and attention mechanism to the best of knowledge. Here, our contributions are as follows.

- The paper applies the lexical ontology WordNet to understand and extend the word embedding for solving the polysemy of homographic puns.
- The paper proposes a neural attention mechanism to extract the collocation for homographic puns classification, which combined with Bi-LSTM to obtain the context weights.
- Experimental results on the datasets of Semeval2017 Task7 and Pun of the Day demonstrate our method outperforms several baselines for recognition homographic puns. Furthermore, visualization of selected examples show the reasons that this model works well.

The rest of this paper is structured in the following. Section 2 mainly reviews the related work on word representation and puns classification. Section 3 presents our proposed word embedding and collocation attention-based network model. Section 4 shows our experiments and discusses evaluation results. Finally, Section 5 concludes our research contributions and offers the future work.

2 Related Work

In this section, we will review related works on word representation and homographic pun recognition for homographic puns classification briefly.

2.1 Word Representation

In recent years, word representation has the great improvement because it solves data sparsity problem and obtain more semantic relations between words compared with one-hot representation.

(Rumelhart et al., 1986) proposed the idea of word distributed representation, which converts all the words into a low-dimensional continuous semantic space. This space took each word as a vector. These distributed low-dimensional word representation have been widely applied in many NLP tasks, including machine translation(Sutskever et al., 2014; Bahdanau et al., 2014), text classification (Niu et al., 2017; Du et al., 2017), neural language models (Mikolov et al., 2010, 2013) and parsing (Chen and Manning, 2014; Chen et al., 2015). Word embedding is taken as the essential and available inputs for NLP tasks, which enables encoding semantic representation in meaningful vector space.

The studies show that word representations are useful to achieve a good balance between effectiveness and efficiency, such as Word2Vec (Mikolov et al., 2013) and GloVe(Pennington et al., 2014). Therefore, the semantic meanings of words can reflect in the contexts according to these distributed representation models.

However, homographic puns always have multiple meanings. The word representation, considering as only one vector for each word, which puzzled by the understanding for polysemy of puns. This paper combines the representations of lemmas, synsets and words from WordNet[1](Miller, 2002) to understand multiple meanings of homographic puns. The lemma and synset annotation in WordNet provide helpful semantic information for detecting homographic puns.

2.2 Homographic Pun Recognition

In recent years, homographic puns have increasingly become a respectable research topic, which widely appears in rhetoric and literary criticism. However, there were little related works in the fields of computational linguistics and natural language processing by (Miller, Tristan and Turković, Mladen, 2016). In this subsection, we mainly introduce some puns detecting methods.

There are many useful methods to classify the puns in NLP. For example, (Kao et al., 2016; Huang et al., 2017) used a probability statistical model to capture the latent semantic information between words for detecting homographic puns. (Jaech et al., 2016) proposed a new prob-

---

[1] WordNet: http://wordnet.princeton.edu/

ability model to learn phoneme edit probabilities for classifying the homophonic puns. The system ECNU(Xiu et al., 2017) applied a supervised training classifier, which helpful features derived from WordNet and Word2Vec embeddings to distinguish between homographic puns. The system Fermi (Indurthi and Oota, 2017) employed a supervised approach for the detection of homographic puns. It used a bi-directional RNN for a classification model and adopted the distributed semantic word embeddings as input features. These methods do not consider the collocation between words in homographic puns.

The attention mechanism proposed by (Bahdanau et al., 2014) to settle machine translation problem, which was used to select the reference words for words before translation. (Xu et al., 2015) used attention model for image generation to select the similar image regions. For text classification, (Yang et al., 2016) applied attention mechanism into solving document-level classification. Many other tasks in NLP used this mechanism, including natural language question answering (Kumar et al., 2015), parsing (Vinyals et al., 2014), image question answering(Yang et al., 2015), and classification(Shen et al., 2018; Tan et al., 2018). Therefore, this model is capable of discovering the important and semantic information. Meanwhile, attention mechanism can also improve the performance of classification tasks.

Hence, we explore an attention mechanism for collocation to mine the latent semantic information between the part of speech words to achieve good result for homographic puns recognition.

3 Methods

Homographic puns recognition could influence by considering both the semantic word embedding and collocation with the context weights for homographic puns. In this section, we propose our model as WordNet-Encoded Collocation-Attention network (WECA). Figure 1 demonstrates the overall structure of our model.

It consists of three main components: an improved word embedding with WordNet-Encoded as inputs, a Bidirectional Long Short-Term Memory (Bi-LSTM) as context weights in a sentence for homographic puns and a fully-connected network as the collocation-attention mechanism. The attention networks combined by a concatenate operation to discover the collocation. Then the context weights and attention networks combined by an element-wise multiplication operation in the classification layer. We describe the details of three components as follows.

3.1 WordNet-Encoded Word Embedding

The homographic pun is a clever trick to let one word relate to two aspects or multiple meanings. For example, “Before he sold Christmas trees, he got himself spruced up” The pun word spruced has two meaning: one meaning is spruce tree, while the other is making oneself or something look neater and tidier. We find this word spruced means the last meaning in this situation. Therefore, the polysemy of the ambiguity from homographic puns need additional large lexical ontology. Thus, we apply WordNet for computational linguistics and natural language processing.

Polysemy is critical factor for recognizing homographic puns. To combine the information of multiple meanings, we propose giving a WordNet-Encoded model (WE) to obtain the word embedding for each word. WordNet is a lexical ontology of words. Each word has multiple semantics corresponding with respect to different senses and each sense corresponds to multiple words.

We introduce lemmas, synsets (senses) and words in WordNet. For example, the word is “interest”. The word “interest” has three main synsets: sake (a reason for wanting something done), pastime (a diversion that occupies one’s time and thoughts) and interest (a sense of concern with and curiosity about someone or something). The lemmas eliminate the ambiguity of each sense. For instance, the synset pastime represents a diversion that occupies one’s time and thoughts, which contains lemmas pastime, interest and pursuit. Then we propose two strategies to generate the Word-Net-Encoded embedding based on the information of lemmas and synsets information, Average Lemma Aggregation Model (ALA) and Weighted Lemma Aggregation Model (WLA).

Average Lemma Aggregation Model (ALA) adopts a strategy of equal weight according to meanings of homographic puns. ALA model mixes all the lemmas of all the senses of a word together for each word. Hence, it represents the target word by using the average of its whole lemma embedding and puts this together on the original

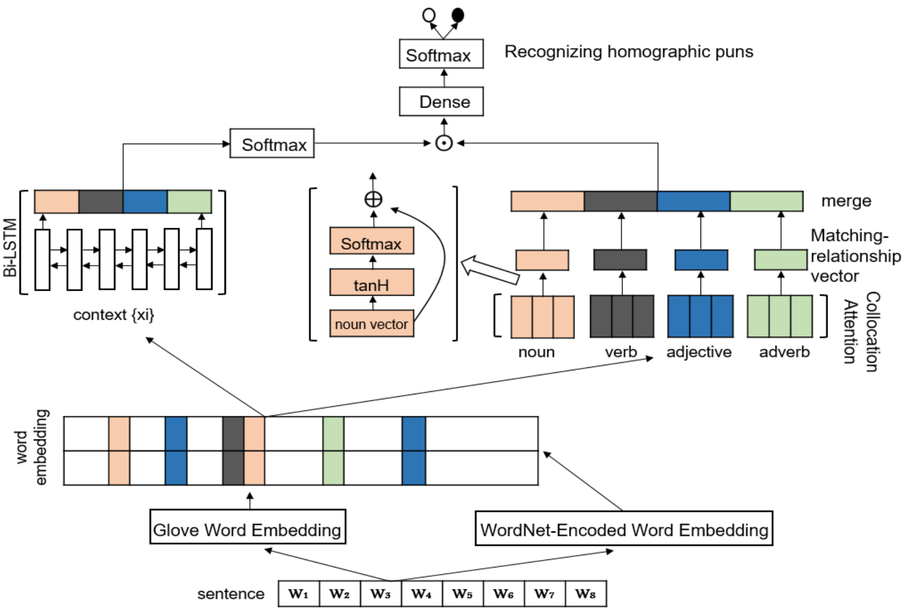

Figure 1: WordNet-Encoded Collocation-Attention network model(WECA)

vector of target word. The formula is as follows:

$$w = \frac{1}{m} \sum_{{s_i}^{(w)} \in S^{(w)}} \sum_{{l_i}^{(s_j)} \in {L_i}^{(s_j)}} w^{{l_j}^{s_j}} \qquad (1)$$

which means the new embedding vector of w is determined by the average of all its lemma embedding. Here, m represents the number of lemmas with overlapping senses with respect to the word w, s_i is the sense i, l_j is the lemma j. Finally, word embedding of w is the concatenation of the original vector and above new vector.

ALA model can apply lemmas to encoding latent semantic relationship because lemmas share the information by multiple words and senses. Therefore, words sharing the same lemmas are likely to obtain the similar representations.

Weighted Lemma Aggregation Model (WLA) The ALA Model takes the lemma embedding to encode lemma information for word representation. Although ALA model represents the average of all the lemma, which does not consider the importance of certain lemmas. Hence, we construct embedding for a target word with the help of word senses and lemmas in WordNet that we called WLA model. The formula is as follows:

$$w = \sum_{{s_i}^{(w)} \in S^{(w)}} \frac{|{L_i}^{(s_i)}|}{m} \sum_{{l_i}^{(s_j)} \in {L_i}^{(s_j)}} w^{{l_j}^{s_j}} \qquad (2)$$

where m represents for all the number of lemmas with overlapping senses with respect to the word w, s_i is the sense i, l_j is the lemma j, ${l_i}^{(s_j)}$ is the number of lemmas in each sense with target word, w is the new embedding considering the weighted lemma information. Then, the target word embedding concatenates new vector to original vector.

The weighted lemma strategy assumes one sense of word obtains more attention if this sense of word has more lemmas. We can show each word as a special distribution on the sense. From the results, WLA model is the best representation.

3.2 Bidirectional Long Short Term Memory(Bi-LSTM) for Recognizing Homographic Puns

Long Short Term Memory (LSTM) was proposed by Hochreiter and Schmiduber (1997), which has been widely adopted for text processing. There are three gates and one cell in LSTM: an input gate i_t, a forget gate f_t, an output gate o_t and a memory cell c_t. They are all vector in R^d. The equations of transition are:

$$i_t = \sigma(W_i x_t + U_i h_{t-1} + V_i c_{t-1}) \qquad (3)$$

$$f_t = \sigma(W_f x_t + U_f h_{t-1} + V_f c_{t-1}) \qquad (4)$$

$$o_t = \sigma(W_o x_t + U_o h_{t-1} + V_o c_{t-1}) \qquad (5)$$

$$\tilde{c_t} = tanh(W_c x_t + U_c h_{t-1}) \qquad (6)$$

$$c_t = f_t \odot c_{t-1} + i_t \odot \tilde{c}_t \tag{7}$$

$$h_t = o_t \odot tanh(c_t) \tag{8}$$

where x_t is an input vector at the current time step, σ is the sigmoid function and $\odot$ is the element-wise multiplication operation, $W_{\{i,f,o,c\}}$,$U_{\{i,f,o,c\}}$,$V_{\{i,f,o,c\}}$ are learned weight parameters, h_t is the hidden state vector. In LSTM, the hidden state h_t only encodes the front context in a forward direction but not consider the backward context.

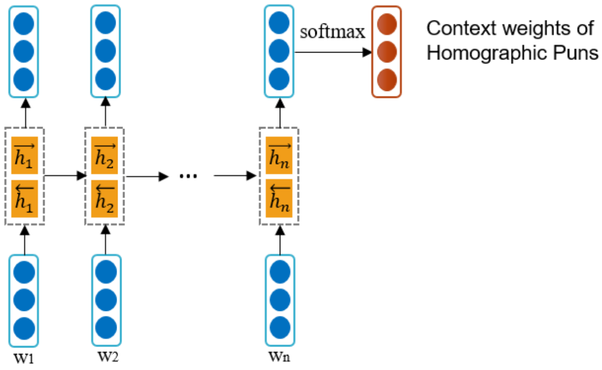

Figure 2: The Structure of Bi-LSTM

In this study, we apply Bi-LSTM model(Graves, 2012) to capture the latent semantic information of homographic puns for obtaining the context weights. For each sentence, it has a forward LSTM $\overrightarrow{h}$ and a backward LSTM $\overleftarrow{h}$ to concatenate the hidden states of two LSTMs as the representation of corresponding word. Figure 2 illustrates the architecture of Bi-LSTM model. $\{w_1, w_2, \cdots, w_n\}$ represent the word vector in a sentence whose length is N. Then, the forward and backward contexts can take into account simultaneously. The equations of transition are:

$$\overrightarrow{h}_t = H(W_{x\overrightarrow{h}} x_t + W_{\overrightarrow{h}\overrightarrow{h}} \overrightarrow{h}_{t-1} + b_{\overrightarrow{h}}) \tag{9}$$

$$\overleftarrow{h}_t = H(W_{x\overleftarrow{h}} x_t + W_{\overleftarrow{h}\overleftarrow{h}} \overleftarrow{h}_{t-1} + b_{\overleftarrow{h}}) \tag{10}$$

$$h_{out} = W_{\overrightarrow{h}y} \overrightarrow{h}_t + W_{\overleftarrow{h}y} \overleftarrow{h}_t + b_y \tag{11}$$

where $\overrightarrow{h}_t$ is a forward LSTM, $\overleftarrow{h}_t$ is a backward LSTM, h_{out} is the output of Bi-LSTM.

3.3 Collocation-Attention Mechansim

It proposes that not all the words provide the same contribution of word representation for the sentence. Especially for homographic puns recognition, the collocation between candidate pun words in a sentence offers more clues for getting the collocational word weights. Miller points out that the candidate pun words mainly consist of nouns, verbs, adjectives and adverbs in each pun. For example, “The money doesn’t grow on the tree, but it can grow on the branch.” The word “branch” is the pun word. From this example, we know that the collocation of candidate pun words {money, grow, tree, branch}, which should be more important for recognizing homographic puns.

Therefore, it is necessary to learn about the latent relationship in collocation of words. We design an attention mechanism to obtain the collocational weights by extracting such words of collocation from nouns, verbs, adjectives and adverbs, respectively. Then we concentrate on the four parts in sentences with pun to aggregate the informative words for classifying the homographic puns. This model uses an attention network taking word embedding with WordNet-Encoded as input then to extract polysemy attention signal, which made use of polysemy to understand ambiguity of homographic puns. The formula is as follows:

$$u_{ijt} = V \cdot tanh(W_u h_{ijt} + b_w) \tag{12}$$

$$\alpha_{ijt} = \frac{exp(u_{ijt})}{\sum_{t=1}^{T_x} exp(u_{ijt})} \tag{13}$$

$$c_{ij} = \sum_{t=1}^{T_x} \alpha_{ijt} h_{ijt} \tag{14}$$

where h_{ijt} is a hidden state at each time step for each part of speech, $j \in \{nouns, verbs, adjectives, adverbs\}$, u_{ijt} is a hidden representation of h_{ijt} through a one-layer MLP, α_{ijt} is a normalized importance weight through a softmax function with each part of speech, c_{ij} is a context vector as a high level representation over the words from attention-based model by the weighted mean of the hidden state sequence h_{ijt} for each part of speech.

After combining the attention networks with the context weights in a sentence, we merge all the c_{ij} vectors from collocation attention model and take the uniformed context weights in a sentence.

Then we mix the two parts results with element wise multiplication operation to recognize the homographic puns. The formula is as follows:

$$c_i = [c_{inouns}; c_{iverbs}; c_{iadjectives}; c_{iadverbs}] \quad (15)$$

$$l_{out} = Softmax(h_{out}) \quad (16)$$

$$s_i = c_i \cdot l_{out} \quad (17)$$

where c_i is merged by c_{ij}, $j \in \{nouns, verbs, adjectives, adverbs\}$, l_{out} is the softmax function of h_{out}, s_i is the result with the multiplication operation of c_i and l_{out}.

The model can be trained in an end-to-end way by backpropagation, where objective function is the cross-entropy loss. Let y be the target distribution and $\hat{y}$ be the predicted distribution. The goal of training is to minimize the cross-entropy error between y and $\hat{y}$ for all sentences.

$$loss = -\sum_i \sum_j y_i^j log\hat{y_i}^j + \lambda\|\theta\|^2 \quad (18)$$

where i is the index of sentence, j is the index of class. Our classification is two way. λ is the L2 regularization term. θ is the parameter set.

4 Experiments and Evaluation

In this section, we first evaluate the effectiveness of our WordNet-Encode model (WE) on two tasks to detect the polysemy of homographic puns. Then, we examine the performance of our WECA model compared with existing methods. Finally, we show the effectiveness of our model.

4.1 Experimental Setting

In this section, we introduce datasets, evaluation metrics, baseline methods, and present the details of the training process of our model.

Datasets To verify the effectiveness of our proposed model, we use two datasets: SemEval2017 Task7[2] and Pun of the Day[3] .

SemEval2017 Task7. This dataset is composed of homographic and heterographic puns for recognizing and interpreting puns. We focus on homographic puns detection in semantic rather than phonology. The homographic pun word will have at least two words sense in the WordNet(Miller and Gurevych, 2015). Table 1 shows a detailed statistical distribution of our datasets.

Pun of the Day. This dataset only includes pun content in the beginning. Then it collects the negative samples from Yahoo! Answer[4] , AP News[5] , Proverb, and New York Times in order to balance the distribution of positive and negative examples, which adapt to decrease the domain discrepancy. Table 2 provides a complete statistical description of our dataset.

Dataset	Positive	Negative	Average Length
Task7	1607	643	13.1
Pun of the Day	2423	2403	13.5

Table 2: Statistics of Datasets

Metrics We apply the standard measures precision, recall, accuracy and F1-score to evaluate the effectiveness for homographic puns recognition, which also adopted as metrics in SemEval 2017 Task7 evaluation.

Baselines We compare several strong baselines as follows.

LSTM: LSTM without WordNet-Encoded embedding and Collocation-Attention mechanism.

Bi-LSTM: Bi-LSTM without WordNet-Encoded embedding and Collocation-Attention.

Bi-LSTM$_E$: Bi-LSTM with WordNet-Encoded embedding used the WLA model.

Bi-LSTM-Attention: Bi-LSTM with single attention mechanism.

Fermi and N-Hance are the good performing model in the SemEval2017 task7.

Top1 Fermi: Fermi took a supervised approach for homographic puns detection. It did not construct own train data set, but rather split the shared task data set into train sets and test sets(Miller, Tristan and Hempelmann, Christian and Gurevych, Iryna, 2017). It used a Bi-RNN to learn a classification model and treat the word embedding as the input features.

Top2 N-Hance: It assumed every pun had a particularly strong association with exactly one other word in context(Miller, Tristan and Hempelmann, Christian and Gurevych, Iryna, 2017). Then it calculated PMI between words in context to detect and locate puns. If the score exceeded

[3] Pun of the Day: htto://www.punoftheday.com/

[4] htto://answers.yahoo.com/

[5] htto://hosted.ap.org/dynamic/fronts/HOME?SITE=AP

a certain threshold, the text assumed to contain a pun. Otherwise, the text assumed to have no pun.

WECA: Here, we use Bi-LSTM with WordNet-Encoded embedding with WLA model and Collocation-Attention mechanism.

Training Details In experiments, our model is tuned with 5-fold cross validation. All word vectors are initialized by GloVe. We use 50, 100, 200 and 300 dimension to verify the performance, respectively. Here, 200 dimension is the best performance. Therefore, we set the dimensions of word, synset and lemma embedding to be 200. The size of units in LSTM is 800. RMSprop is used for our optimization method. We use learning rate decay and early stop in the training process. All models are trained by mini-batch of 64 instances.

4.2 The Effectiveness of WordNet-Encoded Word Embedding

Comparing the GloVe model with our ALA model and WLA model, we evaluate the quality of our improved word representations to detect the homographic puns. In this experiment, we use the same classifier Bi-LSTM and parameters to verify the effectiveness of our word embedding.

Figure 3 and Figure 4 show the results of different word embedding for detecting homographic puns. From the results we can observe that:

(1) Our models ALA and WLA, which outperform the original vector GloVe on both two datasets. It indicates that our model can better capture the semantic relations of words by utilizing lemma annotation properly based on the WordNet.

(2) The ALA model represents each word with the average of its lemma embedding. In general, the ALA model performs better than GloVe, showed that lemma and synset of WordNet is very useful. The reason is the words sharing mutual lemma representation are helpful with each other.

(3) The WLA model mostly performs better than GloVe and ALA model. This model can obtain a weighted distribution according to the senses and lemmas. The results show that their different senses are commonly different from others, but share certain representation.

4.3 Pun Recognition with WordNet-Encoded Collocation-Attention Network (WECA)

Our model WECA, combination of WordNet-Encoded word embedding and Collocation-Attention network with context weight, which performs compared with the suggested baselines.

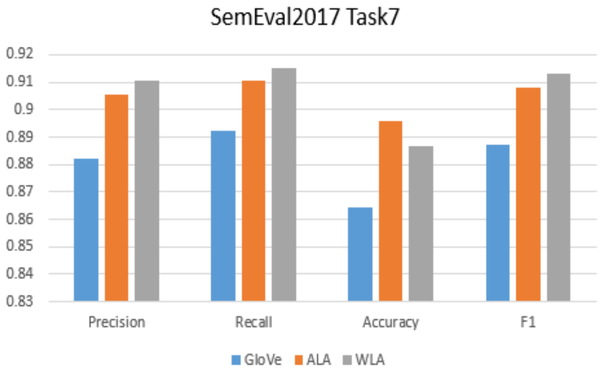

Figure 3: Comparison of Different Word Embedding on SemEval2017 Task7

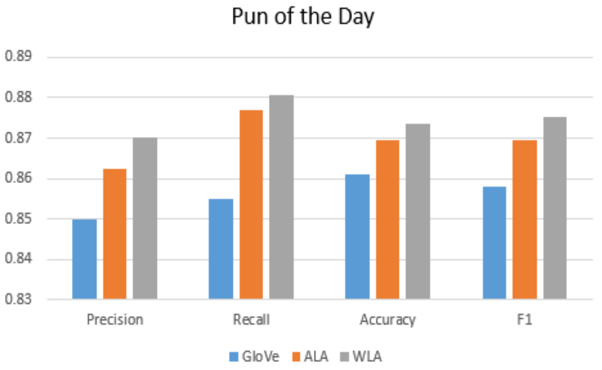

Figure 4: Comparison of Different Word Embedding on Pun of the Day

Here, we use Pun of the Day as the training set to obtain all the parameters, and test the results of homographic pun recognition in SemEval2017 task7. The results are shown in Table 3.

	Precision	Recall	F1
LSTM	81.80	83.7	82.43
Bi-LSTM	85.40	83.64	84.51
Bi-LSTM$_E$	85.87	85.07	85.46
Bi-LSTM-Attention	84.92	85.62	85.26
N-Hance	75.53	**93.34**	83.50
WECA	**89.19**	90.64	**89.21**

Table 3: Comparison of Different Models of Homographic Puns Recognition

(1) Bi-LSTM has the better performance for homographic puns detection compared with LSTM (84.51% vs.82.43%). It shows that Bi-LSTM exploits two parallels to discover more context information. At the same time, Bi-LSTM$_E$ outperforms Bi-LSTM (85.46% vs.84.51%), which demonstrating the effectiveness of the WordNet-Encoded word embedding.

(2) Bi-LSTM-Attention performs slightly better

	Precision	Recall	F1
Fermi	90.24	89.70	89.97
WECA	**91.43**	**90.53**	**90.98**

Table 4: Comparison of WECA and Fermi of Homographic Puns Recognition

than Bi-LSTM and LSTM (85.26% vs. 84.51%, 82.43%). The reason is that the attention mechanism can assign the weight to the whole words according to the context information.

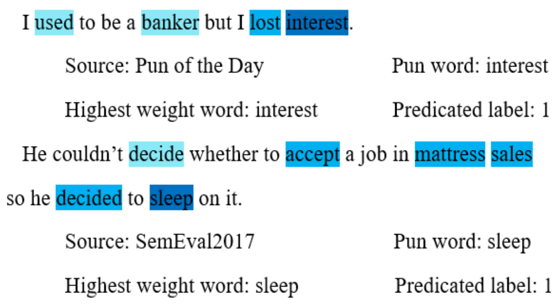
(3) Our model WECA has a better performance compared with Bi-LSTM$_E$, Bi-LSTM-Attention and N-Hance (87.45% vs. 85.46%, 85.26%, 83.50%). N-Hance is the second place in SemEval2017 task7. It shows the WordNet-Encoded word embedding can capture more semantic information between words with the help of lemma and synsets in WordNet. Meanwhile, it presents that the attention network mechanism combined with collocation of the specific part of speech of puns, which capture the characteristic information to recognize the homographic puns.

The best perform of SemEval2017 task7 is Fermi. However, Fermi only evaluates on 675 of 2250 homographic contexts(Miller, Tristan and Hempelmann, Christian and Gurevych, Iryna, 2017) in SemEval2017 task7. Thus, our model uses 675 as a test set and rest of data as a training set. The results are shown in Table 4. Experiment results present our model outperforms Fermi under the same data distribution. It shows the effectiveness of our model again.

4.4 Visualization of Model

In order to verify our model is enable to select the valuable information of words that reflected the collocation, we visualize the attention layers for several sentences in Pun of the Day and SemEval2017 Task7 data sets whose labels are correctly predicted by our model in Figure 5. We choose two examples. One presents collocation between nouns, the other presents collocation between verbs.

Each line is a sentence. Blue denotes word weight. If color of word is darker, the word is more important. Figure 5 shows our WECA model can select words carrying ambiguous meanings from the collocation of homographic puns. For example, in the first sentence, it highlights "interest", which is worthy attracting more attention because of multiple meanings for the pun word. In the second sentence, "sleep" is selected word by our attention model as related to homographic puns. Therefore, attention networks of collocation is effective for recognizing homographic puns.



I used to be a banker but I lost interest.

Source: Pun of the Day
Pun word: interest
Highest weight word: interest
Predicated label: 1

He couldn't decide whether to accept a job in mattress sales so he decided to sleep on it.

Source: SemEval2017
Pun word: sleep
Highest weight word: sleep
Predicated label: 1

Figure 5: Visualization of attention layers

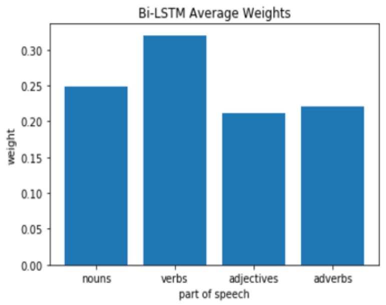


Figure 6: Average context weight of all sentences by Bi-LSTM

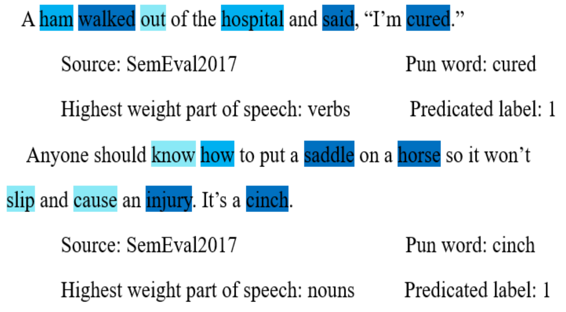
We apply the Bi-LSTM to capture latent semantic context for weighting part of speech which included nouns, verbs, adjectives and adverbs from forward and backward direction. Figure 6 shows Bi-LSTM model distributes weights to the four part of speeches. The weights of verbs occupy the first place, then second one is nouns, adjectives and adverbs are lower. Meanwhile, it demonstrates the importance of part of speech.

Thus, we choose two examples to illustrate weights with the four part of speeches according to context information by Bi-LSTM in Figure7. For the first example, the word "cured", as a verb, which is a pun word. It shows weights of verbs are highest allocation by Bi-LSTM. For the second example, the word "cinch", as a noun, which is a pun word. It illustrates that Bi-LSTM distributes the higher weights to nouns, which presents the importance of nouns from the context semantic information. Hence, context weights providing by Bi-LSTM are helpful of the collocation for recognizing the homographic puns.



A ham walked out of the hospital and said, “I’m cured.”

Source: SemEval2017 Pun word: cured

Highest weight part of speech: verbs Predicated label: 1

Anyone should know how to put a saddle on a horse so it won’t slip and cause an injury. It’s a cinch.

Source: SemEval2017 Pun word: cinch

Highest weight part of speech: nouns Predicated label: 1

Figure 7: Visualization of Bi-LSTM

5 Conclusion and Future Work

In this study, we propose a computational model WECA combined with WordNet-Encoded word embedding and Collocation-Attention network. We extend the semantic information of word embedding by lemma and synset according to WordNet. We also apply a neural attention network, combined with Bi-LSTM, which captures the collocation of homographic puns. Experimental results show our model achieves the best performance and outperforms several baselines.

In future work, we would like to find an appropriate way in incorporating the external linguistic knowledge to improve the performance of homographic puns recognition. We also focus on automatically generating homographic puns. Those are all promising jobs we can pursue in the future.

Abstract

Chinese spelling check (CSC) is a challenging yet meaningful task, which not only serves as a preprocessing in many natural language processing (NLP) applications, but also facilitates reading and understanding of running texts in peoples' daily lives. However, to utilize data-driven approaches for CSC, there is one major limitation that annotated corpora are not enough in applying algorithms and building models. In this paper, we propose a novel approach of constructing CSC corpus with automatically generated spelling errors, which are either visually or phonologically resembled characters, corresponding to the OCR- and ASR-based methods, respectively. Upon the constructed corpus, different models are trained and evaluated for CSC with respect to three standard test sets. Experimental results demonstrate the effectiveness of the corpus, therefore confirm the validity of our approach.

Sentence	Correction
我们应该认真对待这些 $\boxed{己}$ (ji2) 经发生的事	已 (yi3)
在我们班上，$\boxed{她}$ (ta1)是一个很聰明的男孩	他 (ta1)

Table 1: Two examples of Chinese sentences containing spelling errors. Spelling errors are marked in red. The first sentence contains a visually similar spelling error, i.e., 已 (yi3) is misspelled as 己 (ji2). The second sentence contains a phonologically similar spelling error, i.e., 他 (ta1) is misspelled as 她 (ta1).

1 Introduction

Spelling check is a crucial task to detect and correct human spelling errors in running texts (Yu and Li, 2014). This task is vital for NLP applications such as search engine (Martins and Silva, 2004; Gao et al., 2010) and automatic essay scoring (Burstein and Chodorow, 1999; Lonsdale and Strong-Krause, 2003), for the reason that spelling errors not only affect reading but also sometimes completely alter the meaning delivered in a text fragment. Especially, in Chinese language processing, spelling errors can be more serious since they may affect fundamental tasks such as word segmentation (Xue, 2003; Song and Xia, 2012) and part-of-speech tagging (Chang et al., 1993; Jiang et al., 2008; Sun, 2011), etc. Of all causes lead to spelling errors, a major one comes from the misuse of Chinese input methods on daily texts, e.g., emails and social media posts. Table 1 illustrates two examples of such Chinese spelling errors. The first incorrect sentence contains a misused character, 己 (ji2)[1], which has a similar shape to its corresponding correct character, i.e., 已 (yi3). In the second incorrect sentence, the boxed spelling error 她 (ta1) is phonetically identical to its corresponding correct one 他 (ta1).

Owing to the limited number of available datasets, many state-of-the-art supervised models are seldom employed in this field, which hinders the development of CSC. Currently, some mainstream approaches still focus on using unsupervised methods, i.e., language model based ones (Chen et al., 2013; Yu et al., 2014; Tseng et al., 2015; Lee et al., 2016). As a result, the development of CSC techniques are restricted and thus CSC performance is not satisfied so far (Fung et al., 2017). To enhance CSC performance, the biggest challenge is the unavailability of large scale corpora with labeled spelling errors, which is of high value for training and applying supervised models. Such issue of data absence is mainly caused by the fact that annotating spelling errors is an expensive and challenging task.

To address the data unavailability issue so that

---

Brussels, Belgium, October 31 - November 4, 2018.

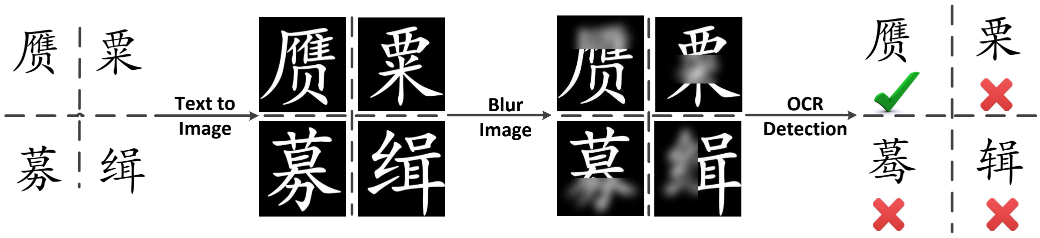

Figure 1: An example process of generating V-style errors by the OCR-based method. In the OCR detection results, except for 赝 (yan4), the other three characters, i.e., 粟 (li4), 募 (mu4), and 缉 (ji1), are incorrectly recognized as 粟 (su4), 蓦 (mo4), and 辑 (ji2), respectively. All the three incorrect characters have similar shapes with their corresponding correct references.

to facilitate CSC with data-driven approaches, in this paper, we propose a novel approach that automatically constructs Chinese corpora with labeled spelling errors. Specifically, given that Chinese spelling errors mainly result from the misuse of visually and phonologically similar characters (Chang, 1995; Liu et al., 2011; Yu and Li, 2014), we propose OCR-based and ASR-based methods to produce the aforementioned two types of misused characters. Note that, different from detecting spelling errors from incorrect sentences, our proposed approach aims at automatically generating texts with annotated spelling errors like those in Table 1. With the help of OCR- and ASR-based methods, CSC corpora are constructed with annotated visual and phonological spelling errors.

In our experiments, qualitative analysis illustrates that incorrectly recognized Chinese characters by OCR or ASR toolkits are not trivial for human to detect, while interestingly, human are likely to make such spelling errors in their daily writing. In the quantitative comparison, we cast Chinese spelling check into a sequence labeling problem and implement a supervised benchmark model, i.e., bidirectional LSTM (BiLSTM), to evaluate the performance of CSC on three standard testing datasets. Experimental results show that the BiLSTM models trained on our generated corpus yield better performance than their counterparts trained on the training dataset provided in the standard testing datasets. To further facilitating the CSC task, we construct confusion sets by collecting all incorrect variants for each character and their corresponding correct references. The effectiveness of the confusion set is confirmed in the error correction task, indicating that the constructed confusion sets are highly useful in many existing Chinese spelling check schemes (Chang, 1995; Wu et al., 2010; Dong et al., 2016).

2 Automatic Data Generation

Spelling errors in Chinese are mainly caused by the misuse of visually or phonologically similar characters (Chang, 1995; Liu et al., 2011; Yu and Li, 2014). Errors of visually similar characters (henceforth V-style errors) are due to the prominence of character pairs visually similar to each other. The reason is that, Chinese, as a hieroglyph language, consists of more than sixty thousand characters[2]. They are constructed by a limited number of radicals and components[3]. As for errors caused by the misuse of phonologically similar characters (henceforth P-style errors), we note that pronunciations of Chinese characters are usually defined by Pinyin, which consists of initials, finals, and tones[4]. According to Yang et al. (2012), there are only 398 syllables for thousands of characters in modern Chinese. As a result, there are many Chinese characters sharing similar pronunciation, which further leads to the prominence of P-style errors. In the rest of this section, we describe how we generate these two types of errors in Section 2.1 and 2.2, respectively.

2.1 OCR-based Generation

Inspired by the observation that optical character recognition (OCR) tools are likely to misidentify characters with those visually similar ones (Tong and Evans, 1996), we intentionally blur images with correct characters, and apply OCR tools on them to produce V-style spelling errors.

In detail, we use Google Tesseract (Smith, 2007) as the OCR toolkit and the generation process is illustrated in Figure 1. Given a sentence,

---

[2] `http://www.hanzizidian.com`.

[3] There are less than three hundred radicals in total. `https://en.wikipedia.org/wiki/Radical_(Chinese_characters)`

[4] `https://en.wikipedia.org/wiki/Pinyin`

as the first step, we randomly select $1 \sim 2$ character(s) from it as our target characters to be detected by Tesseract, denoted as $C_{targets}$. Specifically, except for Chinese characters, other characters like punctuations and foreign alphabets are excluded and we also filter those Chinese characters of low frequency[5] based on the statistics of the Chinese Wikipedia Corpus[6]. Second, we transfer $C_{targets}$ from text to image with 100×100 pixels, namely, each generated image has a same size. Third, we randomly blur a region[7] in the produced images using Gaussian blurring (Bradski, 2000), which aims at leading the OCR toolkit to make mistakes. Finally, we use Google Tesseract to recognize the blurred images. Once the recognized result does not match to the original one, a V-style error is generated, which is used to replace the original character in the sentence, resulting in a sentence with V-style spelling error(s). After the aforementioned steps, we obtain the spelling errors for each sentence with their correct references.

The raw texts used for OCR-based method are mainly from newspaper articles, which are crawled from People's Daily, an official newspaper website[8], of which articles are reported to undergo a strict edition process and assumed to be all correct. We divide these texts into sentences using clause-ending punctuations such as periods (。), question mark (？), and exclamation mark (！) (Chang et al., 1993). In total, we obtain $50,000$ sentences, each of which contains 8 to 85 characters, including punctuations. These sentences are then handled by the OCR-based method as we describe before, resulting in an annotated corpus containing about $40,000$ annotated sentences with $56,857$ spelling errors. Note that in our experiment, we find that the OCR toolkit can still correctly detect the characters in the produced images even we blur part of the images. This explains why the size of generated annotated sentences is smaller than that of the original sentences. We denote the dataset by D-ocr, and show its statistics in the D-ocr column in Table 3.

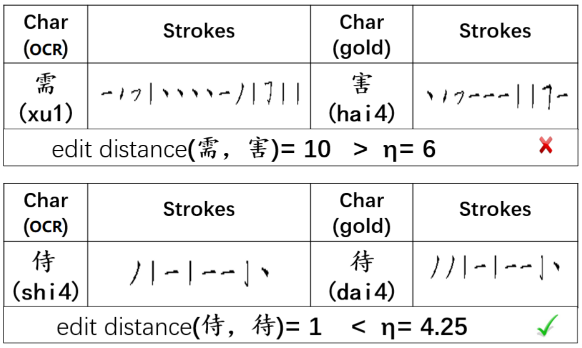

Figure 2: Two cases from the OCR-based method. Char (OCR): the character recognized by the OCR-based method; Char (gold): the corresponding correct character.

Bad Cases and the Solution Although the OCR-based method work smoothly, there are still some cases worth further investigation. By analyzing the generated spelling errors by this method, we find that in terms of shape, there exist some incorrectly recognized characters by the OCR toolkit that greatly differ from their corresponding correct characters. For example, for the blurred image containing the character 领 (ling3), the Tesseract incorrectly recognizes it as 铈 (shi4), which is totally different from 领 (ling3) in shape. Therefore, these cases should be excluded because human are less likely to make such mistakes. In solving this problem, we propose a novel approach to judge whether two characters are visually similar by calculating the edit distance based on the strokes of Chinese characters. Similar to English words consisting of alphabets, a Chinese character can be split into different strokes[9]. To this end, we obtain the strokes of Chinese character from the Online dictionary[10]. Empirically, given two Chinese characters, c_1 and c_2, we set $0.25 * (len(c_1) + len(c_2))$ as the threshold, η, where $len(c)$ denotes the number of strokes for the Chinese character c. If the edit distance of two characters is more than a threshold η, we consider them not to be similar in shape. To better clarify it, a bad case and a good case are shown in Figure 2.

---

[5] In our setting, Chinese characters occurring less than five times in the corpus are considered as low-frequency ones.

[6] https://dumps.wikimedia.org/zhwiki/

[7] A Chinese character may be misspelled to other different characters, resulting in different spelling errors. For example, the Chinese character 缉 (ji1) could be misspelled as 揖 (ji1), 辑 (ji2), or 楫 (ji1), such spelling errors could be obtained by blurring different locations of the given character, which makes it possible for the OCR toolkit to give different recognized results for a same character. According to our experiment, if we blur the entire character, we found that the incorrectly recognized results are almost the same. As a result, we could not obtain different spelling errors for a same character. Specially, the blurred location may be different, but the size of the region to be blurred is the same for all images.

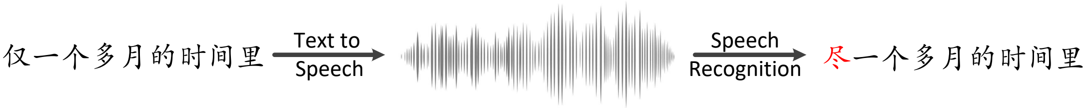

Figure 3: The full pipeline of generating P-style errors by ASR-based method. In this example, 仅 (jin3) is incorrectly recognized as 尽 (jin4) marked in red, both of which have a similar pronunciation.

Case	Gold Sentences	Incorrectly-recognized results	Type
1	而对楼市成交抑制作用最大的限购	而对面楼市成交抑制作用最大的限购	D
2	围绕亚运会进行的城市资金投入	没让亚运会进行的城市改造的资金投入	N
3	与院方协商赔偿问题	与岳风学生赔偿问题	T
4	但是不幸最终还是发生了	但是不行最终还是发生了	C

Table 2: Four incorrectly-recognized cases with different types of errors. D: Different lengths with that of the original one. N: Not a P-style error. T: Too many errors. C: Correct case to collect.

2.2 ASR-based Generation

Similar to OCR tools, automatic speech recognition (ASR) tools may also mistake characters for others with similar pronunciations (Hartley and Reich, 2005). To build an annotated corpus of P-style errors, we follow the similar inspiration with those for V-style errors and OCR tools, and adopted a pipeline as shown in Figure 3. However, given the availability of various speech recognition datasets, we employ a simpler approach. We exploit a publicly available Mandarin speech corpus, AIShell (Bu et al., 2017), which contains around 140,000 sentences with utterances[11]. We use Kaldi (Povey et al., 2011), a speech recognition toolkit, to transcribe the utterances into recognized sentences. Finally, by comparing the recognized sentences with the original ones, we can identify whether the recognition results are correct. If not, they can serve as incorrectly-recognized results and be used to build a corpus with P-style spelling errors.

Bad Cases and the Solution For generated P-style errors, we also identify some bad cases, which potentially introduce much noise. To improve the quality of the generated corpus, a solution is thus needed to remove them. Table 2 gives three types of bad cases with a good one. We describe the solution to deal with them as follows.

First, we discard all incorrectly recognized results similar to Case 1, which has different lengths comparing to the corresponding reference sentence. Second, the incorrect characters in Case 2 have totally different pronunciations with their corresponding characters in the gold sentence. Such cases do not satisfy our requirement in generating P-style errors. To this end, we obtain the pronunciation by pinyin[12] of Chinese characters from an online Chinese lexicon[13]. Then it is easy to identify whether the incorrectly-recognized characters have similar or same pronunciation with their corresponding characters in the gold sentence. Specifically, in terms of Pinyin, two characters have similar pronunciation when they have the same initials and finals but different tones, i.e., *da2* and *da1*. Third, according to Chen et al. (2011), there may have two errors per student essay on average, which reflects the fact that that each sentence will not contain more than two spelling errors on average. Therefore, we remove those incorrectly-recognized results that contains more than two incorrect characters as shown in Case 3. After the aforementioned steps, we generate a corpus with more than 7K P-style spelling errors in total. We denote it D-asr and show its statistics in the D-asr column in Table 3.

3 Evaluation

3.1 Benchmark Data

To evaluate the quality of the generated corpora, we adopt three benchmark datasets from 2013–2015 shared tasks (Wu et al., 2013; Yu et al., 2014; Tseng et al., 2015)[14] on CSC. Table 4 reports the

[13] `http://www.zdic.net`

[14] These datasets are written in traditional Chinese, so to keep the consistency with our generated corpus of simplified

	D-ocr	D-asr	D
Sentences #	40,000	40,000	80,000
Characters #	915,949	716,509	1,632,458
Errors #	56,857	75,667	132,524

Table 3: Statistics of our generated corpus. D-ocr denotes the corpus generated by OCR-based method, D-asr denotes the corpus generated by ASR-based method and D is the combination of D-ocr and D-asr.

statistics of the three standard datasets, including training and test parts. Consider that the quality of the training dataset has a significant impact on models' performance on the test datasets. Thus in this paper, we propose a metric, $\mathrm{C}_{\mathrm{train:test}}$, to measure the correlation degree between the training and test dataset by calculating the number of spelling errors that occur in them:

$$C_{train:test} = \frac{\left|E_{train} \cap E_{test}\right|}{\left|E_{test}\right|} \tag{1}$$

where $\mathrm{E}_{\mathrm{train}}$ and $\mathrm{E}_{\mathrm{test}}$ refer to the set of spelling errors in the training dataset and the test dataset, respectively. Each element in the set is a pair containing a correct character and a misspelled character, e.g., (撼 (han4), 憾 (han4)). Table 5 illustrates that, for three different testing datasets, the entire generated corpus D achieves 74.1%, 80.6% and 84.2% on $\mathrm{C}_{\mathrm{train:test}}$, respectively, which are much higher than that of Trn_{13}, Trn_{14} and Trn_{15}. This difference may denote the validity of the generated corpus, with adequate spelling errors.

3.2 Qualitative Analysis

Setup To evaluate whether the generated corpus contains errors that are easily made by human, we randomly select 300 sentences from it for manual evaluation, with 150 from D-ocr and 150 from D-asr. Three native Chinese speakers, who are college students, are invited to read and annotate errors in these sentences. Then, we analyze the annotated results by three college students from two levels: sentence-level and error-level. On the sentence-level, we consider a sentence to be correctly annotated only if all errors in the sentence are recognized. On the error-level, we calculate the percentage of the number of correctly annotated errors out of the total number of errors.

		Error #	Char #	Sent #
2013[15]	Trn_{13}	324	17,611	350
	Tst_{13}	966	75,328	1,000
2014[16]	Trn_{14}	5,224	330,656	6,527
	Tst_{14}	510	54,176	1,063
2015[17]	Trn_{15}	3,101	95,114	3,174
	Tst_{15}	531	34811	1,100

Table 4: Statistics of three standard datasets. Error # denotes the number of spelling errors, Char # represents the number of Chinese character and Sent # refers to the number of sentences.

Train:Test	C (%)	Train:Test	C (%)
Trn_{13} : Tst_{13}	16.2	D : Tst_{13}	74.1
Trn_{14} : Tst_{14}	53.9	D : Tst_{14}	80.6
Trn_{15} : Tst_{15}	46.7	D : Tst_{15}	84.2

Table 5: Correlation results of Trn_{13}, Trn_{14}, Trn_{15} and D with Tst_{13}, Tst_{14}, Tst_{15}.

Results Table 6 shows the information of 300 sentences and the annotation results on them. The average recall in the table illustrates that three students have a higher recognition rate for errors from D-asr than that from D-ocr, which, to some extent, indicates that P-style errors are easier to be detected than V-style ones. Besides, we observe that three volunteers fail to identify around 36.9% errors on average, which may indicate that our generated sentences include some challenging errors which are likely to be made by human. Such errors are valuable for CSC since they are potential real cases in people's writing or typing.

Case Study To qualitatively analyze why some spelling errors are not detected by human, we conduct a case study on an example sentence containing some spelling errors that are not found by the three students. The sentence is 政企部分是一种痼疾 (translation: politics and industry parts are a kind of a chronic disease), in which the third character 部 (bu4) is a spelling error and should be corrected as 不 (bu4). In this example, 部分 (translation: a part of) and 不分 (translation: equally treat) are two highly common Chinese words and

easy to be considered as correct. However, considering the preceding word 政企 (translation: politics and industry) and the subsequent words 是一种痼疾 (translation: a kind of chronic disease), we can see that 部分 does not fit the current context and should be corrected as 不分. This case study confirms that our generated corpus contains some spelling errors like human made ones in their writing or typing, which further demonstrates its quality and the effectiveness of our approach.

3.3 Quantitative Comparison

3.3.1 Chinese Spelling Error Detection

In this section, we evaluate the quality of our generated corpus through Chinese spelling detection. We firstly explore how different proportions of P-style and V-style errors affect the quality of the corpus. Then we compare the detection performance of the generated corpus with that of training datasets provided in the three shared tasks.

Setup We cast Chinese spelling error detection into a sequence tagging problem on characters, in which the correct and incorrect characters are tagged as 1 and 0, respectively[18]. We then implement a supervised sequence tagging model, i.e., bidirectional LSTM (BiLSTM) (Graves and Schmidhuber, 2005), as our baseline to evaluate the quality of different corpus. The hidden size of the BiLSTM is set to 150 and the other hyper-parameters are tuned on a development set consisting of 10% randomly selected sentences from the training data. We minimize categorical cross-entropy loss for the model, with RMSprop (Graves, 2013) as the optimizer.

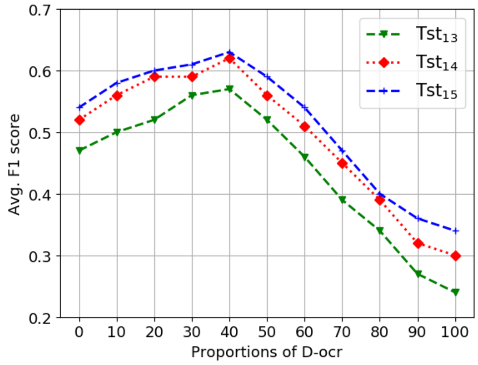

Figure 4: F1 scores achieved by different proportions of D-ocr and D-asr on three testing dataset (Tst_{13},Tst_{14} and Tst_{15}). The total size of the corpus is 40k, the percentage of which the x-axis represents from D-ocr.

Results The performance of BiLSTM trained on different proportions of D-ocr and D-asr aims at exploring the quality of the generated corpus influenced by the distribution of P-style and V-style spelling errors. Figure 4 shows that when the size of training dataset is fixed (=40k), different proportions of P-style and V-style errors achieve different F1 scores, denoting that the proportion of P-style and V-style spelling errors affects the quality of the generated corpus. Specifically, it is observed that a 4:6 proportion of D-ocr and D-asr achieves the best performance on three testing datasets when compared with other proportion ratios. In addition, for the two special proportions (0% and 100%), it is seen that with the same size of corpus, the BiLSTM model trained on D-asr achieves better performance than that on D-ocr, which indicates that P-style spelling error contributes more to the quality of the corpus. This experimental result complies with the previous conclusion (Liu et al., 2009, 2011) that most of spelling errors are related to the pronunciations.

Furthermore, to better illustrate the quality of the generated corpus, we compare it with some training datasets, which are manually annotated (Wu et al., 2013; Yu et al., 2014; Tseng et al., 2015). According to previous analyses on the experimental results shown in Figure 4, we choose the 4:6 proportion of P-style and V-style spelling errors to construct the training data in the following experiments. Specifically, we build five different sizes of datasets: D-10k[19], D-20k, D-30k, D-40k and D-50k, which are extracted from

---

[18] The detection process can be considered as a problem of binary classification.

[19] D-10k denotes the corpus contains 10k sentences, similar for D-20k, D-30k, D-40k and D-50k.

	Tst_{13}			Tst_{14}			Tst_{15}		
	P	R	F1	P	R	F1	P	R	F1
Trn	24.4	27.3	25.8	49.8	51.5	50.6	40.1	43.2	41.6
D-10k	33.3	39.6	36.1	31.1	35.1	32.9	31.0	37.0	33.7
D-20k	41.1	50.2	45.2	41.1	50.2	45.2	43.0	54.9	48.2
D-30k	47.2	59.1	52.5	40.9	48.0	44.2	50.3	62.3	55.7
D-40k	53.4	65.0	58.6	**52.3**	64.3	57.7	**56.6**	66.5	61.2
D-50k	**54.0**	**69.3**	**60.7**	51.9	**66.2**	**58.2**	**56.6**	**69.4**	**62.3**

Table 7: The performance of Chinese spelling error detection with BiLSTM on Tst_{13},Tst_{14},Tst_{15} (%). Best results are in **bold**. Trn represents the training dataset provided in the corresponding shared task, e.g., Trn denotes Trn_{13} in Tst_{13}.

D-ocr and D-asr following the proportion of 4:6. Then, we train the BiLSTM model on these training datasets and evaluate error detection performance on Tst_{13}, Tst_{14} and Tst_{15}. Table 7 shows the detection performance on three different testing datasets. We have the following observations.

The size of training dataset is important for the model training. For Tst_{13}, D-10k achieves a better F1 score than Trn_{13}. A major reason may be the size of Trn_{13} (=350, see in Table 3), which is much smaller than the testing dataset. In this situation, the model can not learn enough information, resulting in being unable to detect unseen spelling errors. Besides, we can see that the detection performance shows a stable improvement as the size of our generated corpus is continuously enlarged. Therefore, for data-driven approaches, it is of great importance to train our model with enough instances having different spelling errors.

The precision may be compromised if the training dataset contains too many "noisy" spelling errors From Table 7, although the overall performance (F1 score) keeps improving as the size of our generated corpus increases, the precision and the recall demonstrate different changing trends. It is observed that as the size of training dataset increases, the model achieves a better performance in terms of the recall. An possible reason is that with more instances containing different spelling error including in the training dataset, the number of unseen spelling error in the testing dataset is reduced, thus facilitating the model to detect more spelling errors. However, the improvement of the precision is not so obvious as that of the recall. Specifically, in Tst_{14} and Tst_{15}, D-50k does not achieve a higher precision than D-40k. A possible explanation is that with a larger training dataset containing more spelling error instances, it may lead the model to misidentify some more correct characters, resulting in a lower precision.

Compared with the limited training dataset manually annotated by human, our generated large-scale corpus can achieves a better performance From Table 7, we can see that with a certain size of our generated corpus, it can train a model that achieve better detection performance than with the manually annotated datasets provided in the corresponding shared tasks. To some extent, this demonstrates the effectiveness of our generated corpus, thus confirms the validity of our approach.

3.3.2 Chinese Spelling Error Correction

Once the Chinese spelling errors are detected, we test on correcting them.[20] from Section 3.3.1.

Following previous studies (Chang, 1995; Huang et al., 2007; Wu et al., 2010; Chen et al., 2013; Dong et al., 2016), we adopt confusion sets[21] and a language model to handle the taks for Chinese spelling error correction. In particular, by collecting all incorrect variants for each correct character, we construct a confusion set for all involved correct characters, denoted as Ours. In addition, to illustrate its effectiveness, we compare it with two publicly available confusion sets (Liu et al., 2009), Con1 and Con2. Specifically, Con1 consists of SC (similar Cangjie), SSST (same-sound-same-tone) and SSDT (same-sound-different-tone), while Con2 consists of all sets, SC, SSST, SSDT, MSST (similar-sound-

---

[20] In particular, we choose the best detected results achieved by D-50k as shown in Table 7.

[21] A confusion set refers to a set that contains confusion characters for a given character. For example, a Chinese character 快 (kuai4) may have a confusion set, {筷 (kuai4),块 (kuai4),怏 (yang1),$\cdots$ }, each of which has a similar pronunciation or a similar shape with 快 (kuai4).

Metrics	Tst_{13}			Tst_{14}			Tst_{15}		
	Con1	Con2	Ours	Con1	Con2	Ours	Con1	Con2	Ours
F1 (%)	47.6	**52.1**	50.3	52.6	**56.1**	53.0	55.6	**57.1**	56.3
Time(s)	290.3	679.9	**101.2**	310.2	792.1	**132.4**	267.6	622.5	**119.2**

Table 8: Error correction results on Tst_{13}, Tst_{14}, Tst_{15}, using Con1, Con2 and Ours, respectively.

Name	# of Char	Min.	Max.	Avg.
Ours	4,676	1	53	5.6
Con1	5,207	8	196	50.6
Con2	5,207	21	323	86.0

Table 9: Statistics of different confusions sets.

same-tone) and MSDT (similar-sound-different-tone). Table 9 shows the statistics information of the three confusion sets.

Setup Similar to Dong et al. (2016), we adopt a tri-gram language model to calculate the probability of a given sentence. Based on the detected results by the sequence labeling models, we choose as the error correction the character from the corresponding confusion set that has the highest probability. For a given sentence containing n words, $W = w_1, w_2, \cdots, w_n$, where w_i represents the i^{th} character in the sentence, E is a set containing the indexes of detected incorrect characters, $W(w_i, c)$ denotes the new generated sentence after the i^{th} character is replaced with c. The process of error correction can be formulated as follows:

$$\forall i \in E: \quad \underset{c \in C(w_i)}{\arg\max} \quad P(W(w_i, c)) \tag{2}$$

where $P(W)$ is the probability of a sentence W approximated by the product of a series of conditional probabilities as described in (Jelinek, 1997) and $C(w_i)$ refers to the confusion set of w_i, one of which with the maximum conditional probability is selected as the correction character.[22]

Results Table 9 shows the running time[23] and the F1 scores achieved by different confusion sets based on a tri-gram language model. We can observe that our constructed confusion sets achieve a better correction performance than that of Con1 while a little lower than Con2. However, from Table 9, we can see that Con2 has a much larger size of confusion characters than Ours; and for the same testing, Con2 needs much more time to finish the task while Ours always uses the least time. These observations indicate that our constructed confusions sets are more efficient in containing fewer redundant confusion characters that seldom serve as correction characters.

Error Analysis We conduct an error analysis on two types of incorrect cases, namely, the false positive and the false negative case, which affect the precision and recall in CSC, respectively.

For the false positive case, we find that one common issue is that for some fixed usages, such as idioms, phrases, and poems, our model often gives incorrect results. For example, in 风雨送春归 (translation: wind and rain escort Spring's departure), a line of a Chinese poem, 送 is incorrectly recognized as an irrelevant character. By checking the annotated corpus generated by the proposed methods, we observe that in most cases, 迎春 is a more common match, and 送 is annotated as an spelling error when it co-occurs with 春 in the generated corpus. To improve the precision, a possible approach to handle such cases is utilizing some external knowledge, such as building a collection of special Chinese usages.

For the false negative case, taking 想想健康，你就会知道应该要禁烟了 (translation: you will realize that you should give up smoking when your consider of your health) as an example, in which 禁 should be corrected as 戒. However, since 戒 and 禁 are neither visually nor phonologically similar, the proposed corpus generation approach is unable to construct such spelling errors, so it is understandable that the trained model can not detect such spelling errors. In addition, on the word-level, 禁烟 (translation: forbid smoking) and 戒烟 (translation: give up smoking) are two related common Chinese words; it needs to incorporate more context in order to improve the recall performance. Similar to our study on character-based corpus generation, one potential solution is to construct a word-level annotated corpus in order to better detect such spelling errors.

---

[22] If more than one character from the confusion set have the same maximum probability, we randomly select one of them as the correction character.

[23] We run the experiments on a computer with Intel Core i5-7500 CPU.

4 Related Work

In the line of research on spelling error detection and correction, most previous efforts focus on designing different models to improve the performance of CSC (Chang, 1995; Huang et al., 2007, 2008; Chang et al., 2013). Different from them, this work contributes to the generation of training datasets, which are important resources and can be used for improving many existing CSC models. Currently, the limited training datasets have set a high barrier for many data-driven approaches (Wang et al., 2013; Wang and Liao, 2015; Zheng et al., 2016). To the best of our knowledge, up to date, there is no large quantities of annotated data sets commonly available for CSC.

Some previous work (Liu et al., 2009; Chang et al., 2013) pointed out that visually and phonologically similar characters are major contributing factors for errors in Chinese texts, where the number of phonologically similar spelling errors is about two times than that of visually similar spelling errors. Vision- and speech-related technologies are then adopted in our approach. As a technology to extract text information from images, optical character recognition recognizes the shapes and assigns characters. According to Nagy (1988); McBride-Chang et al. (2003), incorrectly recognized results are mainly due to the visual similarities among some different Chinese characters. On the other side, automatic speech recognition is an acoustics-based recognition process for handling audio stream, where phonologically similar characters are usually confused (Kaki et al., 1998; Voll et al., 2008; Braho et al., 2014).

5 Conclusion and Future Work

In this paper, we proposed a hybrid approach to automatic generating Chinese corpus for spelling check with labeled spelling errors. Specifically, OCR- and ASR-based methods were used to generate labeled spelling errors by replacing visually and phonologically resembled characters. Human evaluation confirmed that our proposed method can produce common errors that are likely to be made by human and such errors can serve as effective annotated spelling errors for CSC. In our experiment, a neural tagging model was trained on the generated corpus and the results tested on benchmark datasets confirmed the quality of the corpus, which further demonstrated the effectiveness of our corpus generation approach for CSC.

The large scale annotated dataset generated by the proposed approach can potentially serve as useful resources in helping improving the performance of data-driven models for CSC, because the availability of large scale annotated data is the first vital step before applying any algorithms or models. In this paper, we do not put too many efforts into model design for CSC, which we leave as potential future work. To facilitate related research in the community and benefit other researchers, we make our code and data in this work publicly available on: `https://github.com/wdimmy/Automatic-Corpus-Generation`.

Abstract

Grammatical error correction (GEC) systems deployed in language learning environments are expected to accurately correct errors in learners' writing. However, in practice, they often produce spurious corrections and fail to correct many errors, thereby misleading learners. This necessitates the estimation of the quality of output sentences produced by GEC systems so that instructors can selectively intervene and re-correct the sentences which are poorly corrected by the system and ensure that learners get accurate feedback. We propose the first neural approach to automatic quality estimation of GEC output sentences that does not employ any hand-crafted features. Our system is trained in a supervised manner on learner sentences and corresponding GEC system outputs with quality score labels computed using human-annotated references. Our neural quality estimation models for GEC show significant improvements over a strong feature-based baseline. We also show that a state-of-the-art GEC system can be improved when quality scores are used as features for re-ranking the N-best candidates.

1 Introduction

The task of automatically correcting various kinds of errors in written text, termed as grammatical error correction (GEC), is primarily aimed at assisting language learning and providing corrective feedback to second-language learners. GEC systems are expected to give precise corrections and have the ability to correct most learner mistakes. In reality, however, this is not the case. State-of-the-art GEC systems (Junczys-Dowmunt et al., 2018; Grundkiewicz and Junczys-Dowmunt, 2018; Chollampatt and Ng, 2018) have a precision below 70% and a recall around 40% when evaluated on benchmark datasets. This level of performance is impressive since GEC is a difficult task given the diversity and complexity of language errors. However, in real-world use cases such as language learning, erroneous feedback from automatic GEC systems can potentially mislead language learners. To prevent this, the instructor can intervene and re-correct the system's corrections when necessary, before they are provided as feedback to learners. Having quality estimates for the system's output sentences can help instructors to decide whether to check and fix the system's corrections (for higher quality corrections) or to ignore the system's corrections altogether and re-correct the original learner-written sentences (for lower quality ones) instead. This can significantly make the process of post-editing easier and faster. Such quality estimates can also directly help end users — the language learners — to decide on the extent to which the system's corrections can be trusted and seek assistance from instructors and other sources to get better corrective feedback if needed. In this paper, we propose a neural approach to automatic quality estimation of GEC output.

Quality of language output applications can refer to several aspects such as fluency, grammaticality, adequacy, and post-editing effort. While reference-based metrics such as MaxMatch or M^2 (Dahlmeier and Ng, 2012) and GLEU (Napoles et al., 2016a, 2015) are used to evaluate GEC systems with human-annotated references, a few reference-less GEC metrics have been proposed to evaluate fluency, grammaticality, and adequacy (Napoles et al., 2016b; Asano et al., 2017; Choshen and Abend, 2018b). However, there has been no work in GEC addressing the estimation of post-editing effort. Also, to our knowledge, this is the first supervised approach to quality estimation (QE) for GEC system outputs, similar to the supervised QE task in machine translation (MT) (Specia et al., 2009). Our neural models for GEC QE are

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2528–2539
Brussels, Belgium, October 31 - November 4, 2018.

based on variants of the predictor-estimator architecture (Kim et al., 2017a), where knowledge from a pre-trained network for a word-prediction task is transferred to another network that estimates the quality score. Apart from re-implementing the recurrent predictor-estimator models, we propose convolutional variants that are faster to train and run. We release our source code[1] publicly.

In summary, the contributions of this paper are: (1) we propose the first supervised approach to QE of GEC system outputs, (2) we present neural QE models that outperform a strong feature-based baseline for estimating post-editing effort and an automatic GEC evaluation metric, (3) we propose new convolutional neural architectures for QE that can be potentially utilized for QE tasks in other language applications, and (4) we show that the performance of a state-of-the-art GEC system can be improved by adding QE scores as features in re-ranking the N-best candidates.

2 Related Work

The task of quality estimation became popular in machine translation (MT) through the studies by Blatz et al. (2004) and Specia et al. (2009). Much of the later work in QE of MT was through the shared tasks in Workshop on Machine Translation (WMT) campaigns (Bojar et al., 2016b) from 2012 onwards (Callison-Burch et al., 2012). Supervised methods of quality assessment have been applied to other natural language processing tasks such as text simplification (Štajner et al., 2016), language generation (Dušek et al., 2017), and in assisting interpreters (Stewart et al., 2018).

In the context of GEC, Heilman et al. (2014) attempted to predict grammaticality of learner sentences using regression with a variety of linguistic features such as the number of misspellings, language model scores, etc. They use a dataset of learner sentences manually annotated with subjective scores of grammaticality. However, their method was to assess learner writing and not for system evaluation. To evaluate GEC systems, Napoles et al. (2015) developed reference-less metrics known as *grammaticality-based metrics* or GBMs. GBM scores are based on the number of errors detected using third-party tools or determined by a grammaticality prediction model (Heilman et al., 2014). Their method ignores the source sentence completely and judges the system outputs independently for grammaticality. Asano et al. (2017) improved their method to account for fluency as well as faithfulness to the source sentence. Choshen and Abend (2018b) provide another measurement for meaning preservation using a semantic annotation scheme. Contrary to prior work in GEC reference-less evaluation, our work is aimed at estimating post-editing effort in terms of translation error rate (Snover et al., 2006) and an automatic evaluation metric, Max-Match (Dahlmeier and Ng, 2012), in a supervised approach. We propose variants of the predictor-estimator architecture (Kim and Lee, 2016b; Kim et al., 2017a) and compare them to a competitive feature-based baseline, QuEst (Specia et al., 2013, 2015) that has been successfully used for a number of language pairs in MT QE and for other applications (Stewart et al., 2018). It has also been the baseline for WMT QE tasks.

3 Quality Estimation of GEC

Quality estimation (QE) of GEC can be defined as the task of estimating a quality score $\hat{q}$ given a source sentence S and its corresponding GEC system-corrected hypothesis, H. We formulate the GEC QE task as a supervised regression task to predict the quality scores, following the MT QE approach (Specia et al., 2009). The score is estimated using a trained regression model f with parameters θ, such that $\hat{q} = f(S, H, \theta)$. The model f is trained and evaluated by utilizing a set of learner-written sentences and their corresponding corrected hypotheses produced by a "black-box" GEC system, i.e., neither the GEC system's model scores nor internal states will be known to the QE system. The gold-standard quality scores are obtained by comparing the system-corrected sentences and human-corrected references. We are primarily interested in estimating the post-editing effort for correcting the output sentences. Similar to MT QE, we assess GEC post-editing effort scores using human-targeted translation error rate or HTER (Snover et al., 2006). HTER is the minimum number of edit operations (insertions, deletions, substitutions, or shifts of word sequences) needed to transform the hypothesis sentence to the reference sentence, normalized by the length of the reference. A low HTER score indicates less post-editing effort.

$$\text{HTER} = \frac{\text{number of edits}}{\text{number of reference tokens}}$$

---

[1] `https://github.com/nusnlp/neuqe`

In MT, the reference translations for HTER are *targeted*, i.e., they are created by post-editing system translated sentences. However, in GEC, high-quality datasets annotated by experts with minimal edits are available (Dahlmeier et al., 2013; Yannakoudakis et al., 2011) and GEC systems are typically trained to make minimal changes to input sentences. Hence, the actual human annotated references can be substituted for post-edited references of output sentences[2]. We also experiment with estimating an automatic GEC evaluation metric, MaxMatch or M^2 (Dahlmeier and Ng, 2012) as the quality score. M^2 is the most widely used GEC evaluation metric that computes the F$_{0.5}$-score of phrase-level edits made by a system.

4 Neural Quality Estimation Model

Our neural quality estimation (NQE) model uses the predictor-estimator architecture (Kim et al., 2017a) to model the regression function f. Recurrent variants of the model have achieved the first and second places for WMT 2017 and 2016 sentence-level QE tasks, respectively (Kim and Lee, 2016a; Kim et al., 2017b). The key idea behind the model is to employ a preliminary *predictor* neural network that is trained for the "word prediction" task, i.e., to predict the probabilities of the words in the target sentence given the source sentence and the remaining target context (the words in the target sentence other than the predicted word). The predictor networks are trained using large parallel texts (potentially erroneous learner sentences and their corresponding human-corrected sentences). The knowledge from the predictor network is transferred to the *estimator* network that is trained to estimate the quality score $\hat{q}$ given the source sentence S and its corresponding system hypothesis H. Specifically, a pre-trained predictor network takes as input S and H (in place of the target sentence) and predicts probability scores for words in H. The intuition is that hypothesis words that are likely to match the reference sentence will be assigned higher probabilities. The hidden representations from the predictor network, called *quality vectors*, having information about the quality of the hypothesis words, become the input to the estimator network that estimates the quality score. The estimator networks are trained using learner sentences and their corresponding GEC system-corrected hypotheses. The gold quality score is obtained by comparing a hypothesis and the corresponding human-corrected reference. We use high-quality datasets annotated minimally to train the estimator networks. Apart from re-implementing the recurrent neural network (RNN)-based predictor-estimator model, we build fully convolutional neural network (CNN)-based variants for both the predictor and the estimator.

4.1 Predictor Network

The inputs to the predictor network are the source sentence S with source tokens $s_1, ..., s_m$ and its corresponding target sentence T with target tokens $t_1, ..., t_n$. The predictor networks are trained to predict each target token t_j given the source sentence S and the remaining target tokens excluding the predicted target token, denoted by T_{-j}. The output of the predictor network is a softmax probability score normalized across the target vocabulary, V_t:

$$p(t|S, T_{-j}) = \frac{\exp(o_{j,t})}{\sum_{t' \in V_t} \exp(o_{j,t'})}$$

where $o_{j,t}$ is the node corresponding to the word t in the predictor's output vectors $\mathbf{o}_j \in \mathbb{R}^{|V_t|}$, when t_j is predicted (see Figure 1). Predictor networks estimate the output probability by an architecture that extends the encoder-decoder neural network for sequence-to-sequence translation (Bahdanau et al., 2015). Traditional encoder-decoder models use a bidirectional RNN on the source sentence and a forward RNN on the target side to capture the target context preceding the predicted target word. The predictor network additionally employs another backward RNN in the decoder to capture the target context following the predicted word (Kim and Lee, 2016b). In the case of QE, the entire target sentence is available as input, unlike the case of sequence-to-sequence translation. Predictor networks are originally based on RNNs with gated recurrent units or GRUs (Cho et al., 2014) and a soft-attention mechanism similar to that in (Bahdanau et al., 2015). We use separate attention mechanisms for the forward and backward RNNs of the decoder in our implementation of the predictor network.

Due to the recent success of multilayer convolutional encoder-decoder neural networks for MT

---

[2] Since we use the original annotations instead of human post-edits as reference corrections, our HTER scores are the same as TER scores. Nevertheless, we use the term HTER for consistency with the QE task in MT.

(Gehring et al., 2017) and subsequently for GEC (Chollampatt and Ng, 2018) that enables better capturing of the local context, we create a multilayer convolutional variant of the predictor network. Using CNNs also helps in efficient parallelization and improves training and inference speed as shown in (Gehring et al., 2017). We use a similar architecture, which is explained in detail in (Chollampatt and Ng, 2018). In addition, analogous to the backward RNN in the decoder, we use a secondary CNN mechanism in each decoder layer for the convolutional predictor to capture the target words following the predicted target word. The first CNN uses $k-1$ pre-paddings (paddings at the beginning), where k is the convolutional kernel width. This ensures that the decoder state corresponding to the previous target word does not include the target word to be predicted in its computation. For the same reason, the secondary CNN uses $k-1$ post-paddings (paddings at the end). The convolutional predictor uses separate multi-step attention mechanisms (Gehring et al., 2017) for both the CNNs in each decoder layer. Additionally, for the prediction of the target word t_j, the nearby target embeddings $\mathbf{t}_{j-1}$ and $\mathbf{t}_{j+1}$ are also used with a maxout non-linearity (Bahdanau et al., 2015) as done in the RNN-based predictor. The predictor network is trained to minimize the negative log-likelihood loss of the target words, similar to the neural language modeling objective (Bengio et al., 2003). The overall architecture of a predictor model is shown in Figure 1.

Quality Vectors: While training and testing the estimator, the internal hidden representations from the predictor for every hypothesis word, termed as *quality vectors*, are used as inputs to the estimator network. Specifically, we use the "pre-prediction" quality vectors in (Kim et al., 2017a), which performed the best for our GEC QE task. The quality vector $\mathbf{q}_j \in \mathbb{R}^h$ corresponding to the hypothesis word t_j is given by $\mathbf{q}_j = \mathbf{h}_j \circ \mathbf{w}_{t_j}^\top$ where $\mathbf{h}_j \in \mathbb{R}^h$ is the final hidden vector after the maxout layer (Figure 1), $\mathbf{w}_{t_j}$ is the column vector corresponding to the target word t_j in the final linear transformation matrix $\mathbf{W} \in \mathbb{R}^{h\times|V_t|}$ (Figure 1) that projects $\mathbf{h}_j$ to the size of the target vocabulary V_t, and $\circ$ represents element-wise multiplication.

4.2 Estimator Network

The estimator network takes the quality vectors (§4.1) as input and quality scores as labels during training. Our re-implementation of the estimator network in Kim et al. (2017b) uses a bidirectional recurrent network with GRU cells to aggregate the quality vectors. The concatenated final states of the forward and the backward RNNs (with GRU cells) are used as the aggregated summary vector, which is projected to a scalar value using an affine transformation and clipped to the range between 0 and 1 using a sigmoid function.

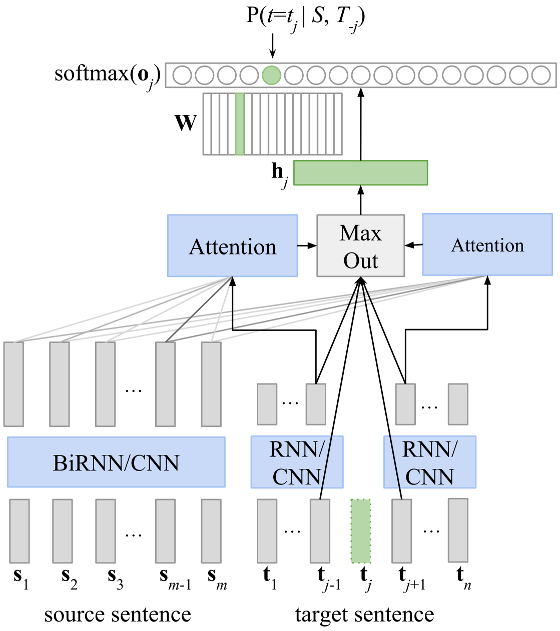

Figure 1: Architecture of a predictor model. For our proposed CNN-based variant multiple layers of CNNs are stacked (only one is shown in the figure).

We also propose a variant of the estimator networks using CNNs that achieves faster training and inference, and performs competitively. CNNs help to aggregate local quality statistics around quality vectors, thereby identifying sequences of words that have a higher or lower quality. In our proposed convolutional estimator model (Figure 2), the quality vectors $\mathbf{q}_1, ..., \mathbf{q}_n$ are transformed to $\mathbf{q}'_1, ..., \mathbf{q}'_n$ where $\mathbf{q}'_j \in \mathbb{R}^{h'}$ and h' is the size of the hidden layer of the estimator. The transformed quality vectors are fed to a convolutional neural network with kernel width k_q and h' filters, followed by the rectified linear units or ReLU (Nair and Hinton, 2010) operation. Sufficient paddings are added on the left and right to retrieve back the same number of output vectors as the input vectors. The input vectors are added to the output vectors as residual connections. The resulting vector

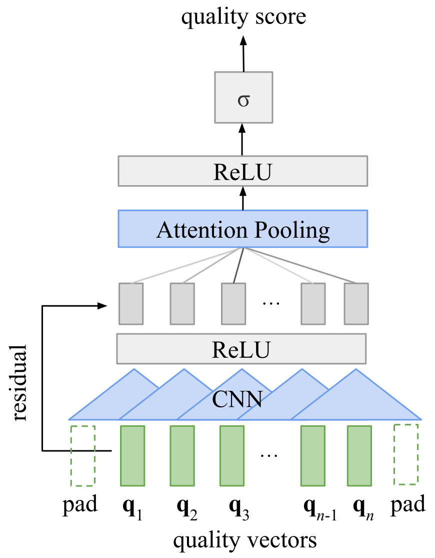

Figure 2: The proposed convolutional estimator neural network with attention-based pooling and residual connections.

after these operations over a single convolutional window around $\mathbf{q}'_j$, denoted by $\mathbf{u}_j \in \mathbb{R}^{h'}$, is given by

$$\mathbf{u}_j = \mathrm{ReLU}\left(\mathrm{Conv}(\mathbf{q}'_{j-\lfloor\frac{k_q}{2}\rfloor}, \cdots, \mathbf{q}'_{j+\lfloor\frac{k_q}{2}\rfloor})\right) + \mathbf{q}'_j$$

$\mathbf{u}_1, ..., \mathbf{u}_j, ..., \mathbf{u}_n$ are aggregated into a summary vector $\mathbf{u} \in \mathbb{R}^{h'}$ using a weighted pooling based on attention weights α_j for each $\mathbf{u}_j$:

$$\alpha_j = \frac{\exp(\mathbf{v}_e \mathbf{u}_j^\top)}{\sum_{k=1}^{n} \exp(\mathbf{v}_e \mathbf{u}_k^\top)}$$
$$\mathbf{u} = \textstyle\sum_{j=1}^{n} \alpha_j \mathbf{u}_j$$

where $\mathbf{v}_e \in \mathbb{R}^{h'}$ is a trainable parameter. The summary vector $\mathbf{u}$ is then fed through another affine transformation with weights $\mathbf{W}_u \in \mathbb{R}^{h' \times h'}$ and biases $\mathbf{b}_u \in \mathbb{R}^{h'}$ followed by ReLU resulting in the output vector $\mathbf{u}'$. The quality score $\hat{q}$ is computed by projecting $\mathbf{u}'$ to a scalar value using an affine transformation with weights $\mathbf{W}_q \in \mathbb{R}^{h' \times 1}$ and bias $b_q \in \mathbb{R}$ followed by a sigmoid operation σ to limit the score to between 0 and 1.

$$\hat{q} = \sigma(\mathbf{u}'\mathbf{W}_q + b_q)$$

The network is trained using mean square error (MSE) as the loss function. We use the pre-trained predictor model only to generate input vectors to the estimator. The predictor parameters are not updated while training the estimator. We apply dropout (Srivastava et al., 2014) to both the RNN-based and CNN-based estimator networks on the inputs to each layer during training. For the CNN-based predictor and estimator, learning is stabilized using strategies in (Gehring et al., 2017) such as the initialization and weight normalization of CNNs and controlling the variance of activations after residual connections.

5 Experimental Setup

5.1 GEC System

The data to train and evaluate the NQE models require GEC system-generated hypotheses. For this, we train a single multilayer convolutional neural network GEC model initialized with pre-trained embeddings following (Chollampatt and Ng, 2018) on Lang-8 corpus only, following the same pre-processing method with 5,000 sentence pairs set aside for validation. The remaining data consists of 2.15M sentence pairs (25.47M source tokens and 28.94M target tokens). For training the model, we use only the annotated sentence pairs after sub-word segmentation (1.28M sentence pairs with 18.50M source sub-words and 21.88 target sub-words). During decoding, a beam width of 12 is used and the top candidate is chosen without any re-scoring.

5.2 Datasets

For training the QE models, we use sentences from the NUS Corpus of Learner English or NUCLE (Dahlmeier et al., 2013) and sentences from the training scripts of the Cambridge Learner Corpus-First Certificate Examination[3] (FCE) (Yannakoudakis et al., 2011) and their corresponding hypotheses generated by the GEC system described in §5.1. We use sentences from the FCE development set and CoNLL-2013 (Ng et al., 2013) test set and their GEC system-generated hypotheses as our development data. We separately test on two datasets, the FCE test set and the CoNLL-2014 test set (Ng et al., 2014). The statistics of the datasets are given in Table 1. The gold-standard scores are obtained by computing HTER using TERp (Snover et al., 2009) and sentence-level M^2 using the MaxMatch scorer with the GEC hypotheses and the reference

---

Development	3,635	63,782	63,890
FCE (test)	2,769	41,457	41,531
CoNLL-2014	1,312	30,144	30,109

Table 1: Statistics of the datasets used for QE.

sentences. When multiple references are available, the gold-standard score is chosen to be the best score (lowest HTER or highest M^2) among the scores computed against each reference separately.

5.3 NQE Models and Training

We build variants of the NQE models denoted by NQE_{XY}, where X indicates the predictor architecture and Y indicates the estimator architecture. X and Y can be recurrent (R) or convolutional (C), of which NQE_{RR} is our replication of (Kim et al., 2017a). The predictor models are trained and validated using parallel data from Lang-8 with 2.15M and 5000 sentence pairs, respectively (described in §5.1). For the predictor models, we use a source and target vocabulary size of 30,000 words, with 500-dimensional source and target embeddings, and 700-dimensional hidden layer. For our convolutional predictor model, a kernel width of 3 and 7 encoder and decoder layers are used. We train the predictor network with ADADELTA optimizer (Zeiler, 2012) with a batch size of 64. We clip gradients by their ℓ^2-norm with a threshold of 5.0 (Pascanu et al., 2013). The estimator networks, both recurrent and convolutional variants, use a hidden layer dimension of 100. They are trained with the Adam optimizer (Kingma and Ba, 2015) with an initial learning rate of 0.0005 and batch size of 32. We use dropout with a probability of 0.5 during training. Our final model is NQE_{ALL}, which averages the estimated scores of all variants, namely, NQE_{RR}, NQE_{CR}, NQE_{CC}, and NQE_{RC}.

5.4 Baselines

We use two non-neural baselines for comparison to our neural QE models.

AVERAGE: The average score of training sentences is used as the estimated score for all test sentences.

QUEST: We use the standard 17 sentence-level features in QuEst++ (Specia et al., 2015) which has been used as the baseline for WMT QE tasks from 2012 to 2017. The features are based on word-level statistics from the source-hypothesis sentence pairs, and statistics and features from language and lexical translation models trained using a parallel corpus. The descriptions of the 17 features can be found in (Bojar et al., 2017). We use the Lang-8 corpus to train the language and translation models for QuEst.

5.5 Evaluation

We evaluate primarily using the Pearson's correlation coefficient (PCC) metric following the recommendations in (Graham, 2015) and the recent WMT shared tasks (Bojar et al., 2016a, 2017). It is shown in (Graham, 2015) that aggregates of gold score distributions are easier to predict and metrics such as mean absolute error (MAE) and root mean square error (RMSE) over-estimate systems that predict the aggregates accurately despite these systems performing poorly on tail ends of the distribution (higher quality and lower quality samples). PCC does not suffer from this weakness. We use William's Test (Williams, 1959) following (Graham, 2015) to assess the significance of the improvements. However, we also report the root mean square error (RMSE) which reflects the estimator's loss and shows the deviation from the AVERAGE baseline.

6 Experiments and Results

6.1 Estimating Post-Editing Effort

We compare the QE models in terms of their performance in estimating the post-editing effort (HTER). The results, including those of the significance tests, are shown in Table 2. On the FCE test set, all NQE models significantly outperform the baseline QuEst ($p < 0.001$), with the best single model being our NQE_{CR} model (78.28% PCC). The NQE models achieve high PCC ($\geq$ 75%) compared to QuEst (35%). On the CoNLL-2014 dataset, however, only the NQE_{RC} model with our proposed convolutional estimator significantly outperforms all other single models including QuEst. The overall best performance on FCE is achieved by the average model, NQE_{ALL}, significantly outperforming NQE_{CR} ($p < 0.05$) and all other systems ($p < 0.001$). On CoNLL-2014, NQE_{ALL} and NQE_{RC} achieve statistically similar results and outperform all other systems significantly ($p < 0.01$).

	FCE		CoNLL-2014		Dev.	
	PCC↑	RMSE↓	PCC↑	RMSE↓	PCC↑	RMSE↓
Average	-	0.2082	-	0.0972	-	0.1755

Table 3: Results of the NQE models for sentence-level M^2 estimation.

6.2 Estimating M^2 Score

We use NQE models to estimate the MaxMatch (M^2) GEC evaluation metric at the sentence-level, which computes F$_{0.5}$ based on phrase-level edits. Results are shown in Table 3. All models significantly outperform the baseline QuEst on FCE ($p < 0.01$) test set. NQE$_{\text{ALL}}$ is significantly better than all other systems except NQE$_{\text{CC}}$ on FCE ($p < 0.01$). The PCC on CoNLL-2014 turns out to be much lower for all systems with the NQE models not significantly better than the baseline. Estimating M^2 appears to be more difficult compared to estimating post-editing effort with HTER scores. This could be because M^2 is a phrase-level measure with phrase-boundaries determined by matching with gold annotations, unlike HTER which is a token-level evaluation measure.

6.3 Improving GEC Performance

We use the estimated sentence-level M^2 scores as features to improve the performance of downstream GEC by using them as an additional feature during re-scoring the N-best candidates from a high-performing GEC baseline. Our GEC baseline is built on the multilayer convolutional architecture initialized with pre-trained embeddings and re-scoring (Chollampatt and Ng, 2018). We use the same hyper-parameter settings. The baseline GEC system consists of an ensemble of 3 sets of 4 models each. The first set consists of the 4 models released by Chollampatt and Ng (2018). The second set of 4 models is trained using a label-smoothed cross entropy loss function (Szegedy et al., 2016) which has been found to be effective in neural machine translation (Vaswani et al., 2017; Edunov et al., 2018). We use a smoothing parameter of 0.1 following Vaswani et al. (2017). The third set of 4 models consists of high-recall models that make use of three techniques proposed by Junczys-Dowmunt et al. (2018): (1) pre-training decoder parameters (2) source word dropout, and (3) edit-weighted negative log-likelihood. The parameters of the decoder are initialized using the parameters from a pre-trained neural language model (NLM) of the same architecture as our decoder except for the attention mechanism. We train this NLM using 100 million sentences (1.42 billion words) from the Common Crawl corpora released by Buck et al. (2014) for one epoch. We use the reported hyper-parameters

(Junczys-Dowmunt et al., 2018) for the other two techniques. The 12-best candidates produced by this ensemble are then re-scored using edit operations and language model features following Chollampatt and Ng (2018).

The performance of the baseline system (Base GEC) in terms of document-level $F_{0.5}$ computed by M^2scorer on the FCE and CoNLL-2014 test sets is reported in Table 4. When we use the development set used by Chollampatt and Ng (2018) consisting of 5.4k sentences from NUCLE to train the re-scorer, Base GEC system achieves a competitive performance compared to the top GEC systems with the best-published results on CoNLL-2014 test set: G&J (Grundkiewicz and Junczys-Dowmunt, 2018), JGGH (Junczys-Dowmunt et al., 2018), and C&N (Chollampatt and Ng, 2018). When we make use of the spelling error correction system (+SpellCheck) proposed by Chollampatt and Ng (2017), which is also used by G&J and C&N, our baseline achieves the highest reported $F_{0.5}$ on the CoNLL-2014 test set (56.43) when trained on public corpora alone. To the Base GEC system, we add the sentence-level M^2 scores estimated by the final NQE model (NQE_{ALL}) as a feature in the re-scorer. Since our NQE models use NUCLE during training, we use our development set consisting of 3.6k sentences from FCE and CoNLL-2013 to re-train the re-scorer instead of sentences from NUCLE so that the feature weights will not be biased. We observe a slight drop in performance upon retraining, potentially due to the fewer number of sentences and error annotations in this new development set. The added feature scores are also in the logarithmic scale, similar to LM and the encoder-decoder model score. When the estimated M^2 score is added, we find a significant improvement of 1.18 $F_{0.5}$ on the FCE test set and a significant improvement of 0.25 $F_{0.5}$ score on the CoNLL-2014 test set ($p < 0.001$). Significance testing is done using sign test by bootstrap re-sampling (Koehn, 2004) with 100 samples. The smaller margin of improvement on CoNLL-2014 is expected due to the low PCC values (Table 3). When we add spelling error correction, the results reach 48.70 $F_{0.5}$ score on FCE and 56.52 $F_{0.5}$ score on CoNLL-2014. However, the results obtained by training the re-scorer with our development set (FCE+CoNLL) and adding the NQE models should not be directly compared to the top systems (G&J, JGGH, and C&N) as they do not make use of the FCE data. We also re-score using oracle sentence-level M^2 scores instead of the NQE estimated scores. We find that GEC performance can reach up to 80.74 $F_{0.5}$ for CoNLL-2014 and 76.70 $F_{0.5}$ on FCE. This shows that improving automatic QE can substantially improve downstream GEC simply via re-scoring.

	FCE	CoNLL-2014
Best published results

7 Discussion and Analysis

Our results show that the NQE models perform better than feature-based baselines for QE of GEC. The crucial component of the NQE model that enables it to make better score estimates is the predictor network whose internal representations (quality vectors) are used as input to the estimator. The sum of nodes of a quality vector corresponds to the output node of the predictor network for a particular target word, and a softmax operation across all vocabulary words results in the predicted probability value. In Figure 3, we analyze the probability outputs by our convolutional predictor network for four GEC hypotheses for a source sentence '*We are all looking forward for you answer .*'. Hypothesis 1 is the source sentence itself and the predictor has rightly identified the location of error by giving a low probability

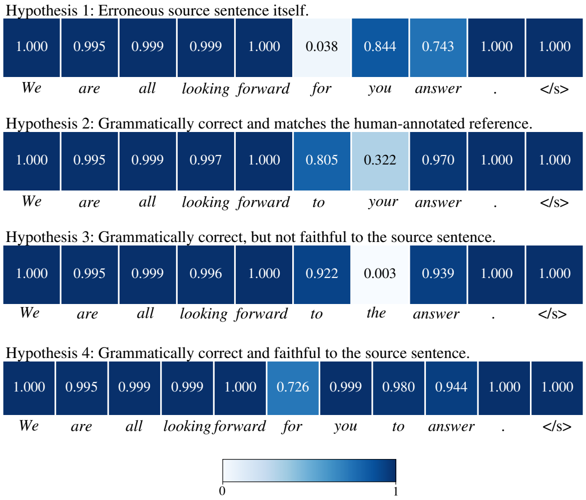

Figure 3: Probabilities predicted by the convolutional predictor for different GEC hypotheses.

score to the erroneous preposition '*for*' (0.038). In Hypothesis 2, which also matches the actual human-annotated reference, the phrase '*for you*' is replaced with '*to your*'. The correct preposition '*to*' gets a higher probability score. In Hypothesis 3, where a less suitable word '*the*' is used, a lower probability score (0.003) is assigned compared to the word '*your*' (0.322) in Hypothesis 2, despite Hypothesis 3 being grammatically correct. This indicates that the predictor rightly considers the faithfulness to the source sentence as well. When we analyze Hypothesis 4, which is grammatically correct and also faithful to the source, the probabilities of all words are much higher. Note that this hypothesis does not match the human annotated reference (Hypothesis 2). It is impractical to have human-annotated references that cover all possible corrections for all source sentences. This issue of reference-coverage has been noted previously in GEC literature (Bryant and Ng, 2015; Napoles et al., 2016b; Choshen and Abend, 2018a). This example shows that QE systems can potentially address this issue, similar to the reference-less evaluation measures for GEC.

We study if the estimator networks are able to count edits, which is the basis of estimating HTER. To do this, we take an example sentence of 14 tokens: '*It will be incredible if we have a chance to watch the show .*' as the source and the hypothesis as well as the reference. We substitute tokens one by one with an arbitrary token '*X*', thereby increasing HTER linearly. Figure 4 shows the performance of the NQE models compared to true HTER scores (straight line). We find that with increasing substitutions, all NQE models show an increasing trend, with the models having convolutional components NQE_{CR}, NQE_{CC}, and NQE_{RC} having Pearson's correlation coefficients (PCC) of 0.982, 0.976, and 0.986, respectively, and 0.939 PCC for the recurrent variant NQE_{RR} compared to true HTER scores. The average model NQE_{ALL} has the highest PCC value of 0.995. This example illustrates that the NQE models are able to capture edit counts for estimating HTER scores.

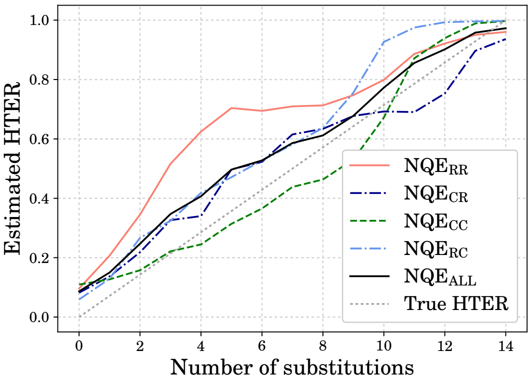

Figure 4: Estimated HTER scores of NQE models increasing with the number of incorrect substitutions.

8 Conclusion and Future Work

We propose the first supervised approach to quality estimation (QE) for GEC system outputs. We propose several neural QE model variants that perform significantly better than feature-based baselines in estimating the post-editing effort of GEC output sentences. We also show that the QE variants perform reasonably well on a more difficult task of estimating quality in terms of a GEC evaluation metric, M^2, by showing that the estimated scores are useful in improving GEC performance via N-best re-scoring. In future, the general framework of QE for GEC can be used to train on subjective human rankings of hypotheses as well, so that the system can learn the intuitions underlying human judgments of quality instead of estimating a pre-defined measure such as HTER or M^2.

Abstract

Part-of-Speech (POS) tagging for Twitter has received considerable attention in recent years. Because most POS tagging methods are based on supervised models, they usually require a large amount of labeled data for training. However, the existing labeled datasets for Twitter are much smaller than those for newswire text. Hence, to help POS tagging for Twitter, most domain adaptation methods try to leverage newswire datasets by learning the shared features between the two domains. However, from a linguistic perspective, Twitter users not only tend to mimic the formal expressions of traditional media, like news, but they also appear to be developing linguistically informal styles. Therefore, POS tagging for the formal Twitter context can be learned together with the newswire dataset, while POS tagging for the informal Twitter context should be learned separately. To achieve this task, in this work, we propose a hypernetwork-based method to generate different parameters to separately model contexts with different expression styles. Experimental results on three different datasets show that our approach achieves better performance than state-of-the-art methods in most cases.

1 Introduction

With the continuous growth of online communication, hundreds of millions of online conversational messages have become important resources for various applications such as real-time event detection (Sakaki et al., 2010), stock prediction (Bollen et al., 2011) and public health analysis (Wilson and Brownstein, 2009). Because these applications need to process natural language text, POS tagging, which is one of the fundamental natural language processing tasks, has become one of the basic pre-processing components of such applications. The performance of POS tagging may highly impact the results of these applications.

RT @jamstik : Lol :) there is more than one way to start living a greener life.

Figure 1: Examples of WSJ and tweets. Segments with red highlights can be regarded as the similar expressions. Segments with blue highlights correspond to expressions that cannot be learned from WSJ.

Most of the POS tagging methods that can achieve state-of-the-art performance are based on supervised learning algorithms (Gimpel et al., 2011). Although these methods can achieve good performance for in-domain data, their performance usually drops quickly when processing data from a domain that is different from that of the training data (Caruana and Niculescu-Mizil, 2006). To achieve better performance, we usually need to manually label a large amount of in-domain data. However, the task of constructing labeled data is time-consuming and tedious. Currently, various methods have been proposed to solve this problem using out-of-domain data, including domain adaptation (Daumé III, 2009; Gui et al., 2017), multi-task learning (Ben-David et al., 2007), and dual learning (Chandrasekaran et al., 2014).

Most existing methods aim to learn the shared representations or parameters, which can reduce the classification or regression model errors of each task/domain. However, these methods usually ignore the fact that each domain has domain-specific features that should not be shared. From

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2540–2549
Brussels, Belgium, October 31 - November 4, 2018.

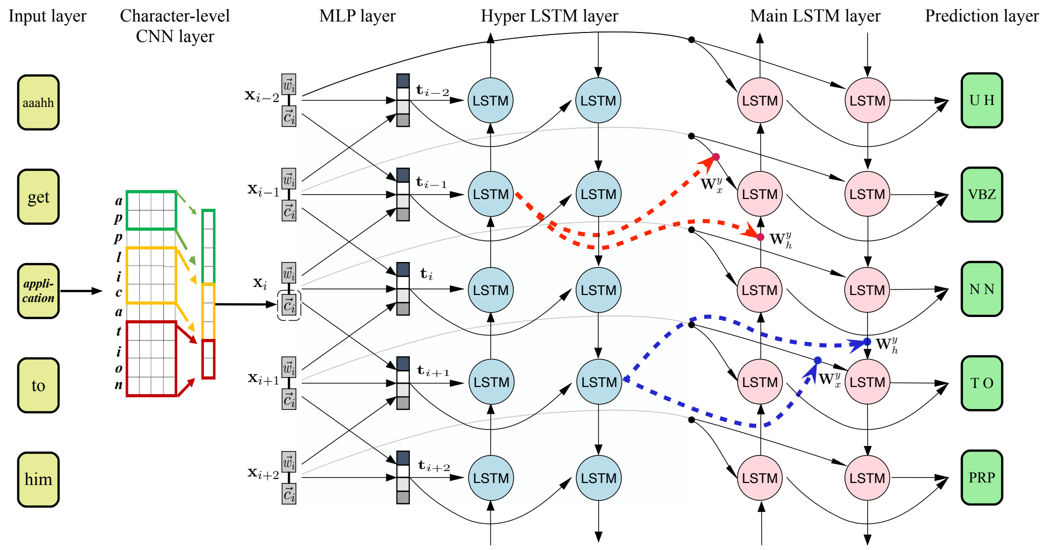

Figure 2: Model architecture of the proposed dynamic conversion neural networks.

the language characteristics, in spite of the expressions that are similar to the newswire text, Twitter has some informal expressions that cannot be shared, as shown in Figure 1. Hu et al. (2013) investigated the characteristics of language on Twitter and found that Twitter users not only tended to mimic the linguistic practices of traditional media, like news, they also appeared to be developing linguistically unique styles. We also believe that the tweets simply follow the standard language rules, and at some point eventually deviate from those. Thus, tweets are a combination of formal expressions and informal expressions with conversions between different expression styles.

Based on the above observations, we believe that annotated sentences of newswire text can be selectively used to help tag contextual segments of tweets, especially for formal expressions. To achieve this goal, in this work we adopt bidirectional long short-term memory (bi-LSTM) networks (Schuster and Paliwal, 1997), which have been successfully used for various sequence tagging problems. However, different from previous methods, the formal expressions and informal expressions in a sentence should be separately modeled. Inspired by recent work on dynamic parameter prediction (Ha et al., 2016), we propose a method to generate the context-specific parameters of the bi-LSTM based on different styles of context for POS tagging. We evaluated our models on three different corpora. The results demonstrated that the proposed method can benefit from annotated newswire text data and achieve competitive performance. In addition, we visualized the context distributions and the change of parameters. The visualization results verified the fact that different contexts produce different parameters for POS tagging.

The main contributions of the paper can be summarized as follows.

1. We study problems in the segment modeling method to apply domain adaptation to the POS tagging task. Based on the observations from a linguistic perspective, we found that there are many shared expressions between the newswire and tweets, and some expressions cannot be shared.

2. A novel neural network architecture based on the bi-LSTM was proposed to perform the task. Different parameters were applied in different contexts.

3. Experimental results demonstrated that the proposed method can benefit from different domains. We also conducted qualitative and quantitative analyses to show why our model can achieve better performance.

2 Approach

Twitter is responsible for colorful linguistic expressions, and full of the conversions between formal expressions and informal expressions. To address this problem, we propose the Dynamic Conversion Neural Networks (DCNN), which can dynamically generate different parameters for POS tagging based on different contexts as shown in Figure 2. Our model mainly consists of four parts: (1) a CNN layer for extracting word representations $\mathbf{x}_i$, (2) an MLP layer for producing low-dimensional context representations $\mathbf{t}_i$, (3) a hyper LSTM layer for generating the weights $\mathbf{W}$ of a main LSTM, and (4) the main LSTM layer with dynamic parameters for POS tagging.

The architecture of the main network is the same with any sequence labeling model, which learns to map the word representations to the corresponding labels. However, the parameters of the main network can be modified according to our purpose. we use a low-dimensional context distribution vector $\mathbf{t}_i$ as the input of the hyper LSTM to generate the weights of the main LSTM. Thus, the weights of the main LSTM will be subject to a change in context vector. Therefore, the main LSTM can predict the POS tag based on the different parameters.

Ha et al. (2016) also proposed a HyperRNN network, in which the hyper net is influenced by the main net. This is inconsistent with our motivation. Different from (Ha et al., 2016), to make the parameters of the main LSTM totally controlled by the context distribution, we changed the architecture by cutting off the data path from the main LSTM to the hyper LSTM. This method can prevent the hidden states of the main LSTM from influencing the hyper LSTM. In addition, we add an extra layer of learning the context representations based on features returned by a CNN.

2.1 Word and Context Representations

Out-of-vocabulary words are frequently used in Twitter. Moreover, new symbols, abbreviations, and words are constantly being created. These make word representations difficult to address. Thus, robust methods should be used to extract the morphological and shape information from words.

Inspired by (Santos and Zadrozny, 2014), we adopted character-level convolutional neural networks (CNN layer) to tackle this problem, which can take all of the characters of the word into consideration and output important orthographic features (Santos and Zadrozny, 2014). Suppose that we are given the sentence $X = \{w_1, w_2, \dots\}$ with vocabulary $\mathcal{V}$ of words. We use multiple filters with varying widths to obtain the orthographic feature vector $\vec{c_i}$ for word w_i. Then, the orthographic feature vector $\vec{c_i}$ is concatenated to the word embedding $\vec{w_i}$ to form word representation $\mathbf{x}_i$ as the input of the main LSTM. Utilizing a bi-LSTM to model sentences, the model can extract the sequential relations and contextual information.

The context is a fixed window of words around target word. The context representations are learned by the MLP later. To do this, we apply a fully connected neural network, which takes sequential word representations in a fixed window as input to generate a low-dimensional vector $\mathbf{t}_i$ as follows:

$$\mathbf{t}_i = softmax(MLP[\mathbf{x}_{i-r}...\mathbf{x}_{i-1} \oplus \mathbf{x}_i \oplus \mathbf{x}_{i+1}...\mathbf{x}_{i+r}]), \quad (1)$$

where $[\cdot \oplus \cdot]$ represents concatenation operation. r represents the length from central word x_i to the edge of the window. MLP is the multilayer perceptrons function, which transfers the context matrix to a low-dimensional vector. We apply MLP to every window of contexts. $softmax$ denotes the softmax function that converts the context vector into a probability distribution. The goal is to learn an MLP layer that, given sequential word representations, estimates a distribution over the contexts.

2.2 Adaptive Weight Generation

The identical weights at each time step will limit the expressiveness of recurrent neural network (RNN) (Ha et al., 2016). To overcome the limitation, our model uses a small network (hyper network) taking low-dimensional context representations as inputs to dynamically generate the parameters of a large network (main network) for POS tagging. Different with (Ha et al., 2016), at every time step, the hyper LSTM only takes the context representation $\mathbf{t}_i$ as an input and generates the hidden state $\hat{\mathbf{h}}_i$ as an output. This hidden state $\hat{\mathbf{h}}_i$ is used to generate the weights for the main LSTM at the same time step. The hyper LSTM and main LSTM are jointly trained with backpropagation and gradient descent. Next, we will give a more formal description of the weight generation.

The hyper LSTM is a standard LSTM (Hochreiter and Schmidhuber, 1997), which takes context vectors as inputs and outputs hidden states. The hyper LSTM is defined as follows:

$$\begin{bmatrix}\hat{\mathbf{g}}_i\\ \hat{\mathbf{i}}_i\\ \hat{\mathbf{f}}_i\\ \hat{\mathbf{o}}_i\end{bmatrix} = \left(\begin{bmatrix}\mathbf{W}_t^{\hat{g}}, \mathbf{W}_{\hat{h}}^{\hat{g}}\\ \mathbf{W}_t^{\hat{i}}, \mathbf{W}_{\hat{h}}^{\hat{i}}\\ \mathbf{W}_t^{\hat{f}}, \mathbf{W}_{\hat{h}}^{\hat{f}}\\ \mathbf{W}_t^{\hat{o}}, \mathbf{W}_{\hat{h}}^{\hat{o}}\end{bmatrix} \bullet \begin{bmatrix}\mathbf{t}_i\\ \hat{\mathbf{h}}_{i-1}\end{bmatrix} + \begin{bmatrix}\hat{\mathbf{b}}^{\hat{g}}\\ \hat{\mathbf{b}}^{\hat{i}}\\ \hat{\mathbf{b}}^{\hat{f}}\\ \hat{\mathbf{b}}^{\hat{o}}\end{bmatrix}\right) \tag{2}$$

$$\begin{aligned}\hat{\mathbf{c}}_i &= \phi(\hat{\mathbf{g}}_i) \odot \sigma(\hat{\mathbf{i}}_i) + \hat{\mathbf{c}}_{i-1} \odot \sigma(\hat{\mathbf{f}}_i)\\ \hat{\mathbf{h}}_i &= \sigma(\hat{\mathbf{o}}_i) \odot \phi\left(\hat{\mathbf{c}}_i\right),\end{aligned}$$

where ϕ denotes the $tanh$ function, and σ is the $sigmoid$ function. $\odot$ and $\bullet$ represent the Hadamard product and matrix product, respectively. We assume that $\hat{y}$ is one of $\{\hat{g}, \hat{i}, \hat{f}, \hat{o}\}$. The hyper LSTM has $N_{\hat{h}}$ hidden units, and N_t is the dimensionality of $\mathbf{t}_i$. Then, $\mathbf{W}_t^{\hat{y}} \in \mathbb{R}^{N_{\hat{h}} \times N_t}$, $\mathbf{W}_{\hat{h}}^{\hat{y}} \in \mathbb{R}^{N_{\hat{h}} \times N_{\hat{h}}}$, $\hat{\mathbf{b}}^{\hat{y}} \in \mathbb{R}^{N_{\hat{h}}}$ are the parameters of the hyper LSTM and stay invariable during one sentential sequence.

Inspired by (Ha et al., 2016), we adopted a *weight scaling vector* $\mathbf{d}$ which is a linear projection of $\hat{\mathbf{h}}_i$. $\mathbf{d}$ is used to linearly scale each row of the weight matrix in the standard LSTM. Because the context vector $\mathbf{t}$ is produced by the different contexts at each time step, the hidden state $\mathbf{h}_i$ and $\mathbf{d}_i$ will change corresponding to $\mathbf{t}_i$. Thus, the main LSTM can be modified as follows:

$$\begin{bmatrix}\mathbf{d}_{i,x}^{y}\\ \mathbf{d}_{i,h}^{y}\\ \mathbf{d}_{i,b}^{y}\end{bmatrix} = \begin{bmatrix}MLP_x^y(\hat{\mathbf{h}}_i)\\ MLP_h^y(\hat{\mathbf{h}}_i)\\ MLP_b^y(\hat{\mathbf{h}}_i)\end{bmatrix}$$

$$\begin{aligned}\mathbf{y}_i = &\left[\mathbf{d}_{i,x}^{y} \otimes \mathbf{W}_x^y, \mathbf{d}_{i,h}^{y} \otimes \mathbf{W}_h^y\right] \bullet \begin{bmatrix}\mathbf{x}_i\\ \mathbf{h}_{i-1}\end{bmatrix} \\ &+ \mathbf{d}_{i,b}^{y} \otimes \mathbf{b}^y\\ \mathbf{c}_i =&\phi(\mathbf{g}_i) \odot \sigma(\mathbf{i}_i) + \mathbf{c}_{i-1} \odot \sigma(\mathbf{f}_i)\\ \mathbf{h}_i =&\sigma(\mathbf{o}_i) \odot \phi\left(\mathbf{c}_i\right),\end{aligned} \tag{3}$$

where $\otimes$ represents the element-wise product with broadcasting. $\mathbf{y}$ is one of $\{\mathbf{g}, \mathbf{i}, \mathbf{f}, \mathbf{o}\}$. Generally, $N_{\hat{h}}$ and N_t are much smaller than N_h and N_x, respectively. Thus, the size of the parameters in the hyper LSTM is hundreds of times less than that of the standard LSTM.

According to the above functions, if the model is given contexts with different styles, it will generate different parameters for all kinds of gates in the main LSTM. Then, the outputs of the main LSTM are used to predict the POS tags of the central words with the cross entropy loss:

$$\mathcal{L}_{POS} = -\sum_i z_i * \log \hat{z}_i, \tag{4}$$

where z_i is the one-hot vector of the POS tagging label corresponding to $\mathbf{x}_i$. $\hat{z}_i$ is the output of the top softmax layer: $\hat{z}_i = softmax(MLP(\mathbf{h}_i))$.

3 Experimental Setup

In this section, we will first detail the datasets we used. Then, we will describe several baseline methods, including a number of classic taggers and a series of deep learning sequence labeling methods.

3.1 Datasets

Following (Derczynski et al., 2013), we use RIT-Twitter (Ritter et al., 2011) as our main dataset. The RIT-Twitter was split into training, development and evaluation sets (RIT-Train, RIT-Dev, RIT-Test). The splitting method was shown in (Derczynski et al., 2013). In order to verify the validity of our model, we also tested it on two more datasets, NPSChat (Forsythand and Martell, 2007), and ARK-Twitter (Gimpel et al., 2011) using standard splits. The tag-sets of the RIT-Twitter and NPSChat are PTB-like, while that of the ARK-Twitter is specific. In order to use WSJ labeled data in experiments on ARK-Twitter, we performed the mapping from PTB tag-sets to ARK tag-sets, according to the PTB POS Tagging Guidelines (Santorini, 1990) and ARK Guidelines[1]. The mapping proceeded from fine to coarse.

For pretraining the word embedding, we constructed a dataset containing 30 million tweets, from Twitter using its API. We introduced a newswire dataset containing 1173K tokens as the written language dataset, namely the Wall Street Journal (WSJ) from the Penn TreeBank v3 (Marcus et al., 1993). During training, we mixed each of RIT-Twitter, NPSChat and ARK-Twitter with WSJ into three kinds of training data.

The detailed data statistics of the above datasets used in this work are listed in Table 1.

Dataset	#Train	#Dev	#Test
RIT-Twitter	10652	2242	2291
NPSChat	40497	-	4500
ARK-Twitter	26594	-	7707

Table 1: The statistics of the datasets used in our experiments, where # represents the number of tokens in datasets.

---

3.2 Competitor Methods

We applied several classic and state-of-the-art methods for comparison. In addition, we used a series of deep learning sequence labeling methods as baselines for comparison, as follows:

Stanford POS Tagger is a widely used part-of-speech taggers described in (Toutanova et al., 2003). It demonstrates the broad use of features and appropriate model regularization, which produces a superior level of performance (97.24%). In this work, we trained it using two different sets: sections 0-18 of the WSJ (**Stanford-WSJ**) and a mixed corpus of WSJ, IRC, and Twitter (**Stanford-MIX**).

T-POS (Ritter et al., 2011) adopts hierarchical clustering and Brown clustering methods to address the issue of OOV words and lexical variations. It also uses conditional random fields and other standard sets of features to perform the task. In this work, we trained it using three different sets: the WSJ (**T-POS-WSJ**), RIT-Train (**T-POS-RIT**) and a mixed corpus of WSJ, IRC, and RIT-Train (**T-POS-MIX**).

GATE Tagger (Derczynski et al., 2013) uses an approach that combines the available taggers for different tagsets. The tagger adopts a vote-constrained bootstrapping method with unlabeled data and assigns prior probabilities to handle of unknown words and slang.

ARK Tagger (Owoputi et al., 2013) is a system that reports the best accuracy on ARK-Twitter. It uses unsupervised word clustering and a variety of lexical features.

TPANN (Gui et al., 2017) applies adversarial networks and autoencoder to model labeled out-of-domain data, unlabeled in-domain data and labeled in-domain data and achieved the best performance on RIT-Twitter.

Bidirectional LSTM (Bi-LSTM) (Wang et al., 2015) has been widely used in a variety of sequence labeling tasks. In this work, we also evaluated it as a baseline.

Bi-HyperLSTM (Ha et al., 2016) was used as a substitute for the standard Bi-LSTM. What makes the Bi-HyperLSTM model different from the proposed model is that we used context distribution to generate the parameters of main LSTM.

3.3 Initialization and Hyperparameter

The word embeddings for all the models were initialized with the word2vec tool (Mikolov et al., 2013) on 30 million tweets. The other parameters excluding the word embeddings, such as the parameters in LSTM and MLP, were initialized by randomly sampling from a uniform distribution in [-0.05, 0.05].

The dimensionality of the word embedding was set at 200. The dimensionality for the randomly initialized character embedding was set at 25. We adopted a hyper LSTM with 160 hidden neurons to produce the weights of each gates of the main LSTM with 250 hidden neurons. The dimensionality of the context vector was set at 10.

Our DCNN could be trained end-to-end with backpropagation and gradient-based optimization was performed using the Adam update rule (Kingma and Ba, 2014) with learning rate 0.0001.

4 Results and Analysis

In this section, we will report the experimental results and a detailed analysis of the results for the three different datasets.

4.1 Evaluation on RIT-Twitter

The RIT-Twitter was introduced in (Ritter et al., 2011). This dataset uses a tagset based on the Penn Treebank tagset with several Twitter-specific tags: *retweets, @usernames, hashtags, and urls.*

Table 2 lists the results of our method compared with other methods on this dataset. The first part shows the results of the classic methods. From the result of Stanford-WSJ, we can see that although it can achieve a superior level of performance (97.24%) on the WSJ dataset, the accuracy drops significantly to 73.37% when applied to the Twitter dataset. If we add some in-domain data to the training set, the Stanford-MIX can improve by 10% compared to the Stanford-WSJ. The same phenomenon can be observed from T-POS tagger. If we apply more features, like clustering, bootstrapping and lexical features, the T-POS, GATE tagger and ARK tagger can achieve better performances. Although TPANN achieve accuracy of 90.92%, it incorporates additional a large amount of in-domain unlabeled data. Our method is more competitive because of the use of much fewer data sets.

Methods	**Training Set**	**RIT-Test**	**RIT-Dev**
Stanford-WSJ (Toutanova et al., 2003)		-	73.37%
Stanford-MIX		-	83.14%
T-POS-WSJ (Ritter et al., 2011)		81.30%	
T-POS-RIT		84.55%	84.83%
T-POS-MIX		88.30%	-
GATE Tagger (Derczynski et al., 2013)		88.69%	89.37%
ARK Tagger (Owoputi et al., 2013)		90.40%	-
TPANN (Gui et al., 2017)		90.92%	91.08%
Bi-LSTM	RIT-Train	89.48%	89.30%
Bi-LSTM*		89.31%	90.37%
Bi-HyperLSTM		88.65%	89.16%
Bi-HyperLSTM*		88.30%	89.56%
DCNN		89.87%	90.50%
Bi-LSTM	WSJ + RIT-Train	90.09%	90.37%
Bi-LSTM*		90.31%	90.81%
Bi-HyperLSTM		90.57%	90.41%
Bi-HyperLSTM*		90.44%	90.54%
DCNN		**91.18%**	**91.17%**

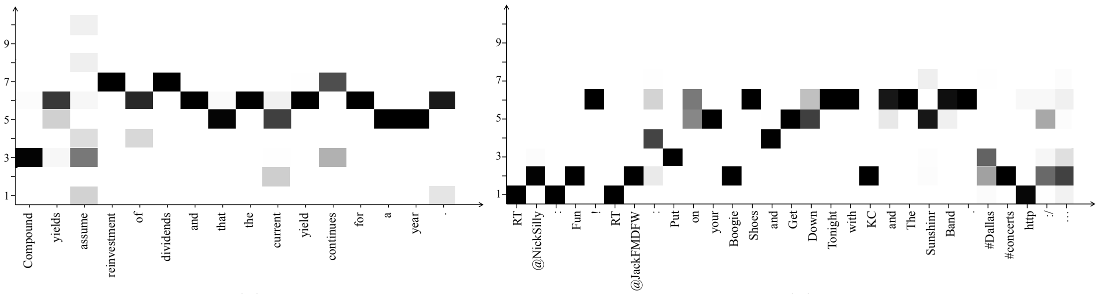
Table 2: Token level accuracies of different methods on RIT-Test and RIT-Dev. The first part demonstrates the results of classic methods. The second part demonstrates a series of deep learning methods trained on RIT-train. The third part demonstrates the same deep learning methods train on the mixed dataset of RIT-train and WSJ. DCNN refers to our dynamic conversion neural network. Other models are described in the Section 3.2. The symbol * represents the model concatenates the context vectors with the word representations as inputs.

The second part shows the results of the deep learning methods trained on the RIT-Train dataset. We can see that if the sequence labeling methods are just trained on the RIT-Train dataset, their accuracies can exceed those of most conventional taggers. Thus, the deep learning methods are competitive and avoid feature engineering. Compared with other models, the DCNN achieved best performance among the models just trained on RIT-Train dataset.

The third part shows the results of the deep learning methods trained on the mixed dataset of the RIT-Train and WSJ. As observed, when we added the WSJ data to train the models, all of them could obtain different degrees of improvement. Moreover, our model could make better use of the out-of-domain data and obtained the best result. Compared with the ARK tagger, which achieved the previous best result in conventional methods, our model was almost 0.78% better. The error reduction rate was more than 8%. Our model also outperformed the TPANN, which incorporated additional unlabeled in-domain data.

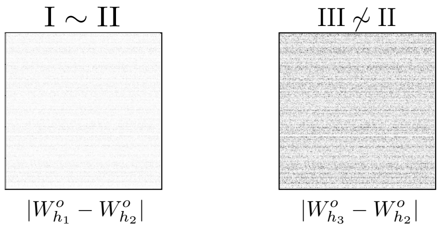
From the perspective of utilizing a low-dimensional context vector, we provided the same information (word information and context information) for all of the deep learning models as shown in Table 2. However, except for the DCNN, the other models were incapable of utilizing the context information. Most of the models could not obtain obvious improvement. In contrast, our DCNN could make better use of the context information to generate more appropriate parameters for POS tagging. Next, we will analyze the behavior how the DCNN changes parameters when encountering different context vectors.

Intuitively, contexts with different language expression styles should be transformed into different vectors. Figure 3 visualizes the context distribution. Subfigure (a) shows the context vector extracted from WSJ. We can see that the formal expressions are mainly concentrated in the middle of the four dimensions. This phenomenon can be observed in the subfigure (b), where the formal expressions in the Twitter are concentrated in the middle of the same dimensions and the informal expressions are concentrated in another three dimensions. Notice that in our experimental setup, the dimensionality of the context vector is



(a) (b)

Figure 3: Visualization of context distribution. The left sentence comes from WSJ, and the right one comes from Twitter.



I ➤ *Compound yields assume reinvestment of dividends and that the current yield continues for a year.* (WSJ Formal)

II ➤ *Very grateful for another Monday and a new week full of endless possibilities ! Go World!* (Twitter Formal)

III ➤ *RT @NickSilly : Fun ! RT @JackFMDFW : Put on your Boogie Shoes and Get Down Tonight with KC and The Sunshine Band . #Dallas #concerts http :/ ...* (Twitter Informal)

Figure 4: Visualization of the comparison of weight matrices. We denote the weight matrix of output gate as W^o_h. Each subgraph represents the result of element-wise subtraction $|W^o_{h_i} - W^o_{h_j}|$, where $|\cdot|$ means absolute value, i and j are the sequence numbers of sentences. If the two sentences have a similar expression style, then the absolute value would be close to zero represented by white color. We use $i \sim j$ to represent it. On the contrary, We use $i \not\sim j$ to represent the different expression styles. We only visualize the weights on the last time step.

set to 10. However, the values of the last three dimensions are close to zero. Consequently, we set this hyperparameter to 7 and we achieve a higher accuracy of 91.27%.

Figure 4 shows how the weight matrix W^o_h in output gate gets changed when the model inputs different kinds of contexts. Through making a comparison among the sentences I, II and III. we can find that although the sentences II and III are both from Twitter, whereas the sentence I is from WSJ, If the style of sentence II is close to that of sentence I, then the model will produce similar weight values to achieve the task. If the style of sentence I is different from that of sentence III, then the model will produce different parameters more suitable for Twitter-specific sentences. The similar phenomena can be found in other gates.

Table 3: Accuracy comparison of different methods on NPSChat Corpus.

4.2 Evaluation on NPSChat

The NPSChat Corpus (Forsythand and Martell, 2007) is a PTB-POS annotated dataset of Internet Relay Chat (IRC) room messages from 2006. The corpus consists of 10,567 posts out of approximately 500,000 posts gathered from various online chat services in accordance with their terms of service. The authors of the corpus made several decisions during the process that were unique to the chat domain regarding some abbreviations, emotions and misspelled words. For example, LOL and :-) were frequently encountered in the chat messages. Because these expressions conveyed emotion, they were treated as individual tokens and tagged as interjections (UH).

Table 3 lists the results of different taggers evaluated on NPSChat. Our method was tested using the same setup as the experiments in (Forsyth, 2007). The training part contained 90% of the data. The testing part contained the remaining 10%. Based on the results, we can see that our method could achieve the best accuracy (94.0%), which was significantly better than 90.8% (Forsyth, 2007). They trained the tagger on a mix of several corpora tagged with the Penn Treebank tag set. Our method also outperformed

the ARK tagger, which applies various external corpus and features, e.g., Brown clustering, PTB, Freebase lists of celebrities, and video games.

4.3 Evaluation on ARK-Twitter

The ARK-Twitter that contains 34K tokens uses a novel tagset. The training set (OCT27) is provided in (Gimpel et al., 2011). It is a dataset of POS-tagged tweets consisting almost entirely of tweets sampled from one particular day (October 27, 2010). However, the test set was introduced in (Owoputi et al., 2013), and contains 574 tweets (DAILY547). The DAILY547 consists of one random English tweet from every day between January 1, 2011 and June 30, 2012. Thus, the distribution between the training set and test set may be slightly different. For example, a substantial fraction of the messages in the training data are about a basketball game that occurred on that day.

The results of the ARK tagger and TweetNLP Tagger in Table 4 are reported in (Owoputi et al., 2013). We can see that our method could significantly outperform the TweetNLP Tagger. However, our method was worse than the ARK tagger. By analyzing the incorrect results, we found that 20.3% of the errors occurred between nouns and proper nouns. Because our model does not incorporate any knowledge of proper nouns, it is difficult for it to recognize proper nouns from datasets. As reported in (Owoputi et al., 2013), if ARK-tagger does not add tag dictionary features and name list features, its performance will drop to 92.38%, which is lower than that of the DCNN. Thus, our model is also competitive when lacking of knowledge.

5 Related Work

At a very early time, Schmidhuber (1992) began to explore the concept of fast weights, in which one network can produce context-dependent weight changes for a second network (Schmidhuber, 1992, 1993). Moreover, they provided the theoretical possibility of a recurrent network version. Recently, numerous studies have been conducted in this field (Moczulski et al., 2015; Fernando et al., 2016). De Brabandere et al. (2016) introduced a new framework called the dynamic filter network where the filters in the CNN are generated dynamically. Ha et al. (2016) explored the use of this approach in recurrent networks. Our work uses a different mechanism to generate parameters, which can make the parameters subject to a change in context representations. we cut off the data path from the main LSTM to the hyper LSTM. This method can prevent the hidden states of the main LSTM from influencing the hyper LSTM.

Recently, deep learning has achieved promising results on POS tagging. Santos and Zadrozny (2014) used a CNN to construct a character-based model for English (PTB) and Portuguese. Wang et al. (2015) used the bi-LSTM on WSJ and reported a state-of-the-art performance. However, because of a lack of training data and an unconstrained writing style, these models encountered resistance in the implementation process on Twitter. In this work, we focused on the linguistic correlation between Twitter and newswire and took the linguistic characteristics into consideration. To selectively utilize out-of-domain data, we used a low-dimensional context vector to generate different parameters for text with different expression styles and obtained better results.

6 Conclusion

In this work, we study the problem of incorporating labeled newswire texts for Twitter POS tagging tasks. From a linguistic perspective, we find that Twitter users not only tend to mimic the formal expressions of traditional media, like news, but they also appear to be developing linguistically informal styles. Hence, we predict that labeled data from the newswire should selectively be used to help tag contextual segments of tweets. To achieve this task, we introduce a novel deep neural network architecture that can dynamically generate different parameters based on different expression styles for POS tagging. To evaluate the performance of the proposed method, we compare the method with previous state-of-the-art methods on three different datasets. Experimental results demonstrate that the proposed method can achieve better performance in most cases. We also visualize some parameters learned for the proposed method to demonstrate the motivation for this work.

Abstract

The configurational information in sentences of a free word order language such as Sanskrit is of limited use. Thus, the context of the entire sentence will be desirable even for basic processing tasks such as word segmentation. We propose a structured prediction framework that jointly solves the word segmentation and morphological tagging tasks in Sanskrit. We build an energy based model where we adopt approaches generally employed in graph based parsing techniques (McDonald et al., 2005a; Carreras, 2007). Our model outperforms the state of the art with an F-Score of 96.92 (percentage improvement of 7.06%) while using less than one tenth of the task-specific training data. We find that the use of a graph based approach instead of a traditional lattice-based sequential labelling approach leads to a percentage gain of 12.6% in F-Score for the segmentation task.[1]

1 Introduction

Sanskrit, a morphologically-rich and a free word order language (Kulkarni et al., 2015), poses a series of challenges even for automation of basic processing tasks such as word segmentation. The recent surge in the digitisation efforts for archiving the works ranging from the pre-classical to modern times (Hellwig, 2010-2016) has led to a growing demand for such tools (Goyal et al., 2012; Huet, 2006). We propose a structured prediction approach that jointly solves the word segmentation and morphological tagging tasks for Sanskrit.

The computational problems arising from the mechanical treatment of Sanskrit fall somewhere between speech recognition and the analysis of written text (Huet, 2005). For instance, consider Figure 1a which shows all the phonetically valid word splits for a Sanskrit poetic verse[2]. The written representation in Sanskrit is actually a phonemic stream (Huet, 2005). The constructions often undergo phonetic transformations at the juncture of successive words, similar to what one observes in connected speech (Morris et al., 2004; Shieber and Tao, 2003). These transformations obscure the word boundaries and often modify the phones at these word boundaries. In Sanskrit, these transformations get reflected in writing as well. This is primarily due to the presence of an advanced discipline of phonetics in Sanskrit which explicitly described euphonic assimilation as *sandhi* (Goyal and Huet, 2016). For instance, words prefixed with numbers 14 and 15 in Figure 1a are valid candidates in spite of the phonetic differences they posses from that of the original sentence.

Sanskrit is rich with syncretisms (Crystal, 2011) and homonyms. For example, the surface form '*satī*', prefixed with numbers 6 and 10, are homonyms, while the root '*satya*' generates identical surface form for three different morphological classes leading to syncretism (1 to 3 in Figure 1a). Hence, in addition to segmentation, the morphological analysis of the segmented word forms will be critical for reducing the ambiguity in further downstream tasks such as syntactic analysis. The sentence construction in the language follows weak non-projectivity (Havelka, 2007) permitting the words to have a relatively free word order structure (Kulkarni et al., 2015). The language is all the more lenient for poetic constructions (Scharf et al., 2015; Kulkarni et al., 2015), where arranging the words to adhere to metri-

Brussels, Belgium, October 31 - November 4, 2018.

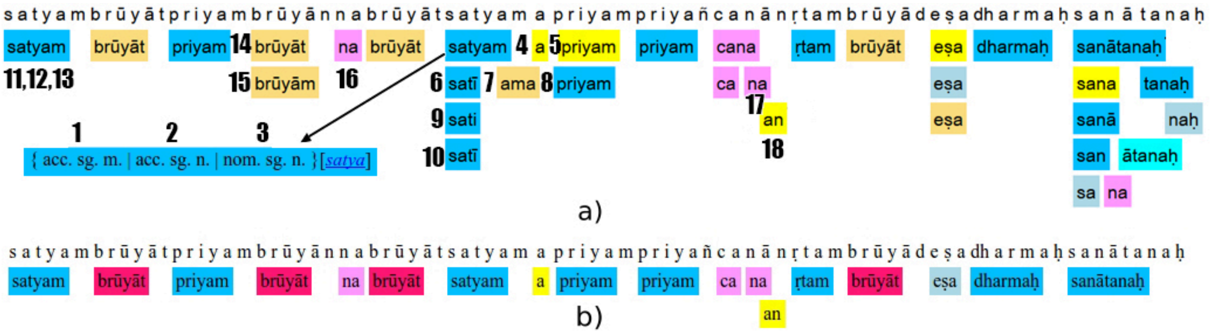

Figure 1: a) All the phonetically valid segmentations (link) for '*satyaṃbrūyātpriyaṃbrūyānnabrūyātsatyamapriyaṃpriyaṃcanānṛtambrūyādeṣadharmaḥsanātanaḥ*' from (*subhāṣitam*) as output by Sanskrit Heritage Reader (SHR) and b) correct segmentation selected from the candidate space.

cal constraints is a bigger concern (Melnad et al., 2013). Hence, the whole input context is desirable when making each prediction at the output (Bahdanau et al., 2015), even for preliminary tasks such as segmentation in Sanskrit (Reddy et al., 2018).

The word splits in Figure 1 are based on the analysis by a lexicon driven analyser, Sanskrit Heritage Reader (SHR)[3]. A total of 1,056 combinations can be formed from the word splits, such that each of those combinations is a solution which covers the entire input. We call such a solution as an '*exhaustive segmentation*'. Out task is to find an '*exhaustive segmentation*', which is also semantically valid. Figure 1b shows the semantically valid solution for the sentence.

We propose our structured prediction framework as an energy based model (LeCun et al., 2006). Considering the free word-orderness, morphological richness and the phenomena of *Sandhi* in Sanskrit, we adopt a graph based treatment for a given input sentence as shown in Figure 2. All the word splits, as predicted by SHR, are treated as the nodes in the graph. Every pair of nodes that can co-occur in at least one '*exhaustive segmentation*'[4] forms directed edges in both the directions. By construction, any subset of nodes that forms a maximal clique will be an '*exhaustive segmentation*'. We formalise our task as the search for a maximal clique. The graph structure eliminates the sequential nature of the input, while the greedy maximal clique selection inference policy of ours can take the entire input context into consideration. We hypothesise that both of these will be beneficial for processing constructions in Sanskrit.

The major contributions of our work are:

1. We propose the first model that performs both word segmentation and morphological tagging for Sanskrit as suggested by Krishna et al. (2017); the combined task reports an F-Score of 90.45.
2. We obtain an F-Score of 96.92 for the word segmentation task, an improvement of 7.06% over the state of the art, a seq2seq model with attention (Reddy et al., 2018).
3. We achieve the results with less than one-tenth of the training data that Reddy et al. (2018) uses, a desirable outcome for a low resource language such as Sanskrit. The pre-training in the form of morphological constraints to form edge vectors enables this.
4. We propose a scheme that uses the Path Ranking Algorithm (Lao and Cohen, 2010) to automate the feature selection and the feature vector generation for the edges. This eliminates the need for manual feature engineering.

2 Proposed Architecture

Given an input construction, we obtain our search space of possible word splits using SHR as shown in Figure 1. The search space represents all the possible exhaustive segmentations with possible gaps and overlaps between the word splits in each of the exhaustive segmentation (Kudo, 2006; Oerder and Ney, 1993; Wolf and Woods, 1977).[5] In such a setting, representing the search space as a lattice (Kudo, 2006; Smith et al., 2005) has been

---

[3] Available at http://sanskrit.inria.fr/, SHR is a lexicon-driven segmenter which produces all the valid word splits. An interface is provided for manual selection of a solution (Goyal and Huet, 2016)

[4] For instance, segments 6 and 7 in Figure 1a are connected, while 6 and 9 are not.

[5] The word splits in an exhaustive segmentation often overlap and sometimes leave gaps by virtue of Sandhi. For examples, please refer the §1 supplementary material.

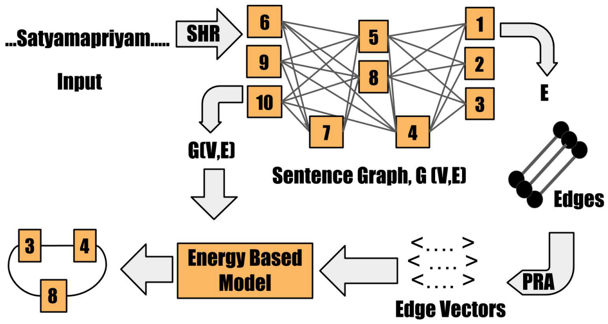

Figure 2: Architecture for the proposed model. Word-splits for '*satyamapriyam*', a sub-sequence of the sentence in Figure 1a are considered here. The nodes are numbered from 1 to 10 and are marked with the same in Figure 1a. For simplicity, we assume that words in nodes 4 to 10 have only one morphological analysis each.

a popular approach for fusional languages (Goldberg and Tsarfaty, 2008; Cohen and Smith, 2007; Hatori et al., 2012). In a lattice, there will be edges only between the adjacent word splits of an exhaustive segmentation. We deviate from this norm in a minor yet fundamental way. In the search space, we choose to add edges between every pair of word splits that are part of a single exhaustive segmentation. Henceforth, we will refer this structure as the sentence graph G. We then employ our minimum cost maximal clique finding energy based model on the sentence graph G. Figure 2 shows the proposed architecture of the model. It shows the sentence graph G for '*satyamapriyam*', a sub-sequence of the sentence in Figure 1a.

Our current design choice results in a denser graph structure as input and a computationally expensive inference. Such a choice requires justification. Currently, there exist digitised versions of texts which spans over a period of 3000 years categorised into pre-classical literature (1500 BCE - 100 BCE), classical literature (300 CE - 800 CE) and modern literature (900 CE to now). Hellwig (2009) assert that the assumption that Sanskrit syntax has remained unchanged over an interval of over 3000 years is not valid. Kulkarni et al. (2015) notes that the constructions in prose generally follow weak non-projectivity (Havelka, 2007; Maier and Lichte, 2011). Kulkarni et al. (2015) also observes that constructions in verses violate weak non-projectivity especially with the adjectival and genitive relations. A large number of texts are written in verses or to complicate things further, they are written as a combination of prose and verse. A lack of consensus among the experts on a common set of rules for works across the different time spans, and the enormous effort in categorising constructions based on their writing styles, motivated us to use this graph construction scheme which is agnostic to word order.

Graph Formation:[6] In Figure 1a, identical surface-forms with the same root are grouped together and displayed as a single entity. But we consider, every unique combination of root, morphological class and the word position in SHR as a separate node in $G(V,E)$. Hence the surface-from *satyam*, appears as 6 separate nodes numbered from 1-3 and 11-13 in Figure 1a. Here the nodes 1-3 differ from each other in terms of their morphological classes. The nodes 1 and 11 differ only in terms of their position owing to its repeated occurrence in the input. The position information is opaque to our proposed system and is used only in forming the nodes for the sentence graph. During the inference, we consider all the pairwise potentials as contexts for each of the prediction made in the search space. The edges in our model should capture the likeliness of two nodes to co-occur in the final solution. Hence, every pair of nodes that can co-occur in an 'exhaustive segmentation' forms two directed edges, one each at either of the directions.

Energy Based Model (EBM) Architecture: Our approach is inspired from the graph based parsing approaches employed generally for dependency parsing (McDonald et al., 2005b; Carreras, 2007) and follows a likewise structured prediction paradigm (Taskar et al., 2005). Specifically, we use an EBM where we model our joint task as search for a maximal clique with minimum energy. Learning consists of finding an energy function that associates lower energies to cliques with increasing similarity to the correct clique. The correct clique configuration will have the lowest energy (LeCun et al., 2006). The inference policy, a maximal clique selection algorithm, is used to make the predictions.

We follow an approach similar to the arc-factored approaches in graphs (McDonald et al., 2005b; Carreras, 2007), where the total energy of a maximal clique, $T_i = (V_{T_i}, E_{T_i})$, is decomposed as the summation of energies of its

---

[6] Our graph construction approach is explained using finite state methods in §1 of the supplementary material

edges (Ishikawa, 2011).

$$\mathcal{S}(T_i) = \sum_{e_{pq}\in E_{T_i}} \mathcal{S}(\vec{e}_{pq})$$

where, $V_{T_i} \subseteq V, E_{T_i} \subseteq E$. The edges are featurised. For an edge $e_{pq} \in E$, the features are represented as a vector, denoted by $\vec{e}_{pq}$. For a given edge, the energy function, $\mathcal{S}(\cdot) : [0,\infty)^{|\vec{e}|} \rightarrow (-\infty,\infty)$, takes the edge feature vector and produces a scalar value as the energy assignment.

Loss Function and Training: We use Hinge Loss (Altun et al., 2003; Taskar et al., 2003) as our loss function. The hinge loss is formulated such that it increasingly penalises those cliques, sampled by our inference algorithm, with increasingly more number of wrong segmentation candidates. We minimise the hinge loss L which is defined as

$$L = max(0, \mathcal{S}(T_{GT}) - \operatorname*{argmin}_{T_i\in A^Q}(\mathcal{S}(T_i) - \Delta(T_i))$$

Here, A^Q denotes the set of all the unique maximal cliques and T_{GT} denotes the maximal clique corresponding to the ground truth.

The margin $\Delta(T_i)$ is defined as $\Delta(T_i) = |V_{T_i} - V_{GT}|^2$. We minimise the given loss function using gradient descent method. The network parameters are updated per sentence using back-propagation. The hinge loss function is not differentiable at the origin. Hence, we use the subgradient method to update the network parameters (Socher et al., 2010; Ratliff et al., 2007). We use a multi-layer perceptron network with a single hidden layer and a leaky ReLU activation function at the hidden layer for the training.

Inference Policy: For the maximal clique selection, we use a greedy heuristic approach inspired from Prim's algorithm (Prim, 1957). The policy is described in Algorithm 1.

In Algorithm 1, we start the clique selection with a single node. At any given instance, we loop through the nodes in the graph which are not yet part of the clique. We add a vertex v to the clique if the cumulative score of all the edges from v to every vertex that is already in the clique is the minimum. We discard all the nodes which are conflicting with vertex v. "Conflicting" nodes are any pair of nodes which are not connected by an edge between them. This follows from the construction of the graph G, as the non-connectivity between the nodes implies that they are proposed as alternative word suggestions in G. As guaranteed by our sentence graph construction, we obtain the maximal clique (*exhaustive segmentation*) when there exist no more vertices to loop through. We perform this for every node in the graph G. From all the cliques so obtained we select the maximal clique with the least score. The approach does not guarantee enumeration of all the cliques, but it is guaranteed that every node will be covered by at least one maximal clique. The heuristic can be seen as a means of sampling some potential minimum energy maximal cliques for the learning task. Energy based models do not require proper normalisation of the solution space (LeCun et al., 2006), a choice that enables the use of the heuristic.

Algorithm 1: Greedy maximal clique selection heuristic

```
1 for each node $v_i$ in $V$ do
2     Initialize a graph $K_i(V_{K_i}, E_{K_i})$ with
        $K_i = G$ such that $V_{K_i} = V$ and
        $E_{K_i} = E$. Initialise a vertex set $V_{T_i}$ with
        $v_i$ as the only element in it. Remove all
        the vertices which are conflicting with $v_i$
        from $K_i$.
3     Add the vertex $v_j \in (V_{K_i} - V_{T_i})$ to $V_{T_i}$,
        such that in $K_i$, the sum of edge weights
        for the edges starting from $v_j$ to all other
        vertices in $V_{T_i}$ is minimum.
4     Remove all the vertexes which are
        conflicting with $v_j$ from $V_{K_i}$.
5     Repeat steps 3 - 4 till $V_{K_i} - V_{T_i} = \varnothing$
6 end
```

During inference, the greedy clique selection heuristic is performed for every node in G. Though the run-time for this inference is polynomial, it can still be computationally expensive. But, in practice we find that our inference procedure results in faster output for graphs with > 19 nodes in comparison to the exponential time Bron-Kerbosch algorithm (Tomita et al., 2006; Bron and Kerbosch, 1973) for clique enumeration (McDonald et al., 2005a). We further improve the run time of our inference procedure by paralleling the clique selection procedure for each node on a separate thread.

3 Feature Generation for the Edges

Given two non-conflicting nodes in G, there exists a pair of directed edges, one each in either direction. For every edge in the sentence graph G, we need to generate features that capture the distributional information between the candidate nodes that the edge connects. Similar in spirit to Bilmes and Kirchhoff (2003) and Krishna et al. (2016), we condition the distributional information based on different morphological constraints to enrich the context. The distributional information is obtained from a morphologically tagged corpus $\mathcal{C}$. Let $\mathcal{V}_w$, $\mathcal{V}_m$ and $\mathcal{V}_r$ be the vocabulary of the inflected word forms, morphological classes and the roots respectively in the corpus. Let $\mathcal{V} = \mathcal{V}_w \cup \mathcal{V}_m \cup \mathcal{V}_r$. For each $n_i, n_j \in \mathcal{V}$, the conditional probability is calculated as $P_{co}(n_j|n_i) = \frac{count(n_j,n_i)}{count(n_i)}$. Here $count(\cdot)$ represents the count of co-occurrence between the entries in the corpus. Also, let MC be the set of morphological constraints used for conditioning the distributional information. Now, for each $n_i, n_j \in \mathcal{V}$ and each $g_k \in MC$, we can obtain the feature value as follows:

$$P_{g_k}(n_j|n_i) = -log(P_{co}(n_j|g_k) \times P_{co}(g_k|n_i))$$

We use the following scheme for feature generation. A node in G essentially contains three attributes, namely, the root, the morphological class and the inflected word form. A feature uses corpus evidence of exactly one of the three attributes. For instance, consider two candidate nodes o_1, o_2 in G with (o_{1w}, o_{1m}, o_{1r}) and (o_{2w}, o_{2m}, o_{2r}) as the respective 3-tuple attributes. Now, one such possible feature value for the edge from o_1 to o_2 can be calculated as $P_{g_1}(o_{1r}|o_{2w})$ where $g_1 \in MC$ and $o_{1r}, o_{2w} \in \mathcal{V}$. Hence, features for a directed edge connecting two different nodes in G can be generated in $3 \times |MC| \times 3$ ways.

We automate the process of feature generation and feature selection using the framework of Path Ranking Algorithm (Lao and Cohen, 2010). Formalising our approach using PRA leads to an efficient and scalable implementation of our scheme. In PRA, enumerating and generating all the possible features needs to be performed only for a sampled set of data pairs from the corpus. By using a supervised feature selection approach, a relevant sub-set of features is filtered. This is a one-time process (Gardner and Mitchell, 2015). During inference, the feature values are computed only for the filtered features. [7]

Morphological Constraints: MC is defined as the set of grammatical category combinations, each combination falling into one of the following two descriptions. a) *Complete combination*, i.e., a morphological class – In Sanskrit, similar to Czech (Smith et al., 2005), a morphological class represents a certain combination of grammatical categories. For instance, a noun is represented by case, gender and number. Hence, the combination 'genitive-masculine-singular' forms a morphological class. b) *Partial combination* - A combination of grammatical categories, which can form a morphological class by adding one or more categories to it. For instance, 'genitive-masculine' is a partial combination that denotes all the possible (three) morphological classes which differ from each other only in terms of the category 'number'. However, 'genitive-present tense' is not a 'valid' combination as it can never form a valid morphological class. The evidence for a partial combination in the corpus $\mathcal{C}$ can be obtained by summing the evidence of all the morphological classes which it denotes. We obtain a total of 528 morphological constraints. A filtered set of 1500 features (out of 4752) is used in our model. Mutual Information Regression (Kraskov et al., 2004) with the word to word co-occurrence probability as label is used for feature selection.[8]

4 Experiments

Dataset: We use the Digital Corpus of Sanskrit (DCS) (Hellwig, 2010-2016), a morphologically tagged corpus of Sanskrit, for all our experiments. DCS contains digitised works from periods that span over 3000 years and contain constructions written in prose or poetry. Identifying sentence boundaries in Sanskrit constructions is a challenge of its own (Hellwig, 2016). DCS currently has split the corpus into more than 560,000 text lines, all of which need not be following explicit sentence boundaries. Krishna et al. (2016) identify 350,000 constructions from the DCS fit for the segmentation task. They use a separate set of 9,577 constructions from the DCS, called as 'DCS10k', and use it as the test set. They ignore the remaining text lines from DCS due to ambiguities either in the provided tagging or alignment with SHR (Krishna et al., 2017). We use the 350,000 constructions used in Krishna et al.

---

[7] The edge vector formation is explained in terms of Metapaths (Sun, 2010) in §3 of the Supplementary.

[8] For different settings we experimented with, for the vector generation, refer to §4 of the supplementary material.

(2016) as the corpus $\mathcal{C}$ (§3) for the generation of our edge vectors. 'DCS10k' was neither used in the training of our model, nor in the generation of edge vectors. Reddy et al. (2018) report their results on a subset of DCS10k containing 4,200 sentences, which we will refer to as 'DCS4k'.

We experiment with the following systems:

SupervisedPCRW: Proposed in Krishna et al. (2016), this model also uses the graph output from SHR. Using PCRW (Lao and Cohen, 2010; Meng et al., 2015), feature vectors for edges are generated using hand-crafted morphological constraints. Starting with the longest word in the graph, the prediction is performed by greedily selecting the candidates as per the edge weights.

EdgeGraphCRF: This is a second order CRF Model (Müller and Behnke, 2014; Ishikawa, 2011) which uses the sentence graph structure G as the input to the system. Every node is represented with fastText (Bojanowski et al., 2017) word embeddings trained under default settings. The edges are featurised with the PRA vectors (§3). We used 1-slack structured SVM for training. For the binary class problem, QPBO (Rother et al., 2007) inference approach provided the best results.

Seq2Seq - Reddy et al. (2018) uses an Encoder-Decoder framework with LSTM cells for the segmentation task. We consider two models from the work, namely, '*segSeq2Seq*' and '*attnSegSeq2seq*' as our baselines. The later which uses attention (Bahdanau et al., 2015) is the current state of the art in Sanskrit word segmentation.

Lattice-EBM: An energy based sequence labelling model, where the input is a lattice (Wolf and Woods, 1977) similar to that of Kudo (2006). The model can be seen as a special case of Graph Transformer Networks (LeCun et al., 1998, 2007). In the lattice structure, the candidate links only to its adjacent nodes in an exhaustive segmentation. We also generate edge vectors for the dummy nodes that act as the start and end markers in the lattice. During prediction, we have to find the best path from the lattice which minimises the sentence score. Here, we consider two variants of Lattice-EBM. *L-EBM-Vanilla* uses the discriminative forward training approach (Collobert et al., 2011) with the standard hinge loss. The second variant *L-EBM-Beam*, uses multi-margin loss (Edunov et al., 2018), instead of the hinge loss. Here, we employ beam search to generate multiple candidates as required by the loss.

Tree-EBM: The baseline model works exactly the same as the proposed model where the only difference between both is in the inference algorithm used. Tree-EBM has an inference that searches for a Steiner Tree (Takahashi, 1980) from the input graph $G(V, E)$, the structure of which is described in §2.[9] The inference procedure outputs a spanning tree that covers a subset of the nodes from G. This raises a challenge while estimating the loss as, unlike in the case of a clique, there can be multiple rooted tress that spans the subset of nodes in the ground truth. In this model, we augment the loss L_{tree} such that the Steiner tree with the least energy that spans the nodes in ground truth is chosen.

$$\begin{aligned} L_{tree} = max(0, & \operatorname*{argmin}_{T_m \in A^G} \mathcal{S}(T_m) \\ & - \operatorname*{argmin}_{T_i \in A^Q} (\mathcal{S}(T_i) - \Delta(T_i)) \end{aligned}$$

Here A^G represents set of all the trees that spans the nodes in the ground truth.

Clique-EBM: The proposed model. The EBM model uses the maximal clique selection heuristic for the inference.

Tasks and Evaluation Measures: We use the macro-averaged Precision (P), Recall (R), F1-score (F) and also the percentage of sentences with perfect matching (PM) as our evaluation metrics. We evaluate the competing systems on the following two different tasks.

*Word Prediction Task **(WPT)*** - The word segmentation task is evaluated based on the correctness of the inflected word forms predicted. This was used in Krishna et al. (2016).

*Word++ Prediction Task **(WP3T)*** - This is a stricter metric for the evaluation of the joint task of segmentation and morphological tag prediction. It evaluates the correctness of each of the inflected word form, lemma and its morphological tag.

4.1 Results

Table 1 provides the results for the best performing configurations for each of the systems. The results for WPT on DCS4k and WP3T on DCS10k for each of the systems are shown in Tables 1.A and 1.B. The proposed model, Clique-EBM (System 8), outperforms all the other models across all the 4 metrics on both the tasks. Clique-EBM shows an

Table 1: Performance evaluation of the competing systems in ascending order of their F-Score.

improvement of 7.06% and 40.79% in terms of F-score and *perfect matching* from the current state of the art (System 6) in WPT. Currently there exists no system that predicts the morphological tags for a given word in Sanskrit. For WP3T, Clique-EBM has shown a percentage increase of 11.64% and 69.65% in F-Score and the perfect matching score from Tree-EBM, the next best system.

All the systems except 1 and 6 in Table 1.A use the linguistically refined output from SHR as their search space to predict the final solution. Out of which 3, 4, 5, 7 and 8 use the edge vectors, which encodes the morphological constraints refined using PRA (Lao and Cohen, 2010), generated by the method discussed in §3. As a result these systems require <10% training data than required by system 6. System 3 was trained on 10,000 sentences, while systems 4 and 5 were trained on 9,000 sentences after which the models got saturated. Systems 7 and 8 were trained on 8,200 sentences which is 7.66% of the training data (107,000) used in System 6. In terms of training time, Reddy et al. (2018) reports a training time of 12 hours on a GPU machine, while systems 7 and 8 take a training time of 8 hours on an Intel Xeon CPU based machine with 24 cores and 256 GB RAM.[10] For systems 4 and 5 it takes roughly 4 hours to train on the same machine. There was no training involved for the prediction of segmentations in system 2.

In systems 4 and 5, the inference is performed sequentially from left to right[11]. The use of beam search with multi margin in System 5 resulted in marginal improvements (<2) in terms of F-Score to that of system 4. Further, the improvement in the results saturated after a beam size of 128. System 3 being a second order CRF model (Ishikawa, 2011), does not take the entire sentence context into account. In fact, about 85.16% of the sentences predicted by the model from DCS10K do not correspond to an '*exhaustive segmentation*'. Prediction of an '*exhaustive segmentation*' is guaranteed in all our EBM models 4, 5, 7 and 8 (also in system 2) by virtue of the inference procedure we use. Both systems 7 and 8, along with System 6 which uses attention, consider the entire input context when making each prediction. System 8 considers all the pairwise potentials between the nodes while making a prediction, but System 7 does not (Steiner tree vs. maximal clique).

Figure 3 reports the performance of the systems 2, 5, 6 and 8 where the sentences in DCS4k[12] are categorised based on the number of words presented in the segmented ground-truth solution. Our proposed system Clique-EBM performs the best across all the lengths with an exception towards shorter constructions of 2 words or less. Interestingly, both the sequential models (systems 5 and 6) show a decreasing trend as the number of words increases, while the Clique-EBM model shows an increasing trend with a larger length, which might indicate that more context helps the model. In fact, the greedy yet non-sequential approach used in Krishna et al. (2016) outperforms both the sequential models at longer lengths. The average length of a sentence in DCS is 6.7 (Krishna et al., 2016), the share of sentences with seven or more words is 62.78%.

4.2 Fine Grained Analysis on Clique-EBM[13]

Pruning the edges in sentence graph G: Constructions in Sanskrit follow weak non-projectivity (with exception to verses), implying that they adhere to the principle of proximity (Kulkarni et al., 2015). By proximity we expect that the words in a phrase go together, without being interrupted by a syntactically unrelated word.

---

[10] Please refer §4 of the supplementary for wall time analysis. System 6, when trained on this CPU based system, did not converge even after 15 hours of training.

[11] We also tried reversing the input effectively enabling the right to left direction but the results were worse than the reported system by an F-Score of 3.

[12] sentences with length more than 12 words are not shown as such sentences appear less than 10 times in DCS4k.

[13] For hyper-parameter settings, and other fine-grained analysis refer to §4 of the supplementary material.

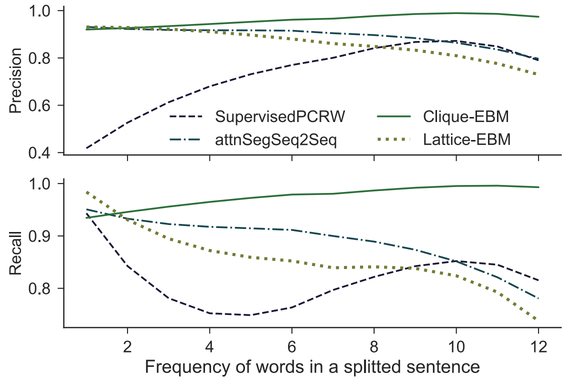

Figure 3: Performance of the competing systems for DCS4k grouped on the word counts in the ground-truth

Verb	89.14	95.91	87.38	94.42
Compound	89.35	93.52	86.01	91.07
Indeclinable	95.07	97.09	94.93	96.47

Table 3: System performance on the coarse level POS for the competing systems Clique-EBM (C-EBM) and Tree-EBM (T-EBM)

But the relative ordering between the phrases in a construction and the order of words within a phrase can be free.

For any two words appearing in an exhaustive segmentation, we keep an edge only if both the words overlap within a distance of k characters. We experiment with k = 5, 10, 15 and 20. Hence, for $K = 20$, a word will form edges with all the words that fall within 20 characters to left and 20 characters to right. The average length of an input sequence in DCS10K is 40.79 characters. We do not modify our inference procedure in system 8 other than to take care of the possibility that a clique need not always be returned. Table 2 shows the results for different values of k. Interestingly, the results show a monotonic increase with the increase in context window, and the results with the entire context are still better than those with $k = 20$, even though only marginally. It is interesting to note that, keeping the entire context does not adversely affect the predictions as none of the pruned models outperforms System 8.

The lattice structure can be seen as an extreme case of pruning. We modify System 4 to use a non-sequential inference procedure, adapted from System 7. Here, the start and end markers were removed. Additionally, a given connected node pair has 2 edges, each in either of the directions. We find that the model gives an F-Score of 87.4 which outperforms System 4 by more than three points.

Out of Vocabulary words: As described in §3, the distributional information from DCS is used as the corpus $\mathcal{C}$ for the feature generation. For the case of OOV in roots ($\mathcal{V}_r$), we use add-1 smoothing. But, for the case of OOV in inflections ($\mathcal{V}_w$) we find that using the evidence from corresponding root of the candidate is beneficial. DCS10k has 8,007 roots of which 514 are OOV and 833 occur only 1 to 5 times. The micro-averaged F-Score for these are 57.98 and 72.87, respectively.

Morphological class specific assessment : Table 3 presents the micro-averaged recall for the words grouped based on their parts of speech (POS) for Clique-EBM and Tree-EBM. Both the systems follow similar trends and the morphological class misprediction is highest among the nouns and compounds (WP3T Recall). It also needs to be noted that the improvement made by Clique-EBM in comparison to Tree-EBM for WP3T was also on prediction of noun and compound morphological classes. Also in Tree-EBM, the mispredictions in compounds were mostly cases of the system getting the compound components confused to one of the morphological classes in nouns.

We find that considering the pairwise potential between all the words in a sentence in Clique-EBM led to improved morphological agreement between the words in comparison to Tree-EBM. In Tree-EBM, the top 5 cases of mispredictions from one morphological class to a particular wrong class were between those classes of nouns that differed in exactly one of the three possible grammatical categories, namely gender, number or declension, that makes up a noun. In Clique-EBM such patterns were not anymore present and more importantly the skewedness in such mispredictions were considerably reduced.[14]

Summarily, our non-sequential method of inference results in better performance in comparison

---

[14] Please refer to Tables 6 and 7 in the supplementary material for details

to the sequential models. We also find that the sequential models see a drop in their performances when the number of words in a sentence increases. Leveraging the pairwise potentials between every connected nodes while making a prediction improves the performance. The performance gain of Clique-EBM over Tree-EBM illustrates the effectiveness of this approach.

5 Discussion

In Sanskrit, syncretism (Crystal, 2011) leads to ambiguity during morphological analysis. It can further be observed that such common root identical surface forms often have one or more common grammatical categories in their morphological classes (Goyal and Huet, 2016). We find that the first three models in Table 1.B often end up predicting an identical surface-form with an incorrect morphological tag, thus affecting the WP3T scores.[15]. The grammatical categories in a morphological class are indicative of the syntactic roles and the morphological agreement between the words in a construction. We empirically observe that the inference procedure for clique-EBM, which considers the entire input context and pairwise potentials between the candidates, helps in improving the performance of the model. A similar observation regarding incompatible morphological agreements between predicted words was made by Hassan et al. (2018) for their NMT model. The authors introduced an elaborate 2 phase decoder and a KL-Divergence based regularisation to combat the issue.

The energy based model (EBM) we propose is a general framework for structured prediction in Sanskrit. EBMs are widely used for various structured prediction tasks (LeCun et al., 2007; Belanger and McCallum, 2016). Belanger (2017) states that, "CRFs are typically attributed to Lafferty et al. (2001), but many of the core technical contributions of the paper appeared earlier in LeCun et al. (1998)." GTNs (LeCun et al., 1998), in fact, work on a graph based input very similar to that of a lattice, a variant of which we use in L-EBM-Vanilla. For dependency parsing, use of a word-level lattice structure similar to Seeker and Çetinoğlu (2015), where all the homonyms and syncertisms of a given surface-form form a lattice, will potentially result in a reduced candidate space than ours. Additionally, our model currently does not take into account the phrasal nature of compounds in Sanskrit (Lowe, 2015). This can further reduce the edge density in our current graph construction. But, this needs further exploration, as current edge vectors may not be suitable for the task. To generate the possible candidates, we rely completely on the SHR. In case of words not recognised by the lexicon driven SHR, analysis of sentences with a partially recognised portion is still possible. Once a root is added, all its inflections can be generated by the SHR automatically.

6 Conclusion

We proposed a novel approach to tackle word segmentation and morphological tagging problem in Sanskrit. Our model outperforms Reddy et al. (2018), the current state of the art, with an F-Score of 96.92. Reddy et al. (2018) report that the extension of their model to perform morphological tagging is not straightforward, as they learn a new sub-word vocabulary using the sentencepiece model (Schuster and Nakajima, 2012).

The free word order nature of the language motivated us to consider the input to be a graph so as to avoid the sequential processing of input. For the EBM we use, there is no requirement of proper normalisation (LeCun et al., 2006). We benefit from this as we perform a search in the space of complete outputs and there is a combinatorial explosion in the output space for a linear increase in the input space (Doppa et al., 2014). The pretraining of the edge vectors with external knowledge in the form of morphological constraints is effective in reducing the task specific training size (Yang et al., 2017; Andor et al., 2016).

Acknowledgements

We are grateful to Oliver Hellwig for providing the DCS Corpus and Gérard Huet for providing the Sanskrit Heritage Engine, to be installed at local systems. We extend our gratitude to Amba Kulkarni and Rogers Mathew, along with Gérard for helpful comments and discussions regarding the work. We thank the anonymous reviewers for their constructive and helpful comments, which greatly improved the paper. We are indebted to Unni Krishnan T A for his contributions towards implementation of the framework.

A Challenge Set and Methods for Noun-Verb Ambiguity

Ali Elkahky, Kellie Webster, Daniel Andor, and Emily Pitler
Google AI Language
`{alielkahky, websterk, andor, epitler}@google.com`

Abstract

English part-of-speech taggers regularly make egregious errors related to noun-verb ambiguity, despite having achieved 97%+ accuracy on the WSJ Penn Treebank since 2002. These mistakes have been difficult to quantify and make taggers less useful to downstream tasks such as translation and text-to-speech synthesis. This paper creates a new dataset of over 30,000 naturally-occurring non-trivial examples of noun-verb ambiguity. Taggers within 1% of each other when measured on the WSJ have accuracies ranging from 57% to 75% accuracy on this challenge set. Enhancing the strongest existing tagger with contextual word embeddings and targeted training data improves its accuracy to 89%, a 14% absolute (52% relative) improvement. Downstream, using just this enhanced tagger yields a 28% reduction in error over the prior best learned model for homograph disambiguation for text-to-speech synthesis.

1 Introduction

Whether a word is functioning as a noun or a verb in a particular linguistic context critically affects the output of tasks including translation and text-to-speech synthesis. The English word *close* may be translated as either *nah* (adjective/non-verb) or *schließen* (verb) (example from Sennrich and Haddow (2016)). In text-to-speech, the homograph *lives* is pronounced /laɪvz/ (noun) or /lɪvz/ (verb; example from Sproat et al. (1992)).

While downstream applications require taggers be sensitive to non-local linguistic context, it is difficult to measure such sensitivity with current tagging evaluation. In the past 15 years since Collins (2002), many models have accuracy exceeding 97% when measured on the WSJ Penn Treebank, which is within the level of human inter-annotator agreement for the corpus. Incorporating non-local context via sentence-based representations (Collobert et al., 2011) or state-of-the-art contextual representations of tokens (ELMo, Peters et al. (2018)) yields the same tagging accuracy as Collobert et al.'s limited window-based representation (97.3%). However, existing local models "regularly make egregious errors" (Manning, 2011), notably on imperative detection[1]. That is, the applicability of the part-of-speech labeling task is limited by its standard evaluation not reflecting difficult cases which require contextual reasoning to resolve ambiguity.

In this paper, we address this mismatch by creating a targeted intrinsic evaluation: a challenge dataset of over 30,000 naturally-occurring non-trivial examples of noun-verb ambiguity spanning multiple domains and containing many imperatives that non-expert humans can annotate with high agreement (Section 2). We will publicly release both the training and evaluation data[2].

We further contribute a series of modeling experiments on this data. We first show that state-of-the-art taggers perform poorly on this challenge (Table 1) and then investigate two simple and orthogonal approaches to enhancing a state-of-the-art tagger: incorporating generic contextual embeddings trained on billions of words, and incorporating thousands of examples of training data targeted for this task. Both of these approaches yield large and complementary improvements: the combined methods give an accuracy of 89.1%, a 14% absolute improvement over a state-of-the-art tagger and a 31% absolute improvement over the widely used Stanford tagger. Section 3 provides an overview of the investigated taggers, experiments, and results.

---

[1] In experiments with recipe data in Kiddon et al. (2015), an unsupervised system had an F1 score over 20% higher in absolute terms than supervised taggers.

Brussels, Belgium, October 31 - November 4, 2018.

Model	WSJ	NV
Existing Taggers		
Toutanova et al. (2003)	97.24	57.6
Choi (2016)	97.64	71.2
Dozat et al. (2017)	97.33	70.4
Bohnet et al. (2018)	**98.00**±.12	74.0±1.2
Enhancements		
+ELMo	**97.94**±.08	82.1±0.9
+NV Data	**97.98**±.11	86.4±0.4
+ELMo+NV Data	**97.97**±.09	**88.9**±0.3

Table 1: Empirical Results. All investigated new and existing taggers are within 1% of each other when measured on the WSJ test set. When evaluated on the Noun-Verb dataset, however, existing taggers range from 57% to 74%. Adding enhancements to the Bohnet et al. (2018) tagger gives over 14% absolute improvement. Best results and results insignificantly different from the best are bolded (two-tailed t-test).

Finally, we demonstrate that these tagging improvements make a positive impact on the downstream task of homograph disambiguation for text-to-speech (Section 4).

2 Noun-Verb Dataset

Consider the ambiguous examples below:

(1) Certain insects can damage plumerias, such as mites, **flies**, or aphids. **NOUN**

(2) **Mark** which area you want to distress. **VERB**

All tested existing part-of-speech taggers (Table 1) mistag both of these examples, tagging *flies* as a verb and *Mark* as a noun[3]. Looking at only the WSJ Penn Treebank, all occurrences of *Mark* are nouns, so a part-of-speech tagger that ignores context completely could appear to do quite well on this word type. Similarly, all occurrences of the word type *share* in the WSJ development set are noun instances.

A baseline of selecting the most frequent tag per word type (ignoring all context) achieves 93.0% accuracy on the ambiguous tokens in the WSJ (Table 2). A simple tagger based on a single hidden layer feed-forward neural network with 128 units that uses a three word window around the focus token as features achieves an accuracy of 97.0% on the WSJ ambiguous words (WSJ:NV).

Train	Dev	Type Majority	NN ±3 Words
WSJ:NV	WSJ:NV	93.0	97.0
NV	NV	70.1	77.6

Table 2: Taggers that use no context (Type Majority) or very little context (NN ±3 words) can achieve high accuracies on the ambiguous tokens in the WSJ (WSJ:NV), but would fare much worse on the Noun-Verb dataset.

We therefore aim to create a dataset in which taggers would have to take into account the surrounding context in order to correctly tag ambiguous words, rather than relying on skewed priors per word type. We design a methodology for identifying and labeling hard cases of noun-verb ambiguity. The result is a dataset of over 30,000 hand-labeled, natural, and non-trivial examples of noun-verb ambiguity, which we will make publicly available to facilitate research on modeling for this task.

2.1 Collection Methodology

Our goal is to build a resource which captures a wide range of challenges that a part-of-speech tagger needs to handle in the wild. To produce this resource, we find large sources of *naturally occurring* examples with a diversity of challenges, identify *noun-verb ambiguity*, find the *non-trivial* examples, and finally acquire *high-precision labels* from humans.

2.1.1 Naturally Occurring Sources

All examples come from naturally occurring English web text from three distinct genres. Typical examples from each are shown in Table 3. These genres present a diverse range of challenges: genre 1 has long well-edited sentences, genre 2 makes heavy use of imperative verbs, and genre 3 contains largely headline style short sentences.

2.1.2 Ambiguous Token Detection

We used an online dictionary to identify ambiguous word *types* (such as *play*) that can be either a noun or a verb.[4] To find ambiguous *instances* of these types, we ran a CRF-based tagger similar to Toutanova et al. (2003) over the input sen-

---

[3] The enhanced tagger that uses both contextual word embeddings and data augmentation (+ELMo+NV Data in Table 1) gets both Example (1) and Example (2) correct.

[4] We exclude a short stop list (*do*, *name*, *state*); the final list contains 24,170 word types.

Representative Examples	Label
Genre 1	
“**Man** With a Vision” peaked at #91 in the UK, spending two weeks on the chart.	**NOUN**
40.7% of the population **benefit** from public assistance as of 2004, up from 23.0% in 2000.	**VERB**
Genre 2	
Your doctor may recommend a diet or **exercise** routine.	**NOUN**
Use within 3 days of cooking.	**VERB**
Genre 3	
Safeguard Infrastructure From Electrical **Surges** & Limit Downtime.	**NOUN**
Stop In Today Or Shop Online!	**VERB**

Table 3: Noun and Verb examples from each genre. All examples are taken from the development set.

tences. We selected tokens tagged as either a noun or a verb[5] and for which the k-best list for that token contained both noun and verb[6] tags with close scores. We used a heuristic that the lower scoring tag had to have a score within 20% of the score of the higher.

2.1.3 Filtering Trivial Examples

Part-of-speech tagging is already a well-established task with plenty of existing labeled examples. Adding more examples similar to *John watched a play* would not affect the output predictions of taggers, which already tend to correctly label tokens as nouns if they follow determiners. Inspired by work on active learning (Tomanek and Hahn, 2009; Small and Roth, 2010), we focused our data collection efforts on difficult examples. To remove easy contexts, we excluded tokens preceded by a determiner or modal verb. Tokens[7] were additionally restricted to be neither adjectival modifiers[8] nor components of noun-compounds[9].

2.1.4 Diversification

Noun-verb disambiguation is a challenge for modern POS taggers both because words can look simultaneously noun- and verb-like to a model, but also because verbs (nouns) can falsely present as nouns (verbs). Our extraction methodology is well-designed to identify the former. To identify tokens on which models are falsely confident, we manually reviewed a sample of tokens discarded in extraction. We found that sentence-initial imperative verbs were very likely to be confidently tagged as nouns. To ensure that this important class of ambiguous tokens was included in our dataset, we made it a special extraction case and did not apply the above filters for trivial examples.

Agreement Type	#	%
Unanimous	23,908	71.4%
Majority	9,122	27.3%
Disagreement	432	1.3%

Table 4: Inter-annotator agreement rates. Unanimous examples had 3/3 agreement, while *majority* examples had 2/3, 3/5, or 4/5 in agreement.

2.1.5 Crowdsourced Annotation

We presented annotators with the extracted tokens in their full sentence context. Annotators were asked to select whether the target word was a “Noun”, a “Verb”, “Ambiguous”, or “Neither” (a noun or a verb). Full annotation guidelines will accompany the dataset release. Each example was annotated by at least three annotators for quality assurance. For batches with larger than average proportions of non-unanimous annotations, the non-unanimous examples were sent to an additional two annotators for a total of five annotations. Table 4 shows that annotators generally had a high level of agreement with each other, with unanimous agreement on 71.4% of the examples and majority agreement on 98.7% of the examples. Annotators achieved an average pace of 40 seconds per sentence.

---

[5] Nouns and verbs were identified by mapping the fine-grained part-of-speech tag to its coarse-grained category (Petrov et al., 2012): `https://github.com/slavpetrov/universal-pos-tags/blob/master/en-ptb.map`

[6] We excluded VBN from the set of verb tags, as it often functions more similarly to non-verbs

[7] Specifically, non-sentence initial tokens

[8] Labeled as *amod* according to a dependency parser

[9] Labeled as *nn* according to a dependency parser

Genre	Train	Dev	Test
1	8621	1081	2711
2	6160	919	2289
3	9473	400	1000
All	24254	2400	6000

Table 5: Noun-Verb dataset statistics.

2.2 Final Dataset

To compile the final dataset, we rejected examples in which there was no majority agreement or in which the majority label was "Ambiguous" or "Neither". This excluded 808 sentences and yielded a final dataset size of 32,654. We divided this into training, development, and test sets. Table 5 shows the dataset sizes and genre distributions. The genre distribution of the training set is intentionally different from that of the development and test sets, as realistically one will often have different distributions at training and test time, and future work may want to model this difference (Donmez et al., 2010; Steinhardt and Liang, 2016).

We asked a professional linguist to independently label 200 examples and adjudicate any differences from the crowd-sourced labels with other professional linguists. The linguists found only 7 actual mistakes (3.5% of examples). Of the remaining 96.5% plausible annotations, the linguist agreed with the crowd in 167 cases (83.5%), and found 26 disparities between PTB-style guidelines and plausible intuitive judgments (13%). All but one of the disparities involved a word ending in *"ing"* inside a noun phrase, such as "*Manufacturing* defects"). Also, all but two of the disparities were cases which the crowd source annotators labeled as nouns while the PTB-style guidelines labeled as verbs.

While humans can do well on these instances, Table 2 shows that baseline taggers that use little or no context have high error rates on this dataset, in contrast to the WSJ.

3 Empirical Evaluation of Taggers

In this section, we demonstrate empirically the limitations of several existing taggers on the new challenge dataset. We then take the most accurate, Bohnet et al. (2018), and investigate how it can be enhanced to be much more discriminative in ambiguous contexts. We finish with some error analysis to inspire future work.

3.1 Experimental Setup

Training All experiments used the standard splits of the WSJ Penn Treebank and the new Noun-Verb dataset. Specifically, WSJ Sections 2-21 were used to train all models; where indicated, this was augmented with the training portion of the Noun-Verb dataset. Neural models (Dozat et al. (2017), Bohnet et al. (2018), and extensions) used WSJ Section 22 for early stopping, and were run with $n = 10$ random restarts to compute standard deviations.

Evaluation Models are evaluated on the Noun-Verb test set. The development set was used for developing the proposed enhancements, as well as to do error analysis. To verify performance on the standard task, we also evaluate accuracy on WSJ Section 23, cf. Table 1 first column.

Our evaluation metric is VERB/NON-VERB classification accuracy over tokens which have gold annotations. To evaluate the taggers we map the fine-grained tag output using Petrov et al. (2012): tags with a coarse-grained VERB category map to the VERB label, and all other tags to the NON-VERB label.

3.2 Existing Taggers

We evaluated four commonly used and/or state-of-the-art taggers on our task. The first investigated tagger is the Stanford POS tagger[10] (Toutanova et al., 2003), part of the Stanford CoreNLP Toolkit (Manning et al., 2014) and widely used. This pre-trained model is a log-linear model with features over the surrounding words and tags in a local window around the focus word.

The second investigated tagger is the publicly available *NLP4J*, a pre-trained tagging model (Choi, 2016)[11]. It used feature induction to expand the feature set during training by adding combinations of low-dimensional features. The approach achieved 97.64% on WSJ evaluation. It is worth noting that this model used a large automatically tagged corpus to get ambiguity classes for each word and Choi (2016) showed that this extra piece of information was responsible for the largest part of the improvement.

The third tagger is Dozat et al. (2017), which won the UPOS portion of the CoNLL 2017 Shared Task on Universal Dependencies (Zeman et al.,

---

[10] `https://nlp.stanford.edu/software/tagger.shtml`

[11] `https://github.com/emorynlp/nlp4j`

2017) by a wide margin. It represents each word by a sum of its pretrained word embedding (glove Pennington et al. (2014)), trained word embedding, and the output from an LSTM runs over word's characters. Those representations are supplied to a deep BiLSTM followed by a Multi-Layer Perceptron (MLP) layer. The output from the MLP layer is multiplied by a learned embedding for tags and the tag with the highest score is selected as the output.

Finally the fourth existing tagger is the Meta-BiLSTM (Bohnet et al., 2018) which is the current state of the art on both WSJ and CoNLL 2017 POS tagging evaluation. This model consists of three components, all of which run over the entire input sentence: a word-BiLSTM that takes a sum of pretrained (GloVe (Pennington et al., 2014)) and trained word embeddings, a char-BiLSTM that consumes trained characters embedding and a Meta component that takes a concatenation of word and character representations (at word boundaries) and feeds it to a Bi-LSTM followed by a MLP layer. The final output is computed using softmax over the Meta-MLP representation but a multi-loss is also optimized at the char and word representations level.

For Dozat et al. (2017) and Bohnet et al. (2018), we trained the model on WSJ PTB training data to get comparable models to the two previous systems. For Dozat et al. (2017) we used the default hyperparameters. For Bohnet et al. (2018), the hyperparameters used are almost identical to the original paper.[12]

The first two taggers are linear models (with feature combinations) while the second two are neural models. Both Dozat et al. (2017) and Bohnet et al. (2018) take non-local context into account through BiLSTMs over the full sentence. However, these models might not use this modeling power when trained on the WSJ, since local context is usually sufficient (Table 2).

3.3 Enhancements

We take the best existing tagger (Bohnet et al., 2018) as our starting point to investigate the efficacy of two simple enhancements and their combination for improving noun-verb disambiguation.

The first enhancement is to add generic, contextual word embeddings trained on a billion words of language modeling data (Peters et al., 2018). The second enhancement is to add task-specific targeted training data, with thousands of examples derived from the Noun-Verb training set.

Contextual Word Embeddings (ELMo) The statistics of the new dataset, shown in Table 2, suggest that this dataset might benefit from more contextual modeling. Although the basic Meta-BiLSTM model is already contextual, one can suspect based on the first row in Table 2 that WSJ training might lead the model to ignore wider context. One way to make the model use more contextual information is to replace the word embedding layer with a contextual embedding. We used ELMo embeddings (Peters et al., 2018), which are generated by training a bi-directional language model on a large corpus of unlabeled data. The aim of using ELMo here is that we expect to get different embeddings for a word like "play" when it is used as a verb, as in "I will come and play", versus when it is used as a noun, as in "I liked the two-act play".

We replaced the word embedding layer in the Word component with ELMo.[13] As in Peters et al. (2018), we trained a task specific weighting of the three ELMo layers:

$$v_i^{(\text{word})} = \gamma \sum_{j=0}^{2} s_j \mathbf{h}_{i,j}^{\text{ELMo}}, \qquad (1)$$

where $\mathbf{h}_{i,j}^{\text{ELMo}}$ is the j-th layer ELMo embedding of word i, s_j are softmax-normalized weights over the layers, and γ is a scalar parameter. We trained this model on the WSJ training data only.

Targeted Data Augmentation (NV Data) Our Noun-Verb training data comes with gold binary labels ("Noun" or "Verb"). To add them to our current model, we took a simple approach to map the Noun-Verb labels into the fine-grained POS tagset used in the WSJ dataset. To do that, we ran the baseline tagger used to extract the annotated examples in §2.1 over the Noun-Verb training data, and extracted all possible tags for the annotated words, sorted by their score. We then assigned to that word the highest scoring tag consistent with the coarse-grained tags. This resulted in a silver training dataset containing partially labeled sentences, each with one word tagged by its

---

[12] Two hyperparameter differences: we used two layers instead of three for the word component and a learning rate decay of 0.99994 instead of 0.999994. These were fixed early on and not tuned.

[13] We used the "Original" model from `https://allennlp.org/elmo`.

Model	SI	¬ SI
Majority class per word type using Noun-Verb training set	74.6	69.3
Existing Taggers		
Toutanova et al. (2003)	47.4	59.6
Choi (2016)	67.8	71.0
Dozat et al. (2017)	68.3	70.7
Bohnet et al. (2018)	68.4±4.0	74.4±0.9
Enhancements		
+ELMo	73.4±2.2	82.1±1.0
+NV Data	**89.3**±0.5	85.4±0.5
+ELMo+NV Data	**90.0**±0.8	**87.6**±0.6

Table 6: Development set accuracies on sentence initial (SI) tokens compared with non-sentence-initial (¬SI) tokens.

fine-grained POS tag. We used this dataset to augment the WSJ training data. Since the Noun-Verb examples only contain one labeled token per sentence, we assigned the unlabeled tokens a cost of zero in the cost function at training time.

ELMo and Data Augmentation Together Finally, we experimented with using both enhancements together. We trained the ELMo-enhanced model on the dataset augmented with the Noun-Verb training set examples. The motivating intuition for combining them is that the inclusion of the difficult Noun-Verb training set examples could encourage the model to make more use of ELMo embeddings than the model trained on the WSJ only. Another possibility is that these two types of enhancements are redundant and that one dominates the other.

3.4 Results

Table 1 shows the main results of both existing taggers and the enhanced models on both WSJ and the Noun-Verb Challenge Set.

Existing Taggers While all four selected taggers achieve accuracies above 97% on WSJ, they all struggle on our noun-verb challenge (Table 1). The widely used tagger of Toutanova et al. (2003) has an accuracy of just 57.6%, below the 70.1% accuracy of a per-word type majority class baseline (Table 2). The best performing tagger (Bohnet et al., 2018) was 3.9% above the next best model. However it still has an error rate of 25%.

The ranking of the four taggers stays the same whether one uses the WSJ or the Noun-Verb Challenge Set for evaluation. However, the magnitude of differences changes drastically. For example, on the WSJ test set, the differences between Dozat et al. (2017) and Toutanova et al. (2003) appear insignificant: Dozat et al. (2017) improves over Toutanova et al. (2003) by 0.09% absolute (3% relative reduction in error). When measured on the Noun-Verb Challenge Set, the differences are stark: the tagger of Dozat et al. (2017) is 12.8% absolute more accurate, which is a 30% relative reduction in error.

Enhancements Experimental results in Table 1 show that ELMo gave 7.2% absolute improvement and did not significantly affect the WSJ results[14]. This is further evidence that WSJ evaluation does not model ambiguities in cases where context matters. Adding the silver Noun-Verb data to the baseline model gave 10% absolute improvement over the baseline. This is significant given that the model capacity remained unchanged. By contrast, hooking up ELMo added a very large multi-layer BiLSTM language model to the parameters.

The best model was the model which used both ELMo embeddings and data augmentation. It achieved 13.1% absolute improvement over the state-of-the-art baseline of Bohnet et al. (2018), equivalent to over a 52% error reduction. This demonstrates that the improvement from ELMo is complementary to that from the additional Noun-Verb data.

Sentence-Initial Examples The trend in Table 1 is magnified in Table 6, which shows development set accuracies separately for tokens that are sentence-initial (SI), which are often imperatives, and for tokens that are not SI.

On SI accuracy, none of the WSJ-trained baselines could beat the most-frequent-tag baseline from the Noun-Verb training data. This shows that these sorts of examples, which are mostly imperatives, are underrepresented in the WSJ corpus. ELMo embeddings were able to improve both SI and non-SI accuracies by roughly the same amount, but again, not as much as adding the Noun-Verb data, which gave a 21.7% boost to SI accuracy. The efficacy of the Noun-Verb data in this case shows that directed training examples can

---

[14] We also ran the experiment using the "Original (5.5B)" ELMo model, trained on a larger and more diverse corpus. We did not find any significant difference between the two.

Model	Tuning Set WSJ	 NV
WSJ Test Set		
Bohnet et al. (2018)	98.00±0.12	97.98±0.13
+ELMo	97.94±0.08	97.85±0.16
+NV Data	97.98±0.11	97.94±0.14
+ELMo+NV Data	97.97±0.09	97.94±0.13
Noun-Verb Test Set		
Bohnet et al. (2018)	74.0±1.2	76.9±0.6 †
+ELMo	82.1±0.9	83.4±0.5 †
+NV Data	86.4±0.4	86.8±0.4
+ELMo+NV Data	88.9±0.3	89.3±0.2 ‡

Table 7: Effect of using different tuning sets. As usual with early stopping, the best tuning set performance was used to evaluate the test set. Here, we evaluated the same experimental runs at two points: when the performance was best on the WSJ development set, and again when the performance was best on the Noun-Verb development set. The increase in Noun-Verb results is significant at the $p < 0.001(\dagger)$ and $p < 0.01(\ddagger)$ levels.

be especially beneficial for fixing some common error patterns.

Impact of Tuning Set Table 7 compares performance of the same experiments on the WSJ and Noun-Verb Challenge test sets, tuned either using the WSJ or the Noun-Verb development set. The only effect of the change in tuning set was for the Noun-Verb tuning to cause the early stopping to sometimes be a little earlier. When we tuned on the Noun-Verb development set, the WSJ results remained almost unchanged, while the Noun-Verb test set results increased significantly. We see that the performance on each dataset is best when matched with its tuning data. The effect was greatest on the unenhanced model, which improved 2.9% absolute on the Noun-Verb evaluation. The best overall Noun-Verb test set result was **89.3**±0.2 when tuned this way.

3.5 Error Analysis

Table 8 shows representative examples that the best baseline run got wrong, along with the predictions from the best runs for each of the different enhancements. While each enhancement reduces all error types, adding Noun-Verb data improves imperatives in particular when compared with adding ELMo. This holds true even when imperatives are not sentence-initial, like the *practice* example in Table 8.

Of the errors made by our best model, roughly a quarter occurred when the focus word was a conjunction. This provides additional evidence for the importance of modeling non-local context in this dataset.

4 Homograph Disambiguation

To show the impact of our best models on a downstream task, we used the text-to-speech homograph disambiguation task described in Gorman et al. (2018). The dataset contains 161 word types, each of which has up to three possible pronunciations. In that work, the authors built a linear model that used lexical features of the focus word and its surrounding words, POS tags, and capitalization, to achieve 95.4% on this task. Here, we want to see the effectiveness of our taggers by using just the POS tag of each word to determine its pronunciation category. To do this, we annotated the homograph disambiguation train and test data with with POS tags using each of our taggers. We collected counts from the training corpus of the form <*word, POS tag, word_sense, Count*>. These counts show how many times a given word got assigned to a certain word sense when it has a certain POS tag. We used those counts to select the most frequent pronunciation for each <*word, POS tag*> pair on the test data. Note that this approach will miss some word senses that cannot be determined from the word and POS tag only, like the difference in pronunciation of the word "jesus" between English: /ˈdʒiːzəs/ and Spanish: /heɪˈsuːs/.

Table 9 shows results for the micro and macro accrucies among different word types in the same way (Gorman et al., 2018) reported their results. The overall results show similar trend to what is observed in the Noun-Verb evaluation results. The Choi (2016), and Bohnet et al. (2018) baseline taggers perform close to the full model in Gorman et al. (2018), which uses a wider context and more features. This is probably due to having a stronger POS tagger than the one used in that model. It is also interesting to see the gap between Toutanova et al. (2003) and the rest of baseline taggers which was measured only on the Noun-Verb evaluation and not in WSJ evaluation. The rest of the results show that using either ELMo achieves a 1.3% absolute improvement over the baseline. while adding data augmentation achieves 0.3% absolute improvement over the baseline. Using both ELMo

Example	Gold	Base	+ELMo	+Data	+ELMo +Data
Will gets his revenge by masquerading as Sue's hairdresser and forcibly shaving her head bald.	**NOUN**	*MD*	**NNP**	*MD*	**NNP**
Will putting a patch over my eye **help** to get the object out of it?	**VERB**	*NN*	**VB**	*NN*	**VB**
If you don't have a table, you can mount the frame on a desk, **stand**, or other structure that will hold the bike off the ground.	**NOUN**	*VB*	*VB*	**NN**	**NN**
For best results, **practice** hitting one note higher than your standard range.	**VERB**	*NN*	*NN*	**VB**	**VB**
Spirit actually suggests unpacking their smokes by rolling the cigarette between your fingers, filter to **end**, so that a pinch or so of tobacco comes out.	**NOUN**	*VB*	*VB*	*VB*	**NN**
Choose the highest combat level and **duel**.	**VERB**	*NN*	*NN*	*NN*	**VB**

Table 8: Development set examples that reflect the types of errors the enhancements address. Base is the tagger of Bohnet et al. (2018), while the remaining columns show the impact of the enhancements. Tags consistent with the gold annotations are in bold and inconsistent are in italics.

Model	Micro	Macro
Best ML system		
Gorman et al. (2018)	95.4	95.1
Existing Taggers		
Toutanova et al. (2003)	91.1	91.5
Choi (2016)	95.8	95.8
Dozat et al. (2017)	94.6	94.7
Bohnet et al. (2018)	95.9±0.2	95.9±0.2
Enhancements		
+ELMo	**96.7**±0.2	**96.7**±0.2
+NV Data	96.2±0.2	96.2±0.2
+ELMo+NV Data	**96.7**±0.3	**96.7**±0.3

Table 9: Accurcies of different models on the homograph disambiguation test set. All enhancements' improvements over (Bohnet et al., 2018) baseline are statistically significant $p < 0.008$. Standard deviations are estimated from $n = 10$ random restarts, and p-values were computed using a heteroscedastic two-tailed t-test.

and data augmentation was not better than just using ELMo. Those improvements correspond to a 28% error reduction compared to the machine-learned model in Gorman et al. (2018).

5 Discussion and Related Work

Dataset Creation Prior work in crowd-sourcing syntactic annotations and using them in models motivated the dataset creation portion of this work. Jha et al. (2010) showed that non-linguists could reliably do aspects of syntactic annotation, and Hovy et al. (2014) showed that non-experts could annotate universal part-of-speech tags (Petrov et al., 2012) almost as well as experts. He et al. (2016) then showed that incorporating crowd-sourced annotations improves parsing by a noticeable margin on the *subset* of sentences in which the human judgments affected the parser's output. Inspired by this result, we focused our efforts on collecting annotations that were likely to change a tagger's predictions and humans can annotate reliably.

This work filtered out trivial examples via hand-written heuristics targeted towards examples that taggers generally get correct (Section 2.1). One interesting direction for future work would be to eliminate this manual step. One option could be to instead use automatically produced high-precision interpretable rules to filter out these examples, such as the Anchor explanations output by Ribeiro et al. (2018). Table 1 in that paper shows how the system can automatically induce that a part-of-speech tagging system will tag the word *play* as a NOUN in the sentence *I went to a play yesterday* because the previous word is a determiner.

Measurement Manning (2011) performed an error analysis for WSJ and discovered that 19% of the errors fall under "Difficult linguistics" which need non-local context modeling to be able to solve them. The negative results of Kiddon et al. (2015) on using existing supervised part-of-speech taggers for imperative detection provided motivation for focusing on noun-verb confusion. However we are not aware of any prior work on trying to measure part-of-speech-tagging accuracy on hard ambiguities that are easily recognized by human using diverse corpora.

6 Conclusion and Future Work

This paper proposes a challenge set approach to evaluating part-of-speech taggers, and builds a new resource for doing so. We show that a part-of-speech tagger can be trained to be better at noun-verb ambiguity by using extra Noun-Verb targeted training data or by adding contextual word embedding. We also show that our evaluation data can measure improvements in Noun-Verb disambiguation that standard evaluation dataset was not able to capture. Those previously unmeasured improvements in the Noun-Verb disambiguation are shown to lead to improvements in a downstream task. Improvements were especially large on sentence-initial tokens, which are often imperatives. Even with these improvements, there is still a large gap between the noun-verb accuracies and overall WSJ tagging accuracy. We expect that closing this gap will make incorporating syntax more useful across natural language understanding applications.

Future work can include exploring ways to incorporate more context into the tagger, possibly by using information from dependency tree. Also investigating more downstream tasks and explore if this dataset can be used directly in downstream tasks in a way similar to what have been done in Swayamdipta et al. (2017) and (Eriguchi et al., 2017; Niehues and Cho, 2017; Kiperwasser and Ballesteros, 2018) for injecting syntax in semantic role labeling and translation tasks. A third direction for research would be using this dataset to evaluate different contextual modeling approaches and investigate the creation and using such context sensitive dataset to create simpler and smaller models that can capture a lot of contextual word representation.

Future work on dataset creation can include generating similar challenge datasets for different key ambiguities in NLP. A collection of such datasets could be one way to cover hard examples that models do not get right but humans are good at. Such targeted datasets can complement the use of large unsupervised contextual embedding models. This can open an avenue to improve core NLP tasks on hard relevant ambiguities that allows making progress on downstream tasks.

Acknowledgments

The authors gratefully acknowledge their anonymous reviewers for their insightful questions and feedback. We are grateful to Alexander Clines, Kazoo Sone, Ashwin Kakarla, Daphne Luong, and Austin Tarango for their assistance in the creation of the dataset. Thanks also go to members of the Google AI Language group for their input to this work, including Slav Petrov, Michael Collins, and all who provided feedback in reading group sessions.

What do character-level models learn about morphology? The case of dependency parsing

Abstract

When parsing morphologically-rich languages with neural models, it is beneficial to model input at the character level, and it has been claimed that this is because character-level models learn morphology. We test these claims by comparing character-level models to an oracle with access to explicit morphological analysis on twelve languages with varying morphological typologies. Our results highlight many strengths of character-level models, but also show that they are poor at disambiguating some words, particularly in the face of case syncretism. We then demonstrate that explicitly modeling morphological case improves our best model, showing that character-level models can benefit from targeted forms of explicit morphological modeling.

1 Introduction

Modeling language input at the character level (Ling et al., 2015; Kim et al., 2016) is effective for many NLP tasks, and often produces better results than modeling at the word level. For parsing, Ballesteros et al. (2015) have shown that character-level input modeling is highly effective on morphologically-rich languages, and the three best systems on the 45 languages of the CoNLL 2017 shared task on universal dependency parsing all use character-level models (Dozat et al., 2017; Shi et al., 2017; Björkelund et al., 2017; Zeman et al., 2017), showing that they are effective across many typologies.

The effectiveness of character-level models in morphologically-rich languages has raised a question and indeed debate about explicit modeling of morphology in NLP. Ling et al. (2015) propose that "prior information regarding morphology ... among others, should be incorporated" into character-level models, while Chung et al. (2016) counter that it is "unnecessary to consider these prior information" when modeling characters. Whether we need to explicitly model morphology is a question whose answer has a real cost: as Ballesteros et al. (2015) note, morphological annotation is expensive, and this expense could be reinvested elsewhere if the predictive aspects of morphology are learnable from strings.

Do character-level models learn morphology? We view this as an empirical claim requiring empirical evidence. The claim has been tested implicitly by comparing character-level models to word lookup models (Qian et al., 2016; Belinkov et al., 2017). In this paper, we test it explicitly, asking how character-level models compare with an oracle model with access to morphological annotations. This extends experiments showing that character-aware language models in Czech and Russian benefit substantially from oracle morphology (Vania and Lopez, 2017), but here we focus on dependency parsing (§2)—a task that benefits substantially from morphological knowledge—and we experiment with twelve languages using a variety of techniques to probe our models.

Our summary finding is that character-level models lag the oracle in nearly all languages (§3). The difference is small, but suggests that there is value in modeling morphology. When we tease apart the results by part of speech and dependency type, we trace the difference back to the character-level model's inability to disambiguate words even when encoded with arbitrary context (§4). Specifically, it struggles with *case syncretism*, in which noun case—and thus syntactic function—is ambiguous. We show that the oracle relies on morphological case, and that a character-level model provided *only* with morphological case rivals the oracle, even when case is provided by another predictive model (§5). Finally, we show that the crucial morphological features vary by language (§6).

2 Dependency parsing model

We use a neural graph-based dependency parser combining elements of two recent models (Kiperwasser and Goldberg, 2016; Zhang et al., 2017). Let $w = w_1, \ldots, w_{|w|}$ be an input sentence of length $|w|$ and let w_0 denote an artificial ROOT token. We represent the ith input token w_i by concatenating its *word representation* (§2.3), $\mathbf{e}(w_i)$ and part-of-speech (POS) representation, $\mathbf{p}_i$.[1] Using a semicolon $(;)$ to denote vector concatenation, we have:

$$\mathbf{x}_i = [\mathbf{e}(w_i); \mathbf{p}_i] \tag{1}$$

We call $\mathbf{x}_i$ the *embedding* of w_i since it depends on context-independent word and POS representations. We obtain a context-sensitive *encoding* $\mathbf{h}_i$ with a bidirectional LSTM (bi-LSTM), which concatenates the hidden states of a forward and backward LSTM at position i. Using $\mathbf{h}_i^f$ and $\mathbf{h}_i^b$ respectively to denote these hidden states, we have:

$$\mathbf{h}_i = [\mathbf{h}_i^f; \mathbf{h}_i^b] \tag{2}$$

We use $\mathbf{h}_i$ as the final input representation of w_i.

2.1 Head prediction

For each word w_i, we compute a distribution over all other word positions $j \in \{0, ..., |w|\}/i$ denoting the probability that w_j is the headword of w_i.

$$P_{head}(w_j \mid w_i, w) = \frac{\exp(a(\mathbf{h}_i, \mathbf{h}_j))}{\sum_{j'=0}^{|w|} \exp(a(\mathbf{h}_i, \mathbf{h}_{j'}))} \tag{3}$$

Here, a is a neural network that computes an association between w_i and w_j using model parameters $\mathbf{U}_a$, $\mathbf{W}_a$, and $\mathbf{v}_a$.

$$a(\mathbf{h}_i, \mathbf{h}_j) = \mathbf{v}_a \tanh(\mathbf{U}_a \mathbf{h}_i + \mathbf{W}_a \mathbf{h}_j) \tag{4}$$

2.2 Label prediction

Given a head prediction for word w_i, we predict its syntactic label $\ell_k \in L$ using a similar network.

$$P_{label}(\ell_k \mid w_i, w_j, w) = \frac{\exp(f(\mathbf{h}_i, \mathbf{h}_j)[k])}{\sum_{k'=1}^{|L|} \exp(f(\mathbf{h}_i, \mathbf{h}_j)[k'])} \tag{5}$$

where L is the set of output labels and f is a function that computes label score using model parameters $\mathbf{U}_\ell$, $\mathbf{W}_\ell$, and $\mathbf{V}_\ell$:

$$f(\mathbf{h}_i, \mathbf{h}_j) = \mathbf{V}_\ell \tanh(\mathbf{U}_\ell \mathbf{h}_i + \mathbf{W}_\ell \mathbf{h}_j) \tag{6}$$

The model is trained to minimize the summed cross-entropy losses of both head and label prediction. At test time, we use the Chu-Liu-Edmonds (Chu and Liu, 1965; Edmonds, 1967) algorithm to ensure well-formed, possibly non-projective trees.

2.3 Computing word representations

We consider several ways to compute the word representation $\mathbf{e}(w_i)$ in Eq. 1:

word. Every word type has its own learned vector representation.

char-lstm. Characters are composed using a bi-LSTM (Ling et al., 2015), and the final states of the forward and backward LSTMs are concatenated to yield the word representation.

char-cnn. Characters are composed using a convolutional neural network (Kim et al., 2016).

trigram-lstm. Character trigrams are composed using a bi-LSTM, an approach that we previously found to be effective across typologies (Vania and Lopez, 2017).

oracle. We treat the morphemes of a morphological annotation as a sequence and compose them using a bi-LSTM. We only use universal inflectional features defined in the UD annotation guidelines. For example, the morphological annotation of "chases" is ⟨`chase, person=3rd, num-SG, tense=Pres`⟩.

For the remainder of the paper, we use the name of model as shorthand for the dependency parser that uses that model as input (Eq. 1).

3 Experiments

Data We experiment on twelve languages with varying morphological typologies (Table 1) in the Universal Dependencies (UD) treebanks version 2.0 (Nivre et al., 2017).[2] Note that while Arabic and Hebrew follow a root & pattern typology, their datasets are unvocalized, which might reduce the observed effects of this typology. Following common practice, we remove language-specific dependency relations and multiword token annotations. We use gold sentence segmentation, tokenization, universal POS (UPOS), and morphological (XFEATS) annotations provided in UD.

Implementation and training Our Chainer (Tokui et al., 2015) implementation encodes words (Eq. 2) in two-layer bi-LSTMs with 200 hidden units, and uses 100 hidden units for head and label

---

[1] This combination yields the best labeled accuracy according to Ballesteros et al. (2015).

[2] For Russian we use the UD_Russian_SynTagRus treebank, and for all other languages we use the default treebank.

Languages	#sents (K)	#tokens (K)	type/token ratio (%)
Finnish	12.2	162.6	28.5
Turkish	3.7	38.1	33.6
Czech	68.5	1173.3	9.5
English	12.5	204.6	8.1
German	14.1	269.6	17.7
Hindi	13.3	281.1	6
Portuguese	8.3	206.7	11.7
Russian	48.8	870	11.4
Spanish	14.2	382.4	11.1
Urdu	4.0	108.7	8.8
Arabic	6.1	223.9	10.3
Hebrew	5.2	137.7	11.7

Table 1: Training data statistics. Languages are grouped by their dominant morphological processes, from top to bottom: agglutinative, fusional, and root & pattern.

predictions (output of Eqs. 4 and 6). We set batch size to 16 for char-cnn and 32 for other models following a grid search. We apply dropout to the embeddings (Eq. 1) and the input of the head prediction. We use Adam optimizer with initial learning rate 0.001 and clip gradients to 5, and train all models for 50 epochs with early stopping. For the word model, we limit our vocabulary to the 20K most frequent words, replacing less frequent words with an unknown word token. The char-lstm, trigram-lstm, and oracle models use a one-layer bi-LSTM with 200 hidden units to compose subwords. For char-cnn, we use the small model setup of Kim et al. (2016).

Parsing Results Table 2 presents test results for every model on every language, establishing three results. First, they support previous findings that character-level models outperform word-based models—indeed, the char-lstm model outperforms the word model on LAS for all languages except Hindi and Urdu for which the results are identical.[3] Second, they establish strong baselines for the character-level models: the char-lstm generally obtains the best parsing accuracy, closely followed by char-cnn. Third, they demonstrate that character-level models rarely match the accuracy of an oracle model with access to explicit morphology. This reinforces a finding of Vania and Lopez (2017): character-level models are effective tools, but they do not learn everything about morphology, and they seem to be closer to oracle accuracy in agglutinative rather than in fusional languages.

4 Analysis

4.1 Why do characters beat words?

In character-level models, orthographically similar words share many parameters, so we would expect these models to produce good representations of OOV words that are morphological variants of training words. Does this effect explain why they are better than word-level models?

Sharing parameters helps with both seen and unseen words Table 3 shows how the character model improves over the word model for both non-OOV and OOV words. On the agglutinative languages Finnish and Turkish, where the OOV rates are 23% and 24% respectively, we see the highest LAS improvements, and we see especially large improvements in accuracy of OOV words. However, the effects are more mixed in other languages, even with relatively high OOV rates. In particular, languages with rich morphology like Czech, Russian, and (unvocalised) Arabic see more improvement than languages with moderately rich morphology and high OOV rates like Portuguese or Spanish. This pattern suggests that parameter sharing between pairs of *observed* training words can also improve parsing performance. For example, if "dog" and "dogs" are observed in the training data, they will share activations in their context *and* on their common prefix.

4.2 Why do morphemes beat characters?

Let's turn to our main question: what do character-level models learn about morphology? To answer it, we compare the oracle model to char-lstm, our best character-level model.

Morphological analysis disambiguates words In the oracle, morphological annotations disambiguate some words that the char-lstm must disambiguate from context. Consider these Russian sentences from Baerman et al. (2005):

(1) Maša čitaet <u>pis′mo</u>
Masha reads <u>letter</u>
'*Masha reads a <u>letter</u>.*'

---

[3] Note that Hindi and Urdu are mutually intelligible.

Table 3: LAS improvements (char-lstm − word) for non-OOV and OOV words on development set.

(2) Na stole ležit pis′mo
on table lies letter
'*There's a letter on the table.*'

Pis′mo ("letter") acts as the subject in (1), and as object in (2). This knowledge is available to the oracle via morphological case: in (1), the case of *pis′mo* is nominative and in (2) it is accusative. Could this explain why the oracle outperforms the character model?

To test this, we look at accuracy for word types

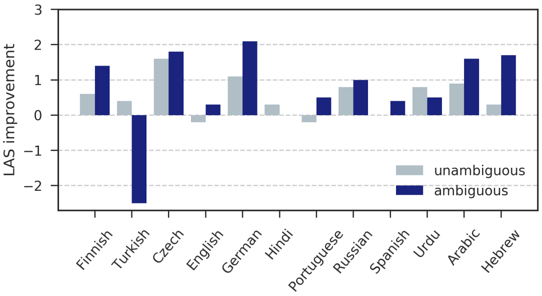

Figure 1: LAS improvements (oracle − char-lstm) for ambiguous and unambiguous words on development set.

that are *empirically* ambiguous—those that have more than one morphological analysis in the training data. Note that by this definition, some ambiguous words will be seen as unambiguous, since they were seen with only one analysis. To make the comparison as fair as possible, we consider only words that were observed in the training data. Figure 1 compares the improvement of the oracle on ambiguous and seen unambiguous words, and as expected we find that handling of ambiguous words improves with the oracle in almost all languages. The only exception is Turkish, which has the least training data.

Morphology helps for nouns Now we turn to a more fine-grained analysis conditioned on the annotated part-of-speech (POS) of the *depen-*

Table 4: Labeled accuracy for different parts of speech on development set.

dent. We focus on four languages where the oracle strongly outperforms the best character-level model on the development set: Finnish, Czech, German, and Russian.[4] We consider five POS categories that are frequent in all languages and consistently annotated for morphology in our data: adjective (ADJ), noun (NOUN), pronoun (PRON), proper noun (PROPN), and verb (VERB).

Table 4 shows that the three noun categories—ADJ, PRON, and PROPN—benefit substantially from oracle morphology, especially for the three fusional languages: Czech, German, and Russian.

Morphology helps for subjects and objects We analyze results by the dependency type of the *dependent*, focusing on types that interact with morphology: *root*, nominal subjects (*nsubj*), objects (*obj*), indirect objects (*iobj*), nominal modifiers (*nmod*), adjectival modifier (*amod*), obliques (*obl*), and (syntactic) case markings (*case*).

Figure 2 shows the differences in the confusion matrices of the char-lstm and oracle for those words on which both models correctly predict the head. The differences on Finnish are small, which we expect from the similar overall LAS of both models. But for the fusional languages, a pattern emerges: the char-lstm consistently underperforms the oracle on nominal subject, object, and indirect object dependencies—labels closely associated with noun categories. From inspection, it appears to frequently mislabel objects as nominal subjects when the dependent noun is morphologically ambiguous. For example, in the sentence of Figure 3, *Gelände* ("terrain") is an object, but the char-lstm incorrectly predicts that it is a nominal subject. In the training data, *Gelände* is ambiguous: it can be accusative, nominative, or dative.

In German, the char-lstm frequently confuses objects and indirect objects. By inspection, we found 21 mislabeled cases, where 20 of them would likely be correct if the model had access to morphological case (usually dative). In Czech and Russian, the results are more varied: indirect objects are frequently mislabeled as objects, obliques, nominal modifiers, and nominal subjects. We note that indirect objects are relatively rare in these data, which may partly explain their frequent mislabeling.

5 Characters and case syncretism

So far, we've seen that for our three fusional languages—German, Czech, and Russian—the or-

---

[4] This is slightly different than on the test set, where the effect was stronger in Turkish than in Finnish. In general, we found it difficult to draw conclusions from Turkish, possibly due to the small size of the data.

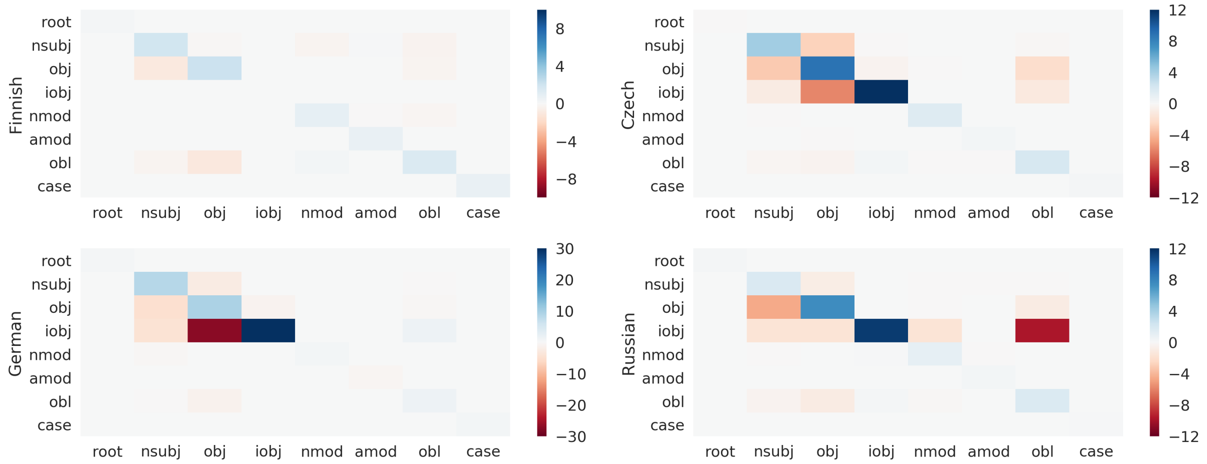

Figure 2: Heatmaps of the difference between oracle vs. char-lstm confusion matrices for label prediction when both head predictions are correct (**x-axis**: predicted labels; **y-axis**: gold labels). Blue cells have higher oracle values, red cells have higher char-lstm values.

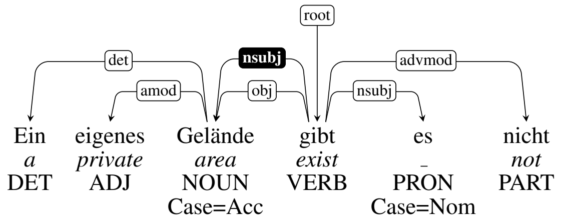

Figure 3: A sentence which the oracle parses perfectly (shown in white) and the char-lstm predicts an incorrect label (shown in black).

acle strongly outperforms a character model on nouns with ambiguous morphological analyses, particularly on core dependencies: nominal subjects, objects and indirect objects. Since the nominative, accusative, and dative morphological cases are strongly (though not perfectly) correlated with these dependencies, it is easy to see why the morphologically-aware oracle is able to predict them so well. We hypothesized that these cases are more challenging for the character model because these languages feature a high degree of *syncretism*—functionally distinct words that have the same form—and in particular case syncretism. For example, referring back to examples (1) and (2), the character model must disambiguate *pis′mo* from its context, whereas the oracle can directly disambiguate it from a feature of the word itself.[5]

To understand this, we first designed an experiment to see whether the char-lstm could successfully disambiguate *noun* case, using a method similar to (Belinkov et al., 2017). We train a neural classifier that takes as input a word representation from the trained parser and predicts a morphological feature of that word—for example that its case is nominative (`Case=Nom`). The classifier is a feedforward neural network with one hidden layer, followed by a ReLU non-linearity. We consider two representations of each word: its embedding ($\mathbf{x}_i$; Eq. 1) and its encoding ($\mathbf{h}_i$; Eq. 2). To understand the importance of case, we consider it alongside number and gender features as well as whole feature bundles.

The oracle relies on case Table 5 shows the results of morphological feature classification on Czech; we found very similar results in German and Russian (Appendix A.2). The oracle embeddings have almost perfect accuracy—and this is just what we expect, since the representation only needs to preserve information from its input. The char-lstm embeddings perform well on number and gender, but less well on case. This results suggest that the character-level models still struggle to learn case when given only the input text. Comparing the char-lstm with a baseline model which predicts the most frequent feature for each type in the training data, we observe that both of them show similar trends even though character models slightly outperforms the baseline model.

The classification results from the encoding are particularly interesting: the oracle still performs very well on morphological case, but less well on other features, even though they appear in

---

[5] We are far from first to observe that morphological case is important to parsing: Seeker and Kuhn (2013) observe the same for non-neural parsers.

Feature	baseline	embedding		encoder	
		char	oracle	char	oracle
Case	71.1	74.4	**100**	86.5	**98.6**
Gender	92.9	98.1	**100**	**71.2**	58.6
Number	88.9	94.7	**100**	84.2	**84.8**
All	70.4	72.5	**99.9**	**58.1**	50.2

Table 5: Morphological tagging accuracy from representations using the char-lstm and oracle embedding and encoder representations in Czech. Baseline simply chooses the most frequent tag. *All* means we concatenate all annotated features in UD as one tag.

the input. In the character model, the accuracy in morphological prediction also degrades in the encoding—*except* for case, where accuracy on case improves by 12%.

These results make intuitive sense: representations learn to preserve information from their input that is useful for subsequent predictions. In our parsing model, morphological case is very useful for predicting dependency labels, and since it is present in the oracle's input, it is passed almost completely intact through each representation layer. The character model, which must disambiguate case from context, draws as much additional information as it can from surrounding words through the LSTM encoder. But other features, and particularly whole feature bundles, are presumably less useful for parsing, so neither model preserves them with the same fidelity.[6]

Explicitly modeling case improves parsing accuracy Our analysis indicates that case is important for parsing, so it is natural to ask: Can we improve the neural model by explicitly modeling case? To answer this question, we ran a set of experiments, considering two ways to augment the char-lstm with case information: multitask learning (MTL; Caruana, 1997) and a pipeline model in which we augment the char-lstm model with either predicted or gold case. For example, we use ⟨`p`, `i`, `z`, `z`, `a`, `Nom`⟩ to represent *pizza* with nominative case. For MTL, we follow the setup of Søgaard and Goldberg (2016) and Coavoux and Crabbé (2017). We increase the biLSTMs layers from two to four and use the first two layers to predict morphological case, leaving out the other two layers specific only for parser. For the pipeline model, we train a morphological tagger to predict morphological case (Appendix A.1). This tagger does not share parameters with the parser.

Language	Input	Dev	Test
Czech	char	91.2	90.6
	char (multi-task)	91.6	91.0
	char + predicted case	**92.2**	**91.8**
	char + gold case	92.3	91.9
	oracle	92.5	92.0
German	char	87.5	84.5
	char (multi-task)	**87.9**	84.4
	char + predicted case	87.8	**86.4**
	char + gold case	90.2	86.9
	oracle	89.7	86.5
Russian	char	91.6	92.4
	char (multi-task)	92.2	92.6
	char + predicted case	**92.5**	**93.3**
	char + gold case	92.8	93.5
	oracle	92.6	93.3

Table 6: LAS results when case information is added. We use **bold** to highlight the best results for models without explicit access to gold annotations.

Table 6 summarizes the results on Czech, German, and Russian. We find augmenting the char-lstm model with either oracle or predicted case improve its accuracy, although the effect is different across languages. The improvements from predicted case results are interesting, since in non-neural parsers, predicted case usually harms accuracy (Tsarfaty et al., 2010). However, we note that our taggers use gold POS, which might help. The MTL models achieve similar or slightly better performance than the character-only models, suggesting that supplying case in this way is beneficial. Curiously, the MTL parser is worse than the the pipeline parser, but the MTL case tagger is better than the pipeline case tagger (Table 7). This indicates that the MTL model must learn to encode case in the model's representation, but must not learn to effectively use it for parsing. Finally, we

---

[6] This finding is consistent with Ballesteros (2013) which performed careful feature analysis on morphologically rich languages and found that lemma and case features provide the highest improvement in a non-neural transition based parser compared to other features.

Language	%case	Dev		Test	
		PL	MT	PL	MT
Czech	66.5	95.4	**96.7**	95.2	**96.6**
German	36.2	**92.6**	92.0	90.8	**91.4**
Russian	55.8	95.8	**96.5**	95.9	**96.5**

Table 7: Case accuracy for case-annotated tokens, for pipeline (**PL**) vs. multitask (**MT**) setup. **%case** shows percentage of training tokens annotated with case.

observe that augmenting the char-lstm with either gold or predicted case improves the parsing performance for all languages, and indeed closes the performance gap with the full oracle, which has access to *all* morphological features. This is especially interesting, because it shows using carefully targeted linguistic analyses can improve accuracy as much as wholesale linguistic analysis.

6 Understanding head selection

The previous experiments condition their analysis on the *dependent*, but dependency is a relationship between dependents and heads. We also want to understand the importance of morphological features to the *head*. Which morphological features of the head are important to the oracle?

Composing features in the oracle To see which morphological features the oracle depends on when making predictions, we augmented our model with a **gated attention mechanism** following Kuncoro et al. (2017). Our new model attends to the morphological features of candidate head w_j when computing its association with dependent w_i (Eq. 3), and morpheme representations are then scaled by their *attention weights* to produce a final representation.

Let $f_{i1}, \cdots, f_{ik}$ be the k morphological features of w_i, and denote by $\mathbf{f}_{i1}, \cdots, \mathbf{f}_{ik}$ their corresponding *feature embeddings*. As in §2, $\mathbf{h}_i$ and $\mathbf{h}_j$ are the encodings of w_i and w_j, respectively. The morphological representation $\mathbf{m}_j$ of w_j is:

$$\mathbf{m}_j = [\mathbf{f}_{j1}, \cdots, \mathbf{f}_{jk}]^\top \mathbf{k} \tag{7}$$

where $\mathbf{k}$ is a vector of attention weights:

$$\mathbf{k} = \mathrm{softmax}([\mathbf{f}_{j1}, \cdots, \mathbf{f}_{jk}]^\top \mathbf{V}\mathbf{h}_i) \tag{8}$$

The intuition is that dependent w_i can choose which morphological features of w_j are most important when deciding whether w_j is its head. Note that this model is asymmetric: a word only attends to the morphological features of its (single) parent, and not its (many) children, which may have different functions. [7]

We combine the morphological representation with the word's encoding via a sigmoid gating mechanism.

$$\mathbf{z}_j = \mathbf{g} \odot \mathbf{h}_j + (1 - \mathbf{g}) \odot \mathbf{m}_j \tag{9}$$

$$\mathbf{g} = \sigma(\mathbf{W}_1 \mathbf{h}_j + \mathbf{W}_2 \mathbf{m}_j) \tag{10}$$

where $\odot$ denotes element-wise multiplication. The gating mechanism allows the model to choose between the computed word representation and the weighted morphological representations, since for some dependencies, morphological features of the head might not be important. In the final model, we replace Eq. 3 and Eq. 4 with the following:

$$P_{head}(w_j | w_i, w) = \frac{\exp(a(\mathbf{h}_i, \mathbf{z}_j))}{\sum_{j'=0}^{N} \exp a(\mathbf{h}_i, \mathbf{z}_{j'})} \tag{11}$$

$$a(\mathbf{h}_i, \mathbf{z}_j) = \mathbf{v}_a \tanh(\mathbf{U}_a \mathbf{h}_i + \mathbf{W}_a \mathbf{z}_j) \tag{12}$$

The modified label prediction is:

$$P_{label}(\ell_k | w_i, w_j, w) = \frac{\exp(f(\mathbf{h}_i, \mathbf{z}_j)[k])}{\sum_{k'=0}^{|L|} \exp(f(\mathbf{h}_i, \mathbf{z}_j)[k'])} \tag{13}$$

where f is again a function to compute label score:

$$f(\mathbf{h}_i, \mathbf{z}_j) = \mathbf{V}_\ell \tanh(\mathbf{U}_\ell \mathbf{h}_i + \mathbf{W}_\ell \mathbf{z}_j) \tag{14}$$

Attention to headword morphological features We trained our augmented model (**oracle-attn**) on Finnish, German, Czech, and Russian. Its accuracy is very similar to the oracle model (Table 8), so we obtain a more interpretable model with no change to our main results.

Next, we look at the learned attention vectors to understand which morphological features are important, focusing on the core arguments: nominal subjects, objects, and indirect objects. Since our model knows the case of each dependent, this enables us to understand what features it seeks in potential heads for each case. For simplicity, we only report results for words where both head and label predictions are correct.

---

[7] This is a simple and much less computationally demanding variant of the model of Dozat et al. (2017), which uses different views for each head/dependent role.

Language	oracle		oracle-attn	
	UAS	LAS	UAS	LAS
Finnish	**89.2**	**87.3**	88.9	86.9
Czech	93.4	91.3	**93.5**	**91.3**
German	90.4	88.7	**90.7**	**89.1**
Russian	**93.9**	**92.8**	93.8	92.7

Table 8: Our attention experiment results on development set.

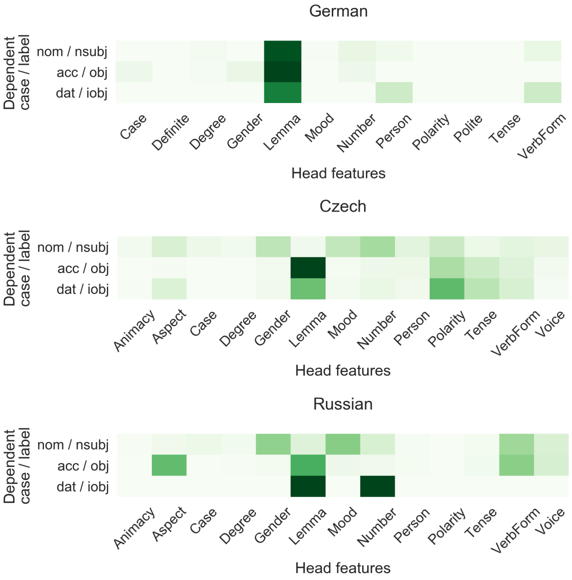

Figure 4: The importance of morphological features of the head for subject and object predictions.

Figure 4 shows how attention is distributed across multiple features of the head word. In Czech and Russian, we observe that the model attends to *Gender* and *Number* when the noun is in nominative case. This makes intuitive sense since these features often signal subject-verb agreement. As we saw in earlier experiments, these are features for which a character model can learn reliably good representations. For most other dependencies (and all dependencies in German), *Lemma* is the most important feature, suggesting a strong reliance on lexical semantics of nouns and verbs. However, we also notice that the model sometimes attends to features like *Aspect*, *Polarity*, and *VerbForm*—since these features are present only on verbs, we suspect that the model may simply use them as convenient signals that a word is verb, and thus a likely head for a given noun.

7 Conclusion

Character-level models are effective because they can represent OOV words and orthographic regularities of words that are consistent with morphology. But they depend on context to disambiguate words, and for some words this context is insufficient. Case syncretism is a specific example that our analysis identified, but the main results in Table 2 hint at the possibility that different phenomena are at play in different languages.

While our results show that prior knowledge of morphology is important, they also show that it can be used in a targeted way: our character-level models improved markedly when we augmented them only with case. This suggests a pragmatic reality in the middle of the wide spectrum between pure machine learning from raw text input and linguistically-intensive modeling: our new models don't need all prior linguistic knowledge, but they clearly benefit from some knowledge in addition to raw input. While we used a data-driven analysis to identify case syncretism as a problem for neural parsers, this result is consistent with previous linguistically-informed analyses (Seeker and Kuhn, 2013; Tsarfaty et al., 2010). We conclude that neural models can still benefit from linguistic analyses that target specific phenomena where annotation is likely to be useful.

Abstract

Character-based neural models have recently proven very useful for many NLP tasks. However, there is a gap of sophistication between methods for learning representations of sentences and words. While, most character models for learning representations of sentences are deep and complex, models for learning representations of words are shallow and simple. Also, in spite of considerable research on learning character embeddings, it is still not clear which kind of architecture is the best for capturing character-to-word representations. To address these questions, we first investigate the gaps between methods for learning word and sentence representations. We conduct detailed experiments and comparisons on different state-of-the-art convolutional models, and also investigate the advantages and disadvantages of their constituents. Furthermore, we propose IntNet, a funnel-shaped wide convolutional neural architecture with no down-sampling for learning representations of the internal structure of words by composing their characters from limited, supervised training corpora. We evaluate our proposed model on six sequence labeling datasets, including named entity recognition, part-of-speech tagging, and syntactic chunking. Our in-depth analysis shows that IntNet significantly outperforms other character embedding models and obtains new state-of-the-art performance without relying on any external knowledge or resources.

1 Introduction

Sequence labeling is the task of assigning a label or class to each element of a sequence of data, and is one of the first stages in many natural language processing (NLP) tasks. For example, named entity recognition (NER) aims to classify words in a sentence into several predefined categories of interest such as person, organization, location, etc. Part-of-speech (POS) tagging assigns a part of speech to each word in an input sentence. Syntactic chunking divides text into syntactically related, non-overlapping groups of words. Sequence labeling is a challenging problem because human annotation is very expensive and typically only a small amount of tagging data is available.

Most traditional sequence labeling systems have been dominated by linear statistical models which heavily rely on feature engineering. As a result, carefully constructed hand-crafted features and domain-specific knowledge are widely used for solving these tasks. Unfortunately, it is costly to develop domain specific knowledge and hand-crafted features. Recently, neural networks using character-level information have been used successfully for minimizing the need of feature engineering. There are basically two threads of character-based modeling, one focuses on learning representations of sentences for semantics and syntax (Zhang et al., 2015; Conneau et al., 2017); the other focuses on learning representations of words for the purpose of eliminating hand-crafted features for word shape information (Lample et al., 2016; Ma and Hovy, 2016).

Two main state-of-the-art approaches of learning character representations for sequence labeling emerged from the latter thread. One is based on RNNs and uses bidirectional LSTMs or GRUs to learn forward and backward character information (Ling et al., 2015; Lample et al., 2016; Yang et al., 2017). The other approach is based on CNNs with a fixed-size window around each word to create character-level representations (Santos and Zadrozny, 2014; Chiu and Nichols, 2016; Ma and Hovy, 2016). However, there is a gap in the sophistication between character-based methods for learning representations of sentences compared to that of words. We found that most of the state-of-the-art character-based CNN models for words

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2584–2593
Brussels, Belgium, October 31 - November 4, 2018.

use a convolution followed by max pooling as a shallow feature extractor, which is very different from the CNN models with deep and complex architecture for sentences. In spite of considerable research on learning character embeddings, it is still not clear which kind of architecture is the best for capturing character-to-word representations.

Therefore, a number of questions remain open:

- Why is there a gap between methods for learning representations of sentences and words? How can this gap be bridged?
- How do state-of-the-art character embedding models differ in term of performance?
- What kind of neural network architecture is better for learning the internal structure of a word? Deep or shallow? Narrow or wide?

To answer these questions, we first investigate the gap between learning word representations and sentence representations for convolutional architectures. The most straightforward idea is to add more convolutional layers which follows the approaches from learning representations of sentences. Interestingly, we observe the accuracy does not increase much and found that accuracy drops when we increased the depth of the network. This observation shows that learning character representations for the internal structure of words is very different than sentences, and also might explain one of the reasons there has been a gap in character-based CNN models for representing words and sentences.

In this paper, we present detailed experiments and comparisons across different state-of-the-art convolutional models from natural language processing and computer vision. We also investigate the advantages and disadvantages of some of their constituents on different convolutional architectures. Furthermore, we propose IntNet, a funnel-shaped wide convolutional neural network for learning the internal structure of words by composing their characters. Unlike previous CNN-based approaches, our funnel-shaped IntNet explores deeper and wider architecture with no down-sampling for learning character-to-word representations from limited supervised training corpora. Lastly, we combine our IntNet model with LSTM-CRF, which captures both word shape and context information, and jointly decode tags for sequence labeling.

The main contributions of this paper are the following:

- We conduct detailed studies on investigating the gap between learning word representations and sentence representations.
- We provide in-depth experiments and empirical comparisons of different convolutional models and explore the advantages and disadvantages of their components for learning character-to-word representations.
- We propose a funnel-shaped wide convolutional neural architecture with no down-sampling that focuses on learning a better internal structure of words.
- Our proposed compositional character-to-word model combined with LSTM-CRF achieves state-of-the-art performance for various sequence labeling tasks.

This paper is organized as follows: Section 2 describes multiple threads of related work. Section 3 presents the whole architecture of the neural network. Section 4 provides details about experimental settings and compared methods. Section 5 reports model results on different benchmarks with detailed analyses and discussion.

2 Related Work

There exist three threads of related work regarding the topic of this paper: (i) different convolutional architectures from different domains; (ii) character embedding models for words; (iii) sequence labeling with deep neural network.

CNN models across domains. Convolutional neural networks (CNNs) are very useful in extracting information from raw signals. In the area of NLP, Kim (2014) was the first to propose shallow CNN with word embeddings for sentence classification. Zhang et al. (2015) proposed CNN with 6 convolutional layers by directly extracting character level information for learning representations of semantic structure on sentences. Recently, Conneau et al. (2017) proposed a VDCNN architecture with 29 convolutional layers using residual connections for text classification. However, one study on randomly dropping layers for training deep residual networks, (Huang et al., 2016), has shown that not all layers may be needed and highlighted there is some amount of redundancy in

ResNet (He et al., 2016). Also, some research has shown promising results with wide architectures, for example, wide ResNet (Zagoruyko and Komodakis, 2016), Inception-ResNet (Szegedy et al., 2017) and DenseNet (Huang et al., 2017). These models use character-level information to learn representations are for sentences, not words.

Character embedding models. Santos and Zadrozny (2014) proposed a CNN model to learn character representations of words to replace hand-crafted features for part-of-speech tagging. Ling et al. (2015) proposed a bidirectional LSTM over characters to use as input for learning character-to-word representations. Chiu and Nichols (2016) proposed a bidirectional LSTM-CNN with lexicons for named entity recognition by applying the CNN-based character embedding model from Santos and Zadrozny (2014). Plank et al. (2016) proposed a bi-LSTM model with auxiliary loss for multilingual part-of-speech tagging by following the LSTM-based character embedding model from Ling et al. (2015). Cotterell and Heigold (2017) proposed a character-level transfer learning model for neural morphological tagging.

Sequence labeling. Collobert et al. (2011) first proposed a method based on CNN-CRF that learns important features from words and requires few hand-crafted features. Huang et al. (2015) proposed a bidirectional LSTM-CRF model by using word embeddings and hand-crafted features for sequence tagging. Lample et al. (2016) applied the LSTM-based character embedding model from Ling et al. (2015) with bidirectional LSTM-CRF and obtained best results on NER for Spanish, Dutch, and German. Ma and Hovy (2016) applied the CNN-based character embedding model from Chiu and Nichols (2016), but without using any data preprocessing or external knowledge and achieved the best result on NER for English and part-of-speech tagging. Also, there have been some joint models which use additional knowledge, like transfer learning (Yang et al., 2017), pre-trained language models (Peters et al., 2017), language model joint training (Rei, 2017), and multi-task learning (Liu et al., 2018). Without any additional supervision or extra resources, LSTM-CRF (Lample et al., 2016) and LSTM-CNN-CRF (Ma and Hovy, 2016) are current state-of-the-art methods. To test the effectiveness of our proposed model, we use these two models as our baselines in the latter sections.

3 Neural Network Architecture

3.1 IntNet

Character embeddings. The first step is to initialize the character embeddings for each word w in the input sequence. We define the finite set of characters V^{char}. This vocabulary contains all the variations of the raw text, including uppercase and lowercase letters, numbers, punctuation marks, and symbols. Unlike some character-based approaches, we do not use any character-level prepossessing which enables our model to learn and capture regularities from prefixes to suffixes to construct character-to-word representations. The input word w is decomposed into a sequence of characters $\{c_1, ..., c_n\}$, where n is the length of w. Character embeddings are encoded by column vectors in the embedding matrix $W^{char} \in \mathbb{R}^{d^{char} \times |V^{char}|}$, where d^{char} is the number of parameters for each character in V^{char}. Given a character c_i, its embedding r_i^{char} is obtained by the matrix-vector product:

$$r_i^{char} = W^{char} v_i^{char}, \tag{1}$$

where v_i^{char} is defined as a one-hot vector for c_i. We randomly initialize a look-up table with values drawn from a uniform distribution with range $[-\sqrt{\frac{3}{d^{char}}}, +\sqrt{\frac{3}{d^{char}}}]$, where d^{char} is empirically chosen by users. The character set includes all unique characters and the special tokens `PADDING` and `UNKNOWN`. We do not perform any character-level preprocessing, including case normalization, digit replacement (e.g. replacing all sequences of digits 0-9 with a single “0”), nor do we use any capitalization features (e.g. `allCaps`, `upperInitial`, `lowercase`, `mixedCaps`, `noinfo`).

Convolutional blocks. The input for the IntNet is the sequence of character embeddings $\{r_1^{char}, ..., r_n^{char}\}$. First is the initial convolutional layer, which is a temporal convolutional module that computes 1-D convolutions. Let $\mathbf{x}_i \in \mathbb{R}^{d^{char} \times r^{char}}$ be the concatenation of the character embeddings for each w. The initial convolutional layer applies a matrix-vector operation to each successive window of size k^{char}. An input k-grams $\mathbf{x}_{i:i+k-1}$ is transformed through a convolution filter $\mathbf{w}_c$:

$$\mathbf{c}_i = f(\mathbf{w}_c \cdot \mathbf{x}_{i:i+k-1} + b_c), \tag{2}$$

where $\mathbf{c}_i$ is the feature map of 1-D convolution, f

is the non-linear ReLU function, and b_c is a bias term. Equation 2 produces m filters with different kernel sizes. The filters are computed with different kernels by the initial convolutional layers are concatenated:

$$\mathbf{g}_0 = [c_1^{k_1} \dots c_m^{k_1}; c_1^{k_2} \dots c_m^{k_2}; c_1^{k_h} \dots c_m^{k_h}], \qquad (3)$$

where h is the number of kernels, $\mathbf{g}_0$ is the output for the initial convolutional layer which feeds into the next convolutional block.

We define $\mathcal{F}(\cdot)$ as a function of several consecutive operations within a convolutional block. Firstly, a N$\times$1 convolution transforms the input. The output size is $4 \times m \times h$ feature maps, like a bottleneck layer. The next step consists of multiple 1-D convolutions with kernels of different sizes. Lastly, we concatenate all the feature maps from kernels of different size. In each convolution, we use a batch normalization, followed by a ReLU activation and N$\times$k temporal convolution.

Funnel-shaped wide architecture. The network comprises of L convolutional layers, which implies $(\frac{L-1}{2})$ convolutional blocks. We use direct connections from every other layer to all subsequent layers, inspired by dense connection. Therefore, the l^{th} layer has access to the feature maps of all the alternate layers:

$$\mathbf{g}_l = \mathcal{F}_l([\mathbf{g}_0, \mathbf{g}_2, \dots, \mathbf{g}_{l-2}]). \qquad (4)$$

Equation 4 ensures maximum information flow between blocks in the network. Compared to residual connection $\mathcal{F}_l(\mathbf{g}_{l-1}) + \mathbf{g}_{l-1}$, it can be viewed as an extreme case of residual connection and makes feature reuse possible. Unlike DenseNet and ResNet, we concatenate feature maps by different kernels in every other convolutional layers, which captures different levels of features and makes our wide architecture possible, inspired by Inception. Different levels of concatenation can help IntNet to learn different patterns of word shape information. We compare our architecture to residual connection and dense connection for learning character-to-word representations in Section 5.

Without down-sampling. Compared to other CNN models like ResNet and DenseNet, our model does not contain any halve down-sampling layer or average pooling to reduce resolution. We did not find these operations to be helpful and, in some cases, found them to be detrimental to performance. These operations are useful for sentences and images, but might break the internal structure of words, like the sequential patterns for prefixes and suffixes.

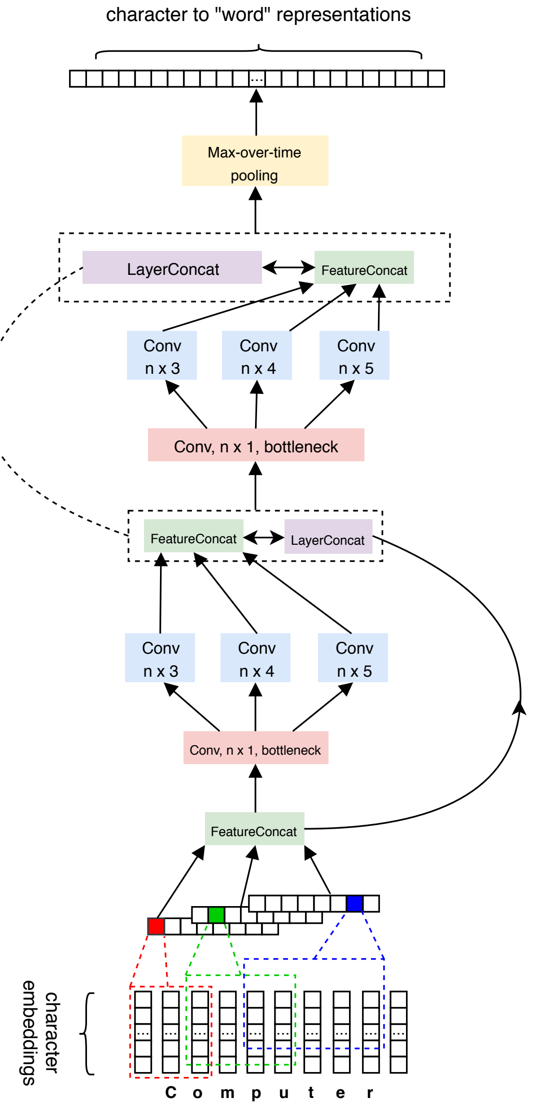

Figure 1: The main architecture of IntNet.

Character-to-word representations. In the last layer, we use a max-over-time pooling operation:

$$\hat{\mathbf{c}}_i = max(\mathbf{c}_i), \qquad (5)$$

which takes the maximum value corresponding to a particular filter. The idea is to capture the most important feature with the highest value for each feature map. Finally, we concatenate all of salient features together as a representation for this word:

$$\mathbf{z} = [\hat{\mathbf{c}_0}, \hat{\mathbf{c}_1}, \dots \hat{\mathbf{c}_u}], \qquad (6)$$

where u is the number of salient features which is equal to the total number of output feature maps in the last layer. If each function $\mathcal{F}_l$ produces p feature maps, we obtain $(p_0 + p \times \frac{L-1}{2})$ representations, where p_0 is the number of output feature maps in the initial convolution layer.

3.2 Bi-directional RNN

Given the character-to-word representations are computed by IntNet in Equation 6, we denote the input vector $(\mathbf{z}_1, \mathbf{z}_2, \ldots, \mathbf{z}_n)$ for a sentence. LSTM (Hochreiter and Schmidhuber, 1997) returns the sequence $(\mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_n)$ that represents the sequential information at every step. We use the following implementation:

$$\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W}_{zi}\mathbf{z}_t + \mathbf{W}_{hi}\mathbf{h}_{t-1} + \mathbf{W}_{ci}\mathbf{c}_{t-1} + \mathbf{b}_i) \\
\mathbf{f}_t &= \sigma(\mathbf{W}_{zf}\mathbf{z}_t + \mathbf{W}_{hf}\mathbf{h}_{t-1} + \mathbf{W}_{cf}\mathbf{c}_{t-1} + \mathbf{b}_f) \\
\widetilde{\mathbf{c}_t} &= tanh(\mathbf{W}_{zc}\mathbf{z}_t + \mathbf{W}_{hc}\mathbf{h}_{t-1} + \mathbf{b}_c) \\
\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \widetilde{\mathbf{c}_t} \\
\mathbf{o}_t &= \sigma(\mathbf{W}_{zo}\mathbf{z}_t + \mathbf{W}_{ho}\mathbf{h}_{t-1} + \mathbf{W}_{co}\mathbf{c}_t + \mathbf{b}_o) \\
\mathbf{h}_t &= \mathbf{o}_t \odot tanh(\mathbf{c}_t),
\end{aligned}$$

where σ is the element-wise sigmoid function and $\odot$ is the element-wise product. $\mathbf{z}_t$ is the input vector at time t and $\mathbf{i}_t$, $\mathbf{f}_t$, $\mathbf{o}_t$, $\mathbf{c}_t$ are the input gate, forget gate, output gate, and cell vectors, all of which are the same size as the hidden vector $\mathbf{h}_t$. $\mathbf{W}_{zi}$, $\mathbf{W}_{zf}$, $\mathbf{W}_{zo}$, $\mathbf{W}_{zc}$ denote the weight matrices of different gates for input $\mathbf{z}_t$; $\mathbf{W}_{hi}$, $\mathbf{W}_{hf}$, $\mathbf{W}_{ho}$, $\mathbf{W}_{hc}$ are the weight matrices for hidden state $\mathbf{h}_t$, and $\mathbf{b}_i$, $\mathbf{b}_f$, $\mathbf{b}_o$, $\mathbf{b}_c$ denote the bias vectors. Forward LSTM and backward LSTM compute the representations of $\overrightarrow{\mathbf{h}_t}$ and $\overleftarrow{\mathbf{h}_t}$ for left and right context of the sentence, respectively. We concatenate two hidden states to form the output of bi-directional LSTM $[\overrightarrow{\mathbf{h}_t}, \overleftarrow{\mathbf{h}_t}]$ for capturing context information from both sides.

3.3 Scoring Function

Instead of predicting each label independently, we consider the correlations between labels in neighborhoods and jointly decode the best chain of labels for a given input sentence by leveraging a conditional random field (Lafferty et al., 2001). Formally, the sequence of labels is defined as:

$$\mathbf{y} = (y_1, y_2, ..., y_T). \tag{7}$$

To define the scoring function $f(\mathbf{h}, \mathbf{y})$ for each position t, we multiply the hidden state $\mathbf{h}_t^w$ with a parameter vector $\mathbf{w}_{y_t}$ that is indexed by the tag y_t to obtain the matrix of scores output by the bidirectional LSTM network. Therefore, the function f can be written as:

$$f(\mathbf{h}, \mathbf{y}) = \sum_{t=1}^{T} \mathbf{w}_{y_t}\mathbf{h}_t^w + \sum_{t=1}^{T} \mathbf{A}_{y_{t-1},y_t}. \tag{8}$$

In Equation 8, $\mathbf{A}$ is a matrix of transition scores, $\mathbf{A}_{i,j}$ represents the score of a transition from the tag i to tag j, y_1 is the start tag of a sentence. Let $\mathcal{Y}(\mathbf{h})$ denote the set of possible label sequences for $\mathbf{h}$. A probabilistic model for a sequence defines a family of conditional probabilities $p(\mathbf{y}|\mathbf{h})$ over all possible label sequences $\mathbf{y}$ given $\mathbf{h}$ with the following form:

$$p(\mathbf{y}|\mathbf{h}) = \frac{e^{f(\mathbf{h},\mathbf{y})}}{\sum_{y' \in \mathcal{Y}(\mathbf{h})} e^{f(\mathbf{h},\mathbf{y}')}}. \tag{9}$$

3.4 Objective Function and Inference

For end-to-end network training, we use maximum conditional likelihood estimation to maximize the log probability of the correct tag sequence:

$$log(p(\mathbf{y}|\mathbf{h})) = f(\mathbf{h}, \mathbf{y}) - log\left(\sum_{y' \in \mathcal{Y}(\mathbf{h})} e^{f(\mathbf{h},\mathbf{y}')}\right).$$

While decoding, we predict the label sequence that obtains the highest score given by:

$$\mathbf{y}^* = \arg \max_{y' \in \mathcal{Y}(\mathbf{h})} f(\mathbf{h}, \mathbf{y}'). \tag{10}$$

The objective function and its gradients can be efficiently computed by dynamic programming; for inference, we use the Viterbi algorithm to find the best tag path which maximizes the score.

4 Experiments

4.1 Datasets

We performed experiments on six standard datasets for sequence labeling tasks, i.e. named entity recognition, part-of-speech tagging, and syntactic chunking. To test the effectiveness of our proposed model, we do not use language-specific resources (such as gazetteers), external knowledge

Model	Spanish NER	Dutch NER	English NER	German NER	Chunking	PTB POS
Baseline	70.73±0.42	63.49±0.42	77.51±0.39	54.07±0.42	91.97±0.21	95.76±0.13

Table 1: F1 score of different character-to-word models.

(such as transfer learning, joint training), hand-crafted features, or any character preprocessing, we do not replace any rare words into `UNKNOWN`.

Named entity recognition. CoNLL-2002 and CoNLL2003 datasets (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003) contain named entity labels for Spanish, Dutch, English and German as separate datasets. These four datasets contain different types of named entities: locations, persons, organizations, and miscellaneous entities. Unlike some approaches, we do not combine the validation set with the training set. Although POS tags were made available for these datasets, we do not leverage those as additional information which sets our approach apart from that of transfer learning.

Part-of-speech tagging. The Wall Street Journal (WSJ) portion of Penn Treebank (PTB) (Marcus et al., 1993) contains 25 sections and categorizes each word into one out of 45 POS tags. We adopt the standard split and use sections 0-18 as training data, sections 19-21 as development data, and sections 22-24 as test data.

Syntactic chunking. The CoNLL 2000 chunking task (Tjong Kim Sang and Buchholz, 2000) uses sections 15-18 from the Wall Street Journal corpus for training and section 20 for testing. It defines 11 syntactic chunk types (e.g., NP, VP, ADJP), we adopt the standard split and sample 1000 sentences from the training set as the development set.

4.2 Training Settings

Initialization. The size of the dimensions of character embeddings is 32 which are randomly initialized using a uniform distribution. We adopt the same initialization method for randomly initialized word embeddings that are updated during training. For IntNet, the filter size of the initial convolution is 32 and that of other convolutions is 16. We have used filters of size $[3, 4, 5]$ for all the kernels. The number of convolutional layers are 5 and 9 for IntNet-5 and IntNet-9, respectively, and we have adopted the same weight initialization as that of ResNet. We use pre-trained word embeddings for initialization, GloVe (Pennington et al., 2014) 100-dimension word embeddings for English, and fastText (Bojanowski et al., 2017) 300-dimension word embeddings for Spanish, Dutch, and German. The state size of the bi-directional LSTMs is set to 256. We adopt standard BIOES tagging scheme for NER and Chunking.

Optimization. We employ mini-batch stochastic gradient descent with momentum. The batch size, momentum and learning rate are set to 10, 0.9 and $\eta_t = \frac{\eta_0}{1+\rho t}$, where η_0 is the initial learning rate 0.01 and $\rho = 0.05$ is the decay ratio, the value of gradient clipping is 5. Dropout is applied on the input of IntNet, LSTMs, and CRF, and its ratio 0.5 is fixed, but with no dropout inside of IntNet.

4.3 Compared Methods

To address those open questions in Section 1, we conduct detailed experiments and empirical comparisons on different state-of-the-art character embedding models across different domains. Firstly, we use LSTM-CRF with randomly initialized word embeddings as our initial baseline. We adopt two state-of-the-art methods in sequence labeling, denoted as char-LSTM (Lample et al., 2016) and char-CNN (Ma and Hovy, 2016). We add more layers to the char-CNN model and refer to that as char-CNN-5 and char-CNN-9, respectively for 5 and 9 convolutional layers. Furthermore, we add residual connections to the char-CNN-9 and refer it as char-ResNet. Also, we apply 3 dense blocks based on char-ResNet which we refer to as char-DenseNet, to compare the difference between residual connection and dense connection. Lastly, we refer to our proposed

model, which uses different convolution layers, as char-IntNet-5 and char-IntNet-9.

5 Results and Analysis

5.1 Character-to-word Models

Table 1 presents the performance of different character-to-word models on six benchmark datasets. For sequence labeling, char-LSTM and char-CNN are current state-of-the-art character embedding models for learning character-to-word representations. We observe that char-LSTM performs better than char-CNN in most cases, however, char-CNN uses a convolution layer followed by max pooling as a shallow feature extractor, that does not explore the full potential of CNNs.

Therefore, we implement two variations based on char-CNN, referred to as char-CNN-5 and char-CNN-9. The result shows that for most of the datasets, the F1 score does not improve much when we directly add more layers. We also observe some accuracy drop when we continuously increase the depth. This confirms why most CNN-based approaches for learning representations on words are shallow, which is very different from learning representations for sentences. Furthermore, we add residual connections to char-CNN-9 as char-ResNet-9, which confirms that residual connections can help train deep layers. We further improve char-ResNet-9 by changing residual connections into dense connection blocks as char-DenseNet-9, which shows that the dense connections are better than residual connections for learning word shape information.

Our proposed character-to-word model, char-IntNet-5 and char-IntNet-9 generally improves the results across all datasets. Our IntNet significantly outperforms other character embedding models, for example, the improvement is more than 2% in terms of F1 score for German and Dutch. Also, we observe that char-IntNet-5 is more effective for learning character-to-word representations than char-IntNet-9 in most of the cases. The only exception is German which seems to require a deeper and wider model for learning better representations.

5.2 State-of-the-art Results

Table 2 presents our proposed model in comparison with state-of-the-art results. LSTM-CRF is our baseline which uses fine-tuned pre-trained word embeddings. Its comparison with LSTM-CRF using random initializations for word embeddings, as shown in Table 1, confirms that pre-trained word embeddings are useful for sequence labeling. Since the training corpus for sequence labeling is relatively small, pre-trained embeddings learned from a huge unlabeled corpus can help to enhance word semantics. Furthermore, we adopt and re-implement two state-of-the-art character models, char-LSTM and char-CNN, by combining with LSTM-CRF, which we

Table 4: Nearest neighbours of different models for frequent words, rare words and OOV words.

refer to as LSTM-CRF-char-LSTM and LSTM-CRF-char-CNN. Lastly, we combine our proposed model with LSTM-CRF which we refer to as LSTM-CRF-char-IntNet-9 and LSTM-CRF-char-IntNet-5.

These experiments show that our char-IntNet generally improves results across different models and datasets. The improvement is more pronounced for non-English datasets, for example, IntNet improves the F-1 score over the state-of-the-art results by more than 2% for Dutch and Spanish. It also shows that the results of LSTM-CRF are significantly improved after adding character-to-word models, which confirms that word shape information is very important for sequence labeling. Figure 2 presents the details of training epochs in comparison with other state-of-the-art character models for different languages. It shows that char-CNN and char-LSTM converge early whereas char-IntNet takes more epochs to converge and generally performs better. It alludes to the fact that IntNet is suitable for reducing over-fitting, since we have used early stopping while training.

5.3 Rare and OOV Words Analysis

Another advantage of learning internal structure of words is that it can capture representations for out-of-vocabulary (OOV) words. To better understand the behavior of IntNet, Table 3 presents error analysis on in-vocabulary words (IV), out-of-training-vocabulary words (OOTV), out-of-embedding-vocabulary words (OOEV), and out-of-both-vocabulary words (OOBV) compared to different character models. The result shows that our proposed model significantly outperforms other character models on OOV words including OOTV, OOEV, and OOBV. For example, in OOBV category, our IntNet outperforms other models by more than 3% in terms of F1 score for Dutch and German datasets.

Furthermore, we present comparisons of nearest neighbors with different models for frequent words, rare words, and OOV words. Table 4 shows the results of nearest neighbors for learning word shape information, which gives insights on what kind of character-to-word representations can be learned by different models. For example, in OOV words, our IntNet model learns a better *xx-month* shape pattern when matching 11-*month* compared to other models.

5.4 Discussion

In many situations, learning character-to-word representations of subword sequences that exceed the typical length of word shape pattern or morpheme sequences might result in noise. RNNs can capture longer sequences in theory, however, longer sequences do not guarantee better results when learning prefixes and suffixes. The funnel-shaped wide architecture of IntNet, uses different kernels with different levels of concatenation to capture patterns of different subword lengths and that is flexible than char-LSTM and char-CNN. For example, Table 4 shows $Thursday$ in OOV words, our model learns a better word-shape structure for character-to-word representations compared to other methods.

When considering training time, IntNet is only 20% slower than char-CNN for the whole training process. Also, learning word representations use fewer parameters than learning sentence representations. Therefore, the impact of training speed for sequence labeling is limited. The inference time of IntNet is almost the same as char-CNN.

6 Conclusion

We presented empirical comparisons of different character embedding models for learning character-to-word representations and investigated the gaps between methods for learning representations of words and sentences. We conducted detailed experiments of different state-of-the-art convolutional models, and explored the advantages and disadvantages of their components for learning word shape information. Furthermore, we presented IntNet, a funnel-shaped wide convolutional neural architecture with no down-sampling that focuses on learning better internal structure of words by composing their characters from limited supervised training corpora. Our in-depth analysis showed that a shallow wide architecture is better than a narrow deep architecture for learning character-to-word representations. Omitting down-sampling operations is useful for capturing the sequential patterns of prefixes and suffixes. Our proposed compositional character-to-word model does not leverage any external resources, hand-crafted features, additional knowledge, joint training, or character-level preprocessing, and achieves new state-of-the-art performance for various sequence labeling tasks, including named entity recognition, part-of-speech tagging and syntactic chunking. In the future, we would like to explore using the IntNet model for other NLP tasks.

Abstract

Emotion recognition in conversations is crucial for building empathetic machines. Current work in this domain do not explicitly consider the inter-personal influences that thrive in the emotional dynamics of dialogues. To this end, we propose Interactive COnversational memory Network (ICON), a multimodal emotion detection framework that extracts multimodal features from conversational videos and hierarchically models the *self*- and *inter-speaker* emotional influences into global memories. Such memories generate contextual summaries which aid in predicting the emotional orientation of utterance-videos. Our model outperforms state-of-the-art networks on multiple classification and regression tasks in two benchmark datasets.

1 Introduction

Emotions play an important role in our daily life. A long-standing goal of AI has been to create affective agents that can detect and comprehend emotions. Research in affective computing has mainly focused on understanding affect (emotions and sentiment) in monologues. However, with increasing interactions of humans with machines, researchers now aim at building agents that can seamlessly analyze affective content in conversations. This can help in creating empathetic dialogue systems, thus improving the overall human-computer interaction experience (Young et al., 2018).

Analyzing emotional dynamics in conversations, however, poses complex challenges. This is due to the presence of intricate dependencies between the affective states of speakers participating in the dialogue. In this paper, we address the problem of emotion recognition in conversational videos. We specifically focus on dyadic conversations where two entities participate in a dialogue.

We propose Interactive COnversational memory Network (ICON), a multimodal network for identifying emotions in utterance-videos. Here, utterances are units of speech bounded by breaths or pauses of the speaker. Emotional dynamics in conversations consist of two important properties: *self* and *inter-personal dependencies* (Morris and Keltner, 2000). Self-dependencies, also known as *emotional inertia*, deal with the aspect of emotional influence that speakers have on themselves during conversations (Kuppens et al., 2010). On the other hand, inter-personal dependencies relate to the emotional influences that the counterparts induce into a speaker. Conversely, during the course of a dialogue, speakers also tend to mirror their counterparts to build rapport (Navarretta et al., 2016).

Figure 1 demonstrates a sample conversation from the dataset involving both self and inter-personal dependencies. While most conversational frameworks only focus on self dependencies, ICON leverages both such dependencies to generate affective summaries of conversations. First, it extracts multimodal features from all utterance-videos. Next, given a test utterance to be classified, ICON considers the preceding utterances of both speakers falling within a context-window and models their self-emotional influences using local gated recurrent units (GRUs).

Furthermore, to incorporate inter-speaker influences, a global representation is generated using a GRU that intakes output of the local GRUs. For each instance in the context-window, the output of this global GRU is stored as a memory cell. These memories are then subjected to multiple read/write cycles that include attention mechanism for generating contextual summaries of the conversational history. At each iteration, the representation of the test utterance is improved with this summary representation and finally used for prediction.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2594–2604
Brussels, Belgium, October 31 - November 4, 2018.

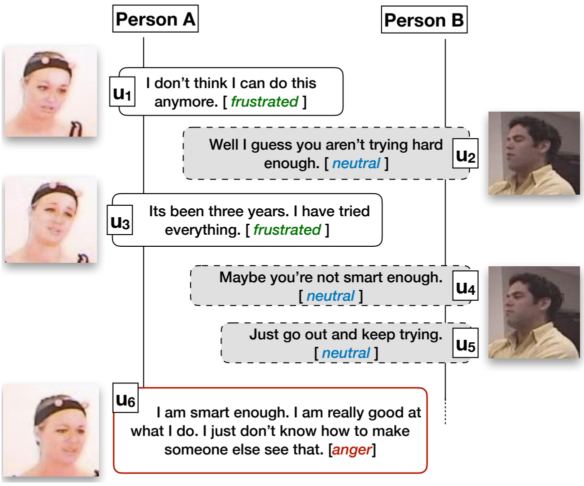

Figure 1: An abridged dialogue from the IEMOCAP dataset. P_a is frustrated over her long term unemployment and seeks encouragement (u_1, u_3). P_b, however, is pre-occupied and replies sarcastically (u_4). This enrages P_a to appropriate an angry response (u_6). In this dialogue, *emotional inertia* is evident in P_b who does not deviate from his nonchalant behavior. P_a, however, gets emotionally influenced by her counterpart. This influence is content-based, not label-based.

The contributions of this paper are as follows:

- We propose ICON, a novel model for emotion recognition that incorporates self and inter-speaker influences in a dialogue. Memory networks are used to model contextual summaries for prediction.
- We introduce a multimodal approach that provides comprehensive features from modalities such as language, visual, and audio in utterance-videos.
- ICON can be considered as a generic framework for conversational modeling that can be extended to multi-party conversations.
- Experiments on two benchmark datasets show that ICON significantly outperforms existing models on multiple discrete and continuous emotional categories.

The remainder of the paper is organized as follows: Section 2 presents related works; Section 3 formalizes the problem statement and Section 4 describes our proposed approach; Section 5 provides details on experimental setup; Section 6 reports the results and related analysis; finally, Section 7 concludes the paper.

2 Related Works

Emotion recognition is an interdisciplinary field of research with contributions from psychology, cognitive science, machine learning, natural language processing, and others (Picard, 2010).

Initial research in this area primarily involved visual and audio processing (Ekman, 1993; Datcu and Rothkrantz, 2008). The role of text in emotional analysis became evident with later research such as Alm et al. (2005); Strapparava and Mihalcea (2010). Current research in this domain is mainly performed from a multimodal learning perspective (Poria et al., 2017a; Baltrušaitis et al., 2018). Numerous previous approaches have relied on fusion techniques that leverage multiple modalities for affect recognition (Soleymani et al., 2012; Zadeh et al., 2017; Chen et al., 2017; Tzirakis et al., 2017; Zadeh et al., 2018b).

Understanding conversations is crucial for machines to replicate human language and discourse. Emotions play an important role in shaping such social interactions (Ruusuvuori, 2013). Richards et al. (2003) attribute emotional dynamics to be an interactive phenomena, rather than being within-person. We utilize this trait in the design of our model that accommodates inter-personal dynamics. Being a temporal event, context also plays an important role in conversational analysis. Poria et al. (2017b) use contextual information from neighboring utterances of the same speaker to predict emotions. However, there is no provision to model interactive influences. Work by Yang et al., 2011; Xiaolan et al., 2013 stresses the study of patterns for emotion transitions. In contrast, we posit the use of utterance content to model context with multimodal features.

In the literature, memory networks have been successfully applied in many areas, including question-answering (Weston et al., 2014; Sukhbaatar et al., 2015; Kumar et al., 2016), machine translation (Bahdanau et al., 2014), speech recognition (Graves et al., 2014), and others. In emotional analysis, Zadeh et al. (2018a) propose a memory-based sequential learning for multi-view signals. Although we utilize memory networks, our work is different as we use memories to encode whole utterances. Also, each memory cell in our network is processed using GRUs to capture temporal dependencies. This technique deviates from the traditional use of embedding matrices to encode information into memory cells.

ICON builds on our previous research (Hazarika et al., 2018) that used separate memory networks for both interlocutors participating in a dyadic conversation. In contrast, ICON adopts an interactive scheme that actively models inter-speaker emotional dynamics with fewer trainable parameters.

3 Problem Setting

Let us define a conversation U to be a set of asynchronous exchange of utterances between two persons P_a and P_b over time. With T utterances, $U = \{u_1, u_2, ..., u_T\}$ is a totally ordered set which can be arranged as a sequence $(u_1, ..., u_T)$ based on temporal occurrence. Here, each utterance u_i is spoken by either P_a or P_b. Furthermore, for each $\lambda \in \{a, b\}$, U_λ denotes person P_λ's individual utterances in U, i.e., $U_\lambda = \{u_i \mid u_i \in U \text{ and } u_i \text{ spoken by } P_\lambda, \ \forall i \in [1, |U|]\}$. This provides two sets of utterances for both the respective speakers, such that $U = U_a \cup U_b$.

Our aim is to identify the emotions of utterances in conversational videos. At each time step $t \in [1, T]$ of video U, our model is provided with the utterance spoken at that time, i.e. u_t, and tasked to predict its emotion. Moreover, we also utilize the previous utterances within U spoken by both persons. Considering a context-window of size K, the preceding utterances of P_a and P_b (starting with the most recent) within this context-window can be represented by H_a and H_b, respectively. Formally, for each $\lambda \in \{a, b\}$, H_λ is created as,

$$H_\lambda = \{u_i \mid i \in [t - K, t - 1] \text{ and } u_i \in U_\lambda\} \quad (1)$$

$$\text{and} \quad |H_a| + |H_b| \leq K \quad (2)$$

Table 1 provides a sample conversation with a context-window of size $K = 5$.

U	$\{ u_1^a, u_2^a, u_3^b, u_4^a, u_5^a, u_6^b \}$
U_a, U_b	$\{ u_1, u_2, u_4, u_5 \}, \{ u_3, u_6 \}$
test utterance	u_7^a
H_a, H_b	$\{ u_2, u_4, u_5 \}, \{ u_3, u_6 \}$

Table 1: Sample conversation U with test utterance u_7. Context-window $K = 5$. Here, $u_i^\lambda = i^{th}$ utterance by P_λ.

4 Methodology

ICON has been designed as a generic framework for affective modeling of conversations. Its computations can be categorized as a sequence of four successive modules: Multimodal Feature Extraction, Self-Influence Module, Dynamic Global-Influence Module, and Multi-hop Memory. Figure 2 illustrates the overall model.

4.1 Multimodal Feature Extraction

ICON adopts a multimodal framework and performs feature extraction from three modalities, i.e., language (transcripts), audio and visual.

These features are extracted for each utterance in the conversation and their concatenated vectors serve as the utterance representations. The motivation of this setup derives from previous works that demonstrate the effectiveness of multimodal features in creating rich feature representations (D'mello and Kory, 2015). These features provide complementary information from heterogeneous sources which helps to accumulate comprehensive features. Its need is particularly pronounced in videos as they are often plagued with noisy signals and missing-information within individual modalities (e.g., facial occlusion, loud background music, imperfect transcriptions).

4.1.1 Textual Features

We employ a convolutional neural network (CNN) to extract textual features from the transcript of each utterance. CNNs are capable of learning abstract semantic representations of a sentence based on its words and n-grams (Kalchbrenner et al., 2014). For our purpose, we utilize a simple CNN with a single convolutional layer followed by max-pooling (Kim, 2014). The input to this network consists of pre-trained word embeddings extracted from the 300-dimensional FastText embeddings (Bojanowski et al., 2016). The convolution layer consists of three filters with sizes f_t^1, f_t^2, f_t^3 with f_{out} feature maps each. We perform 1D convolutions using these filters followed by max-pooling on its output. The pooled features are finally projected onto a dense layer with dimension d_t and its activations are used as the textual representation $\boldsymbol{t_u} \in \mathbb{R}^{d_t}$.

4.1.2 Audio Features

Audio plays a significant role in determining the emotional states of a speaker (De Silva and Ng, 2000; Song et al., 2004). To extract audio features, we first format the audio of each utterance-video as a 16-bit PCM WAV file and use the open-sourced software openSMILE (Eyben et al., 2010). This tool provides high dimensional vectors for audio files that summarizes important statistical descriptors such as loudness, pitch, Mel-spectra, MFCC, etc. Specifically, we use the *IS13_ComParE*[1] extractor which provides 6373 features for each utterance. The features are then normalized using Min-Max scaling followed by L2-based feature selection. This selection provides low-dimensional audio features $\boldsymbol{a_u} \in \mathbb{R}^{d_a}$ of dimensions d_a.

---

[1] `http://audeering.com/technology/opensmile`

4.1.3 Visual Features

Visual indicators such as facial expressions are key to understand emotions. In our work, we use a deep 3D-CNN to model spatiotemporal features of each utterance video (Tran et al., 2015). 3D-CNN helps to understand emotional concepts such as smiling or frowning that are often spread across multiple frames of a video with no predefined spatial location. The input to this network is a video with dimensions (c, h, w, f), where c is the number of channels, h, w are the height and width of each frame, with a total of f frames per video.

The network contains three blocks of convolution where each block contains two convolutional layers followed by max-pooling. For the convolution, 3D filters are employed having dimensions $(f_{out}, f_{in}, f_h, f_w, f_d)$, where, $f_{[out/in/h/w/d]}$ represents the number of feature maps, input channels, height, width, and depth of the filter, respectively. After a non-linear reLU activation (LeCun et al., 2015), max-pooling is performed using a sliding window of dimensions (m_p, m_p, m_p). For an input utterance video, the final features of the third convolutional block is mapped onto a dense layer of dimension d_v whose activations are used as the visual features $\boldsymbol{v_u} \in \mathbb{R}^{d_v}$.

4.1.4 Fusion

We generate the final representation of an utterance u by concatenating all three multimodal features:

$$\boldsymbol{u} = tanh((W^f[\boldsymbol{t_u}; \boldsymbol{a_u}; \boldsymbol{v_u}]) + \boldsymbol{b}^f) \qquad (3)$$

Concatenation is one of the most common fusion methods (Shwartz et al., 2016). Its simplicity also allows us to emphasize the contribution of the remaining components of ICON.

4.2 SIM: Self-Influence Module

Given a test utterance u_t to be classified, this module independently processes the histories of both speakers. SIM consists of two GRUs, GRU_a^s and GRU_b^s, for H_a and H_b, respectively. For each $\lambda \in \{a, b\}$, GRU_λ^s attempts to model the *emotional inertia* of speaker P_λ which represents the emotional dependency of a speaker with their own previous states. In particular, for each historical utterance $\boldsymbol{u}_{i<t} \in H_\lambda$, an internal memory state $\boldsymbol{h}_\lambda^{(j)}$ is computed by GRU_λ^s conditioned on utterance $\boldsymbol{u}_i$ and previous memory state $\boldsymbol{h}_\lambda^{(j-1)}$. This can be abbreviated as $\boldsymbol{h}_\lambda^{(j)} = GRU_\lambda^s(\boldsymbol{u}_i, \boldsymbol{h}_\lambda^{(j-1)})$.

Gated Recurrent Unit: GRUs are gated recurrent cells introduced by Cho et al. (2014). At time step j, GRU computes hidden state $s_j \in \mathbb{R}^{d_{em}}$ by calculating two gates, r_j (*reset gate*) and z_j (*update gate*) with j^{th} input $\boldsymbol{x}_j$ and previous state $\boldsymbol{s}_{j-1}$. The computations are:

$$\begin{aligned}
\boldsymbol{z}_j &= \sigma(V^z\boldsymbol{x}_j + W^z\boldsymbol{s}_{j-1} + \boldsymbol{b}^z) \\
\boldsymbol{r}_j &= \sigma(V^r\boldsymbol{x}_j + W^r\boldsymbol{s}_{j-1} + \boldsymbol{b}^r) \\
\boldsymbol{v}_j &= tanh(V^h\boldsymbol{x}_j + W^h(\boldsymbol{s}_{j-1} \otimes \boldsymbol{r}_j) + \boldsymbol{b}^h) \\
\boldsymbol{s}_j &= (1 - \boldsymbol{z}_j) \otimes \boldsymbol{v}_j + \boldsymbol{z}_j \otimes \boldsymbol{s}_{j-1}
\end{aligned}$$

In this work, input $\boldsymbol{x}_j = \boldsymbol{u}_i$ and $\boldsymbol{s}_j = \boldsymbol{h}_\lambda^{(j)}$. SIM computes both sequences $H_a^* \in \mathbb{R}^{d_{em} \times |H_a|}$ and $H_b^* \in \mathbb{R}^{d_{em} \times |H_b|}$ using the respective GRUs,

$$H_\lambda^* = [\boldsymbol{h}_\lambda^{(j)}]_{j=1}^{|H_\lambda|} = GRU_\lambda^s(H_\lambda)\ ,\ \lambda \in \{a, b\} \qquad (4)$$

4.3 DGIM: Dynamic Global Influence Module

Emotions are not only regarded as internal-psychological phenomena but also interpreted and processed communicatively through social interactions (Fiehler, 2002). Conversations exemplify such a scenario where inter-personal emotional influence persists. Theories in cognitive science also suggest the existence of *emotional contagion* that causes humans to mirror their counterpart's gesture, posture and emotional state (Chartrand and Bargh, 1999; Navarretta et al., 2016). Additionally, these interactions occur dynamically through the discourse of a dialogue.

While modeling the contextual history, we incorporate such properties using a dynamic influence module. This module maintains a global representation of the conversation and updates it recurrently at each time step of the K-length conversation history. For any $k \in [1, K]$, the global state is updated using a GRU operation on the previous state $\boldsymbol{s}_{k-1}$ and current speaker P_λ's SIM memory $\boldsymbol{h}_\lambda^{(j)}$ for the corresponding spoken utterance $\boldsymbol{u}_{(t-K+k-1)}$, i.e., $\boldsymbol{h}_\lambda^{(j)} = GRU_\lambda^s(\boldsymbol{u}_{(t-K+k-1)})$.

Formally, DGIM consists of a GRU network, GRU^g, where the k^{th} global state $\boldsymbol{s}_k$ is computed as:

$$\boldsymbol{s}_k = \begin{cases} GRU^g(\boldsymbol{h}_a^{(j)}, \boldsymbol{s}_{k-1}), & \text{if } \boldsymbol{u}_{(t-K+k-1)} \in H_a \\ GRU^g(\boldsymbol{h}_b^{(j)}, \boldsymbol{s}_{k-1}), & \text{if } \boldsymbol{u}_{(t-K+k-1)} \in H_b \end{cases} \qquad (5)$$

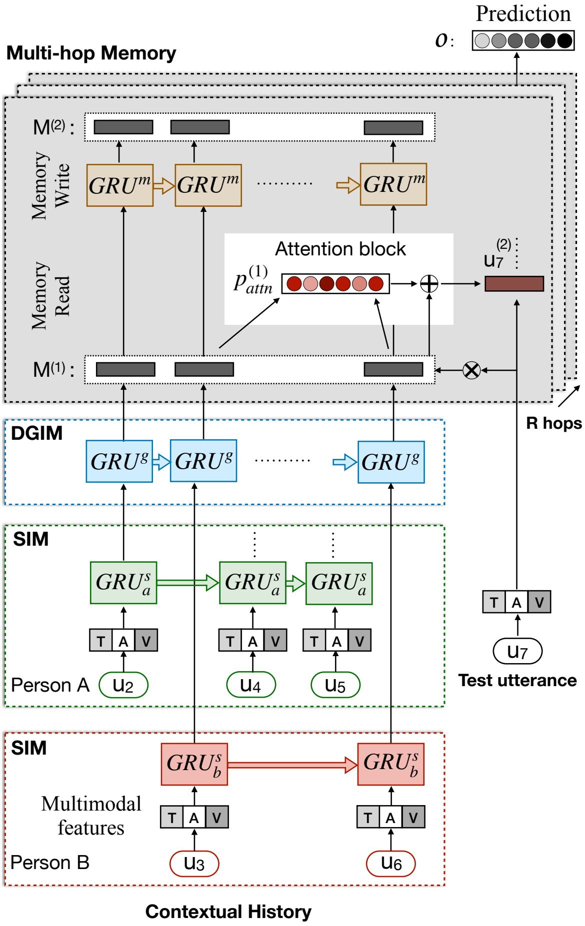

Figure 2: Illustration of ICON. Input conversation is as presented in Table 1.

4.4 Multi-hop Memory

The overall operation of the GRU^g produces a sequence of memories $M = [\boldsymbol{s}_1, ..., \boldsymbol{s}_K] \in \mathbb{R}^{d_{em} \times K}$. These memories incorporate dynamic influences from each of the K utterances spoken in the history. They serve as a contextual memory bank from which selective person-specific information can be incorporated into test utterance u_t to get discriminative features. To achieve this, a series of R memory read/write cycles are performed that are coupled with soft attention for refinement of u_t into a context-aware representation.

The need for multiple hops is inspired by recent works on memory networks (Kumar et al., 2016; Weston et al., 2014), which suggests the importance of multiple read/write iterations for performing transitive inference. Multiple hops also help in improving the focus of attention heads which might miss essential memories in a single hop. At the r^{th} hop, the computations are as follows:

- **Memory Read:** An attention mechanism is used to read the memories from r^{th} memory bank $M^{(r)}$ (Weston et al., 2014). First, each memory $\boldsymbol{m}_{\boldsymbol{k}}^{(r)} \in M^{(r)}$ is matched with test utterance $\boldsymbol{u}_t^{(r)}$ (initially, $\boldsymbol{u}_t^{(1)} = \boldsymbol{u}_t$ and $M^{(1)} = M$).

  This matching generates an attention vector $\boldsymbol{p}_{attn}^{(r)} \in \mathcal{R}^K$ whose k^{th} normalized score represents the relevance of k^{th} memory cell with respect to the test utterance. Inner product is used for the matching as follows:

  $$\boldsymbol{p}_{attn}^{(r)} = softmax(\ (M^{(r)})^T \boldsymbol{u}_t^{(r)}\ ) \tag{6}$$

  Where, $softmax(x_i) = e^{x_i} / \sum_j e^{x_j}$. These scores are then used to find a weighted representation of the memories as

  $$\boldsymbol{m}^{(r)} = \sum_{k=1}^{K} (\boldsymbol{p}_{attn}^{(r)})^k . (\boldsymbol{m}_k) = M^{(r)} \boldsymbol{p}_{attn}^{(r)} \tag{7}$$

  This vector denotes the summary of the context that is person-specific and based on the test utterance. Finally, the representation of the test utterance is updated by consolidating itself with the weighted memory $\boldsymbol{m}$ as:

  $$\boldsymbol{u}_t^{(r+1)} = tanh(\boldsymbol{m}^{(r)} + \boldsymbol{u}_t^{(r)}) \tag{8}$$

- **Memory Write:** After the read operation at each hop, memories are updated for the next hop. For this purpose, a GRU network, GRU^m, takes the r^{th} memory cells $M^{(r)}$ as input and reprocesses this sequence to generate memories $M^{(r+1)}$, i.e., $M^{(r+1)} = GRU^m(M^{(r)})$. Across all hops, this write operation can be viewed as that of a stacked recurrent neural network (RNN) where each level (or hop) improves the representational output of the RNN. The parameters of GRU^m are shared across all hops.

Final Prediction: We use the $(R+1)^{th}$ test utterance vector $\boldsymbol{u}_t^{(R+1)}$ and get the final prediction vector through its affine transformation,

$$\boldsymbol{o} = softmax(W^o \boldsymbol{u}_t^{(R+1)} + \boldsymbol{b}^o) \tag{9}$$

For classification, dimensions of vector $\boldsymbol{o}$ is the number of classes C, i.e., $\boldsymbol{o} \in \mathbb{R}^C$ and *categorical cross-entropy* loss is used as the cost measure for training. For regression, $\boldsymbol{o}$ is a scalar (without softmax normalization) whose scores are used to calculate the *mean squared error* cost metric.

Dataset	Fold	No. of Utterances	No. of Videos	Avg. history length
IEMOCAP	train/val	5810	120	36.54
	test	1623	31	39.00
SEMAINE	train/val	4368	63	43.61
	test	1430	32	45.61

* val = validation set.

Table 2: Summary of datasets. Note: Avg. history length represents the expected number of historical utterances available for any utterance in the dataset.

5 Experiments

5.1 Datasets

We perform experiments on two benchmark datasets in dialogue-based emotion detection: *IEMOCAP*[2] (Busso et al., 2008) and *SEMAINE*[3] (McKeown et al., 2012).

IEMOCAP is a database consisting of videos of dyadic conversations between pairs of 10 speakers. Grouped into five sessions, each pair is assigned with diverse scenarios for dialogues. Videos are segmented into utterances with annotations of fine-grained emotion categories. We consider six such categories for the classification task: *anger, happiness, sadness, neutral, excitement,* and *frustration*. The training set is curated using the first 8 speakers from session 1-4 while session 5 is used for testing.

SEMAINE is a video database of human-agent interactions. Here, users interact with characters whose responses are based on users' emotional state. Specifically, we utilize the AVEC 2012's *fully continuous sub-challenge* (Schuller et al., 2012) that requires predictions of four continuous affective dimensions: arousal, expectancy, power, and valence. The gold annotations are available for every 0.2 seconds in each video (Nicolle et al., 2012). However, to align with our problem statement, we approximate the utterance-level annotation as the mean of the continuous values within the spoken utterance. The sub-challenge provides standard training and testing splits which has been summarized in Table 2.

5.2 Training Details

20% of the training set is used as validation set for hyper-parameter tuning. We use the Adam optimizer (Kingma and Ba, 2014) for training the parameters starting with an initial learning rate of 0.001. Termination of the training-phase is decided by early-stopping with a patience of 10 epochs. The network is subjected to regularization in the form of Dropout (Srivastava et al., 2014) and Gradient-clipping for a norm of 40. Finally, the best hyper-parameters are decided using a grid-search. Their values are summarized in Table 3.

$(f_t^1, f_t^2, f_t^3) = (3, 4, 5)$	$f_{[h,w,d]} = 3$	$f_{out} = 64$
$d_{[t,a]} = 100$	$d_v = 512$	$d_{em} = 100$
$K = 40$	$R = 3$	

Table 3: Hyper-parameter values for the best model.

For multimodal feature extraction, we explore different designs for the employed CNNs. For text, we find the single layer CNN to perform at par with deeper variants. For visual features, however, a deeper CNN provides better representations. We also find that contextually conditioned features perform better than context-less features. Thus, in our experiments, we extract video-level contextual features for utterances from each modality using the network proposed by Poria et al. 2017b. These modified features are then used to form the multimodal utterance representations using equation 3.

5.3 Baselines

We compare our proposed model with multiple state-of-the-art networks in multimodal utterance-level emotion detection.

- *memnet* (Sukhbaatar et al., 2015) is an end-to-end memory network. For comparison, we modify our network to adopt their embedding-based memory-encoding in the multi-hop stage.
- *cLSTM*[4] (Poria et al., 2017b) classifies utterances using neighboring utterances (of same speaker) as context. LSTM is used for this purpose.
- *TFN*[5] (Zadeh et al., 2017) models intra- and inter-modality dynamics by explicitly aggregating uni-, bi- and trimodal interactions. Unlike cLSTM, contextual utterances are not considered.
- *MFN* (Zadeh et al., 2018a) performs multi-view learning by using Delta-memory Attention Network, a fusion mechanism to learn cross-view interactions. Similar to TFN, the modeling is performed within utterances.
- *CMN* (Hazarika et al., 2018) models separate contexts for both speaker and listener to an utterance. These contexts are stored as memories and combined with test utterance using attention mechanism.

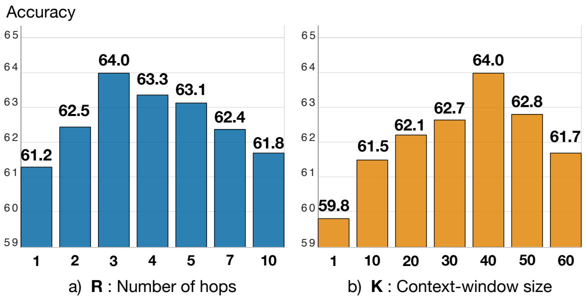
6 Results

Tables 4 and 5 present the results on the IEMOCAP and SEMAINE testing sets, respectively. In Table 4, we evaluate the mean classification performance using Weighted Accuracy (*acc.*) and F1-Score (*F1*) on the discrete emotion categories. ICON performs better than the compared models with significant performance increase in emotions (~2.1% *acc.*). For each emotion, ICON outperforms all the compared models except for *happiness* emotion. However, its performance is still at par with *cLSTM* without a significant gap. Also, ICON manages to correctly identify the relatively similar *excitement* emotion by a large margin.

In Table 5, evaluations of the four continuous labels from SEMAINE are performed using Mean Absolute Error (*MAE*) and Pearson's Correlation Coefficient (*r*). In all the labels, ICON attains improved performance over its counterparts, suggesting the efficacy of its context-modeling scheme.



a) **R** : Number of hops

b) **K** : Context-window size

Figure 3: Trends in the performance of ICON on IEMOCAP dataset with varying R (hops) and K (Context-window size).

Hyperparameters: We plot the performance trends of ICON on the IEMOCAP dataset concerning the two main hyperparameters, R (number of hops) and K (context-window size). For R, the performance initially improves showing the importance of multiple hops in the memories. However, with a further increase, the hopping recurrence deepens and causes the *vanishing gradient* problem. This leads to decrease in performance. The best performance is obtained at $R = 3$. For K, similar trends are observed where performance improvement is seen by increasing the number of historical utterances. The best results are obtained for $K = 40$ which also aligns with the average number of historical utterances in the dataset (Table 2). Further increase in context does not provide relevant information and rather leads to performance degradation due to model confusion.

Multimodality: We investigate the importance of multimodal features for our task. Table 6 presents the results for different combinations of modes used by ICON on IEMOCAP. As seen, the trimodal network provides the best performance which is preceded by the bimodal variants. Among

ICON variants				IEMOCAP		SEMAINE

Table 7: Ablation study for components of ICON.

unimodals, language modality performs the best, reaffirming its significance in multimodal systems. Interestingly, the audio and visual modality, on their own, do not provide good performance, but when used with text, complementary data is shared to improve overall performance.

6.1 Ablation Study

To check the importance of the modules present in ICON, we perform an ablation study where we remove constituent components and evaluate the model's performance. Table 7 provides the results on this study. In the first variant, none of the histories and the associated context-modeling is used. This provides the worst relative performance.

Self vs Dual History: We evaluate the scenarios where only self-history of the speaker is considered (variants 2, 4, and 6). Compared to the dual-history variants (variants 3, 5, and 7), these models provide lesser performance. Reasons involve the provision of partial information from the conversational histories. Similar trends can be seen for the *cLSTM* model in Table 4 which works in the same regime.

DGIM vs no-DGIM: Variants 4 and 5 do not contain the DGIM. In variant 5, separate memory banks are created for both histories ($M_a = H_a^*$ and $M_b = H_b^*$). Memory hops are also separately performed without parameter sharing. Absence of DGIM prevents the storage of dynamic influences between speakers at each historical time step and leads to performance deterioration.

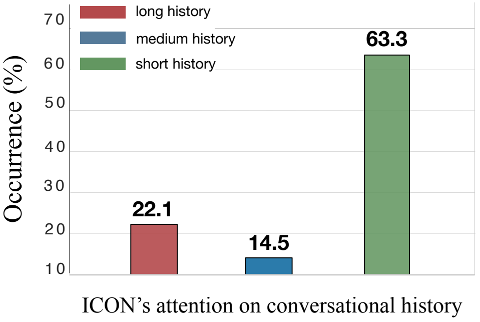

Figure 4: Distribution of top-attention by ICON on correctly classified instances in the testing set.

Multi-hop vs No-hop: Variants 2 and 3 represent cases where multi-hop is omitted, i.e., $R = 1$. Performance for them are poorer than variants having multi-hop mechanism (variants 4-7). Also, removal of multi-hop leads to worse performance than the removal of DGIM. This suggests that multi-hop is more crucial than the latter. However, best performance is achieved by variant 6 which contains all the proposed modules in its pipeline.

6.2 Dependency on distant history

For all the test utterances of IEMOCAP correctly classified by ICON, we analyze the global memories receiving the highest attention. First, we divide the conversational history (context-length $K = 40$) into three regions: *long*, *short*, and *medium*. Figure 4 provides a summary of how much the model attends each of these regions. The short region (labeled green) covering 10 utterances, corresponds to conversational history just preceding the test utterance. Utterances which occur more than 30 time steps behind the current test utterance are considered part of the long region (labeled red). Remaining utterances in between fall on the medium region (labeled blue).

The distribution of top-valued attention scores across the histories reveal interesting insights. Most of the correctly classified instances focus on the immediate or short history. In other words, 63% of the time, at least one of the top-5 attention value belongs to a memory in the short-history range. A significant share is also present for distant history (22%). This result indicates the presence of long-term emotional dependencies and the need to consider histories far away from the current test utterance.

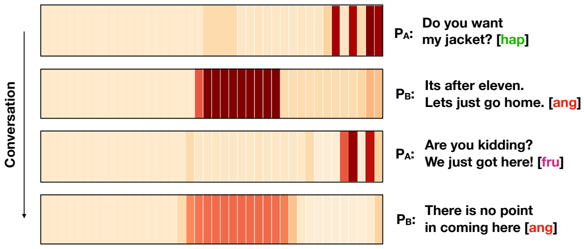

Figure 5: As a conversation develops, different speakers induce different affective bias which reflects in the memory selection for generation of the summaries.

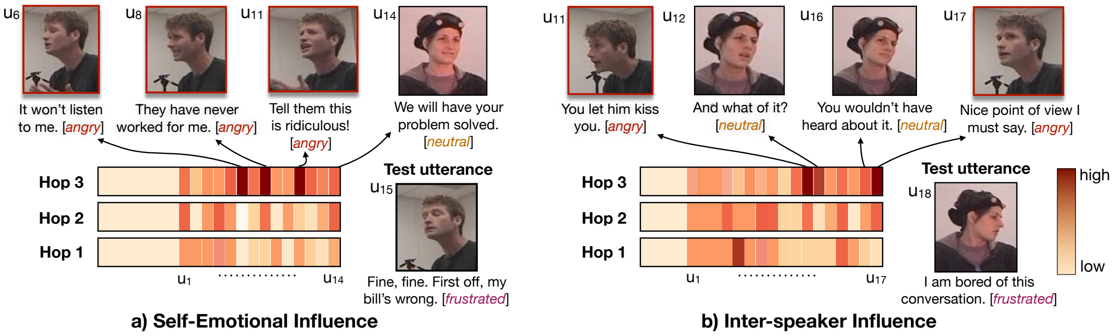

Figure 6: Case studies for emotional influence. 20 memories in the history which are nearest to test utterance, i.e. $k \in [21, 40]$ are visualized from the trained ICON.

6.3 Dynamic Modeling of Global Memories:

ICON holds the capability to model dynamic interactions between speakers. The memories by its DGIM (§4.3) are used to create summaries conditioned on the test utterance. Consequently, these summaries contain characteristics that are specific to the affective state of the current speaker (of the test utterance).

Figure 5 presents a sample slice of conversation from the dataset. As seen, summary selection for Person A varies from Person B. Such differences arise due to person-specific characteristics and unique affective interpretations of the conversation. Apart from the inter-speaker variance, the emotional state of a speaker also varies across turns.

6.4 Case Studies

To understand ICON's behavior while processing the global memories through multi-hop, we manually explore the utterances in the testing set of IEMOCAP. Figure 6 presents two cases which provide traces of self and inter-personal emotional influences and were correctly classified by ICON. Both the figures show the trend where multiple hops gradually improve the focus of attention mechanism on relevant memories.

In Figure 6a, person P_a registers a complaint to an operator P_b. Throughout the dialogue, P_a maintains an angry demeanor while P_b remains calm and neutral (u_{14}). While classifying utterance u_{15}, ICON focuses more on the histories uttered by P_a (u_6, u_8, and u_{11}). This demonstrates ICON's ability to model self-emotional influences. It should be noted that emotion of P_a here also depends on the utterances of P_b but compared to self-utterances, this dependency is much less. Figure 6b presents another scenario where a couple argue over an alleged affair.

A man (P_b) is angry over this fact and questions his partner (P_a) asking for details. The woman tries to behave unperturbed by providing neutral responses (u_{12}, u_{16}) but is eventually affected by P_b's continuous anger and expresses a frustrated response (u_{18}). These characteristics are captured by the attention mechanism applied on the global memories (generated by DGIM), which finds contextual information from histories that are relevant to the test utterance u_{18}. This example displays the role of inter-speaker influences and how ICON processes such dependencies.

7 Conclusion

In this paper, we presented ICON, a multimodal framework for emotion detection in conversations. ICON capitalizes on modeling contextual information that incorporates self and inter-speaker influences. We accomplish this by using an RNN-based memory network with multi-hop attention modeling. Experiments show that ICON outperforms state-of-the-art models on multiple benchmark datasets. Extensive evaluations and case studies demonstrate the effectiveness of our proposed model. Additionally, the ability to visualize the attentions brings a sense of interpretability to the model, as it allows us to investigate which utterances in the conversational history provide important emotional cues for the current emotional state of the speaker.

In the future, we plan to test ICON on other relevant dialogue-based applications and also use it for empathetic dialogue generation.

Discriminative Learning of Open-Vocabulary Object Retrieval and Localization by Negative Phrase Augmentation

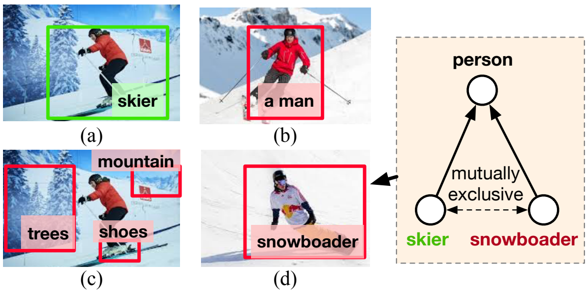
Ryota Hinami[1,2] **and Shin'ichi Satoh**[2,1]
[1]The University of Tokyo, [2]National Institute of Infomatics
`hinami@nii.ac.jp, satoh@nii.ac.jp`

Abstract

Thanks to the success of object detection technology, we can retrieve objects of the specified classes even from huge image collections. However, the current state-of-the-art object detectors (such as Faster R-CNN) can only handle pre-specified classes. In addition, large amounts of positive and negative visual samples are required for training. In this paper, we address the problem of open-vocabulary object retrieval and localization, where the target object is specified by a textual query (e.g., a word or phrase). We first propose Query-Adaptive R-CNN, a simple extension of Faster R-CNN adapted to open-vocabulary queries, by transforming the text embedding vector into an object classifier and localization regressor. Then, for discriminative training, we then propose negative phrase augmentation (NPA) to mine hard negative samples which are visually similar to the query and at the same time semantically mutually exclusive of the query. The proposed method can retrieve and localize objects specified by a textual query from one million images in only 0.5 seconds with high precision.

1 Introduction

Our goal is to retrieve objects from large-scale image database and localize their spatial locations given a textual query. The task of object retrieval and localization has many applications such as spatial position-aware image searches (Hinami et al., 2017) and it recently has gathered much attention from researchers. While much of the previous work mainly focused on object instance retrieval wherein the query is an image (Shen et al., 2012; Tao et al., 2014; Tolias et al., 2016), recent approaches (Aytar and Zisserman, 2014; Hinami and Satoh, 2016) enable retrieval of more generic concepts such as an object category. Although such approaches are built on the recent successes of object detection including that of R-CNN (Girshick et al., 2014), object detection methods can generally handle only closed sets of categories (e.g., PASCAL 20 classes), which severely limits the variety of queries when they are used as retrieval systems. Open-vocabulary object localization is also a hot topic and many approaches are proposed to solve this problem (Plummer et al., 2015; Chen et al., 2017). However, most of them are not scalable to make them useful for large-scale retrieval.



(a) (b) (c) (d)

Figure 1: Training examples in open-vocabulary object detection. (a) positive example of skier classifier. (b) examples without positive annotation, which can be positive. (c) examples without positive annotation from an image that contains a positive example. (d) proposed approach to select hard and true negative examples by using linguistics knowledge.

We first describe *Query-Adaptive* R-CNN as an extension of the Faster R-CNN (Ren et al., 2015) object detection framework to open-vocabulary object detection simply by adding a component called a *detector generator*. While Faster R-CNN learns the class-specific linear classifier as learnable parameters of the neural network, we generate the weight of the classifier adaptively from text descriptions by learning the detector generator (Fig. 2b). All of its components can be trained in an end-to-end manner. In spite of its simple archi-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2605–2615
Brussels, Belgium, October 31 - November 4, 2018.

tecture, it outperforms all state-of-the-art methods in the Flickr30k Entities phrase localization task. It can also be used for large-scale retrievals in the manner presented in (Hinami and Satoh, 2016).

However, training a discriminative classifier is harder in the open-vocabulary setting. Closed-vocabulary object detection models such as Faster R-CNN are trained using many negative examples, where a sufficient amount of good-quality negative examples is shown to be important for learning a discriminative classifier (Felzenszwalb et al., 2010; Shrivastava et al., 2016). While closed-vocabulary object detection can use all regions without positive labels as negative data, in open-vocabulary detection, it is not guaranteed that a region without a positive label is negative. For example, as shown in Fig. 1b, a region with the annotation `a man` is not always negative for `skier`. Since training data for open-vocabulary object detection is generally composed of images, each having region annotations with free descriptions, it is nearly impossible to do an exhaustive annotation throughout the dataset for all possible descriptions. Another possible approach is to use the regions without positive labels in the image that contains positive examples, as shown in Fig. 1c. Although they can be guaranteed to be positive by carefully annotating the datasets, negative examples are only limited to the objects that cooccur with the learned class.

To exploit negative data in open-vocabulary object detection, we use mutually exclusive relationships between categories. For example, an object with a label `dog` is guaranteed to be negative for the `cat` class because `dog` and `cat` are mutually exclusive. In addition, we propose an approach to select *hard negative* phrases that are difficult to discriminate (e.g., selecting `zebra` for `horse`). This approach, called *negative phrase augmentation (NPA)*, significantly improves the discriminative ability of the classifier and improves the retrieval performance by a large margin.

Our contributions are as follows. 1) We propose Query-Adaptive R-CNN, an extension of Faster R-CNN to open vocabulary, that is a simple yet strong method of open-vocabulary object detection and that outperforms all state-of-the-art methods in the phrase localization task. 2) We propose negative phrase augmentation (NPA) to exploit hard negative examples when training for open-vocabulary object detection, which makes the classifier more discriminative and robust to distractors in retrieval. Our method can accurately find objects amidst one million images in 0.5 second.

2 Related work

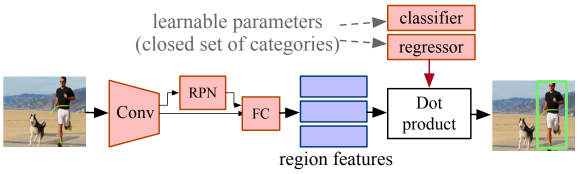
Phrase localization. Object grounding with natural language descriptions has recently drawn much attention and several tasks and approaches have been proposed for it (Guadarrama et al., 2014; Hu et al., 2016; Kazemzadeh et al., 2014; Mao et al., 2016; Plummer et al., 2015). The most related task to ours is the phrase localization introduced by Plummer et al. (Plummer et al., 2015), whose goal is to localize objects that corresponds to noun phrases in textual descriptions from an image. Chen et al. (Chen et al., 2017) is the closest to our work in terms of learning region proposals and performing regression conditioned upon a query. However, most phrase localization methods are not scalable and cannot be used for retrieval tasks. Some approaches (Plummer et al., 2017b; Wang et al., 2016a) learn a common subspace between the text and image for phrase localization. Instead of learning the subspace between the image and sentence as in standard cross-modal searches, they learn the subspace between a region and a phrase. In particular, Wang et al. (Wang et al., 2016a) use a deep neural network to learn the joint embedding of images and text; their training uses structure-preserving constraints based on structured matching. Although these approaches can be used for large-scale retrieval, their accuracy is not as good as recent state-of-the-art methods.

Object retrieval and localization. Object retrieval and localization have been researched in the context of particular object retrieval (Shen et al., 2012; Tao et al., 2014; Tolias et al., 2016), where a query is given as an image. Aytar et al. (Aytar and Zisserman, 2014) proposed retrieval and localization of generic category objects by extending the object detection technique to large-scale retrieval. Hinami and Satoh (Hinami and Satoh, 2016) extended the R-CNN to large-scale retrieval by using approximate nearest neighbor search techniques. However, they assumed that the detector of the category is given as a query and require many sample images with bounding box annotations in order to learn the detector. Several other approaches have used the external search engines (e.g., Google image search) to get training images from textual queries (Arandjelovi et al., 2012; Chatfield et al., 2015). Instead, we generate an object detector directly from the given textual query by using a neural network.

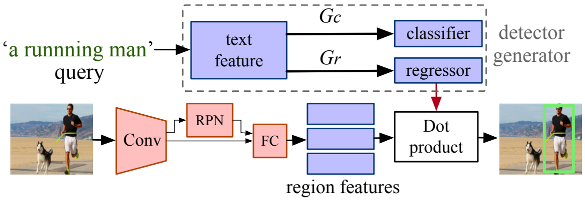
Parameter prediction by neural network. Query-Adaptive R-CNN generates the weights of the detector from the query instead of learning them by backpropagation. The dynamic filter network (De Brabandere et al., 2016) is one of the first methods that generate neural network parameters dynamically conditioned on an input. Several subsequent approaches use this idea in zero-shot learning (Ba et al., 2016) and visual question answering (Noh et al., 2016). Zhang et al. (Zhang et al., 2017) integrates this idea into the Fast R-CNN framework by dynamically generating the classifier from the text in a similar manner to (Ba et al., 2016). We extend this work to the case of large-scale retrieval. The proposed Query-Adaptive R-CNN generates the regressor weights and learn the region proposal network following Faster R-CNN. It enables precise localization with fewer proposals, which makes the retrieval system more memory efficient. In addition, we propose a novel hard negative mining approach, called negative phrase augmentation, which makes the generated classifier more discriminative.

3 Query-Adaptive R-CNN

Query-adaptive R-CNN is a simple extension of Faster R-CNN to open-vocabulary object detection. While Faster R-CNN detects objects of fixed categories, Query-Adaptive R-CNN detects any objects specified by a textual phrase. Figure 2 illustrates the difference between Faster R-CNN and Query-Adaptive R-CNN. While Faster R-CNN learns a class-specific classifier and regressor as parameters of the neural networks, Query-Adaptive R-CNN generates them from the query text by using a detector generator. Query-Adaptive R-CNN is a simple but effective method that surpasses state-of-the-art phrase localization methods and can be easily extended to the case of large-scale retrieval. Furthermore, its retrieval accuracy is significantly improved by a novel training strategy called negative phrase augmentation (Sec. 3.2).



(a) Faster R-CNN



(b) Query-Adaptive R-CNN

Figure 2: Difference in network architecture between (a) Faster R-CNN and (b) Query-Adaptive R-CNN. While Faster R-CNN learns the classifier of a closed set of categories as learnable parameters of neural networks, Query-Adaptive R-CNN generates a classifier and regressor adaptively from a query text by learning a detector generator that transforms the text into a classifier and regressor.

3.1 Architecture

The network is composed of two subnetworks: a *region feature extractor* and *detector generator*, both of which are trained in an end-to-end manner. The region feature extractor takes an image as input and outputs features extracted from sub-regions that are candidate objects. Following Faster R-CNN (Ren et al., 2015), regions are detected using a region proposal network (RPN) and the features of the last layer (e.g., fc7 in VGG network) are used as region features. The detector generator takes a text description as an input and outputs a linear classifier and regressor for the description (e.g., if `a dog` is given, `a dog` classifier and regressor are output). Finally, a confidence and a regressed bounding box are predicted for each region by applying the classifier and regressor to the region features.

Detector generator. The detector generator transforms the given text t into a classifier $\mathbf{w}^c$ and regressor $(\mathbf{w}^r_x, \mathbf{w}^r_y, \mathbf{w}^r_w, \mathbf{w}^r_h)$, where $\mathbf{w}_c$ is the weight of a linear classifier and $(\mathbf{w}^r_x, \mathbf{w}^r_y, \mathbf{w}^r_w, \mathbf{w}^r_h)$ is the weight of a linear regressor in terms of x, y, width w, and height h, following (Girshick et al., 2014). We first transform a text t of variable length into a text embedding vector $\mathbf{v}$. Other phrase localization approaches uses the Fisher vector encoding of word2vec (Klein et al., 2015; Plummer et al., 2015) or long-short term memory

(LSTM) (Chen et al., 2017) for the phrase embedding. However, we found that the simple mean pooling of word2vec (Mikolov et al., 2013) performs better than these methods for our model (comparisons given in the supplemental material). The text embedding is then transformed into a detector, i.e., $\mathbf{w}_c = G_c(\mathbf{v})$ and $(\mathbf{w}^r_x, \mathbf{w}^r_y, \mathbf{w}^r_w, \mathbf{w}^r_h) = G_r(\mathbf{v})$. Here, we use a linear transformation for G_c (i.e., $\mathbf{w}_c = \mathbf{W}\mathbf{v}$, where $\mathbf{W}$ is a projection matrix). For the regressor, we use a multi-layer perceptron with one hidden layer to predict each of $(\mathbf{w}^r_x, \mathbf{w}^r_y, \mathbf{w}^r_w, \mathbf{w}^r_h) = G_r(\mathbf{v})$. We tested various architectures for G_r and found that sharing the hidden layer and reducing the dimension of the hidden layer (up to 16) does not adversely affect the performance, while at the same time it significantly reduces the number of parameters (see Sec. 5.2 for details).

3.2 Training with Negative Phrase Augmentation

All components of Query-Adaptive R-CNN can be jointly trained in an end-to-end manner. The training strategy basically follows that of Faster R-CNN. The differences are shown in Figure 3. Faster R-CNN is trained with the fixed closed set of categories (Fig. 3a), where all regions without a positive label can be used as negative examples. On the other hand, Query-Adaptive R-CNN is trained using the open-vocabulary phrases annotated to the regions (Fig. 3b), where sufficient negative examples cannot be used for each phrase compared to Faster R-CNN because a region without a positive label is not guaranteed to be negative in open-vocabulary object detection. We solve this problem by proposing negative phrase augmentation (NPA), which enables us to use good quality negative examples by using the linguistic relationship (e.g., mutually exclusiveness) and the confusion between the categories (Fig. 3c). It significantly improves the discriminative ability of the generated classifiers.

3.2.1 Basic Training

First, we describe the basic training strategy without NPA (Fig. 3b). Training a Query-Adaptive R-CNN requires the phrases and their corresponding bounding boxes to be annotated. For the ith image (we use one image as a minibatch), let us assume that C_i phrases are associated with the image. The C_i phrases can be considered as the classes to train in the minibatch. The labels $\mathbf{L}_i \in \{0,1\}^{C_i \times n_r}$ are assigned to the region proposals generated by RPN (each of the dotted rectangles in Fig 3b); a positive label is assigned if the box overlaps the ground truth box by more than 0.5 in IoU and negative labels are assigned to other RoIs under the assumption that all positive objects of C_i classes are annotated (i.e., regions without annotations are negative within the image).[1] We then compute the classification loss by using the training labels and classification scores.[2] The loss in terms of RPN and bounding box regression is computed in the

(c) Negative phrase augmentation

Figure 3: Difference in training between (a) closed-vocabulary and (b) open-vocabulary object detection. The approach of NPA is illustrated in (c).

---

[1] Although this assumption is not always true for datasets such as Flickr30k Entities, it nonetheless works well for them because exceptions are rare.

[2] Whereas Faster R-CNN uses the softmax cross entropy over the $C + 1$ (background) classes, where C is the number of closed sets of a category, we use the sigmoid cross entropy because the C_i classes are not always mutually exclusive and a background class cannot be defined in the context of open-vocabulary object detection.

same way as Faster R-CNN (Ren et al., 2015).

3.2.2 Negative Phrase Augmentation

Here, we address the difficulty of using negative examples in the training of open-vocabulary object detection. As shown in Fig. 1b, our generated classifier is not discriminative enough. The reason is the scarcity of negative examples when using the training strategy described in Sec. 3.2.1; e.g., the `horse` classifier is not learned with the `zebra` as a negative example except for the rare case that both a `zebra` and a `horse` are in the same image. Using hard negative examples has proven to be effective in the object detection to train a discriminative detector (Felzenszwalb et al., 2010; Girshick et al., 2014; Shrivastava et al., 2016). However, adding negative examples is usually not easy in the open-vocabulary setting, because it is not guaranteed that a region without a positive label is negative. For example, an object with the label `man` is not a negative of `person` even though `person` is not annotated. There are an infinite number of categories in open-vocabulary settings, which makes it difficult to exhaustively annotate all categories throughout the dataset.

How can we exploit hard examples that are guaranteed to be negative? We can make use of the mutually exclusive relationship between categories: e.g., an object with a `dog` label is negative for `cat` because `dog` and `cat` are mutually exclusive. There are two ways we can add to a minibatch: add negative images (regions) or negative phrases. Adding negative phrases (as in Fig. 3c) is generally better because it involves a much smaller additional training cost than adding images in terms of the both computational cost and GPU memory usage. In addition, to improve the discriminative ability of the classifier, we select only hard negative phrases by mining the confusing categories. This approach, called *negative phrase augmentation (NPA)*, is a generic way of exploiting hard negative examples in open-vocabulary object detection and leads to large improvements in accuracy, as we show in Sec. 5.3.

Confusion table. We create a confusion table that associates a category with its hard negative categories, from which negative phrases are picked as illustrated in Fig. 3c. To create the entry for category c, we first generate the candidate list of hard negative categories by retrieving the top 500 scored objects from all objects in the validation set of Visual Genome (Krishna et al., 2016) (using c as a query). After that, we remove the mutually non-exclusive category relative to c from the list. Finally, we aggregate the list by category and assign a weight to each category. Each of the registered entries becomes like `dog:{cat:0.5, horse:0.3, cow:0.2}`. The weight corresponds to the probability of selecting the category in NPA, which is computed based on the number of appearances and their ranks in the candidate list.[3]

Removal of mutually non-exclusive phrases. To remove non-mutually exclusive phrases from the confusion table, we use two approaches that estimate whether the two categories are mutually exclusive or not. 1) The first approach uses the *WordNet hierarchy*: if two categories have parent-child relationships in WordNet (Miller, 1995), they are not mutually exclusive. However, the converse is not necessarily true; e.g., `man` and `skier` are not mutually exclusive but do not have the parent-child relationship in the WordNet hierarchy. 2) As an alternative approach, we propose to use *Visual Genome annotation*: if two categories co-occur more often in the Visual Genome dataset (Krishna et al., 2016), these categories are considered to be not mutually exclusive.[4] These two approaches are complementary, and they improve detection performance by removing the mutually non-exclusive words (see Sec. 5.3).

The training pipeline with NPA is as follows:

(1) **Update the confusion table:** The confusion table is updated periodically (after every 10k iterations in our study). Entries were created for categories that frequently appeared in 10k successive batches (or the whole training set if the size of the dataset is not large).

(2) **Add hard negative phrases:** Negative phrases are added to each of the C_i phrases in a minibatch. We replace the name of the category in each phrase with its hard negative category (e.g., generate `a running woman` for `a running man`), where the category name is obtained by extracting nouns. A negative phrase is randomly selected from the confusion table on the basis of the assigned probability.

---

[3] We compute the weight of each category as the sum of 500 minus the rank for all ranked results in the candidate lists normalized over all categories in order to sum to one.

[4] We set the ratio at 1% of objects in either category. For example, if there are 1000 objects with the `skier` label and 20 of those objects are also annotated with `man` (20/1000=2%), we consider that `skier` and `man` are not mutually exclusive.

(3) **Add losses:** As illustrated in Fig. 3c, we only add negative labels to the regions where a positive label is assigned to the original phrase. The classification loss is computed only for the regions, which is added to the original loss.

4 Large-Scale Object Retrieval

Query-Adaptive R-CNN can be used for large-scale object retrieval and localization, because it can be decomposed into a query-independent part and a query-dependent part, i.e., a region feature extractor and detector generator. We follow the approach used in large-scale R-CNN (Hinami and Satoh, 2016), but we overcome its two critical drawbacks. First, a large-scale R-CNN can only predict boxes included in the region proposals; these are detected offline even though the query is unknown at the time; therefore, to get high recall, a large number of object proposals should be used, which is memory inefficient. Instead, we generate a regressor as well as a classifier, which enables more accurate localization with fewer proposals. Second, a large-scale R-CNN assumes that the classifier is given as a query, and learning a classifier requires many samples with bounding annotations. We generate the classifier from a text query directly by using the detector generator of Query-Adaptive R-CNN. The resulting system is able to retrieve and localize objects from a database with *one million images* in *less than one second.*

Database indexing. For each image in the database, the region feature extractor extracts region proposals and corresponding features. We create an index for the region features in order to speed up the search. For this, we use the IVFADC system (Jégou et al., 2011) in the manner described in (Hinami and Satoh, 2016).

Searching. Given a text query, the detector generator generates a linear classifier and bounding box regressor. The regions with high classification scores are then retrieved from the database by making an IVFADC-based search. Finally, the regressor is applied to the retrieved regions to obtain the accurately localized bounding boxes.

5 Experiments

5.1 Experimental Setup

Model: Query-Adaptive R-CNN is based on VGG16 (Simonyan and Zisserman, 2015), as in other work on phrase localization. We first initialized the weights of the VGG and RPN by using Faster R-CNN trained on Microsoft COCO (Lin et al., 2014); the weights were then fine-tuned for each dataset of the evaluation. In the training using Flickr30k Entities, we first pretrained the model on the Visual Genome dataset using the object name annotations. We used Adam (Kingma and Ba, 2015) with a learning rate starting from 1e-5 and ran it for 200k iterations.

Tasks and datasets: We evaluated our approaches on two tasks: phrase localization and open-vocabulary object detection and retrieval. The **phrase localization task** was performed on the Flickr30k Entities dataset (Plummer et al., 2015). Given an image and a sentence that describes the image, the task was to localize region that corresponds to the phrase in a sentence. Flickr30k datasets contain 44,518 unique phrases, where the number of words of each phrase is 1–8 (2.1 words on average). We followed the evaluation protocol of (Plummer et al., 2015). We did not use Flickr30k Entities for the retrieval task because the dataset is not exhaustively annotated (e.g., not all men appearing in the dataset are annotated with `man`), which makes it difficult to evaluate with a retrieval metric such as AP, as discussed in Plummer et al. (Plummer et al., 2017b). Although we cannot evaluate the retrieval performance directly on the phrase localization task, we can make comparisons with other approaches and show that our method can handle a wide variety of phrases.

The **open-vocabulary object detection and retrieval task** was evaluated in the same way as the standard object detection task. The difference was the assumption that we do not know the target category at training time in open-vocabulary settings; i.e., the method does not tune in to a specific category, unlike the standard object detection task. We used the Visual Genome dataset (Krishna et al., 2016) and selected the 100 most frequently object categories as queries among its 100k or so categories.[5] [6] We split the dataset into training, validation, and test sets following (Johnson et al., 2016). We also evaluated our approaches on the PASCAL VOC 2007 dataset, which is a widely used dataset

---

[5] Since the WordNet synset ID is assigned to each object, we add objects with labels of hyponyms as positives (e.g., `man` is positive for the `person` category).

[6] We exclude the background (e.g., `grass`, `sky`, `field`), multiple objects (e.g., `people`, `leaves`), and ambiguous categories (e.g, `top`, `line`).

for object detection.[7] As metrics, we used top-k precision and average precision (AP), computed from the region-level ranked list as in the standard object detection task.[8]

5.2 Phrase localization

Comparison with state-of-the-art. We compared our method with state-of-the-art methods on the Flickr30k Entities phrase localization task. We categorized the methods into two types, i.e., non-scalable and scalable methods (Tab. 1). 1) *Non-scalable methods* cannot be used for large-scale retrieval because their query-dependent components are too complex to process a large amount of images online, and 2) *Scalable methods* can be used for large-scale retrieval because their query-dependent components are easy to scale up (e.g., the L_2 distance computation); these include common subspace-based approaches such as CCA. Our method also belongs to the scalable category. We used a simple model without a regressor and NPA in the experiments.

Table 1 compares Query-Adaptive R-CNN with the state-of-the-art methods. Our model achieved *65.21%* in accuracy and outperformed all of the previous state-of-the-art models including the non-scalable or joint localization methods. Moreover, it significantly outperformed the scalable methods, which suggests the approach of predicting the classifier is better than learning a common subspace for the open-vocabulary detection problem.

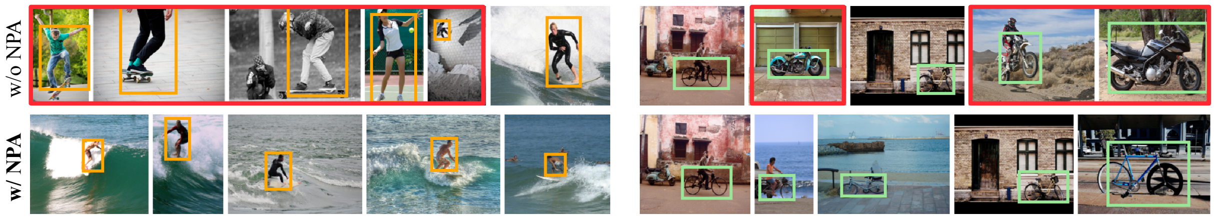
Bounding box regressor. To demonstrate the effectiveness of the bounding box regressor for precise localization, we conducted evaluations with the regressor at different IoU thresholds. As explained in Sec. 3.1, the regressor was generated using G_r, which transformed 300-d text embeddings x into 4096-d regressor weights $\mathbf{w}_x^r$, $\mathbf{w}_y^r$, $\mathbf{w}_w^r$, and $\mathbf{w}_h^r$. We compared three network architectures for G_r: 1) `300-n(-4096)` MLP having a hidden layer with n units that is shared across the four outputs, 2) `300(-n-4096)` MLP having a hidden layer that is not shared, and 3) `300(-4096)` linear transformation (without a hidden layer).

Table 2 shows the results with and without regressor. The regressor significantly improved the accuracy with high IoU thresholds, which demonstrates that the regressor improved the localization accuracy. In addition, the accuracy did not decrease as a result of sharing the hidden layer or reducing the number of units in the hidden layer. This suggests that the regressor lies in a very low-dimensional manifold because the regressor for one concept can be shared by many concepts (e.g., the `person` regressor can be used for `man`, `woman`, `girl`, `boy`, etc.). The number of parameters was significantly reduced by these tricks,

---

[7] We used the model trained on Visual Genome even for the evaluation on the PASCAL dataset because of the assumption that the target category is unknown.

[8] We did not separately evaluate the detection and retrieval tasks because both can be evaluated with the same metric.



Query: surfer

Query: bicycle

Table 3: **Open-vocabulary object detection** performance on Visual Genome and PASCAL VOC 2007 datasets. WN and VG are the strategies to remove mutually non-exclusive phrases.

Query	Most confusing class				2nd most confusing class			
girl	man	19	→	3	boy	4	→	2
skateboard	surfboard	12	→	0	snowboard	11	→	0
train	bus	17	→	1	oven	3	→	0
helmet	hat	18	→	1	cap	6	→	4
elephant	bear	14	→	0	horse	6	→	0

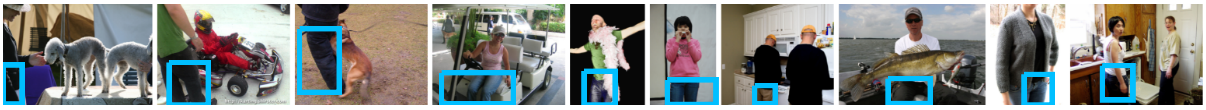
Table 4: Number of false alarms in top 100 results for five queries (**w/o NPA** → **w/ NPA**). The top 2 confusing categories are shown for each query.

to even fewer than in the linear transformation. The accuracy slightly decreased with a threshold of 0.5, because the regressor was not learned properly for the categories that did not frequently appear in the training data.

5.3 Open-Vocabulary Object Retrieval

Main comparison. Open-vocabulary object detection and retrieval is a much more difficult task than phrase localization, because we do not know how many objects are present in an image. We used NPA to train our model. As explained in Sec. 3.2.2, we used two strategies, *Visual Genome annotation (VG)* and *WordNet hierarchy (WN)*, to remove mutually non-exclusive phrases from the confusion table. As a baseline, we compared with region-based CCA (Plummer et al., 2017b), which is scalable and shown to be effective for phrase localization; for a fair comparison, the subspace was learned using the same dataset as ours. An approximate search was not used to evaluate the actual performance at open-vocabulary object detection.

Table 3 compares different training strategies. NPA significantly improved the performance: *more than 25% relative improvement* for all metrics. Removing mutually non-exclusive words also contributed the performance: WN and VG both improved performance (5.8% and 6.9% relative AP gain, respectively). Performance improved even further by combining them (11.8% relative AP gain), which shows they are complementary. AP was much improved by NPA for the PASCAL dataset as well (47% relative gain). However, the performance was still much poorer than those of the state-of-the-art object detection



Query: blue jeans

Query: shark

Query: black dog

Figure 6: Retrievals from one million images. Top-k results for three queries are shown.

methods (Redmon and Farhadi, 2017; Ren et al., 2015), which suggests that there is a large gap between open-vocabulary and closed-vocabulary object detection.

Detailed results of NPA. To investigate the effect of NPA, we show the AP with and without NPA for individual categories in Figure 5, which are sorted by relative AP improvement. It shows that AP improved especially for animals (`elephant`, `cow`, `horse`, etc.) and person (`skier`, `surfer`, `girl`), which are visually similar within the same upper category. Table 4 shows the most confused category and its total count in the top 100 search results for each query, which shows what concept is confusing for each query and how much the confusion is reduced by NPA.[9] This shows that visually similar categories resulted in false positive without NPA, while their number was suppressed by training with NPA. The reason is that these confusing categories were added for negative phrases in NPA, and the network learned to reject them. Figure 4 shows the qualitative search results for each query with and without NPA (and CCA as a baseline), which also showed that NPA can discriminate confusing categories (e.g., `horse` and `zebra`). These results clearly demonstrate that NPA significantly improves the discriminative ability of classifiers by adding hard negative categories.

Large-scale experiments. Finally, we evaluated the scalability of our method on a large image database. We used one million images from the ILSVRC 2012 training set for this evaluation. Table 5 show the speed and memory. The mean and standard deviation of speed are computed over 20 queries in PASCAL VOC dataset. Our system could retrieve objects from one million images in around 0.5 seconds. We did not evaluate accuracy because there is no such large dataset with bounding box annotations.[10] Figure 6 shows the retrieval results from one million images, which demonstrates that our system can accurately retrieve and localize objects from a very large-scale database.

Database size	10K	50K	100K	500K	1M
Time (ms)	183±16	196±21	242±28	314±90	484±165
Memory (GB)	0.46	1.23	2.19	9.87	19.47

Table 5: Speed/memory in **large-scale** experiments.

6 Conclusion

Query-Adaptive R-CNN is a simple yet strong framework for open-vocabulary object detection and retrieval. It achieves state-of-the-art performance on the Flickr30k phrase localization benchmark and it can be used for large-scale object retrieval by textual query. In addition, its retrieval accuracy can be further increased by using a novel training strategy called negative phrase augmentation (NPA) that appropriately selects hard negative examples by using their linguistic relationship and confusion between categories. This simple and generic approach significantly improves the discriminative ability of the generated classifier.

Grounding Semantic Roles in Images

Abstract

We address the task of visual semantic role labeling (vSRL), the identification of the participants of a situation or event in a visual scene, and their labeling with their semantic relations to the event or situation. We render candidate participants as image regions of objects, and train a model which learns to ground roles in the regions which depict the corresponding participant. Experimental results demonstrate that we can train a vSRL model without reliance on prohibitive image-based role annotations, by utilizing noisy data which we extract automatically from image captions using a linguistic SRL system. Furthermore, our model induces frame–semantic visual representations, and their comparison to previous work on supervised visual verb sense disambiguation yields overall better results.

1 Introduction

Images of everyday scenes can be interpreted and described in many ways, depending on the perceiver and the context in which the image is presented. The latter may be natural language data or a visual sequence. As an example, consider the two scenes in Figure 1 and the question *What is the man doing?* The interpretation of the first target image (left) in isolation would allow many answers. Taking into account the visual context, however, may disprove many of those answers (e.g., *He is questioning the women.*). For the target image on the right, the reason for *Why there is so much food on the table?* can be inferred from its textual context.

As the examples illustrate, the interpretation of a (visual) scene is related to the determination of its events, their participants and the roles they play therein (i.e., distill *who did what to whom, where, why and how*), and this may require a joint processing or reasoning with possibly multiple (extra-)linguistic information sources (e.g., text, images). In NLP, the well-established and studied task of semantic role labeling (SRL) aims to extract such knowledge in the form of shallow semantic structures from natural language texts (e.g., *questioning(Agent:man, Theme:women)*); see, e.g., Gildea and Jurafsky (2002); Palmer et al. (2010), for an overview). It is considered an essential task towards text understanding, and was shown to be beneficial for applications such as information extraction (see Roth and Lapata (2016) and the references therein) and question answering (Shen and Lapata, 2007). In computer vision research, recent efforts have been made on *visual* SRL or *situation recognition*, a task coined by transferring the use of semantic roles to produce similar structured meaning descriptions for visual scenes (e.g., Yang et al. (2016); Yatskar et al. (2016)). To facilitate the endeavor of joint processing over multiple sources, it is desirable to induce representations of texts and visual scenes which do encode this kind of information, and in, essentially, a congruent and generic way. The latter would furthermore support the induction of a desired level of abstraction as needed.

In this paper we propose an approach towards this goal: We address the task of visual SRL (vSRL) and learn frame–semantic representations of images. Specifically, we present a model that learns to ground the semantic roles of a *semantic frame* in image *regions*, which may be crucial for, e.g., human-robot interaction or surveillance (e.g., *Who/Where* is the robber?). For example, the image shown in Figure 2 evokes the ARREST frame, and its semantic roles `Authorities`, `Suspect`, and `Place` are grounded in the image regions (delineated by bounding boxes) which depict their corresponding fillers. While being trained on this task, our model learns distributed *situation representations* (for images and frames), and *participant representations* (for image regions and roles) which

Well, the fridge broke, so I had to eat everything.

TARGET IMAGE CONTEXT TARGET IMAGE CONTEXT

Figure 1: Example images along with their visual (left) or textual (right) contexts.

capture the visual–frame-semantic features of situations and participants, respectively.

We train our model on data that we automatically extract by running a linguistic SRL system on image captions—human produced data that is abundant and requires less time and expertise than frame-semantic annotations. Supervised SRL has suffered from data sparsity since it relies on labor-intensive human annotations. Analogous issues on manually annotated images have been addressed by Yatskar et al. (2017). By leveraging existing efforts made in NLP, we explore whether we can alleviate the supervision bottleneck in visual SRL

Our experiments yield promising results, and our models are even able to make correct predictions for erroneous data points. Furthermore, we evaluate the induced situation representations on the task of supervised visual verb sense disambiguation, where it outperforms or is comparable to previous work (on motion or non-motion verbs, respectively).

2 Related Work

Yatskar et al. (2016) introduced the *ImSitu* dataset for the task of *situation recognition*, i.e., the problem of, given an image, predicting a structured output which specifies the depicted activity (e.g., *jumping*) and its associated semantic roles paired with their nominal fillers (e.g., {*(agent, bear), (obstacle, water)*}. To address the task, Yatskar et al. (2016, 2017) train conditional random field (CRF) models on ImSitu (Yatskar et al., 2016) and on additional training data for rarely occurring noun-role combinations which they source from the web (Yatskar et al., 2017). Mallya and Lazebnik (2017) assume that the roles associated with each activity are in a fixed order, and treat the above task as one of recognizing activities and generating a sequence of nouns, for which they use a recurrent neural network. They show how hereby learned features can be transferred to tackle image caption generation. Li et al. (2017) explicitly model role dependencies through a gated graph neural network. Given an image, they instantiate a fully connected graph with a verb and its roles as nodes. Each node's hidden state vector is initialized with image features from two CNNs, which were pre-trained for the prediction of verbs and nouns, respectively. Using a softmax layer augmented with hidden state vectors, they predict the verb and the nominal fillers of its roles.

In contrast to above works on ImSitu, we do not link the roles of a verb to their lexical fillers. We address the related task of explicitly grounding roles in the corresponding image regions, since our focus is on the relation between semantic roles and the typical visual features of their fillers (e.g., a `Body_part` is typically not a *bike* but *arms*). Gupta and Malik (2015) introduced this task as *visual semantic role labeling*. Similarly, Yang et al. (2016) formulate a CRF that jointly processes a cooking video and its natural language descriptions in order to ground the semantic roles associated with the verbs in corresponding object tracks. Both of these studies are limited to a small number of activities performed by people and a few semantic roles (26 and 11 verbs, 3 and 6 roles, respectively).

Unlike related work, our approach does not rely on manual role annotations of images, but exploits a linguistic SRL system for data creation. With more than 1k frame-specific roles, our data is of a larger scope than Gupta and Malik (2015) and Yang et al. (2016). Further, unlike the CRF-based approaches, our model induces frame-semantic representations during training.

ARREST		PLACING

3 Grounding Semantic Roles in Images

We first define the task of vSRL and then present our model and our approach for data creation.

3.1 Task Definition: vSRL

Our approach is based on the linguistic theory of frame-semantics (Fillmore, 1982), which underlies the idea that words evoke semantic frames. Frames describe prototypical situations or events and contain semantic roles. For example, in the sentence *They arrested him for assault*, the argument *they* fills the `Authorities` role, *him* is the `Suspect`, and *assault* the `Charges` of the ARREST frame, which was evoked by the verb *arrest*.

Let F be a set of frames, E be the set of all semantic role labels, and E_f be the inventory of roles associated with the frame f (e.g., E_{ARREST} =\{`Authorities`, `Suspect`, `Charges`, `Offense`, `Place`\})[1]. Assume we are given an image i, which evokes a frame f, and a set of image regions R_i, which render one or several objects in i. The task of vSRL is to link each role $e \in E_f$ to the object $r \in R_i$ that fills role e in the situation or event which f describes. We call a role e to be *realized* in an image, if it can be grounded in an image (region). The object r shown in the image region is called the *filler* or *realization* of e. The structure $A_f = \{(r, e) | r \in R_i, e \in E_f\}$ overall represents the frame f in the image i.

In SRL, the task of identifying the frame which a *predicate* evokes is a prerequisite, but it is usually treated as a subtask of SRL. We follow this approach and consider the identification of the frames evoked by an image as a subtask of vSRL. We formulate two further subtasks for vSRL, namely *role prediction*—determining the correct role for a relevant image region, and *role grounding*—linking a realized role to its filler.

Note that not all roles of a frame may be realized in an image, and not all objects may play a role in an evoked frame. Figure 2, for instance, shows an image with some of its objects delineated by six bounding boxes $R_i = \{r_1, r_2, r_3, r_4, r_5, r_6\}$. The target outputs (bottom, Fig. 2) are the frames ARREST and PLACING, as well as their realized roles which are aligned with their fillers (marked by colors). The FrameNet roles `Charges` and `Offense` are not realized in the image, i.e., they cannot be grounded. The vehicle, box r_4, in turn, does not participate in the ARREST frame.

3.2 Model: Visual-Frame–Semantic Embedder

Our model, illustrated in Figure 3, is formulated as a neural network architecture. Its input is a tuple $q = (i, r, f, e) \in Q$ of an image i, an object which is delineated by bounding box r, a frame $f \in F$, and a role label $e \in E_f$ (e.g., q = (img_1, r_5, ARREST, `Suspect`); cf. Fig. 2). The model output is a score $s(q) \in [-1, 1]$ which quantifies the visual–frame-semantic correspondence between the box r and the role e of f (Fig. 3, right).

More specifically, the model maps visual encodings of i and r (e.g., vectors of a pre-trained CNN), and frame-semantic representations of f and e (randomly initialized embeddings) to common visual–frame-semantic spaces (*cross-modal layers* in Fig. 3).

We assume that images capture different frame-semantic features than image regions—an image encodes the whole scene and its participants and thus evokes a frame, while individual image regions of participants capture the participant-specific features of the semantic roles they fill. We therefore distinguish between two different cross-modal spaces: a situation space for images and frames, and a participant space for regions and roles. Using the respective representations in these spaces, the model then estimates the situation similar-

---

[1] We use FrameNet 1.5 (Ruppenhofer et al., 2006).

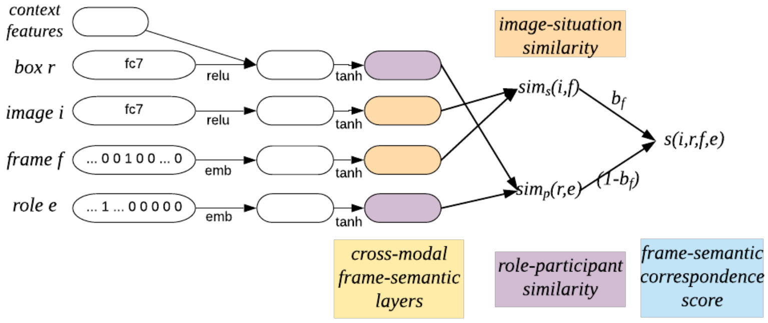

Figure 3: The **ImgObjLoc** model which scores the correspondence between a semantic role and its frame, respectively, and a candidate role filler (an image region) and the whole image, respectively.

ity, $\mathrm{sim}_s(i, f)$, between the image and the frame, and the participant-role similarity, $\mathrm{sim}_p(r, e)$, between the box and the role. Finally, the overall frame-semantic score $s(q)$ is the aggregation of sim_s and sim_p:

$$\mathrm{s}(q) = b_f\, \mathrm{sim}_s(i, f) + (1 - b_f)\, \mathrm{sim}_p(r, e), \quad (1)$$

where parameter $b_f \in \theta$ weights the contribution of the situation and participant scores to the overall score and is learned along all model parameters θ.

By definition of the output function s (Equ. 1), each role-object pair is scored independently of the decisions made for the other roles and regions of the same frame and image, respectively. Technically, this allows for the use of partially labeled training data, where not every realized role of a frame has been linked to its filler, as we will explain in Section 3.3.

Below we describe how we use our model to address the subtasks of role prediction and grounding (Section 3.1), respectively, for which we will report experimental results in Section 5.[2] In any case, the method is based on the visual-frame–semantic correspondence $\mathrm{s}(q)$ (Equ. 1), where we discard all candidates of role-filler pairings with a score less than zero.

Role Prediction Given an image i, we formulate the role prediction problem as a mapping L:

$$\begin{aligned} L :& \{i\} \times R_i \rightarrow F \times E \\ L(i, r) =& \operatorname*{arg\,max}_{(f,e), f \in F, e \in E_f} s(i, r, f, e) \end{aligned} \quad (2)$$

That is, the predicted role (and the frame it is associated with) which an image region $r \in R_i$ of i fills is that $e \in E$ to which r is most similar in the visual–frame-semantic space.

Role Grounding is the equivalent to linguistic semantic role labeling.[3] Given a frame f realized in i, we ground each role $e \in E_f$ in the region $r \in R_i$ with the highest visual–frame-semantic similarity to e:

$$\begin{aligned} G :& \{i\} \times \{f\} \times E_f \rightarrow R_i \\ G(i, f, e) =& \operatorname*{arg\,max}_{r \in R_i} s(i, r, f, e) \end{aligned} \quad (3)$$

Training We train the model by using a ranking criterion designed to give higher scores to true cross-modal frame-semantic combinations (i, r, f, e) than to mismatches, by a margin M. To this end, for each positive example $q = (i, r, f, e)$ of a training set Q, we sample K negative examples $q'_k = (i, r, f', e')$ of a frame f' and role $e' \in E_{f'}$ not true for image i and box r,[4] and learn model parameters θ by minimizing the maximum margin hinge loss function on the tuples (q, q') (Equ. 4) . Ideally, using this loss function would guide the parameter learning towards mapping images and the frames they evoke, and regions and the roles they fill, respectively, nearby each other in the cross-modal spaces.

$$\theta = \operatorname*{arg\,min}_{\theta} \sum_{q \in Q} \frac{1}{K} \sum_{k=1}^{K} \max(0, M - \mathrm{s}(q) + \mathrm{s}(q'_k)) \quad (4)$$

Margin M is found during hyperparameter optimization on a validation set.

---

[2] We refer to Appendix A.2 in the supplemental material for the production of the structure $A_{i,f}$ of all role–filler pairs for a frame f evoked by image i.

[3] More formally, the task of SRL is the determination of the arguments and their semantic roles of a predicate in a sentence.

[4] We could extend the model to also sample a negative image and box for f and e, and a negative role r' for f that is filled by another box in the image. We refrain from this since we create our training data from automatically labeled data, which hence could contain erroneous role-filler pairs.

3.3 Using Linguistic Knowledge for Data Creation

SRL systems in NLP research use training data which have been carefully created by linguistic experts (e.g., Ruppenhofer et al. (2006); Palmer et al. (2005)) for many years. To train our model on the *visual* SRL task, we build upon the annotation efforts made in NLP. The exploitation of existing resources which were developed for the analogous goal means to get around the time-consuming and costly annotation effort involved in the creation of training data. Moreover, adopting an established framework in NLP for shallow semantic representations (FrameNet, Ruppenhofer et al. (2006), in our case), including the therein defined frame and role labels, could facilitate cross-modal interactions—advances in vSRL can help to improve SRL and vice versa, or jointly draw inferences from both modalities (e.g., a text and its illustration).

Our data creation approach is to use a (linguistic) SRL system to extract frame-semantic annotations from a corpus of images paired with captions. We use the Flickr30k Entities dataset (Plummer et al., 2015)[5] which contains 30k images and five captions per image. We chose this dataset since its captions are augmented with entity mention annotations, associating them with the 276k manually annotated bounding boxes (i.e., entities are grounded in the image). To create the set $Q = \{(i^{(j)}, r^{(k_j)}, f^{(l_j)}, e^{(l_j,k_j)}) | j \in \{1, \ldots, 30k\}\}$ of training instances, we run PathLSTM (Roth, 2016; Roth and Lapata, 2016) on all captions, and extract all semantic frame annotations whose roles are filled by a grounded entity. As a result, our training corpus comprises images, the frames they evoke, and the associated semantic roles paired with their grounded fillers (i.e., bounding boxes).

Sentences (1a)–(1c) in Figure 4 (left), for example, are three human produced captions for the image in Figure 2, in which entity mentions are linked to their image regions (indicated by colors). Using PathLSTM, we extract the grounded frame-semantic annotations (2a)–(2c) (Fig. 4, right), which results in the following six instances of our corpus Q:

$(\text{img}_1, r_5, \text{PLACING}, \texttt{Theme})$
$(\text{img}_1, r_1, \text{PLACING}, \texttt{Agent})$
$(\text{img}_1, r_4, \text{PLACING}, \texttt{Goal})$

$(\text{img}_1, r_1\_r_2, \text{ARREST}, \texttt{Authorities})$
$(\text{img}_1, r_5, \text{ARREST}, \texttt{Suspect})$
$(\text{img}_1, r_3, \text{ARREST}, \texttt{Place})$

4 Data

Training Data We adopt the training, validation and test splits provided in the Flickr30k Entities dataset (Plummer et al., 2015) and create our dataset Q with the method described above. Some verbs and the frame types which they evoke occur very frequently in the set of annotations (e.g., BEING_LOCATED) and therefore allow the induction of a finer-grained frame inventory. Specifically, we transform each frame which is evoked by an individual *verb* (e.g., *stand* or *sit*) for at least 100 images (as obtained from the captions) in the Flickr30k Entities training split to a finer-grained frame type by concatenating it with the verb (e.g., BEING_LOCATED-*sit*). Finally, we keep all *frame types* (fine-grained or coarse) which had been assigned to at least 100 different images. This amounts to an inventory of 252 frame types (102 coarse types, e.g., STATEMENT), 1,409 frame-specific role types (e.g., STATEMENT.`speaker`), 169 role labels (e.g., `Speaker`) and 76,939 training instances. We derive our validation and test splits from the original splits on the basis of above modifications. See Table 1 for the quantitative details on the dataset, which we henceforth call *Flickr30k Roles*.

Table 1: Overview of our *Flickr30K Roles* dataset.

Reference Data *Flickr30k Roles* may contain false instances due to its creation on the basis of automatic frame–semantic annotations. ImSitu (Yatskar et al., 2016) is, to the best of our knowledge, the only existing benchmark dataset for vSRL. As explained in Section 2, however, it is image-based, and does not provide explicit links between roles and the regions which depict their fillers. It cannot be used for the evaluation of role prediction and grounding without additional annotations.

We therefore created a set of reference instances by presenting a subset of the *Flickr30k Roles* test data to two human subjects (both students of computational linguistics) for annotation. We chose all instances which agree in their frame label with instances extracted from at least two other captions of the underlying image. This amounts to 201 images and 715 instances. The annotators were presented with an image with relevant objects rendered by bounding boxes, along with the automatically grounded semantic frame annotations. Figure 5 gives an example image along with the 4 automatically obtained instances. They were asked to judge the correctness of the frame (e.g., INGESTION, Fig. 5), the verb (in the case of a fine-grained frame type; e.g., *eat*) and each of the role–filler links (e.g., `Ingestor`–226403). They further linked wrong role assignments to their correct fillers when possible. We created the reference set as the intersection of all correct instances of the two annotators (frame and role–filler linkings), which amounts to 554 instances.

Visual Representations We use high-dimensional distributed vectors to represent images and regions (bounding boxes), and represent the latter by additional contextual features. These encode a region's relative location and size with respect to the whole image (cf. (Mao et al., 2016)):

$$\left[\frac{x_{tl}}{W}, \frac{y_{tl}}{H}, \frac{x_{br}}{W}, \frac{y_{br}}{H}, \frac{w \cdot h}{W \cdot H}\right], \tag{5}$$

where (x_{tl}, y_{tl}) and (x_{br}, y_{br}) are the coordinates of the top left and bottom right corners of the bounding box, H and W are the height and width of the image, and h and w the height and width of the box. These features have been found useful for referring expression generation/interpretation for objects in images (Mao et al., 2016). We hypothesize that the relative position and size of an object can be likewise informative for the roles it can(not) realize. For example, an object that is located at the bottom of an image is probably rather the `Patient` of a KICKing event than the `Agent`.

INGESTION-***eat***			1–1
Role	Entity ID	(obj. name)	
`Ingestor`	226403	woman	1
`Ingestibles`	226404	lunch/hotdog	1
`Place`	226408	at_diner	1
`Ingestor`	226409	table/at_table	0

instances *label*

Figure 5: Automatically derived instances in *Flickr30k Roles* (colored, left columns) and the human correctness judgments of the frame, verb, and role fillers (right-most column; 1 is *correct*, 0 *wrong*). The object names were presented to facilitate the annotation, but are not part of the instance.

5 Experiments

We first evaluate our model in terms of different aspects related to visual SRL on the two subtasks role prediction and grounding (see Section 3).

Our second experiment assesses the usefulness of the learned frame-semantic image representations on the task of visual verb disambiguation: given an image and a verb, assign the correct sense of the verb, i.e., the one that describes the action depicted in the image (e.g., *play* an instrument; *play* sport). This task is different from visual SRL, but forms a prerequisite for it, since in frame semantics, roles are defined on the basis of frames evoked by verb *senses*.

Model Details For each bounding box and image, we use the VGG16 network (Simonyan and Zisserman, 2014), trained on ImageNet (Deng et al., 2009), to extract a $4,096$-dimensional feature vec-

tor from the fully connected fc7 layer. To transform the feature vectors into the visual–frame-semantic embedding space, we use two two-layer networks which are composed of a layer with rectified linear activation units (relu) followed by a layer with tanh activations (see Fig. 3, top left). We furthermore concatenate the first hidden layer (relu layer) of each image region (i.e., box) with a vector of contextual features (relative box size and location, Equ. 5).

Frames and roles, in turn, are encoded as one-hot vectors and mapped to randomly initialized embedding layers, which are then transformed into the visual–frame-semantic representations using tanh activation layers (Fig. 3, bottom). We use the cosine similarity to quantify visual-frame–semantic correspondences in the cross-modal space (Equ. 1).

Throughout our experiments we compare our model (**ImgObjLoc**), which takes into account the contextual features (Equ. 5), to a model that does not use contextual box features (**ImgObject**), and one that only uses the image as visual input (**Image-only**). **Image-only** derives its cross-modal *role* representation by augmenting both, the image *and* the box input layers with the image's fc7 feature vector.

The network parameters were optimized using AdaGrad (Duchi et al., 2011) with a learning rate of 0.003. We monitored the role prediction performance on the validation set of Flickr30k Roles and kept the best performing model. See Appendix A.1 for further details on the model hyperparameters.

5.1 Exp.1: Semantic Role Prediction and Local Grounding

In the role prediction evaluation, the model is given an image and a bounding box, which represents a candidate role filler, and needs to predict the frame and role which the entity (or entities) in the box fills.

In the grounding experiment, the model is given an image, a frame and an associated role which is realized in the image, and needs to determine the correct role filler from a list of boxes. We report results on using ground truth boxes as well as box proposals, extracted with selective search (Uijlings et al., 2013). Regarding the latter, we apply the intersection over union (IoU) metric (e.g., Everingham et al. (2010)), and consider a role to be grounded in the correct box proposal $\tilde{r}$ if the area of overlap between $\tilde{r}$ and the reference box, divided by the area of their union, exceeds 50%.

Results We report top-1 and top-k accuracy (i.e., the frame and role is among the top-k scored predictions) on the *Flickr30k Roles* test and reference sets for both subtasks (recall that Flickr30k Entities provides ground truth alignments between entity mentions and objects).

Table 2 gives the results on role *prediction* with ground truth bounding boxes (i.e., for all entities which fill at least one semantic role). We report the accuracy for predicting the correct frame and role (columns fr.role), for predicting the correct frame (columns frame), and the correct role regardless of its frame (columns role; e.g., a prediction of STATEMENT.`Speaker` would be considered correct even if the reference was SPEAK_ON_TOPIC.`Speaker`). We further give results for the coarse frame types, where verbs are stripped off the frame labels (i.e., STATEMENT-*speak* is STATEMENT). Since the role prediction performance is equal for both frame types, we report the results for the fine-grained frames only.

As Table 2 shows, the models which use participant representations extracted from the relevant image regions (**ImgObject** and **ImgObjLoc**) perform better than **Image-only** which considers the

	`Buyer`	`Manner`	`Purpose`

Table 4: Roles which were most difficult to predict by **ImgObjLoc**, in the order of their total frequency in the reference set (top left to bottom right), distinguished by the prediction precision of PathLSTM.

global image only, except for the top-1 frame prediction. This indicates that the two models are able to learn useful role-specific visual representations. Contextual features in the form of the relative size and location of a region (cf. Equ. 5) seems to be also beneficial, due to **ImgObjLoc** yielding the overall best results.

These features are furthermore beneficial for role *grounding* in automatically selected bounding boxes: When using automatically selected boxes, **ImgObjLoc** is significantly more effective than **ImgObject** in all settings (rows props, right block in Table 3). The Random baseline, which assigns each role randomly to a box in the image, performs unsurprisingly worst.

Interestingly, the models perform substantially better on the reference set than on the noisy test set (top and bottom blocks in Tables 2,3).[6] This indicates that they were able to generalize over wrong role-filler pairs in the training data, and are able to make correct predictions even for erroneous instances (see the qualitative analysis below). When assuming that the correct frame has been identified (columns gt fr.), the best role prediction accuracy reaches 70.3% on the reference set, and grounding accuracy with box proposals is at 35.5% (**ImgObjLoc**, Tables 2,3, respectively).

Finally, frame prediction proves to be a difficult task, especially for fine-grained frame types (e.g., BEING_LOCATED-*sit*; left block in Table 2).

Qualitative Analysis Notably, our analysis revealed that **ImgObjLoc** could correctly predict roles for cases in which PathLSTM failed, especially for highly visual entities (e.g., `performance` vs. `location`, `goal` vs. `path`). Overall, **ImgObjLoc** was often able to identify location roles which PathLSTM had missed, but may confuse the specific labels (e.g., `area` vs. `path` or `location`) for reasons discussed below. See Figure 6 for the recall of **ImgObjLoc** on the reference set for individual roles (top-20).

In an error analysis of the predictions of **ImgObjLoc** we identified several classes of errors. Typical errors in *role* prediction were in cases in which an image region contained multiple objects, and the system predicted a label for an object which was occluded by the target or vice versa (e.g., `ingestibles` vs. `source`; `clothing` vs. `wearer` or `body_part`; `path` vs. `area`). We found that this error was propagated from noise in the training data. Table 4 shows the roles which were most difficult to predict by **ImgObjLoc**, and which the textual SRL system (PathLSTM) could predict with a high precision (top; as calculated from the human annotations, cf. Section 4), or with a low precision (bottom), respectively. As may be expected, among these are also highly non-visual roles, such as `manner` and `purpose`.

Other noise propagated from the training data was caused by wrong frame predictions of PathLSTM (e.g., TRAVERSE-*pass* instead of BRINGING-*carry*; CONTAINING-*hold*.`contents` vs. IN-

---

[6] The accuracy scores on the uncorrected instances in the reference set yield comparable or worse accuracy scores than those on the test set, except for the top-5 predicted frames.

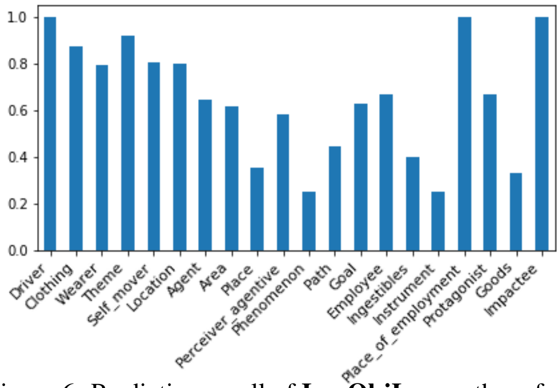

Figure 6: Prediction recall of **ImgObjLoc** on the reference set for the top-20 roles, ordered by their frequency.

Features	Motion	Non-motion

Gella–CNN+O$^+$	83.0	80.0
Gella–CNN+C$^+$	82.3	80.3
CNN (reproduced)	83.1	79.8 ± 0.53
ImgObjLoc	**84.8 ± 0.69**	**80.4 ± 0.57**

Table 5: Sense prediction accuracy for motion (left) and non-motion verbs (right) using different image representations. $^+$ marks results taken from Gella et al. (2018). MFS is the most frequent sense heuristic.

GESTION.ingestibles). Frequent patterns of incorrect frame predictions were furthermore a failure of the system to distinguish between fine-grained frames (e.g., BEING_LOCATED-*sit* vs. *-lie* or SELF_MOTION-*walk* vs. *-run*), or between motion and non-motion actions (e.g., POSTURE vs. SELF_MOTION).

Finally, we observed that often the reference did not contain an actually valid frame which had been predicted by the system for an image, due to different levels of frame specificity, i.e., the output of **ImgObjLoc** was more specific (e.g., ASSISTANCE-*help*.helper vs. WEARING.wearer; OPERATE_VEHICLE-*ride*.vehicle vs. PERCEPTION_ACTIVE-*look*.location_of_perceiver) or it was more general (e.g., WEARING.wearer vs. IMPACT-*hit*.impactor).

5.2 Exp.2: Visual Verb Sense Disambiguation

We evaluate the effectiveness of the frame-semantic *image* representations that can be extracted with our **ImgObjLoc** model on the VerSe (visual Verb Sense disambiguation) dataset (Gella et al., 2018). It covers 90 verbs and 163 senses used to annotate $3,510$ images. We follow the supervised method applied in (Gella et al., 2018), divide VerSe into training and test data, and train logistic regression classifiers for sense prediction on 19 motion verbs and 19 non-motion verbs (those which have at least 20 images and at least 2 senses). Input to the sense classifiers are the frame-semantic image representations (second top cross-modal layer in Fig. 3) of the VerSe images, which we extract with the **ImgObjLoc** model, trained on Flickr30k Roles.

Table 5 gives the mean accuracy obtained on the test data (of 100 runs). Our **ImgObjLoc** vectors outperform all comparison models on motion verbs, including CNN-based image features and the best-performing models of (Gella et al., 2018), namely Gella–CNN+O and Gella–CNN+C (CNN features concatenated with predicted object labels and image captions, respectively). On non-motion verbs, the best models, including our own, perform only comparably to the most frequent sense heuristic. Note that we examine the simplest representation **ImgObjLoc** can yield, i.e., frame-semantic representations for individual images. More complex representations are left for future work. See Appendix A.3 for examples.

6 Conclusions

We addressed the task of grounding semantic roles of frames which an image evokes in the corresponding image regions of its fillers. We found that our model can be trained without the need of manual role annotations of image data, and that the frame-semantic image representations it learns can be used for related tasks. Encouraged by our findings, future work includes the exploration of the model and its learned frame-semantic representations for tasks such as the interpretation of multimodal scenes and stories and referring expressions.

A Supplemental Material

A.1 Model Parameters

We optimized the network parameters using AdaGrad (Duchi et al., 2011) with a learning rate of 0.003. Dropout with rate 0.25 was added on top of the visual–frame-semantic layers. We monitored the role prediction performance on the validation

Algorithm 1 vSRL algorithm which grounds each semantic role e of a frame f^* in at most one region $r \in R_i$ of image i. $s(.)$ denotes the visual-frame–semantic correspondence score (Equation (1)).

```
Require: a frame $f^*$ for image $i$, $R_i$    // Equ. (6)
  $S_{i,f^*} \leftarrow ((s(i,r,f^*,e), r, e) : r \in R_i, e \in E_{f^*})$,
  sorted in descending order of $s(.)$
  $A_{i,f^*} \leftarrow \emptyset$, grounded realization of $f^*$
  for all $(s,r,e) \in S_{i,f^*}$ do
      if $(r,.) \notin A_{i,f^*} \wedge (.,e) \notin A_{i,f^*}$ then
          $A_{i,f^*} \leftarrow A_{i,f^*} \cup \{(r,e)\}$
      end if
  end for
  return $A_{i,f^*}$
```

set of Flickr30k Roles and kept the best performing model, which was obtained after about 20 epochs for each model. For all models, the first visual hidden layer has 1000 dimensions, and all other layers have 250 units. The margin M (Equation 4 in the main paper) was set to 0.3, and $K = 10$ negative frame-role examples were sampled for each training instance.

A.2 Model: vSRL

The full vSRL task requires, given an image i, the computation of the set $A_{i,f}$ of role-object pairs which comprises the semantic roles of a frame f grounded to their fillers, i.e., $A_{i,f} = \{(r,e) | r \in R_i, e \in E_f\}$. Using our model, we first determine the frame f^* which image i evokes on the basis of all role-filler predictions, i.e.,

$$f^* = \arg\max_{f \in F} \sum_{\{r \in R_i, e \in E_f\}} s(i,r,f,e) \tag{6}$$

We then apply a simple algorithm (Algorithm 1) which chooses the filler–role pairs with maximum similarity from the set S_{i,f^*} of all scored frame-specific filler-role pairings for image i given frame f^* (cf. Equation 1 in the main paper), such that every role is grounded in at most one region, and every region fills at most one role (line 6, Algorithm 1).

A.3 Examples for VSD

Figure 7 shows example images of non-motion verbs for which ImgObjLoc achieved a high (*serve*, 95%) and a low accuracy (*reach*, 50%), their ground truth senses (gt) and the predictions of **ImgObjLoc** (sys).

serve (95%):
dish out, hand out something, often food
sys: ✓

serve (95%):
put a ball into play
sys: ✓

reach (50%)
extend physically/by influence
sys: ✓

reach (50%)
extend physically/by influence
sys: ✓

reach (50%):
gt: *pass or transfer something*
✗sys: *attain/arrive at a state, real or abstract*

reach (50%):
gt: *pass or transfer something*
✗sys: *extend physically/by influence*

Abstract

To enable collaboration and communication between humans and agents, this paper investigates learning to acquire commonsense evidence for action justification. In particular, we have developed an approach based on the generative Conditional Variational Autoencoder (`CVAE`) that models object relations/attributes of the world as latent variables and jointly learns a performer that predicts actions and an explainer that gathers commonsense evidence to justify the action. Our empirical results have shown that, compared to a typical attention-based model, `CVAE` achieves significantly higher performance in both action prediction and justification. A human subject study further shows that the commonsense evidence gathered by `CVAE` can be communicated to humans to achieve a significantly higher common ground between humans and agents.

1 Introduction

To make AI more accessible, transparent, and trustworthy, recent years have seen an increasing effort on Explainable AI (XAI) which develops explainable models that attempts to explain the agent's decision making behaviors while maintaining a high-level of performance. Two types of explanation have been explored by the research community: *introspective explanation* which addresses the process of decision making (e.g., how a decision is made) and *justification explanation* which gathers evidence to support a certain decision (Park et al., 2018; Biran and McKeown, 2017). In this paper we focus on justification explanation, particularly identifying ***commonsense evidence*** to justify the prediction of an action. The key question we are addressing is: when an AI agent makes a prediction about an action in the world, how can the system justify its prediction that makes sense to the human?

Humans have tremendous commonsense knowledge about actions in the world (e.g., key constituents of an action) which allows them to quickly recognize and infer actions in the environment from millions of available features (Rensink, 2000). As a first step in our investigation, we initiated a human study to observe the kind of commonsense reasoning used by humans to justify the prediction of an action. From this study, we identified several dimensions of commonsense evidence which is commonly used to explain an action. Motivated by this study, we frame our task as follows: given all the symbolic descriptions of the perceived physical world (e.g., object relations and attributes as a result of vision or other processing), the goal is to identify a small set of descriptions which can justify an action prediction in line with humans' commonsense knowledge about that action. The lack of commonsense knowledge is a major bottleneck in artificial agents which jeopardizes the common ground between humans and agents for successful communication. If artificial agents ever become partners with humans in joint tasks, the ability to learn and acquire commonsense evidence for action justification is crucial.

To address this problem, we developed an approach based on the generative Conditional Variational Autoencoder (`CVAE`). This approach models the perceived attributes/relations as latent variables and jointly learns a ***performer*** which predicts actions based on attributes/relations and a ***explainer*** which selects a subset of attributes/relations as commonsense evidence to justify the action prediction. Our empirical results on a subset of the Visual Genome data (Krishna et al., 2016) have shown that, compared to a typical attention-based model, `CVAE` has a significantly higher explanation ability in terms of identifying correct commonsense evidence to justify

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2627–2637
Brussels, Belgium, October 31 - November 4, 2018.

the predicted action. When adding the supervision of commonsense evidence during training, both the explainability and the performance (i.e., action prediction) are further improved.

As commonsense evidence is intuitive to humans, the agent's ability to select the right kind of commonsense evidence will allow the human and the agent to come to a common understanding of actions and their justifications, in other words, *common ground*. To evaluate the role of commonsense evidence in facilitating common ground, we conducted additional human subject studies. In these experiments, the agent is given a set of images and applies our models to predict actions and select commonsense evidence to justify the prediction. For each image, the agent communicates the selected commonsense evidence to the human. The human, who does not have access to the original image, makes a guess on the action only based on the communicated evidence. The agreement between the action guessed by the human and the action predicted by the agent is used to measure how well the selected commonsense evidence serves to bring the human and the agent to a common ground of perceived actions. Our experimental results have shown that the commonsense evidence selected by `CVAE` leads to a significantly higher common ground.

The contributions of this paper are three folds. First we identified several key dimensions of commonsense evidence, from a human's perspective, to justify concrete actions in the physical environment. These dimensions provide a basis for justification explanation that is aligned with human's commonsense knowledge about the action. Second we proposed a method using `CVAE` to jointly learn to predict actions and select commonsense evidence as action justification. `CVAE` naturally models the generation process of both actions and commonsense evidence. Inferring commonsense evidence is equivalent to the posterior inference of the `CVAE` model, which is flexible and powerful by incorporating actions as context. Our experimental results have shown a higher explainability of `CVAE` in action justification without sacrificing performance. Finally our dataset of commonsense evidence for action explanation is available to the community[1]. It can serve as a benchmark for future work on this topic.

2 Related Work

Advanced machine learning such as deep learning approaches have shown effectiveness in many applications, however, they often lack transparency and interpretability. This makes it difficult for humans to understand the agent's capabilities and limitations. To address this problem, there is a growing interest in Explainable AI. For example, previous work has applied high-precision rules to explain classifiers' decisions (Ribeiro et al., 2016, 2018). For Convolutional Neural Networks (CNNs), recent work attempts to explain model behaviors by mining semantic meanings of filters (Zhang et al., 2017a,b) or by generating language explanations (Hendricks et al., 2016; Park et al., 2018). An increasing amount of work on the Visual Question Answering (VQA) task (Antol et al., 2015; Lu et al., 2016) has also looked into more interpretable approaches, for example, by utilizing attention-based models (Fukui et al., 2016) or reasoning based on explicit evidence (Wang et al., 2017).

Specifically for action understanding, recent work explicitly models commonsense knowledge including causal relations (Gao et al., 2016; Forbes and Choi, 2017; Zellers and Choi, 2017; Gao et al., 2018) related to concrete actions, which can facilitate action explanation. Commonsense knowledge can be acquired from image annotations (Yatskar et al., 2016) or learned from visual abstraction (Vedantam et al., 2015). Different from the above work, our work here focuses on learning to acquire commonsense evidence for action justification.

3 A Study on Justification Explanation

While there is a rich literature on explanations in Psychology, Philosophy, and Linguistics, particularly for higher-level events and decision making (Thagard, 2000; Lombrozo, 2012; Dennett, 1987), explanations for recognition of lower-level concrete physical actions (e.g., drink, brush, cook, etc.) occurred in our daily life are rarely studied. One possible reason is that we humans are so intuitive in recognizing these actions, which are often taken for granted without the need for any further explanation. However, despite recent advances, the ability to recognize and understand actions in the real world is extremely challenging for artificial agents. Thus it becomes important for the agent to have an ability to explain and justify its

---

[1] The dataset is available at `https://github.com/yangshao/Commonsense4Action`

action prediction. What can be used to justify an action prediction, and more importantly, in a human understandable way? To address this question, we initiated a human study to examine what kind of evidence humans would gather in justifying their recognition of an action perceived from the physical world.

More specifically, we selected a set of 12 short video clips (each about 14 seconds) from the Microsoft Research Video to Text dataset (Xu et al., 2016). For each video clip, we asked human subjects to explain why they think a certain action is happening in the video. The answers were collected via an online interface. A total of about 140 responses from 67 Michigan State University engineering students were collected. From the data, we identified the following categories of evidence commonly used by the subjects in their justifications. Most responses contain multiple categories of explanation.

- **Transitive-Relation**. This kind of explanation does not directly focus on the structural relations between an action and its participants, but rather transits to the relation between the participant of the action and other related evidence. For example, using *a woman wears an apron* to justify the *cook* action. In the collected responses, 64% of them used transitive relations.
- **Subaction-Relation**. Lower-level subactions are used to justify a higher-level action. For example, the action is *cook* because there are sub-actions like *cutting* and *heating meat*. Almost 75% of the responses used subactions.
- **Spatial-Relation**. Spatial relations between the participants of the action play an important role. For example, *the knife is on the cutting board* is used to explain *cooking*; and *the water is in the bottle* to explain *drinking*. Around 15% of responses are in this category.
- **Effect-Attribute**. A change in the state of an object, in other words the effect state after the action, is often used as evidence. For example, *cucumber in small pieces* is used as the evidence for *chop*. Over 28% of the responses are in this category.
- **Associated-Attribute**. Other attributes associated with the participants of the action, but not the effect state of the participants as a result of the action (20%). While these attributes are not directly related to the action, they are linked to the action by association. For example, *banana is sliced* is used as evidence to justify *blend*.
- **Other**. Participants have also cited other commonsense such as the “definition” of the action (5%), or the manner associated with different sub actions(12%).

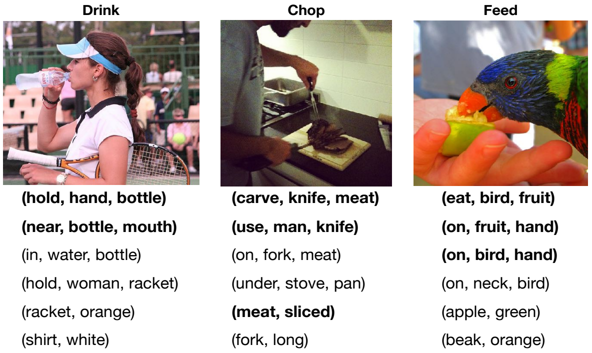

Figure 1: Examples of commonsense evidence selected by the crowd (in bold) from the list of relations and attributes.

Most of the above categories can be potentially perceived and represented through symbolic descriptions such as logic predicates to capture object attributes and relations between objects. This study has motivated us to collect additional data (Section 4) and formulate the task of commonsense justification as described in Section 5.

4 Data Collection

Motivated by the human study described above, we created a dataset based on the Visual Genome (VG) data (Krishna et al., 2016) for our investigation. Each image in the VG dataset is annotated with bounding boxes, attributes of the bounding boxes, and relations between the bounding boxes. The available annotation provides an ideal setup for us to focus on commonsense justification.

In this work, we are interested in the concrete physical actions that involve physical objects that can be perceived. We selected ten frequently occurred concrete actions: *feed, pull, ride, drink, chop, brush, fry, bake, blend, eat* and manually identified a set of images from the VG dataset depicting these actions. This has led to a dataset of 853 images with annotated ground-truth actions.

We conducted a crowd-source study to collect responses from the crowd in terms of common-

Table 1: The average number of available relations/attributes and the average number of annotated commonsense evidence relations/attributes across the corresponding images for each verb in the dataset.

sense evidence for action justification. As shown in Figure 1, for each image, we showed to the crowd (through Amazon Mechanical Turk) the image itself, the ground-truth action, and a list of relations/attributes. The workers were instructed to select the relations/attributes that were deemed to justify the corresponding action. We randomly assigned three workers to each image. The relations or attributes that were selected by the majority (two or more) workers were considered *gold commonsense evidence* for action justification.

Table 1 shows the average number of relations/attributes available (i.e., `Rel#` and `Att#`) for the corresponding images for each verb. It also shows the number of relations/attributes selected by the workers as commonsense evidence (i.e., `Gold_Rel#` and `Gold_Att#`). The average number of relations and attributes in each image for different actions varies slightly. However, only a small percentage of them are considered commonsense evidence. What's interesting is that the percentage of attributes considered good evidence is significantly less than the percentage of the relations. The sparsity of gold relations/attributes shows that it's a challenging task to learn an explainer for a target action.

We further inspected the selected gold commonsense relations and attributes. As shown in Table 2, they nicely fall into the categories of commonsense evidence discussed in Section 3. The ratios of `Transitive-Relation` are similar across different actions. The ratios of `Subaction-Relation` and `Spatial-Relation` vary for different verbs. For instance, *ride, bake, blend* tend to be justified by spatial relations more often than sub-actions. In addition, *feed, pull, ride* are rarely justified by `Effect-Attribute` while *chop* is mainly explained by the effect state of its direct object. These results will provide insight for generating justification explanations for a variety of verbs in the future.

5 Method

Before we formulate the problem, we will first give some formal definitions. The set of relations $\mathbf{R}$ is defined as $\{r_1, r_2, ..., r_m\}$ where each r_i is a tuple (r_i^p, r_i^s, r_i^o) corresponding to the *predicate*, *subject*, and *object*; and the set of attributes $\mathbf{E}$ is represented as $\{e_1, e_2, ..., e_n\}$ where each e_i is a tuple (e_i^o, e_i^p) corresponding to the *object* and *attribute*. We introduce $\mathbf{z}$ as a discrete vector $(\mathbf{z}_1, \mathbf{z}_2, ..., \mathbf{z}_{m+n})$ where $\mathbf{z}_i \in \{0, 1\}$ represents the hidden explainable variable. $\mathbf{z}$ is interpreted as an evidence selector: $\mathbf{z}_i = 1$ means the corresponding relation/attribute justifies the target action $\mathbf{a}$. We define $\mathbf{A}$ as the vocabulary of target actions. Based on all these definitions, our goal is to jointly select evidence $\mathbf{z}$ and predict target action $\mathbf{a} \in \mathbf{A}$. In other words, to learn the probability $\mathbf{p}(\mathbf{a}, \mathbf{z}|\mathbf{R}, \mathbf{E})$.

5.1 Conditional Variational Autoencoder

The varational autoencoder(`VAE`) (Kingma and Welling, 2013) is proposed as a generative model to combine the power of both directed continuous

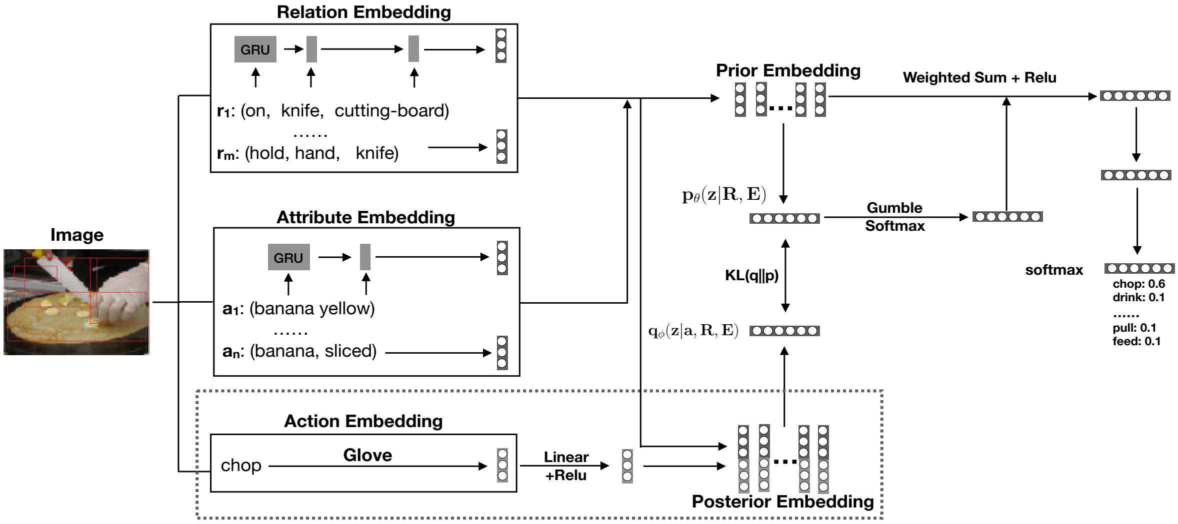

Figure 2: System architecture for the `CVAE` model. The dotted region is only used during the model training process.

or discrete graphical models and neural network with latent variables. The `VAE` models the generative process of a random variable $\mathbf{x}$ as following: first the latent variable $\mathbf{z}$ is generated from a prior probability distribution $\mathbf{p}(\mathbf{z})$, then a data sample $\mathbf{x}$ is generated from a conditional probability distribution $\mathbf{p}(\mathbf{x}|\mathbf{z})$. The `CVAE` (Zhao et al., 2017) is a natural extension of `VAE`: Both the prior distribution and conditional distribution now are conditioned on an additional context $\mathbf{c}$: $\mathbf{p}(\mathbf{z}|\mathbf{c})$ and $\mathbf{p}(\mathbf{x}|\mathbf{z},\mathbf{c})$.

In our task, we decompose the inference problem $\mathbf{p}(\mathbf{a},\mathbf{z}|\mathbf{R},\mathbf{E})$ into two smaller problems. The first sub-problem is to infer $\mathbf{p}(\mathbf{a}|\mathbf{R},\mathbf{E})$, which is a **performer**. The second problem is to infer $\mathbf{p}(\mathbf{z}|\mathbf{a},\mathbf{R},\mathbf{E})$ which is an **explainer**. These two problems are closely coupled, hence we model them jointly. The probability distribution $\mathbf{p}(\mathbf{a}|\mathbf{R},\mathbf{E})$ can be written as :

$$\mathbf{p}(\mathbf{a}|\mathbf{R},\mathbf{E}) = \sum_{\mathbf{z}} \mathbf{p}_\theta(\mathbf{a}|\mathbf{z},\mathbf{R},\mathbf{E})\mathbf{p}(\mathbf{z}|\mathbf{R},\mathbf{E})$$

Directly optimizing this conditional probability is not feasible. Usually the Evidence Lower Bound (`ELBO`) (Sohn et al., 2015) is optimized, which can be derived as the following:

$$\begin{aligned}
&\mathrm{ELBO}(\mathbf{a},\mathbf{R},\mathbf{E};\theta,\phi) \\
&= -\,\mathrm{KL}(\mathbf{q}_\phi(\mathbf{z}|\mathbf{a},\mathbf{R},\mathbf{E})||\mathbf{p}_\theta(\mathbf{z}|\mathbf{R},\mathbf{E})) \\
&+ \mathbf{E}_{\mathbf{q}_\phi(\mathbf{z}|\mathbf{a},\mathbf{R},\mathbf{E})}[\log p_\theta(\mathbf{a}|\mathbf{z},\mathbf{R},\mathbf{E})] \\
&\leq \log \mathbf{p}(\mathbf{a}|\mathbf{R},\mathbf{E})
\end{aligned} \tag{1}$$

The first KL divergence term is to minimize the distance between the posterior distribution and the prior distribution. The second term is to maximize the expectation of the target action based on the posterior latent distribution.

In most previous work using `VAE`, there is no explicit meaning for the hidden representation $\mathbf{z}$, thus it's hard for humans to interpret. For example, $\mathbf{z}$ is simply assumed as a Gaussian distribution or a categorical distribution. In order to have a more explicit representation for the purpose of explanation, our latent discrete variable $\mathbf{z}$ is used to indicate whether the corresponding relation or attribute can be used for justifying the action.

The whole system architecture is shown in Figure 2. From an image, we first extract a candidate relation set $\mathbf{R}$ and an attribute set $\mathbf{E}$. Every relation $\mathbf{r}$ and attribute $\mathbf{e}$ are embedded using a Gated Recurrent Neural Network (Chung et al., 2014).

$$\mathbf{r}^{emb} = \mathrm{GRU}([r^p, r^s, r^o])$$

$$\mathbf{e}^{emb} = \mathrm{GRU}([e^o, e^p])$$

The action $\mathbf{a}$ is represented by a GloVe embedding (Pennington et al., 2014), followed by another non-linear layer:

$$\mathbf{a}^{emb} = \mathrm{ReLU}(\mathbf{W}_i\mathbf{a}^{glove} + \mathbf{b}_i)$$

where $\mathbf{a}^{glove} \in \mathbb{R}^k$ is the pre-trained GloVe embedding. Then the latent variable $\mathbf{z}$ can be calculated as:

$$\mathbf{q}_\phi(\mathbf{z}|\mathbf{a},\mathbf{R},\mathbf{E}) = \mathrm{softmax}(\mathbf{W}_\mathbf{z}[\mathbf{U};\mathbf{a}^{emb}] + \mathbf{b}_\mathbf{z})$$

where $\mathbf{U} = [\mathbf{r}_1^{emb}, ..., \mathbf{r}_m^{emb}, \mathbf{e}_1^{emb}, ..., \mathbf{e}_n^{emb}]$ and $[\mathbf{U}, \mathbf{a}^{emb}]$ means the concatenation of $\mathbf{U}$ and $\mathbf{a}^{emb}$. and $W_{\mathbf{z}} \in \mathbb{R}^{2\times 2k}$ as we assume each $\mathbf{z}_i$ belongs to one of the two classes $\{0, 1\}$.

The prior distribution can be calculated as:

$$\mathbf{p}_\theta(\mathbf{z}|\mathbf{R}, \mathbf{E}) = \text{softmax}(\mathbf{W}_{\mathbf{z}}^{'}\mathbf{U} + \mathbf{b}_{\mathbf{z}}^{'})$$

The KL divergence between the prior random variable $\mathbf{z}_{prior}$ from $\mathbf{p}_\theta(\mathbf{z}|\mathbf{R}, \mathbf{E})$ and the posterior random variable $\mathbf{z}_{posterior}$ from $\mathbf{q}_\phi(\mathbf{z}|\mathbf{a}, \mathbf{R}, \mathbf{E})$ is:

$$\text{KL}(\mathbf{z}_{prior}, \mathbf{z}_{posterior}) = -p_i \log \frac{p_i}{p_i^{'}} - (1 - p_i) \log \frac{1 - p_i}{1 - p_i^{'}}$$

here $\mathbf{z}_{prior} \sim \text{Bern}\,(p_i)$, $\mathbf{z}_{posterior} \sim \text{Bern}\left(p_i^{'}\right)$.

Another challenge is that $\mathbf{z}$ is a discrete variable which blocks the gradient and makes the end-to-end training infeasible. Gumbel-Softmax (Jang et al., 2016) is a re-parameterization trick to deal with the discrete variables in the neural network. We use this trick to sample discrete $\mathbf{z}$. Then we do a weighted sum pooling between discretized $\mathbf{z}$ and $\mathbf{U}$:

$$\mathbf{h}_z = \text{ReLU}(\sum_i \mathbf{z}_i * \mathbf{U}_i)$$

$$\mathbf{h} = \text{ReLU}(\mathbf{W}_h\mathbf{h}_z + \mathbf{b}_h)$$

$$\mathbf{p}_\theta(\mathbf{a}|\mathbf{z}, \mathbf{R}, \mathbf{E}) = \text{softmax}(\mathbf{W}\mathbf{h} + \mathbf{b})$$

During training, we also add a sparsity regularization on the latent variable $\mathbf{z}$ besides the ELBO. So our final training objective is

$$\begin{aligned} \mathcal{L}_{CVAE} = &-\text{ELBO}(\mathbf{a}, \mathbf{R}, \mathbf{E}; \theta, \phi) \\ &+ \beta\, \text{KL}(\mathbf{q}_\phi(\mathbf{z}|\mathbf{a}, \mathbf{R}, \mathbf{E}) || \,\text{Bern}(0)) \end{aligned} \quad (2)$$

During testing, we have two objectives. First we want to infer the target action $\mathbf{a}$, which can be computed through sampling:

$$\begin{aligned} \mathbf{p}(\mathbf{a}|\mathbf{R}, \mathbf{E}) &= \sum_{\mathbf{z}} \mathbf{p}_\theta(\mathbf{z}|\mathbf{R}, \mathbf{E})\mathbf{p}_\theta(\mathbf{a}|\mathbf{z}, \mathbf{R}, \mathbf{E}) \\ &\approx \frac{1}{S}\sum_{s=1}^{S} \mathbf{p}_\theta(\mathbf{a}|\mathbf{z}_s, \mathbf{R}, \mathbf{E}) \end{aligned} \quad (3)$$

where $\mathbf{z}_s \sim \mathbf{p}(\mathbf{z}|\mathbf{R}, \mathbf{E})$ and S is the number of samples. After obtaining the predicted action $\hat{\mathbf{a}}$, the posterior explanation is inferred as $\mathbf{q}_\phi(\mathbf{z}|\hat{\mathbf{a}}, \mathbf{R}, \mathbf{E})$.

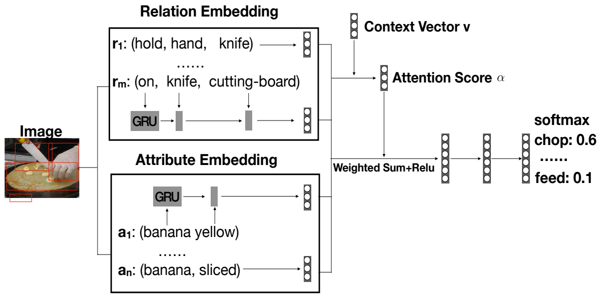

Figure 3: The system architecture for attention-based method.

5.2 Conditional Variational Autoencoder with Supervision (`CVAE+SV`)

In this setting, we assume we have the supervision for the discrete latent variable z, which is more like a multi-task setting. We optimize both the action prediction loss and the evidence selection loss. The final loss function is defined as:

$$\mathcal{L}_{SV} = \lambda\mathcal{L}_{CVAE} + (1 - \lambda)\mathcal{L}_{evidence}$$

where

$$\mathcal{L}_{evidence} = -\sum_k (\mathbf{z}_k \log \mathbf{p}(\hat{\mathbf{z}}_k) + (1 - \mathbf{z}_k)\log(1 - \mathbf{p}(\hat{\mathbf{z}}_k)))$$

in which $\mathbf{z}_k \in \{0, 1\}$ is the ground truth label, $\hat{\mathbf{z}}_k$ is the predicted label and λ is a hyper-parameter.

6 Evaluation on Action Explanation

To evaluate our model, we randomly split our dataset (853 images) into 60% for training, 20% for validation, and 20% for test. For all the models we use the Adam optimizer (Kingma and Ba, 2014) with a starting learning rate 1e-4. All other hyperparameters are tuned on the validation set.

6.1 Baseline: Attention Model

We use an attention-based model as a baseline, which is similar to the model originally proposed for document classification (Yang et al., 2016). The architecture is shown in Figure 3. Different from the CVAE-based method, this model directly learns a context parameter instead of learning from the posterior action context. The attention is calculated as:

$$\alpha_i = \frac{\exp(\mathbf{u}_i^T\mathbf{v})}{\sum_j \exp(\mathbf{u}_i^T\mathbf{v})}$$

where $\mathbf{v}$ is the context parameter, and $\mathbf{u}_i$ is the GRU embedding of the corresponding relation/attribute. The learned attention weights are used for the selection of commonsense evidence.

Table 3: Action prediction accuracy and evidence selection MAP.

	Action Accuracy	Evidence MAP
Attention	0.789	0.442
CVAE	0.835	0.572
CVAE+SV	0.871	0.690
Upper Bound	0.918	1.0

6.2 Evaluation Metrics and Comparison

Our evaluation compares the performance from the following models:

- `Baseline`. The attention model presented in Section 6.1.
- `CVAE`. The conditional variational autoencoder model presented in Section 5.1.
- `CVAE+SV`. The `CVAE` model with supervision as presented in Section 5.2.
- `Upper Bound`. We also calculate the upper bound of the `CVAE` model using the human annotated gold evidence.

For each of the above model, evaluate model performance on both action prediction (i.e., performer) and action justification (i.e., explainer)

- **Performer**: Accuracy is used to measure the percentage of actions that are correctly predicted by the model.
- **Explainer**: As discussed in Section 5, the binary random variable $\mathbf{z}$ is used to capture commonsense evidence. The probability of each $\mathbf{z}$ represents the model's belief that the corresponding evidence supports the action decision. As we hope to rank the gold evidence higher, the Mean Average Precision (MAP) metric is calculated for evaluating evidence selection.

6.3 Evaluation Results

The results are shown in Table 3. Since the `Upper Bound` method directly uses the human annotated gold evidence, its MAP for selecting evidence is always 1.0.

The `CVAE` model outperforms the attention-based model in both action prediction and evidence selection. This indicates that the `CVAE` model can incorporate a better guidance for evidence selection during the training process. One possible explanation is that the CVAE model incorporates the target action as the context during learning instead of directly learning a context parameter. Furthermore, after adding the evidence supervision, the `CVAE+SV` model gives even better performance in both action prediction and evidence selection. We notice that for the `CVAE+SV` model, its action prediction accuracy is approaching the upper bound 91.8%, however the evidence selection MAP is still far from the upper bound even with supervision.

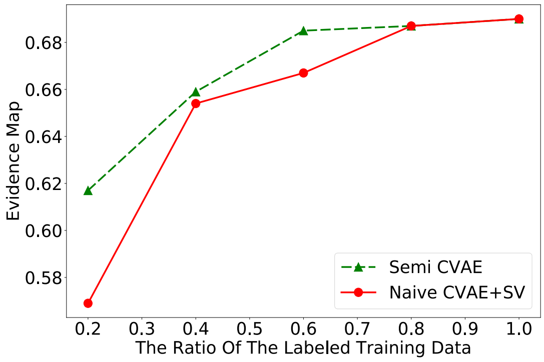

Figure 4: Evidence selection MAP for semi-supervised learning.

6.4 Semi-Supervised Learning

Although we have shown that adding supervision on the latent variable $\mathbf{z}$ improves the model performance, collecting this label information through human annotation is usually time consuming and expensive. In this section, we explore how semi-supervised learning can help to alleviate this difficulty.

As a generative model, `VAE` has shown its advantage on semi-supervised learning (Kingma et al., 2014). Following the method in (Kingma et al., 2014), our semi-supervised learning loss function is defined as:

$$\mathcal{L} = \sum_{(\mathbf{a},\mathbf{R},\mathbf{E},\mathbf{z})\sim\mathbf{p}_l} \mathcal{L}_{SV} + \sum_{(\mathbf{a},\mathbf{R},\mathbf{E})\sim\mathbf{p}_u} \mathcal{L}_{CVAE}$$

where $\mathcal{L}_{SV}$ is defined in section 5.2 and $\mathcal{L}_{CVAE}$ is detailed in section 5.1. In other words, the data sample with evidence label is fed to $\mathcal{L}_{SV}$, otherwise is fed to $\mathcal{L}_{CVAE}$.

The results are shown in Figure 4 where the x-axis shows the ratio of labeled examples. The incremental `Naive CVAE+SV` model only uses the labeled evidence examples while the `Semi CVAE` model also uses unlabeled evidence examples. The figure shows that the `Semi CVAE`

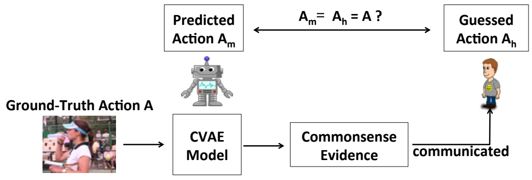

Figure 5: The experimental setup for the human subject study examining the role of commonsense justification towards common ground.

model outperforms the `Naive CVAE+SV` model. This indicates that the semi-supervised method can improve the evidence selection by making use of unlabeled examples.

7 Commonsense Justification towards Common Ground

In human-agent communication, the success of communication is largely dependent on common ground which captures shared knowledge, beliefs, or past experience (Clark, 1996). As commonsense evidence what humans use to justify actions, To validate this hypothesis, we conducted a human-subject experiment to examine the role of commonsense justification in facilitating common ground.

7.1 Experiment Setup

Figure 5 shows the setup of our experiment. The agent is provided with an image and applies various models (e.g., `CVAE`) to jointly predict the action and identify commonsense evidence. The human is provided with a list of six action choices and does not have access to the image. The agent communicates to the human only the identified commonsense evidence and the human makes a guess on the action from the candidate list purely based on the communicated evidence. The idea is that, if the human and the agent share the same beliefs about evidence to justify an action, then the action guessed by the human should be the same as the action predicted by the agent.

Generating Distracting Verbs. For each image, the human is provided with a list of six action/verb candidates. To generate this list, we mix four distracting verbs with the ground-truth action verb plus a default `Other`. Most of the distracting verbs come from the concrete action verbs made available by (Gao et al., 2018). We first manually filtered out the verbs which have the same meaning with the ground-truth verb. We then selected two groups of distracting verbs: an *easy* group (where the distracting verbs have larger distance from the ground-truth verb in the embedding space, with an average similarity of 0.284) and a *hard* group (more close to the ground-truth verbs with an average similarity of 0.479). The temperature based softmax distribution (Chorowski and Jaitly, 2016) was used to sample the easy and the hard distracting verbs based on the pre-trained GloVe (Pennington et al., 2014) embedding cosine similarity.

Process. A total of 170 images were used in this experiment, and 24 workers from AMT participated in our study. For each image, we applied three different models: `Attention` baseline, `CVAE`, and `CVAE+SV` to generate the commonsense evidence. An upper bound based on gold commonsense evidence was also measured. Note that, the agent has no knowledge of the human's action choices when generating the commonsense evidence. Theory of mind is an important aspect in human-agent communication. Incorporating human's action choices in justifying action is an interesting however a different problem which requires different solutions. In this paper, we only focus on the situation where the mind of the human is opaque to the agent.

For each model and each image under the easy or hard configurations, the top five predicted commonsense evidence (associated with the predicted action) were shown to a worker. The the worker was requested to select the most probable action from the distracting list only based on these five pieces of evidence. We randomly assigned three workers to each image. The majority of three selections was considered as the final answer. If all three selections disagreed, one worker's choice was randomly selected as the final answer.

Metrics for Common Ground. We use the agreement between the action guessed by the human and the action predicted by the agent to measure how well the selected commonsense evidence serves to bring the human and the agent to a common ground of perceived actions. More formally, as shown in Figure 5, given an image, suppose its ground-truth action is A, the action predicted by the agent/machine is A_m, and the action guessed by the human is A_h, the *Common Ground* is defined as: $A_m = A_h = A$. Here we also enforce that the predicted action should be the same as the ground-truth action. The percentage of trials based on different models that have led to a com-

	Attention	CVAE	CVAE+SV	Gold

	• The bread is **next to** the bread. • The bread is **on** the rack. • The bread is **on** the pan. • The man **has** keys. • The man **has** the band.	• The bread is **on** the rack. • The bread is **on** the pan. • The bread is **on** the tray. • The bread is **next to** the bread. • The bread is **baked**.	• The bread is **baked**. • The bread is **next to** the bread. • The person is **pushing** the tray. • The bread is **on** the pan. • The bread is **on** the rack.	• The bread is **on** the tray. • The person is **pushing** the tray. • The bread is **baked**.
Gold Action: Brush	A_m: Brush A_h: Skin	A_m: Brush A_h: Brush	A_m: Brush A_h: Brush	A_m: Brush A_h: Brush
	• The baby **has** a mouth. • The baby **has** a hand. • The baby **has** eyeballs. • The baby **has** fingers. • The baby **has** a nose.	• The hand **holds** the toothbrush. • The toothbrush **is** in the mouth. • The baby **has** a mouth. • The baby **has** fingers. • The baby **has** a nose.	• The hand **holds** the toothbrush. • The toothbrush **is** in the mouth. • The baby **has** eyeballs. • The baby **has** a mouth. • The baby **has** a hand.	• The toothbrush **is** in the mouth. • The hand **holds** the toothbrush.

Figure 6: Two examples of the common ground study based on different models. In each example, a ranked list of commonsense evidence generated by different models is shown. A_m captures the action predicted by the agent. A_h captures the action guessed by the human based on the selected commonsense evidence.

Table 4: Results from the human subject study on common ground.

	Attenton	CVAE	CVAE+SV	Gold
Easy	0.665	0.776	0.818	0.888
Hard	0.576	0.718	0.788	0.841

mon ground is measured and compared.

7.2 Experimental Results

Table 4 shows the comparison results among various models and the upper bound where the gold commonsense evidence provided to the human. It's not surprising that performance on common ground is worse in the *hard* configuration as the distracting verbs are more similar to the target action. The `CVAE`-based method is better than the attention-based method in facilitating common ground.

Figure 6 shows two examples of the top five predicted evidence under different models. For each model, it also shows the agent predicted action (A_m) and the human guessed action (A_h). In both examples, all models were able to establish a common ground except for the attention-based model. The evidence selected by the `CVAE+SV` model is clearly more accurate than the `CVAE` model and is more close to the ground-truth evidence. The second example shows that although the attention-based model predicts a correct target action, it fails to convey correct commonsense evidence to establish a common ground with the human.

8 Conclusion

This paper describes an approach for action justification using commonsense evidence. As demonstrated in our experiments, commonsense evidence is selected to align with humans' justification of an action and is therefore critical in establishing a common ground between humans and agents.

For all experiments in this paper, we use the annotated relations/attributes from the original Visual Genome data. As the state-of-the-art recall@50 on the relation detection with a limited vocabulary is only around 20% (Liang et al., 2018). Using annotated relations and attributes allows us to focus on the study of commonsense evidence and its role in action justification and common ground. Nevertheless, our proposed method has the potential to handle the erroneous relations/entities, e.g., as a result of vision processing, for example, by avoiding to select erroneous relations as they do not correlate with actions and other indicative relations/attributes. Our future work will extend the model and findings from this work to vision processing that will not only identify commonsense evidence but also explain where and how in the perceived environment the evidence is gathered.

Abstract

The ability to infer persona from dialogue can have applications in areas ranging from computational narrative analysis to personalized dialogue generation. We introduce neural models to learn persona embeddings in a supervised character trope classification task. The models encode dialogue snippets from IMDB into representations that can capture the various categories of film characters. The best-performing models use a multi-level attention mechanism over a set of utterances. We also utilize prior knowledge in the form of textual descriptions of the different tropes. We apply the learned embeddings to find similar characters across different movies, and cluster movies according to the distribution of the embeddings. The use of short conversational text as input, and the ability to learn from prior knowledge using memory, suggests these methods could be applied to other domains.

1 Introduction

Individual personality plays a deep and pervasive role in shaping social life. Research indicates that it can relate to the professional and personal relationships we develop (Barrick and Mount, 1993), (Shaver and Brennan, 1992), the technological interfaces we prefer (Nass and Lee, 2000), the behavior we exhibit on social media networks (Selfhout et al., 2010), and the political stances we take (Jost et al., 2009).

With increasing advances in human-machine dialogue systems, and widespread use of social media in which people express themselves via short text messages, there is growing interest in systems that have an ability to understand different personality types. Automated personality analysis based on short text analysis could open up a range of potential applications, such as dialogue agents that sense personality in order to generate more interesting and varied conversations.

We define persona as a person's social role, which can be categorized according to their conversations, beliefs, and actions. To learn personas, we start with the character tropes data provided in the CMU Movie Summary Corpus by (Bamman et al., 2014). It consists of 72 manually identified commonly occurring character archetypes and examples of each. In the character trope classification task, we predict the character trope based on a batch of dialogue snippets.

In their original work, the authors use Wikipedia plot summaries to learn latent variable models that provide a clustering from words to topics and topics to personas – their persona clusterings were then evaluated by measuring similarity to the ground-truth character trope clusters. We asked the question – could personas also be inferred through dialogue? Because we use quotes as a primary input and not plot summaries, we believe our model is extensible to areas such as dialogue generation and conversational analysis.

Our contributions are:

1. Data collection of IMDB quotes and character trope descriptions for characters from the CMU Movie Summary Corpus.
2. Models that greatly outperform the baseline model in the character trope classification task. Our experiments show the importance of multi-level attention over words in dialogue, and over a set of dialogue snippets.
3. We also examine how prior knowledge in the form of textual descriptions of the persona categories may be used. We find that a 'Knowledge-Store' memory initialized with descriptions of the tropes is particularly useful. This ability may allow these models to be used more flexibly in new domains and with

different persona categories.

2 Related Work

Prior to data-driven approaches, personalities were largely measured by asking people questions and assigning traits according to some fixed set of dimensions, such as the Big Five traits of openness, conscientiousness, extraversion, agreeability, and neuroticism (Tupes and Christal, 1992). Computational approaches have since advanced to infer these personalities based on observable behaviors such as the actions people take and the language they use (Golbeck et al., 2011).

Our work builds on recent advances in neural networks that have been used for natural language processing tasks such as reading comprehension (Sukhbaatar et al., 2015) and dialogue modeling and generation (Vinyals and Le, 2015; Li et al., 2016; Shang et al., 2015). This includes the growing literature in attention mechanisms and memory networks (Bahdanau et al., 2014; Sukhbaatar et al., 2015; Kumar et al., 2016).

The ability to infer and model personality has applications in storytelling agents, dialogue systems, and psychometric analysis. In particular, personality-infused agents can help "chit-chat" bots avoid repetitive and uninteresting utterances (Walker et al., 1997; Mairesse and Walker, 2007; Li et al., 2016; Zhang et al., 2018). The more recent neural models do so by conditioning on a 'persona' embedding – our model could help produce those embeddings.

Finally, in the field of literary analysis, graphical models have been proposed for learning character personas in novels (Flekova and Gurevych, 2015; Srivastava et al., 2016), folktales (Valls-Vargas et al., 2014), and movies (Bamman et al., 2014). However, these models often use more structured inputs than dialogue to learn personas.

3 Datasets

Characters in movies can often be categorized into archetypal roles and personalities. To understand the relationship between dialogue and personas, we utilized three different datasets for our models: (a) the Movie Character Trope dataset, (b) the IMDB Dialogue Dataset, and (c) the Character Trope Description Dataset. We collected the IMDB Dialogue and Trope Description datasets, and these datasets are made publicly available [1].

3.1 Character Tropes Dataset

The CMU Movie Summary dataset provides tropes commonly occurring in stories and media (Bamman et al., 2014). There are a total of 72 tropes, which span 433 characters and 384 movies. Each trope contains between 1 and 25 characters, with a median of 6 characters per trope. Tropes and canonical examples are shown in Table 1.

3.2 IMDB Dialogue Snippet Dataset

To obtain the utterances spoken by the characters, we crawled the IMDB Quotes page for each movie. Though not every single utterance spoken by the character may be available, as the quotes are submitted by IMDB users, many quotes from most of the characters are typically found, especially for the famous characters found in the Character Tropes dataset. The distribution of quotes per trope is displayed in Figure 1. Our models were trained on 13,874 quotes and validated and tested on a set of 1,734 quotes each.

We refer to each IMDB quote as a (contextualized) dialogue snippet, as each quote can contain several lines between multiple characters, as well as italicized text giving context to what might be happening when the quote took place. Figure 2 show a typical dialogue snippet. 70.3% of the quotes are multi-turn exchanges, with a mean of 3.34 turns per multi-turn exchange. While the character's own lines alone can be highly indicative of the trope, our models show that accounting for context and the other characters' lines and context improves performance. The context, for instance, can give clues to typical scenes and actions that are associated with certain tropes, while the other characters' lines give further detail into

Stacks Edwards: Be ready in a minute.
Tommy DeVito: Yeah, you were always fuckin' late, you were late for your own fuckin' funeral.
[*shoots him*]

Figure 2: Example IMDB dialogue snippet containing multiple characters and context.

the relationship between the character and his or her environment.

3.3 Character Trope Description Dataset

We also incorporate descriptions of each of the character tropes by using the corresponding descriptions scraped from TVTropes[2]. Each description contains several paragraphs describing typical characteristics, actions, personalities, etc. about the trope. As we demonstrate in our experiments, the use of these descriptions improves classification performance. This could allow our model to be applied more flexibly beyond the movie character tropes – as one example, we could store descriptions of personalities based on the Big Five traits in our Knowledge-Store memory.

4 Problem Formulation

Our goal is to train a model that can take a batch of dialogue snippets from the IMDB dataset and predict the character trope.

Formally, let N_P be the total number of character tropes in the character tropes dataset. Each character C is associated with a corresponding ground-truth trope category P. Let $S = (D, E, O)$ be a dialog snippet associated with a character C, where $D = [w_{D_1}, w_{D_2} ..., w_{D_T}]$ refers to the character's own lines, $E = [w_{E_1}, w_{E_2} ..., w_{E_T}]$ is the contextual information and $O = [w_{O_1}, w_{O_2} ..., w_{O_T}]$ denotes the other characters' lines. We define all three components of S to have fixed sequence length T and pad when necessary. Let N_S be the total number of dialogue snippets for a trope. We sample a set of N_{diag} (where $N_{diag} \ll N_S$) snippets from N_S snippets related to the trope as inputs to our model.

5 Attentive Memory Network

The Attentive Memory Network consists of two major components: (a) Attentive Encoders, and (b) a Knowledge-Store Memory Module. Figure 3 outlines the overall model. We describe the components in the following sections.

5.1 Attentive Encoders

Not every piece of dialogue may be reflective of a latent persona. In order to learn to ignore words and dialogue snippets that are not informative about the trope we use a multi-level attentive encoder that operates at (a) the individual snippet level, and (b) across multiple snippets.

Attentive Snippet Encoder

The snippet encoder extracts features from a single dialogue snippet S, with attention over the words in the snippet. A snippet $S = (D, E, O)$ is fed to the encoder to extract features from each of these textual inputs and encode them into an embedding space. We use a recurrent neural network as our encoder, explained in detail in Section 5.1.1. In order to capture the trope-reflective words from the input text, we augment our model with a self-attention layer which scores each word in the given text for its relevance. Section 5.1.2 explains how the attention weights are computed. The output of this encoder is an encoded snippet embedding $S^e = (D^e, E^e, O^e)$.

Attentive Inter-Snippet Encoder

As shown in Figure 3, the N_{diag} snippet embeddings S^e from the snippet encoder are fed to our inter-snippet encoder. This encoder captures inter-snippet relationship using recurrence over the N_{diag} snippet embeddings for a given trope and determines their importance. Some of the dialogue snippets may not be informative about the trope, and the model learns to assign low attention scores to such snippets. The resulting attended

Hellboy: Hecate, seen your statue - aren't you missing a couple of heads?
Hecate: Why do you walk this lesser world? Mortals they don't know you. We are greater beings than they could ever dream!"
Hellboy: Yeah, well I'm doing just fine. Now ah, I'm kinda busy - I gotta go...
Hecate: Why, to save them? They're nothing to us! Only a few remain that observe the old rituals so I give them back the priestess and they give me sacrifices of blood. Now accept what you are and come and walk with me!
Hellboy: Lady, I was going to cut you some slack because you're a major mythological figure - but that? That's crazy talk. Now leave me alone!

James Bond: [*during briefing in the Bahamas*] So you want me to be half-monk, half-hitman.
M: Any thug can kill. I need you to take your ego out of the equation.

James Bond: [*after reading a note left by M and seeing the Aston Martin*] I love you too M.

Ram: [*about Flynn*] The new guy was asking about you.
Tron: It's too bad he's in a match now. I'll probably never meet him.
Ram: You might. There's something different about him.

Carter: [*sees Mollaka in the crowd, watching animals fight*] Looks like our man, burn scars on his face.
James Bond: Hmm. I wonder if bomb-makers are insured for things like that.

Ram: You really think the Users are still there?
Tron: They better be. I don't wanna bust out of here and find nothing but a lot of cold circuits waiting for me.

[*from trailer*]
Hellboy: Destiny is overrated!

Ram: You really think the Users are still there?
Tron: They better be. I don't wanna bust out of here and find nothing but a lot of cold circuits waiting for me.

Figure 3: Illustration of the Attentive Memory Network. The network takes dialogue snippets as input and predicts its associated character trope. In this example, dialogue snippets associated with the character trope "Bruiser with a Soft Corner" is given as input to the model.

summary vector from this phase is the persona representation z, defined as:

$$\begin{gathered} z = \gamma_D^s D^s + \gamma_E^s E^s + \gamma_O^s O^s \\ \gamma_D^s + \gamma_E^s + \gamma_O^s = 1 \end{gathered} \tag{1}$$

where $\gamma_D^s, \gamma_E^s, \gamma_O^s$ are learnable weight parameters. D^s, E^s, O^s refers to summary vectors of the N_{diag} character's lines, contextual information, and other characters' lines, respectively. In Section 7, we experiment with models that have γ_E^s and γ_O^s set to 0 to understand how the contextual information and other characters' lines contribute to the overall performance.

5.1.1 Encoder

Given an input sequence $(x_1, x_2, ..., x_T)$, we use a recurrent neural network to encode the sequence into hidden states $(h_1, h_2, ..., h_T)$. In our experiments, we use a gated recurrent network (GRU) (Chung et al., 2014) over LSTMs (Hochreiter and Schmidhuber, 1997) because the latter is more computationally expensive. We use bidirectional GRUs and concatenate our forward and backwards hidden states to get $\overleftrightarrow{h_t}$ for $t = 1, ..., T$.

5.1.2 Attention

We define an attention mechanism $Attn$ that computes s from the resultant hidden states $\overleftrightarrow{h_t}$ of a GRU by learning to generate weights α_t. This can be interpreted as the relative importance given to a hidden state h_t to form an overall summary vector for the sequence. Formally, we define it as:

$$a_t = f_{attn}(h_t) \tag{2}$$

$$\alpha_t = softmax(a_t) \tag{3}$$

$$s = \sum_{t=1}^{T} \alpha_t h_t \tag{4}$$

where f_{attn} is a two layer fully connected network in which the first layer projects $h_t \in \mathbb{R}^{d_h}$ to an attention hidden space $g_t \in \mathbb{R}^{d_a}$, and the second layer produces a relevance score for every hidden state at timestep t.

5.2 Memory Modules

Our model consists of a read-only 'Knowledge-Store' memory, and we also test a recent read-write memory. External memories have been shown to help on natural language processing tasks (Sukhbaatar et al., 2015; Kumar et al., 2016; Kaiser and Nachum, 2017), and we find similar improvements in learning capability.

5.2.1 Knowledge-Store Memory

The main motivation behind the Knowledge-Store memory module is to incorporate prior domain knowledge. In our work, this knowledge refers to the trope descriptions described in Section 3.3.

Related works have initialized their memory networks with positional encoding using word embeddings (Sukhbaatar et al., 2015; Kumar et al., 2016; Miller et al., 2016). To incorporate the descriptions, we represent them with skip thought vectors (Kiros et al., 2015) and use them to initialize the memory keys $K_M \in \mathbb{R}^{N_P \times d_K}$, where N_P is the number of tropes, and d_K is set to the size of embedded trope description R^D, i.e. $d_K = ||R^D||$.

The values in the memory represent learnable embeddings of corresponding trope categories $V_M \in \mathbb{R}^{N_P \times d_V}$, where d_V is the size of the trope category embeddings. The network learns to use the persona representation z from the encoder phase to find relevant matches in the memory. This corresponds to calculating similarities between z and the keys K_M. Formally, this is calculated as:

$$z_M = f_z(z) \tag{5}$$

$$p_M^{(i)} = softmax(z_M \cdot K_M[i]) \quad \forall i \in \{1, .., N_P\} \tag{6}$$

where $f_z : \mathbb{R}^{d_h} \mapsto \mathbb{R}^{d_K}$ is a fully-connected layer that projects the persona representation in the space of memory keys K_M. Based on the match probabilities $p_M^{(i)}$, the values V_M are weighted and cumulatively added to the original persona representation as:

$$r_{out} = \sum_{i=1}^{N_P} p_M^{(i)} \cdot V_M[i] \tag{7}$$

We iteratively combine our mapped persona representation z_M with information from the memory r_{out}. The above process is repeated n_{hop} times. The memory mapped persona representation z_M is updated as follows:

$$z_M^{hop} = f_r(z_M^{hop-1}) + r_{out} \tag{8}$$

where $z_M^0 = z_M$, and $f_r : \mathbb{R}^{d_V} \mapsto \mathbb{R}^{d_K}$ is a fully-connected layer. Finally, we transform the resulting $z_M^{n_{hop}}$ using another fully-connected layer, $f_{out} \in \mathbb{R}^{d_K} \mapsto \mathbb{R}^{d_h}$, via:

$$\hat{z}_M = f_{out}(z_M^{n_{hop}}) \tag{9}$$

5.2.2 Read-Write Memory

We also tested a Read-Write Memory following Kaiser et. al (Kaiser and Nachum, 2017), which was originally designed to remember rare events. In our case, these 'rare' events might be key dialogue snippets that are particularly indicative of latent persona. It consists of keys, which are activations of a specific layer of model, i.e. the persona representation z, and values, which are the ground-truth labels, i.e. the trope categories. Over time, it is able to facilitate predictions based on past data with similar activations stored in the memory. For every new example, the network writes to memory for future look up. A memory with memory size N_M is defined as:

$$M = (K_{N_M \times d_H}, V_{N_M}, A_{N_M}) \tag{10}$$

Memory Read We use the persona embedding z as a query to the memory. We calculate the cosine similarities between z and the keys in M, take the softmax on the top-k neighbors, and compute a weighted embedding $\hat{z}_M$ using those scores.

Memory Write We update the memory in a similar fashion to the original work by (Kaiser and Nachum, 2017), which takes into account the maximum age of items as stored in A_{N_M}.

6 Objective Losses

To train our model, we utilize the different objective losses described below.

6.1 Classification Loss

We calculate the probability of a character belonging to a particular trope category P through Equation 11, where $f_P : \mathbb{R}^{d_h} \mapsto \mathbb{R}^{N_P}$ is a fully-connected layer, and z is the persona representation produced by the multi-level attentive encoders described in Equation 1. We then optimize the categorical cross-entropy loss between the predicted and true tropes as in Equation 12, where N_P is the total number of tropes, q_j is the predicted distribution that the input character fulls under trope j, and $p_j \in \{0, 1\}$ denotes the ground-truth of whether the input snippets come from characters from the j^{th} trope.

$$q = softmax(f_P(z)) \tag{11}$$

$$J_{CE} = \sum_{j=1}^{N_P} -p_j \log(q_j) \tag{12}$$

6.2 Trope Description Triplet Loss

In addition to using trope descriptions to initialize the Knowledge-Store Memory, we also test learning from the trope descriptions through a triplet loss (Hoffer and Ailon, 2015). We again use the skip thought vectors to represent the descriptions. Specifically, we want to maximize the similarity of representations obtained from dialogue snippets with their corresponding description, and minimize their similarity with negative examples. We implement this as:

$$R^P = f_D(z) \tag{13}$$

$$J_T = max(0, s(R^P, R_n^D) - s(R^P, R_p^D) + \alpha_T) \tag{14}$$

where $f_D : \mathbb{R}^{d_h} \mapsto \mathbb{R}^{||R^D||}$ is a fully-connected layer. The triplet ranking loss is then Equation 14, where α_T is a learnable margin parameter and $s(\cdot, \cdot)$ denotes the similarity between trope embeddings (R^P), positive (R_p^D) and negative (R_n^D) trope descriptions.

Trope Description Triplet Loss with Memory Module

If a memory module is used, we compute a new triplet loss in place of the one described in Equation 14. Models that use a memory module should learn a representation $\hat{z}_M$, based on either the prior knowledge stored in the memory (as in Knowledge-Store memory) or the top-k key matches (as in Read-Write memory), that is similar to the representation of the trope descriptions.

This is achieved by replacing the persona embedding z in Equation 13 with the memory output $\hat{z}_M$ as shown in Equation 15, where $f_{D_M} : \mathbb{R}^{d_h} \mapsto \mathbb{R}^{||R^D||}$ is a fully-connected layer. To compute the new loss, we combine the representations obtained from Equations 13 and 15 through a learnable parameter γ that determines the importance of each representation. Finally, we utilize this combined representation $\hat{R}^P$ to calculate the loss as shown in Equation 17.

$$R^P_M = f_{D_M}(\hat{z}_M) \tag{15}$$

$$\hat{R}^P = \gamma R^P + (1 - \gamma) R^P_M \tag{16}$$

$$J_{MT} = max(0, s(\hat{R}^P, R^D_n) - s(\hat{R}^P, R^D_p) + \alpha_{MT}) \tag{17}$$

6.3 Read-Write Memory Losses

When the Read-Write memory is used, we use two extra loss functions. The first is a Memory Ranking Loss J_{MR} as done in (Kaiser and Nachum, 2017), which learns based on whether a query with the persona embedding z returns nearest neighbors with the correct trope. The second is a Memory Classification Loss J_{MCE} that uses the values returned by the memory to predict the trope. The full details for both are found in Supplementary Section A.

6.4 Overall Loss

We combine the above losses through:

$$\begin{gathered} J = \beta_{CE} \cdot J_{CE} \\ + \beta_T \cdot \hat{J}_T \\ + \beta_{MR} \cdot J_{MR} + \beta_{MCE} \cdot J_{MCE} \end{gathered} \tag{18}$$

$$\hat{J}_T = \begin{cases} J_{MT} & \text{if memory module is used} \\ J_T & \text{otherwise.} \end{cases}$$

where $\beta = [\beta_{CE}, \beta_{MCE}, , \beta_T, \beta_{MR}]$ are learnable weights such that $\sum_i \beta_i = 1$. Depending on which variant of the model is being used, the list β is modified to contain only relevant losses. For example, when the Knowledge-Store memory is used, we set $\beta_{MR} = \beta_{MCE} = 0$ and β is modified to $\beta = [\beta_{CE}, \beta_T]$. We discuss different variants of our model in the next section.

7 Experiments

We experimented with combinations of our various modules and losses. The experimental results and ablation studies are described in the following sections, and the experimental details are described in Supplementary Section B. The different model permutation names in Table 2, e.g. "attn_3_tropetrip_ks-mem_ndialog16", are defined as follows:

- *baseline vs attn*: The 'baseline' model uses only one dialogue snippet S to predict the trope, i.e. $N_{diag} = 1$. Hence, the inter-snippet encoder is not used. The 'attn' model operates on N_{diag} dialogue snippets using the inter-snippet encoder to assign an attention score for each snippet S_i.
- *char vs. 3*: To measure the importance of context and other characters' lines, we have two variants – 'char' uses only the character's lines, while '3' uses the character's lines, other character's lines, and all context lines. Formally, in 'char' mode, we set γ^s_E and γ^s_O to 0 in Equation 1. In 'attn' mode, $(\gamma^s_E, \gamma^s_O, \gamma^s_D)$ are learned by the model.
- *tropetrip*: The presence of 'tropetrip' indicates that the triplet loss on the trope descriptions was used. If '-500' is appended to 'tropetrip', then the 4800-dimensional skip embeddings representing the descriptions in Equations 15 and 17 are projected to 500 dimensions using a fully connected layer.
- *ks-mem vs. rw-mem*: 'ks-mem' refers to the Knowledge-Store memory, and 'rw-mem' refers to the Read-Write memory.
- *ndialog*: The number of dialogue snippets N_{diag} used as input for the attention models. Any attention model without the explicit N_{diag} listed uses $N_{diag} = 8$.

7.1 Ablation Results

Baseline vs. Attention Model. The attention model shows a large improvement over the baseline models. This matches our intuition that not every quote is strongly indicative of character trope. Some may be largely expository or 'chit-chat' pieces of dialogue. Example attention scores are shown in Section 7.2.

Model	Accuracy	Precision	Recall	F1
baseline_char	0.286	0.538	0.286	0.339
baseline_3	0.287	0.552	0.288	0.349
attn_char	**0.630**	0.586	0.628	0.600
attn_3	0.630	**0.590**	**0.630**	**0.603**
attn_3_tropetrip	0.615	0.566	0.615	0.583
attn_3_tropetrip-500	**0.644**	**0.601**	**0.642**	**0.615**
attn_3_ks-mem	**0.678**	**0.648**	**0.676**	**0.657**
attn_3_rw-mem	0.635	0.598	0.635	0.611
attn_3_tropetrip_ks-mem	**0.663**	**0.628**	**0.662**	**0.639**
attn_3_tropetrip-500_ks-mem	0.654	0.618	0.652	0.629
attn_3_tropetrip_rw-mem	0.649	0.602	0.648	0.617
attn_3_tropetrip-500_rw-mem	0.644	0.608	0.644	0.619
attn_3_tropetrip-500_ks-mem_ndialog16	0.740	0.707	0.741	0.718
attn_3_tropetrip-500_ks-mem_ndialog32	**0.750**	**0.750**	**0.750**	**0.750**
attn_3_tropetrip_ks-mem_ndialog16	0.740	0.722	0.741	0.728
attn_3_tropetrip_ks-mem_ndialog32	0.731	0.712	0.731	0.718

Table 2: Experimental results. Details and analysis are given in Section 7.1. The best performing results in each block are bolded. The first block examines the baseline model vs. the attention model, as well as use of different inputs. The second block uses the triplet loss, and the third block uses our memory modules. The fourth block combines the triplet loss and memory module, which the fifth block extends to larger N_{diag}.

Rumors of my death have been greatly exaggerated.

What does it matter? Nothing's real down there. Our life is here.

I don't give a shit who he's connected to. … I want you vacate this guy off the premises, and I want you to exit him off his feet and use his head to open the fucking door.

I'm the man.

I had to see you. Stacy, I swear... I- I don't blame you for hating me. Or for wanting to break up. I just- Let me explain. About my family. I ju- I didn't want you to know. See, my dad's a drunk. Alright? … Cause when you love somebody, you never give up on them.

Not so bad... Oh! 'Ello, beastie.

I heard things.

Fuck! Fuck! That's it, I'm screwed. It's over.

Figure 4: Attention scores for a batch of dialogues for the "byronic hero" trope [3].

Though our experiments showed marginal improvement between using the 'char' data and the '3' data, we found that using all 3 inputs had greater performance for models with the triplet loss and read-only memory. This is likely because the others' lines and context capture more of the social dynamics and situations that are described in the trope descriptions. Subsequent results are shown only for the 'attn_3' models.

Trope Description Triplet Loss. Adding the trope description loss alone provided relatively small gains in performance, though we see greater gains when combined with memory. While both use the descriptions, perhaps the Knowledge Store memory matches an embedding against all the tropes, whereas the trope triplet loss is only provided information from one positive and one negative example.

Memory Modules. The Knowledge-Store memory in particular was helpful. Initialized with the trope descriptions, this memory can 'sharpen' queries toward one of the tropes. The Read-Write memory had smaller gains in performance. It may be that more data is required to take advantage of the write capabilities.

Combined Trope Description Triplet Loss and Memory Modules. Using the triplet loss with memory modules led to greater performance when compared to the $attn\_3$ model, but the performance sits around the use of either triplet only or memory only. However, when we increase the N_{diag} to 16 or 32, we find a jump in performance. This is likely the case because the model has both increased learning capacity and a larger sample of data at every batch, which means at least some of the N_{diag} quotes should be informative about the trope.

7.2 Attention Scores

Because the inter-snippet encoder provides such a large gain in performance compared to the baseline model, we provide an example illustrating the weights placed on a batch of N_{diag} snippets. Figure 4 shows the attention scores for the character's lines in the "byronic hero" trope. Matching what we might expect for an antihero personality, we find the top weighted line to be full of confidence and heroic bluster, while the middle lines

---

[3] TVtropes.org defines a byronic hero as "Sometimes an Anti-Hero, others an Anti-Villain, or even Just a Villain, Byronic heroes are charismatic characters with strong passions and ideals, but who are nonetheless deeply flawed individuals...."

hint at the characters' personal turmoil. We also find the lowly weighted sixth and seventh lines to be largely uninformative (e.g. "I heard things."), and the last line to be perhaps too pessimistic and negative for a hero, even a byronic one.

7.3 Purity scores of character clusters

Finally, we measure our ability to recover the trope 'clusters' (with one trope being a cluster of its characters) with our embeddings through the purity score used in (Bamman et al., 2014). Equation 19 measures the amount of overlap between two clusterings, where N is the total number of characters, g_i is the i-th ground truth cluster, and c_j is the j-th predicted cluster.

$$\text{Purity} = \frac{1}{N} \sum_i \max_j |g_i \cap c_j| \tag{19}$$

We use a simple agglomerative clustering method on our embeddings with a parameter k for the number of clusters. The methods in (Bamman et al., 2014) contain a similar hyper-parameter for the number of persona clusters. We note that the metrics are not completely comparable because not every character in the original dataset was found on IMDB. The results are shown in Table 3. It might be expected that our model perform better because we use the character tropes themselves as training data. However, dialogue may be noisier than the movie summary data; their better performing Persona Regression (PR) model also uses useful metadata features such as the movie genre and character gender. We simply note that our scores are comparable or higher.

k	PR	DP	AMN
25	42.9	39.63	**48.4**
50	36.5	31.0	**48.1**
100	30.3	24.4	**45.2**

Table 3: Cluster purity scores. k is the number of clusters, PR and DP are the Persona Regression and Dirichlet Persona models from (Bamman et al., 2014), and AMN is our attention memory network.

8 Application: Narrative Analysis

We collected IMDB quotes for the top 250 movies on IMDB. For every character, we calculated a character embedding by taking the average embedding produced by passing all the dialogues through our model. We then calculated movie embeddings by taking the weighted sum of all the character embeddings in the movie, with the weight as the percentage of quotes they had in the movie. By computing distances between pairs of character or movie embeddings, we could potentially unearth notable similarities. We note some of the interesting clusters below.

8.1 Clustering Characters

- Grumpy old men: Carl Fredricksen (Up); Walk Kowalski (Gran Torino)
- Shady tricksters, crooks, well versed in deceit: Ugarte (Casablanca); Eames (Inception)
- Intrepid heroes, adventurers: Indiana Jones (Indiana Jones and the Last Crusade); Nemo (Finding Nemo); Murph (Interstellar)

8.2 Clustering Movies

- Epics, historical tales: Amadeus, Ben-Hur
- Tortured individuals, dark, violent: Donnie Darko, Taxi Driver, Inception, The Prestige
- Gangsters, excess: Scarface, Goodfellas, Reservoir Dogs, The Departed, Wolf of Wall Street

9 Conclusion

We used the character trope classification task as a test bed for learning personas from dialogue. Our experiments demonstrate that the use of a multi-level attention mechanism greatly outperforms a baseline GRU model. We were also able to leverage prior knowledge in the form of textual descriptions of the trope. In particular, using these descriptions to initialize our Knowledge-Store memory helped improved performance. Because we use short text and can leverage domain knowledge, we believe future work could use our models for applications such as personalized dialogue systems.

Abstract

We develop a semantic parser that is trained in a grounded setting using pairs of videos captioned with sentences. This setting is both data-efficient, requiring little annotation, and similar to the experience of children where they observe their environment and listen to speakers. The semantic parser recovers the meaning of English sentences despite not having access to any annotated sentences. It does so despite the ambiguity inherent in vision where a sentence may refer to any combination of objects, object properties, relations or actions taken by any agent in a video. For this task, we collected a new dataset for grounded language acquisition. Learning a grounded semantic parser — turning sentences into logical forms using captioned videos — can significantly expand the range of data that parsers can be trained on, lower the effort of training a semantic parser, and ultimately lead to a better understanding of child language acquisition.

1 Introduction

Children learn language from observations that are very different in nature from what parsers are trained on today. Most of the time, rather than receiving direct feedback such as annotated sentences or answers to direct questions, children observe and occasionally interact with their environment. They must use these observations to learn the structure of the speaker's language despite never seeing that structure overtly. This weak and indirect supervision where most of the information is obtained through passive observation poses a difficult disambiguation problem for learners: how do you know what the speaker is referring to in the environment, i.e., what does the speaker mean? Speakers can refer to actions, objects, the properties of actions and objects, relations between those actions and objects, as well as other features in the environment and generally do so by combining multiple features into complex sentences. Moreover, speakers need not refer to the most visually salient parts of a visual scene. Here, we induce a semantic parser by simultaneously resolving visual ambiguities and grounding the semantics of language using a corpus of sentences paired with videos without other annotations.

The woman walks by the table with a yellow cup.
λxyz.woman x, walk x, near x y, table y,
hold x z, yellow z, cup z

Figure 1: We develop a semantic parser trained on video-sentence pairs, *without parses*. At inference time a sentence, *without a video*, is presented and a logical form is produced.

The goal of semantic parsing is to convert a natural-language sentence into a representation that encodes its meaning. The parser takes sentences as input and produces these representations – a lambda-calculus expression in our case – that can be used for a variety of tasks such as querying databases, understanding references in images and videos, and answering questions. To train the parser presented here we collected a video dataset, balanced such that the raw statistics of the co-occurrences of objects and events are not informative, and asked annotators on Mechanical Turk to produce sentences that are true of those videos. The parser is presented with pairs of short clips and sentences. It hypothesizes potential meanings for those sentences as lambda-calculus expressions. Each hypothesized expression serves as input for a modular vision system that constructs a specific detector for that lambda-calculus expression and determines the likelihood of the parse being true of the video. The likelihood of the parse with respect to the video is used as supervision for the parser. To

Brussels, Belgium, October 31 - November 4, 2018.

test the parser, we annotated each sentence with its ground-truth semantic parse, but this information is not available at training time.

This process introduces ambiguity. For example, Figure 1 shows a frame from a video annotated with the sentence *"The woman walks by the table with a yellow cup."*, yet the parse, $\lambda x.\ \text{object}(x)$, corresponding to a sentence like *"There exists an object."*, is also true of that video. For a single video there exists an infinite number of true parses that have high likelihood with respect to the vision system because they are indeed indicative of something that is occurring in the video. We demonstrate how to construct a semantic parser that resolves this ambiguity and acquires language from captioned videos by learning to tune the amount of polysemy in the induced lexicon.

This work makes several contributions: We show how to construct a semantic parser that learns language in a setting closer to that of children. We demonstrate how to jointly resolve linguistic and visual ambiguities at training time in a way that can be adapted to other semantic parsing approaches. We demonstrate how such an approach can be used to augment data where a small number of directly annotated sentences can be combined with a large number of videos paired with sentences in order to improve performance. We release a dataset systematically constructed and annotated on Mechanical Turk for joint visual and linguistic learning tasks.

2 Prior work

Learning to understand language in a multimodal environment is a well-developed task. For example, visual question answering (VQA) datasets have led to a number of systems capable of answering complex questions about scenes (Antol et al., 2015). The goal of our work is not to produce answers for any one set of questions, although it is possible to do so from our results; it is instead to learn to predict the structure of the sentences and their meaning. This is a more general and difficult problem, in particular because at test time we do not receive any visual input, only the sentence. The resulting approach is reusable, generic and more similar to the kind of general-purpose linguistic knowledge that humans have. For example, one could use it to guide robotic actions. Al-Omari et al. (2017) acquire a grammar for a fragment of English and Arabic from videos paired with sentences. They learn a small number of grammar rules for a language restricted to robotic commands. Learning occurs mostly in simulation and with little visual ambiguity, and the resulting model is not a parser but a means of associating n-grams with visual concepts.

Siddharth et al. (2014) and Yu et al. (2015) acquire the meaning of a lexicon from videos paired with sentences but assume a fully-trained parser. Matuszek et al. (2012) similarly present a model to learn the meanings and referents of words restricted to attributes and static scenes. Hermann et al. (2017) extend these notions to train agents that learn to carry out instructions in simulated environments without the need for a parser, but do so using simple adjective-noun-relation utterances. Kollar et al. (2013) learn to parse similar utterances in an interactive setting. Wang et al. (2016) create a language game to learn a parser but do not incorporate visual ambiguity or fallible perception.

Berant et al. (2013) describe semantic parsing with execution by annotating answers to database queries. This learning mechanism provides the same results as the one described here: a parser produces the meanings of sentences at inference time without requiring the database, or in our case a video. Databases have far less ambiguity than videos; there is not a temporal aspect to their contents and there is not a notion of unreliable perception. Berant and Liang (2014) learn to parse sentences from paraphrases; one might consider the work here as concerned with visual and not just linguistic paraphrases. Artzi and Zettlemoyer (2013) consider a setting where a validation function involves the dynamic actions of a simulated robot while sentences describe its actions.

3 Task

Given a dataset of captioned videos, D, we train the parameters and lexicon, θ and Λ, of a semantic parser. At training time, we perform gradient descent over the parameters θ and employ *GENLEX* (Zettlemoyer and Collins, 2005) to augment the lexicon Λ. The objective function of the semantic parser is written in terms of a visual-linguistic compatibility between a hypothesized parse p and video v. This compatibility computes the likelihood of the parse being true of the video, $P(v|p)$. At test time, we take as input a sentence without an associated video and produce a semantic parse. We could in principle also take as input the video and produce a targeted parse for that visual scenario. This is a problem similar to that considered by Berzak et al. (2015), but we do not do so here.

We create a CCG-based (Combinatory Categorical Grammar; Steedman (1996)) semantic parser capable of being trained in this setting. To do so, we adapt the objective function, training procedure, and feature set to this new scenario. The visual-linguistic compatibility function is similar to the Sentence Tracker developed in Siddharth et al. (2014) and Yu et al. (2015). Given a parse, the Sentence Tracker produces a targeted detector that determines if the parse is true of a video, which provides a weak supervision signal for the parser.

Parses are represented as lambda-calculus expressions consisting of a set of binders and a conjunction of literal expressions referring to those binders. The domain of the variables are the potential object locations, or object tracks, in the videos. For example, in the parse presented in Figure 1, three potential object track slots are available, represented by the binders x, y, and z. Because of perceptual ambiguities and the large number of possible referents in any one video, we do not explicitly enumerate the space of object tracks. Instead, we rely on a joint-inference process between the parser and the Sentence Tracker. Intuitively, each literal expression of the parse asserts a constraint; for example, if an expression conveys that one object is approaching another, the Sentence Tracker will search the space of object tracks and attempt to satisfy these constraints. In Figure 1, for instance, there is a constraint that for whichever objects are bound to x and z, x must be near y, x must be walking, x must be a person, etc.

4 Model

We develop an approach that combines a semantic parser with a vision system at training time, but does not require the vision system at test time.

4.1 Semantic Parsing

We adopt a semantic parsing framework similar to that of Artzi and Zettlemoyer (2013), although the general approach of using vision as weak supervision for semantic parsing generalizes to other parsers. CCG-based parsing employs a small number of fixed unary and binary derivation rules (Steedman, 2000) while learning a lexicon. In CCG-based parsing, a parser takes as input a sequence of tokens and a lexicon that maps tokens to potential syntactic types and derives parse trees by creating and ranking multiple hypotheses that combine those types together. The syntactic types are richer than other approaches and include forward and backward function application (the forward and backward slash) in addition to the standard syntactic categories. Each derivation has a current syntactic type that is the result of the application of a sequence of rules. To create a derivation, at each step the parser applies each rule to either an individual subderivation or to a pair of subderivations. This process produces multiple hypotheses. Parsing rules are generic, polymorphic, and language-neutral and include concepts like function application and type raising (Carpenter, 1997). The parser accepts a derivation when the tree reaches a single node. We refer to the single node of the parse tree as the logical form. Figure 2 shows a parse starting with tokens and their syntactic types along with each rule being applied.

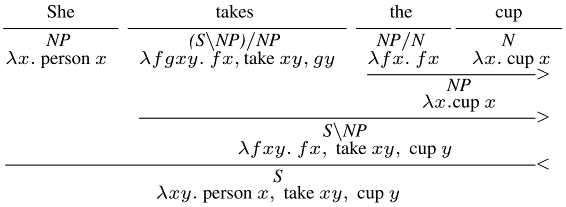

Figure 2: A simple sentence parsed into a lambda-calculus expression using a CCG-based grammar. The parse is determined by the lexicon that associates tokens with syntactic and semantic types as well as the order of function applications. Here, we acquire this lexicon and a means to score derivations.

Semantic parsing with CCGs extends this framework to simultaneously derive a logical form while performing syntactic parsing. Each syntactic rule includes a simple semantic component that manipulates the logical form of its arguments. For example, the forward application rule reduces the syntactic type by applying the syntactic type of the right argument to that of the left, while at the same time performing a lambda-calculus reduction of the semantic types of those same arguments. Concretely, consider a case from Figure 2 where a determiner is attached to a noun, *the cup*. The tokens the and cup are hypothesized to have syntactic types NP/N and N (a function returning NP given an argument on the right side and a noun) and semantic type $\lambda fx.fx$ and $\lambda x.\text{cup}(x)$ (the identity function and a function that adds a cup constraint). These two derivations can be reduced by forward application, denoted by $>$. Both the syntactic and semantic types are applied and reduced, which means the semantics helps guide the syntax. Derivations that produce illegal operations, such as applying an argument to a constant, are forbidden.

Following Zettlemoyer and Collins (2005) and Curran et al. (2007), we adopt a weighted linear semantic parser. For each sentence paired with its hypothesized derivation, this approach computes a feature vector ϕ and a parameter vector θ. Given a sentence s, a parse p, a lexicon Λ, the set of all possible parses for that sentence with that lexicon, $P(s, \Lambda)$, and an n-dimensional feature vector computed for that sentence and parse, $\phi(s, p)$, the parser optimizes

$$\underset{p \in P}{\operatorname{argmax}} \; \theta \cdot \phi(s, p) \tag{1}$$

to find the best parse p^*. Using a fixed-width beam search, the parser enumerates derivations by choosing a potential syntactic and semantic type for each token from the lexicon and choosing a set of derivation rules to apply. For the i-th training sample d_i, consisting of a sentence d_i^s and a video d_i^v in dataset D and the feature function, the parser finds margin-violating positive, E^+, and negative, E^-, parses, and then uses

$$\theta + \frac{1}{|E_i^+|} \sum_{e \in E_i^+} \phi_i(e, d_i^v) - \frac{1}{|E_i^-|} \sum_{e \in E_i^-} \phi_i(e, d_i^v) \tag{2}$$

to update the parameter θ. After each sweep through the dataset, the lexicon Λ is augmented using the modified *GENLEX* from Artzi and Zettlemoyer (2013), which does not require the ground-truth logical form. At no point is the logical form needed for updating the lexicon or parameters; we rely instead on a visual validation function to compute the margin-violating examples.

Rather than attempting to learn a fixed lexicon that directly maps tokens to semantic and syntactic parses, we use a factored lexicon like that of Kwiatkowski et al. (2011). This represents tokens and any associated constants separately from potential syntactic and semantic types. For example, the token *chair* is associated with a single constant `chair`; *chair* $\vdash$ [`chair`]. In addition to the token-constants pairs, there exists a list of pairs of syntactic and semantic types along with placeholders for constants; in the case for *chair*, a useful type might be $\lambda v.[N : \lambda x.\texttt{placeholder}(x)]$. When parsing, each token is applied to a potential syntactic and semantic type and the derivation proceeds from there. The factored lexical entries allow for far greater reuse; the model learns a small number of constants that a word can imply separately from a small number of syntactic and semantic types for any word. The weighted linear CCG-based parser searches over potential lexical entries, applying the token to different syntactic and semantic types and over multiple hypotheses for which rule should be applied. At training time, in order to learn a reasonable lexicon and set of parameters, a supervision signal is required to validate candidates. We provide that supervision using the vision system described below.

4.2 Sentence Tracking

To score a video-parse pair, we employ a framework similar to that of Yu et al. (2015). This approach constructs a parse-specific model by extracting the number of participants in the scene described by a caption as well as the relationships and properties of those participants. It builds a graphical model where each participant is localized by an object tracker and each relationship is encoded by temporal models that express the properties of the trackers that those models refer to. The parser's output representation is chosen to make building the vision system possible. Each target logical form is a lambda expression with a set of binders, whose domain are objects, and a conjunction of constraints that refer to those binders. In essence, this notes which objects should be present in a scene and what static and changing properties and relationships those objects should have with respect to one another.

The Sentence Tracker creates one Viterbi-based tracker for each participant and, given a mapping from constraints to Hidden Markov models (HMMs), connects each tracker and each constraint together. Given a video v and a parse p, first a large number of object detections are computed for the video by using a low confidence threshold of an object detector. Trackers weave these bounding-box detections into high-scoring object tracks and use constraints to verify if the tracks have the desired properties and relations. Inference proceeds jointly between vision and the parse to allow the parse to focus the vision component on events and properties that might otherwise be missed.

Understanding the relationship between a sentence and a video requires finding the objects that the sentence refers to and determining if those objects follow the behavior implied by the sentence. We carry out a joint optimization that finds objects whose behavior follows certain rules. For clarity, the two steps are presented separately, while we find the global optimum for a linear combination of Equation (3) and Equation (4). Object trackers are a maximum-entropy Markov model with a per-frame score f, the likelihood that any one object detection is true, as well as a motion-coherence score g, the likelihood that the bounding boxes selected between frames refer to the same object instance. Given a parse p with L participants and a video v of length T, Equation (3) shows the optimization where J is a set of L candidate tracks ranging over every hypothesis from the object detector and b is a candidate object detection.

$$\max_{J} \sum_{l=1}^{L} \left(\sum_{t=1}^{T} f(b^{t}_{j^{t}_{l}}) + \sum_{t=1}^{T} g(b^{t-1}_{j^{t-1}_{l}}, b^{t}_{j^{t}_{l}}) \right) \tag{3}$$

Determining if an object track follows a set of behaviors implied by a sentence is done using a collection of HMMs. Each has a per-frame score h that observes one or more objects tracks, depending on the number of participants in the behavior being modeled, and a transition function a that determines the temporal sequence of the behavior. Given a parse p with C behaviors, also termed constraints, along with a video v of length T, Equation (4) shows the optimization where K is a set of states, one for each constraint, and γ is a linking function.

$$\max_{J,K} \sum_{c=1}^{C} \left(\sum_{t=1}^{T} h_c(b^{t-1}_{j^{t-1}_{\gamma^1_c}}, b^{t}_{j^{t}_{\gamma^2_c}}, k^t_c) + \sum_{t=1}^{T} a_c(k^{t-1}_c, k^t_c) \right) \tag{4}$$

The linking function is an indicator variable that encodes the structure of the logical form thereby filling in the correct trackers as arguments for the corresponding constraints. The exposition above presents a variant using binary constraints that is trivially generalized to n-ary constraints by extending γ and adding arguments to the appropriate constraint observation functions h_c. The domain of the optimization problem is the combination of all objects at all timesteps that the logical form can refer to as well as every state of each constraint. The Viterbi algorithm carries out this optimization in time linear in the length of the video and quadratic in the number of detections per frame. The result is a likelihood of the parse being true of a video. This is used to create the joint model that supervises the parser with vision. The tracker can also produce a time series of bounding boxes that make explicit the groundings of the sentences, though we do not use these directly here.

4.3 Joint Model

At training time, we jointly learn using both the semantic parser and the language-vision component. At test time, only the parser is used. Two parameters are learned, a set of weights θ and the lexicon Λ. For both the parser and the associated language-vision component, Λ is used to structure inference. To induce new lexical entries, we employ a variant of *GENLEX* (Artzi and Zettlemoyer, 2013) that takes as input a validation function — the compatibility between a parse and the video. This *GENLEX* uses an ontology of predicates, a validation function, and templates from the current lexicon to construct new syntactic and semantic forms. A ground-truth logical form is not required or used.

The joint model must learn these parameters despite three sources of noise. First, the vision-language component may simply fail to produce the correct likelihood because machine vision is far from perfect. Overcoming this requires large beam widths to avoid falling into local minima due to these errors.

Second, an infinite number of possibly-erroneous parses are true of a video. When children learn language, they face this same challenge as they do not have access to bounding boxes or to logical forms. The parse $\lambda x.person(x)$ as well as many other seemingly reasonable parses are true and cannot be distinguished from the ground-truth parse — which is not available — by the vision component. This is a far less constrained environment than other approaches to semantic parsing. It is easy to be misguided by a loss function that is often true when it should not be and thus create many special-purpose definitions of words that happen to fit the peculiarities of any video. This results in two different problems: assigning empty semantics to many words since the likelihood of a subset of a parse is always the same or higher than the whole parse and excessive polysemy where the meaning of a word is highly specific to some irrelevant feature in a video. We introduce two features to the parser that bias it against empty semantics and against excessive polysemy. Models of communication such as the Rational Speech Acts model (Frank and Goodman, 2012) predict that speakers will avoid inserting meaningless words. One feature counts the number of predicates mapped onto semantic forms which are empty that occur in each parse. The other feature attempts to prevent excessive polysemy by counting how many new semantic forms are introduced for existing tokens by the generated entries from each parse. As the parser becomes more capable of handling sentences in the training set, these features begin to bias it against adding empty semantics and new semantic forms.

Third, models in computer vision are computationally expensive while many evaluations of parse-video pairs are required to train a parser. To overcome this, we construct a provably-correct cache that keeps track of failing subexpressions. This is possible because of a feature of this particular vision-language scoring function: the score decreases monotonically with the number of constraints. With these improvements, the modified semantic parser employing vision-language-based validation learns to map sentences into semantic parses despite facing a challenging setting with few examples and much ambiguity.

5 Dataset

We collected and annotated a dataset of captioned videos with fully annotated semantic parses of the captions. The videos contain people carrying out one of 15 actions, such as picking things up and putting things down, with one of 20 objects spanning 10 different colors. We control for 11 spatial relations between objects and actors. Many videos depict multiple agents performing actions leading to additional ambiguity. Videos were filmed in multiple locations with multiple agents but care was taken to ensure that the background and agents are not informative of the events depicted.

On Mechanical Turk we asked participants to provide sentences that describe something about the video. We did not specify what participants should describe to avoid biasing them and to add richness to the dataset. This sometimes led to sentences that referred to properties of the video that are well beyond the capacities of the vision system, e.g., descriptions of an agent being lazy or references to the camera's movement. We removed such sentences. At training time, the parser receives captioned videos but no annotations about which objects those captions refer to. Each sentence was annotated with a ground-truth semantic form by two trained annotators using a set of 34 predicates. Each sentence was then reviewed and corrected by one other annotator.

To detect the objects in the videos, we used two off-the-shelf detectors, OpenPose (Cao et al., 2017) for person detection and YOLO version 3 (Redmon and Farhadi, 2018) for the remaining objects. In each case we significantly lowered the confidence threshold to avoid false negatives. Many objects in this dataset are small and are handled by humans, which leads to regular object detector failures that are only partially compensated for by lowering the detection threshold at the cost of a large number of false positives. We rely on the inference mechanism of the grounded parser to automatically eliminate these numerous false positives as candidates when grounding sentences due to their low likelihoods. False negatives are much more misleading and difficult to overcome than false positives. It is harder to read in where an unseen object might be than to eliminate a low-confidence detection.

In total, the dataset contains 1200 captions from 401 videos, which selected out of a larger body of sentences collected and pruned as described above. This is comparable to the size of other datasets used for semantic parsing such as two datasets from Tang and Mooney (2001) with 880 and 640 examples respectively and the navigation instruction dataset (Chen and Mooney, 2011) with 706 examples (containing 3236 single sentences). The sentences comprising our dataset contain 169 unique tokens with an average of 7.93 tokens per caption. There are an average of 2.31 objects per caption.

6 Evaluation

6.1 Experimental Setup

We adapted the Cornell SFP (Semantic Parsing Framework) developed by Artzi (2016) to jointly reason about sentences and videos. We selected 720 examples for training and used 120 examples for the validation set to fine-tune the model parameters. We used the remaining 360 examples for the test set. This split was fixed and used in all experiments below. No sentences or videos occurred in both the training and test sets. During training, each hypothesized parse for each sentence is marked as either correct or incorrect, using either direct supervision with the target parse or compatibility with the video, depending on the experiment.

We use beams of 80 for the CKY-parser and *GENLEX*. CCG-based semantic parsers are seeded with a small number of generic combinations of syntactic and semantic types. For example, Artzi (2016) seed with 141 lexical entries; we provide 98. *GENLEX* uses these entries along with an ontology to form new syntactic and semantic types.

Condition	Precision		Recall		F1	
Direct supervision	0.851	*0.946*	0.84	*0.933*	0.846	*0.939*
Noisy supervision (60%)	0.235	*0.423*	0.201	*0.362*	0.217	*0.390*
Shuffled labels (direct supervision)	0.147	*0.384*	0.122	*0.321*	0.136	*0.349*
Shuffled videos (weak supervision)	0.000	*0.106*	0.000	*0.103*	0.000	*0.104*
Object-only vision	0.051	*0.387*	0.042	*0.349*	0.046	*0.367*
Vision-language	0.223	*0.663*	0.183	*0.553*	0.201	*0.591*

Figure 3: Pairs of results for each condition. On the left, we show exact match results and on the right, in *italics*, results for the near miss metric. In the case of *direct supervision*, we train with the target parses. In the case of *noisy supervision*, a percentage of the time (60% here) the parser randomly accepts or rejects a parse. In the case of *shuffled labels*, the target logical forms are assigned to random sentences. For *shuffled videos* the sentences are assigned to random videos. The likelihood of any sentence being true of a random video is low. In the case of *object-only vision*, the vision system consists solely of an object detector discarding any other predicates. The full *vision-language* approach learns to parse a significant fraction of sentences, far outperforming the object-only approach, and usually being within one predicate of the correct answer.

6.2 Results

Figures 3 and 4 summarize the experiments and ablation studies performed. The metrics we use when reporting results are *exact* matches, where the predicted parses must perfectly match the target parses, and *near misses*, where a single predicate in the semantic parse is allowed to differ from the target. Experiments were averaged across 5 runs.

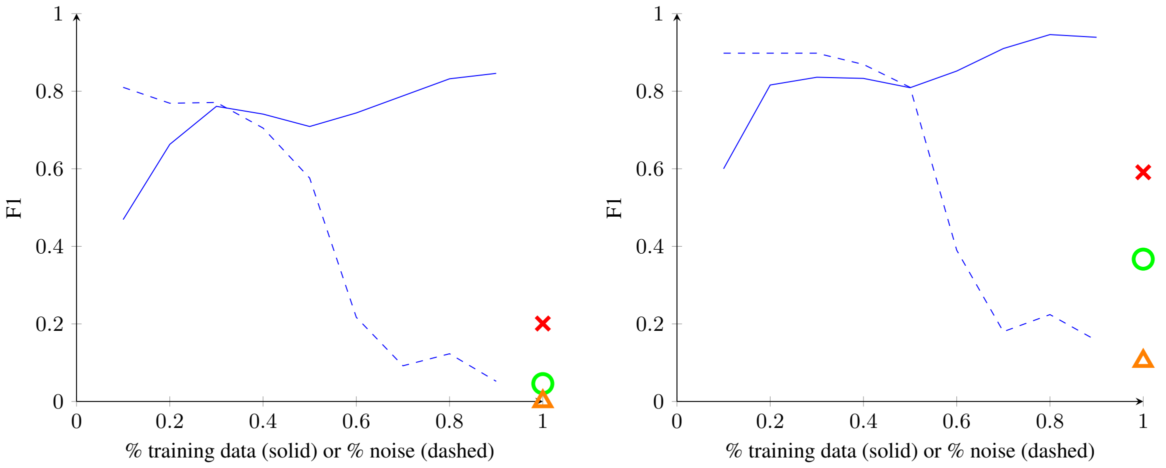
To establish chance-level performance, we trained the directly supervised approach on shuffled labels, assigning random correct parses to random sentences. This is more powerful than a simple chance-level performance calculation as the parser can still take advantage of any dataset biases. Even with the ability to exploit potential biases, performance is very low with F1 scores of 0.136 and 0.349 for the exact and near miss metrics. Both metrics pose a challenging learning problem.

As a baseline, we directly supervised the parser with the target logical forms. When doing so, it achieved high performance with F1 scores of 0.841 and 0.911 for the exact match and near miss cases. Figure 4 shows performance of direct supervision as a function of training set size.

We then added noise to the directly supervised parser. Doing so simulates the unreliable nature of vision and, to an extent, the ambiguities inherent in vision. Noise was introduced by modifying the compatibility function which determines if a parse is correct. A certain percentage of the time, that function returned true or false randomly when given a hypothesized logical form. With around 60% noise, performance was 0.22 and 0.39 F1 for the noisy and near miss cases. Figure 4 shows performance of the noisy baseline as a function of how much noise was introduced.

The fully grounded parser produced 0.2 and 0.6 F1 scores for the exact and near miss metrics. This is far beyond chance performance and corresponds to direct supervision with around 55% noise. There are a number of reasons for why performance is not perfect. First, the evaluation metrics cannot consider equivalences in meaning, just form. A hypothesized parse may carry the same meaning as the target logical form yet it will be considered incorrect. This is less of a problem with direct supervision where the preferences that annotators have for a particular way of encoding the meaning of a sentence can be learned. In the grounded case, this cannot be learned; visually equivalent parses are equally likely. Second, computer vision is unreliable, i.e., object detectors fail. We find that in many of our videos while person detection is fairly reliable, object detection is unreliable. Third, vision in the real world is very ambiguous. Predicates like *hold* are true in almost every interaction. This makes learning the meanings of words much more difficult resulting in the grounded parser often adding useless entries into the predicted logical forms or substituted one predicate for a similar one. The near miss metric shows that overall the parser learned reasonable logical forms. Figure 5 shows six examples from our dataset along with expected and predicted parses, both correct and incorrect.

To understand how much of the performance of the grounded parser comes from visual correlations, like the presence or absence of particular objects, as opposed to more complex and cognitively relevant spatio-temporal relations like actions, we ablated the parser. We removed all features other than objects. The resulting grounded parser accepts any hypothesized parse as long as the objects mentioned in that parse are present in the video. This led to a significant performance drop, near-chance level performance on the exact metric, F1 0.05, and nearly half the F1 score on the near miss metric, 0.37. Having a sophisticated vision system to infer about agents and interactions is crucial for learning.



(a) Exact match

(b) Near miss

Figure 4: Results from training the grounded semantic parser. In blue, *direct supervision* as a function of the amount of training data. In dashed blue, *noisy supervision* uses the whole training set but accepts and rejects parses at random for a given fraction of the time. The red cross is the full vision system while the green o is the object detector ablation. The orange triangle represents *shuffled videos* and shows chance performance. While direct supervision outperforms vision-only supervision, the grounded parser closes the gap and operates like noisy direct supervision with roughly 55% noise.

7 Discussion

We present a semantic parser that learns the structure of language using weak supervision from vision. At test time, the model parses sentences without the need for visual input. Learning by passive observation in this way extends the capabilities of semantic parsers and points the way to a more cognitively plausible model of language acquisition. Several limits remain. Evaluating parses as correct or incorrect depending on a match to a human-annotated logical form is an overly strict criterion and is a problem that also plagues fully-supervised syntactic parsing (Berzak et al., 2016). Since two logical forms may express the same meaning, it is not yet clear what an effective evaluation metric is for these grounded scenarios. In addition, learning in such a passive scenario is hard as correlations between events, e.g., every *pick up* event involves a *touch* event, are very difficult to disentangle.

An interesting source of error in the experimental results comes from visual ambiguities. At the level of relative motions of labeled bounding boxes, the analysis performed by the language-vision system we employed here has difficulty distinguishing certain parts of actions. For example, carrying a shirt and wearing a shirt appear very similar to one another as they are actions that mostly involve moving alongside a person detection. Moreover, since every agent is wearing a shirt it becomes more difficult to learn to distinguish the two actions using positive evidence alone, i.e., a maximum likelihood approach. A more robust vision system, perhaps including object segmentations, person pose, and weak negative evidence for the occurrence of actions, would likely significantly improve the results presented.

In the future, we intend to add a generative model along with a physical simulation allowing the learner to imagine scenarios where a predicate might not hold. This would help mitigate systematic correlations between sentences and videos. The sentences selected here were all chosen such that they are true of the video being shown, yet much of what people discuss is ungrounded, or at least not grounded in the current visual scene. We intend to combine the weakly supervised parser with an unsupervised parser and learn to determine whether a sentence should be grounded visually during training. We hope this work will find applications in robotics where learning to adapt to the specific language of a user while engaging with them is of utmost importance when deploying robots in users' homes.

(i)

Annotated sentence: *The woman is picking up an apple.*
Ground-truth parse: λxy.woman x, pick_up x y, apple y
Predicted parse: λxy.woman x, pick_up x y, apple y

(ii)

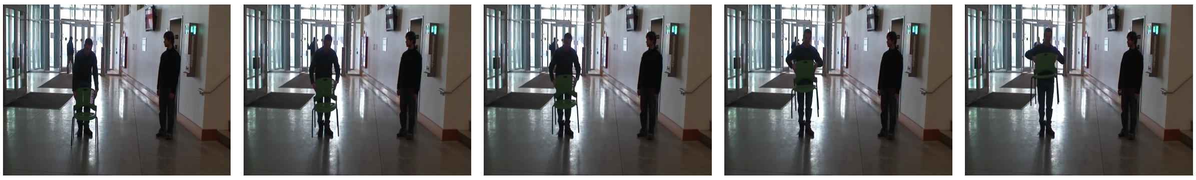
Annotated sentence: *A man walks across the hall holding a chair.*
Ground-truth parse: λxyz.person x, walk x, across x y, hallway y, hold x z chair z
Predicted parse: λxyz.person x, from x y, person y, hold x z chair z

(iii)

Annotated sentence: *A man is walking toward a chair.*
Ground-truth parse: λxy.person x, walk x, toward x y, chair y
Predicted parse: λxy.person x, walk x, toward x y, chair y

(v)

Annotated sentence: *She places the toy car down on the table.*
Ground-truth parse: λxyz.person x, put_down x y, toy y, car y, on y z table z
Predicted parse: λxyz.person x, in x y, toy y, car y, on y z table z



(iv)

Annotated sentence: *A man is lifting the chair.*
Ground-truth parse: λxy.person x, pick_up x y, chair y
Predicted parse: λxy.person x, pick_up x y, chair y

(vi)

Annotated sentence: *A woman reaches for a book on the table.*
Ground-truth parse: λxyz.person x, pick_up x y, book y, on y z table z
Predicted parse: λxyz.person x, stand x, in x y, book y, on y z table z

Figure 5: Six examples of frames from videos in the dataset along with target and predicted logical forms showing both successes and failures. Failures are highlighted in red. Note how incorrect parses are usually similar to the correct semantic forms. The intended meaning is often preserved even in these cases.

Abstract

We propose an end-to-end deep learning model for translating free-form natural language instructions to a high-level plan for behavioral robot navigation. The proposed model uses attention mechanisms to connect information from user instructions with a topological representation of the environment. To evaluate this model, we collected a new dataset for the translation problem containing 11,051 pairs of user instructions and navigation plans. Our results show that the proposed model outperforms baseline approaches on the new dataset. Overall, our work suggests that a topological map of the environment can serve as a relevant knowledge base for translating natural language instructions into a sequence of navigation behaviors.

1 Introduction

Enabling robots to follow navigation instructions in natural language can facilitate human-robot interaction across a variety of applications. For instance, within the service robotics domain, robots can follow navigation instructions to help with mobile manipulation (Tellex et al., 2011) and delivery tasks (Veloso et al., 2015).

Interpreting navigation instructions in natural language is difficult due to the high variability in the way people describe routes (Chen and Mooney, 2011). For example, there are a variety of ways to describe the route in Fig. 1(a):

- *"Exit the room, turn right, follow the corridor until you pass a vase on your left, and enter the next room on your left"*; or
- *"Turn right after you exit the room, and enter the room on the left right before the end of the corridor"*; or
- *"Advance forward to the right after going out of the door. Enter the room which is in the middle of two vases on your left."*

Each fragment of a sentence within these instructions can be mapped to one or more than one navigation behaviors. For instance, assume that a robot counts with a number of primitive, navigation behaviors, such as *"enter the room on the left (or on right)"* , *"follow the corridor"*, *"cross the intersection"*, etc. Then, the fragment *"advance forward"* in a navigation instruction could be interpreted as a *"follow the corridor"* behavior, or as a sequence of *"follow the corridor"* interspersed with *"cross the intersection"* behaviors depending on the topology of the environment. Resolving such ambiguities often requires reasoning about "common-sense" concepts, as well as interpreting spatial information and landmarks, e.g., in sentences such as *"the room on the left right before the end of the corridor"* and *"the room which is in the middle of two vases"*.

In this work, we pose the problem of interpreting navigation instructions as finding a mapping (or grounding) of the commands into an executable navigation plan. While the plan is typically modeled as a formal specification of low-level motions (Chen and Mooney, 2011) or a grammar (Artzi and Zettlemoyer, 2013; Matuszek et al., 2010), we focus specifically on translating instructions to a high-level navigation plan based on a topological representation of the environment. This representation is a *behavioral navigation graph*, as recently proposed by (Sepúlveda et al., 2018), designed to take advantage of the semantic structure typical of human environments. The nodes of the graph correspond to semantically meaningful locations for the navigation task, such as kitchens or entrances to rooms in corridors. The edges are parameterized, visuo-motor behaviors that allow a robot to navigate between neighboring nodes, as illustrated in Fig. 1(b). Under this framework, complex navigation routes can be achieved by sequencing behaviors without an explicit metric representation of the world.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2657–2666
Brussels, Belgium, October 31 - November 4, 2018.

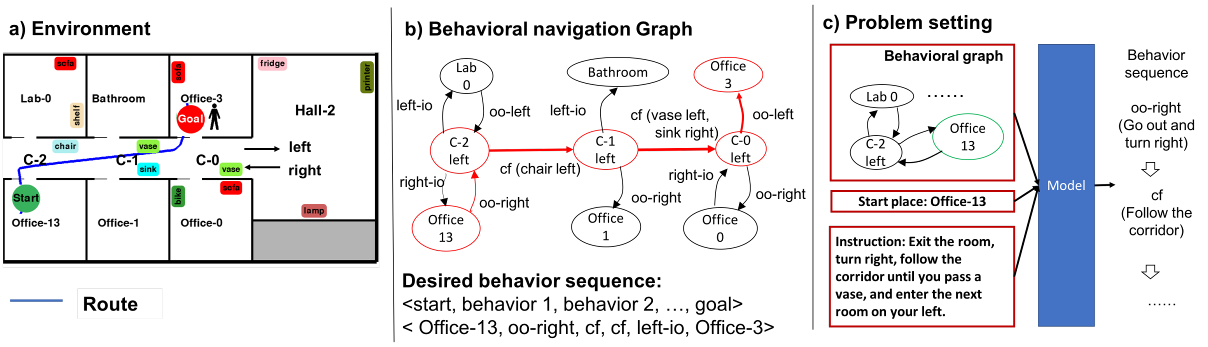

Figure 1: Map of an environment (a), its (partial) behavioral navigation graph (b), and the problem setting of interest (c). The red part of (b) corresponds to the representation of the route highlighted in blue in (a). The codes "oo-left", "oo-right", "cf", "left-io", and "right-io" correspond to the behaviors "go out and turn left", "go out and turn right", "follow the corridor", "enter the room on left", and "enter office on right", respectively.

We formulate the problem of following instructions under the framework of (Sepúlveda et al., 2018) as finding a path in the behavioral navigation graph that follows the desired route, given a known starting location. The edges (behaviors) along this path serve to reach the – sometimes implicit – destination requested by the user. As in (Zang et al., 2018), our focus is on the problem of interpreting navigation directions. We assume that a robot can realize valid navigation plans according to the graph.

We contribute a new end-to-end model for following directions in natural language under the behavioral navigation framework. Inspired by the information retrieval and question answering literature (Lewis and Jones, 1996; Seo et al., 2017; Xiong et al., 2016; Palangi et al., 2016), we propose to leverage the behavioral graph as a knowledge base to facilitate the interpretation of navigation commands. More specifically, the proposed model takes as input user directions in text form, the behavioral graph of the environment encoded as ⟨`node; edge; node`⟩ triplets, and the initial location of the robot in the graph. The model then predicts a set of behaviors to reach the desired destination according to the instructions and the map (Fig. 1(c)). Our main insight is that using attention mechanisms to correlate navigation instructions with the topological map of the environment can facilitate predicting correct navigation plans.

This work also contributes a new dataset of $11,050$ pairs of free-form natural language instructions and high-level navigation plans. This dataset was collected through Mechanical Turk using 100 simulated environments with a corresponding topological map and, to the best of our knowledge, it is the first of its kind for behavioral navigation. The dataset opens up opportunities to explore data-driven methods for grounding navigation commands into high-level motion plans.

We conduct extensive experiments to study the generalization capabilities of the proposed model for following natural language instructions. We investigate both generalization to new instructions in known and in new environments. We conclude this paper by discussing the benefits of the proposed approach as well as opportunities for future research based on our findings.

2 Related work

This section reviews relevant prior work on following navigation instructions. Readers interested in an in-depth review of methods to interpret spatial natural language for robotics are encouraged to refer to (Landsiedel et al., 2017).

Typical approaches to follow navigation commands deal with the complexity of natural language by manually parsing commands, constraining language descriptions, or using statistical machine translation methods. While manually parsing commands is often impractical, the first type of approaches are foundational: they showed that it is possible to leverage the compositionality of semantic units to interpret spatial language (Bugmann et al., 2004; Levit and Roy, 2007).

Constraining language descriptions can reduce the size of the input space to facilitate the interpretation of user commands. For example, (Talbot et al., 2016) explored using structured, symbolic language phrases for navigation. As in this earlier work, we are also interested in navigation with a topological map of the environment. However, we do not process symbolic phrases. Our aim is to translate free-form natural language instructions to a navigation plan using information from a high-level representation of the environment. This translation problem requires dealing with missing actions in navigation instructions and actions with preconditions, such as *"at the end of the corridor, turn right"* (MacMahon et al., 2006).

Statistical machine translation (Koehn, 2009) is at the core of recent approaches to enable robots to follow navigation instructions. These methods aim to automatically discover translation rules from a corpus of data, and often leverage the fact that navigation directions are composed of sequential commands. For instance, (Wong and Mooney, 2006; Matuszek et al., 2010; Chen and Mooney, 2011) used statistical machine translation to map instructions to a formal language defined by a grammar. Likewise, (Kollar et al., 2010; Tellex et al., 2011) mapped commands to spatial description clauses based on the hierarchical structure of language in the navigation problem. Our approach to machine translation builds on insights from these prior efforts. In particular, we focus on end-to-end learning for statistical machine translation due to the recent success of Neural Networks in Natural Language Processing (Goodfellow et al., 2016).

Our work is inspired by methods that reduce the task of interpreting user commands to a sequential prediction problem (Shimizu and Haas, 2009; Mei et al., 2016; Anderson et al., 2018). Similar to Mei et al. and Anderson et al., we use a *sequence-to-sequence* model to enable a mobile agent to follow routes. But instead leveraging visual information to output low-level navigation commands, we focus on using a topological map of the environment to output a high-level navigation plan. This plan is a sequence of behaviors that can be executed by a robot to reach a desired destination (Sepúlveda et al., 2018; Zang et al., 2018).

We explore machine translation from the perspective of automatic question answering. Following (Seo et al., 2017; Xiong et al., 2016), our approach uses attention mechanisms to learn alignments between different input modalities. In our case, the inputs to our model are navigation instructions, a topological environment map, and the start location of the robot (Fig. 1(c)). Our results show that the map can serve as an effective source of contextual information for the translation task. Additionally, it is possible to leverage this kind of information in an end-to-end fashion.

3 Problem Formulation

Our goal is to translate navigation instructions in text form into a sequence of behaviors that a robot can execute to reach a desired destination from a known start location. We frame this problem under a behavioral approach to indoor autonomous navigation (Sepúlveda et al., 2018) and assume that prior knowledge about the environment is available for the translation task. This prior knowledge is a topological map, in the form of a behavioral navigation graph (Fig. 1(b)). The nodes of the graph correspond to semantically-meaningful locations for the navigation task, and its directed edges are visuo-motor behaviors that a robot can use to move between nodes. This formulation takes advantage of the rich semantic structure behind man-made environments, resulting in a compact route representation for robot navigation.

Fig. 1(c) provides a schematic view of the problem setting. The inputs are: (1) a navigation graph m, (2) the starting node s of the robot in m, and (3) a set of free-form navigation instructions I in natural language. The instructions describe a path in the graph to reach from s to a – potentially implicit – destination node g. Using this information, the objective is to predict a suitable sequence of robot behaviors $b_1, \ldots, b_T$ to navigate from s to g according to I. From a supervised learning perspective, the goal is then to estimate:

$$\underset{b_1,\ldots,b_T}{\operatorname{argmax}} P(b_1, \ldots, b_T | m, s, I) \tag{1}$$

based on a dataset of input-target pairs $\{(\mathbf{x}_i, \mathbf{y}_i) \,|\, 0 \leq i \leq N\}$, where $\mathbf{x}_i = (m, s, I)_i$ and $\mathbf{y}_i = (b_1, \ldots, b_T)_i$, respectively. The sequential execution of the behaviors $b_1, \ldots, b_T$ should replicate the route intended by the instructions I.

We assume no prior linguistic knowledge. Thus, translation approaches have to cope with the semantics and syntax of the language by discovering corresponding patterns in the data.

3.1 The Behavioral Graph: A Knowledge Base For Navigation

We view the behavioral graph m as a knowledge base that encodes a set of navigational rules as triplets $\langle p_i; b_l[attr]; p_j\rangle$, where p_i and p_j are adjacent nodes in the graph, and the edge b_l is an executable behavior to navigate from p_i to p_j. In general, each behaviors includes a list of relevant navigational attributes $attr$ that the robot might encounter when moving between nodes.

Behavior	Description
oo<d>	Go out of the current place and turn <d>
io<d>	Turn <d> and enter the place straight ahead
oio	Exit current place and enter straight ahead
<d>t	Turn <d> at the intersection
cf	Follow (or go straight down) the corridor
sp	Go straight at a T intersection
ch<d>	Cross the hall and turn <d>

Table 1: Behaviors (edges) of the navigation graphs considered in this work. The direction <d> can be left or right.

We consider 7 types of semantic locations, 11 types of behaviors, and 20 different types of landmarks. A location in the navigation graph can be a room, a lab, an office, a kitchen, a hall, a corridor, or a bathroom. These places are labeled with unique tags, such as "room-1" or "lab-2", except for bathrooms and kitchens which people do not typically refer to by unique names when describing navigation routes.

Table 1 lists the navigation behaviors that we consider in this work. These behaviors can be described in reference to visual landmarks or objects, such as paintings, book shelfs, tables, etc. As in Fig. 1, maps might contain multiple landmarks of the same type. Please see the supplementary material (Appendix A) for more details.

4 Approach

We leverage recent advances in deep learning to translate natural language instructions to a sequence of navigation behaviors in an end-to-end fashion. Our proposed model builds on the sequence-to-sequence translation model of (Bahdanau et al., 2015), which computes a soft-alignment between a source sequence (natural language instructions in our case) and the corresponding target sequence (navigation behaviors).

As one of our main contributions, we augment the neural machine translation approach of Bahdanau et al. to take as input not only natural language instructions, but also the corresponding behavioral navigation graph m of the environment where navigation should take place. Specifically, at each step, the graph m operates as a knowledge base that the model can access to obtain information about path connectivity, facilitating the grounding of navigation commands.

Figure 2 shows the structure of the proposed model for interpreting navigation instructions. The model consists of six layers:

Embed layer: The model first encodes each word and symbol in the input sequences I and m into fixed-length representations. The instructions I are embedded into a 100-dimensional pre-trained GloVe vector (Pennington et al., 2014). Each of the triplet components, p_i, $b_l[attr]$, and p_j of the graph m, are one-hot encoded into vectors of dimensionality $2N+E$, where N and E are the number of nodes and edges in m, respectively.

Encoder layer: The model then uses two bidirectional Gated Recurrent Units (GRUs) (Cho et al., 2014) to independently process the information from I and m, and incorporate contextual cues from the surrounding embeddings in each sequence. The outputs of the encoder layer are the matrix $\bar{I} \in \mathbb{R}^{T\times 2H}$ for the navigational commands and the matrix $\bar{G} \in \mathbb{R}^{L\times 2H}$ for the behavioral graph, where H is the hidden size of each GRU, T is the number of words in the instruction I, and L is the number of triplets in the graph m.

Attention layer: Matrices $\bar{I}$ and $\bar{G}$ generated by the encoder layer are combined using an attention mechanism. We use one-way attention because the graph contains information about the whole environment, while the instruction has (potentially incomplete) local information about the route of interest. The use of attention provides our model with a two-step strategy to interpret commands. This resembles the way people find paths on a map: first, relevant parts on the map are selected according to their affinity to each of the words in the input instruction (attention layer); second, the selected parts are connected to assemble a valid path (decoder layer). More formally, let $\bar{G}_i$ ($i \in [1, L]$) be the i-th row of $\bar{G}$, and $\bar{I}_j$ ($j \in [1, T]$) the j-th row of $\bar{I}$. We use each encoded triplet $\bar{G}_i$ in $\bar{G}$ to calculate its associated attention distribution $a_i \in \mathbb{R}^T$ over all the atomic instructions $\bar{I}_j$:

$$e_i = [\bar{G}_i W \bar{I}_1^{\intercal}, \ldots, \bar{G}_i W \bar{I}_T^{\intercal}] \quad (2)$$

$$a_i = softmax(e_i) \quad (3)$$

where the matrix $W \in \mathbb{R}^{2H\times 2H}$ serves to combine the different sources of information $\bar{G}$ and $\bar{I}$. Each component a_{ij} of the attention distributions a_i quantifies the affinity between the i-th triplet in $\bar{G}$ and the j-th word in the corresponding input I.

The model then uses each attention distribution a_i to obtain a weighted sum of the encodings of the words in $\bar{I}$, according to their relevance to the corresponding triplet $\bar{G}_i$. This results in L attention vectors $R_i \in \mathbb{R}^{2H}$, $R_i = \sum_{j=1}^{T} a_{ij} I_j$.

The final step in the attention layer concatenates each R_i with $\bar{G}_i$ to generate the outputs

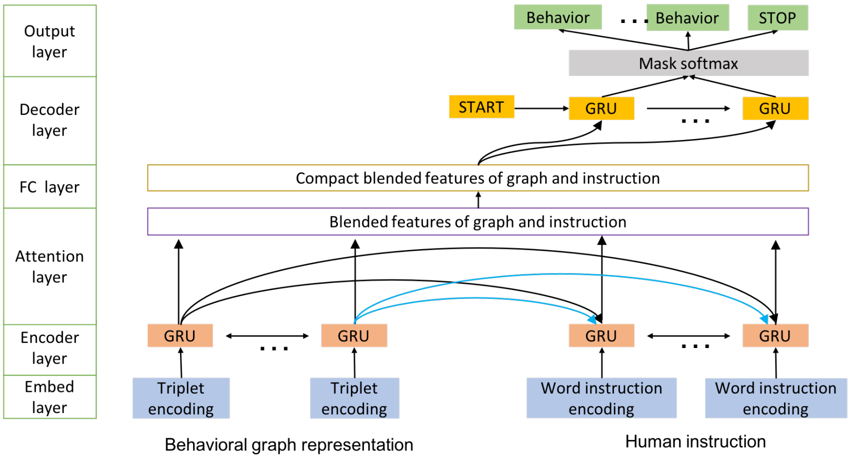

Figure 2: Model overview. The model contains six layers, takes the input of behavioral graph representation, free-form instruction, and the start location (yellow block marked as START in the decoder layer) and outputs a sequence of behaviors.

$F_i = [R_i; \bar{G}_i]$, $i \in [1, L]$. Following (Seo et al., 2017), we include the encoded triplet $\bar{G}_i$ in the output tensor F_i of this layer to prevent early summaries of relevant map information.

FC layer: The model reduces the dimensionality of each individual vector F_i from $4H$ to H with a fully-connected (FC) layer. The resulting L vectors are output to the next layer as columns of a context matrix $C \in \mathbb{R}^{H \times L}$.

Decoder layer: After the FC layer, the model predicts likelihoods over the sequence of behaviors that correspond to the input instructions with a GRU network. Without loss of generality, consider the t-th recurrent cell in the GRU network. This cell takes two inputs: a hidden state vector h_{t-1} from the prior cell, and a one-hot embedding of the previous behavior b_{t-1} that was predicted by the model. Based on these inputs, the GRU cell outputs a new hidden state h_t to compute likelihoods for the next behavior. These likelihoods are estimated by combining the output state h_t with relevant information from the context C:

$$\hat{d}_{ts} = v_a^\intercal \tanh(W_1 h_t + W_2 C_s) \quad (4)$$

$$d_t = softmax(\hat{d}_{t1}, \ldots, \hat{d}_{tL}) \quad (5)$$

where W_1, W_2, and v_a are trainable parameters. The attention vector $d_t \in \mathbb{R}^L$ in Eq. (5) quantifies the affinity of h_t with respect to each of the columns C_s of C, where $s \in [1, L]$. The attention vector also helps to estimate a dynamic contextual vector $S_t = \sum_{s=1}^{L} d_{ts} C_s$ that the t-th GRU cell uses to compute logits for the next behavior:

$$o_t = W_3 [S_t; h_t] \quad (6)$$

with W_3 trainable parameters. Note that o_t includes a value for each of the pre-defined behaviors in the graph m, as well as for a special "*stop*" symbol to identify the end of the output sequence.

Output layer: The final layer of the model searches for a valid sequence of robot behaviors based on the robot's initial node, the connectivity of the graph m, and the output logits from the previous decoder layer. Again, without loss of generality, consider the t-th behavior b_t that is finally predicted by the model. The search for this behavior is implemented as:

$$b_t = argmax(softmax(o_t + mask(m, n_t))) \quad (7)$$

with $mask(m, n_t)$ a masking function that takes as input the graph m and the node n_t that the robot reaches after following the sequence of behaviors $b_1, \ldots, b_{t-1}$ previously predicted by the model. The $mask$ function returns a vector of the same dimensionality as the logits o_t, but with zeros for the valid behaviors after the last location n_t and for the special stop symbol, and $-\inf$ for any invalid predictions according to the connectivity of the behavioral navigation graph.

5 Dataset

We created a new dataset for the problem of following navigation instructions under the behavioral navigation framework of (Sepúlveda et al., 2018).[1] This dataset was created using Amazon Mechanical Turk and 100 maps of simulated indoor environments, each with 6 to 65 rooms. To the best of our knowledge, this is the first bench-

---

[1] The dataset is publicly available through the website: `follow-nav-directions.stanford.edu`.

Dataset	# Single	# Double	Total
Training	4062	2002	8066
Test-Repeated	944	34	1012
Test-New	962	0	962

Table 2: Dataset statistics. "# Single" indicates the number of navigation plans with a single natural language instruction. "# Double" is the number of plans with two different instructions. The total number of plans is (# Single) × 2(# Double).

mark for comparing translation models in the context of behavioral robot navigation.

As shown in Table 2, the dataset consists of 8066 pairs of free-form natural language instructions and navigation plans for training. This training data was collected from 88 unique simulated environments, totaling 6064 distinct navigation plans (2002 plans have two different navigation instructions each; the rest has one). The dataset contains two test set variants:

1) Test-Repeated: Contains 1012 pairs of instructions and navigation plans. These routes are not part of the training set; however, they are collected using environments that are part of the training set.

2) Test-New: Contains 962 pairs of instructions and navigation plans. This test set is more challenging than the Test-Repeated dataset because it contains new routes on 12 new indoor environments not included in the training set.

While the dataset was collected with simulated environments, no structure was imposed on the navigation instructions while crowd-sourcing data. Thus, many instructions in our dataset are ambiguous. Moreover, the order of the behaviors in the instructions is not always the same. For instance, a person said *"turn right and advance"* to describe part of a route, while another person said *"go straight after turning right"* in a similar situation. The high variability present in the natural language descriptions of our dataset makes the problem of decoding instructions into behaviors not trivial. See Appendix A of the supplementary material for additional details on our data collection effort.

6 Experiments

This section describes our evaluation of the proposed approach for interpreting navigation commands in natural language. We provide both quantitative and qualitative results.

6.1 Evaluation Metrics

While computing evaluation metrics, we only consider the behaviors present in the route because they are sufficient to recover the high-level navigation plan from the graph. Our metrics treat each behavior as a single token. For example, the sample plan "R-1 oor C-1 cf C-1 lt C-0 cf C-0 iol O-3" is considered to have 5 tokens, each corresponding to one of its behaviors ("oor", "cf", "lt", "cf", "iol"). In this plan, "R-1","C-1", "C-0", and "O-3" are symbols for locations (nodes) in the graph.

We compare the performance of translation approaches based on four metrics:

- Exact Match (EM). As in (Shimizu and Haas, 2009), EM is 1 if a predicted plan matches exactly the ground truth; otherwise it is 0.

- F1 score (F1). The harmonic average of the precision and recall over all the test set (Chinchor and Sundheim, 1993).

- Edit Distance (ED). The minimum number of insertions, deletions or swap operations required to transform a predicted sequence of behaviors into the ground truth sequence (Navarro, 2001).

- Goal Match (GM). GM is 1 if a predicted plan reaches the ground truth destination (even if the full sequence of behaviors does not match exactly the ground truth). Otherwise, GM is 0.

6.2 Models Used in the Evaluation

We compare the proposed approach for translating natural language instructions into a navigation plan against alternative deep-learning models:

Baseline model. The baseline approach is based on (Shimizu and Haas, 2009). It divides the task of interpreting commands for behavioral navigation into two steps: path generation, and path verification. For path generation, this baseline uses a standard sequence-to-sequence model augmented with an attention mechanism, similar to (Bahdanau et al., 2015; Zang et al., 2018). For path verification, the baseline uses depth-first search to find a route in the graph that matches the sequence of predicted behaviors. If no route matches perfectly, the baseline changes up to three behaviors in the predicted sequence to try to turn it into a valid path.

Ablation model. To test the impact of using the behavioral graphs as an extra input to our translation model, we implemented a version of our approach that only takes natural language instructions as input. In this ablation model, the output of the bidirectional GRU that encodes the input instruction I is directly fed to the decoder layer. This model does not have the attention and FC layers described in Sec. 4, nor uses the masking function in the output layer.

Ablation with mask model. This model is the same as the previous Ablation model, but with the masking function in the output layer.

6.3 Implementation Details

We pre-processed the inputs to the various models that are considered in our experiment. In particular, we lowercased, tokenized, spell-checked and lemmatized the input instructions in text-form using WordNet (Miller, 1995). We also truncated the graphs to a maximum of 300 triplets, and the navigational instructions to a maximum of 150 words. Only 6.4% (5.4%) of the unique graphs in the training (validation) set had more than 300 triplets, and less than 0.15% of the natural language instructions in these sets had more than 150 tokens.

The dimensionality of the hidden state of the GRU networks was set to 128 in all the experiments. In general, we used 12.5% of the training set as validation for choosing models' hyperparameters. In particular, we used dropout after the encoder and the fully-connected layers of the proposed model to reduce overfitting. Best performance was achieved with a dropout rate of 0.5 and batch size equal to 256. We also used scheduled sampling (Bengio et al., 2015) at training time for all models except the baseline.

We input the triplets from the graph to our proposed model in alphabetical order, and consider a modification where the triplets that surround the start location of the robot are provided first in the input graph sequence. We hypothesized that such rearrangement would help identify the starting location (node) of the robot in the graph. In turn, this could facilitate the prediction of correct output sequences. In the remaining of the paper, we refer to models that were provided a rearranged graph, beginning with the starting location of the robot, as models with "Ordered Triplets".

6.4 Quantitative Evaluation

Table 3 shows the performance of the models considered in our evaluation on both test sets. The next two sections discuss the results in detail.

6.4.1 Performance in the Test-Repeated Set

First, we can observe that the final model "Ours with Mask and Ordered Triplets" outperforms the Baseline and Ablation models on all metrics in previously seen environments. The difference in performance is particularly evident for the Exact Match and Goal Match metrics, with our model increasing accuracy by 35% and 25% in comparison to the Baseline and Ablation models, respectively. These results suggest that providing the behavioral navigation graph to the model and allowing it to process this information as a knowledge base in an end-to-end fashion is beneficial.

We can also observe from Table 3 that the masking function of Eq. (7) tends to increase performance in the Test-Repeated Set by constraining the output sequence to a valid set of navigation behaviors. For the Ablation model, using the masking function leads to about 10% increase in EM and GM accuracy. For the proposed model (with or without reordering the graph triplets), the increase in accuracy is around 4%. Note that the impact of the masking function is less evident in terms of the F1 score because this metric considers if a predicted behavior exists in the ground truth navigation plan, irrespective of its specific position in the output sequence.

The results in the last four rows of Table 3 suggest that ordering the graph triplets can facilitate predicting correct navigation plans in previously seen environments. Providing the triplets that surround the starting location of the robot first to the model leads to a boost of 4% in EM and GM performance. The rearrangement of the graph triplets also helps to reduce ED and increase F1.

Lastly, it is worth noting that our proposed model (last row of Table 3) outperforms all other models in previously seen environments. In particular, we obtain over 4% increase in EM and GM between our model and the next best two models.

6.4.2 Performance in the Test-New Set

The previous section evaluated model performance on new instructions (and corresponding navigation plans) for environments that were previously seen at training time. Here, we examine whether the trained models succeed on environments that are completely new.

The evaluation on the Test-New Set helps understand the generalization capabilities of the models under consideration. This experiment is more challenging than the one in the previous sec-

Model	Test-Repeated Set				Test-New Set			
	EM ↑	F1 ↑	ED ↓	GM ↑	EM ↑	F1↑	ED ↓	GM ↑
Baseline	25.30	79.83	2.53	26.28	25.44	81.38	2.39	25.44
Ablation	36.36	90.28	1.36	36.36	24.82	88.65	1.71	24.92
Ablation with Mask	45.95	90.08	1.20	46.05	36.45	88.31	1.45	36.56
Ours without Mask	52.47	91.74	0.95	53.95	21.94	87.50	1.78	22.65
Ours with Mask	57.31	91.91	0.91	57.31	38.52	88.98	1.32	38.52
Ours without Mask and with Ordered Triplets	57.21	93.37	0.79	57.71	33.36	**91.02**	1.37	33.78
Ours with Mask and Ordered Triplets	**61.17**	**93.54**	**0.75**	**61.36**	**41.71**	90.22	**1.22**	**41.81**

Table 3: Performance of different models on the test datasets. EM and GM report percentages, and ED corresponds to average edit distance. The symbol ↑ indicates that higher results are better in the corresponding column; ↓ indicates that lower is better.

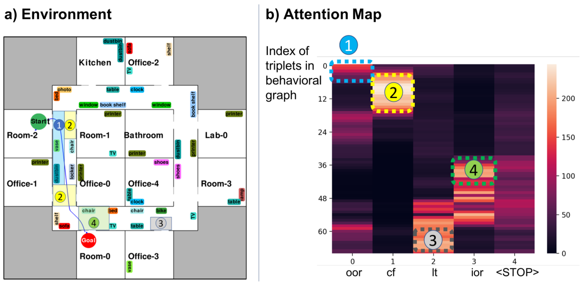

Figure 3: Visualization of the attention weights of the decoder layer. The color-coded and numbered regions on the map (left) correspond to the triplets that are highlighted with the corresponding color in the attention map (right).

tion, as can be seen in performance drops in Table 3 for the new environments. Nonetheless, the insights from the previous section still hold: masking in the output layer and reordering the graph triplets tend to increase performance.

Even though the results in Table 3 suggest that there is room for future work on decoding natural language instructions, our model still outperforms the baselines by a clear margin in new environments. For instance, the difference between our model and the second best model in the Test-New set is about 3% EM and GM. Note that the average number of actions in the ground truth output sequences is 7.07 for the Test-New set. Our model's predictions are just 1.22 edits off on average from the correct navigation plans.

6.5 Qualitative Evaluation

This section discusses qualitative results to better understand how the proposed model uses the navigation graph.

6.5.1 Attention Visualization

We analyze the evolution of the attention weights d_t in Eq. (5) to assess if the decoder layer of the proposed model is attending to the correct parts of the behavioral graph when making predictions. Fig 3(b) shows an example of the resulting attention map for the case of a correct prediction. In the Figure, the attention map is depicted as a scaled and normalized 2D array of color codes. Each column in the array shows the attention distribution d_t used to generate the predicted output at step t. Consequently, each row in the array represents a triplet in the corresponding behavioral graph. This graph consists of 72 triplets for Fig 3(b).

We observe a locality effect associated to the attention coefficients corresponding to high values (bright areas) in each column of Fig 3(b). This suggests that the decoder is paying attention to graph triplets associated to particular neighborhoods of the environment in each prediction step. We include additional attention visualizations in the supplementary Appendix, including cases where the dynamics of the attention distribution are harder to interpret.

6.5.2 Experiments with Sub-Optimal Paths

All the routes in our dataset are the shortest paths from a start location to a given destination. Thus, we collected a few additional natural language instructions to check if our model was able to follow navigation instructions describing sub-optimal paths. One such example is shown in Fig. 4, where the blue route (shortest path) and the red route (alternative path) are described by:

- **Blue route:** "*Go out the office and make a left. Turn right at the corner and go down the hall. Make a right at the next corner and enter the kitchen in front of table.*"
- **Red route:** "*Exit the room 0 and turn right, go to the end of the corridor and turn left, go straight to the end of the corridor and turn left again. After passing bookshelf on your left and table on your right, Enter the kitchen on your right.*"

For both routes, the proposed model was able to predict the correct sequence of navigation behaviors. This result suggests that the model is indeed using the input instructions and is not just approximating shortest paths in the behavioral graph.

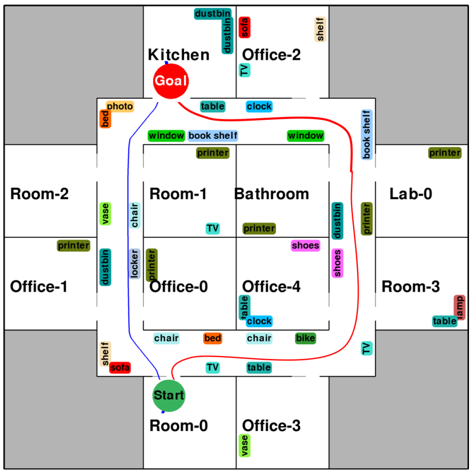

Figure 4: An example of two different navigation paths between the same pair of start and goal locations.

Other examples on the prediction of sub-optimal paths are described in the Appendix.

7 Conclusion

This work introduced behavioral navigation through free-form natural language instructions as a challenging and a novel task that falls at the intersection of natural language processing and robotics. This problem has a range of interesting cross-domain applications, including information retrieval.

We proposed an end-to-end system to translate user instructions to a high-level navigation plan. Our model utilized an attention mechanism to merge relevant information from the navigation instructions with a behavioral graph of the environment. The model then used a decoder to predict a sequence of navigation behaviors that matched the input commands.

As part of this effort, we contributed a new dataset of 11,051 pairs of user instructions and navigation plans from 100 different environments. Our model achieved the best performance in this dataset in comparison to a two-step baseline approach for interpreting navigation instructions, and a sequence-to-sequence model that does not consider the behavioral graph. Our quantitative and qualitative results suggest that attention mechanisms can help leverage the behavioral graph as a relevant knowledge base to facilitate the translation of free-form navigation instructions. Overall, our approach demonstrated practical form of learning for a complex and useful task.

In future work, we are interested in investigating mechanisms to improve generalization to new environments. For example, pointer and graph networks (Vinyals et al., 2015; Defferrard et al., 2016) are a promising direction to help supervise translation models and predict motion behaviors.

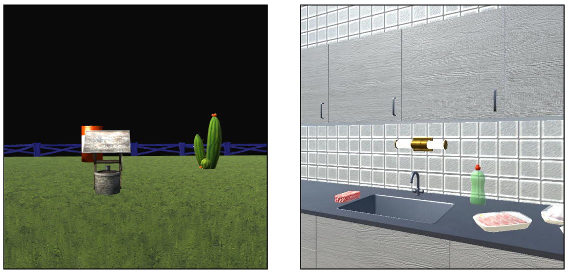
Abstract

We propose to decompose instruction execution to goal prediction and action generation. We design a model that maps raw visual observations to goals using LINGUNET, a language-conditioned image generation network, and then generates the actions required to complete them. Our model is trained from demonstration only without external resources. To evaluate our approach, we introduce two benchmarks for instruction following: LANI, a navigation task; and CHAI, where an agent executes household instructions. Our evaluation demonstrates the advantages of our model decomposition, and illustrates the challenges posed by our new benchmarks.



After reaching the hydrant head towards the blue fence and pass towards the right side of the well.

Put the cereal, the sponge, and the dishwashing soap into the cupboard above the sink.

Figure 1: Example instructions from our two tasks: LANI (left) and CHAI (right). LANI is a landmark navigation task, and CHAI is a corpus of instructions in the CHALET environment.

1 Introduction

Executing instructions in interactive environments requires mapping natural language and observations to actions. Recent approaches propose learning to directly map from inputs to actions, for example given language and either structured observations (Mei et al., 2016; Suhr and Artzi, 2018) or raw visual observations (Misra et al., 2017; Xiong et al., 2018). Rather than using a combination of models, these approaches learn a single model to solve language, perception, and planning challenges. This reduces the amount of engineering required and eliminates the need for hand-crafted meaning representations. At each step, the agent maps its current inputs to the next action using a single learned function that is executed repeatedly until task completion.

Although executing the same computation at each step simplifies modeling, it exemplifies certain inefficiencies; while the agent needs to decide what action to take at each step, identifying its goal is only required once every several steps or even once per execution. The left instruction in Figure 1 illustrates this. The agent can compute its goal once given the initial observation, and given this goal can then generate the actions required. In this paper, we study a new model that explicitly distinguishes between goal selection and action generation, and introduce two instruction following benchmark tasks to evaluate it.

Our model decomposes into goal prediction and action generation. Given a natural language instruction and system observations, the model predicts the goal to complete. Given the goal, the model generates a sequence of actions.

The key challenge we address is designing the goal representation. We avoid manually designing a meaning representation, and predict the goal in the agent's observation space. Given the image of the environment the agent observes, we generate a probability distribution over the image to highlight the goal location. We treat this prediction as image generation, and develop LINGUNET, a language conditioned variant of the U-NET image-to-image architecture (Ronneberger et al., 2015). Given the visual goal prediction, we generate actions using a recurrent neural network (RNN).

Our model decomposition offers two key advantages. First, we can use different learning methods as appropriate for the goal prediction and action

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2667–2678
Brussels, Belgium, October 31 - November 4, 2018.

generation problems. We find supervised learning more effective for goal prediction, where only a limited amount of natural language data is available. For action generation, where exploration is critical, we use policy gradient in a contextual bandit setting (Misra et al., 2017). Second, the goal distribution is easily interpretable by overlaying it on the agent observations. This can be used to increase the safety of physical systems by letting the user verify the goal before any action is executed. Despite the decomposition, our approach retains the advantages of the single-model approach. It does not require designing intermediate representations, and training does not rely on external resources, such as pre-trained parsers or object detectors, instead using demonstrations only.

We introduce two new benchmark tasks with different levels of complexity of goal prediction and action generation. LANI is a 3D navigation environment and corpus, where an agent navigates between landmarks. The corpus includes 6,000 sequences of natural language instructions, each containing on average 4.7 instructions. CHAI is a corpus of 1,596 instruction sequences, each including 7.7 instructions on average, for CHALET, a 3D house environment (Yan et al., 2018). Instructions combine navigation and simple manipulation, including moving objects and opening containers. Both tasks require solving language challenges, including spatial and temporal reasoning, as well as complex perception and planning problems. While LANI provides a task where most instructions include a single goal, the CHAI instructions often require multiple intermediate goals. For example, the household instruction in Figure 1 can be decomposed to eight goals: opening the cupboard, picking each item and moving it to the cupboard, and closing the cupboard. Achieving each goal requires multiple actions of different types, including moving and acting on objects. This allows us to experiment with a simple variation of our model to generate intermediate goals.

We compare our approach to multiple recent methods. Experiments on the LANI navigation task indicate that decomposing goal prediction and action generation significantly improves instruction execution performance. While we observe similar trends on the CHAI instructions, results are overall weaker, illustrating the complexity of the task. We also observe that inherent ambiguities in instruction following make exact goal identification difficult, as demonstrated by imperfect human performance. However, the gap to human-level performance still remains large across both tasks. Our code and data are available at `github.com/clic-lab/ciff`.

2 Technical Overview

Task Let $\mathcal{X}$ be the set of all *instructions*, $\mathcal{S}$ the set of all *world states*, and $\mathcal{A}$ the set of all *actions*. An instruction $\bar{x} \in \mathcal{X}$ is a sequence $\langle x_1, \ldots, x_n \rangle$, where each x_i is a token. The agent executes instructions by generating a sequence of actions, and indicates execution completion with the special action `STOP`.

The sets of actions $\mathcal{A}$ and states $\mathcal{S}$ are domain specific. In the navigation domain LANI, the actions include moving the agent and changing its orientation. The state information includes the position and orientation of the agent and the different landmarks. The agent actions in the CHALET house environment include moving and changing the agent orientation, as well as an object interaction action. The state encodes the position and orientation of the agent and all objects in the house. For interactive objects, the state also includes their status, for example if a drawer is open or closed. In both domains, the actions are discrete. The domains are described in Section 6.

Model The agent does not observe the world state directly, but instead observes its pose and an RGB image of the environment from its point of view. We define these observations as the agent context $\tilde{s}$. An agent model is a function from an agent context $\tilde{s}$ to an action $a \in \mathcal{A}$. We model goal prediction as predicting a probability distribution over the agent visual observations, representing the likelihood of locations or objects in the environment being target positions or objects to be acted on. Our model is described in Section 4.

Learning We assume access to training data with N examples $\{(\bar{x}^{(i)}, s_1^{(i)}, s_g^{(i)})\}_{i=1}^N$, where $\bar{x}^{(i)}$ is an instruction, $s_1^{(i)}$ is a start state, and $s_g^{(i)}$ is the goal state. We decompose learning; training goal prediction using supervised learning, and action generation using oracle goals with policy gradient in a contextual bandit setting. We assume an instrumented environment with access to the world state, which is used to compute rewards during training only. Learning is described in Section 5.

Evaluation We evaluate task performance on a test set $\{(\bar{x}^{(i)}, s_1^{(i)}, s_g^{(i)})\}_{i=1}^M$, where $\bar{x}^{(i)}$ is an instruction, $s_1^{(i)}$ is a start state, and $s_g^{(i)}$ is the goal state. We evaluate task completion accuracy and the distance of the agent's final state to $s_g^{(i)}$.

3 Related Work

Mapping instruction to action has been studied extensively with intermediate symbolic representations (e.g., Chen and Mooney, 2011; Kim and Mooney, 2012; Artzi and Zettlemoyer, 2013; Artzi et al., 2014; Misra et al., 2015, 2016). Recently, there has been growing interest in direct mapping from raw visual observations to actions (Misra et al., 2017; Xiong et al., 2018; Anderson et al., 2018; Fried et al., 2018). We propose a model that enjoys the benefits of such direct mapping, but explicitly decomposes that task to interpretable goal prediction and action generation. While we focus on natural language, the problem has also been studied using synthetic language (Chaplot et al., 2018; Hermann et al., 2017).

Our model design is related to hierarchical reinforcement learning, where sub-policies at different levels of the hierarchy are used at different frequencies (Sutton et al., 1998). Oh et al. (2017) uses a two-level hierarchy for mapping synthetic language to actions. Unlike our visual goal representation, they use an opaque vector representation. Also, instead of reinforcement learning, our methods emphasize sample efficiency.

Goal prediction is related to referring expression interpretation (Matuszek et al., 2012a; Krishnamurthy and Kollar, 2013; Kazemzadeh et al., 2014; Kong et al., 2014; Yu et al., 2016; Mao et al., 2016; Kitaev and Klein, 2017). While our model solves a similar problem for goal prediction, we focus on detecting visual goals for actions, including both navigation and manipulation, as part of an instruction following model. Using formal goal representation for instruction following was studied by MacGlashan et al. (2015). In contrast, our model generates a probability distribution over images, and does not require an ontology.

Our data collection is related to existing work. LANI is inspired by the HCRC Map Task (Anderson et al., 1991), where a leader directs a follower to navigate between landmarks on a map. We use a similar task, but our scalable data collection process allows for a significantly larger corpus. We also provide an interactive navigation environment, instead of only map diagrams. Unlike Map Task, our leaders and followers do not interact in real time. This abstracts away interaction challenges, similar to how the SAIL navigation corpus was collected (MacMahon et al., 2006). CHAI instructions were collected using scenarios given to workers, similar to the ATIS collection process (Hemphill et al., 1990; Dahl et al., 1994). Recently, multiple 3D research environments were released. LANI has a significantly larger state space than existing navigation environments (Hermann et al., 2017; Chaplot et al., 2018), and CHALET, the environment used for CHAI, is larger and has more complex manipulation compared to similar environments (Gordon et al., 2018; Das et al., 2018). In addition, only synthetic language data has been released for these environment. An exception is the Room-to-Room dataset (Anderson et al., 2018) that makes use of an environment of connected panoramas of house settings. Although it provides a realistic vision challenge, unlike our environments, the state space is limited to a small number of panoramas and manipulation is not possible.

4 Model

We model the agent policy as a neural network. The agent observes the world state s_t at time t as an RGB image $\mathbf{I}_t$. The agent context $\tilde{s}_t$, the information available to the agent to select the next action a_t, is a tuple $(\bar{x}, \mathbf{I}_P, \langle(\mathbf{I}_1, p_1), \ldots, (\mathbf{I}_t, p_t)\rangle)$, where $\bar{x}$ is the natural language instructions, $\mathbf{I}_P$ is a panoramic view of the environment from the starting position at time $t = 1$, and $\langle(\mathbf{I}_1, p_1), \ldots, (\mathbf{I}_t, p_t)\rangle$ is the sequence of observations $\mathbf{I}_t$ and poses p_t up to time t. The panorama $\mathbf{I}_P$ is generated through deterministic exploration by rotating 360° to observe the environment at the beginning of the execution.[1]

The model includes two main components: goal prediction and action generation. The agent uses the panorama $\mathbf{I}_P$ to predict the goal location l_g. At each time step t, a projection of the goal location into the agent's current view $\mathbf{M}_t$ is given as input to an RNN to generate actions. The probability of an action a_t at time t decomposes to:

$$P(a_t \mid \tilde{s}_t) = \sum_{l_g} \Big(P(l_g \mid \bar{x}, \mathbf{I}_P) \\ P(a_t \mid l_g, (\mathbf{I}_1, p_1), \ldots, (\mathbf{I}_t, p_t)) \Big) \ ,$$

where the first term puts the complete distribution mass on a single location (i.e., a delta function). Figure 2 illustrates the model.

---

[1] The panorama is a concatenation of deterministic observations along the width dimension. For simplicity, we do not include these deterministic steps in the execution.

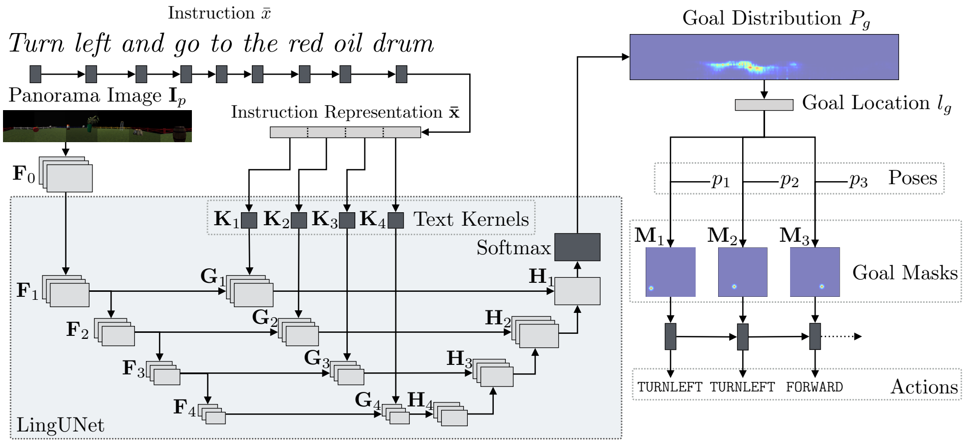


Figure 2: An illustration for our architecture (Section 4) for the instruction *turn left and go to the red oil drum* with a LINGUNET depth of $m = 4$. The instruction $\bar{x}$ is mapped to $\bar{\mathbf{x}}$ with an RNN, and the initial panorama observation $\mathbf{I}_P$ to $\mathbf{F}_0$ with a CNN. LINGUNET generates $\mathbf{H}_1$, a visual representation of the goal. First, a sequence of convolutions maps the image features $\mathbf{F}_0$ to feature maps $\mathbf{F}_1,\ldots,\mathbf{F}_4$. The text representation $\bar{\mathbf{x}}$ is used to generate the kernels $\mathbf{K}_1,\ldots,\mathbf{K}_4$, which are convolved to generate the text-conditioned feature maps $\mathbf{G}_1,\ldots,\mathbf{G}_4$. These feature maps are de-convolved to $\mathbf{H}_1,\ldots,\mathbf{H}_4$. The goal probability distribution P_g is computed from $\mathbf{H}_1$. The goal location is the inferred from the max of P_g. Given l_g and p_t, the pose at step t, the goal mask $\mathbf{M}_t$ is computed and passed into an RNN that outputs the action to execute.

Goal Prediction To predict the goal location, we generate a probability distribution P_g over a feature map $\mathbf{F}_0$ generated using convolutions from the initial panorama observation $\mathbf{I}_P$. Each element in the probability distribution P_g corresponds to an area in $\mathbf{I}_P$. Given the instruction $\bar{x}$ and panorama $\mathbf{I}_P$, we first generate their representations. From the panorama $\mathbf{I}_P$, we generate a feature map $\mathbf{F}_0 = [\text{CNN}_0(\mathbf{I}_P); \mathbf{F}^p]$, where CNN_0 is a two-layer convolutional neural network (CNN; LeCun et al., 1998) with rectified linear units (ReLU; Nair and Hinton, 2010) and $\mathbf{F}^p$ are positional embeddings.[2] The concatenation is along the channel dimension. The instruction $\bar{x} = \langle x_1, \cdots x_n \rangle$ is mapped to a sequence of hidden states $\mathbf{l}_i = \text{LSTM}_x(\psi_x(x_i), \mathbf{l}_{i-1})$, $i = 1, \ldots, n$ using a learned embedding function ψ_x and a long short-term memory (LSTM; Hochreiter and Schmidhuber, 1997) RNN LSTM_x. The instruction representation is $\bar{\mathbf{x}} = \mathbf{l}_n$.

We generate the probability distribution P_g over pixels in $\mathbf{F}_0$ using LINGUNET. The architecture of LINGUNET is inspired by the U-NET image generation method (Ronneberger et al., 2015), except that the reconstruction phase is conditioned on the natural language instruction. LINGUNET first applies m convolutional layers to generate a sequence of feature maps $\mathbf{F}_j = \text{CNN}_j(\mathbf{F}_{j-1})$, $j = 1 \ldots m$, where each CNN_j is a convolutional layer with leaky ReLU non-linearities (Maas et al., 2013) and instance normalization (Ulyanov et al., 2016). The instruction representation $\bar{\mathbf{x}}$ is split evenly into m vectors $\{\bar{\mathbf{x}}_j\}_{j=1}^{m}$, each is used to create a 1×1 kernel $\mathbf{K}_j = \text{AFFINE}_j(\bar{\mathbf{x}}_j)$, where each AFFINE_j is an affine transformation followed by normalizing and reshaping. For each $\mathbf{F}_j$, we apply a 2D 1×1 convolution using the text kernel $\mathbf{K}_j$ to generate a text-conditioned feature map $\mathbf{G}_j = \text{CONVOLVE}(\mathbf{K}_j, \mathbf{F}_j)$, where CONVOLVE convolves the kernel over the feature map. We then perform m deconvolutions to generate a sequence of feature maps $\mathbf{H}_m,\ldots,\mathbf{H}_1$:

$$\begin{aligned}\mathbf{H}_m &= \text{DECONV}_m(\text{DROPOUT}(\mathbf{G}_m))\\ \mathbf{H}_j &= \text{DECONV}_j([\mathbf{H}_{j+1}; \mathbf{G}_j])\ .\end{aligned}$$

DROPOUT is dropout regularization (Srivastava et al., 2014) and each DECONV_j is a deconvolution operation followed a leaky ReLU nonlinearity and instance norm.[3] Finally, we generate P_g by applying a softmax to $\mathbf{H}_1$ and an additional learned scalar bias term b_g to represent events where the goal is out of sight. For example, when the agent already stands in the goal position and therefore the panorama does not show it.

We use P_g to predict the goal position in the environment. We first select the goal pixel in $\mathbf{F}_0$ as the pixel corresponding to the highest probability element in P_g. We then identify the corresponding 3D location l_g in the environment using backward camera projection, which is computed given the

---

[2] We generate $\mathbf{F}^p$ by creating a channel for each deterministic observation used to create the panorama, and setting all the pixels corresponding to that observation location in the panorama to 1 and all others to 0. The number of observations depends on the agent's camera angle.

[3] DECONV_1 does deconvolution only.

camera parameters and p_1, the agent pose at the beginning of the execution.

Action Generation Given the predicted goal l_g, we generate actions using an RNN. At each time step t, given p_t, we generate the goal mask $\mathbf{M}_t$, which has the same shape as the observed image $\mathbf{I}_t$. The goal mask $\mathbf{M}_t$ has a value of 1 for each element that corresponds to the goal location l_g in $\mathbf{I}_t$. We do not distinguish between visible or occluded locations. All other elements are set to 0. We also maintain an out-of-sight flag o_t that is set to 1 if (a) l_g is not within the agent's view; or (b) the max scoring element in P_g corresponds to b_g, the term for events when the goal is not visible in $\mathbf{I}_P$. Otherwise, o_t is set to 0. We compute an action generation hidden state y_t with an RNN:

$$y_t = \mathrm{LSTM}_A\left(\textsc{Affine}_A([\textsc{Flat}(\mathbf{M}_t); o_t]), y_{t-1}\right) \quad ,$$

where $\textsc{Flat}$ flattens $\mathbf{M}_t$ into a vector, $\textsc{Affine}_A$ is a learned affine transformation with ReLU, and LSTM_A is an LSTM RNN. The previous hidden state y_{t-1} was computed when generating the previous action, and the RNN is extended gradually during execution. Finally, we compute a probability distribution over actions:

$$\begin{aligned} P(a_t \mid l_g, (\mathbf{I}_1, p_1), \ldots, (\mathbf{I}_t, p_t)) &= \\ \textsc{Softmax}(\textsc{Affine}_p([y_t; \psi_T(t)])) & \quad , \end{aligned}$$

where ψ_T is a learned embedding lookup table for the current time (Chaplot et al., 2018) and $\textsc{Affine}_p$ is a learned affine transformation.

Model Parameters The model parameters θ include the parameters of the convolutions CNN_0 and the components of $\textsc{LingUNet}$: CNN_j, $\textsc{Affine}_j$, and $\textsc{Deconv}_j$ for $j = 1, \ldots, m$. In addition we learn two affine transformations $\textsc{Affine}_A$ and $\textsc{Affine}_p$, two RNNs LSTM_x and LSTM_A, two embedding functions ψ_x and ψ_T, and the goal distribution bias term b_g. In our experiments (Section 7), all parameters are learned without external resources.

5 Learning

Our modeling decomposition enables us to choose different learning algorithms for the two parts. While reinforcement learning is commonly deployed for tasks that benefit from exploration (e.g., Peters and Schaal, 2008; Mnih et al., 2013), these methods require many samples due to their high sample complexity. However, when learning with natural language, only a relatively small number of samples is realistically available. This problem was addressed in prior work by learning in a contextual bandit setting (Misra et al., 2017) or mixing reinforcement and supervised learning (Xiong et al., 2018). Our decomposition uniquely offers to tease apart the language understanding problem and address it with supervised learning, which generally has lower sample complexity. For action generation though, where exploration can be autonomous, we use policy gradient in a contextual bandit setting (Misra et al., 2017).

We assume access to training data with N examples $\{(\bar{x}^{(i)}, s_1^{(i)}, s_g^{(i)})\}_{i=1}^N$, where $\bar{x}^{(i)}$ is an instruction, $s_1^{(i)}$ is a start state, and $s_g^{(i)}$ is the goal state. We train the goal prediction component by minimizing the cross-entropy of the predicted distribution with the gold-standard goal distribution. The gold-standard goal distribution is a deterministic distribution with probability one at the pixel corresponding to the goal location if the goal is in the field of view, or probability one at the extra out-of-sight position otherwise. The gold location is the agent's location in $s_g^{(i)}$. We update the model parameters using Adam (Kingma and Ba, 2014).

We train action generation by maximizing the expected immediate reward the agent observes while exploring the environment. The objective for a single example i and time stamp t is:

$$J = \sum_{a \in \mathcal{A}} \pi(a \mid \tilde{s}_t) R^{(i)}(s_t, a) + \lambda H(\pi(. \mid \tilde{s}_t)) \quad ,$$

where $R^{(i)} : \mathcal{S} \times \mathcal{A} \rightarrow \mathbb{R}$ is an example-specific reward function, $H(\cdot)$ is an entropy regularization term, and λ is the regularization coefficient. The reward function $R^{(i)}$ details are described in details in Appendix B. Roughly speaking, the reward function includes two additive components: a problem reward and a shaping term (Ng et al., 1999). The problem reward provides a positive reward for successful task completion, and a negative reward for incorrect completion or collision. The shaping term is positive when the agent gets closer to the goal position, and negative if it is moving away. The gradient of the objective is:

$$\begin{aligned} \nabla J &= \sum_{a \in \mathcal{A}} \pi(a \mid \tilde{s}_t) \nabla \log \pi(a \mid \tilde{s}_t) R(s_t, a) \\ &\quad + \lambda \nabla H(\pi(. \mid \tilde{s}_t) \quad . \end{aligned}$$

We approximate the gradient by sampling an action using the policy (Williams, 1992), and use the gold goal location computed from $s_g^{(i)}$. We perform several parallel rollouts to compute gradients and update the parameters using Hogwild! (Recht et al., 2011) and Adam learning rates.

Dataset Statistic	Lani	Chai
Number paragraphs	6,000	1,596
Mean instructions per paragraph	4.7	7.70
Mean actions per instruction	24.6	54.5
Mean tokens per instruction	12.1	8.4

Table 1: Summary statistics of the two corpora.

6 Tasks and Data

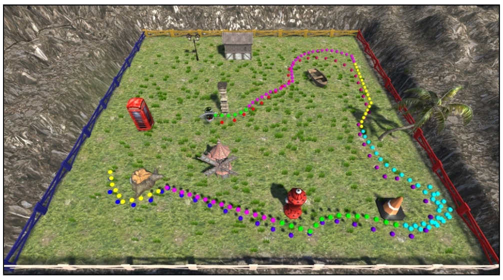
6.1 Lani

The goal of Lani is to evaluate how well an agent can follow navigation instructions. The agent task is to follow a sequence of instructions that specify a path in an environment with multiple landmarks. Figure 1 (left) shows an example instruction.

The environment is a fenced, square, grass field. Each instance of the environment contains between 6–13 randomly placed landmarks, sampled from 63 unique landmarks. The agent can take four types of discrete actions: `FORWARD`, `TURNRIGHT`, `TURNLEFT`, and `STOP`. The field is of size 50×50, the distance of the `FORWARD` action is 1.5, and the turn angle is 15°. The environment simulator is implemented in Unity3D. At each time step, the agent performs an action, observes a first person view of the environment as an RGB image, and receives a scalar reward. The simulator provides a socket API to control the agent and the environment.

Agent performance is evaluated using two metrics: task completion accuracy, and stop distance error. A task is completed correctly if the agent stops within an aerial distance of 5 from the goal.

We collect a corpus of navigation instructions using crowdsourcing. We randomly generate environments, and generate one reference path for each environment. To elicit linguistically interesting instructions, reference paths are generated to pass near landmarks. We use Amazon Mechanical Turk, and split the annotation process to two tasks. First, given an environment and a reference path, a worker writes an instruction paragraph for following the path. The second task requires another worker to control the agent to perform the instructions and simultaneously mark at each point what part of the instruction was executed. The recording of the second worker creates the final data of segmented instructions and demonstrations. The generated reference path is displayed in both tasks. The second worker could also mark the paragraph as invalid. Both tasks are done from an overhead view of the environment, but workers are instructed to provide instructions for a robot that observes the environment from a first person view. Figure 3 shows a reference path and the written instruction. This data can be used for evaluating both executing sequences of instructions and single instructions in isolation.



[*Go around the pillar on the right hand side*] [*and head towards the boat, circling around it clockwise.*] [*When you are facing the tree, walk towards it, and the pass on the right hand side,*] [*and the left hand side of the cone. Circle around the cone,*] [*and then walk past the hydrant on your right,*] [*and the the tree stump.*] [*Circle around the stump and then stop right behind it.*]

Figure 3: Segmented instructions in the Lani domain. The original reference path is marked in red (start) and blue (end). The agent, using a drone icon, is placed at the beginning of the path. The follower path is coded in colors to align to the segmented instruction paragraph.

Table 1 shows the corpus statistics.[4] Each paragraph corresponds to a single unique instance of the environment. The paragraphs are split into train, test, and development, with a 70% / 15% / 15% split. Finally, we sample 200 single development instructions for qualitative analysis of the language challenge the corpus presents (Table 2).

6.2 Chai

The Chai corpus combines both navigation and simple manipulation in a complex, simulated household environment. We use the Chalet simulator (Yan et al., 2018), a 3D house simulator that provides multiple houses, each with multiple rooms. The environment supports moving between rooms, picking and placing objects, and opening and closing cabinets and similar containers. Objects can be moved between rooms and in and out of containers. The agent observes the world in first-person view, and can take five actions: `FORWARD`, `TURNLEFT`, `TURNRIGHT`, `STOP`, and `INTERACT`. The `INTERACT` action acts on objects. It takes as argument a 2D position in the agent's view. Agent performance is evaluated with two metrics: (a) stop distance, which measures the distance of the agent's final state to the final annotated position; and (b) manipulation accuracy, which compares the set of manipulation actions

Table 2: Qualitative analysis of the LANI and CHAI corpora. We sample 200 single development instructions from each corpora. For each category, we count how many examples of the 200 contained it and show an example.

Scenario

You have several hours before guests begin to arrive for a dinner party. You are preparing a wide variety of meat dishes, and need to put them in the sink. In addition, you want to remove things in the kitchen, and bathroom which you don't want your guests seeing, like the soaps in the bathroom, and the dish cleaning items. You can put these in the cupboards. Finally, put the dirty dishes around the house in the dishwasher and close it.

Written Instructions

[*In the kitchen, open the cupboard above the sink.*] [*Put the cereal, the sponge, and the dishwashing soap into the cupboard above the sink.*] [*Close the cupboard.*] [*Pick up the meats and put them into the sink.*] [*Open the dishwasher, grab the dirty dishes on the counter, and put the dishes into the dishwasher.*]

Figure 4: Scenario and segmented instruction from the CHAI corpus.

to a reference set. When measuring distance, to consider the house plan, we compute the minimal aerial distance for each room that must be visited. Yan et al. (2018) provides the full details of the simulator and evaluation. We use five different houses, each with up to six rooms. Each room contains on average 30 objects. A typical room is of size 6×6. We set the distance of `FORWARD` to 0.1, the turn angle to 90°, and divide the agent's view to a 32×32 grid for the `INTERACT` action.

We collected a corpus of navigation and manipulation instructions using Amazon Mechanical Turk. We created 36 common household scenarios to provide a familiar context to the task.[5] We use two crowdsourcing tasks. First, we provide workers with a scenario and ask them to write instructions. The workers are encouraged to explore the environment and interact with it. We then segment the instructions to sentences automatically. In the second task, workers are presented with the segmented sentences in order and asked to execute them. After finishing a sentence, the workers request the next sentence. The workers do not see the original scenario. Figure 4 shows a scenario and the written segmented paragraph. Similar to LANI, CHAI data can be used for studying complete paragraphs and single instructions.

Table 1 shows the corpus statistics.[6] The paragraphs are split into train, test, and development, with a 70% / 15% / 15% split. Table 2 shows qualitative analysis of a sample of 200 instructions.

7 Experimental Setup

Method Adaptations for CHAI We apply two modifications to our model to support intermediate goal for the CHAI instructions. First, we train an additional RNN to predict the sequence of intermediate goals given the instruction only. There are two types of goals: `NAVIGATION`, for action sequences requiring movement only and ending with the `STOP` action; and `INTERACTION`, for sequence of movement actions that end with an `INTERACT` action. For example, for the instruction *pick up the red book and go to the kitchen*, the sequence of goals will be $\langle$`INTERACTION`, `NAVIGATION`, `NAVIGATION`$\rangle$. This indicates the agent must first move to the object to pick it up via interaction, move to the kitchen door, and finally move within the kitchen. The process of executing an instruction starts with predicting the sequence of goal types. We call our model (Section 4) separately for each goal type. The execution concludes when the final goal is completed. For learning, we create a separate example for each intermediate goal and train the additional RNN separately. The second modification is replacing the backward camera projection for inferring the goal location with ray casting to iden-

---

[5] We observed that asking workers to simply write instructions without providing a scenario leads to combinations of repetitive instructions unlikely to occur in reality.

[6] The number of actions per instruction is given in the more fine-grained action space used during collection. To make the required number of actions smaller, we use the more coarse action space specified.

Table 5: Development goal prediction performance. We measure distance (Dist) and accuracy (Acc).

tify `INTERACTION` goals, which are often objects that are not located on the ground.

Baselines We compare our approach against the following baselines: (a) Stop: Agent stops immediately; (b) RandomWalk: Agent samples actions uniformly until it exhausts the horizon or stops; (c) MostFrequent: Agent takes the most frequent action in the data, `FORWARD` for both datasets, until it exhausts the horizon; (d) Misra17: the approach of Misra et al. (2017); and (e) Chaplot18: the approach of Chaplot et al. (2018). We also evaluate goal prediction and compare to the method of Janner et al. (2018) and a Center baseline, which always predict the center pixel. Appendix C provides baseline details.

Evaluation Metrics We evaluate using the metrics described in Section 6: stop distance (SD) and task completion (TC) for Lani, and stop distance (SD) and manipulation accuracy (MA) for Chai. To evaluate the goal prediction, we report the real distance of the predicted goal from the annotated goal and the percentage of correct predictions. We consider a goal correct if it is within a distance of 5.0 for Lani and 1.0 for Chai. We also report human evaluation for Lani by asking raters if the generated path follows the instruction on a Likert-type scale of 1–5. Raters were shown the generated path, the reference path, and the instruction.

Parameters We use a horizon of 40 for both domains. During training, we allow additional 5 steps to encourage learning even after errors. When using intermediate goals in Chai, the horizon is used for each intermediate goal separately. All other parameters and detailed in Appendix D.

8 Results

Tables 3 and 4 show development and test results. Both sets of experiments demonstrate similar trends. The low performance of Stop, RandomWalk, and MostFrequent demonstrates the challenges of both tasks, and shows the tasks are robust to simple biases. On Lani, our approach outperforms Chaplot18, improving task completion (TC) accuracy by 5%, and both methods outperform Misra17. On Chai, Chaplot18 and Misra17 both fail to learn, while our approach shows an improvement on stop distance (SD). However, all models perform poorly on Chai, especially on manipulation (MA).

To isolate navigation performance on Chai, we limit our train and test data to instructions that include navigation actions only. The Stop baseline on these instructions gives a stop distance (SD) of 3.91, higher than the average for the entire data as these instructions require more movement. Our approach gives a stop distance (SD) of 3.24, a 17% reduction of error, significantly better than the 8% reduction of error over the entire corpus.

We also measure human performance on a sample of 100 development examples for both tasks. On Lani, we observe a stop distance error (SD) of 5.2 and successful task completion (TC) 63% of the time. On Chai, the human distance error (SD) is 1.34 and the manipulation accuracy is 100%. The imperfect performance demonstrates the inherent ambiguity of the tasks. The gap to human performance is still large though, demonstrating that both tasks are largely open problems.

The imperfect human performance raises questions about automated evaluation. In general, we observe that often measuring execution quality with rigid goals is insufficient. We conduct a human evaluation with 50 development examples from Lani rating human performance and our approach. Figure 5 shows a histogram of the ratings. The mean rating for human followers is 4.38, while our approach's is 3.78; we observe a similar trend to before with this metric. Using

Category	Present	Absent	p-value

judgements on our approach, we correlate the human metric with the SD measure. We observe a Pearson correlation -0.65 (p=5e-7), indicating that our automated metric correlates well with human judgment.[7] This initial study suggests that our automated evaluation is appropriate for this task.

Our ablations (Table 3) demonstrate the importance of each of the components of the model. We ablate the action generation RNN (w/o RNN), completely remove the language input (w/o Language), and train the model jointly (w/joint Learning).[8] On CHAI especially, ablations results in models that display ineffective behavior. Of the ablations, we observe the largest benefit from decomposing the learning and using supervised learning for the language problem.

We also evaluate our approach with access to oracle goals (Table 3). We observe this improves navigation performance significantly on both tasks. However, the model completely fails to learn a reasonable manipulation behavior for CHAI. This illustrates the planning complexity of this domain. A large part of the improvement in measured navigation behavior is likely due to eliminating much of the ambiguity the automated metric often fails to capture.

Finally, on goal prediction (Table 5), our approach outperforms the method of Janner et al. (2018). Figure 6 and Appendix Figure 7 show example goal predictions. In Table 6, we break down LANI goal prediction results for the analysis categories we used in Table 2 using the same sample of the data. Appendix E includes a similar table for CHAI. We observe that our approach finds instructions with temporal coordination or co-reference challenging. Co-reference is an expected limitation; with single instructions, the model can not resolve references to previous instructions.

9 Discussion

We propose a model for instruction following with explicit separation of goal prediction and action generation. Our representation of goal prediction is easily interpretable, while not requiring the design of logical ontologies and symbolic representations. A potential limitation of our approach is cascading errors. Action generation relies completely on the predicted goal and is not exposed to the language otherwise. This also suggests a second related limitation: the model is unlikely to successfully reason about instructions that include constraints on the execution itself. While the model may reach the final goal correctly, it is unlikely to account for the intermediate trajectory constraints. As we show (Table 2), such instructions are common in our data. These two limitations may be addressed by allowing action generation access to the instruction. Achieving this while retaining an interpretable goal representation that clearly determines the execution is an important direction for future work. Another important open question concerns automated evaluation, which remains especially challenging when instructions do not only specify goals, but also constraints on how to achieve them. Our resources provide the platform and data to conduct this research.

---

[7] We did not observe this kind of clear anti-correlation comparing the two results for human performance (Pearson correlation of 0.09 and p=0.52). The limited variance in human performance makes correlation harder to test.

[8] Appendix C provides the details of joint learning.

Deconvolutional Time Series Regression: A Technique for Modeling Temporally Diffuse Effects

`schuler.77@osu.edu`

Abstract

Researchers in computational psycholinguistics frequently use linear models to study time series data generated by human subjects. However, time series may violate the assumptions of these models through temporal diffusion, where stimulus presentation has a lingering influence on the response as the rest of the experiment unfolds. This paper proposes a new statistical model that borrows from digital signal processing by recasting the predictors and response as convolutionally-related signals, using recent advances in machine learning to fit latent impulse response functions (IRFs) of arbitrary shape. A synthetic experiment shows successful recovery of true latent IRFs, and psycholinguistic experiments reveal plausible, replicable, and fine-grained estimates of latent temporal dynamics, with comparable or improved prediction quality to widely-used alternatives.

1 Introduction

Time series are abundant in many naturally-occurring phenomena of interest to science, and they frequently violate the assumptions of linear modeling and its generalizations. One confound that may be widespread in psycholinguistic data is *temporal diffusion*: the dependent variable may evolve slowly in response to its inputs, with the result that a particular predictor observed at a particular time may continue to exert an influence on the response as the rest of the process unfolds. If not properly controlled for, such a confound could have a detrimental impact on parameter estimation, model interpretation, and hypothesis testing.

The problem of temporal diffusion remains largely unsolved in the general case.[1] A standard approach for handling the possibility of temporally diffuse relationships between the predictors and the response is to use spillover or lag regressors, where the observed predictor value is used to predict subsequent observations of the response (Erlich and Rayner, 1983). But this strategy has several undesirable properties. First, the choice of spillover position(s) for a given predictor is difficult to motivate empirically. Second, in experiments with variably long trials the use of relative event indices obscures potentially important details about the actual amount of time that passed between events. And third, including multiple spillover positions per predictor quickly leads to parametric explosion on realistically complex models over realistically sized data sets, especially if random effects structures are included.

As a solution to the problem of temporal diffusion, this paper proposes deconvolutional time series regression (DTSR), a technique that directly models diffusion by learning parametric *impulse response functions* (IRFs) of the predictors that mediate their relationship to the response variable over time. Parametric deconvolution is difficult in the general case because the likelihood surface depends on the choice IRF kernel, requiring the user to re-derive estimators for each unique model structure. Furthermore, arbitrary IRF kernels are not guaranteed to afford analytical estimator functions or unique real-valued solutions. However, recent advances in machine learning have led to libraries like Tensorflow (Abadi et al., 2015) — which uses auto-differentiation to support optimization of arbitrary computation graphs — and Edward (Tran et al., 2016) — which enables black box variational inference (BBVI) on Tensorflow graphs. While these libraries are typically used to build and train deep networks, DTSR uses them

---

[1] Although recent work in computational psycholinguistics has begun to address separate but related problems in time series modeling (auto-correlation and non-stationarity) using generalized additive models (GAM) with a particular structure (Baayen et al., 2017, 2018).

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2679–2689
Brussels, Belgium, October 31 - November 4, 2018.

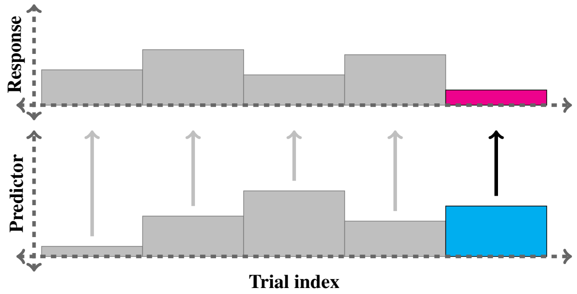

Figure 1: Effects in a linear time series model

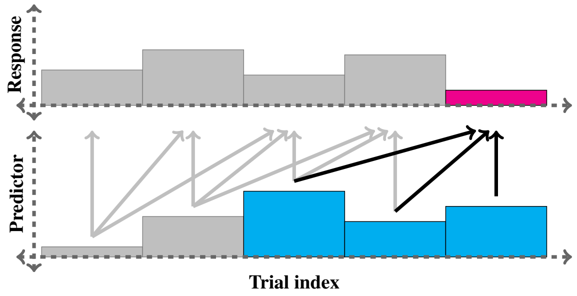

Figure 2: Linear time series model with spillover

to overcome the aforementioned difficulties with general-purpose temporal deconvolution by eliminating the need for hand-derivation of estimators and sampling distributions for each model.

The IRFs learned by DTSR are interpretable as estimates of the temporal shape of predictors' influence on the response variable. By convolving predictors with their IRFs, DTSR is able to consider arbitrarily long histories of independent variable observations in generating a given prediction, and (in contrast to spillover) model complexity is constant on the length of the history window. DTSR is thus a parsimonious technique for directly measuring temporal diffusion.

Figures 1–3 illustrate the present proposal and how it differs from linear time series models. As shown in Figure 1, a standard linear model assumes conditional independence of the response from all preceding observations of the predictor. This independence assumption can be weakened by including additional spillover predictors (Figure 2), at a cost of requiring additional parameters. In both cases, only the relative order of events is considered, not their actual distance in time. By contrast, DTSR recasts the predictor and response vectors as streams of impulses and responses (respectively) localized in time. It then fits latent IRFs that govern the influence of each predictor value on the response as a function of time (Figure 3).

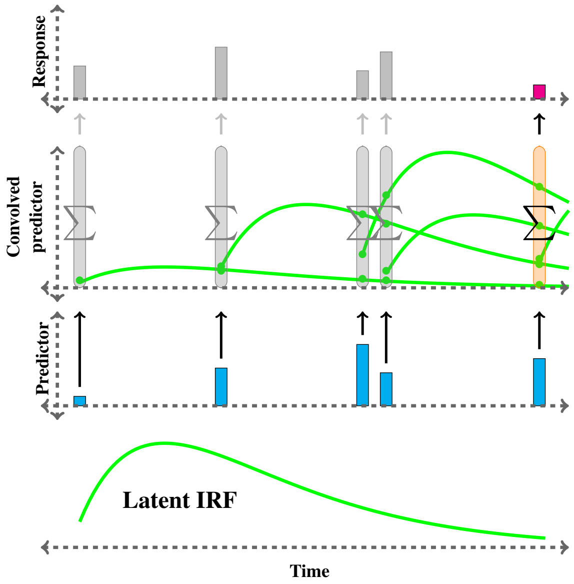

Figure 3: Effects of predictors in DTSR

This paper presents evidence that DTSR can (1) recover known underlying IRFs from synthetic data, (2) discover previously unknown temporal structure in human data (psycholinguistic reading time experiments), (3) provide support for the *absence* of temporal diffusion in settings where it might exist in principle, and (4) provide comparable (or in some cases improved) prediction quality to standard linear mixed-effects (LME) and generalized additive (GAM) models.

2 Related work

2.1 Non-deconvolutional time series modeling

The two most widely used tools for analyzing psycholinguistic time series are linear mixed effects regression (LME) (Bates et al., 2015) and generalized additive models (GAM) (Hastie and Tibshirani, 1986; Wood, 2006). LME learns a linear combination of the predictors that generates a given response variable. GAM generalizes linear models by allowing the response variable to be computed as the sum of smooth functions of one or more predictors.

In both approaches, responses are modeled as conditionally independent of preceding observations of predictors unless spillover terms are added, with the attendant drawbacks discussed in Section 1. To make this point more forcefully, take for example Shain et al. (2016), who find significant effects of constituent wrap-up ($p = 2.33\text{e-}14$) and dependency locality ($p = 4.87\text{e-}10$) in the

Natural Stories self-paced reading corpus (Futrell et al., 2018). They argue that this constitutes the first strong evidence of memory effects in broad-coverage sentence processing. However, it turns out that when one baseline predictor — probabilistic context free grammar (PCFG) surprisal — is spilled over one position, the reported effects disappear: p = 0.816 for constituent wrap-up and p = 0.370 for dependency locality. Thus, a reasonable but ultimately inaccurate assumption about baseline effect timecourses can have a dramatic impact on the conclusions supported by the statistical model. DTSR offers a way forward by bringing temporal diffusion under direct statistical control.

2.2 Deconvolutional time series modeling

Deconvolutional modeling has long been used in a variety of scientific fields, including economics (Ramey, 2016), epidemiology (Goldstein et al., 2011), and neuroimaging (Friston et al., 1998). Non-parametric deconvolutional models quantize the time series and fit estimates for each time point within some window, similarly to the spillover approach discussed above. These estimates can be unconstrained, as in finite impulse response models (FIR) (H. Glover, 1999; Ward, 2006), or smoothed with some form of regularization (Goutte et al., 2000; Pedregosa et al., 2014). Additional post-hoc interpolation is necessary in order to obtain a closed-form continuous IRF. These non-parametric approaches are prone to parametric explosion as well as sparsity problems when trials are variably spaced in time.

Parametric deconvolutional approaches (i.e. specific instantiations of DTSR) have evolved in certain fields (e.g. fMRI modeling) to solve particular problems, generally with some independently-motivated IRF kernel like the hemodynamic response function (HRF) (Friston et al., 1998; Lindquist and Wager, 2007; Lindquist et al., 2009). However, to our knowledge DTSR constitutes the first mathematical formulation and software implementation of general-purpose mixed effects parametric deconvolutional regression for arbitrary impulse response kernels. DTSR also supports Bayesian inference, enabling quantification of uncertainty in the absence of analytic formulae for standard errors. With these properties, DTSR expands the range of possible applications of parametric deconvolution beyond those fields for which appropriate formulations have already been developed.

3 Model definition

This section presents the mathematical definition of DTSR. For readability, only a fixed effects model is presented below, since mixed modeling substantially complicates the equations. The full model definition is provided in Appendix A. Note that the full definition is used to construct all reading time models reported in subsequent sections, since they contain random effects.

Let $\mathbf{X} \in \mathbb{R}^{M \times K}$ be a design matrix of M observations for K predictor variables and $\mathbf{y} \in \mathbb{R}^N$ be a vector of N responses, both of which contain contiguous temporally-sorted time series. DTSR models the relationship between $\mathbf{X}$ and $\mathbf{y}$ using parameters consisting of:

- a scalar intercept $\mu \in \mathbb{R}$
- a vector $\mathbf{u} \in \mathbb{R}^K$ of K coefficients
- a matrix $\mathbf{A} \in \mathbb{R}^{R \times K}$ of R IRF kernel parameters for K fixed impulse vectors
- a scalar variance $\sigma^2 \in \mathbb{R}$ of the response

To define the convolution step, let g_k for $k \in \{1, 2, \ldots, K\}$ be a set of parametric IRF kernels, one for each predictor; let $\mathbf{a} \in \mathbb{R}^M$ and $\mathbf{b} \in \mathbb{R}^N$ be vectors of timestamps associated with each observation in $\mathbf{X}$ and $\mathbf{y}$, respectively; and let $\mathbf{c} \in \mathbb{N}^M$ and $\mathbf{d} \in \mathbb{N}^N$ be vectors of series ID's associated with each observation in $\mathbf{X}$ and $\mathbf{y}$, respectively. A filter $\mathbf{F} \in \mathbb{R}^{N \times M}$ admits only those observations in $\mathbf{X}$ that precede $\mathbf{y}_{[n]}$ in the same time series:

$$\mathbf{F}_{[n,m]} \overset{\text{def}}{=} \begin{cases} 1 & \mathbf{c}_{[m]} = \mathbf{d}_{[n]} \wedge \mathbf{a}_{[m]} \leq \mathbf{b}_{[n]} \\ 0 & \text{otherwise} \end{cases} \tag{1}$$

The inputs $\mathbf{X}$ can be convolved with each IRF g_k by premultiplication with sparse matrix $\mathbf{G}_k \in \mathbb{R}^{N \times M}$ for $k \in \{1, 2, ..., K\}$ as defined below:

$$\mathbf{G}_k = g_k \left(\mathbf{b}\mathbf{1}^\top - \mathbf{1}\mathbf{a}^\top ; \mathbf{A}_{[*,k]} \right) \odot \mathbf{F} \tag{2}$$

The convolution that yields the design matrix of convolved predictors $\mathbf{X}' \in \mathbb{R}^{N \times K}$ is then defined using products of the $\mathbf{G}$ matrices and the design matrix $\mathbf{X}$:[2]

$$\mathbf{X}'_{[*,k]} \overset{\text{def}}{=} \mathbf{G}_k \, \mathbf{X}_{[*,k]} \tag{3}$$

---

[2] This implementation of convolution is only exact when the predictors fully describe a discrete impulse signal. Exact convolution of samples from continuous signals is generally not possible because the signal is generally not analytically integrable. For continuous signals, DTSR can approximate the convolution as long as the predictor is interpolated between sample points at a fixed frequency prior to fitting.

Following convolution, DTSR is simply a linear model. The full model mean is the sum of (1) the intercept μ and (2) the product of the convolved predictor matrix $\mathbf{X}'$ and the coefficient vector $\mathbf{u}$:

$$\mathbf{y} \sim \mathcal{N}\left(\mu + \mathbf{X}'\mathbf{u}, \sigma^2\right) \tag{4}$$

4 Implementation

The present implementation defines the aforementioned equations[3] as a Bayesian computation graph in Tensorflow and Edward and trains it with black box variation inference (BBVI) using the Nadam optimizer (Dozat, 2016)[4] with a constant learning rate of 0.01 and minibatches of size 1024. For computational efficiency, histories are truncated at 128 timesteps. Prediction from the network uses an exponential moving average of parameter iterates with a decay rate of 0.998. Convergence was visually diagnosed.

The present experiments use a ShiftedGamma IRF kernel:

$$f(x;\alpha,\beta,\delta) = \frac{\beta^{\alpha}(x-\delta)^{\alpha-1}e^{-\beta(x-\delta)}}{\Gamma(\alpha)} \tag{5}$$

This is simply the PDF of the Gamma distribution augmented with a shift parameter δ allowing the lower bound of the support of the distribution to deviate from 0. We constrain δ to be strictly negative, thereby allowing the model to find a non-zero instantaneous response. We also constrain k to be strictly greater than 1, which deconfounds the shape and shift parameters. All bounded variables are constrained using the softplus bijection:

$$\text{softplus}(x) = \log(e^x + 1) \tag{6}$$

The ShiftedGamma kernel is used here because it can fit a wide range of response shapes and has precedent in the fMRI literature, where HRF kernels are often assumed to be Gamma-shaped (Lindquist et al., 2009).[5]

All parameters are given normal priors with unit variance. Prior means for the fixed IRF kernel parameters are domain-specific and discussed in the experiments sections below. To center the prior at an intercept-only model,[6] prior means for the intercept μ and variance σ^2 are set (respectively) to the empirical mean and variance of the response, and prior means for both fixed coefficients and random effects[7] are set to 0. Although the Bayesian implementation of DTSR is used for this study because it provides quantification of uncertainty, placing priors on the IRF kernel parameters is not crucial to the success of the system. In all experiments reported below, the MLE implementation arrives at similar solutions and achieves slightly better error.

In the interests of enabling the use of DTSR by the scientific community, the implementation of DTSR used here is offered as a documented open-source Python package with support for (1) Bayesian, variational Bayesian, and MLE inferences and (2) a variety model structures and impulse response kernels. The Tensorflow backend also enables GPU acceleration where available. Source code and links to documentation are available at `https://github.com/coryshain/dtsr`.

5 Experiment 1: Synthetic data

An initial experiment fits DTSR estimates to synthetic data to determine whether the model can recover known ground truth IRFs. Synthetic data were synthesized using the following procedure. First, 20 input vectors of size 10,000 were drawn from a standard normal distribution. These values synthesize an impulse stream containing 20 covariates, each with 10,000 observations. A ShiftedGamma IRF was then drawn for each of the 20 covariates. Coefficients were drawn from a uniform distribution $\mathcal{U}(-50, 50)$, and IRF parameters were drawn from the following distributions: $\alpha \sim \mathcal{U}(1, 6)$, $\beta \sim \mathcal{U}(0, 5)$, $\delta \sim \mathcal{U}(-1, 0)$. The prior means for the corresponding IRF kernel parameters are placed at the centers of these ranges. The stream of responses was generated by convolving the covariates with their corresponding IRFs. Gaussian noise with standard deviation 20 was injected into the response following generation. The 10,000 trials were spaced 100ms apart. As shown in Figure 4, the DTSR estimates for the

---

[3] As noted above, for expository purposes the definition in Section 3 only supports fixed-effects models. The full definition for mixed-effects DTSR models is provided in Appendix A. Mixed models are used throughout the experiments reported below.

[4] The Adam optimizer (Kingma and Ba, 2014) with Nesterov momentum (Nesterov, 1983)

[5] Other IRF kernels, including spline functions and composition of convolutions, are supported by the current implementation of DTSR but are not explored in these experiments. More details are provided in the software documentation.

[6] A model in which the response is insensitive to the model structure.

[7] See Appendix A for the definition of the mixed-effects DTSR model, which includes random effects.

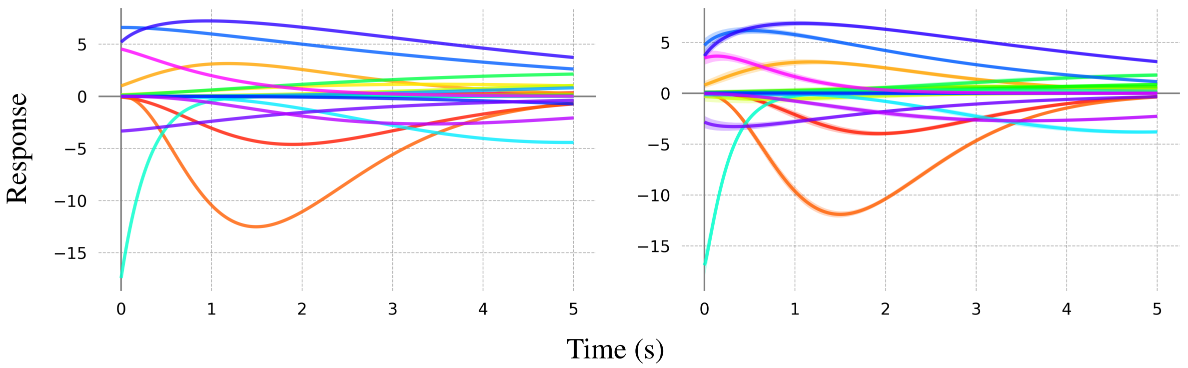

Figure 4: *Synthetic data*. True IRFs (left) and estimated IRFs with 95% credible intervals (right).

synthetic data are very similar to the ground truth, confirming that when the data-generating model matches the assumptions of DTSR, DTSR can recover its latent structure with high fidelity.

6 Experiment 2: Human reading times

6.1 Background and experimental design

The main interest of DTSR is the potential to better understand real-world dynamical systems like the human sentence processing response. Therefore, Experiment 2 applies DTSR to three existing datasets of naturalistic reading: Natural Stories (Futrell et al., 2018), Dundee (Kennedy et al., 2003), and UCL (Frank et al., 2013).

Natural Stories is a self-paced reading (SPR) corpus consisting of narratives designed to provide context-rich, fluent-sounding stimuli that nonetheless contain many grammatical constructions that rarely occur naturally in texts. The public release of the corpus contains data collected from 181 subjects. The stimulus set contains 10 stories with a total of 485 sentences and 10,245 tokens, for a total 848,768 fixation events.

Dundee is an eye-tracking (ET) corpus containing newspaper editorials read by 10 subjects, with incremental eye fixation data recorded during reading. The stimulus set contains 20 editorials with a total of 2,368 sentences and 51,502 tokens, for a total of 260,065 fixation events.

UCL is a reading corpus containing individual sentences that were extracted from novels written by amateur authors. The sentences were shuffled and presented in isolation to 42 subjects. The eye-tracking portion of the UCL corpus used in these experiments contains 205 sentences with a total of 1,931 tokens, for a total of 53,070 fixation events.

In all experiments, the response variable is log fixation duration (go-past duration for ET). Models use the following set of predictor variables in common use in psycholinguistics: *Sentence position* (index of word in sentence), *Trial* (index of trial in series),[8] *Saccade Length* (in words, ET only), *Word Length* (in characters), *Unigram Logprob*, and *5-gram Surprisal*. *Unigram Logprob* and *5-gram Surprisal* are computed by the KenLM toolkit (Heafield et al., 2013) trained on Gigaword 4 (Parker et al., 2009). In addition, DTSR enables fitting of a *Rate* predictor, which is simply a vector of ones, one for each observation, that is convolved using a latent IRF. *Rate* thus measures the response to density of stimulus presentation in the recent past. Since without deconvolution *Rate* is identical to the intercept, it is excluded from non-deconvolutional baseline models. Following standard practice in psycholinguistics, by-subject random coefficients for each of these predictors are included in all models (baseline and DTSR).[9]

ShiftedGamma IRFs are fitted to all predictors except *Sentence Position*, which is assigned a Dirac delta IRF (i.e. a linear coefficient) since it increases linearly within the sentence and is not expected to have a diffuse response. In plots, the *Sentence Position* estimate is shown as a stick function at time 0s. Prior means used for the IRF kernel parameters are $\alpha = 2$, $\beta = 5$, and $\delta = -0.5$. Together, these priors define an expected exponential-like IRF which decays to near-zero in about 1s, which seems plausible for human reading times. In practice they do not appear to be very constraining, since posterior means of fitted

---

[8] Except UCL, which contains isolated sentences, in which case *Trial* is identical to *Sentence Position*.

[9] By-subject IRF parameters were not used for this study because they substantially complicate the model and initial experiments using them showed little benefit on training data.

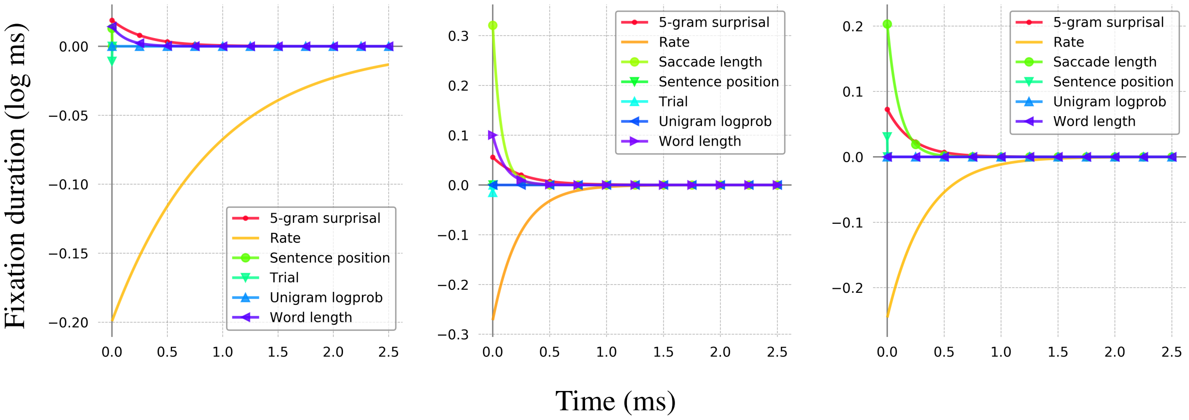

Figure 5: *Human data.* Estimated IRFs with 95% credible intervals for Natural Stories (left), Dundee (center) and UCL (right). Intervals are too tight to be seen.

models often deviate quite far from these values.

Existing work provides some expectations about the relationships of these variables to reading time. Processing difficulty is expected to increase with *Saccade Length*, *Word Length*, and *5-gram Surprisal*, and positive linear relationships have been shown experimentally (Demberg and Keller, 2008). *Unigram Logprob* is expected to be negatively correlated with reading times, since more frequent words are expected to be easier to process. *Sentence Position*, *Trial*, and *Rate* index different kinds of change in the response over time and their relationship has not been carefully studied, in part for lack of deconvolutional regression tools. Although reading times tend to decrease over the course of the experiment (Baayen et al., 2018), suggesting an expected negative effect of *Trial*, this may be partially explained by temporal diffusion. For the present study, all predictors are rescaled by their standard deviations.[10]

In all reading experiments, data are partitioned into training (50%), development (25%) and test (25%) sets. Outlier filtering is also performed. For Natural Stories, following Shain et al. (2016), items are excluded if they have fixations shorter than 100ms or longer than 3000ms, if they start or end a sentence, or if subjects missed 4 or more subsequent comprehension questions. For Dundee, following van Schijndel and Schuler (2015), unfixated items are excluded as well as (1) items following saccades longer than 4 words and (2) starts and ends of sentences, screens, documents, and lines. For UCL, unfixated items are excluded as well as (1) items following saccades longer than 4 words and (2) sentence starts and ends. Partitioning and filtering are applied only to the response series. The entire predictor history remains visible to the model.

From a modeling perspective, the primary results of interest in Experiment 2 are the IRFs themselves and the insights they provide into human sentence processing. However, to check the reliability of the DTSR estimates, prediction quality on unseen data is compared to that of non-deconvolutional baseline models fitted with LME and GAM.[11] Both baselines are fitted with and without three preceding spillover positions for each predictor (baselines with spillover are designated throughout this paper with the suffix -*S*).[12]

6.2 Results

The fitted IRFs for Natural Stories, Dundee, and UCL are shown in Figure 5. Effect sizes by corpus — computed here as the integral of each IRF over the first 10s — are shown in Table 1, along with

---

[10] Except *Rate*, which has no variance and therefore cannot be scaled by its standard deviation of 0.

[11] Formulae used to construct each model reported in this study are available in the associated code repository.

[12] This number of spillover positions is among the largest attested in the psycholinguistic literature because model complexity in LME and GAM increases substantially with each spillover position added, especially when by-subject random slopes are included for each spillover position for each variable. Indeed, many of the baseline models run for these experiments are already at the limits of tractability, as shown by the non-convergence reported in certain cells of Table 2. An advantage of the DTSR approach is that it can consider arbitrarily long histories at no cost to model complexity. While this permits DTSR to consider longer histories than its competitors (in these experiments, 128 timepoints vs. 4), DTSR is more constrained in its use of history since it must apply the same set of IRFs to all datapoints, while the baselines essentially fit separate models for each spillover position.

Table 1: Effect sizes by corpus with 95% credible intervals based on 1024 posterior samples

95% credible intervals (CI). The IRFs (curves) in these plots represent the expected change in the response over time from observing a unit impulse of the predictor. For example, the Dundee model estimates that observing a standard deviation of *5-gram surprisal* engenders a slowdown of about 0.05 log ms instantaneously and a slowdown of about 0.03 log ms 250 ms after stimulus presentation. Because the response is reading time, positive IRFs represent inhibition and negative IRFs represent facilitation. Detailed interpretation of these curves is provided below in Section 6.3.

Table 2 shows prediction error from DTSR vs. baselines fitted to the same feature set. As shown, DTSR provides comparable or improved prediction performance to the baselines, even against the *-S* models which are more heavily parameterized. DTSR outperforms LME models on unseen data across all corpora and generally improves upon or closely matches the performance of GAM (with no spillover). Compared to GAM-S (with three additional spillover positions), there is a clear advantage of DTSR for Natural Stories but not for the eye-tracking (ET) datasets. This is likely due to more pronounced temporal confounds in Natural Stories (especially of *Rate*, which the baseline models cannot estimate) compared to the other corpora.[13] However, even in the absence of sufficiently diffuse effects to afford prediction improvements, the ability to measure diffusion directly is a major advantage of the DTSR model, since it can be used to detect the *absence* of diffusion in settings where it might in principle exist. Further discussion of the DTSR IRF estimates themselves is provided in Section 6.3.

As shown in Table 3, pooling across corpora, permutation testing reveals a significant improvement in MSE on test data of DTSR over each baseline system ($p = 0.0001$ for all comparisons).[14]

6.3 Discussion

Some key generalizations emerge from the DTSR estimates shown in Figure 5. The first is the pronounced facilitative role of *Rate* in all three models, but especially in Natural Stories. This means that fast reading in the recent past engenders fast reading in the present, because (1) observing a stimulus exerts a large-magnitude, diffuse, and negative (facilitative) influence on the subsequent response, and (2) the *Rate* contributions of the stimuli are additive. This result demonstrates an important pre-linguistic influence of *inertia* — a tendency toward slow overall change in base response rate. This effect is especially large-magnitude and diffuse in Natural Stories, which is self-paced reading and therefore differs in modality from the other datasets (which are eye-tracking). This suggests that SPR participants strongly habituate to repeated button pressing and stresses the importance of deconvolutional regression for bringing this low-level confound under control in analyzing SPR data, since it appears to have a large influence on the response and might otherwise confound model interpretation.

Second, effects are generally consistent with expectations: positive effects for *Saccade Length*, *Word Length*, and *5-gram Surprisal*, and a negative effect of *Trial*. The null influence of *Unigram Logprob* is likely due to the presence in the model of both *5-gram Surprisal* (which interpolates unigram probabilities) and *Word Length* (which is inversely correlated with *Unigram Logprob*). The biggest departure from prior expectations is the null estimate for *Word Length* in UCL. It appears

---

[13] Note that GAM-S is more heavily parameterized than DTSR in that it fits multidimensional spline functions of each spillover position of each predictor. This makes it difficult to generalize information about effect timecourses from GAM fits, motivating the use of DTSR for studies in which timecourses are a quantity of interest.

[14] To ensure comparability across corpora with different error variances, per-datum errors were first scaled by their standard deviations within each corpus. Standard deviations were computed over the joint set of error values in each pair of DTSR and baseline models.

GAM-S	0.051	0.0001***

Table 3: Overall pairwise significance of prediction improvement from DTSR vs. baselines

that the contribution of *Word Length* in this corpus can be effectively explained by other variables.

Third, the response estimates for Dundee and UCL (both of which are eye-tracking) are very similar, which suggests that DTSR is discovering replicable population-level features of the temporal profile for eye-tracking data.

Fourth, there is a general asymmetry in degree of diffusion between low-level perceptual-motor variables like *Saccade Length* and *Word Length*, whose responses tend to decay quickly, and the high-level *5-gram Surprisal* variable, whose response tends to decay more slowly. This is consistent with expectations from the sentence processing literature. Perceptual-motor variables involve rapid bottom-up computation (e.g. visual processing or motor planning/execution) and are therefore not expected to have a diffuse response, while surprisal involves top-down computation of future words given context, which might be more computationally expensive and therefore engender a slower response. While this outcome is suggested e.g. by the aforementioned finding that spillover 1 winds up being a stronger position for a surprisal predictor in the Shain et al. (2016) models, DTSR permits direct investigation of these dynamics.

7 A note on hypothesis testing

As a Bayesian model, DTSR supports hypothesis testing by querying the variational posterior. For example, as shown in Table 1, the credible interval (CI) for *5-gram Surprisal* in Natural Stories does not include zero (rejecting the null hypothesis of no effect), while the CI for *Unigram logprob* does (failing to reject). To control for effects of multicolinearity, one could perform ablative tests of fitted null and alternative models using (1) likelihood comparison or (2) predictive performance on unseen data.

However, DTSR estimates are obtained through non-convex stochastic optimization, which complicates hypothesis testing because of possible *estimation noise* due to (1) convergence to a local but not global optimum, (2) imperfect convergence to the local optimum, and/or (3) Monte Carlo estimation of the test statistic via posterior sampling. It cannot therefore be guaranteed that hypothesis testing results are due to differences in model structure rather than differences in relative amounts of estimation noise introduced by the fitting procedure. Thus, p-values (and, consequently, hypothesis tests) based on direct comparison of DTSR models should be considered approximate.

However, even in situations where such uncertainty in hypothesis testing is not acceptable, DTSR is appropriate for certain important use cases. First, DTSR can be used for *exploratory data analysis* in order to empirically motivate the spillover structure of the linear model. Spillover variables can be excluded or included based on the degree of temporal diffusion revealed by DTSR, permitting construction of linear models that are both parsimonious and effective for controlling temporal diffusion. Second, DTSR can be used to fit a *data transform* which is then applied to the data prior to statistical analysis. This approach is identical in spirit to e.g. the use of the canonical HRF to convolve predictors in fMRI models prior to linear regression. However, since DTSR is domain-general, it can be a valuable component in any analysis toolchain for time series.

8 Conclusion

This paper presented a variational Bayesian deconvolutional time series regression method as a solution to the problem of temporal diffusion in psycholinguistic time series data and applied it to both synthetic and human responses in order to better understand and control for latent temporal dynamics. Results showed that DTSR can yield a plausible, replicable, parsimonious, insightful, and predictive model of a complex dynamical system like the human sentence processing response and therefore support the use of DTSR for psycholinguistic time series modeling. While the present study explored the use of DTSR to understand human reading times, DTSR can in principle also be used to deconvolve other kinds of response variables, such as the HRF in fMRI modeling or the power/coherence response in oscillatory measures like electroencephalography, suggesting a rich array of potential applications of DTSR in computational psycholinguistics.

A Definition of mixed effects DTSR

For expository purposes, in Section 3 the DTSR model was defined only for fixed effects. However, DTSR is compatible with mixed modeling and the implementation used here supports random effects in the model intercepts, coefficients, and IRF parameters. The full mixed-effects DTSR equations are presented below.

The definitions of $\mathbf{X}$, $\mathbf{y}$, μ, σ^2, $\mathbf{a}$, $\mathbf{b}$, $\mathbf{c}$, $\mathbf{d}$, $\mathbf{F}$, M, N, K, and R presented in Section 3 are retained for the mixed model definition. The remaining variables and equations must be redefined to some extent. Mixed-effects DTSR models additionally contain the following parameters:

- a vector $\mathbf{o} \in \mathbb{R}^O$ of O random intercepts
- a vector $\mathbf{u} \in \mathbb{R}^U$ of U fixed coefficients
- a vector $\mathbf{v} \in \mathbb{R}^V$ of V random coefficients
- a matrix $\mathbf{A} \in \mathbb{R}^{R\times L}$ of R fixed IRF kernel parameters for L fixed impulse vectors
- a matrix $\mathbf{B} \in \mathbb{R}^{R\times W}$ of R random IRF kernel parameters for W random impulse vectors

Random parameters $\mathbf{o}$, $\mathbf{v}$, and $\mathbf{B}$ are constrained to be zero-centered within each random grouping factor.

To support mixed modeling, the fixed and random effects must first be combined using additional utility matrices. Let $\mathbf{O} \in \{0,1\}^{N\times O}$ be a mask matrix for random intercepts. A vector $\mathbf{q} \in \mathbb{R}^N$ of intercepts is:

$$\mathbf{q} \overset{\text{def}}{=} \mu + \mathbf{O}\,\mathbf{o} \tag{7}$$

Let $\mathbf{U} \in \{0,1\}^{L\times U}$ be an indicator matrix for fixed coefficients, $\mathbf{V} \in \{0,1\}^{L\times V}$ be an indicator matrix for random coefficients, and $\mathbf{V}' \in \{0,1\}^{N\times V}$ be a mask matrix for random coefficients. A matrix $\mathbf{Q} \in \mathbb{R}^{N\times L}$ of coefficients is:

$$\mathbf{Q} \overset{\text{def}}{=} \mathbf{1}\,(\mathbf{U}\,\mathbf{u})^\top + \mathbf{V}'\,\mathrm{diag}(\mathbf{v})\,\mathbf{V}^\top \tag{8}$$

Let $\mathbf{W} \in \{0,1\}^{L\times W}$ be an indicator matrix for random IRF parameters and $\mathbf{W}'_1, \dots, \mathbf{W}'_n \in \{0,1\}^{R\times W}$ be mask matrices for random IRF parameters. Then matrices $\mathbf{P}_n \in \mathbb{R}^{R\times L}$ for $n \in \{1,2,\dots,N\}$ are:

$$\mathbf{P}_n \overset{\text{def}}{=} \mathbf{A} + (\mathbf{W}'_n \odot \mathbf{B})\,\mathbf{W}^\top \tag{9}$$

In each equation above, the random effects parameters are masked using the random effects filter associated with each data point. $\mathbf{Q}$ and $\mathbf{P}_n$ are then transformed into the impulse vector space using the indicator matrices $\mathbf{V}$ and $\mathbf{W}$, respectively. This procedure sums the random effects associated with each data point and adds them to the population-level parameters.

To define the convolution step, let g_l for $l \in \{1,2,\dots,L\}$ be parametric IRF kernels, one for each impulse. Convolution of $\mathbf{X}$ with each IRF kernel is performed by premultiplying the inputs

$\mathbf{X}$ with sparse matrix $\mathbf{G}_l \in \mathbb{R}^{N \times M}$ for $l \in \{1, 2, ..., L\}$:

$$(\mathbf{G}_l)_{[n,*]} \stackrel{\text{def}}{=} g_l \left(\mathbf{b}_{[n]} - \mathbf{a}^\top ; (\mathbf{P}_n)_{[*,l]} \right) \odot \mathbf{F}_{[n,*]} \tag{10}$$

Finally, let $\mathbf{L} \in \{0, 1\}^{K \times L}$ be an indicator matrix mapping the K predictors of $\mathbf{X}$ to the corresponding L impulse vectors of the model.[15] The convolution that yields the design matrix of convolved predictors $\mathbf{X}' \in \mathbb{R}^{N \times L}$ is then defined using a product of the convolution matrices $\mathbf{G}$, the design matrix $\mathbf{X}$, and the impulse indicator $\mathbf{L}$:

$$\mathbf{X}'_{[*,l]} \stackrel{\text{def}}{=} \mathbf{G}_l \, \mathbf{X} \, \mathbf{L}_{[*,l]} \tag{11}$$

The full model mean is the sum of (1) the intercepts and (2) the sum-product of the convolved predictors $\mathbf{X}'$ with the coefficient parameters $\mathbf{Q}$:

$$\mathbf{y} \sim \mathcal{N} \left(\mathbf{q} + (\mathbf{X}' \odot \mathbf{Q}) \, \mathbf{1}, \sigma^2 \right) \tag{12}$$

---

[15] Predictors and impulse vectors are distinguished because in principle multiple IRFs can be applied to the same predictor. In the usual case where this distinction is not needed, $\mathbf{L}$ is identity and $K = L$.

Abstract

In this paper, we present a crowdsourcing-based approach to model the human perception of sentence complexity. We collect a large corpus of sentences rated with judgments of complexity for two typologically-different languages, Italian and English. We test our approach in two experimental scenarios aimed to investigate the contribution of a wide set of lexical, morpho-syntactic and syntactic phenomena in predicting i) the degree of agreement among annotators independently from the assigned judgment and ii) the perception of sentence complexity.

1 Introduction

Linguistic complexity is a well-studied and multifaceted notion for which several measures have been proposed in different frameworks ranging from First and Second Language Acquisition, language typology and readability assessment. Such measures depend on the perspective from which linguistic complexity is considered. According to one established distinction, linguistic complexity should be divided into an *absolute* vs a *relative* notion (Miestamo, 2008). While the former is driven by theory and aims at assessing the complexity of a language according to some formal properties of the linguistic system, the latter defines complexity in relation to the language user (e.g. speaker, listener or learner) thus considering complexity in terms of processing difficulty. From this second perspective, sentence complexity is analyzed in terms of cognitive load, which can be inferred using both off-line (e.g. complexity judgments, error rates on comprehension test, preference for a structure over a meaning-equivalent one in elicited production tasks) and online processing measures (e.g. eye-tracking data such as total gaze time, fixation duration and pupil dilation). To operationalize factors underlying sentence processing performance, several complexity metrics have been proposed which consider properties of single word and sentence, as well as experience-based expectations. Word-level predictors shown to correlate with greater processing difficulties are e.g. word frequency, age of acquisition, root frequency effect, orthographic neighbourhood frequency. At syntactic level, a well-studied measure of sentence complexity takes into account dependency length (Gibson, 1998, 2000), which has been used to explain a wide range of psycholinguistic phenomena, such as the subject/object relative clauses asymmetry or the garden path effect in main verb/reduced-relative ambiguities (Gordon et al., 2001; Staub et al., 2010), as well as variations in word order patterns (Gildea and Temperley, 2010), also in a diachronic perspective (Gulordava and Merlo, 2015). Alternatively, processing difficulty has been explained in terms of surprisal (Hale, 2001). Computational models to calculate lexical and syntactic surprisal have been developed by e.g. Roark et al. (2009) using a broad-coverage probabilistic PCFG parser and Demberg and Keller (2009), who introduced Prediction Theory, which aims at unifying Dependency Length Theory with syntactic surprisal, by making use of a psycholinguistically-motivated version of tree-adjoining grammar.

Unlike more conventional studies on human sentence processing carried out in experimental settings, in this study we rely on crowdsourcing methods to investigate how people perceive sentence complexity. The reliability of crowdsourced data for linguistics and computational linguistics research is well acknowledged as shown in the survey by Munro et al. (2010) proving that the quality of findings obtained from the crowd is comparable, if not higher, to controlled laboratory experiments. In addition, crowdsourcing reaches a

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2690–2699
Brussels, Belgium, October 31 - November 4, 2018.

broader population, in terms of age, education, profession etc. and it is thus more suitable to catch the "layman" intuition of sentence complexity. For these reasons, this method has been used in recent works in the field of readability and text simplification; it is the case of Lasecki et al. (2015); Clercq et al. (2013); Brunato et al. (2016) where the crowd was asked to evaluate the level of complexity or the degree of informativeness of simplified sentences compared to the original one.

In our study, we adopted a similar perspective relying on a crowdsourcing approach to collect a wide resource containing multiple annotations of sentence complexity given by humans. Unlike traditional studies which typically assess either lexical or structural complexity phenomena, we focused on the analysis of a wide set of linguistic features to investigate how all contribute to human perception of sentence complexity. This choice is also motivated by previous studies focused on the "form" of a text all related to the assessment of complexity, e.g. readability assessment (Collins-Thompson, 2015), first language acquisition (Sagae et al., 2005) and Native Language Identification (Malmasi et al., 2017).

2 Our Contributions

Our contribution to the study of sentence complexity is multiple:

- we address two research questions aimed to investigate the role played by a set of linguistic phenomena in characterizing a) the agreement among annotators when they rated the sentences independently from the assigned score and b) the human perception of complexity.
- we introduce a new crowdsourcing-based method to assess how people perceive sentence complexity and we test it for two languages;
- we collect two corpora of sentences annotated by humans with a judgment of complexity;

The two research questions refer to two phenomena that are by definition highly subjective and difficult to define. Our study intends to address this vagueness providing the following main contributions: i) detecting the main linguistic phenomena involved in the prediction of agreement and ii) which phenomena characterize a sentence that is perceived complex by a high number of human subjects.

All the data discussed here are made available at www.italianlp.it/resources/.

3 Approach

We collected a dataset of rated sentences through a crowdsourcing task in which annotators were asked to give a score of complexity to a sentence. The task was carried out on two languages, Italian and English, which have different morpho-syntactic and syntactic properties such as morphological richness and word order freedom. This choice was aimed to investigate whether there are linguistic complexity parameters shared by typologically different languages. Starting from the collected rated sentences, we automatically extracted a wide set of features spanning across multiple levels of linguistic description, which have been acknowledged in the literature on human sentence processing to be involved in sentence complexity. The contribution of these features in modeling the perception of sentence complexity was tested in two different scenarios: i) a classification experiment to assess which features contribute more in the automatic prediction of the degree of agreement among annotators and which features vary in a statistically significant way between agreed and not-agreed sentences; ii) a regression experiment to evaluate if the considered features allow predicting the complexity judgment assigned by humans and how they contribute to the prediction.

In what follows, we introduce the three main ingredients of our approach, i.e. the set of linguistic features (Section 3.1), the datasets of sentences (Section 3.2) and the crowdsourcing task (Section 3.3). In the rest of the paper, we describe the experimental scenarios raised by our two research questions and discuss the results (Sections 4 and 5).

3.1 Linguistic Features

The set of features considered in this study captures different aspects of sentence complexity.

Raw text features:

word length, i.e. average number of characters per words (*char_tok* in all tables and figures that follow) and **sentence length**, i.e. average number of words per sentence (*n_tokens*), which are typically used as a proxy of lexical and syntactic complexity in traditional readability metrics (Collins-Thompson, 2015);

Morpho-syntactic features:

distribution of part-of-speech types; **type/token ratio**, calculated as the ratio between the number of lexical types, the number of tokens, in terms of both lemma and forms (*ttr_form*, *ttr_lemma*); **verbal features**, i.e. the distribution of verbs according to mood (*verbs_mood*), tense (*verbs_tense*) and persons (*verbs_num_per*), and **lexical density** (*lex_density*), calculated as the ratio of content words (verbs, nouns, adjectives and adverbs) to the total tokens in a text. Psycholinguistic studies highlight that higher lexical density implies greater cognitive load (Gibson, 1993);

Syntactic features:

probability of syntactic dependency types e.g. subject, direct object, modifier, etc., calculated as the *distribution* of each type out of the total dependency types. Some syntactic relations have been shown to be harder to process, e.g. object-relative clauses and prepositional-phrase attachments (Gibson and Pearlmutter, 1994; Gibson, 2000), or the subject and object relations especially in free word-order languages;

distribution of verbal roots, i.e. the *distribution of verbal roots* out of the total of sentence roots. A lower percentage of verbal roots implies a higher number of nominal sentences which have a less-standard structure due to verb ellipsis thus possibly causing processing ambiguity;

parse tree depth features: the *depth of the whole parse tree* (*max_depth*), calculated in terms of the longest path from the root of the dependency tree to some leaf; the *depth of embedded complement chains* governed by a nominal head and including either prepositional complements or nominal and adjectival modifiers, calculated as the *total* number of prepositional chains (*n_prep_chains*) and the *average* depth of chains (*prep_chain_l*); the *distribution of embedded complement chains by depth*, calculated as the number of chains out of the total number of chains in a sentence (*prep_depth*). All these features are related to length factors and correlate with processing difficulty (Frazier, 1985), as in the case of long sequences of embedded prepositional complements;

verbal predicate features: the distribution of verbal head (*verb_head*); the *arity of verbs*, meant as the average number of instantiated dependency links sharing the same verbal head covering both arguments and modifiers *verb_arity*); the *distribution of verbal head by arity*, calculated as the total number of verbal heads with the same arity in a sentence (*verb_head_arity*); the *relative ordering of subject and object with respect to the verbal head* (*order_subj* and *order_obj*);

subordination features include the *distribution of main vs. subordinate clauses* (*n_subord_clauses* and *n_princ_clauses*; the *average depth of chains of embedded subordinate clauses*, calculated as the *total* number of subordinate chains (*n_subord_chain*) and the *average* depth of subordinate chains (*subord_chain_l*); the *distribution of embedded subordinate clauses chains by depth*, calculated as the number of chains out of the total number of chains in a sentence (*subord_depth*). We also calculated the order of the subordinate clause with respect to the main clause (*order_subord*), since according to e.g. (Miller and Weinert, 1998), sentences containing subordinate clauses in postverbal than in preverbal position are easier to process;

length of dependency links calculated as the number of words between the syntactic head and the dependent: the feature includes the *length of all dependency links* (*links_len)* and of the *maximum dependency links* (*max_links_l*). It is widely known that long-distance constructions cause cognitive load (Gibson, 1998; Gildea and Temperley, 2010);

clause length measured as the number of tokens occurring within a clause (*token_clause*). Syntactic metrics relying on this feature, such as the T-Unit (Hunt, 1966), are widely used e.g. in first and second language acquisition to assess the development of syntactic competence.

3.2 Data

The experiments were carried out on a subset of sentences extracted from two manually revised treebanks. We chose this kind of data in order to prevent possible errors produced by the automatic annotation of sentences. Specifically, we considered the newspaper section of the Italian Universal Dependency Treebank (UDT) (Simi et al., 2014) and the automatically converted Wall Street Journal section of the Penn Treebank (McDonald et al., 2013). Since we wanted to investigate the human perception of complexity with respect to standard language, we didn't use the English version of the UDT containing different genres of web media (e.g. blogs, emails). Although the two selected treebanks have different annotation schemes, the annotation scheme of the UDT project (McDonald et al., 2013) is based on an evolution of (universal) Stanford dependencies (de Marneffe et al., 2006). This allowed us to compare linguistic phenomena correlated with sentence complexity minimizing possible cross-linguistic differences due to not uniform principles of sentence structure representation. In order to reduce the influence of lexicon on the study of sentence complexity we pruned from the two treebanks those sentences containing low-frequency lemmas with respect to a lemma frequency list that we automatically extracted from a large reference corpus, excluding numerals and proper nouns. For what concerns Italian, we used as a reference corpus PAISÁ (Lyding et al., 2014), which is one of the biggest corpus of authentic contemporary Italian texts. For English, we selected a large corpus of sentences from the Wall Street Journal (Nivre et al., 2007). For both languages, all the sentences contained in the two treebanks were grouped into 6 bins based on a different sentence length, i.e. 10, 15, 20, 25, 30, 35 tokens (only for Italian with a range of +/- 1 tokens each). This was meant to investigate if some linguistic features that are known to correlate with sentence length (e.g. parse tree depth features and dependency links) still play an influence on sentence complexity judgments when sentence length is controlled. Sentences in each subset were then ranked according to the sum of the average frequency of their lemmas. We extracted for each bin the first 200-top ranked sentences, with the exception of Italian for which the last bin contains 123 sentences. As a result of the whole selection process, we obtained 1,200 sentences for English and 1,123 for Italian used for experiments.

3.3 Collection of Judgments of Complexity

To collect human complexity judgments, we administered a crowdsourcing task through the platform CrowdFlower[1]. For each language we recruited 20 native speakers who were asked to read a sentence and rate how difficult it was on a 7-point scale where 1 means "very easy" and 7 "very difficult". Sentences were randomly ordered and presented on distinct pages containing five sentences each. To improve the quality of the collected annotations we chose workers with a "high quality" level assigned by the platform on the basis of their performance in previous tasks and we set a minimum of ten seconds to complete a page. We computed the Krippendorff's alpha reliability corresponding to the number of annotators who assigned the same judgment. We obtained a reliability of 26% for Italian and 24% for English.

4 Studying the Agreement between Human Judgments

Our first research question concerned the investigation of linguistic phenomena characterizing the agreement among annotators in assigning the same judgment of complexity to a sentence. To this end, we split the whole set of rated sentences into ten sets corresponding to the number of annotators giving a judgment of complexity within a same range, hereafter referred to *degrees of agreement*[2]. Figure 1 reports the number of sentences for each degree of agreement. For both languages, if we consider a minimum number of 10 agreeing annotators, very few sentences were discarded (∼50 for Italian and 70 for English). As the number of agreeing annotators increases, the number of sentences progressively decreases but we still have a considerable number of sentences (∼600) when 14 annotators agree.

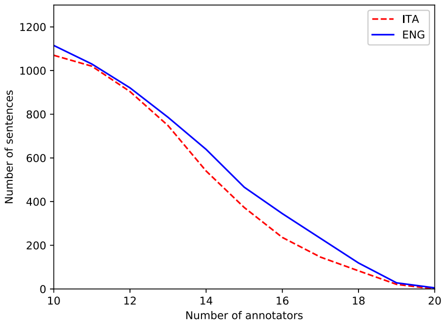

Figure 1: Number of sentences at different degrees of agreement.

To study the linguistic phenomena characterizing the agreement, we firstly extracted the features described in Section 3.1 from sentences on which annotators agreed (*agreed sentences*) and from the rest of sentences (*not-agreed sentences*); we assessed if the difference is statistically significant

---

[1] www.crowdflower.com

[2] Each range was calculated in terms of standard deviation from the mean judgment values given to each sentence.

using Wilcoxon Rank-sum test. This was done for each agreement threshold.

We then performed a feature selection process to identify the features that maximize the accuracies of a classifier in predicting *agreed* vs *not-agreed* sentences. To create a ranking of feature relevance, we used the Recursive Feature Elimination (RFE) algorithm implemented in the Scikit-learn library (Pedregosa et al., 2011), using Linear SVM as estimator algorithm, and we dropped 1 feature in each iteration. We evaluated the classifier performance using a 3-fold cross validation method. At the end of this process we selected the top ranked features. This procedure was iterated 10 times for each degree of agreement.

In order to evaluate the accuracy of the SVM classifier we computed a baseline corresponding to the performance of the classifier using a most-likely class classification method, where each sentence is always classified into the most likely class.

Table 1 reports the features that vary in a statistically significant way (✓in table) and the ones selected in classification (marked with $\star$) for both languages and degrees of agreement levels. As it can be seen, there is an opposite trend between the statistically significant features and those selected by the classifier as the degree of agreement increases. For what concerns the Wilcoxon test, very few features have significantly different values at lower degrees of agreement. That is to say that very few features are involved in discriminating the *agreed* vs *not-agreed* sentences, especially when the agreement is lower than 14.

For both languages, raw text features (*n_tokens* and *char_tok*) vary significantly at all degrees of agreement. Interestingly, these two features are not considered by the classifier which uses more complex syntactic features, such as features related to subordination (e.g. *subord_depth*) and nominal modification (e.g. *prep_chain_l*). Syntactic features start to vary significantly as the agreement increases, e.g. parse tree depth features such as the depth of the whole parse tree (*max_depth*) and the complement chains (*dep_mark*), and features related to the use of subordination. Comparing the two languages we also found a number of differences. For example, at the lowest agreement (degree 10), features of all types turned out to vary significantly for English, while the Italian *agreed* and *not-agreed* sentences do not vary for any features. At higher agreement, Italian *agreed* sentences are characterized by the variation of two language-specific features: the position of the object with respect to the verb head (*order_obj*) and some verbal morphological features (*verbs_num_pers*, *verbs_tense*), which also contributes to the classification only for Italian.

Table 2 reports the accuracy of SVM classifier for each degree of agreement[3] and the baseline. At lower degrees of agreement (i.e. $<$14) the classifier achieves lower accuracy compared to the baseline showing that the selected features do not contribute to discriminate *agreed* vs *not-agreed* sentences. Instead, these features start to have a greater impact for the classification of sentences at degrees 14, 15, 16, 17. This means that at these degrees of agreement the values of the features characterizing the *agreed* sentences are significantly different from those of the *not-agreed* sentences. In addition, even though for these sentences a very high number of features are considered statistically significant by the Wilcoxon test the classifier needs less features to assign the correct class (as shown in Table 1).

5 Correlation of Linguistic Features with Sentence Complexity

The second research question aims to model the human perception of complexity studying the correlation between the set of linguistic features extracted from sentences and the judgments of complexity assigned to each sentence. We firstly calculated the average complexity judgments for the six bins of sentences of the same length (i.e. 10, 15, 20, 25, 30, 35 tokens). As expected, long sentences were judged as more complex for both languages even though all sentences were always rated as more complex for Italian (see Figure 2).

We then calculated the Spearman's rank correlation coefficient between the values of each feature and the average judgments of complexity thus obtaining a ranking of features. The correlation was computed at two distinct degrees of agreement, i.e. 10 and 14. We chose these two thresholds since at 10 the *agreed* sentences correspond to almost all the rated sentences and at 14 the SVM classifier starts to outperform the baseline (see Table 2). Besides, at 14 we still have a quite large set of *agreed* sentences allowing a reliable statistical study of the features (see Figure 1). Only at threshold 10

---

[3] The accuracy was computed as the average classification score of the 10 best results of the feature selection process.

Table 2: Baseline and SVM classifier accuracy at different degrees of human agreement.

we also calculated the ranking of the features with respect to the six bins of sentences of the same length (L10, L15, L20, L25, L30, L35). Figure 3 reports the ranking of features with p <0.05. Positive numbers mean that the higher the feature value the more complex the sentence was judged (i.e. the feature ranked +1 is the top-ranked one since it is the most positively correlated). Instead, negative numbers mean that the lower the feature value, the more complex the sentence was judged (i.e. the feature ranked -1 is the highest negatively correlated). In both languages, the correlation between the top 20 ranked features and the complexity judgment is extremely high, ranging from 0.30 to 0.85 when we consider sentences at agreement 14. At the two agreement thresholds, for all lengths (columns *T10*, *T14*), they concern not only sentence length but also deep syntactic

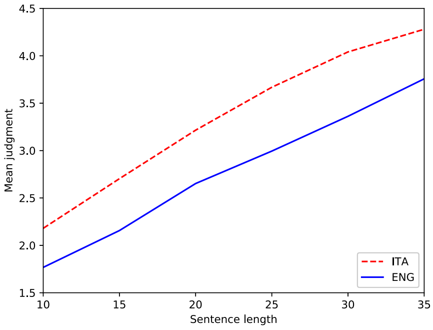

Figure 2: Mean complexity judgment at different sentence length.

features, in terms of e.g. the depth of the whole parse tree (*max_depth*), the length of dependency links (*links_len*), and features related to subordination (e.g. *n_subord_clauses*). Specifically, the 1st-ranked feature in Italian (parse tree depth) and the one in English (sentence length) have a correlation of 0.64 and 0.84 respectively. Nominal modification (*n_prep_chains*) is also highly correlated (Italian r_s=0.59, English 0.54) and similarly ranked in the two languages at 3rd position. The distribution of *verbs_num_pers* makes the sentence harder only for Italian; this is possibly related to the higher complexity of verbal morphology since the 3rd person verb in impersonal structures might increase the ambiguity of the sentence with respect to the referent. Only in English, sentence complexity is affected by the distribution of cardinal numbers (*cpos_NUM*) and the dependency type "numeric modifier" (*dep_num*), in line with the difficulty of numerical information shown in readability studies (Bautista and Saggion, 2014). Conversely, the verbal arity and the relative ordering of subjects with respect to the verb have a lower position in the negative ranking, suggesting that these features make a sentence easier: this might be due to a more fixed predicate-argument structure and word order in this language.

If we focus on sentences of the same length, features considered as a proxy of lexical complexity are in the top positions in both languages. It is the case of the average word length (*char_tok*) and the lexical density (*lex_density*) only for English. Interestingly, while for English the majority of features are similarly ranked in all bins of sentences of the same length, for Italian we observe differences between the rankings of features extracted from sentences $\leq$ and $\geq$20 token long. Namely, when the average sentence length is $\geq$20 tokens, features related to subordination make the sentence more complex.

5.1 Predicting Human Complexity Judgments

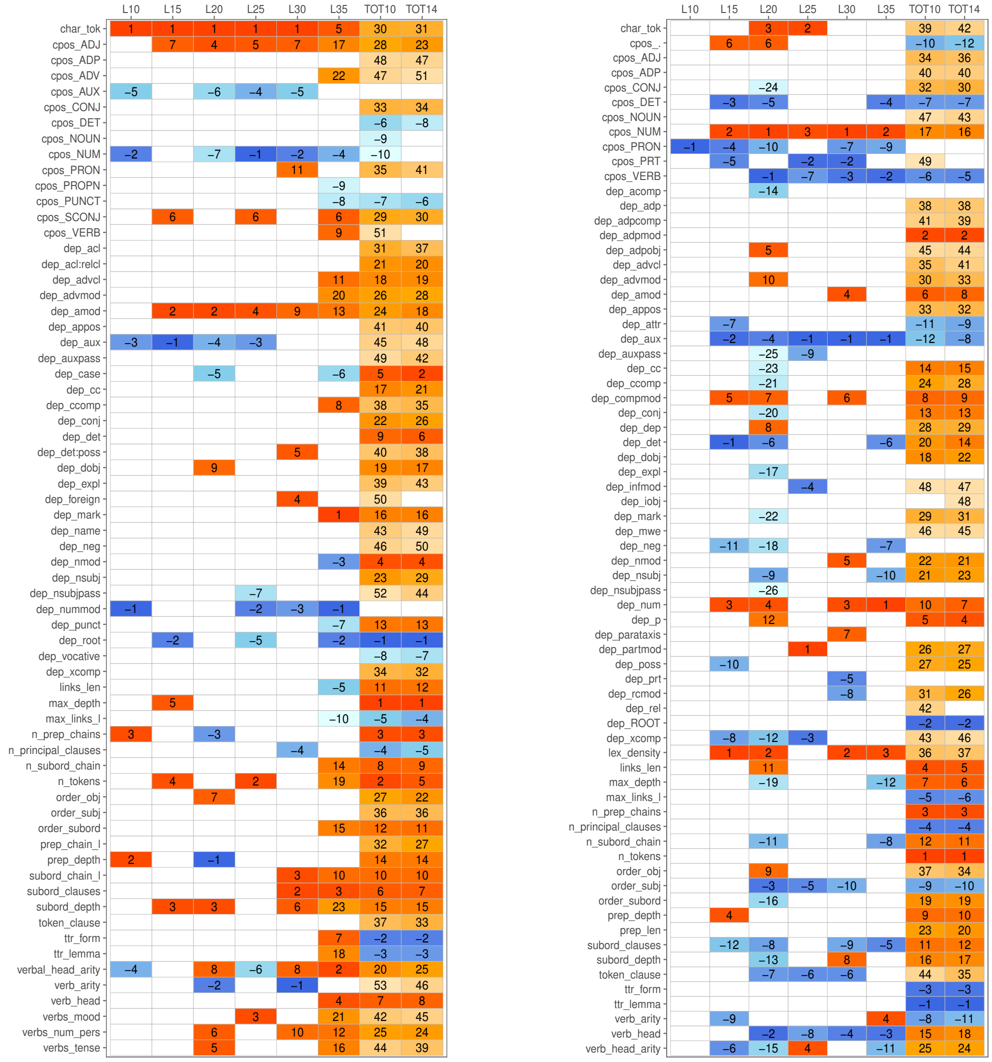
To asses the contribution of the linguistic features to predict the judgment of sentence complexity we trained a linear SVM regression model with default parameters. We performed a 3-fold cross validation over each subset of *agreed* sentences at agreement 10 and 14. We measured two performance metrics: the *mean absolute error* to evaluate the accuracy of the model to predict the same complexity judgment assigned by humans; the *Spearman correlation* to evaluate the correlation between the ranking of features produced by the regression model with the ranking produced by the human judgments. Table 3 reports the results and the average score of the two metrics. As it can be seen, the model is very accurate and achieves a very high correlation (>0.56 with p <0.001) with an average error difference (*avg mean abs err*) below 1. In particular, the model obtained higher performance in predicting the ranking of features extracted from sentences at agreement 14. This might be due to the fact these sentences are characterized by a more uniform distribution of linguistic phenomena and that these phenomena contribute to predict the same judgment of complexity. This is in line with the results obtained by the SVM classifier in predicting agreement (Table 2). This is particularly the case of English and it possibly suggests that the set of sentences similarly judged by humans are characterized by a lower variability of the values of the features.

	IT-10	**IT-14**	**EN-10**	**EN-14**
mean abs err 1	0.77	0.78	0.71	0.68
Spearman 1	0.57	0.64	0.68	0.64
mean abs err 2	0.79	0.80	0.70	0.70
Spearman 2	0.55	0.63	0.67	0.73
mean abs err 3	0.85	0.75	0.77	0.60
Spearman 3	0.55	0.64	0.61	0.71
avg mean abs err	**0.80**	**0.78**	**0.72**	**0.66**
avg Spearman	**0.56**	**0.63**	**0.65**	**0.69**

Table 3: Performance of the linear SVM regression model and the avg score at different agreements.

6 Discussion and Conclusion

In this paper, we introduced a method to model the human perception of sentence complexity relying on a new corpus of Italian and English sen-



(a) Italian.

Figure 3: Features correlating with human judgments at different sentence lengths and with respect to the sentences at agreement 10 (*TOT 10*) and 14 (*TOT 14*).

tences rated with human complexity judgments. We tested the contribution of a wide set of linguistic features automatically extracted from these sentences in two experimental scenarios. The first one highlighted that we can reliably predict the degree of agreement between human annotators, independently from the assigned judgment of complexity: given the high subjectivity of the task, this is a quite notable result that to our knowledge has never been reported. We observed in particular that deep syntactic features related to e.g. the use of subordination and nominal modification play a main role in the automatic prediction of human agreement. This is true for the two languages even though we found that some features resulted to be more relevant in the classification of *agreed* Italian sentences, e.g. the relative ordering of the object. Interestingly, we also noticed that the classifier needs few features to predict agreed sentences when more than half of annotators shares the same judgment.

In the second experiment, we studied the correlation between linguistic features and complexity judgments. The resulting ranking highlighted the key role played by syntactic phenomena: features related to sentence structure are among the top-ranked features characterizing sentences that were rated highly complex by a given number of agreeing annotators. When sentence length was controlled, the relevance of the considered features changes in particular for Italian: e.g. features concerning the use of subordination make the sentence more complex when sentence length is ≥20 tokens. As showed by the results of the regression model, the set of studied features contribute significantly to automatically predict the human judgment of sentence complexity.

In addition, the presented corpus can be useful for different applications. From a psycholinguistic perspective, it can be used for comparison with data collected through controlled experimental scenarios assessing sentence complexity in terms of cognitive measures (offline and online), which are also more constrained and costly to acquire in large-dimensions. The corpus also allows to study whether features of linguistic complexity are implied in modeling other properties of texts, such as the level of engagement or subjectivity. From a NLP perspective, the corpus can be exploited to train systems able to predict people's perception of complexity. For example, it can support a range of related tasks, such as the development of linguistically-informed algorithms for the automatic assessment of text difficulty, as well as in Natural Language Generation tasks, going from text simplification to the automatic generation/evaluation of highly-engaging texts.

Neural Transition Based Parsing of Web Queries: An Entity Based Approach

Rivka Malca and **Roi Reichart**
Technion, Israel Institute of Technology
srikim@st.technion.ac.il, roiri@technion.ac.il

Abstract

Web queries with question intent manifest a complex syntactic structure and the processing of this structure is important for their interpretation. Pinter et al. (2016) has formalized the grammar of these queries and proposed semi-supervised algorithms for the adaptation of parsers originally designed to parse according to the standard dependency grammar, so that they can account for the unique forest grammar of queries. However, their algorithms rely on resources typically not available outside of big web corporates. We propose a new BiLSTM query parser that: (1) Explicitly accounts for the unique grammar of web queries; and (2) Utilizes named entity (NE) information from a BiLSTM NE tagger, that can be jointly trained with the parser. In order to train our model we annotate the query treebank of Pinter et al. (2016) with NEs. When trained on 2500 annotated queries our parser achieves UAS of 83.5% and segmentation F1-score of 84.5, substantially outperforming existing state-of-the-art parsers.[1]

1 Introduction

Web queries, authored by users in order to search for information, form a major gate to the Web, and their correct interpretation is hence invaluable. While earlier research (Bergsma and Wang, 2007; Barr et al., 2008) suggested that many queries are trivial in structure, Pinter et al. (2016) (henceforth PRS16) demonstrated that this is often not the case. Particularly, they demonstrated that queries related to questions that are answered in Community Question Answering (CQA) sites (social QA forums such as Yahoo Answers), follow a complex dependency grammar. As such queries are quite frequent (e.g. an early study (White et al., 2015) showed that they constitute ∼10% of all queries issued to search engines) and their interpretation can benefit from structural analysis (e.g. (Tsur et al., 2016)), effective query parsing is of importance.[2]

In order to properly describe the syntactic structure of queries, PRS16 extended the standard dependency grammar so that it accounts for dependency forests that consist of syntactically independent segments, each of which has its own internal dependency tree. Additionally, they constructed a query treebank consisting of 4,000 CQA queries, manually annotated according to the query grammar. Examples of annotated queries from the treebank are given in Figures 2 and 4.

PRS16 presented two algorithms that can adapt off-the-shelf dependency parsers trained on standard edited text, so that they can produce syntactic structures that conform to the query grammar. Importantly, their methods do not contain any change to the states and transitions of the parser. Instead, they require millions of unannotated queries each paired with the title (usually a grammatical question) of the Yahoo Answers question page that was clicked by the user who initiated the query; it is the alignment between the query and the title that provides the training signal for their algorithms. Unfortunately, millions of (query, title) pairs are typically not available outside of big web corporates, and the practical value of the PRS16 algorithms is hence limited. Moreover, despite the unique supervision signal, their parsers achieve a segmentation F1-score of up to 70.4, which leaves a large room for improvement.

In this paper we present a transition-based BiLSTM query parser that requires no distant supervision. Our parser is based on two ideas: (a) We change the standard transition system so that the parser explicitly supports the PRS16 query gram-

---

[1] Our code and data are available at: `https://bitbucket.org/riki_malca/ptsparser/src/master`.

[2] In the rest of the paper we will refer to queries with question intent, like those addressed in PRS16, simply as queries.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2700–2710
Brussels, Belgium, October 31 - November 4, 2018.

mar (§ 3.2); and (b) Observing that entities are very frequent in CQA queries and provide a strong structural signal (§ 4), we extend our parser to consider information from a named entity (NE) tagger. We explore both sequential and joint training of the NE tagger and the parser and demonstrate the superiority of the joint approach.

As another contribution of this paper, we annotate the dataset of PRS16 with NEs (§ 4). We use this data to establish our observation about the importance of NEs for query parsing, and in order to train and test our entity-aware parser.

We split the PRS16 corpus to train (2500 queries), development (750) and test (750) sections (§ 6). In this training setup our segmentation and entity-aware parser achieves a segmentation F1-score of 84.5 (100 on single-segment queries, 60.7 on multi-segment queries) and a dependency parsing UAS of 83.5. Our model outperforms its simpler variants that do not utilize segmentation and/or NE information. For example, the BiLSTM parser of Kiperwasser and Goldberg (2016), which forms the basis for our model, scores 67.7 in segmentation F1 and 77.0 in UAS.

We note that our training setup is very different than that of PRS16. They trained their parser on edited text from the OntoNotes 5 corpus (Weischedel et al., 2013) augmented with millions of (query, title) pairs, and their test set consists of the 4000 queries of the query treebank, as they do not train on queries.[3] While our work is not directly comparable to theirs, it is worth mentioning that their best model scores 70.4 in segmentation F1 and 76.4 in UAS, much lower than the numbers we report here for our best models.

2 Previous Work

We divide this section to two: We start with works that analyze the structure of queries and the role of NEs in their processing, and then discuss work on parsing of user generated content on the web.

Query structure and entity analysis As noted in PRS16, web queries differ from standard sentences, as they tend to be shorter and have a unique dependency structure. Hence, prior to PRS16 several works have addressed the syntactic structure of web queries. However, all these works were restricted to tasks that are much simpler than full dependency parsing, including POS tagging (Bendersky et al., 2010; Ganchev et al., 2012), phrase chunking (Bendersky et al., 2011), semantic tagging (Manshadi and Li, 2009; Li, 2010) and classification of queries into syntactic classes (Allan and Raghavan, 2002; Barr et al., 2008).

NER has been recognized as a fundamental problem in query processing by Guo et al. (2009), and many works since (e.g. (Alasiry et al., 2012; Eiselt and Figueroa, 2013; Zhai et al., 2016)) explored various models and features for the task. Differently from those works, our goal is to design a BiLSTM model that can be easily integrated with modern BiLSTM parsers. We hence use simple input features and a simple NE scheme (e.g. see (Guo et al., 2009) for more fine-grained distinctions). More sophisticated features, entity schemes and deep learning architectures (e.g. (Lample et al., 2016)) are left for the future.

Syntactic parsing of Web data Only a handful of papers aimed to parse web data. One important example is the shared task of Petrov and McDonald (2012) on parsing web data from the Google Web Treebank, consisting of texts from the email, weblog, CQA, newsgroup, and review domains. Other relevant works are the tweet parsers of Foster et al. (2011), Kong et al. (2014) and Liu et al. (2018). However, all these works did not address the unique properties of web queries with question intent that express information needs in a concise manner (e.g. with one or more phrases or sentence fragments) and follow a forest-based grammar.

PRS16 were the first, and to the best of our knowledge the only work to address the parsing of web queries with question intent. However, as noted in § 1 their algorithms rely on millions of (query, title) pairs, which deems their algorithm impractical for most users. In practice, they started with a query log of 60M Yahoo Answers pages and ended up using 7.5M queries as distant supervision. In this paper we aim to overcome this limitation by introducing a high quality query parser that can train on several thousands annotated queries to provide higher UAS and segmentation F1 figures compared to those reported in PRS16 (see footnote 3 for their training protocol and data).

We finally note that joint parsing and NER was explored in past (Reichart et al., 2008; Finkel and Manning, 2009, 2010), but for edited text, standard grammar and different modeling techniques. Our work re-emphasizes the strong ties between

---

[3] In some setups they used the segmentation signal from the queries and experimented with a five fold cross-validation over the 4000 queries

NER and parsing, in the context of query analysis.

3 Segmentation-Aware Parsing

In this section we present a parser that explicitly accounts for the query dependency grammar of PRS16. We start (§ 3.1) with a brief description of the BiLSTM parser of Kiperwasser and Goldberg (2016) (henceforth KG16), that forms the basis for our parser, and then describe our query parser.

3.1 The KG16 BiLSTM Parser

KG16 presented a BiLSTM model for transition based dependency parsing (Figure 1). Given a sentence s with words $w_1, ..., w_n$ and corresponding POS tags $p_1, ..., p_n$, the word w_i is represented as:

$$x_i = e(w_i) \circ e(p_i) \tag{1}$$

where $e(w_i)$ and $e(p_i)$ are the embeddings of w_i and p_i, respectively, and $\circ$ is the vector concatenation operator. [4]

The BiLSTM consists of two LSTMs: $LSTM_{forward}$ and $LSTM_{backward}$. Given an input vector x_i, $LSTM_{forward}(x_i)$ captures the past context, and is calculated using the information in the input vectors $x_1, \ldots, x_{i-1}$. Similarly, $LSTM_{backward}(x_i)$ captures the future context and is calculated using the information in the input vectors $x_n, \ldots, x_{i+1}$. v_i, the resulting representation of x_i, is given by:

$$\begin{aligned} v_i &= BiLSTM(x_{1..n}, i) \\ &= LSTM_{forward}(x_i) \circ LSTM_{backward}(x_i) \end{aligned} \tag{2}$$

The parser implements the arc-hybrid system (Kuhlmann et al., 2011) which uses a configuration $c = (\sigma, \beta, A)$ where $\sigma = [s_0, s_1, ..]$ is a stack, $\beta = [b_0, b_1..]$ is a buffer and A is a set of dependency arcs. The arc-hybrid system allows three transitions: $SHIFT$, $LEFT_{arc}$ and $RIGHT_{arc}$. At each step the parser scores the possible transitions and selects the highest scoring one.

The parser represents each configuration by the concatenation of the BiLSTM embeddings of the first word in the buffer (b_0) and the three words at the top of the stack (s_0, s_1 and s_2). Then, a multi-layer perceptron (MLP) with one hidden layer scores the possible transitions given the current configuration:

$$MLP_\theta(c) = W^2 \cdot tanh(W^1 \cdot c + b^1) + b^2 \tag{3}$$

where $\theta = W^1, W^2, b^1, b^2$ are the MLP parameters and $c = v_{s_0} \circ v_{s_1} \circ v_{s_2} \circ v_{b_0}$.

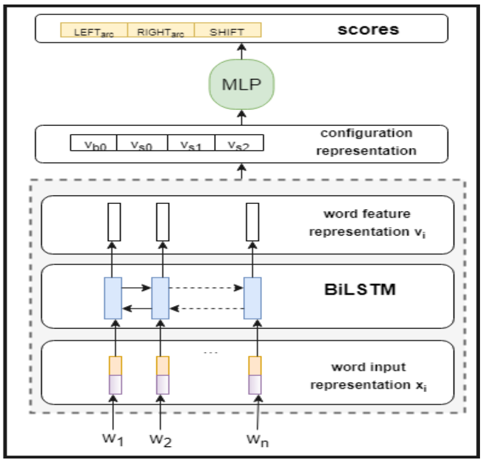

Figure 1: A sketch of the KG16 arc-hybrid parser.

The parser employs a margin-based loss (MBL) function at each step:

$$\begin{aligned} MBL = max(0, 1 - \max_{t_o \in G} MLP_\theta(c)[t_o] \\ + \max_{t_p \in T \setminus G} MLP_\theta(c)[t_p]) \end{aligned} \tag{4}$$

where T is the set of possible transitions and G is the set of correct transitions. The losses are summed throughout the parsing of a sentence and the parameters are updated accordingly.

The parser employs a *dynamic oracle* (Goldberg and Nivre, 2013), which enables exploration in training. We next describe our modification of the KG16 parser. Specifically, we change the transition logic so that it can directly account for the query grammar defined in PRS16.

3.2 A Segmentation-Aware BiLSTM Parser

In order for our parser to directly account for the forest-based query grammar of PRS16, we follow previous work (e.g. Nivre (2009)) and modify its set of actions and transition logic. Before we do that, we start with a more standard modification.

An arc-eager KG16 parser The first step in the design of our parser is changing the arc-hybrid system of the KG16 parser to an arc-eager system (Nivre, 2008). To do that we change the definitions of the $RIGHT_{arc}$ and $LEFT_{arc}$ transitions and add a *REDUCE* transition. The (original) arc-hybrid and the (modified) arc-eager KG16 parsers are denoted with P^H and P^E, respectively.

The motivation for this change is the addition of the $REDUCE$ transition that explicitly facili-

---

[4] The embedding vectors are initialized using the Xavier initialization (Glorot and Bengio, 2010) and trained as part of the BiLSTM.

tates segmentation. After the words in the stack σ are reduced, they cannot be connected to the unprocessed words in the buffer β. This state constitutes a *segmentation point*. We use this connection between the $REDUCE$ transition and the segmentation operation as an integral part of our new segmentation-aware parser, and hence all the following parsers extend this arc-eager parser.

A segmentation-aware parser In our parser, denoted as P^B (for BASIC), a configuration $c = (\sigma, \beta_1, \beta_2, A)$ consists of a stack $\sigma = [s_0, s_1, ..]$, two buffers: $\beta_1 = [b_{10}, .., b_{1last}]$ and $\beta_2 = [b_{20}, .., b_{2last}]$, and a dependency arcs set A. The buffers β_1, β_2 contain the unprocessed tokens, and the words within β_2 form the current segment. We expand the configuration representation to include not only the representations of the first token in the buffer β_1 (b_{10}) and the three tokens at the top of the stack σ (s_0, s_1, s_2) but also the representation of the last token in the buffer β_2 (b_{2last}).

Given a sentence $s = w_1, \ldots, w_n$, the initial configuration is $([ROOT], [w_i \mid i > 1], [w_1], \emptyset)$. In the final configuration the stack σ contains only the $ROOT$ token (we refer to this as an empty stack) and both buffers, β_1 and β_2 are empty. The new transition set, described in Table 1, includes a new transition: *PushToSeg*. This transition adds a new token to the current segment by pushing the top token of β_1 to the end of β_2. The $REDUCE$ transition preconditions have also been modified: this transition is only allowed if β_2 is empty or there is more then one word in the stack.

This new parser performs a two-step process that repeats until convergence, to induce a parse forest. The first step is segment allocation, consisting of a sequence of PushToSeg transitions. When the parser reaches a configuration in which β_2 and σ are empty, only this transition is allowed. There can be one or more consecutive PushToSeg transitions, each pushes a new token from β_1 to β_2. This step ends once the parser selects any other transition, to form a segmentation point. In the second step the allocated segment is parsed. In this step the parser acts as an arc-eager parser with β_2 as the main buffer, and the PushToSeg transition and the β_1 buffer being ignored until the segment is completely parsed (the PushToSeg transition is forbidden while the stack is not empty).

An example of the parsing process is provided in Figure 2. Appendix A provides a proof that the parser is complete and sound as required in Nivre (2008) from any dependency parser.

We next describe two auxiliary segmentation models that can be integrated with our parser.

3.3 Auxiliary Segmentation Models

We consider two models: one is independent of the parser while the other is added as a component to the parser.

Independent segmentation model Similarly to our parser, this model, denoted as SEG, is a BiLSTM that feeds an MLP classifier which predicts for every input word whether it is a segmentation point or not. The loss is a sum of word level MBL functions (equation 4). The input word representation, x_i, and the definition of the hidden word vector, v_i, are as in equations 1 and 2, respectively; the output scores vector $o^{seg}(w_i)$ is derived from the hidden vector, h^{seg}, as in equation 3:

$$\begin{aligned} h^{seg}(v_i) &= tanh(W_s^1 \cdot v_i + b_s^1) \\ o^{seg}(v_i) &= W_s^2 \cdot h^{seg}(v_i) + b_s^2 \end{aligned} \tag{5}$$

where $W_s^1, W_s^2, b_s^1, b_s^2$ are parameters.

We consider two ways through which our P^B parser uses the information from the SEG model. The parser we denote with P^S concatenates the SEG hidden vector of the top word of the stack to the configuration representation:

$$c_{seg} = v_{s_0} \circ v_{s_1} \circ v_{s_2} \circ v_{b_{10}} \circ v_{b_{2last}} \circ h^{seg}(s_0)$$

Alternatively, the parser we denote with P^{FS} (for $FULL\_SEG$) concatenates the hidden vectors of all the configuration elements to the configuration representation:

$$\begin{aligned} c_{full\_seg} =& v_{s_0} \circ v_{s_1} \circ v_{s_2} \circ v_{b_{10}} \circ v_{b_{2last}} \\ &\circ h^{seg}(s_0) \circ h^{seg}(s_1) \circ h^{seg}(s_2) \\ &\circ h^{seg}(b_{10}) \circ h^{seg}(b_{2last}) \end{aligned}$$

This segmentation model can be trained independently of the parser or jointly with it. In development data experiments independent training was superior so we report results with this option.

Configuration-based segmentation model This model, denoted as *FLAG*, predicts whether a given parser configuration is a segmentation point. The answer is positive if the processed words (words in the stack σ) are in the same segment and the unprocessed words (words in the buffer β_2 or β_1) are not in this segment.

Transition		**Precondition**
$LEFT_{arc}$	$(\sigma\mid i, \beta_1, j\mid\beta_2, A) \Rightarrow (\sigma, \beta_1, j\mid\beta_2, A \cup (j, l, i))$	$\neg[i = 0] \wedge \neg\exists k \exists l'[(k, l', i) \in A]$
$RIGHT_{arc}$	$(\sigma\mid i, \beta_1, j\mid\beta_2, A) \Rightarrow (\sigma\mid i\mid j, \beta_1, \beta_2, A \cup (i, l, j))$	
$REDUCE$	$(\sigma\mid i, \beta_1, \beta_2, A) \Rightarrow (\sigma, \beta_1, \beta_2, A)$	$[\exists k \exists l[(k, l, i) \in A]]$ $\wedge\neg[\boldsymbol{size(\beta_2)! = 0 \wedge (size(\sigma) == 1)}]$
$SHIFT$	$(\sigma, \beta_1, i\mid\beta_2, A) \Rightarrow (\sigma\mid i, \beta_1, \beta_2, A)$	
$\boldsymbol{PushToSeg}$	$(\sigma, i\mid\beta_1, \beta_2, A) \Rightarrow (\sigma, \beta_1, \beta_2\mid i, A)$	$size(\sigma) == 1$

Table 1: The transition logic of the segmentation-aware parser. The bold items are the new transitions and conditions of our parser, compared to a standard arc-eager parser.

Figure 2: Example of the application of our segmentation-aware parser to the multi-segment query *invent toy school project* (borrowed from PRS16). First, a sequence of PushToSeg transitions is performed in order to insert the first segment *invent toy* to the buffer β_2 (transitions 1-2). Then, the segment is parsed until the buffer β_2 and the stack σ are empty (3-6). Similarly, the second segment *school project* is pushed to the buffer β_2 through a sequence of PushToSeg transitions (7-8) and then parsed (9-12).

The model is a simple MLP that receives a parser configuration as input and produces a hidden vector (denoted with $h^{flag}(c)$) and a scores vector (denoted with $o^{flag}(c)$). The equations for $h^{flag}(c)$ and $o^{flag}(c)$ are similar to equation 5, and the loss is an MBL loss as in equation 4.

Information from this model is integrated into the parser configuration representation through:

$$c_{flag}(c) = c \circ h^{flag}(c)$$

We refer to this parser as P^{Fl} (for FLAG). The $FLAG$ model must be trained jointly with the parser as its input is a parser configuration.

As shown in § 7, adapting the KG16 parser to explicitly account for multiple segments improves over the KG16 parser in the task of query parsing. We next show how additional gains can be achieved when recognizing the role of NEs.

4 Entities in Query Parsing

In this section we explore the role of NEs in the syntactic structure of queries. We first describe our NE annotation process, and then qualitatively demonstrate the valuable structural cues they provide. In § 5 we will describe extensions of the segmentation-aware BiLSTM parser (§ 3.2) that integrate information from a BiLSTM NE tagger.

Data We consider five entity types: Location (e.g ”London”), Person (e.g ”Marilyn Monroe”), Organization (e.g ”Google”), Product (e.g ”Iphone 4”) and Other (e.g. see Figure 4 for NEs such as ”song name” and ”computer game”). Two human annotators annotated the dataset. Of the 4000 queries, 400 were randomly selected for initial tagging by both annotators, so that they could discuss ambiguous cases and resolve conflicts (the labeled micro-F1 score between the annotators at this stage was 85.6). Then, the remaining 3600 queries were equally split between the two annotators, who again consulted each other in ambiguous cases (the inter-annotator micro-F1, measured on a randomly sampled set of 100 queries, was 92.0).

NEs as a dependency parsing signal The dataset consists of 3010 single-segment (henceforth *SSG*) and 990 multi-segment (henceforth *MSG*) queries. 62.5% of the queries (59% of the SSG and 72% of the MSG) contain at least one NE. Figure 3 (top) provides segment and query level NE statistics. The middle part of the figure shows the proportion of segments and queries that start with an NE. Finally, the bottom part of the table provides word level statistics. The figures clearly demonstrate the prominence of NEs

Figure 3: Top: Query and segment level NE distribution (numbers are averages across the queries in the relevant subset). Middle: NE type distribution (the ”only names” column refers to queries that consist of named entities only, and the ”any name” column refers to queries that contain at least one named entity). Bottom: The percentage of queries and segments that start with an NE.

in queries and the segmentation signal they provide. For example, as many as 35.4% of segments within the MSG queries start with an NE (42% of the first segments and 30% of the other segments). Finally, Figure 4 presents three example queries where NEs provide invaluable cues about the syntactic structure.

Now that we have established the importance of NEs for query parsing, we are ready to describe our entity-aware query parser.

5 A Segmentation and Entity-Aware BiLSTM Parser

Here we describe the integration of NE signals in our segmentation-aware query parser (§ 3.2).

A BiLSTM NE tagger Our NE tagger is a BiLSTM with an MLP classification layer, very similar to our independent segmentation model (SEG, § 3.3). We denote the MLP's hidden state with $h^{ne}(w_i)$ and its output scores vector with $o^{ne}(w_i)$. The model equations are:

$$\begin{aligned} h^{ne}(w_i) &= tanh(W_n^1 \cdot v_i + b_n^1) \\ o^{ne}(w_i) &= W_n^2 \cdot h^{ne}(w_i) + b_n^2 \end{aligned} \tag{6}$$

The margin-based loss (MBL) function we use in this model is:

$$\begin{aligned} MBL = max(0, 1 - MLP_\theta(w_i)[ne_{correct}] + \\ MLP_\theta(w_i)[ne_{predicted}]) \end{aligned} \tag{7}$$

where $\theta = (W_n^1, b_n^1, W_n^2, b_n^2)$ are the model parameters, $ne_{predicted}$ is the named entity type predicted by model and $ne_{correct}$ is the gold named entity type. $MLP_\theta(w_i)[ne_i]$ is the score given by the MLP to the ne_i named entity type.

NE-aware parsing We consider two methods for integrating information from the NE tagger into the parser. In both methods, we construct a new feature representation for each input word, denoted with v_i^M, where M stands for the integration method. The new word representations are then used in the configuration representation (§ 3).

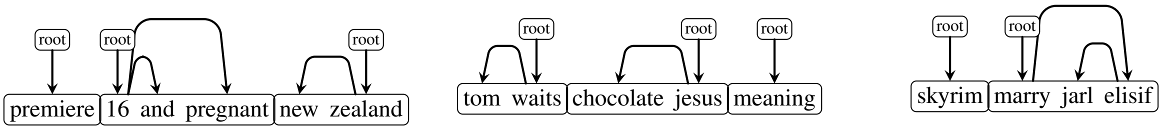
The first method, denoted with *Hi* (for Hidden), uses the hidden vector $h^{ne}(w_i)$:

$$v_i^{Hi} = v_i \circ h^{ne}(w_i)$$

The second method, denoted with *Fi* (for Final), uses the NE embeddings:

$$v_i^{Fi} = v_i \circ e(ne_{predicted}(w_i))$$

For both methods v_i is the word representation generated by the parser (equation 2). For v_i^{Fi}, $ne_{predicted}(w_i)$ is the named entity type predicted by the tagger for the word w_i and $e(ne_{predicted}(w_i))$ is its embedding (part of the parser parametrization).



(a) "16 and pregnant" is a name of a television series; "new zealand" is a name of a place.

(b) "tom waits" is a name of a person; "chocolate jesus" is a name of a song.

(c) "skyrim" is a name of a computer game; "jarl elisif" is a name of a character in the game.

Figure 4: Three example queries from the PRS16 dataset, along with their parse trees. NEs provide an important signal about the structure of the queries.

Tagger and parser training We consider two approaches:

(a) Independent training: First, the tagger is trained with the gold NEs of the training set (§ 4), then the tagger is applied to the training set, and finally the parser is trained with the gold parse trees and the tagger's NE tagging of the training set.

(b) Joint training: The parameters of both models are updated together, each update is taking place after observing a single input sentence. In this joint model, the parser and the tagger are both using the same BiLSTM to learn the word representation v_i. The loss function of this model is the sum of the losses of the parser (sum of the stepwise losses of Eq. 4) and the tagger (Eq. 7):

$$MBL_{joint} = MBL_{parser} + MBL_{ner} \quad (8)$$

6 Experiments

Task and data Our task is the query parsing task of PRS16, but unlike them we do not use millions of unannotated queries. Instead, we experiment with a supervised setup were the parser is trained on parsed web queries and no unannotated queries are used. For our experiments we randomly split the PRS16 dataset of 4000 queries annotated with dependency structures and POS tags,[5] into train, development and test sections. This split is done so that: (a) The train set consists of 2500 queries while the dev and the test sets consist of 750 queries each; (b) For each $k \geq 1$, k-segment queries are split between the three sets so that to keep the 2500:750:750 proportion. As a result, the train, dev and test sets contain 618, 185 and 186 MSG queries, respectively, for the total of 989 MSG queries.

We consider the evaluation measures of PRS16: (a) The standard dependency parsing Unlabeled Attachment Score (UAS); and (b) Segmentation F1-score, where a segment is considered correct if both its start and end point are correctly identified.

Hyper-parameter	Value
Word embedding dim.	100, 200, 300
POS tag embedding dim.	25, 50, 100
Named entity embedding dim.	6
Hidden units in MLP	100
BiLSTM hidden dim.	50,125,200
BiLSTM output dim.	125
α (for word dropout)	0.25
p_{agg} (for exploration training)	1

Table 2: The hyper-parameters considered in our development data experiments.

Models and baselines We experiment with three model families: (a) The baseline KG16 parser and our arc-eager variant of the parser (§ 3.1, § 3.2); (b) Our segmentation-aware parsers (§ 3.2, § 3.3); and (c) Our segmentation and entity-aware parsers (§ 5) where the parser and the NE tagger are trained either jointly or independently (we also consider the integration of NE information into the original (arc-hybrid) KG16 parser).[6]

Hyper-parameter tuning Following (Kiperwasser and Goldberg, 2016) and due to the large number of models we experiment with, we consider a relatively small grid of hyper-parameter values, focused around the values chosen by these authors, as described in Table 2.

To avoid a very large number of experiments, we tune the parameters for the original KG16 arc-hybrid model (P^H) and for our arc-eager version of the parser (P^E). We then report test-set results for the P^H model with its tuned hyper-parameters, and for all the other models with the hyper-parameters that were estimated for the P^E model. While this setup gives an unfair advantage

---

[5] `webscope.sandbox.yahoo.com` (dataset L-28)

[6] A comment about naming conventions: unless H (for the arc-hybrid KG16 parser) or E (for the arc-eager KG16 parser) is part of the model name, a model is an extension of our P^B parser.

for the baseline P^H model, it helps us avoid an expensive model-specific tuning process. The auxiliary segmentation models (§ 3.3) and the NE tagger (§ 5) use the hyper-parameters of Table 2, but for these models we do not perform any tuning – for each hyper-parameter with more than one option, we use the leftmost number from the table.

7 Results

Our results are presented in Table 3. We focus on selected members of each model family, and within each model family we focus on the simplest models (P^H, P^E and P^B, with segmentation and entity information when appropriate), and on the most complex ones. We make sure to include the best performing model of each category, which happens to be one of the most complex models for all families, emphasizing the quality of our modeling choices. The results for the full list of models are in the spp. material.

The *Baseline parsers* section of the table demonstrates the impact of moving from the arc-hybrid variant to an arc-eager variant of KG16, to better support segmentation. While the P^H model performs slightly better than P^E in terms of UAS (78.3 vs. 77.0), the segmentation F1-score of P^E is 4.3 points better (72.0 vs. 67.7). Interestingly, this improvement is not achieved through better segmentation of MSG queries, but by avoiding unnecessary segmentation decisions on SSG queries.

The *segmentation-aware parsers* section of the table shows that further extending the arc-eager KG16 parser to explicitly account for segmentation results in substantial segmentation improvements. Particularly, the overall F1-score of P^B – our segmentation-aware parser that does not use information from any auxiliary segmentation models – is as high as 77.4. This amounts to 5.4 and 9.7 additional F1 points compared to the arc-eager and the original arc-hybrid KG16 parsers, respectively. Information from auxiliary segmentation models (P^{S+Fl} and P^{FS+Fl}) does not substantially increase performance in this family.

When considering entity information, the performance of our models and of the P^E baseline substantially improves. However, while the UAS of the P^E baseline increases to 80.2 (P^{E+Fi} with independent training), its segmentation F1-score does not cross the 66.9 bound (P^{E+Hi} with joint training).[7] The gain of the segmentation-aware parser from entity information is much more substantial. First, regardless of how the entity information is integrated into the model (Hi vs. Fi) and of whether the auxiliary segmentation models (S, FS and Fl) are used or not, the model perfectly segments the SSG queries. Moreover, it demonstrates substantial performance boosts with respect to all measures. Our best performing model, $P^{S+Fl+Fi}$ with joint training (bold result in the bottom model section of the table) improves the original KG16 parser (P^H, top row of the table) by 6.5 UAS points (83.5 vs. 77.0) and by 16.8 segmentation F1 scores (84.5 vs. 67.7).

Model	UAS			Seg. F1-score		
	all	msg	ssg	all	msg	ssg
Baseline parsers						
P^H	**77.0**	**74.9**	**78.3**	67.7	**51.5**	77.9

models improves over independent training for both segmentation F1 and parsing UAS (in 5 of 8 cases for each measure, two bottom model sections of the table). This improvement comes mostly from SSG queries (7 of 8 UAS cases and the 2 cases where segmentation F1 could improve), but at the cost of some degradation on MSG queries. Moreover, our best model is a jointly trained one.

While the goal of this paper is mostly to improve the syntactic analysis of web queries, our simple NE tagger provides decent results. When trained independently of the parser its test-set (labeled) micro-F1 score is 85.6. When trained jointly with the parser it achieves similar scores in some cases: e.g. when jointly trained with the best performing parsing model, $P^{S+Fl+Fi}$, it achieves a micro-F1 of 85.2. Yet, in other cases such as joint training with P^{S+H} and P^{S+Fi} its micro-F1 drops to 78.0 and 78.5, respectively.

Finally, figure 5-7 provide some qualitative analysis of our models and baselines.

8 Conclusions

We presented a new BiLSTM transition-based parser for web queries. Our parser is the first that explicitly accounts for the forest-based query grammar of PRS16. Moreover, we demonstrated the importance of NEs for understanding the syntactic structure of web queries, annotated the Query Treebank of PRS16 with NEs, and demonstrated how to effectively use NE information in the syntactic parsing of web queries.

In future work we intend to explore methods for closing the performance gap our algorithms still have for MSG queries (both UAS and segmentation F1) and for SSG queries (UAS only). Relevant directions include improving the transition logic of our parser, the BiLSTM NE model and the interactions between the two models.

A Parser correctness

In this appendix we discuss the correctness of our segmentation-aware dependency parser, as described in §3.2 of the main paper.

According to Nivre (2008), a parsing system is correct for a class $\mathbb{G}$ of dependency graphs if and only if it is sound and complete for $\mathbb{G}$. We prove correctness for the set $\mathbb{G}$ of all possible dependency trees. The system is *sound* if and only if for every sentence x and every transition sequence $C_{0,m}$ for x, it holds that $G_{C_{0,m}} \in \mathbb{G}$. The system is *complete* for the class $\mathbb{G}$ of all possible dependency trees if and only if for every sentence x and every dependency graph $G_x \in \mathbb{G}$, there is a transition sequence $C_{0,m}$ for x such that $G_{C_{0,m}} = G_x$.

We prove that our segmentation-aware parser is sound by showing that its resulting dependency graph is necessarily a valid parse tree. In order to do that we show that in every possible output graph of the parser each word has exactly one head.

We start by showing that a word must have at least one head. This stems from the fact that a word processing is completed once it is reduced. This can be done using the $REDUCE$ transition or the $LEFT_{arc}$ transition. The preconditions of the $REDUCE$ transition prevent a node from being reduced without a head. The $LEFT_{arc}$ transition, by definition, reduces the node after assigning it with a head. There can be no more than one head to each node as the arcs are created using the $RIGHT_{arc}$ and $LEFT_{arc}$ transitions. If the $RIGHT_{arc}$ transition is applied to a word, it inserts the node to the stack. Once a node is in the stack, $RIGHT_{arc}$ cannot be applied to it and the $LEFT_{arc}$ preconditions prevent the generation of a second head. If the $LEFT_{arc}$ transition applies to the word, the word is automatically reduced and cannot have additional heads, as discussed above.

To prove completeness we develop a valid transition sequence that produces any given dependency tree G_x for a sentence x. We denote the transition sequence that produces a dependency graph G_x for a sentence x in the arc-eager system as $C^{eager}_{0,m}(x, G_x)$. $C^{eager}_{0,m}(x, G_x)$ exists according to the completeness of the arc-eager system. We also denote the sub-graph of a segment s within a dependency tree G_x as G^s_x. An input sentence contains one or more segments. We construct the transition sequence by performing $|s|$ $PushToSeg$ transitions for every segment s in x followed by performing $C^{eager}_{0,m'}(s, G^s_x)$ with the stack σ and the buffer β_2. This transition sequence produces a valid tree G_x for sentence x.

An Investigation of the Interactions Between Pre-Trained Word Embeddings, Character Models and POS Tags in Dependency Parsing

Aaron Smith **Miryam de Lhoneux** **Sara Stymne** **Joakim Nivre**
Department of Linguistics and Philology, Uppsala University

Abstract

We provide a comprehensive analysis of the interactions between pre-trained word embeddings, character models and POS tags in a transition-based dependency parser. While previous studies have shown POS information to be less important in the presence of character models, we show that in fact there are complex interactions between all three techniques. In isolation each produces large improvements over a baseline system using randomly initialised word embeddings only, but combining them quickly leads to diminishing returns. We categorise words by frequency, POS tag and language in order to systematically investigate how each of the techniques affects parsing quality. For many word categories, applying any two of the three techniques is almost as good as the full combined system. Character models tend to be more important for low-frequency open-class words, especially in morphologically rich languages, while POS tags can help disambiguate high-frequency function words. We also show that large character embedding sizes help even for languages with small character sets, especially in morphologically rich languages.

1 Introduction

The last few years of research in natural language processing (NLP) have witnessed an explosion in the application of neural networks and word embeddings. In tasks ranging from POS tagging to reading comprehension to machine translation, a unique dense vector is learned for each word type in the training data. These word embeddings have been shown to capture essential semantic and morphological relationships between words (Mikolov et al., 2013), and have precipitated the enormous success of neural network-based architectures across a wide variety of NLP tasks (Plank et al., 2016; Dhingra et al., 2017b; Vaswani et al., 2017).

When task-specific training data is scarce or the morphological complexity of a language leads to sparsity at the word-type level, word embeddings often need to be augmented with sub-word or part-of-speech (POS) tag information in order to release their full power (Kim et al., 2016; Sennrich et al., 2016; Chen and Manning, 2014). Initialising vectors with embeddings trained for a different task, typically language modelling, on huge unlabelled corpora has also been shown to improve results significantly (Dhingra et al., 2017a). In dependency parsing, the use of character (Ballesteros et al., 2015) and POS (Dyer et al., 2015) models is widespread, and the majority of parsers make use of pre-trained word embeddings (Zeman et al., 2017).

While previous research has examined in detail the benefits of character and POS models in dependency parsing and their interactions (Ballesteros et al., 2015; Dozat et al., 2017), there has been no systematic investigation into the way these techniques combine with the use of pre-trained embeddings. Our results suggest a large amount of redundancy between all three techniques: in isolation, each gives large improvements over a simple baseline model, but these improvements are not additive. In fact combining any two of the three methods gives similar results, close to the performance of the fully combined system.

We set out to systematically investigate the ways in which pre-trained embeddings, character and POS models contribute to improving parser quality. We break down results along three dimensions—word frequency, POS tag, and language—in order to tease out the complex interactions between the three techniques. Our main findings can be summarized as follows:

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2711–2720
Brussels, Belgium, October 31 - November 4, 2018.

- For all techniques, improvements are largest for low-frequency and open-class words and for morphologically rich languages.
- These improvements are largely redundant when the techniques are used together.
- Character-based models are the most effective technique for low-frequency words.
- Part-of-speech tags are potentially very effective for high-frequency function words, but current state-of-the-art taggers are not accurate enough to take full advantage of this.
- Large character embeddings are helpful for morphologically rich languages, regardless of character set size.

2 Related Work

Chen and Manning (2014) introduced POS tag embeddings: a learned dense representation of each tag designed to exploit semantic similarities between tags. In their greedy transition-based parser, the inclusion of these POS tag embeddings improved labelled attachment score (LAS) by 1.7 on the English Penn Treebank (ETB) and almost 10 on the Chinese Penn Treebank (CTB). They also tested the use of pre-trained word embeddings for initialisation of word vectors, finding gains of 0.7 for PTB and 1.7 for CTB.

Dyer et al. (2015) in their Stack Long Short-Term Memory (LSTM) dependency parser, show that POS tag embeddings in their architecture improve LAS by 0.6 for English and 6.6 for Chinese. Unlike Chen and Manning (2014), they do not use pre-trained word embeddings for initialisation, instead concatenating them as a fixed vector representation to a separate randomly-initialised learned representation. This leads to improvements in LAS of 0.9 and 1.6 of English and Chinese, respectively.

Following on from the work of Dyer et al. (2015), Ballesteros et al. (2015) introduced the first character-based parsing model. They found that a model based purely on character information performed at the same level as a model using a combination of word embeddings and POS tags. Combining character and POS models produced even better results, but they conclude that POS tags are less important for character-based parsers. They also showed that character models are particularly effective for morphologically rich languages, but that performance remains good in languages with little morphology, and that character models help substantially with out-of-vocabulary (OOV) words, but that this does not fully explain the improvements they bring. The use of pre-trained embeddings was not considered in their work.

Kiperwasser and Goldberg (2016), in the transition-based version of their parser based on BiLSTM feature extractors, found that POS tags improved performance by 0.3 LAS for English and 4.4 LAS for Chinese. Like Dyer et al. (2015), they concatenate a randomly-initialised word embeddings to a pre-trained word vector; however in this case the pre-trained vector is also updated during training. They find that this helps LAS by 0.5–0.7 for English and 0.9–1.2 for Chinese, depending on the specific architecture of their system.

Dozat et al. (2017), building on the graph-based version of Kiperwasser and Goldberg (2016), confirmed the relationship between character models and morphological complexity, both for POS tagging and parsing. They also examined the importance of the quality of POS tags on parsing, showing that their own tagger led to better parsing results than a baseline provided by UDPipe v1.1 (Straka et al., 2016).

3 The Parser

We use and extend UUParser[1] (de Lhoneux et al., 2017a; Smith et al., 2018), a variation of the transition-based parser of Kiperwasser and Goldberg (2016) (K&G). The K&G architecture can be adapted to both transition- and graph-based dependency parsing, and has quickly become a *de facto* standard in the field (Zeman et al., 2017). In a K&G parser, BiLSTMs (Hochreiter and Schmidhuber, 1997; Graves, 2008) are employed to learn useful representations of tokens in context. A multi-layer perceptron (MLP) is trained to predict transitions and possible arc labels, taking as input the BiLSTM vectors of a few tokens at a time. Crucially, the BiLSTMs and MLP are trained together, enabling the parser to learn very effective token representations for parsing. For further details we refer the reader to Nivre (2008) and Kiperwasser and Goldberg (2016), for transition-based parsing and BiLSTM feature extractors, respectively.

Our version of the K&G parser is extended with a SWAP transition to facilitate the construction

---

[1] `https://github.com/UppsalaNLP/uuparser`

of non-projective dependency trees (Nivre, 2009). We use a static-dynamic oracle to allow the parser to learn from non-optimal configurations at training time in order to recover better from mistakes at test time, as described in de Lhoneux et al. (2017b).

In this paper we experiment with a total of eight variations of the parser, where the difference between each version resides in the vector representations x_i of word types w_i before they are passed to the BiLSTM feature extractors (see Section 3 of Kiperwasser and Goldberg (2016)). In the simplest case, we set x_i equal to the word embedding $e^r(w_i)$:

$$x_i = e^r(w_i)$$

The superscript r refers to the fact that the word embeddings are initialised randomly at training time. This is the setup in our BASELINE system.

For our +CHAR system, the word embedding $e^r(w_i)$ is concatenated to a character-based vector, obtained by running a BiLSTM over the characters $ch_{1:m}$ of w_i:

$$x_i = e^r(w_i) \circ \text{BiLSTM}(ch_{1:m})$$

In the +POS setting, the word embedding is instead concatenated to an embedding $p(w_i)$ of the word's universal POS tag (Nivre et al., 2016):

$$x_i = e^r(w_i) \circ p(w_i)$$

This scenario necessitates knowledge of the POS tag of w_i; at test time, we therefore need a POS tagger to provide predicted tags.

In another version of our parser (+EXT), pre-trained embeddings are used to initialise the word embeddings.[2] We use the superscript t to distinguish these from randomly initialised vectors:

$$x_i = e^t(w_i)$$

We use the embeddings that were released as part of the 2017 CoNLL Shared Task on Universal Dependency Parsing (CoNLL-ST-17) (Zeman et al., 2017). Words in the training data that do not have pre-trained embeddings are initialised randomly. At test time, we look up the updated embeddings for all words seen in the training data; OOV words are assigned their un-updated pre-trained embedding where it exists, otherwise a learnt OOV vector.

In our COMBINED setup, we include pre-trained embeddings along with the character vector and POS tag embedding:

$$x_i = e^t(w_i) \circ \text{BiLSTM}(ch_{1:m}) \circ p(w_i)$$

The three remaining versions of the vector x_i constitute all possible combinations of two techniques of pre-trained embeddings, the character model and POS tags. We refer to these versions of the parser as −EXT, −CHAR, and −POS, respectively.

4 Experimental setup

4.1 Data

We ran our experiments on nine treebanks from Universal Dependencies (Nivre et al., 2016) (v2.0): Ancient Greek PROIEL, Arabic, Chinese, English, Finnish, Hebrew, Korean, Russian and Swedish. Inspired partially by de Lhoneux et al. (2017c), these treebanks were chosen to reflect a diversity of writing systems, character set sizes, and morphological complexity. As error analysis is carried out on the results, we perform all experiments on the *dev* data sets.

Table 1 shows some statistics of each treebank. Of particular note are the large character set sizes in Chinese and Korean, an order of magnitude bigger than those of all other treebanks. The high type-token ratio for Finnish, Russian and Korean also stands out; this is likely due to the high morphological complexity of these languages.

Treebank	Sentences		TTR	Chars
Ancient Greek	14864	1019	0.15	179
Arabic	6075	909	0.10	105
Chinese	3997	500	0.16	3571
English	12534	2002	0.07	108
Finnish	12217	1364	0.26	244
Hebrew	5241	484	0.11	53
Korean	4400	950	0.46	1730
Russian	3850	579	0.30	189
Swedish	4303	504	0.16	86

Table 1: Treebank statistics. Number of sentences in *train* and *dev* sets, type-token ratio (TTR), and character set size.

4.2 Parser settings

The parser is trained three times for each language with different random seeds for 30 epochs each. At the end of each epoch we parse the *dev* data

---

[2] This strategy proved more successful in preliminary experiments than others for incorporating pre-trained embeddings discussed in Section 2.

Word embedding size	100
Character embedding size	500
Character BiLSTM output size	100
POS tag embedding size	20

Table 2: Embedding sizes.

and calculate LAS. For each training run, results are averaged over the five best epochs for each language. In this way, we attempt to make our results more robust to variance due to randomness in the training procedure.[3] Our macro-averaged scores are based on a total of 135 different epochs (3 random seeds × 5 best epochs × 9 languages).

Table 2 shows the embedding sizes we found to produce best results in preliminary work and which we use in all experiments in Section 5. Note our unusually large character embedding size; we will discuss this in more detail in Section 6. We use predicted UPOS tags from the system of Dozat et al. (2017) for experiments with POS tags,[4] other than in Section 7 where we compare results with different taggers and gold POS tags, in order to set a ceiling on the potential gains from a perfect POS tagger. For all other hyperparameters we use default values (Smith et al., 2018).

4.3 Analysis

The hypothesis underlying our choice of analysis is that the three techniques under study here—pretrained embeddings, character vectors and POS tag embeddings—affect words differently depending on their frequencies, POS tags, and the language of the sentence. We do not claim this to be an exhaustive list; many other dimensions of analysis are clearly possible (dependency relation would be another obvious choice for example), but we believe that these are likely to be three of the most informative factors. In the frequency and POS tag cases, we want to examine the overall contribution to LAS of words from each category. We expect changing the representation of a token to affect how likely it is to be assigned the correct head in the dependency tree, but also how likely it is to be assigned correctly as the head of other words. We thus introduce a new metric for this part of the analysis: the head and dependents labelled attachment score, which we refer to as HDLAS.

When calculating HDLAS, the dependency analysis for a given token is only considered correct if the token has the correct labelled head *and* the complete set of correctly labelled dependents. This is a harsher metric than LAS, which only considers whether a token has the correct labelled head. Note that when calculating HDLAS for all tokens in a sentence, each dependency relation is counted twice, once for the head word and once for the dependent. It only makes sense to use this metric when analysing individual tokens in a sentence, or when grouping tokens into different categories across multiple sentences.

4.3.1 Frequency

In this analysis, we first label each token in the *dev* data for each language by its relative frequency in the *train* data, with add-one smoothing.[5] Frequency categories are created by rounding the log relative frequency down to the nearest integer. We calculate the HDLAS for each frequency category for each language, before macro-averaging the results across the nine languages to produce a final score for each frequency class.

4.3.2 POS tag

In this case, we label each word from the *dev* data by its gold POS tag, before calculating HDLAS for each category and taking the macro average across languages. Here the total number of tokens in each category varies across several orders of magnitude: the most common category NOUNs make up 26.0% of all words, while the smallest class SYM represents just 0.1%. For this reason, and to make our graphs more readable, we do not show results for the six smallest categories: INTJ, NUM, PART, SCONJ, SYM, and X.

4.3.3 Language

Here we consider LAS directly for each language; the HDLAS metric used in the previous two sections is not relevant as all tokens in a given sentence are assigned to the same category determined by the language of the sentence.

5 Results

Table 3 gives the LAS for each of the eight systems described in Section 3. We observe that pre-

---

[3] Changing the random seed has been shown to produce results that appear statistically significant different in neural systems (Reimers and Gurevych, 2017).

[4] Available at `https://web.stanford.edu/~tdozat/`.

[5] The smoothing ensures that OOV tokens, those that appear in *dev* but not *train*, are not assigned zero frequency; this alleviates the problem of taking log(0) in the subsequent conversion to log relative frequency.

BASELINE	67.7	COMBINED	81.0
+EXT	76.1	−EXT	79.9
+CHAR	78.3	−CHAR	79.2
+POS	75.9	−POS	80.3

Table 3: Mean LAS across nine languages for a baseline system employing randomly-initialised word embeddings only, compared to three separate systems using pre-trained word embeddings (+EXT), a character model (+CHAR), and POS tags (+POS). Scores are also shown for a combined system that utilises all three techniques and corresponding systems where one of the three techniques is ablated (−EXT, −CHAR and −POS).

trained embeddings (+8.4), the character model (+10.6) and POS tags (+8.2) all give large improvements in LAS over the baseline system. The combined system is the best overall, but the improvement of 13.3 LAS is far from the sum of its components. Employing two of the techniques at a time reduces LAS by only 0.7–1.8 compared to the combined system.

5.1 Frequency

Fig. 1 and Fig. 2 compare systems by word frequency. As expected, accuracy improves with frequency for all systems: the parser does better with words it sees more often during training. There is a levelling off for the highest frequency words, probably due to the fact that these categories contain a small number of highly polysemous word types.

Fig. 1 demonstrates a clear trend in the improvement achieved by each of the individual techniques over the baseline, with larger gains for lower frequency words. This confirms a result from Ballesteros et al. (2015), who found that character models help substantially with OOV words. We can generalise this to say that character models improve parsing quality most for low frequency words (including OOV words), and that this is also true, albeit to a slightly lesser effect, of POS tags and pre-trained word embeddings. It is notable however that HDLAS increases universally across all frequency classes: even the highest frequency words benefit from enhancements to the basic word representation.

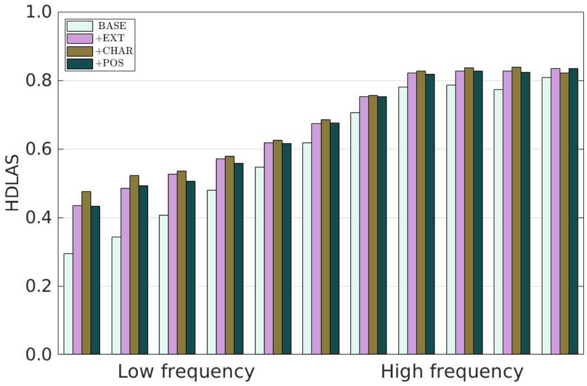

Figure 1: BASELINE system compared to pre-trained embeddings (+EXT), character model (+CHAR) and POS tags (+POS).

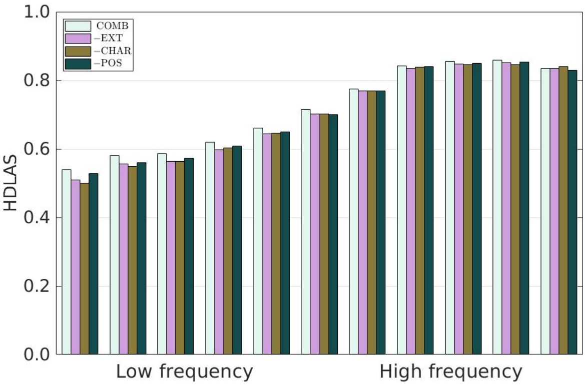

Figure 2: COMBINED system compared to ablated systems where pre-trained embeddings (−EXT), character models (−CHAR) and POS tags (−POS) are removed.

What immediately stands out in Fig. 2 is that for mid- and high frequency words, there is little difference in HDLAS between different combinations of two of the three techniques, and for the highest frequency words this is at a level almost indistinguishable from the full COMBINED system. The slight improvements we see for COMBINED in Table 3 compared to the three ablated systems thus principally also come from the low-frequency range.

5.2 POS tags

In Fig. 3 systems are compared by POS tag. We observe a universal improvement across all POS tags for each of the three variations of the system compared to the baseline. However, it is notable that the biggest gains in HDLAS are for open word classes: NOUNs, VERBs and ADJs. As these make up a large overall proportion of words, these differences have an overall relatively large impact on LAS.

For the most frequent POS categories NOUN and VERB we again see a clear victory for the character model (note that while these POS categories are frequent, they contain a large number of low-frequency words). Overall the character model succeeds best for the open-class POS categories, while having the right POS tag is marginally better for closed-class categories such as DET, CCONJ, and AUX. It is interesting that the character model is not as strong for PROPN, despite the fact that these are open-class low-frequency words; for these words pre-trained embeddings are the best single technique. This may be due to the fact that the rules governing the composition of names at the character level are different from other words in the language.

It is perhaps surprising that the advantage of POS tag embeddings is not greater when it comes to auxiliary verbs, for example, where the distinction from main verbs can be difficult and crucial for a correct syntactic analysis. The reason probably lies in the fact that this distinction is equally difficult for the POS tagger. We will investigate this further in Section 7.

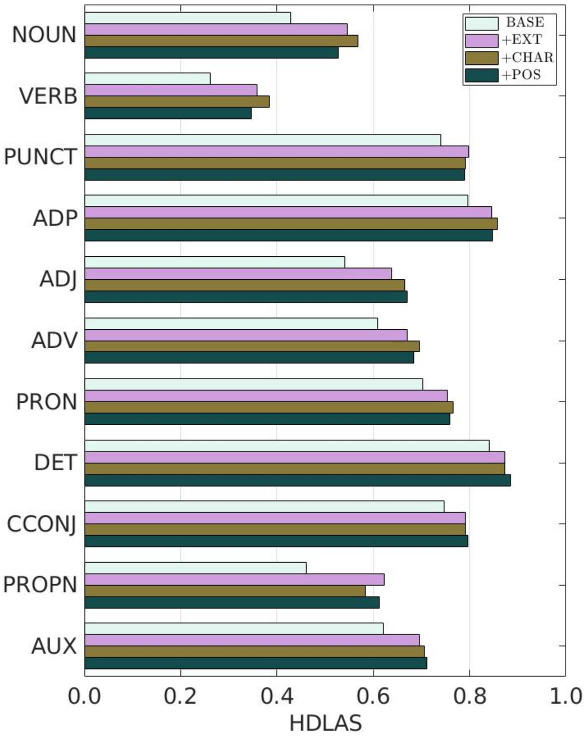

Figure 3: Comparison by POS tag of BASELINE system to +EXT, +CHAR, and +POS. Tags are sorted by frequency.

5.3 Language

Fig. 4 compares the systems by language. Once again improvement is universal for each system compared to the baseline. There are however substantial differences between languages. The three biggest overall improvements are for Finnish, Korean and Russian, with a particularly notable increase in the Korean case. This suggests that the baseline model struggles to learn adequate representations for each word type in these languages. These are the three languages we identified in Section 4.1 as having high type-token ratios in their training data. It is also notable that the character model becomes more important compared to other methods for these three languages. In fact, despite the overall superiority of the character model (see Table 3), it is only the best single technique for 4 of the 9 languages, the three already mentioned plus Ancient Greek.

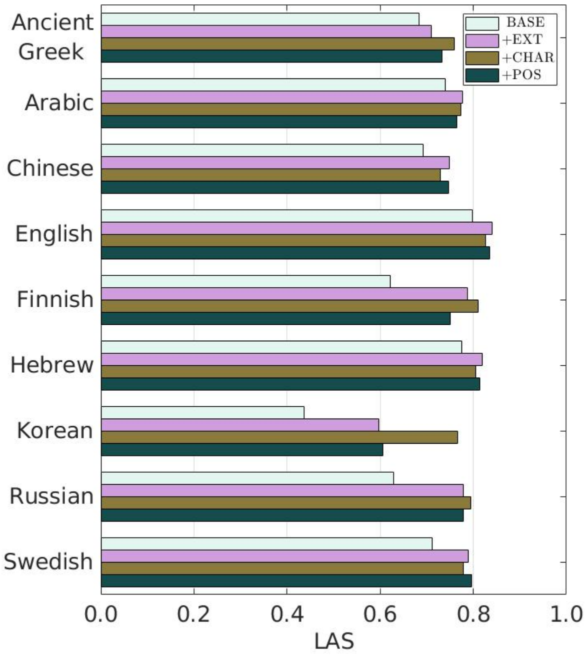

Figure 4: Comparison by language of BASELINE system to +EXT, +CHAR, and +POS.

6 Character Embedding Size

All results with character models observed thus far make use of a character embedding of dimension 500. This value is large compared to typical sizes used for character models (Kim et al., 2016; Ballesteros et al., 2015). A common belief is that larger character embedding sizes are justified for languages with larger character set sizes such as Chinese: in other words, the embedding size should be related to the number of entities being embedded (Shao, 2018).

In Table 4, we show how LAS varies with a few values of this hyperparameter when averaged across our nine-language sample. We see a steady

BASELINE	67.7	−CHAR	79.2
+CH-24	76.8	+CH-24	80.5
+CH-100	77.7	+CH-100	80.6
+CH-500	78.3	+CH-500	81.0

Table 4: Mean LAS across nine languages for BASELINE system compared to systems with character vectors of different sizes. Comparison also shown for systems employing pre-trained word vectors and POS tag embeddings.

improvement in LAS as the character embedding size increases, both when compared to a baseline with randomly initialised word embeddings only and when compared to a system that also employs pre-trained word vectors and POS tag embeddings.[6]

It is particularly interesting to break down the effects here by language. In Table 5 we show results for Chinese, Finnish, Korean and Russian. It is particularly striking that the larger character embeddings do not help for Chinese; the score for the largest character embedding size is actually marginally lower than a baseline without a character model at all. This is despite the fact that a small character embedding improves LAS, albeit marginally, suggesting that there is some useful information in the characters even when pre-trained embeddings and POS tags are present. Conversely, the large character models are very effective for Finnish, a treebank with a character set less than a tenth of the size of Chinese (see Table 1).

	−CHAR	+CH-24	+CH-100	+CH-500
Chinese	76.0	76.1	75.9	75.8
Finnish	81.9	83.7	83.8	84.7
Korean	70.1	78.0	78.2	79.4
Russian	82.0	81.4	81.5	82.5

Table 5: Comparison by language of different character embedding sizes.

We claim therefore that character set size is not in fact a good metric to use in determining character embedding sizes. Our tentative explanation is that while languages like Finnish have relatively small character sets, those characters interact with each other in much more complex ways, thus requiring larger embeddings to store all the necessary information. While there are many characters in Chinese, the entropy in the interactions between characters appears to be smaller, enabling smaller character embeddings to do just as good a job.

It is also worth noting from Tables 4 and 5 that, in the presence of POS tags and pre-trained embeddings, the improvement gained from increasing the character embedding size from 24 to 100 is small (0.1 LAS for Finnish, 0.2 for Korean, 0.1 for Russian; 0.1 on average across the nine treebanks). This perhaps gives the impression of diminishing returns; that going even larger is likely to lead to ever smaller improvements. This may be the reason that smaller character embeddings have generally been preferred previously. However, we in fact observe a much *greater* gain when increasing from 100 to 500 (0.9 for Finnish, 1.2 for Korean, 1.0 for Russian; 0.4 on average across the nine treebanks), suggesting that very large character embeddings are effective, and particularly useful for morphologically rich languages.

7 POS tagger

In this section we apply our POS tag analysis to the effect of the POS tagger used to produce tags at test time. We compare three setups: firstly using tags predicted by UDPipe (Straka and Straková, 2017), which was the baseline model for CoNLL-ST-2017, secondly using tags predicted by the winning Stanford system (Dozat et al., 2017), and thirdly using gold tags. Note that for the Stanford system, we train on gold tags and use predicted tags at test time, while for UDPipe we train on a jackknifed version of the train data with predicted tags that was released as part of CoNLL-ST-2017.

BASELINE	67.7	−POS	80.3
UDPipe	73.4	UDPipe	80.2
Stanford	75.9	Stanford	81.0
Gold	78.4	Gold	83.8

Table 6: Mean LAS across nine languages for BASELINE system compared to systems with POS tags predicted by different systems. Comparison also shown for systems employing pre-trained word vectors and a character vector.

Table 6 shows how LAS varies with the different POS taggers when averaged across the nine-language sample. We see a clear improvement

---

[6] Note that for character embeddings of dimension 24, we use an output size for the character BiLSTM of 50, for character embeddings of dimension 100, we use an output size of 75, and for character embeddings of dimension 500, we use an output size of 100. We checked in separate experiments that the improvements are not simply due to the increase in output size.

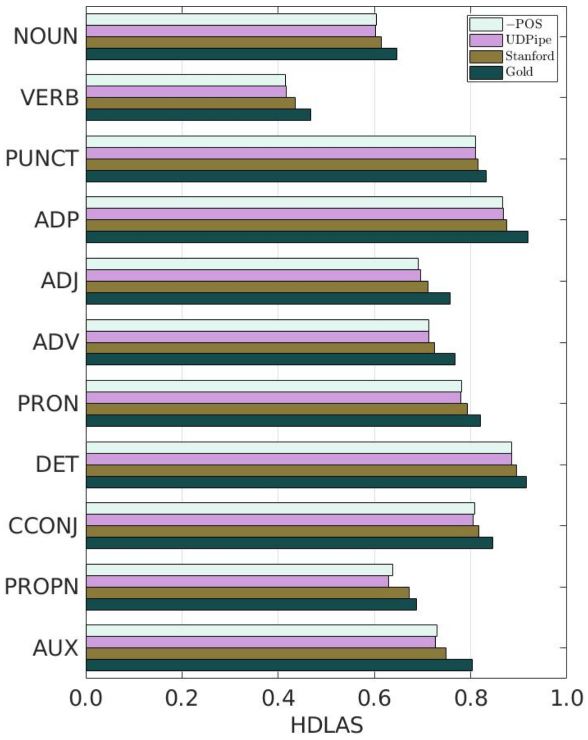

Figure 5: Comparison by POS tag of POS taggers.

from UDPipe to Stanford and then from Stanford to gold tags over the baseline system. This partially confirms results from Dozat et al. (2017), where the Stanford tagger was found to improve parsing results significantly over the UDPipe baseline. More surprising perhaps is the result when comparing to the −POS system, which also makes use of pre-trained word embeddings and a character model. Here, results do not improve at all by adding predicted tags from UDPipe. Stanford tags do give an improvement of 0.7 LAS over −POS, but this is a long way from the improvement of 8.2 LAS we see when adding them on top of BASELINE. Gold tags do however still give a big improvement over −POS (3.5 LAS), suggesting strongly that both UDPipe and Stanford struggle with the decisions that would be most beneficial to parsing accuracy.

In Fig. 5 we present the parsing results broken down by POS tag for the various POS taggers. It is particularly notable that results when tagging with UDPipe are no better than for −POS, which does not use POS tags at all, across most categories, and particularly for the closed-classes ADP, PRON, DET, CCONJ and AUX. Stanford tags do marginally better, but access to gold tags is particularly important in these cases; we see a particularly striking improvement when ADPs and AUXs are correctly tagged over an already strong baseline.

8 Parser speed

It should be noted that increasing the character embedding size and character BiLSTM output dimension as in Section 6 slows down the parser during training and at test time. We found no noticeable difference in speed between the baseline system and versions of the parser with smaller character embedding sizes (24/100), with approximately 20 sentences per second being processed on average during training and 65 sentences per second parsed at test time on the Taito super cluster.[7] There was however a discernible difference when the character embedding size was increased to 500, with only 12 sentences processed per second during training and 44 during testing.

Adding a POS tag embedding makes no appreciable difference to parser speed,[8] but necessitates a pipeline system that first predicts POS tags (assuming gold tags are unavailable). The application of pre-trained embeddings, meanwhile, requires expensive pre-training on large unlabelled corpora. Loading these embeddings into the parser takes time and can occupy large amounts of memory, but does not directly impact the time it takes to process a sentence during training or parsing.

9 Conclusions and Future Work

In this article we examined the complex interactions between pre-trained word vectors, character models and POS tags in neural transition-based dependency parsing. While previous work had shown that POS tags are not as important in the presence of character models, we extend that conclusion to say that in the presence of two of the three techniques, the third is never as important. The best system, however, is always a combination of all three techniques.

We introduced the HDLAS metric to capture the overall effect on parsing quality of changes to the representation of a particular word. We found that all three techniques produce substantial improvements across a range of frequency classes, POS tags, and languages, but the biggest improvements for all techniques were for low-frequency, open-class words. We suggest that this goes some way

---

[7] `https://research.csc.fi/taito-supercluster`

[8] Note that the POS tag embedding we use is small relative to the other components of the word type representation (see Table 2).

to explaining the redundancy between the three techniques: they target the same weaknesses in the baseline word-type level embedding.

We confirmed a previous result that the character model is particularly important for morphologically rich languages with high type-token ratios, and went on to show that these languages also benefit from larger character embedding sizes, whereas morphologically simpler languages make do with small character embeddings, even if the character set size is large.

POS tag embeddings can improve results for difficult closed-class categories, but our current best POS taggers are not capable of making the distinctions necessary to really take advantage of this. The strength of pre-trained embeddings is that they are trained on much larger corpora than the task-specific data; the use of character models and POS tag embeddings however seems to allow us to generalise much better from smaller data sets, as each character and each POS tag is normally seen many times, even if each word type is rare.

We saw that increasing the character embedding size slows the parser down; whether this tradeoff is worthwhile will depend on the application in question. If accuracy is all that matters, we recommend using a fully combined system with large character embeddings in tandem with POS tags and pre-trained embeddings. Where speed is more important, it may be worth considering a system that employs a smaller character embedding and does without POS tags, using just pre-trained embeddings.

In future work it would be interesting to investigate whether the patterns observed here also hold true for other types of models in dependency parsing; possible variations to examine include alternative character models such as convolutional neural networks, joint tagging-parsing models, and graph-based parsers.

Acknowledgments

Abstract

There have been several recent attempts to improve the accuracy of grammar induction systems by bounding the recursive complexity of the induction model (Ponvert et al., 2011; Noji and Johnson, 2016; Shain et al., 2016; Jin et al., 2018). Modern depth-bounded grammar inducers have been shown to be more accurate than early unbounded PCFG inducers, but this technique has never been compared against unbounded induction within the same system, in part because most previous depth-bounding models are built around sequence models, the complexity of which grows exponentially with the maximum allowed depth. The present work instead applies depth bounds within a chart-based Bayesian PCFG inducer (Johnson et al., 2007b), where bounding can be switched on and off, and then samples trees with and without bounding.[1] Results show that depth-bounding is indeed significantly effective in limiting the search space of the inducer and thereby increasing the accuracy of the resulting parsing model. Moreover, parsing results on English, Chinese and German show that this bounded model with a new inference technique is able to produce parse trees more accurately than or competitively with state-of-the-art constituency-based grammar induction models.

1 Introduction

Unsupervised grammar inducers hypothesize hierarchical structures for strings of words. Using context-free grammars (CFGs) to define these structures, previous attempts at either CFG parameter estimation (Carroll and Charniak, 1992; Schabes and Pereira, 1992; Johnson et al., 2007b) or directly inducing a CFG as well as its probabilities (Liang et al., 2009; Tu, 2012) have not achieved as much success as experiments with other kinds of formalisms (Klein and Manning, 2004; Seginer, 2007; Ponvert et al., 2011). The assumption has been made that the space of grammars is so big that constraints must be applied to the learning process to reduce the burden of the learner (Gold, 1967; Cramer, 2007; Liang et al., 2009).

One constraint that has been applied is recursion depth (Schuler et al., 2010; Ponvert et al., 2011; Shain et al., 2016; Noji and Johnson, 2016; Jin et al., 2018), motivated by human cognitive constraints on memory capacity (Chomsky and Miller, 1963). Recursion depth can be defined in a left-corner parsing paradigm (Rosenkrantz and Lewis, 1970; Johnson-Laird, 1983). Left-corner parsers require only minimal stack memory to process left-branching and right-branching structures, but require an extra stack element to process each center embedding in a structure. For example, a left-corner parser must add a stack element for each of the first three words in the sentence, *For parts the plant built to fail was awful,* shown in Figure 1. These kinds of depth bounds in sentence processing have been used to explain the relative difficulty of center-embedded sentences compared to more right-branching paraphrases like *It was awful for the plant's parts to fail.*

However, depth-bounded grammar induction has never been compared against unbounded induction in the same system, in part because most previous depth-bounding models are built around sequence models, the complexity of which grows exponentially with the maximum allowed depth. In order to compare the effects of depth-bounding more directly, this work extends a chart-based Bayesian PCFG induction model (Johnson et al., 2007b) to include depth bounding, which allows both bounded and unbounded PCFGs to be induced from unannotated text.

Experiments reported in this paper confirm that

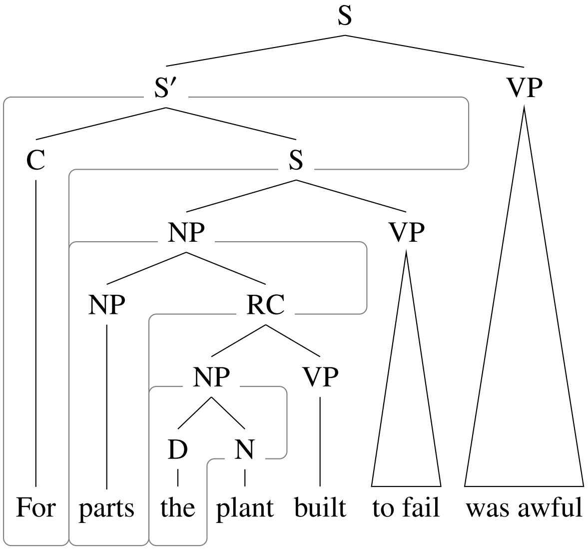

Figure 1: Stack elements after the word *the* in a left-corner parse of the sentence *For parts the plant built to fail was awful.*

depth-bounding does empirically have the effect of significantly limiting the search space of the inducer. Analyses of this model also show that the posterior samples are indicative of implicit depth limits in the data. This work also shows for the first time that it is possible to induce an accurate unbounded PCFG from raw text with no strong linguistic constraints. With a novel grammar-level marginalization in posterior inference, comparisons of the accuracy of bounded grammar induction using this model against other recent constituency grammar inducers show that this model is able to achieve state-of-the-art or competitive results on datasets in multiple languages.

2 Related work

Induction of PCFGs has long been considered a difficult problem (Carroll and Charniak, 1992; Johnson et al., 2007b; Liang et al., 2009; Tu, 2012). Lack of success for direct estimation was attributed either to a lack of correlation between the linguistic accuracy and the optimization objective (Johnson et al., 2007b), or the likelihood function or the posterior being filled with weak local optima (Smith, 2006; Liang et al., 2009). Much of this grammar induction work used strong linguistically motivated constraints or direct linguistic annotation to help the inducer eliminate some local optima. Schabes and Pereira (1992) use bracketed corpora to provide extra structural information to the inducer. Use of part-of-speech (POS) sequences in place of word strings is popular in the dependency grammar induction literature (Klein and Manning, 2002, 2004; Berg-Kirkpatrick et al., 2010; Jiang et al., 2016; Noji and Johnson, 2016). Combinatory Categorial Grammar (CCG) induction also relies on POS tags to assign basic categories to words (Bisk and Hockenmaier, 2012, 2013), among other constraints such as CCG combinators. Other linguistic constraints such as constraints of root nodes (Noji and Johnson, 2016), attachment rules (Naseem et al., 2010) or acoustic cues (Pate, 2013) have also been used in induction.

Depth-like constraints have been applied in work by Seginer (2007) and Ponvert et al. (2011) to help with the search. Both of these systems are successful in inducing phrase structure trees from only words, but only generate unlabeled constituents.

Depth-bounds are directly used by induction models in work by Noji and Johnson (2016), Shain et al. (2016) and Jin et al. (2018), and are shown to be beneficial to induction. Noji and Johnson (2016) apply depth-bounding to dependency grammar induction with POS tags. However the constituency parsing evaluation scores they report are low compared to other induction systems. The model in Shain et al. (2016) is a hierarchical sequence model instead of a PCFG. Although depth-bounding limits the search space, the sequence model has more parameters than a PCFG, therefore benefits brought by depth-bounding may be offset by this larger parameter space.

Jin et al. (2018) also apply depth-bounding to a grammar inducer and induce depth-bounded PCFGs and show that the depth-bounded grammar inducer can learn labeled PCFGs competitive with state-of-the-art grammar inducers that only produce unlabeled trees. However, because of the cognitively motivated left-corner HMM sampler used in the model, its state space grows exponentially with the maximum depth and polynomially with the number of categories. This renders the transition matrix and the trellis of the inducer too big to be practical in exploring models with higher depth limits, let alone unbounded models. By using Gibbs sampling for PCFGs (Goodman, 1998; Johnson et al., 2007b), here described as the inside-sampling algorithm, the state space of the model proposed in this work grows only polynomially with both the maximum depth and the number of categories. This allows experiments with more complex models and also achieves a faster processing speed due to an overall smaller state space.

3 Proposed model

The model described in this paper follows Jin et al. (2018) to induce a depth-bounded PCFG by first inducing an unbounded PCFG and then deterministically deriving the parameters of a depth-bounded PCFG from it. The main difference between this model and the model in Jin et al. (2018) is that they use the bounded PCFG to derive parameters for a factored HMM sequence model, where a forward-filtering backward-sampling algorithm (Carter and Kohn, 1996) can be used in inference. In contrast, the model described in this paper transforms the unbounded PCFG into a bounded PCFG, and then uses the inside-sampling algorithm (Goodman, 1998) to sample from the posterior of the parse trees given the bounded PCFG in inference. This section first gives an overview of the model, then briefly reviews the depth-bounding algorithm for PCFGs (van Schijndel et al., 2013; Jin et al., 2018), and finally describes the inference.

As defined in Jin et al. (2018), a Chomsky normal form (CNF) unbounded PCFG is a matrix $\mathbf{G}$ of binary rule probabilities with one row for each of C parent symbols c and one column for each of $C^2{+}W$ combinations of left and right child symbols a and b, which can be pairs of nonterminals or observed words from vocabulary W followed by null symbols $\perp$:

$$\mathbf{G} = \sum_{a,b,c} \mathsf{P}(c \rightarrow a\ b \mid c)\ \delta_c\ (\delta_a \otimes \delta_b)^\top \tag{1}$$

where δ_c is a Kronecker delta (a vector with value one at index c and zeros elsewhere) and $\otimes$ is a Kronecker product (multiplying two matrices[2] of dimension $m \times n$ and $o \times p$ into a matrix of dimension $mo \times np$ composed of products of all pairs of elements in the operands). A deterministic depth-bounding transform ϕ is then applied to $\mathbf{G}$ to create a depth-bounded version $\mathbf{G}_D$. A depth-bounded grammar is composed of a set of side- and depth-specific distributions $\mathbf{G}_{s,d}$:

$$\mathbf{G}_D = \sum_{s \in \{1,2\}} \sum_{d \in \{1..D\}} \mathbf{D}_{s,d}\, \mathbf{G}_{s,d}\, \mathbf{E}_{s,d}{}^\top \tag{2}$$

where side $s \in \{1,2\}$ indicates left (1) or right (2) child. Categories in $\mathbf{G}_D$ are made to be side- and depth-specific using transforms $\mathbf{D}_{s,d}$ and $\mathbf{E}_{s,d}$:[3]

$$\mathbf{D}_{s,d} = \delta_s \otimes \delta_d \otimes \mathbf{I} \tag{3a}$$

$$\mathbf{E}_{1,d} = \delta_1 \otimes \delta_d \otimes \mathbf{I} \otimes \delta_2 \otimes \delta_d \otimes \mathbf{I} \tag{3b}$$

$$\mathbf{E}_{2,d} = \delta_1 \otimes \delta_{d+1} \otimes \mathbf{I} \otimes \delta_2 \otimes \delta_d \otimes \mathbf{I} \tag{3c}$$

The generative story of this model is as follows. The model first generates an unbounded grammar $\mathbf{G}$ from the Dirichlet prior. Distributions over expansions $\mathsf{P}(c \rightarrow a\ b \mid c)$ of each category c in this model are drawn from a Dirichlet with symmetric parameter β:

$$\mathbf{G} \sim \text{Dirichlet}(\beta) \tag{4}$$

Trees for sentences $1..N$ are each drawn from a PCFG given parameters $\mathbf{G}_D = \phi(\mathbf{G})$:

$$\tau_{1..N} \sim \text{PCFG}(\mathbf{G}_D) \tag{5}$$

Each tree τ is a set $\{\tau_\epsilon, \tau_1, \tau_2, \tau_{11}, \tau_{12}, \tau_{21}, ...\}$ of category labels τ_η where $\eta \in \{1,2\}^*$ is a Gorn address specifying a path of left or right branches from the root. Categories of every pair of left and right children $\tau_{\eta 1}, \tau_{\eta 2}$ are drawn from a multinomial defined by the grammar $\mathbf{G}_D$ and the category of the parent τ_η:

$$\tau_{\eta 1}, \tau_{\eta 2} \sim \text{Multinomial}(\delta_{\tau_\eta}{}^\top \mathbf{G}_D) \tag{6}$$

where $\mathsf{P}_{\mathbf{G}_D}(a\ b \mid w) = \mathsf{P}_{\mathbf{G}_D}(a\ b \mid \perp) = [\![a, b{=}\perp, \perp]\!]$ for $w \in W$, and $[\![\cdot]\!]$ is an indicator function.

In inference, a Gibbs sampler can be used to iteratively draw samples from the conditional posteriors of the unbounded grammar and the parse trees. For example, at iteration t:

$$\mathbf{G}^t \sim \mathsf{P}(\mathbf{G}^t \mid \tau^{t-1}_{1..N}, \sigma_{\tau^{t-1}_{1..N}}, \beta) \tag{7}$$

$$\tau^t_{1...N} \sim \mathsf{P}(\tau^t_{1..N} \mid \mathbf{G}^t_D, \sigma_{\tau^t_{1..N}}) \tag{8}$$

where σ_τ denotes the terminals in τ. These distributions will be defined in Section 3.2.

3.1 Depth-bounding a PCFG

This section summarizes the depth-bounding function ϕ for PCFGs described in van Schijndel et al. (2013) and Jin et al. (2018). Depth-bounding essentially creates a set of PCFGs with depth- and side-specific categories where no tree that exceeds

---

[2] or vectors in case n and p equal one

[3] Note that this correctly stipulates depth increases for left children of right children.

its depth bound can be generated by the bounded grammar. Because depth increases when a left child of a right child of some parent category performs non-terminal expansion, the probability of such expansions at the maximum depth limit as well as non-depth-increasing expansions beyond the maximum depth limit must be removed from the unbounded grammar. Following van Schijndel et al. (2013) and Jin et al. (2018), this can be done by iteratively defining a side- and depth-specific containment likelihood $\mathbf{h}^{(i)}_{s,d}$ for left- or right-side siblings $s \in \{1, 2\}$ at depth $d \in \{1..D\}$ at each iteration $i \in \{1..I\}$, as a vector with one row for each nonterminal or terminal symbol (or null symbol $\perp$) in $\mathbf{G}$, containing the probability of each symbol generating a complete yield within depth d as an s-side sibling:

$$\mathbf{h}^{(0)}_{s,d} = \mathbf{0} \tag{9a}$$

$$\mathbf{h}^{(i)}_{1,d} = \begin{cases} \mathbf{G}\,(\mathbf{1} \otimes \delta_\perp \ + \ \mathbf{h}^{(i-1)}_{1,d} \otimes \mathbf{h}^{(i-1)}_{2,d}) & \text{if } d \leq D+1 \\ \mathbf{0} & \text{if } d > D+1 \end{cases} \tag{9b}$$

$$\mathbf{h}^{(i)}_{2,d} = \begin{cases} \delta_\mathrm{T} & \text{if } d = 0 \\ \mathbf{G}\,(\mathbf{1} \otimes \delta_\perp \ + \ \mathbf{h}^{(i-1)}_{1,d+1} \otimes \mathbf{h}^{(i-1)}_{2,d}) & \text{if } 0 < d \leq D \\ \mathbf{0} & \text{if } d > D \end{cases} \tag{9c}$$

where ‘T’ is a top-level category label at depth zero. Following previous work, experiments described in this paper use $I = 20$.

A depth-bounded grammar $\mathbf{G}_{s,d}$ can then be defined to be the original grammar $\mathbf{G}$ reweighted and renormalized by this containment likelihood:

$$\mathbf{G}_{1,d} = \frac{\mathbf{G}\,\mathrm{diag}(\mathbf{1} \otimes \delta_\perp \ + \ \mathbf{h}^{(I)}_{1,d} \otimes \mathbf{h}^{(I)}_{2,d})}{\mathbf{h}^{(I)}_{1,d}} \tag{10a}$$

$$\mathbf{G}_{2,d} = \frac{\mathbf{G}\,\mathrm{diag}(\mathbf{1} \otimes \delta_\perp \ + \ \mathbf{h}^{(I)}_{1,d+1} \otimes \mathbf{h}^{(I)}_{2,d})}{\mathbf{h}^{(I)}_{2,d}} \tag{10b}$$

3.2 Gibbs sampling of unbounded grammars and bounded trees

As defined above, this model samples iteratively from the conditional posteriors of $\mathsf{P}(\mathbf{G} \mid \tau_{0..N}, \sigma_{\tau_{0..N}}, \beta)$ and $\mathsf{P}(\tau_{0..N} \mid \mathbf{G}_D, \sigma_{\tau_{0..N}})$ in inference, extending the Gibbs sampling algorithm for PCFG induction introduced in Johnson et al. (2007b) to depth-bounded grammars. The below equations will omit the superscript t for the iteration number of inference for clarity.

To sample from the conditional posterior of $\mathbf{G}$, it is necessary to first sum over all rule applications in all sampled trees:

$$\mathbf{C}_D = \sum_{\tau \in \tau_{1..N}} \sum_{\tau_\eta \in \tau} \delta_{\tau_\eta}\,(\delta_{\tau_{\eta 1}} \otimes \delta_{\tau_{\eta 2}})^\top \tag{11}$$

then remove side- and depth-specificity from category labels:

$$\mathbf{C} = \sum_s \sum_d \mathbf{D}_{s,d}{}^\top \mathbf{C}_D\, \mathbf{E}_{s,d} \tag{12}$$

A side- and depth-independent grammar is then sampled from these counts, plus the pseudocount β:

$$\mathbf{G} \sim \mathrm{Dirichlet}(\beta + \mathbf{C}) \tag{13}$$

Inside-sampling (Goodman, 1998; Johnson et al., 2007b) is then used to sample from the posterior of trees $\mathsf{P}(\tau_{0..N} \mid \mathbf{G}_D, \sigma_{\tau_{0...N}})$. Given a depth-bounded grammar and a sentence, this algorithm first constructs the inside chart $\mathbf{V} \in \mathbb{R}^{L \times L \times C}$, where L is the length of the sentence. A chart vector $\mathbf{V}_{[i,j,1..C]}$ for the span i, j where $i < j \leq L$ in some sentence $w_{1..L}$ is the likelihood $\mathsf{P}_{\mathbf{G}_D}(w_{i..j} \mid c)$ of the span for all side- and depth-specific categories c:

$$\mathbf{V}_{[i,j,1..C]} = \begin{cases} \mathbf{G}_D\,(\delta_{w_i} \otimes \delta_\perp) & \text{if } j{-}i = 1 \\ \sum_k \mathbf{G}_D\,(\mathbf{V}_{[i,k,1..C]} \otimes \mathbf{V}_{[k,j,1..C]}) & \text{if } j{-}i > 1 \end{cases} \tag{14}$$

Trees are sampled iteratively from the top down by first choosing a split point $k_{i,j}$ for the current span i, j such that $i < k_{i,j} < j$:

$$k_{i,j} \sim \mathrm{Mul}\left(\sum_k \delta_k\, \delta^\top_{c_{i,j}} \mathbf{G}_D\,(\mathbf{V}_{[i,k,1..C]} \otimes \mathbf{V}_{[k,j,1..C]}) \right) \tag{15}$$

The algorithm then samples pairs of category labels $c_{i,k_{i,j}}$ and $c_{k_{i,j},j}$ adjacent at this split point $k_{i,j}$:

$$c_{i,k}, c_{k,j} \sim \mathrm{Mul}\left(\delta^\top_{c_{i,j}} \mathbf{G}_D\, \mathrm{diag}(\mathbf{V}_{[i,k,1..C]} \otimes \mathbf{V}_{[k,j,1..C]}) \right) \tag{16}$$

Empirically the sampler spends most of its time constructing the inside chart. The model described in this paper therefore efficiently computes the inside chart using matrix multiplication, which is able to exploit GPU optimization.

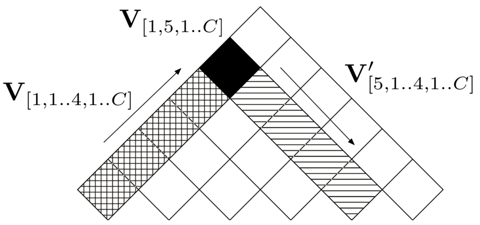

Figure 2: Example of matrix multiplication in place of looping over break points for the span (0,5). Each chart cell represents a likelihood vector for the span between i and j where i is the leftmost delimiting index of the span and j the rightmost. The arrows represent the order in which the cells are stored in the chart matrices $\mathbf{V}$ and $\mathbf{V}'$.

Efficient inside score calculation

The complexity of the inside algorithm is cubic on the length of the sentence because it has to iterate over all start points i, all end points j and all split points k of a span. For a dense PCFG with a large number of states, the explicit looping is undesirable, especially when it can be formulated as matrix multiplication. The split point loop is therefore replaced with a matrix multiplication in order to take advantage of highly optimized GPU linear algebra packages like cuBLAS and cuSPARSE, whereas previous work explores how to parse efficiently on GPUs (Johnson, 2011; Canny et al., 2013; Hall et al., 2014).

Inside likelihoods are propagated using a copy $\mathbf{V}'$ of the inside likelihood tensor $\mathbf{V}$ with the first and second indices reversed:

$$\mathbf{V}'_{[j,i,c]} = \mathbf{V}_{[i,j,c]} \tag{17}$$

This reversal allows the sum over split points $k \in \{i{+}1, ..., j{-}1\}$ to be calculated as a product of contiguous matrices, which can be efficiently implemented on a GPU:

$$\mathbf{V}_{[i,j,1..C]} = \mathbf{G}_D \, \mathrm{vec}(\mathbf{V}_{[i,i+1..j-1,1..C]}{}^{\top}\mathbf{V}'_{[j,i+1..j-1,1..C]}) \tag{18}$$

where vec($\mathbf{M}$) flattens a matrix $\mathbf{M}$ into a vector.

3.3 Posterior inference on constituents

Prior work (Johnson et al., 2007a) shows that using EM-like algorithms, which seek to maximize the likelihood of data marginalizing out the latent trees, does not yield good performance. Because trees are the main target for evaluation, it may be preferable to find the most probable tree structures given the marginal posterior of tree structures compared to finding the most probable grammar. Some recent work (McClosky and Charniak, 2015; Keith et al., 2018) explores how to use marginal distributions of tree structures from supervised parsers to create more accurate parse trees. Based on these arguments, this model performs maximum a posteriori (MAP) inference on constituents (PIoC) using approximate conditional posteriors of spans to create final parses for evaluation.

Formally, let $\sigma^{\star}_{i,j}$ be an MAP unlabeled span of words in a sentence from a corpus σ, with start point i and end point j, and $\sigma_{i,k}, \sigma_{k,j}$ its possible children. This algorithm iteratively looks for the best pair of children $\sigma^{\star}_{i,k}, \sigma^{\star}_{k,j}$ according to the posterior of the children, using all posterior samples. The spans are sentence-specific, but the below equations omit the sentence index for brevity:

$$\begin{aligned} \sigma^{\star}_{i,k}, \sigma^{\star}_{k,j} &= \operatorname*{arg\,max}_{\sigma_{i,k},\sigma_{k,j}} \mathsf{P}(\sigma_{i,k}, \sigma_{k,j} \mid \sigma^{\star}_{i,j}, \sigma) \\ &= \operatorname*{arg\,max}_{\sigma_{i,k},\sigma_{k,j}} \int \mathsf{P}(\sigma_{i,k}, \sigma_{k,j}, \mathbf{G} \mid \sigma^{\star}_{i,j}, \sigma) \, d\mathbf{G} \\ &\approx \operatorname*{arg\,max}_{\sigma_{i,k},\sigma_{k,j}} \sum_{\hat{\mathbf{G}} \sim \mathsf{P}(\mathbf{G}|\sigma)} \mathsf{P}(\sigma_{i,k}, \sigma_{k,j}, \hat{\mathbf{G}} \mid \sigma^{\star}_{i,j}, \sigma) \end{aligned} \tag{19}$$

where σ is the training corpus. Starting from the whole sentence $\sigma_{0,N}$, this algorithm finds the best children for a span from the Monte Carlo estimation of the marginal posterior distribution of children for the span, and then continues to split the found children spans. Because samples from different runs at different iterations can be used to approximate the span posteriors, the process marginalizes out sampled grammars, whole-sentence parse trees and constituent labels to only consider split points for spans. In terms of input and output, the PIoC algorithm takes in posterior samples of trees for a sentence, and outputs an unlabeled binary-branching tree.

There are a few benefits of doing posterior inference on constituents. First, the distribution $\mathsf{P}(\sigma_{i,k}, \sigma_{k,j} \mid \sigma^{\star}_{i,j}, \sigma)$ quantifies how much uncertainty there is in splitting a span $\sigma_{i,j}$ at all possible k's. One way of using this uncertainty information is to merge spans where uncertainty is high, effectively weakening or removing the constraint of binary-branching from the grammar inducer. Second, this algorithm produces trees that may not be seen in the samples, potentially helping aggregate evidence across different iterations within a run and across runs. Third, the multimodal nature of the joint posterior of grammars and trees often makes the sampler get stuck at local modes, but doing MAP on constituents may allow information about trees from different modes to come together. If different grammars all consider certain children for a span to be highly likely, then these children should be in the final parse output. Finally, it is a nonparametric way of doing model selection. As will be shown, model selection relies on the log likelihood of the data, but the log likelihood of the data is only weakly correlated with parsing accuracy. Performing PIoC with multiple runs can increase accuracy without depending too heavily on log likelihood for model selection.

4 Model analysis and evaluation

The model described above has hyperparameters for maximum depth D, number of categories C and the symmetric Dirichlet prior β. Following Jin et al. (2018), this evaluation uses the first half of the WSJ20 corpus as the development set (WSJ20dev) for all experiments. However instead of using the development set only to set the hyperparameters of the model, this evaluation also uses it to explore interactions among parsing accuracy, model fit, depth limit and category domain. The first set of experiments explores various settings of D in the hope of acquiring a better picture of how depth-bounding affects the inducer. The second set of experiments uses the value of D tuned in the first experiments, and does PIoC on different sets of samples to examine the effect it has on parse quality. Optimal parameter values from these first two experiments are then applied in experiments on English (The Penn Treebank; Marcus et al., 1993), Chinese (The Chinese Treebank 5.0; Xia et al., 2000) and German (NEGRA 2.0; Skut et al., 1998) data to show how the model performs compared with competing systems.

Each run in evaluation uses one sample of parse trees from the posterior samples after convergence. Preliminary experiments show that the samples after convergence are very similar within a run and their parsing accuracies differ very little. This evaluation follows Seginer (2007) by running unlabeled PARSEVAL on parse trees collected from each run. Punctuation is retained in the raw text in induction, and removed in evaluation, also following Seginer (2007).

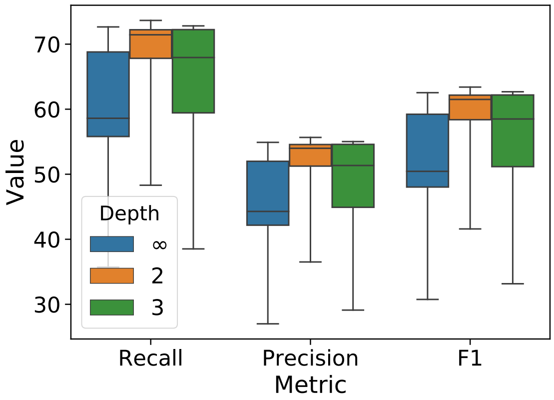

Figure 3: PARSEVAL scores for runs with different depth limits. The difference of all PARSEVAL scores between depth ∞ and depth 2 is significant (p=0.017, Student's t test).

4.1 Analysis of model behavior

The first experiment explores the effects of depth-bounding on linguistic grammar quality. The hypothesis is that depth-bounding limits the search space of possible grammars, so the inducer will be less likely to find low-quality local optima where cognitively implausible parse trees are assigned non-zero probabilities, because such local optima would be removed from the posterior by limiting the maximum depth of parse trees to a small number d.

The effect of depth-bounding

Figure 3 shows the effect of depth bounding using 60 data points of unlabeled PARSEVAL scores from 20 different runs for each of three different depth bounds: 2, 3, and ∞ (unbounded). The range of possible parsing accuracy scores is very wide, as mapped out by the runs. Although the unbounded model is able to reach the performance upper bound seen from the figure, most of the time its results are in the middle of the range. By bounding the maximum depth to 2, the sampler is able to stay in the region of high parsing accuracy. This may be because the majority of the modes in the region of low parsing accuracy require higher depth limits, and humans who produce the sentences do not have access to those higher depth limits. The difference between depth ∞ and depth 2 is significant (p=0.017, Student's t test), showing that depth-bounding does have a positive effect on the linguistic grammar quality of the induced grammars. Data from depth 3 also shows a positive trend of inducing better grammars than

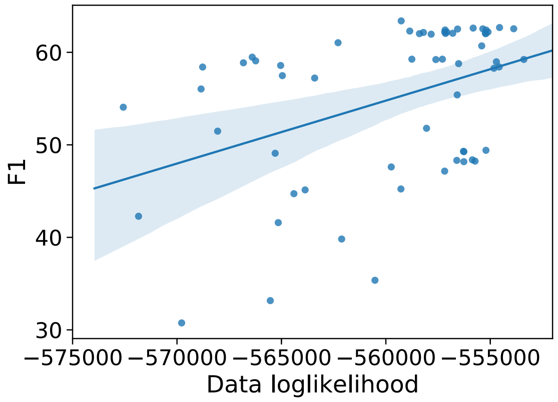

Figure 4: The correlation between data likelihood and parsing accuracy of all 60 runs. Calculations show that there is a significant ($p = 0.007$) positive correlation (Pearson's r=0.39) between data likelihood and parsing accuracy at convergence for our model.

unbounded.

A purely right-branching baseline achieves an F1 score of 48 on the WSJ20 development dataset. A majority of induction runs perform better than this baseline, which indicates that the PCFG induction model with the inside-sampling algorithm is able to find good solutions, most of the time much better than the right-branching baseline. This is especially interesting when the grammar is unbounded with almost no other constraint, which had previously been shown to converge to weak local optima.

Correlation of model fit and parsing accuracy

Model fit, or data likelihood, has been reported not to be correlated or to be correlated only weakly with parsing accuracy for some unsupervised grammar induction models (Smith, 2006; Johnson et al., 2007b; Liang et al., 2009) when the model has converged to a local maximum. Figure 4 shows the correlation between data likelihood and parsing accuracy at convergence for all the runs. There is a significant ($p = 0.007$) positive correlation (Pearson's r=0.39) between data likelihood and parsing accuracy at convergence for our model. This indicates that although noisy and unreliable, the data likelihood can be used as a metric to do preliminary model selection.

The bounded unbounded PCFG

We also examine the distribution of tree depths in unbounded runs. For a run, we compute the percentage of parse trees with a certain depth, and then examine how these percentages vary across

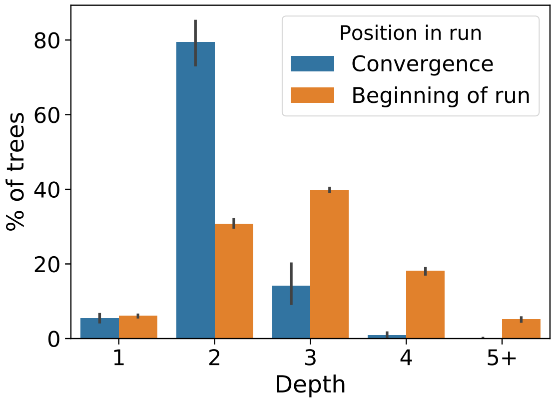

Figure 5: The usage of different depths for parse trees in the samples from 20 runs with the unbounded grammar.

different runs. Theoretically the possible maximum depth of a parse for a sentence is the sentence length divided by 2. For example, a 20-word sentence can have a parse of depth 10 because at least two words are needed to create a new depth with a center embedded phrase, but under most PCFGs this maximally center embedded configuration is not very likely. Figure 5 shows the percentage of tree depths from samples in the beginning of each unbounded run and at convergence. It shows that at the beginning of the sampling process with a random model sampled from the prior, the distribution of parse tree depths seems to be centered around depth 2 and 3, with non-negligible probability mass at other depth levels. At convergence, the distribution of parse tree depths is very peaked with a large portion of the probability mass concentrated at depth 2. Given that an unbounded PCFG has no constraint on depth, this convergence of the marginal posterior distribution of parse tree depth shows that the depth limit seems to be a natural tendency in the data, rather than an arbitrary preference of corpus annotators.

4.2 Posterior uncertainty of constituents

Experiments were also conducted to determine whether posterior inference on constituents (PIoC) has any effect on parsing accuracy. These experiments use 10 runs on WSJ20dev with depth 2 that have the highest log-likelihoods for exploration. In this data, some spans have a strikingly higher degree of uncertainty than other spans. For example, the posterior probability of splitting the phrase *the old story*, into *the old* and *story* is 0.55, and the

System	Rec	Prec	F1
Best	73.65	55.66	63.40
Best w/ PIoC	73.59	56.41	63.87
All w/ PIoC	72.99	59.21	65.38
All w/ PIoC w/o best	73.00	59.06	65.29

Table 1: Development results for different systems using posterior inference on constituents (PIoC).

probability of splitting it into *the* and *old story* is 0.45. Some other spans like *use old tools* have virtually no uncertainty in how the inducer evaluates the splits. Many such spans with high uncertainty are noun phrases, which are not annotated with subconstituents in the Penn Treebank annotation. The parser can therefore avoid precision losses by not splitting constituents with 3 or 4 words if there is large uncertainty in this posterior.[4] This experiment only merges spans that would cover 3 or 4 words and leave merging spans with larger coverage to future work.

Table 1 shows parsing results on the WSJ20dev dataset. The *Best* result is from an arbitrary sample at convergence of the oracle best run. The *Best with PIoC* is the same run, but with PIoC to aggregate 100 posterior samples at convergence. *All with PIoC* uses 100 posterior samples from all of the 10 chosen runs, and finally *All with PIoC without best* excludes the best run in PIoC calculation.

There is almost a point of gain in precision going from *Best* to *Best with PIoC* with virtually no recall loss, showing that the posterior uncertainty is helpful in flattening binary trees. As more samples from the posterior are collected, as shown in *All with PIoC without best*, the precision gain is even more substantial. This shows that with PIoC there is no need to know which sample from which run is the best. Model selection in this case is only needed to weed out the runs with very low likelihood.

4.3 Multilingual PARSEVAL

A final set of experiments compare the proposed model with several state-of-the-art constituency grammar induction systems on three different languages. The competing systems are CCL (Seginer, 2007)[5] and UPPARSE (Ponvert et al., 2011).[6] We also include the published results of DB-PCFG (Jin et al., 2018) on English for comparison.[7] The corpora used are the WSJ20test dataset used in Jin et al. (2018), the CTB20 (sentences with 20 words or fewer from the Chinese Treebank) and NEGRA20 (sentences with 20 words or fewer from the German NEGRA Treebank) datasets used in Seginer (2007). All systems are trained and evaluated on the same datasets to ensure fair and direct comparison. Five different induction runs were run on each dataset with the same hyperparameters D=2, C=15, β=0.2 as tuned on the development set, and three runs with the highest likelihood at convergence were chosen for comparison with other models. Parse trees were then calculated using PIoC as previously described, removing punctuation to calculate the unlabeled PARSEVAL scores with EVALB. Multiple runs of CCL and UPPARSE on the same data yield the same results.

Table 2 shows the unlabeled PARSEVAL scores for the competing systems. The model described in this paper shows strong performance in all languages. On English and Chinese, this model achieves the new state-of-the-art recall and F1 numbers. On German, this model also achieves the best recall scores among all models, showing that more constituents found in the gold annotation are discovered. It is worth noting that the CCL and UPPARSE models do take advantage of additional linguistic constraints, e.g. using punctuation as delimiters of constituents. Experiments described in this paper show that this system can perform better than or competitive with these existing models without similar heuristics and constraints.

The model described in this paper performs relatively poorly on precision due to the fact that trees produced by this system are mostly binary-branching with some constituents flattened by PIoC. This issue is most evident on Negra, where fully binary-branching trees have nearly twice as many constituents as are annotated in gold. This puts any system that produces binary-branching trees under a precision celling of 0.51, and F1 celling of 0.675.

5 Conclusion

Experiments in this work confirm that depth-bounding does empirically have the effect of limiting the search space of an unsupervised PCFG in-

---

ducer. Analysis of a depth-bounded model demonstrates desirable engineering properties, including a significant correlation between parsing accuracy and data likelihood, and interesting linguistic properties such as implicit bounding for unbounded grammars. This paper also introduces the Posterior Inference on Constituents technique for model selection and shows for the first time that it is possible to accurately induce a PCFG with no strong universal linguistic constraints. Comparisons of the proposed model with other state-of-the-art constituency grammar inducers show that this model is able to achieve state-of-the-art or competitive results on datasets in multiple languages.

Incremental Computation of Infix Probabilities for Probabilistic Finite Automata

Marco Cognetta, Yo-Sub Han, and **Soon Chan Kwon**
Department of Computer Science

`{mcognetta, emmous, soon--chan}@yonsei.ac.kr`

Abstract

In natural language processing, a common task is to compute the probability of a given phrase appearing or to calculate the probability of all phrases matching a given pattern. For instance, one computes affix (prefix, suffix, infix, etc.) probabilities of a string or a set of strings with respect to a probability distribution of patterns.

The problem of computing infix probabilities of strings when the pattern distribution is given by a probabilistic context-free grammar or by a probabilistic finite automaton is already solved, yet it was open to compute the infix probabilities in an incremental manner. The incremental computation is crucial when a new query is built from a previous query. We tackle this problem and suggest a method that computes infix probabilities incrementally for probabilistic finite automata by representing all the probabilities of matching strings as a series of transition matrix calculations. We show that the proposed approach is theoretically faster than the previous method and, using real world data, demonstrate that our approach has vastly better performance in practice.

1 Introduction

Probabilistic grammars and finite automata are commonly used to model distributions in natural language processing. Among language models, probabilistic finite automata (PFAs) provide a simple, yet powerful and well-understood representation of many probabilistic language phenomena. Numerous speech processing tasks rely on PFAs in practice (Gyawali et al., 2013; Mohri et al., 2002; Wilson and Raaijmakers, 2008; Ng et al., 2000).

An important problem regarding PFAs is to calculate the probability of some affix (prefix, suffix, infix, etc.) of a string with respect to a given distribution. That is, given a PFA $\mathcal{P}$ and a string w, one might ask the probability of w appearing as a prefix, suffix, or infix in the distribution modeled by $\mathcal{P}$—in other words, the sum of the probabilities of all strings in the form of wx, xw, or xwy with respect to $\mathcal{P}$, for some strings x and y. A more general problem is to compute the sum of the probabilities of all strings in a regular language with respect to a PFA. Computing affix probabilities in probabilistic models is an important problem in natural language processing. For probabilistic context-free grammars (PCFGs) and PFAs, the problem of calculating the prefix or suffix probability of a string can be efficiently solved (Fred, 2000; Corazza et al., 1991). However, calculating the infix probability of a string or the weight of a regular language is not as straightforward (Corazza et al., 1991). Additionally, computing affix probabilities for more general probabilistic language models has proven to be quite difficult. Nevertheless, there are some approaches for computing the exact affix probabilities over a variety of models. Lattice posterior probabilities for n-grams, which are a restricted form of PFA (Vidal et al., 2005b), have a variety of uses in speech processing and can be computed efficiently (de Gispert et al., 2013; Can and Narayanan, 2015). For several affixes, Corazza et al. (1991) described algorithms to determine the probability of a string appearing as that affix in a PCFG. They made an important note that, unlike computing prefix or suffix probabilities, infix probability calculations are prone to double counting in the event of the infix appearing multiple times in a string. Then, they provided an algorithm for computing the infix probability of a string in restricted cases. Stolcke (1995) described a series of recurrences that can be used to compute affix probabilities and variations of the most probable parse of a string for PCFGs. For the general class of linear context-free rewriting systems, a method

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2732–2741
Brussels, Belgium, October 31 - November 4, 2018.

to compute prefix probabilities is known (Nederhof and Satta, 2011b). Fred (2000) also considered these problems and described a method to compute the infix probabilities under the condition that the infix appears at most once in any nonzero probability string when the language model is a stochastic regular grammar, which is equivalent in power to a PFA. These assumptions are rather strict and led researchers to consider a more general problem. Nederhof and Satta (2011a) solved the general infix probability problem for PCFGs. In fact, their method can be used to compute the weight of any regular language with respect to a PCFG. They also proposed an open problem of *incrementally* computing the infix probability of a string—using the numerical result of one infix computation to speed up the evaluation of another.

We design a new method for solving the infix probability problem for PFAs incrementally. Unlike the previous methods involving recurrence calculations or intersection constructions, our method is based on evaluating a series of matrices formed from regular expressions. Additionally, our method has no constraints on the input string. We show that our method is both theoretically and practically more performant than the previous algorithms. Our experimental results show a greater than 80% performance improvement. In Section 2, we review PFAs and other necessary formalisms. We recall how to obtain unambiguous regular expressions in Section 3, and introduce a matrix representation for computing the weight of a regular language in Section 4. In Section 5, we propose an algorithm to incrementally compute the infix probability of a given string. We validate the practical performance of the incremental method using a test set of PFAs obtained from real life data in Section 6 and conclude with a discussion and some open problems in Section 7.

2 Preliminaries

2.1 Finite Automata and PFAs

Following standard notation in automata theory, we let Σ be a set of characters and Σ^* be the set of all strings. For a string $w = w_1 w_2 \dots w_n \in \Sigma^*$, we write $|w| = n$ as its length. The empty string is written as λ.

A deterministic finite automaton (DFA) is a 5-tuple $\mathcal{D} = (Q, \Sigma, \delta, s, F)$, where Q is a finite set of states, Σ is a finite alphabet, $\delta : Q \times \Sigma \to Q$ is the transition function, $s \in Q$ is the initial state, and $F \subset Q$ is the set of final states. A language is a set of strings, and $\mathcal{D}$ recognizes a regular language denoted by $L(\mathcal{D})$. For a summary of automata theory (including regular expressions and formal language theory), we direct the reader to Hopcroft and Ullman (1979).

A PFA is a weighted finite automaton that computes a function $\mathcal{P} : \Sigma^* \to [0, 1]$. We abuse function notation and write $\mathcal{P}(w)$ or $\mathcal{P}(\pi)$ to denote the weight of a word or a path, respectively. These values are defined later. A PFA $\mathcal{P}$ is specified by a 5-tuple $\mathcal{P} = (Q, \Sigma, \delta, I, F)$, where Q is a finite set of states, Σ is a finite alphabet, $\delta : Q \times \Sigma \times Q \to [0, 1]$ is the transition function, $I : Q \to [0, 1]$ and $F : Q \to [0, 1]$ are the initial and final functions, respectively. The transition function is assumed to have a default value of 0, in other words, if a transition does not exist it can be considered as having weight 0. A PFA has three additional requirements:

1. $\sum\limits_{q \in Q} I(q) = 1$
2. $\forall q \in Q,\ F(q) + \sum\limits_{q' \in Q, c \in \Sigma} \delta(q, c, q') = 1$
3. All states are both accessible and co-accessible[1].

If these conditions hold, then for all strings w, $0 \leq \mathcal{P}(w) \leq 1$ and $\sum_{w \in \Sigma^*} \mathcal{P}(w) = 1$. A PFA can be represented in the form of transition matrices, which simplifies several computations. We denote the matrix formulation of a PFA by $\mathcal{P} = (Q, \Sigma, \{\mathbb{M}(c)\}_{c \in \Sigma}, \mathbb{I}, \mathbb{F})$ where $\{\mathbb{M}(c)\}_{c \in \Sigma}$ is a set of $|Q| \times |Q|$ transition matrices with $\mathbb{M}(c)_{i,j} = \delta(q_i, c, q_j)$. Likewise, $\mathbb{I}$ and $\mathbb{F}$ are $1 \times |Q|$ and $|Q| \times 1$ vectors with $\mathbb{I}_i = I(q_i)$ and $\mathbb{F}_j = F(q_j)$.

Consider a string $w = w_1 w_2 \cdots w_n \in \Sigma^*$ and a corresponding labeled path

$$\pi = (q_0, w_1, q_1), (q_1, w_2, q_2), \dots, (q_{n-1}, w_n, q_n)$$

in $\mathcal{P}$. Then the probability of a path π in $\mathcal{P}$ is

$$\mathcal{P}(\pi) = I(q_0) \left(\prod_{i=1}^{n} \delta(q_{i-1}, w_i, q_i) \right) F(q_n).$$

Let Φ_w be the set of all labeled paths corresponding to w. The probability of w is now

---

[1] Accessible states are states reachable from a state with non-zero initial weight and co-accessible states are those that can reach a state with non-zero final weight.

$\sum_{\pi\in\Phi_w}\mathcal{P}(\pi)$. There exist two equivalent dynamic programming methods—the forwards and backwards algorithms—to compute the probability of a given string (Vidal et al., 2005a). Using the matrix formulation, the probability of a string is given succinctly as

$$\mathbb{I}\prod_{i=1}^{|w|}\mathbb{M}(w_i)\mathbb{F}.$$

For brevity, we write $\mathbb{M}(\Sigma) = \sum_{c\in\Sigma}\mathbb{M}(c)$ and $\mathbf{0}$ and $\mathbf{1}$ for the zero and identity matrices when the dimensions are clear. Further, we compute

$$\sum_{i=0}^{\infty}\mathbb{M}(\Sigma)^i = (\mathbf{1} - \mathbb{M}(\Sigma))^{-1},$$

which we denote $\mathbb{M}(\Sigma^*)$. We can compute the prefix and suffix probabilities of a string w as

$$\mathcal{P}(w\Sigma^*) = \mathbb{I}\left(\prod_{i=1}^{|w|}\mathbb{M}(w_i)\right)\mathbb{M}(\Sigma^*)\mathbb{F}$$

and

$$\mathcal{P}(\Sigma^* w) = \mathbb{I}\mathbb{M}(\Sigma^*)\left(\prod_{i=1}^{|w|}\mathbb{M}(w_i)\right)\mathbb{F},$$

respectively. If an automaton $\mathcal{M}$ satisfies all of the requirements for a PFA except that $\sum_{q\in Q} I(q) \leq 1$ or $\forall\ q \in Q$, $F(q) + \sum_{q'\in Q, c\in\Sigma}\delta(q,c,q') \leq 1$, then we call $\mathcal{M}$ a sub-PFA. These machines have the property that for any string w over Σ, $0 \leq \mathcal{M}(w) \leq 1$ and $\sum_{w\in\Sigma^*}\mathcal{M}(w) \leq 1$. Since a sub-PFA $\mathcal{M}$ may not describe a probability distribution over strings, we call $\mathcal{M}(w)$ the *weight* of w instead of probability. A stochastic language over an alphabet Σ is a set $\mathcal{S} \subseteq \Sigma^*$ where each string in $\mathcal{S}$ has an associated probability, $0 \leq Pr_{\mathcal{S}}(w) \leq 1$, such that $\sum_{w\in\Sigma^*} Pr_{\mathcal{S}}(w) = 1$. Given a stochastic language $\mathcal{S}$, if there exists a PFA $\mathcal{P}$ such that $\forall w \in \Sigma^*$, $\mathcal{P}(w) = Pr_{\mathcal{S}}(w)$, we call $\mathcal{S}$ a *regular stochastic language*.

2.2 Unambiguous Regular Expressions

Regular expressions are a common representation of regular languages. A string that can be matched with a regular expression is said to be in the language of the regular expression. A match occurs when there is a valid assignment of symbols in the regular expression to the queried string. We denote the set of all strings that match a regular expression as $L(R)$. An *unambiguous* regular expression has only one valid assignment for any string in the language. For example, consider the regular expression $(a \cup b)^*aa(a \cup b)^*$, which accepts the set of strings over $\Sigma = \{a, b\}$ containing aa as an infix. We assign different subscripts to symbols that appear in more than one position to form $(a_1 \cup b_1)^*a_2a_3(a_4 \cup b_2)^*$. Given the string $baaa$, we find that $b_1a_1a_2a_3$ and $b_1a_2a_3a_4$ are both valid assignments, hence $baaa$ is in the language. However, since there are two valid assignments, we say that this regular expression is ambiguous (Book et al., 1971). An unambiguous expression for the same language is $b^*a(bb^*a)^*a(a\cup b)^*$.

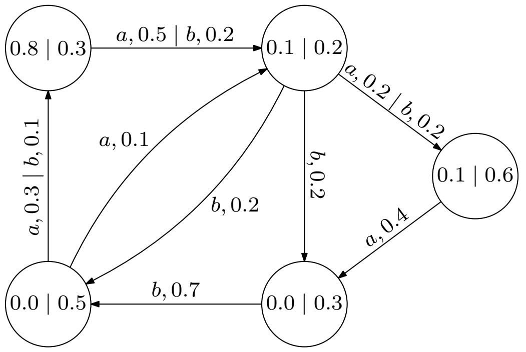

Figure 1: An example PFA over $\Sigma = \{a, b\}$. Each state has an initial and final probability, separated by a bar. The edges hold a character and the probability of the corresponding transition.

2.3 Intersecting a DFA and a PFA

The standard method to compute the weight of a regular language with respect to a PFA is to intersect its DFA representation with the PFA. This construction was already discussed in (Vidal et al., 2005a). Nederhof and Satta (2011a) considered a similar construction for DFAs and PCFGs and solved the infix problem for that class of machine. The construction creates a new sub-PFA $[\mathcal{D} \cap \mathcal{P}]$ such that:

$$[\mathcal{D} \cap \mathcal{P}](w) = \begin{cases}\mathcal{P}(w), & w \in L(\mathcal{D});\\ 0, & \text{otherwise.}\end{cases}$$

It follows that

$$\sum_{w\in\Sigma^*}[\mathcal{D} \cap \mathcal{P}](w) = \sum_{w\in L(\mathcal{D})}\mathcal{P}(w),$$

as desired.

The intersection algorithm is similar to that of the cross product of two automata from classical automata theory. Given a DFA $\mathcal{D}$ and a PFA $\mathcal{P}$, we construct a new machine $\mathcal{W}$ with states $Q_{\mathcal{W}} = Q_{\mathcal{D}} \times Q_{\mathcal{P}}$. For two states (x, y), (x', y') and a character $c \in \Sigma$, $\delta_{\mathcal{W}}((x, y), c, (x', y')) = \delta_{\mathcal{P}}(y, c, y')$ if $\delta_{\mathcal{D}}(x, c) = x'$ and 0 otherwise. Likewise, $I_{\mathcal{W}}((p, q)) = I_{\mathcal{P}}(q)$ if p is the initial state of $\mathcal{D}$ and $F_{\mathcal{W}}((p', q')) = F_{\mathcal{P}}(q')$ if p' is a final state of $\mathcal{D}$ and are 0 otherwise.

Using Algorithm 1, we can now efficiently compute the sum of the weight of all strings in $\mathcal{L}(\mathcal{D})$ by evaluating

$$\mathbb{I}_{[\mathcal{D}\,\cap\,\mathcal{P}]}(\mathbf{1} - \mathbb{M}_{[\mathcal{D}\,\cap\,\mathcal{P}]}(\Sigma))^{-1}\mathbb{F}_{[\mathcal{D}\,\cap\,\mathcal{P}]}.$$

Algorithm 1 DFA/PFA intersection

```
procedure INTERSECT(DFA $\mathcal{D}$, PFA $\mathcal{P}$)
    $Q' = Q_{\mathcal{D}} \times Q_{\mathcal{P}}$
    for $(d, p) \in Q'$ do
        if $d$ is $q_0$ then
            $I'((d, p)) = I(p)$
        else
            $I'((d, p)) = 0$
        end if
        if $d \in F_{\mathcal{D}}$ then
            $F'((d, p)) = F(p)$
        else
            $F'((d, p)) = 0$
        end if
        for $c \in \Sigma$, $(d', p') \in Q'$ do
            if $\delta_{\mathcal{D}}(d, c) = d'$ then
                $\delta'((d, p), c, (d', p')) = \delta_{\mathcal{P}}(p, c, p')$
            else
                $\delta'((d, p), c, (d', p')) = 0$
            end if
        end for
    end for
    return $[\mathcal{D} \cap \mathcal{P}] = (Q', \Sigma, \delta', I', F')$
end procedure
```

To find the infix probability of a given string $w = w_1 w_2 \cdots w_n$, we take $\mathcal{D}$ to be a DFA that recognizes the language of all strings containing w as an infix. The Knuth-Morris-Pratt (KMP) algorithm produces such a DFA (with $O(n)$ states) in $O(n)$ time (Knuth et al., 1977). Thus, computing the infix probabilities of each of w's prefixes takes $O(n(n|Q_{\mathcal{P}}|)^m)$ time, where m is the matrix multiplication constant[2], as at each step one needs to rebuild the entire intersection automaton for the current prefix and compute an inverse on its transition matrices.

Nederhof and Satta (2011a) demonstrated that a similar method can be used to compute the infix probability of a given string in PCFGs.

3 Generating Unambiguous Regular Expressions

Book et al. (1971) showed that, given a regular language (in the form of an automaton or regular expression), one can find an equivalent unambiguous regular expression by constructing an equivalent DFA and using state elimination on the resulting DFA.

Let $\mathcal{D} = (Q, \Sigma, \delta, q_1, F)$ be a DFA with $|Q| = n$ and the states being ordered from 1 to n. We add two new states, q_0 and q_{n+1} such that q_0 is the new start state and q_{n+1} is the only final state, and add the following transitions: $\delta(q_0, \lambda) = q_1$ and $\forall q \in F,\ \delta(q, \lambda) = q_{n+1}$. We then dynamically eliminate states using the following recurrence:

$$\alpha^k_{i,j} = \alpha^{k-1}_{i,j} + \alpha^{k-1}_{i,k}(\alpha^{k-1}_{k,k})^*\alpha^{k-1}_{k,j}$$

with the base cases:

$$\alpha^0_{i,j} = \begin{cases} \lambda, & i = 0, j = 1; \\ \lambda, & q_i \in F \wedge j = n + 1; \\ \{c \mid \delta(q_i, c) = q_j\}, & \text{otherwise.} \end{cases}$$

The equations follow the general concatenation, union, and Kleene star rules for regular expressions. In addition, we have:

- $\emptyset + c = c + \emptyset = c$, for $c \in \Sigma$
- $\emptyset c = c\emptyset = \emptyset$, for $c \in \Sigma$
- $\lambda c = c\lambda = c$, for $c \in \Sigma$
- $\emptyset^* = \lambda$.

The term $\alpha^{k-1}_{i,j}$ corresponds to the set of strings for which, starting from state q_i, describe a path to q_j where all intermediate states are of the form q_ℓ, where $\ell < k$ (the terminal state in the path has no such restriction). Similarly, $\alpha^{k-1}_{i,k}(\alpha^{k-1}_{k,k})^*\alpha^{k-1}_{k,j}$ corresponds to all of the strings which, beginning

---

[2] The matrix multiplication constant, m, is the order of the polynomial for the runtime of multiplying two $n \times n$ matrices together, i.e. a function in $O(n^m)$. In practice, Strassen's algorithm is often used, yielding $m \approx 2.81$ (Strassen, 1969).

at state q_i, end at q_j going through q_k, where all intermediate states have label at most k (McNaughton and Yamada, 1960).

We extract $\alpha^n_{0,n+1}$, which is an unambiguous regular expression for the language recognized by $\mathcal{D}$ (Book et al., 1971). Note that the requirement of an input automaton being deterministic is not strict. In fact, state elimination generates unambiguous regular expressions from any unambiguous automaton.

From now on, we only consider unambiguous regular expressions for any regular languages.

4 The Weight of a Regular Language

In Section 2.3, we reviewed the classical way of computing the weight of a regular language with respect to a PFA using an intersection construction. Here, we present a new method based on unambiguous regular expressions. We describe a simple transformation to convert regular expressions into operations on transition matrices. Consider the following mapping from regular expressions to matrices:

- $\emptyset \rightarrow \mathbf{0}$
- $\lambda \rightarrow \mathbf{1}$
- $c \in \Sigma \rightarrow \mathbb{M}(c)$.

Now, let R and S be regular expressions with $\mathbb{M}(R)$ and $\mathbb{M}(S)$ being their corresponding matrices:

- $R \cup S \rightarrow \mathbb{M}(R) + \mathbb{M}(S)$
- $RS \rightarrow \mathbb{M}(R)\mathbb{M}(S)$
- $R^* \rightarrow (\mathbf{1} - \mathbb{M}(R))^{-1}$.

Using these definitions, we can build a matrix calculation out of a given regular expression. We then obtain the weight of a regular expression R with respect to some PFA $\mathcal{P}$ by evaluating $\mathbb{I}_{\mathcal{P}}\mathbb{M}_{\mathcal{P}}(R)\mathbb{F}_{\mathcal{P}}$. However, the straightforward application of this method is prone to overcounting when there are many ways for a string to be matched to the expression.

We present a simple example where an ambiguous expression overcounts whereas an unambiguous expression returns the correct result when transformed into matrix calculations:

Let $R = b^*a(bb^*a)^*a(a \cup b)^*$ and $S = (a \cup b)^*aa(a \cup b)^*$, which are both regular expressions for all strings containing aa as an infix. Using the PFA in Figure 1, we have:

$$\mathbb{IM}(b^*a(bb^*a)^*a(a \cup b)^*)\mathbb{F} \approx 0.153,$$

$$\mathbb{IM}((a \cup b)^*aa(a \cup b)^*)\mathbb{F} \approx 0.198.$$

This gap can be made arbitrarily large by adding ambiguity to the regular expression without changing the described language.

We now show that, given a PFA $\mathcal{P}$ and a DFA $\mathcal{D}$, we can compute the weight of $L(\mathcal{D})$ with respect to $\mathcal{P}$.

Lemma 1. *Let $\mathcal{P}$ be a PFA, $\mathcal{D}$ be a DFA and R be an unambiguous regular expression for $L(\mathcal{D})$ generated by state elimination. Then* $\mathbb{I}_{\mathcal{P}}\mathbb{M}_{\mathcal{P}}(R)\mathbb{F}_{\mathcal{P}} = \sum_{w \in L(\mathcal{D})} \mathcal{P}(w)$.

Proof. Let $\mathcal{D}$ have n states, labeled q_1 to q_n. We proceed as in (Book et al., 1971) by adding two new states, q_0 and q_{n+1}. We fill out the base case table α^0. We then construct a new table, β where $\beta^k_{i,j} = \mathbb{M}_{\mathcal{P}}(\alpha^k_{i,j})$. In other words, α holds the regular expressions generated during state elimination while β holds the corresponding matrices. Since α^0 contains only unambiguous regular expressions, $\mathbb{M}_{\mathcal{P}}(\alpha^0_{i,j})$ is the matrix corresponding to the sum of $\mathbb{M}_P(w)$ for all w that, starting from state q_i travel to state q_j without passing through any states with label greater than 0. We continue the elimination process until we reach α^n and β^n. The regular expression in $\alpha^n_{0,n+1}$ corresponds to the unambiguous regular expression containing all strings accepted by $\mathcal{D}$. Thus, the matrix stored in $\beta^n_{0,n+1}$ is the matrix such that

$$\mathbb{I}_{\mathcal{P}}\mathbb{M}_{\mathcal{P}}(\alpha^n_{0,n+1})\mathbb{F}_{\mathcal{P}} = \mathbb{I}_{\mathcal{P}}\beta^n_{0,n+1}\mathbb{F}_{\mathcal{P}} = \sum_{w \in L(\mathcal{D})} \mathcal{P}(w).$$

□

5 Incremental Infix Calculation

We now tackle the open problem of incrementally computing the infix probability of a string with respect to a PFA. Suppose we have computed the infix probability of a string w. We want to use the result of that computation to compute the infix probability of wa without simply starting the computation again from scratch. Such a calculation is relatively easy for other affixes. For the prefix probability of a string represented by the unambiguous regular expression $w\Sigma^*$, one can simply compute $\mathbb{IM}(w)\mathbb{M}(\Sigma^*)\mathbb{F}$ and save the vector $\mathbb{IM}(w)$. When the prefix is extended to wa, the saved vector can be multiplied by $\mathbb{M}(a)\mathbb{M}(\Sigma^*)\mathbb{F}$ and obtain the result (we can save the vector $\mathbb{IM}(w)\mathbb{M}(a)$ to use in future incremental calculations). A similar process works for the incremental suffix probability of a string ($\Sigma^* w$ to $\Sigma^* aw$). These incremental approaches are due to the inherent unambiguity of regular expressions for strings appearing as a prefix or suffix.

Unfortunately, the analogous method for infix probabilities is not as straightforward. We cannot simply append (or prepend) the desired character to a precomputed regular expression because the resulting expression may not be unambiguous or may represent the a different language. To tackle this problem, we first define the language $\mathcal{F}(w)$ to be the set of strings that end in the first occurrence of w. In other words,

$$\mathcal{F}(w) = \{x \mid w \text{ appears only as a suffix of } x\}.$$

It follows that $\mathcal{F}(w) \cdot \Sigma^*$ is exactly the set of strings containing w as an infix. Thus, given an unambiguous regular expression for $\mathcal{F}(w)$, we can build an unambiguous regular expression for the infix of w by concatenating with Σ^*.

Next, we find a regular language $\mathcal{L}$ such that $\mathcal{F}(wa) = \mathcal{F}(w) \cdot \mathcal{L}$ for a character $a \in \Sigma$, which gives rise to an incremental computation using the previous result $\mathcal{F}(w)$. Given two languages R and S, we define the *left quotient* $R \backslash S$ to be:

$$R \backslash S = \{y \mid \exists x \in R \text{ such that } xy \in S\}.$$

It is known that regular languages are closed under the left quotient operation (Hopcroft and Ullman, 1979).

Corollary 2 follows from the definition of the left quotient and describes the desired $\mathcal{L}$.

Corollary 2. *Given* $\mathcal{F}(w)$ *and* $\mathcal{F}(w) \backslash \mathcal{F}(wa)$*,* $\mathcal{F}(wa) = \mathcal{F}(w) \cdot \mathcal{F}(w) \backslash \mathcal{F}(wa)$*.*

We use this characteristic and compute $\mathcal{F}(w) \backslash \mathcal{F}(wa)$ without explicitly computing $\mathcal{F}(wa)$ based on state elimination—the procedure is detailed later in this section. Figure 2 is an annotated example of unambiguous regular expressions for $\mathcal{F}$ of a, aa, and aab.

$$\mathcal{F}(a) = b^*a$$

$$\mathcal{F}(aa) = \underbrace{b^*a}_{\mathcal{F}(a)} \cdot \underbrace{(bb^*a)^*a}_{\mathcal{F}(a)\backslash\mathcal{F}(aa)}$$

$$\mathcal{F}(aab) = \underbrace{b^*a(bb^*a)^*a}_{\mathcal{F}(aa)} \cdot \underbrace{a^*b}_{\mathcal{F}(aa)\backslash\mathcal{F}(aab)}$$

Figure 2: An example of $\mathcal{F}$ for a, aa, aab. We annotate them to show how $\mathcal{F}$ can be built up incrementally using previously computed regular expressions.

Let $\mathcal{D}$ be the DFA for $\mathcal{F}(w_1 w_2 \cdots w_n)$ generated by the KMP algorithm (Knuth et al., 1977). Two examples are depicted in Figure 3. $\mathcal{D}$ has $n + 1$ states, with state q_{n+1} being final and having no outgoing transitions. Furthermore, each state q_i with $i < n + 1$ has exactly one outgoing transition to state q_{i+1} and all other transitions are to states with labels at most i. Thus, removing state q_{n+1} and all incoming and outgoing transitions and making q_n the only final state results in the DFA for $\mathcal{F}(w_1 w_2 \cdots w_{n-1})$. This process can be repeated until the empty string is reached. This leads to the observation that, when constructing an unambiguous expression for $\mathcal{F}(w_1 w_2 \cdots w_n)$, we can recover the expression for $\mathcal{F}(w_1 w_2 \cdots w_{n-1})$ extracting the regular expression at $\alpha_{0,n}^{n-1}$. Similarly, the expression for $\mathcal{F}(w_1 w_2 \cdots w_k)$ is stored at $\alpha_{0,k+1}^{k}$.

At stage k of the state elimination procedure on $\mathcal{D}$, state q_0 is only connected to states up to label $k - 1$, thus $\alpha_{0,k+1}^{k-1} = \emptyset$. Since

$$\alpha_{0,k+1}^{k} = \alpha_{0,k+1}^{k-1} + \alpha_{0,k}^{k-1}(\alpha_{k,k}^{k-1})^* \alpha_{k,k+1}^{k-1},$$

we can simplify the expression as

$$\alpha_{0,k+1}^{k} = \alpha_{0,k}^{k-1}(\alpha_{k,k}^{k-1})^* \alpha_{k,k+1}^{k-1}.$$

In addition, we recall

$$\alpha_{0,k}^{k-1} = \mathcal{F}(w_1 w_2 \cdots w_{k-1}).$$

Therefore,

$$\mathcal{F}(w_1 \cdots w_k) = \mathcal{F}(w_1 \cdots w_{k-1})(\alpha_{k,k}^{k-1})^* \alpha_{k,k+1}^{k-1}$$

and

$$(\alpha_{k,k}^{k-1})^* \alpha_{k,k+1}^{k-1} = \mathcal{F}(w_1 \cdots w_{k-1}) \backslash \mathcal{F}(w_1 \cdots w_k).$$

Algorithm 2 is for the offline setting—we know the entire string ahead of time and compute the infix probabilities of each of its prefixes incrementally. In Algorithm 2, following Section 3 and the relationship between the tables α and β in the proof of Lemma 1, we run the matrix evaluations of each regular expression instead of the

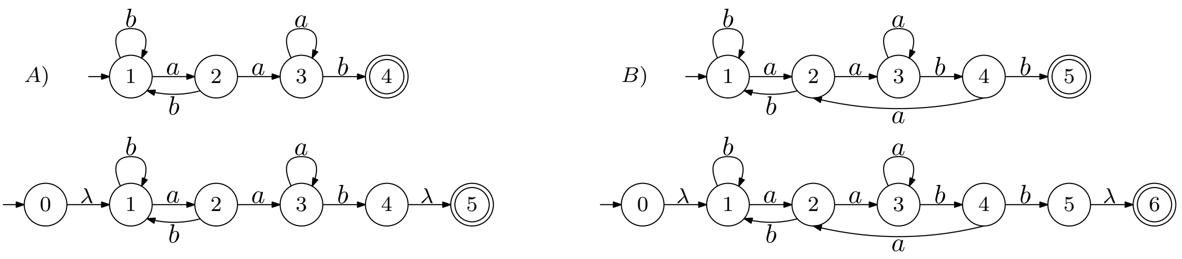

Figure 3: DFAs generated by the KMP algorithm. DFA A) accepts $\mathcal{F}(aab)$ and B) accepts $\mathcal{F}(aabb)$. The automata below are the new finite automata after adding the new initial and final state for the state elimination procedure, as described in Section 3.

regular expressions directly. At any step k, we only consider tables α^k and α^{k-1} and, thus, we can employ a standard sliding window technique for dynamic programming to reduce the required space complexity. In this scheme, instead of holding all tables up to α^k, we simply hold the two most previous ones, reducing the space complexity required by a factor of $O(k)$. We call our two tables T and T' and, to simplify the pseudocode, make elements of these two tables behave as both matrices and regular expressions. For example, $(T_{i,j})^*$ simultaneously corresponds to the regular expression $(\alpha_{i,j})^*$ and the matrix $\mathbb{M}((\alpha_{i,j})^*) = (\mathbf{1} - \mathbb{M}(\alpha_{i,j}))^{-1}$.

18:         end for
19:         $T \leftarrow T'$
20:     end for
21: end procedure
```

Algorithm 2 begins by constructing DFA for $\mathcal{F}(w)$, which takes linear time in the length of w (Knuth et al., 1977) on Line 2. This DFA is modified to contain the new start and end state as described in Section 3 for a total of $n + 3$ states. We then begin to step through the state elimination algorithm. After constructing the initial table based on the base cases described in Section 3 from Line 3 to 10, we prepare our vector $\mathbb{V}$ that will record results from the previous infix calculation. At the beginning, $\mathbb{V}$ should hold $\mathbb{IM}(\mathcal{F}(\lambda)) = \mathbb{I}$. In the first step, we eliminate state q_1 of the automaton. Since state q_0 leads to state q_1 with a λ-transition, $\mathcal{F}$ at this step corresponds to $\mathcal{F}(\lambda)$ and $\mathcal{F}(\lambda) \cdot \Sigma^* = \Sigma^*$, which trivially has infix probability 1. At stage k of the for loop, we compute $\mathcal{F}(w_1 w_2 \cdots w_{k-1}) \backslash \mathcal{F}(w_1 w_2 \cdots w_k)$ on Line 13. We multiply this by $\mathbb{V}$, which holds $\mathcal{F}(w_1 w_2 \cdots w_{k-1})$, which makes $\mathbb{V}$ now store $\mathcal{F}(w_1 w_2 \cdots w_k)$. On Line 14, we emit the infix probability of $w_1 w_2 \cdots w_k$ by evaluating $\mathbb{V}\mathbb{M}_{\mathcal{P}}(\Sigma^*)\mathbb{F}_{\mathcal{P}}$. From Line 15 to 18, we update our state elimination table. On Line 19, we use the sliding window technique and copy our updated table into T which allows for T' to be safely overwritten in the next iteration. This process repeats until we have removed all states q_i for $1 \leq i \leq n+1$, and therefore have computed the infix probability of each prefix of w.

The loop starting on Line 12 executes $O(|w|)$ times since the automaton has $|w| + 3$ states. At each iteration, we recompute the state-elimination table, which has size $O(|w|^2)$. For each element of the table we must perform one matrix addition, two matrix multiplications, and one matrix inverse on the matrices from the PFA, which has overall time complexity $O(|Q|^m)$. Thus, the runtime of Algorithm 2 is $O(|w|(|w|^2|Q|^m)) = O(|w|^3|Q|^m)$, where m is the matrix multiplication constant. Throughout the computa-

tion, we generate a series of tables of size $O(|w| \times |w|)$ with elements of size $O(|Q_{\mathcal{P}}| \times |Q_{\mathcal{P}}|)$. However, since we use the sliding window technique, we only save $O(1)$ of these tables, leading to an overall space complexity of $O((|w||Q_{\mathcal{P}}|)^2)$. Note that the space complexity matches that of the intersection method, but the time complexity of the incremental method is asymptotically faster; $O(|w|^3|Q_{\mathcal{P}}|^m)$ compared to $O(|w|(|w||Q_{\mathcal{P}}|)^m) = O(|w|^{m+1}|Q_{\mathcal{P}}|^m)$.

6 Experimental Results

We verify the effectiveness of our method using real-world data. We present 3 n-grams[3] (two 2-grams and one 3-gram) and their 3 PFAs with 614, 1028, and 1455 states extracted from the Brown Corpus tagged with the Penn Tree Bank tagset using the NLTK library (Bird and Loper, 2004). As a preprocessing step, we convert all punctuation to the `PUNC` tag for a total of 35 tags. The n-grams are built by computing the probability of reading a given tag under the condition that we have just seen a specific sequence of n tags. We then randomly select a sequence of 9 tags as our string across all experiments. For each of the n-grams, we calculate the infix probability of each prefix of our input string using the incremental regular expression method and the intersection method. We record the average of 10 runs per infix calculation. All experiments were written in Python 3.5 and the automata and matrices were implemented using NumPy. The experiments were run on an AMD Ryzen 7 1700 (3.0 GHz) 8-Core Processor with 16GB of RAM.

In the worst-case (the case when $|Q| = 1028$ in Table 1), the cumulative time for the incremental shows an 556.77% speed-up. The largest individual infix probability calculation is in the experiment with $|Q| = 1455$ when calculating the infix of length 9, where the incremental method obtains a 560.76% speed-up. These results show that the incremental method is not only theoretically faster, but also much faster in practice when compared to the intersection method.

The runtime gap is quite large compared to what is expected from the theoretical analysis of the two algorithms. Additionally, in theory, the time for each step of the incremental calculation should remain essentially constant, but the experimental results show that it grows at a slow rate. These are most likely implementation issues stemming from the large memory requirements involved in the calculations.

The experimental results show that the incremental infix method vastly outperforms the naive intersection method. The ability to memoize previous calculations allows the incremental approach to calculate the next infix probability much faster than simply restarting the entire calculation. This empirically verifies the asymptotic analysis of the two approaches.

7 Conclusions

We have presented a new method for solving the open problem of incrementally computing the infix probabilities of a given string with respect to a PFA. Our method utilizes unambiguous regular expressions and is distinguished from the previous

---

[3] We have a similar performance improvement for all other test cases that we extract from the dataset.

methods in that it does not alter the structure of the PFA during the evaluation. Similarly to the algorithm presented in (Nederhof and Satta, 2011a), this method imposes no restrictions on the input string.

We have showed that our method is asymptotically faster than the previously best-known method. Furthermore, we have experimentally evaluated the performance of our algorithm on a real life dataset and have observed that the proposed algorithm performs significantly better than the intersection method in all cases.

Future directions of this line of research are to determine a method for two sided incremental infix computation—that is, given a computation for the infix of w, compute the infix of wa or aw at will. Currently, it is only possible to do one sided incremental infix calculations. Computing the infix incrementally in an online fashion—in which we do not know the entire string ahead of time and receive new characters in a stream—would be another improvement. We believe that the current method can be modified to work in an online setting, possibly with an increase in runtime. Furthermore, finding new classes of problems that can benefit from a similar incremental calculation is also interesting. Finally, extending this method to work for PCFGs and more complex probabilistic models is an important open problem.

Abstract

We propose a novel strategy to encode the syntax parse tree of sentence into a learnable distributed representation. The proposed syntax encoding scheme is provably information-lossless. In specific, an embedding vector is constructed for each word in the sentence, encoding the path in the syntax tree corresponding to the word. The one-to-one correspondence between these "syntax-embedding" vectors and the words (hence their embedding vectors) in the sentence makes it easy to integrate such a representation with all word-level NLP models. We empirically show the benefits of the syntax embeddings on the Authorship Attribution domain, where our approach improves upon the prior art and achieves new performance records on five benchmarking data sets.

1 Introduction

Syntactic parse information plays an essential role in interpreting natural languages because natural language sentences are typically structured in a linguistic grammar. As such, in many NLP applications it is desirable to extract syntactic features from text or sentences, for which there exist a rich body of literature (Baayen et al., 1996; Hirst, 2007; Massung et al., 2013; Wang et al., 2015; Socher et al., 2011; Zhu et al., 2015b; Tai et al., 2015; Zhu et al., 2015a)

To date, existing approaches to exploit syntactic information can be categorized into two categories. The first category may be regarded as "syntactic feature engineering". In such approaches, certain properties or statistics are extracted from the syntax parse tree of a sentence as the syntactical feature. For example, the extracted feature may include the depths of the tree, frequency of certain structural patterns in the tree and so on (Massung et al., 2013; Wang et al., 2015). The advantage of such a method is that the extracted feature can be used for any kind of classifier, if the feature is deemed relevant to the classification task. The limitation of such an approach is however that rich structural information contained in the syntax tree is lost in the feature extraction process. Additionally, with such a strategy, the model designer is often required to design syntactic feature extractors specific for his tasks.

The second category may be regarded as "syntax-assisted sentence coding". This category of approaches build upon neural network models. Examples of such approaches include Tree-LSTM (Tai et al., 2015; Zhu et al., 2015b) and Recursive Neural Networks (Socher et al., 2011), in which the networks are structured according to the syntax tree of the input sentence. The network, after being trained, is capable of encoding a sequence of word embeddings, in a bottom-up manner, to a vector representing the entire sentence. It is worth noting that with these approaches, the encoded feature vector, although containing syntactical information, mainly serves as a *semantic* representation of the input sentence, and the syntactic information exploited therein primarily serves to assist the semantic representation. Additionally, such an approach is not flexible enough to be integrated with another popular class of NLP models, CNN.

One motivation of this work is to develop a generic representation of the parse structure of sentences. Ideally, we would like the representation to maximally preserve the syntactical information and can be integrated easily with any neural network NLP models. This latter requirement is particularly desirable, in light of the competitive performance of CNN and their advantages in training efficiency.

Another motivation of this work is the application of Authorship Attribution (AA) (Hirst, 2007; Stamatatos, 2009; Ouamour and Sayoud, 2012; Stamatatos, 2011; De Vel et al., 2001; Rocha et al.,

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2742–2753
Brussels, Belgium, October 31 - November 4, 2018.

2017b; Binongo, 2003; Sohn et al., 2015; Shrestha et al., 2017b). In this application, one is to extract information from a document so as to infer the document's author, from a given list of candidates. There have been a variety of use cases of AA in practice, which include, amongst many others, plagiarism detection (Stamatatos and Koppel, 2011), forensics (Rocha et al., 2017a), suicidal note verification (Chaski, 2005), and intelligent question answering (Stamatatos, 2006). In this application, previous works have mostly focused on building a classifier based on content-level features. The hypothesis underlying our approach to AA in this paper is that syntactic information is a useful additional feature that can characterize an author. This is not only because that syntactical information complements the document content in language understanding, it is also due to the fact that different authors may construct sentences with varying distributions of syntactical structures. In a sense, the "syntactical pattern" of an author may characterize in part the "writing style" of the author, which is independent of the content he writes and the semantics of the document.

To that end, we propose a novel strategy to encode the syntax parse tree of sentence into a learnable distributed representation. Briefly, in this representation, an embedding vector is constructed for each word in the sentence, encoding the path in the syntax tree corresponding to the word. The one-to-one correspondence between these "syntax-embedding" vectors and the words (hence their embedding vectors) in the sentence makes it easy to integrate such a representation with all word-level NLP models.

The proposed syntax encoding scheme has a remarkable property, namely that it is provably information-lossless, as long as the syntax embedding space has adequate dimension. This property also distinguishes the proposed scheme from other distributed representations of syntax.

We apply the proposed syntax encoding approach to the state-of-the-art CNN-based AA model and evaluate its performance over five benchmarking datasets. Experimental study verifies the effectiveness of the proposed syntax encoding scheme. In fact, over all five datasets, syntax-augmented CNN model demonstrates new state-of-the-art performance.

2 Related Work

The aim of the related work here is twofold: syntax encoding and authorship attribution.

2.1 Syntax Encoding

Including syntactic parse information to benefit NLP models have been actively investigated in decades. Syntactic feature engineering refers to efforts to statically extract domain specific features from syntax parse tree of the given text (Massung et al., 2013; Wang et al., 2015). Recent attempts also include leveraging syntactic parse tree structure to recursively generate sentence representations bottom-up (Socher et al., 2011; Zhu et al., 2015b; Tai et al., 2015; Zhu et al., 2015a).

Both the above two categories of methods have severe limitations. The former parse representation typically fails to encode the parse tree structure, and the latter is constrained by the tree structures favored by the parser. Furthermore, the recent distributed word embedding techniques, such as Glove (Pennington et al., 2014) and W2V (Mikolov et al., 2013), have been shown to encode limited syntax knowledge of the given corpus (Andreas and Klein, 2014). This shortcoming has also promoted recent research on creating syntax-aware word embedding, which enhances the distributed embedding vectors with position information of the word within its surrounding context (Cheng and Kartsaklis, 2015), which again encodes limited syntax information.

Our syntax embedding method overcomes the above mentioned limitations, as previously discussed in Section 1.

2.2 Authorship Attribution

Various AA models make use of SVM classifiers on some carefully engineered lexical or syntactic feature. These works include (Pillay and Solorio, 2010; Varela et al., 2011; Segarra et al., 2013; Seker et al., 2013; Seroussi et al., 2010; Castillo et al., 2015). In many of these models and among many others (e.g., (Koppel et al., 2009; Peng et al., 2003; Apté et al., 1994)), character n-grams are chosen as an important feature.

Recently, researchers have relied on CNN to extract features automatically. In (Ferracane et al., 2017), for instance, a CNN is used on 2-gram embeddings to learn the discourse information for the AA task. In (Shrestha et al., 2017b), a CNN is employed on n-gram embeddings to learn richer

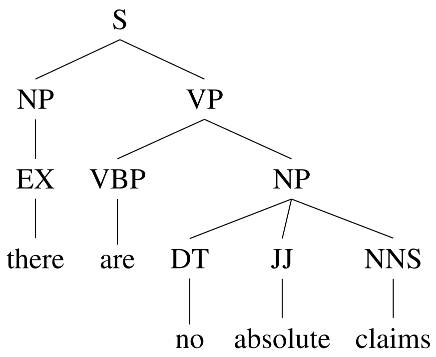

Figure 1: Syntax Tree Example

Words	Syntax Path
there	S→NP→EX
are	S→VP→VBP
no	S→VP→NP→DT
absolute	S→VP→NP→JJ
claims	S→VP→NP→NNS

Table 1: Syntax Path Example

features. A study by (Tang, 2013) considers using SVM as an activation layer for the CNN, replacing the soft-max layer. Nevertheless, a small performance advantage is demonstrated by the method at a high computation cost.

Our proposed model, apart from syntax encoding, is the most close to the CNN architecture of (Shrestha et al., 2017b) where n-grams are used to extract global content information representing content features. The detailed model architecture will be given in a later section.

3 Syntax Encoding

The syntactical structure of a given sentence can be uniquely represented by a tree, which we refer to as the *syntax tree*. An example of such a syntax tree is given in Figure 1. As seen in the example, a syntax tree has labeled nodes. Specifically, the label of each node is a "syntax token", such as `S`, `NP`, `VP`, etc., representing the grammatical property of the word sequences covered by tree branches underneath the node. For example, the root of the tree is always labeled by `S` ("sentence"), and the branches underneath the tree cover the entire sentence. On the other hand, the labels for terminals or leafs of the tree, such as `EX`, `VBP`, `JJ` etc., correspond to "part-of-speech" tags of each word in this sentence. We will denote by $\mathcal{T}$ the set of all syntax tokens.

Given this syntactic tree structure for a sentence s, each word w in sentence s has a unique path in the tree leaving the root and arriving at a terminal. Such a "syntax path" for the word w can then be represented by a sequence of node labels along the path. Some examples of syntax paths are given in Table 1. The following lemma is easy to verify.

Lemma 1 *Let a sentence s be written as a sequence of words $(w_1, w_2, \ldots, w_n)$. For each word position $i = 1, 2, \ldots, n$, let $r(w_i)$ denote the syntax path of word w_i. Let $\mathcal{R} := \{(i, r(w_i)) : i = 1, 2, \ldots, n\}$ be an (unordered) set containing precisely all syntax paths for the words in s. Then the syntax tree of s can be uniquely recovered by $\mathcal{R}$.*

In the lemma, we note that $\mathcal{R}$ is an unordered set. That is, regardless of the ordering of the paths in $\mathcal{R}$, one can always recover the syntax tree from $\mathcal{R}$.

Let $r(w)$ be the syntax path of a word w in the sentence s of interest. Specifically, $r(w)$ can be written as the sequence $(t_1, t_2, \ldots, t_L)$, where L is the number of nodes in the path r, and each t_i is a syntax token.

Let the Euclidean space $\mathbb{R}^K$ be the embedding space which we will use to encode syntax. We now describe a method that encodes the path $r(w)$ into a vector $\overline{r(w)} \in \mathbb{R}^K$.

Let $L_{\max}$ be maximum depth of the syntax trees in the corpus. For each $i = 1, 2, \ldots, L_{\max}$, let $\overline{p}_i$ be a vector in $\mathbb{R}^K$ serving as the embedding for integer i. Here integer i is meant to indicate the location of a token in a syntax path. For each $t \in \mathcal{T}$, let $\overline{t}$ also be a vector in $\mathbb{R}^K$, serving as the embedding for syntax token t. Let vector $\overline{r(w)} \in \mathbb{R}^K$, the embedding of path $r(w)$, be defined by

$$\overline{r(w)} := \sum_{t_j \in r(w)} \overline{t}_j \circ \overline{p}_j \tag{1}$$

where $\circ$ is the element-wise product operation. For example in Table 1, the syntax path for word "there" will have embedding $\overline{\mathrm{NP}} \circ \overline{p}_1 + \overline{\mathrm{EX}} \circ \overline{p}_2$; the syntax path for word "no" will have embedding $\overline{\mathrm{VP}} \circ \overline{p}_1 + \overline{\mathrm{NP}} \circ \overline{p}_2 + \overline{\mathrm{DT}} \circ \overline{p}_3$. Note that when embedding a syntax path, the beginning token S is removed from the path since it exists in every path.

Lemma 2 *There exists a random assignment of the vectors $\{\overline{t} : t \in \mathcal{T}\}$ and $\{\overline{p}_i : i = 1, 2, \ldots, L\}$ such that the syntax path $r(w)$ can be recovered from its embedding $\overline{r(w)}$ almost surely for sufficiently large K.*

This lemma (proof given in Appendix) suggests that as long as we choose a sufficiently large embedding dimension K, the above introduced encoding for syntax paths is essentially lossless. Thus, for a given n-word sentence $s = (w_1, w_2, \dots, w_n)$, if we collect the embedding vectors $\overline{r(w_1)}, \overline{r(w_2)}, \dots, \overline{r(w_n)}$ of all syntax paths and list them as the columns of a $K \times n$ matrix, then by Lemmas 1 and 2, the syntax tree of s can be recovered from the matrix. Such a matrix is then an information lossless encoding of the syntax tree.

We note however that in practice, when the tokens embeddings and the position (integer) embeddings are learned, there is no longer a guaranty that a syntax path can be recovered from its embedding. This is particularly the case for supervised tasks. During the training for such tasks, the information irrelevant to the training objective is necessarily "squeezed out", and the representations of those syntax paths that provide no distinguishing features are "pulled closer". This will cause these paths non-distinguishable (and hence non-recoverable) from their embeddings. This is also the reason that in practice there is no need to have very large embedding dimension K.

Nonetheless, since different supervised tasks may have distinct training objectives, a "lossy" syntax encoding suitable for one task may prove ineffective for other tasks. Thus it is still essential to adopt an information-lossless encoding framework, as we propose in this paper, that is universally applicable.

Next, we will discuss the application of our syntax encoding approach to AA models.

4 Authorship Attribution Model

4.1 Problem Definition

The objective of Authorship Attribution is to develop a classifier that predicts the authors of unseen documents based on a given set of documents and their corresponding authors. Despite the previous successes in solving the AA problem discussed in a previous section, we argue that the syntactic parse information in an author's writing can characterize in part the "writing style" of the author. Specifically, even when writing the same content, two authors may prefer using different syntax structure in constructing their sentences. Consider the following two sentences.

A1: Take a left at the end of the street, you will see the house.

A2: You will see the house, if you go down to the end of the street and take a left.

The two sentences have the same meaning and yet two different authors may favor different ones over the other. This provides opportunity for leveraging such syntactical information as an additional feature, beyond the lexical and semantic features, to distinguish the two authors.

Detecting the syntactical differences among authors suits well the application scope of the proposed syntax encoding scheme. As such, in this work, we will use the AA problem as an test bed to examine the effectiveness of our scheme.

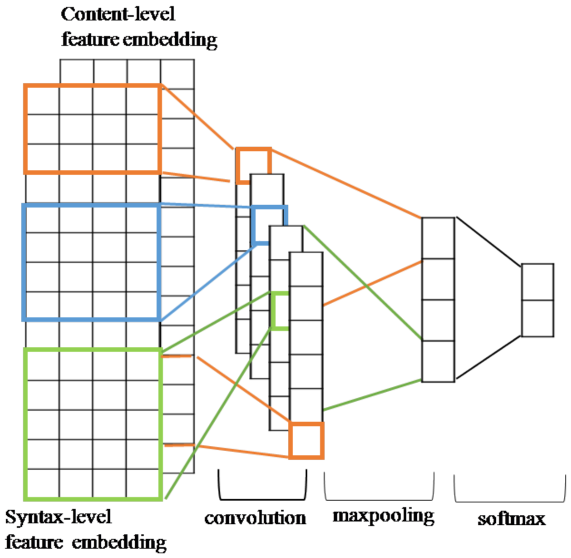

Figure 2: Single Layer CNN Architecture

4.2 Syntax-augmented CNN Model

The overall architecture of our model is shown in Figure 2. Our model takes advantage of the expressive power of convolutional neural networks(CNNs) to learn the embeddings for both of the content-level features and the syntax-level features. The model consists of 5 types of layers: *Syntax-level feature embedding, Content-level feature embedding, Convolution, Max-pooling* and *Softmax*.

4.2.1 Overall Structure

The model takes both the context-level features and the syntax-level features as the input.

As the character n-gram features have been used successfully in both of the text classification tasks (Kim, 2014; Chen et al., 2017) and the AA tasks (Shrestha et al., 2017b; Sapkota et al., 2015; Shrestha et al., 2017a; Sari et al., 2017; Ruder et al., 2016), in this study, we use the character n-grams to represent the content-level features.

We align in tandem the embedding vectors of consecutive n-grams of a document to form a content-level embedding matrix, and the consecutive syntax-path embeddings of each word to form the syntax-level embedding matrix. These embedding matrices are individually passed to 2 parallel CNNs having different filter lengths. The convolutional layer outputs feature maps via convolutional filtering. The max-pool layer is then applied across different feature maps to form the content-level and syntax-level representation of a document respectively. These two representations are then concatenated to form the final feature vector characterizing the author of the document. Finally, this feature vector is passed to a learnable softmax layer. The number of outputs of the softmax layer is the number of authors, which the i^{th} output is the probability that the document written by author i.

4.2.2 Convolution and Max-pool

In the convolutional layer, we capture local contextual information using kernels, which combine the vectors within it's window as it slides over the embedding matrix. A linear transformation processes the output of the kernel.

We present a clean description for this operation. Let $E \in \mathbb{R}^{k \times d}$ be the embedding matrix containing embeddings $e_{1:k}$, where $e_i \in \mathbb{R}^d$ is the i-th embedding in E, l is the number of filters and w is the filter length or window size. Let $F \in \mathbb{R}^{w \times d}$ be the filter matrix and a bias vector b. We define the vector $g_i \in \mathbb{R}^{w \times d}$ as the concatenation of w embeddings in the i-th window, where

$$g_i = e_{i-w+1:i} \quad 1 \leq i \leq k+w-1 \tag{2}$$

The result of filter F across embedding matrix E outputs a feature map $f_j \in \mathbb{R}^d$ for the j-th kernel where the i-th value of f_j is computed as

$$f_{ji} = F \otimes g_i + b \tag{3}$$

where $\otimes$ denotes the convolution operator. Let $f \in \mathbb{R}^{l \times d}$ denote the concatenation of the l feature maps for compactness. Further to this, we apply a ReLU activation function before passing the output to the max-pool layer. Given l filters of different dimensions, we obtain l feature maps. Each feature map encodes different types of abstract contextual information globally for the matrix E. To obtain the most relevant features from each dimension of the feature maps, we max-over feature map dimensions expressed as:

$$m_i = max(f(\cdot, i)), \quad 1 \leq i \leq d \tag{4}$$

where m_i represents the maximum value for dimension i across the l feature maps. The feature vector m from the max-pool operation is the concatenation of all m_i. For our 2 CNN's we obtain a content-level vector representation and a syntax-level representation for an author's text. We denote $\bar{m} \in \mathbb{R}^t$ as the concatenation of these 2 vectors representing an author's style. We obtain the confidence of an author's attribution to a text by feeding this final vector to a softmax layer. In the next section, we give a brief description of the softmax layer.

4.2.3 Softmax Layer

Given a text input x and CNN parameters θ, this layer outputs a score for all n authors. The output of the softmax layer is a vector with dimension equal to the number of author labels. To compute the confidence of author's attribution, the author's style representation $\bar{m}$ is transformed by a transformation matrix $W \in \mathbb{R}^{n \times t}$.

$$o = W\bar{m} \tag{5}$$

where the i-th component of o corresponds to the confidence score of author i. A softmax operation is called on o to compute the conditional probability for each dimension. This is calculated by:

$$p(i|x, \theta) = \frac{e^{o_i}}{\sum_{j=1}^{n} e^{o_j}} \tag{6}$$

To train our model, the log-likelihood of the probability should be maximized. To predict the attribution of authors, the label with the highest probability is selected. For the optimization of our model, we use SGD algorithm to solve the optimization problem.

We denote our syntax augmented CNN model as Syntax-CNN.

5 Experimental Studies

We first empirically show the predictive performance of the Syntax-CNN strategy, which establishes new state-of-the-art accuracy for several

benchmarking data sets. We then provide ablation studies, aiming at better understanding the contributions of the syntax embeddings to the Syntax-CNN method.

5.1 Experimental Setup

5.1.1 Datasets

We test the Syntax-CNN approach on several benchmarking datasets. Summary statistics of the datasets are in Table 2.

CCAT10: 100 newswire stories, written by 10 authors, in English taken from Reuters Corpus Volume 1 (RCV1) (Stamatatos, 2008).

CCAT50: Same as CCAT10 but with 100 news article written by 50 authors.

IMDB62: 62,000 movie reviews and 17,550 message posts from 62 prolific authors obtained from Internet Movie Database(IMDb) (Seroussi et al., 2010).

Blogs10: The original data set contains 681,288 blog posts by 19,320 bloggers for blogger.com. Posts written by the top ten bloggers are selected for the Blogs10 data set (Schler et al., 2006).

Blogs50: Same as Blogs50 but with the posts written by the top 50 bloggers.

5.1.2 Compared Prior Art

We compare our method with various baseline approaches, which represent the current art in the AA problem. They include SCAP (Frantzeskou et al., 2007), SVM with 2,500 most frequent 3-grams (Plakias and Stamatatos, 2008), SVM with bag of local histogram (Escalante et al., 2011), Imposters (Koppel et al., 2011), LDAH-S (Seroussi et al., 2011),SVM with affix and punctuation 3-grams (Sapkota et al., 2015), CNN-char (Ruder et al., 2016), Continuous n-gram representation (Sari et al., 2017), and N-gram CNN (Shrestha et al., 2017a). Except the last two methods, all the results reported in this paper were obtained from their respective papers. In all our experiments, we partitioned the datasets into train/dev/test in the same way as are used in the literature in order for fair comparison.

5.1.3 Hyperparameters and Training

Our experimental setup follows that of the current state-of-the-art AA method (Shrestha et al., 2017b). In specific, the networks are trained using mini-batches with size of either 16 (for IMDB62,Blogs10 and Blogs50) or 32 (for CCAT10 and CCAT50). We use 3-gram with embedding size of 300 for character, and embedding size of 60 for syntax vector; these embeddings are randomly initialized. We apply Adagrad (Duchi et al., 2011) with initial learning rate of 1e-4. For the CNN, we use filter sizes of 3, 4, and 5 with 50 feature maps for syntax embedding; 500 dimensional character embedding for CCAT, IMDB, and Blogs50, and 200 for Blog10. We train for at most 300 epochs, with a dropout rate of 0.25. We deploy early stop strategy for the training using a validation data set, which contain 10% of the randomly selected samples from the training set. We stop the training when the validation loss goes up.

In our experiments, we use the Stanford CoreNLP parser. For documents contain more than one sentences, each sentence is parsed separately. The syntax encoding for each word is done according to its syntax path in syntax tree containing the word. The syntax embeddings of all words in the document form the input matrix to the CNN responsible for extracting syntactical features.

5.2 Predictive Performance

Table 3 presents the accuracy obtained by various testing methods on the five benchmarking datasets, where the best result of each data set is highlighted in bold.

5.2.1 Accuracy Obtained by Syntax-CNN

Results in Table 3 indicate that the Syntax-CNN outperformed all the testing methods on the five benchmarking datasets, beating the current best records on these testing AA tasks. Our further

analysis also shows that, the predictive improvement on some datasets is large. For example, against the CCAT50 and Blogs50 datasets, the relative error reductions over the current state-of-the-art result are 5.5% and 3.64% , respectively.

5.2.2 Contribution of Syntax Encoding

We also include the accuracy obtained by using the syntax embeddings alone on the second last row in Table 3. These results indicate that using only the syntax style embeddings achieved very low accuracy on some of the datasets, for example, with only 10.08% on the CCAT50 dataset. As shown in Table 4, the CCAT50 is, indeed, one of hardest datasets, as judged by the Hemingway Editor tool [1], which aims to measure the syntax correction of a given piece of text. Nevertheless, such syntax style embeddings can bring significant accuracy gain to the CNN strategies. As shown in Table 3, for the CCAT50 dataset, a relative error reduction of 5.5% (which represents the largest error reduction of the five testing datasets) was achieved by Syntax-CNN over the best performed CNN model, i.e., the N-gram CNN. Similar behavior can also been observed for the CCAT10 dataset as shown in Tables 4 and 3. These results suggest that the Syntax-CNN may favor sentences with syntax difficulties.

We also provide, in Table 5, further information about the percentage of classifications corrected or mislabeled when enabling the syntax style embeddings in the Syntax-CNN method on both the CCAT10 and CCAT50 datasets. Table 5 clearly indicates that with the syntax style embeddings deployed, the Syntax-CNN was able to, respectively for the CCAT10 and CCAT50 datasets, correct 43.48% and 37.7% of the testing examples which were mislabeled when the syntax embeddings was disabled in the Syntax-CNN.

data set	**CCAT10**	**CCAT50**
wrong-to-correct	43.48%	37.7%
correct-to-wrong	4.87%	6.1%

Table 5: Percentage of classifications corrected (wrong-to-correct) or mislabeled (correct-to-wrong) when using the syntax style embeddings.

5.2.3 Syntactic Style Examples

The contributions of the syntax information is further justified by examining documents whose classifications are corrected when enabling the syntax embedding of the Syntax-CNN. For example, the following two excerpts, extracted from documents written by two different authors, share great semantic similarity. But they show a difference in

---

[1] http://www.hemingwayapp.com

terms of syntax information contained. In particular, the former is constructed by deep parse trees, but the later has a succinct parse tree structure.

> author1:
>
> China's long-delayed bid to enter the World Trade Organization will fall under the spotlight when the world's richest nations meet to discuss its application this week. United States says Beijing must comply with a "road map" to open its markets and eliminate trade and non-trade barriers before it can win U.S. support for its entry.
>
> author2:
>
> China must make real changes to its economy if it wants to join the World Trade Organization and should replace anti-U.S. rhetoric with international cooperation.

Using the two documents containing these two excerpts, we perform a separate small experiment. When we remove syntax encoding and its corresponding feature from Syntax-CNN, the model fails to classify the authors of the two documents. But when syntax encoding is included, the model can distinguish the two authors. Additionally, on the syntax encoding side, when we only keep the syntax path encoding for these two excerpts in their respective documents and remove all other sentences from the two documents, Syntax-CNN is still able to classify the two authors correctly.

This suggests that syntactic information is indeed useful for authorship attribution, and Syntax-CNN is able to extract such information effectively.

5.3 Model Behaviors

This section aims to further evaluate the behaviors of the Syntax-CNN model.

5.3.1 Sensitivity to Syntax Embedding Dimension

To understand the impact of the embedding size of the syntax tree in the Syntax-CNN method, we conduct further experiments on the Blogs50 dataset. We vary the dimension of the syntax tree embedding, from 5 up to 150. The experimental results are reported in Table 6.

Table 6 shows that Syntax-CNN is robust to the dimension size of syntax style embedding. The lowest accuracy was obtained by Syntax-CNN with an embedding dimension of 150. Although we have noted earlier that using a higher syntax embedding dimension allows the syntactical information to be better preserved. A downside of such a choice is however the risk of overfitting, which is expectedly the cause of the degradation of the performance at dimension 150. Note that even in this case, the performance of Syntax-CNN is still higher than the current state-of-the-art accuracy of 53.09% achieved by the N-gram CNN.

dimension	**Syntax-CNN**
5	54.96
30	55.86
60	56.82
100	56.42
150	53.34

Table 6: Accuracy obtained by Syntax-CNN on the Blogs50 while varying the syntax style embedding dimension.

data set	**with**	**without**
Blogs50	56.73	55.05
Blogs10	64.10	62.70

Table 7: Accuracy obtained by Syntax-CNN with and without position vector.

5.3.2 Impact of Position Vector

We further evaluate the impact of the position embedding vectors (i.e., the $\overline{p}_j$ vectors in Section 3) in syntax encoding. We conduct experiments on both the Blogs10 and Blogs50 datasets with and without the position embedding. In particular, by "without position", we mean that the element-wise multiplication with the $\overline{p}_j$ is removed from equation (1) in Section 3. The results are reported in Table 7.

Table 7 indicates that the position vectors play an important role in capturing syntactical information. In fact, it is possible to prove that without multiplying with the position vectors, in general the syntax tree is no longer recoverable from the encoding $\overline{r(w)}$ of syntax path $r(w)$. Additionally, the results in Table 7 suggest that depth information in the syntax tree is an important feature for distinguishing the writing styles of the authors.

6 Conclusion

We propose a novel strategy to encode a syntax tree into a learnable distributed representation.

This representation can be easily integrated into any NLP neural network model and entails no loss of information. Using this representation as an additional input, we extend the CNN architecture introduced in (Shrestha et al., 2017b) for the authorship attribution problem. Experimental evaluation of the extended model on the standard author attribution datasets demonstrates the effectiveness of the proposed syntax encoding approach. Record-breaking performances are obtained.

Appendix: Proof of Lemma 2

We first establish some elementary results.

Lemma 3 *Suppose that random variables* X, Y, Z, U *are independent standard normal random variables. Then*

1. $\mathrm{E}(XYZU) = 0$ *and* $\mathrm{VAR}(XYZU) = 1$.
2. $\mathrm{E}(X^2YZ) = 0$ *and* $\mathrm{VAR}(X^2YZ) = 3$.
3. $\mathrm{E}(X^2Y^2) = 1$ *and* $\mathrm{VAR}(X^2Y^2) = 8$.

These results follow from the independence among (X, Y, Z, U) and the fact that the square of a standard normal random variable is a Chi-Square random variable.

We now construct a random assignment scheme and a recovery scheme.

Random Assignment: Generate each vector in $\{\overline{t} : t \in \mathcal{T}\}$ and in $\{\overline{p}_i : i = 1, 2, \ldots, L_{\max}\}$ by assigning independent values drawn from a standard normal distribution.

Recovery Scheme: Let a path embedding $\overline{r(w)}$ be given. For each token-integer pair $(u, i) \in \mathcal{T} \times \{1, 2, \ldots, L_{\max}\}$, compute vector $\mathbf{a} \in \mathbb{R}^K$ and scalar b by

$$\mathbf{a} := \overline{r(w)} \circ \overline{u} \circ \overline{p}_i, \quad b := \frac{1}{K}\sum_{k=1}^{K} \mathbf{a}[k]$$

where $\mathbf{a}[k]$ is the k^{th} element of $\mathbf{a}$. Choose an arbitrary positive value $\epsilon < 1/2$. If $|b - 1| < \epsilon$, claim the i^{th} token on path $r(w)$ is u.

Now we prove that using this scheme, when the embedding dimension K is sufficiently large, one can recover the path $r(w)$ with probability arbitrarily close to 1.

First

$$\mathbf{a} = \sum_{t_j \in r(w)} \overline{t}_j \circ \overline{p_j} \circ \overline{u} \circ \overline{p}_i$$

Note that this summation contains summing of L K-vectors, which we will re-denote by $\mathbf{c}_1, \mathbf{c}_2, \ldots, \mathbf{c}_L$. Also we denote

$$C_l := \frac{1}{K}\sum_{k=1}^{K} \mathbf{c}_l[k].$$

Then we have

$$\mathbf{a} = \sum_{l=1}^{L} \mathbf{c}_l \tag{7}$$

and

$$b = \sum_{l=1}^{L} C_l \tag{8}$$

Each of $\mathbf{c}_l$ terms in Equation (7) corresponds to one of the four cases below.

Case 1: $i = j$ and $u = t_j$. This corresponds to case 3 of Lemma 3, and we have $\mathrm{E}(\mathbf{c}_l[k]) = 1$ and $\mathrm{VAR}(\mathbf{c}[k]) = 8$. It follows that $\mathrm{E}(C_l) = 1$ and $\mathrm{VAR}(C_l) = 8/K$.

Case 2: $i = j$ and $u \neq t_j$. This corresponds to case 2 of Lemma 3, and we have $\mathrm{E}(\mathbf{c}_l[k]) = 0$ and $\mathrm{VAR}(\mathbf{c}[k]) = 3$. It follows that $\mathrm{E}(C_l) = 0$ and $\mathrm{VAR}(C_l) = 3/K$.

Case 3: $i \neq j$ and $u = t_j$. This also corresponds to case 2 of Lemma 3, and we also have $\mathrm{E}(C_l) = 0$ and $\mathrm{VAR}(C_l) = 3/K$.

Case 4: $i \neq j$ and $u \neq t_j$. This corresponds to case 1 of Lemma 3, and we have $\mathrm{E}(\mathbf{c}_l[k]) = 0$ and $\mathrm{VAR}(\mathbf{c}[k]) = 1$. It follows that $\mathrm{E}(C_l) = 0$ and $\mathrm{VAR}(C_l) = 1/K$.

For each of these cases, the distribution of C_l can be made concentrated at its mean when K is made large enough (by invoking either the Weak Law of Large Number or the Central Limit Theorem). Therefore, if there exists a token in the path $r(w)$ that makes Case 1 satisfied, the distribution of b is concentrated at 1, and our recovery scheme will detect, with probability close to 1, the token and its position in the path. On the other hand, if there is no such token, the distribution of b is concentrated at 0, and with probability close to 0 our scheme will make a false detection. $\square$

Abstract

The paper introduces end-to-end neural network models that tokenize Sanskrit by jointly splitting compounds and resolving phonetic merges (Sandhi). Tokenization of Sanskrit depends on local phonetic and distant semantic features that are incorporated using convolutional and recurrent elements. Contrary to most previous systems, our models do not require feature engineering or extern linguistic resources, but operate solely on parallel versions of raw and segmented text. The models discussed in this paper clearly improve over previous approaches to Sanskrit word segmentation. As they are language agnostic, we will demonstrate that they also outperform the state of the art for the related task of German compound splitting.

1 Introduction

Sanskrit is an Indo-Aryan language that served as lingua franca for the religious, scientific and literary communities of ancient India. Text production in Sanskrit started in the 2. millenium BCE and has continued until today.[1] A 19th century cataloguing project recorded more than 40,000 Sanskrit texts known at that time (Aufrecht, 1891–1903), which covers only a small part of the extant Sanskrit literature. Apart from the oldest Vedic texts, Sanskrit has little diachronic variation on the morphological level, because it was regularized by the grammarian Pāṇini in the 3rd c. BCE.

NLP of Sanskrit is challenging due to compounding (see Ex. 1) and the phonetic processes called Sandhi (‘connection’; see Ex. 2–5). Compounding is widely used in other languages, and NLP has developed methods for analyzing compounds (Macherey et al., 2011; Ma et al., 2016). In Sanskrit, however, syntactic co- and subordination tend to be diachronically replaced by compounding (Lowe 2015; see also Sec. 3), so that many sentences in later literature consist only of a few long compounds that are loosely connected by a semantically light verb or an (optional) copula, as shown in this example:

(1) *āśrayabhūtakhādikathanena*
foundation-become-air-etc.-mentioning
“(Something is described) by mentioning air etc. that have become [its] foundations.”

The term Sandhi denotes a set of phonetic processes by which the contact phonemes of neighboring word tokens are changed and merged, and which create unseparated strings spanning multiple tokens (Whitney, 1879). Sandhi occurs between adjacent vowels (vocalic Sandhi; Ex. 2), between consonants and vowels (Ex. 4) and between adjacent consonants (Ex. 5):

(2) *rājā+uvāca* ‘the king said’ $\xrightarrow{\text{ā+u=o}}$ *rāj*$\underline{o}$*vāca*

(3) **rāja+uvāca* ‘O king, he said’ $\xrightarrow{\text{a+u=o}}$ *rāj*$\underline{o}$*vāca*

(4) *prāc+eva* ‘before indeed’ $\xrightarrow{\text{c+e=ge}}$ *prā*$\underline{g}$*eva*

(5) *tad+hi* ‘because this ...’ $\xrightarrow{\text{d+h=ddh}}$ *tad*$\underline{dh}$*i*

In addition, Sandhi occurs between independent inflected words (Ex. 2–5) as well as between members of compounds.[2] Because different combinations of unsandhied phonemes can result in the same surface phoneme, Sandhi resolution is non-deterministic and depends on the semantic context of the sentence (see Ex. 3 for a morphologically and lexically valid, but semantically dispreferred reading of the string *rājovāca*).

---

[1] Text production was oral until the first centuries BCE (Falk, 1993). The texts were transmitted by memorization in this period, making them less (!) prone to transmission errors than in written form.

[2] The compound in Ex. 1 is split as *āśraya-bhūta-kha-ādi-kathanena*, and *kha +ādi = khādi* is a Sandhi phenomenon.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2754–2763
Brussels, Belgium, October 31 - November 4, 2018. ©2018 Association for Computational Linguistics

Scriptorial and editorial conventions further complicate the analysis of compounds and Sandhi. While most Indian manuscripts don't insert spaces between strings, modern editors use spaces a gusto. Moreover, the (correct) application of Sandhi is not followed by all authors and editors to the same extent, so that the unsandhied tokens *tat hi asti* ('as this is ...') can occur as *taddhyasti*, *taddhy asti*, *tad dhy asti*, *tad dhyasti* or even *tat hi asti* (unchanged).

Our models aim at transforming a given sentence into a sequence of unsandhied tokens. We refer to this task as *Sanskrit word splitting* (SWS), and subsume Sandhi and compounding phenomena under the common term *splits*. We address SWS by using a combination of convolutional and recurrent elements. The recurrent elements integrate sentence level information that leads to qualified decisions about the semantic meaningfulness of possible compound and Sandhi splits (see Ex. 2 and 3), while the convolutional elements are meant to replace n-gram extraction, which is frequently used in word segmentation architectures. As our models operate on the character level, SWS can be formulated in a sequence labeling framework.

Consequently, this paper has three main contributions:

1. We introduce novel character-based models for SWS that beat state of the art models by large margins.
2. We compare against sequence-to-sequence models and demonstrate that our models work on par with them, but need significantly less time for training and inference.
3. We publish a new dataset for Sanskrit word splitting that consists of more than 560,000 sentences with manually validated splits. The dataset and the code are released at `https://github.com/OliverHellwig/sanskrit/papers/2018emnlp`.

In the rest of this paper, we use the following terminology. A *token* is an unsandhied word that is not itself a compound. A *string* is a sequence of characters that is delimited by a space or a *daṇḍa*. Each string contains at least one token, at least one compound (that itself consists of at least two tokens) or a Sandhied mixture of both. A *sentence* is a piece of Sanskrit text that is terminated by the punctuation mark called *daṇḍa* "stick" (|) and consists of at least one string. Any sentence can consist of multiple independent clauses, which are not demarcated by punctuation in Sanskrit, or consist of a part of a larger clause only.

The paper proceeds as follows: Section 2 gives an overview of related work in NLP. Section 3 introduces our SWS dataset. Section 4 describes the sequence labeling models developed for this paper and three baseline systems, whose evalution is presented in Sec. 5. Section 6 summarizes the paper.

2 Related Research

Most NLP systems for SWS combine Pāṇinis phonetic and morphological rules with a lexical resource, either by using formal (Huet, 2005; Goyal et al., 2009; Kulkarni and Shukla, 2009) or statistical methods, including Dirichlet processes (Natarajan and Charniak, 2011), finite state methods (Mittal, 2010), graph queries (Krishna et al., 2016) and hybrid systems (Hellwig, 2015a).

A number of recent papers approaches SWS with deep learning models. Hellwig (2015b) splits isolated strings by applying a one-layer bidirectional LSTM to two parallel character based representations of a string. The restriction to isolated strings is problematic, because SWS relies on the grammatical and semantic context of the full sentence in many cases. Restricting a model to isolated strings ignores these linguistic clues.

Reddy et al. (2018) formulate SWS as a translation task on the sentence level. They transform surface and unsandhied sentences using the *sentencepiece* model and "translate" the surface into the unsandhied sentence using a seq2seq model with attention. Gantayat et al. (2018) use an encoder-decoder architecture with a global attention mechanism and apply their model to isolated strings from a small dataset (Bhardwaj et al., 2018). So far, no direct comparison of deep learning models for SWS has been done, because the authors used different, partly unpublished datasets and reported performance on different linguistic levels (sentence, string) and with different evaluation methods. We will therefore try to make a fair and comprehensive comparison with the state of the art in Sec. 5.

SWS is closely related to word segmentation for other Asian languages such as Thai (Haruechaiyasak et al., 2008), Chinese or Japanese

(Kanji), with most research being done for Chinese and Japanese. Contrary to Sanskrit, Chinese and Japanese don't exhibit Sandhi phenomena and their logographic scripts condense information, making it possible to use "word-level" CRFs on the output, for example. Chen et al. (2015) interpret Chinese word segmentation (CWS) as a sequence labeling task and evaluate a range of (stacked) bidirectional recurrent architectures that are combined with a final sentence level likelihood layer (Collobert et al., 2011) maximizing the transition score of the BMES encoded target sequence. Their best model uses a single layer bidirectional LSTM with bigrams of pre-trained character embeddings as inputs. Cai and Zhao (2016) deal with CWS by first forming word hypotheses from characters using a gated unit and then processing the word hypotheses with an LSTM-based language model. They minimize the combined word and sentence level scores using a structured margin loss and achieve better performance than Chen et al. (2015) on standard CWS datasets. Kitagawa and Komachi (2017) adapt the model proposed by Chen et al. (2015) for Japanese word splitting, but use characters, character n-grams and lexicon-based word boundary features as inputs. The authors report state of the art performance, but observe a clear drop in the F score of their model, when texts contain a high proportion of Hiragana characters and thus come closer to syllabic or alphabetic scripts.

3 Data

Several datasets for SWS have been published in the last years. While the dataset of Bhardwaj et al. (2018) may be too small and unvaried for training deep learning models, Krishna et al. (2017) re-analyze 560,000 sentences from the Digital Corpus of Sanskrit (DCS)[3] using the Sanskrit Heritage Reader (Goyal and Huet, 2016). Re-analysis is necessary, because the DCS stores the morpho-lexical analysis of strings, but does not record split points and Sandhi rules applied. Due to different linguistic choices (Pāṇinian vs. corpus-oriented) and to different ideas about the (non-)compositional meanings of compounds their final dataset contains only 115,000 sentences (see the discussion in Krishna et al. 2017 and the analysis in Sec. 3.1). As the size of the dataset is crucial for most deep learning methods, we decided to release a new dataset along with this paper. Each sentence contained in the DCS is re-analyzed using the SanskritTagger software (Hellwig, 2009). Our dataset contains the surface forms of sentences in the DCS and the split points and Sandhi rules that the tagger proposes for their morpho-lexical gold analyses stored in the DCS. We didn't differentiate between compound and inter-word splits, as this distinction introduces morphological categories into the dataset. Table 1 shows an example of the annotation format.

Surface	r	ā	j	o	v	ā	c	a
Unsandhied	r	ā	j	ā-u	v	ā	c	a

Table 1: Data extracted from the string *rājovāca*, which is split into the two tokens *rājā* ("king") and *uvāca* ("(he, she) said"; see Ex. 2).

Table 2 shows the statistics of our dataset, split by text genres (first column). The dataset contains 2,978,509 strings and 4,171,682 tokens in 561,596 sentences. Most sentences come from the Epic and scientific (medicine, alchemy, astronomy) domain. While Epic texts are mostly written in easy, plain Sanskrit, the scientific works use many uncommon terms (likely to reoccur in the lexicographic domain) and long compounds. Sentence length is higher in the prose subcorpora (Buddhist, Vedic prose, ritualistic texts).

The fourth column shows that split phenomena are frequent in Sanskrit, occurring for more than 8% of all characters. Columns 5 and 6 report the proportions of complicated splits in relation to all splits. While 15% of all splits are resolved into a vocalic Sandhi, compound breaks are the dominant split type, which is also responsible for the majority of errors and ambiguities (see Sections 3.1 and 5.2). The last column also reflects the diachronic development from earlier texts with limited compounding (Vedic, ritualistic and Dharma texts) towards classical Sanskrit, which shows a strong preference for compounding. We use a fixed split of 90% of the sentences for training, a development set of 5% for parameter optimization and 5% for testing.

3.1 Quality of the training data

The dataset released by Krishna et al. (2017) and the one released with this paper both build on the DCS as gold standard. As this corpus was curated by a single user and the project never released a proper annotation guideline, one may suspect that it contains a certain level of inconsistencies and errors that influence the quality of the models and impose an upper limit for the model accuracy. In order to estimate the size of these effects, the authors of this paper independently corrected the analyses of 50 sentences randomly drawn from the training set (250 words, 2,354 characters including spaces). The corrections made by the authors differed at 23 character positions, corresponding to 20 strings in 15 sentences. 16 of these differences concerned compound splits, where the authors disagreed about the (non-)compositional meaning of compounds. A good example for such a disagreement is the string *rājayoga*, which was split as *rāja-yoga* “king-Yoga” = “Yoga of a king” by one author (compositional reading), but left unchanged as the name of a school of Yoga by the other one (non-compositional reading). After adjudicating these disagreements, there remain 5 of 250 strings with annotation errors in the training data, which corresponds to an error level of 2% of all strings and 0.2% of all characters for this sample.

We further explored the effect of compositionality by independently splitting 56 sentences of the Buddhist treatise Triṃśikāvijñaptibhāṣya, which is not part of the DCS. As the text uses highly technical terminology, the degree of disagreement can be expected to be higher than for plain narrative texts. We adjudicated our Sandhi annotations, but kept conflicts in compound splitting unresolved. 94.5% of all strings (394 of 417) and 69.7% of all sentences obtained the same compound analysis by both authors. Again, the majority of differences (11 of 23) showed up when a compound can have a non-compositional meaning that is closely connected with its compositional reading. Evaluation will show that these cases are responsible for a large parts of the model errors.

4 Models

4.1 Input Features

The character based models are trained with embeddings of the indidual surface characters, which are initialized with uniform random values from $[-1, +1]$ and updated during training. Following Kitagawa and Komachi (2017), the input can be enriched with multinomial *split probabilities* that are built from the training data. When the training data contain a split rule for surface character t_i at position i, we extract left ($g^L_{i,n}$) and right ($g^R_{i,n}$) character n-grams with lengths $n \in [2, 7]$[4] that end/start at position i, so that $g^L_{i,n} = \{t_{i-n+1}, t_{i-n+2}, \ldots t_i\}$ and $g^R_{i,n} = \{t_i, t_{i+1}, \ldots t_{i+n-1}\}$. Counts $\#(.)$ for individual n-grams are accumulated over the whole training set. At training and test time, a vector $\mathbf{v}_p \in \mathbb{R}^{2\cdot(7-2+1)=12}$ is assigned to each character position. Its element corresponding to the left n-gram of length 2, for example, is calculated as

$$\mathbf{v}_p(L, 2) = \frac{\#(g^L_{i,2})}{\max \#(g^L_{*,2})} \qquad (6)$$

We evaluate the influence of split probabilities in the ablation study (Sec. 5.2).

4.2 Extern Models for Comparison

We compare our models against the following baselines:

Bidirectional RNN We re-implement the model described in Hellwig (2015b), but apply it to full sentences instead of isolated strings. Character embeddings are fed into a bidirectional recurrent

---

[4] Longer n-grams did not produce improvements on the dev set.

layer with LSTM units. The output of the recurrent layer is additionally regularized by using dropout (Srivastava et al., 2014), and classification is performed using softmax with cross-entropy loss. We decode the output of the softmax in a greedy fashion without considering interactions between adjacent output classes.

seq2seq We retrain the model described in Reddy et al. (2018) with our data after pre-processing them with the unsupervised text tokenizer *sentencepiece* (Schuster and Nakajima, 2012).[5]

Transformer As an alternative to recurrency based seq2seq, we apply the model described in Vaswani et al. (2017) to the input pre-processed with *sentencepiece*. This model relies entirely on an attention mechanism to draw global dependencies between input and output. To our best knowledge, this is the first time that this model has been used for SWS. We use the publicy available implementation tensor2tensor.[6].

4.3 Models Combining RNN and CNN

Convolutional Element Combinations of recurrent and convolutional (LeCun et al., 1998) elements are effective for tasks where complex local features are extracted by the convolutional element and then considered in larger contexts by the recurrent element (and vice versa; see Bjerva et al. 2016 or Ma and Hovy 2016). We use convolutional features c_i as proposed by Kim (2014). Let w denote the width of the input matrix $\mathbf{X}$ of the convolution (= number of time steps), h its height, n the width of the convolutional filter $f^n \in \mathbb{R}^{n \times h}$, $\sigma(.)$ a non-linearity (Rectified Linear Units (Nair and Hinton, 2010) in this paper) and b a bias. A convolutional feature at character position i and for filter j is defined as:

$$c^n_{ij} = \sigma(f^n_j \cdot \mathbf{X}_{[i:i+n-1,*]} + b) \tag{7}$$

The feature map $\mathbf{c}^n_i$ for m different filters is formed by concatenating the convolutional features ($\mathbf{c}^n_i = [c^n_{i1}, c^n_{i2}, \ldots c^n_{im}]$) and the output $\mathbf{c}$ of the convolutional element is formed by concatenating the feature maps ($\mathbf{c}_i = c^1_i \oplus c^3_i \oplus \ldots$). We use use odd filter widths only to avoid problems with patch alignment. We tested convolution with small quadratic filters as used in image convolution as well as other methods for combining the learned filter such as averaging, addition or max-pooling of the stacked filters, but did not observe improved performance on the dev set.

Model 1: Convolution → Recurrency (crNN) As an alternative to n-gram extraction (Chen et al., 2015; Kitagawa and Komachi, 2017), a convolutional element is applied to the character embeddings (see Fig. 1a). Its outputs (Eq. 7) are fed into a bidirectional recurrent layer (Schuster and Paliwal, 1997). As in the baseline RNN (Sec. 4.2), dropout is inserted after the recurrent layer, and classification is performed using softmax with cross-entropy loss and greedy decoding.

Model 2: Recurrency → Convolution (rcNN) The order of convolutional and recurrent elements is switched (see Fig. 1b), so that the convolutional operation replaces additive n-gram formation before the classification layer. The remaining architecture is identical to that of crNN

Model 3: rcNN with Shortcuts ($\mathbf{rcNN_{short}}$) This model extends rcNN by adding shortcut connections (Bishop, 2000) that concatenate the character embeddings and the RNN outputs with the concatenated feature maps $\mathbf{c}$ (see Fig. 1c). When $\mathbf{e}_i$ denotes the embedding of character i and $\mathbf{r}_i$ the output of the recurrent layer at position i, the input to the classification layer is defined as $\mathbf{e}_i \oplus \mathbf{r}_i \oplus \mathbf{c}_i$. Shortcuts are evaluated because we hypothesized that the access to unconvolved information about the input sequence and the output of the recurrent layer would facilitate the exact prediction of split locations. For a better control of information flow, we also experimented with residual (He et al., 2016) and highway (Srivastava et al., 2015) instead of shortcut layers, but could not observe improvements on the dev set, most probably because our models are not deep enough for these layer types to show effects.

5 Evaluation

5.1 Evaluation Settings

We use the following settings found on the dev set for the character based models: embedding size: 128; 200 hidden recurrent units; 100 convolutional feature maps with filter widths of 3,5 and 7. We use regularized (Zaremba et al., 2014) instead of

Figure 1: Character based models, unfolded for the sequence labeling task $j{+}o{+}v \rightarrow j{+}a\text{-}u{+}v$.

vanilla LSTM units. All models are trained with the Adam optimizer (Kingma and Ba, 2015), an initial learning rate of 0.005 and batch size of 100. Gradients with a magnitude higher than 5.0 are cut. The models used for model selection (Sec. 5.2) are trained for 5, the other character-based models for 10 iterations. We train the Transformer in its default configuration as described in Vaswani et al. (2017) with a vocabulary size 5k[7] and report performance on the test set based on evaluations on the dev set. The model of Reddy et al. (2018) is trained for 80 epochs with our training data and the same parameters as described in the original paper. All calculations are run on a Maxwell Titan X GPU. We compare the models using sentence accuracy ($\frac{\text{\#sens. with errors}}{\text{\#all sens.}}$) and string based P(recision), R(ecall) and F score (Ma et al., 2016), where P and R are equivalent to the measures used in the CWS bakeoffs (Sproat and Emerson, 2003).

5.2 Model Selection

The upper half of Tab. 3 compares the evaluation metrics for the three character based models introduced in this paper trained with and without split probabilities (Sec. 4.1). We test differences in string accuracy using the McNemar test.[8] In general, all models that use recurrency *before* convolution (rcNN*) have string accuracy rates that are significantly higher at the 0.001 level than for models that use convolution before recurrency (crNN).

Table 3 shows that the differences in the performance of crNN and rcNN* are almost as large as between the RNN baseline and the best model from this paper (lower half of Tab. 3), although crNN and rcNN* differ only by the switched order of recurrent and convolutional elements. We found this result surprising, because applying convolution to the character embeddings appeared like a good parametrized alternative to n-gram extraction, which is often the first step in architectures for Chinese and Japanese word segmentation.

To further investigate this phenomenon, we evaluated 60 randomly chosen strings from the test set in which either crNN$^{\text{split}}$ or (XOR) rcNN$^{\text{split}}_{\text{short}}$ made an error. 45 of the errors relate to compound splitting, partly combined with vocalic Sandhi, either by missing a split (rcNN$^{\text{split}}_{\text{short}}$: 11, crNN$^{\text{split}}$: 15) or by oversegmenting compounds (rcNN$^{\text{split}}_{\text{short}}$: 13, crNN$^{\text{split}}$: 6). Most notably, rcNN$^{\text{split}}_{\text{short}}$ tends to insert more splits than crNN$^{\text{split}}$. This behavior can be observed for missing splits and especially for oversegmentations. A more detailed inspection shows that 11 of 13 oversegmentations actually induce a compositional reading of a compound. *saralāṅga* “name of a pine resin”, for example, is oversegmented into *sarala-aṅga* “pine-limb”, which is the etymological derivation of this compound. In contrast, crNN creates oversegmentations such as *śṛṅgavanti-aḥ*, where *śṛṅgavanti* “having horns” (nom. pl. neutre) is a valid form, while *aḥ* is not an independent word form in Sanskrit. Interestingly, rcNN$^{\text{split}}_{\text{short}}$ mis-segments the same string into *śṛṅga-vantyaḥ* in another sentence of the test set. Though differing from the

---

[7] Larger vocabulary sizes did not improve on the dev set, but performance gains by further decreasing the vocabulary size appear to be possible.

[8] Testing the sentence accuracy produced highly correlated test statistics. Results are therefore not discussed.

Table 4: P, R and F for rules that produce the surface phoneme *ā*. Data in the left half are from the original publication. As all metrics are consistently better for this paper, we refrain from highlighting the best results in the right half of the table.

gold analysis, this segmentation gives the correct derivational analysis of the adjective (noun *śṛṅga* "horn" + inflected form of the adjectivizing possessive affix *-vat*). The results of rcNN$^{\text{split}}_{\text{short}}$ thus reflect the inherent inconsistencies of the dataset on the level of compound splitting (see Sec. 3.1), and their erroneous splits are frequently semantically meaningful while glossing over minute semantic distinctions. Errors of crNN, in contrast, tend to be real mis-segmentations, indicating that its ability to reflect the semantic level is underdeveloped.

Split probabilities (Sec. 4.1) have a small, but positive effect on string accuracy of the rcNN* models. When the same model with and without split probabilities is compared using the McNemar test, split probabilities significantly increase string accuracy at the 0.1 level for rcNN and at the 0.001 level for rcNN$_{\text{short}}$, while they don't result in significantly better performance for crNN.

5.3 Comparison with Baseline Models

The lower half of Tab. 3 compares the best model introduced in this paper (rcNN$^{\text{split}}_{\text{short}}$) with baselines proposed for SWS in previous research. rcNN$^{\text{split}}_{\text{short}}$ outperforms the character based RNN described in Hellwig (2015b) by a wide margin. While Tab. 3 shows differences of almost 8% in sentence and 3% in string accuracy, Tab. 4 presents the improvements for the single surface character *ā*, which can correspond to a compound split (*ā-*) or to various vocalic Sandhis (*a-a* etc.). For this complicated character, rcNN$^{\text{split}}_{\text{short}}$ achieves consistent improvements of up to 15% on all metrics. We found it especially relevant to observe that rcNN$^{\text{split}}_{\text{short}}$ made large progress for rare rule types such as *ā-ā* or *ā-a*, indicating its increased ability for semantic generalization.

The seq2seq model (Reddy et al., 2018) performs on a similar level of accuracy as the one proposed in Hellwig (2015b). Similar to crNN (Sec. 5.2) it tends to miss splits and to insert faulty ones (e.g., *dānādānaratiḥ*, should: *dāna-ādānaratiḥ* "pleasure in giving and taking", is: *dānāt-ānaratiḥ* "from giving … UNK").

Gantayat et al. (2018) evaluate their model using location and split[9] prediction accuracy. The authors report 95.0 location and 79.5 split accuracy, but don't specify how they calculated these values. For this reason and because they evaluate on isolated strings only, we cannot compare directly against their work, but would like to report the following measures for rcNN$^{\text{split}}_{\text{short}}$:

- P, R and F for location prediction[10]: 97.64/98.19/97.91
- Micro-averaged P, R and F for individual rule types such as vocalic Sandhi or compound

---

[9] This seems to mean prediction of the correct Sandhi rule; see Gantayat et al. (2018, 4.2).

[10] $P = \frac{TP}{TP+FP}$, $R = \frac{TP}{TP+FN}$, TP: number of characters for which gold and model both record a split (though not necessarily of the same type), FP: number of characters at which the model over-segmentates, FN: number of character where the model fails to detect a valid split.

Model	S/A	P	R	A
Triṃśikāvijñaptibhāṣya				
rcNN$^{\text{split}}_{\text{short}}$	73.9	78.7	68.6	87.1
Transformer (5K)	72.6	77.5	66.9	86.8
Nyāyamañjarī				
rcNN$^{\text{split}}_{\text{short}}$	60.2	66.4	63.3	84.8
Transformer (5K)	62.1	68.6	63.5	85.2

Table 5: Results for evaluation on the Triṃśikāvijñaptibhāṣya and the Nyāyamañjarī; S/A: sentence accuracy

split: 95.12/95.12/95.12

The Transformer performs almost on par with rcNN$^{\text{split}}_{\text{short}}$, and the differences in string accuracy are not statistically significant, although rcNN$^{\text{split}}_{\text{short}}$ takes less time for training (2 h vs. 55 h) and inference (less than 1 min vs. 30 min when analyzing the test set). To better understand if the systems make orthogonal errors and could therefore be used in a mixture of experts, we performed a domain-specific evaluation with 73 sentences from the Buddhist treatise *Triṃśikāvijñaptibhāṣya* and 104 sentences from the philosophical text *Nyāyamañjarī*. We preserved the non-standard orthography of both texts in order to simulate the application of the models to real-world data. This includes the presence of typos, unsolved textual problems and erratic (non)-application of Sandhi.

Both models show a significant drop in overall performance when applied to these data (see Tab. 5). This is not surprising, because the input conventions of these files do not match the conventions of the training-data. Most errors arise again from disagreement about the (non-)compositional reading of technical compounds such as *sarvajña-tva* "all-knowing-ness" (see Sec. 3.1). It has to be noted that both models agree well in their correct decisions and in the type of errors they produce on these data. This indicates that the discrepancy in the orthographical conventions is indeed responsible for a large part of the drop in performance. Given the fact that both texts exhibit a lot of special vocabulary that is not present or used in a very different way in the training set, both models perform surprisingly well. Typical errors common to both models are for example *svalpam* instead of *su-alpam* "very small". Both models have difficulties to seperate Sandhi in passages that do not adhere to the common practice for typesetting of Indian texts in Latin transliteration. *ayaṃpariṇāmaḥ*, for example, was not separated into the usual form *ayaṃ pariṇāmaḥ*. There are certain cases of disagreement between both models that are noteworthy. While Transformer has changed the misspelled word *abhupagamyate* to the correct form *abhyupagamyate* in one case (overlooked by rcNN$^{\text{split}}_{\text{short}}$), rcNN$^{\text{split}}_{\text{short}}$ correctly identified the verbal form *upacaryante iti*, where Transformer inserted the semantically dispreferred, but grammatically possible present participle *upacaryantaḥ iti*. Overall, none of the models shows a generally better or worse performance in these cases of disagreement.

Table 6: Results for splitting German compounds; evaluation metrics according to Koehn and Knight (2003)

5.4 Application to German Compounds

In order to test if the character based models generalize well to other languages with limited training resources, we applied rcNN$_{\text{short}}$ with split probabilities and the same settings as for SWS to the task of splitting German compounds. The current state of the art is set with a CRF operating on n-grams of characters (Ma et al., 2016). Table 6 shows that our model achieves an improvement of about 1% for recall and accuracy when trained with the training set of Ma et al. (2016) only. We sampled 20 examples for the three error classes "wrong split", "wrong faulty split" and "wrong non-split" (Ma et al., 2016, 78). While our model failed to detect splits for all 20 examples of the type "wrong non-split", the type "wrong split" contained 10 cases, where the split(s) proposed by the model make(s) good sense for us, but are not recorded in the test set (e.g. "Viermaster" 'four-master', "Viermaster" in test; already remarked by Ma et al. 2016). We observed a similar level of inconsistencies for the "wrong faulty split" type (8 instances), where, for example, our model analyzed "Bundes-tags-vize-präsident" 'vice president of the Federal Parliament', while the test set had "Bundes-tags-vizepräsident".

6 Conclusion

While the models discussed in this paper have produced clear performance gains when compared with previous research on SWS, we expect that future research will improve over our results, but it will be difficult to approach error-free performance. The reservation is due to the errors in the training data and especially the question of (non-)compositional readings of compounds, which seems to produce related levels of confusion for human annotators and ML models. While following this track of research, we would like to expand its scope to joint learning of splits, lexical and morphological annotations. Here, we expect that especially lexical and morphological analysis will benefit from a joint model. We hypothesize that CTC (Graves, 2012) trained as a co-task or segmental NNs (Lu et al., 2016) with a modified objective (including split probabilities) may be suitable for this task.

Abstract

We propose to generalize language models for conversational speech recognition to allow them to operate across utterance boundaries and speaker changes, thereby capturing conversation-level phenomena such as adjacency pairs, lexical entrainment, and topical coherence. The model consists of a long-short-term memory (LSTM) recurrent network that reads the entire word-level history of a conversation, as well as information about turn taking and speaker overlap, in order to predict each next word. The model is applied in a rescoring framework, where the word history prior to the current utterance is approximated with preliminary recognition results. In experiments in the conversational telephone speech domain (Switchboard) we find that such a model gives substantial perplexity reductions over a standard LSTM-LM with utterance scope, as well as improvements in word error rate.

1 Introduction

Over the past decade the state of the art in language modeling has shifted from N-gram models to feed-forward networks (Bengio et al., 2006), and then to recurrent neural networks (RNNs) that read a list of words sequentially and predict the next word at each position. Starting with standard recurrent networks (Mikolov et al., 2010) the sequential modeling approach was later improved using the long-short-term memory (LSTM) architecture of (Hochreiter and Schmidhuber, 1997) for further gains (Sundermeyer et al., 2012; Medennikov et al., 2016; Xiong et al., 2017). RNN models give two fundamental advantages over the old N-gram framework. First, the continuous-space embedding of word identities allows word similarities to be exploited for generalization (Bengio et al., 2006; Mikolov et al., 2013). Second, the recurrent architecture allows, in principle at least, an unlimited history to condition the prediction of next words.

The potential advantage of unlimited history, however, is not commonly used to its full benefit, since the language model (LM) is typically “reset” at the start of each utterance in current state-of-the-art recognition systems (Saon et al., 2017; Xiong et al., 2018). This presumes that each utterance is independent of the others, and clearly violates what we know about how language and conversation works, as discussed in the next section. Consequently, there have been many proposals to inject information from a longer context into standard LM architectures, going back to N-gram models (Bellegarda, 2004), or to generalize N-grams LMs to operate across utterance boundaries and speakers (Ji and Bilmes, 2004). Based on the RNN framework, (Mikolov and Zweig, 2012) proposed augmenting network inputs with a more slowly varying context vector that would encode longer-range properties of the history, such as a latent semantic indexing vector. The problem with these approaches is that the modeler has to make design decisions about how to encapsulate contextual information as network inputs. Therefore, our approach here is to simply provide the entire conversation history as input to a standard LSTM-LM, and let the network learn the information that is relevant to next-word prediction.

We start by discussing linguistic phenomena that could potentially help in conversational LM (Section 2), followed by a description of the LSTM model we propose to capture them (Section 3). Section 4 describes the data and recognition system we used to test our models, with results reported in Section 5. We end with conclusions and future directions.

2 Conversation-level Phenomena

Here we review a few of the conversation-level phenomena that could be used for predicting words from longer context. Perhaps the most widely studied effect is topical coherence, or the tendency of words that are semantically related to one or more underlying topics to appear together in the conversation. Consequently, topic-related words are bound to re-occur across utterances, or certain related words appear to trigger one another (such as “children” and “school”). This should be especially true for conversations in the Switchboard (and Fischer) corpora, which were collected by pairing up strangers to talk about a mutually agreeable topic.

Another phenomenon that could lead to words reoccurring is lexical entrainment (Brennan and Clark, 1996), or the tendency of conversants to adopt the same words and phrases. Entrainment can also apply to speaking style, so the use of common discourse particles, syntactic patterns (like question tags), or even disfluencies could be triggered across speakers.

Other phenomena operate more locally, but across speaker turn boundaries. Linguistic conversation analysis has long noted that utterance types come in *adjacency pairs* (Schegloff, 1968), with preferences for certain pairs over others (like a statement is preferentially followed by agreement rather than disagreement). Therefore, words in an utterance should be more predicable based on the previous utterance. In the past, this has been modeled by conditioning utterance words on an underlying dialog act label, which in turn is conditioned on adjacent dialog act labels via a dialog act grammar (Stolcke et al., 2000).

A good part of conversational behavior has to do with how turn-taking is negotiated (Sacks et al., 1974). Speakers use special discourse devices, such as backchannel words and pause fillers, to signal when they want to take the floor, or to signal that the other party should keep the floor. Conversants also anticipate the ends of turns and jump in before the other speaker is completely done, making for very efficient use of time. As a result of all of these mechanisms, a good portion of conversations consists of overlapping (simultaneous) speaking. It was shown (Shriberg et al., 2001) that such overlap locations can be partly predicted by word-based language models. This suggests reversing the modeling and using overlap (the timing of utterances) to help predict the words.

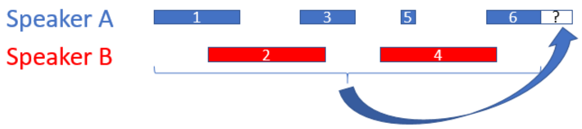

Figure 1: Use of conversation-level context in session-based LM. The utterance numbering shows how overlapping utterances are serialized (according to onset times).

3 Models

Our baseline language model is a standard LSTM that models utterances independently from one another, i.e., the history at the onset of each utterance is the start-of-sentence token. In fact, we used two version of this basic LSTM-LM:

- Word inputs encoded with one-hot vectors, combined with a jointly trained embedding layer
- Words encoded by multiple-hot vectors corresponding to the letter trigrams making up the words.

Both types of LSTM-LMs use three 1000-dimensional hidden layers with recurrence. The word embedding layer is also of size 1000, and the letter-trigram encoding has size 7190 (the number of unique trigrams in our vocabulary).

The main addition for session-level modeling is that the LSTM history consists of all the utterances preceding the current utterance, followed by all words in the current utterance preceding the word to be predicted. The preceding utterances are serialized in the order of their onset times, so that the flow of words within an utterance is not disrupted. The resulting total word history and next-word prediction is depicted in Figure 1. Information about utterance boundaries is encoded using a boundary tag, similar to the start-of-sentence token that is commonly used in LMs.

Several of the conversational phenomena described in Section 2 refer to turn-taking between speakers; to capture this in the model we augment the word input encoding with an extra bit that indicates whether a speaker change occurred. This bit is turned on only for the start-of-utterance token.

We also want to capture some information about utterance overlap, since, as described earlier, speech overlap interacts with word choice. Possible events to model would be overlap (exceedings a time threshold) at the starts and ends of utterances, or maybe a continuous measure of such overlaps. As a first proof of concept we chose to encode only one type of overlap, i.e., when the utterance in question is completely overlapped temporally by the other speaker's turn. This is typical of backchannel acknowledgments ("uh-huh") and short utterances that attempt to grab the floor ("um", "but"). Complete utterance overlap is also encoded by an additional input bit that is turned on for the start-of-utterance token.

4 Experiments

4.1 Recognition system

We used a single bidirectional LSTM acoustic model in experiments reported here, trained on the commonly used conversational telephone speech corpora (Switchboard, Fisher, CallHome English), estimating frame-level posterior probabilities for 9000 context-dependent phone units. The system decodes speech utterances using a 4-gram language model, generating lattices. These are then expanded to 500-best lists, which in turn are rescored using the various LMs.

The recognition system and the N-gram LM used in decoding have a vocabulary of 165k words, but the LSTM-LMs are trained on only the 38k words occurring at least twice in the in-domain conversational training data. Words outside of the LSTM-LM vocabulary are penalized in rescoring with a constant weight that is empirically optimized on the development set.

4.2 Data

Language model training uses the Switchboard-1, BBN Switchboard-2, Fisher, and English CallHome transcripts (about 23 million words in total) as well as the UW conversational Web corpus (Bulyko et al., 2003) for pre-training (see below). The N-gram LM used for N-best generation also includes the LDC Hub4 (Broadcast News) corpus. The Switchboard-1 and Switchboard-2 portions of the NIST 2002 CTS test set were used for tuning and development. Evaluation is carried out on the NIST 2000 CTS test set, consisting of Switchboard (SWB) and CallHome (CH) subsets.

As an expedient, we refrained from resegmenting utterances based on forced alignments of words, and instead use utterance boundaries as given in the available transcripts (corresponding to the audio segments used in acoustic training). Similarly, in testing, we use the presegmented utterances provided by NIST. No doubt there are inconsistencies in how the different corpora define utterance units, and a consistent, alignment-based resegmentation of all training and test data based on the durations nonspeech regions and/or lexical tagging might give improved results.

Table 1: Perplexities with session-based LSTM-LMs. The last two lines reflect use of errorful recognition output for preceding utterances.

Model inputs	devset SWB	test SWB	test CH
Utterance words, letter-3grams	48.90	44.56	54.57
+ session history words	38.86	36.81	44.31
+ speaker change	37.25	35.33	42.23
+ speaker overlap	37.09	35.12	42.02
Using recognized word histories			
single system	39.55	37.45	46.49
full system (Xiong et al., 2018)	39.41	37.29	45.99

4.3 Model training

All LSTM-LMs are trained using the Microsoft Cognitive Toolkit, or CNTK (Yu et al., 2014; Microsoft Research, 2016) on a Linux-based multi-GPU server farm. Training is parallelized using CNTK's distributed stochastic gradient descent (SGD) with 1-bit gradient quantization (Seide et al., 2014). We use the CNTK "FsAdaGrad" learning algorithm, which is an implementation of Adam (Kingma and Ba, 2015).

All LSTM-LMs are pretrained for one or two epochs on a large corpus of "conversational Web" data (Bulyko et al., 2003), followed by normal training to convergence on the in-domain data. Each utterance in the Web data is treated as a single session for purposes of session-based LM, i.e., the extra bits for speaker change and overlap are never turned on.

5 Results

When evaluating the session-based LMs on speech test data, the true utterance contexts are not known, and we must use hypothesized words for word histories preceding the current utterance. In our case, the histories were obtained using the output of our best recognition system, which uses a combination of acoustic models (Xiong et al., 2018), but excluding the session-based LM.[1] Per-

---

[1] We also omitted the final confusion network rescoring stage described in (Xiong et al., 2018).

Table 2: Recognition results with standard and session-based LSTM-LMs, measured by word error rates (WER).

Word encoding	Model	WER devset	WER test SWB	CH
Letter 3gram	LSTM-LM	10.01	6.88	12.79
	Session LSTM-LM	9.67	6.81	12.54
	Session LSTM-LM, 2nd iteration	9.66	6.77	12.56
One-hot	LSTM-LM	9.81	6.89	13.02
	Session LSTM-LM	9.47	6.81	12.60
	Session LSTM-LM, 2nd iteration	9.50	6.83	12.73
Letter 3gram + One-hot	LSTM-LM	9.66	6.63	12.77
	Session LSTM-LM	9.28	6.52	12.34
	LSTM-LM + Session LSTM-LM	9.22	6.45	12.11

plexity was evaluated on reference transcripts, as is customary.

Table 1 shows the effect of session-level modeling and of optional model elements on perplexity, based on LSTMs using letter-trigram encoding. Baseline is the standard utterance-scope LSTM-LM. We see a large perplexity reduction of 17-21% by conditioning on session history words, with smaller incremental reductions from adding speaker change and overlap information.

The last two table rows show that some of the perplexity gain over the baseline is negated by the use of errorful recognition output for the conversation history. It does not make much difference whether the recognized word history is generated by just the subsystem being rescored ("single system", with 6% word error on SWB) or the full recognition system using multiple acoustic models ("full system", with about 5% word error rate on SWB and 10% on CH). Using recognition output as history, the perplexity degrades about 6% relative for SWB, and 11% on CH, relative to using the true word histories. Even with the more errorful recognition on CH, the session-based LM still gives a perplexity reduction of 14% relative to the baseline.

Table 2 presents recognition results, comparing baseline LSTM-LMs to the full session-based LSTM-LMs. Both the letter-trigram and one-word word encoding versions are reported. The different models may also be used jointly, using log-linear score combination in rescoring, shown in the third section of the table. We also tried iterating the session LM rescoring, after the recognized word histories were updated from the first rescoring pass (shown as "2nd iteration" in the table).

Results show that the session-based LM yields between 1% and 4% relative word error reduction for the two word encodings, and test sets. When the two word encoding types are combined by log-linear combination of model scores, the gain from session-based modeling is preserved. Iterating the session LM rescoring to improve the word histories did not give consistent gains.

Even though the session-based LSTM subsumes all the information used in the standard LSTM, there is an additional gain to be had from combining those two model types (last row in the table). Thus, the overall gain from adding the session-based models to the two baseline models is 3-5% relative word error reduction.

6 Conclusion and Future Work

We have proposed a simple generalization of utterance-level LSTM language models aimed at capturing conversational phenomena that operate across utterances and speakers, such as lexical entrainment, adjacency pairs, speech overlap, and topical coherence. To capture non-local conditioning information, the LSTM-LM is trained to read the entire sequence of utterances making up a conversation, along with side information encoding speaker changes and overlap of utterances. This is found to reduce perplexity by about 25%, most of which is retained when errorful recognition output is used to represent the word history in previous utterances. The session-based LM yields up to 5% relative reduction in word error when the utterance- and session-based LMs are combined.

It would be worthwhile to investigate which conversational phenomena are actually being exploited by the session LSTM model. The ease with which additional information can be input to the LSTM-LM also suggests encoding other conditioning information, such a more details about utterance timing, as well as semantic features that capture topical coherence.

Abstract

Sequence-to-sequence neural generation models have achieved promising performance on short text conversation tasks. However, they tend to generate generic/dull responses, leading to unsatisfying dialogue experience. We observe that in conversation tasks, each query could have multiple responses, which forms a *1-to-n* or *m-to-n* relationship in the view of the total corpus. The objective function used in standard sequence-to-sequence models will be dominated by loss terms with generic patterns. Inspired by this observation, we introduce a statistical re-weighting method that assigns different weights for the multiple responses of the same query, and trains the standard neural generation model with the weights. Experimental results on a large Chinese dialogue corpus show that our method improves the acceptance rate of generated responses compared with several baseline models and significantly reduces the number of generated generic responses.

1 Introduction

Many recent works have been proposed to use neural networks to generate responses for open-domain dialogue systems (Shang et al., 2015; Sordoni et al., 2015; Vinyals and Le, 2015; Li et al., 2016a,c; Serban et al., 2017; Shen et al., 2017; Li et al., 2017; Yu et al., 2017; Xu et al., 2017). These methods are inspired by the sequence-to-sequence (Seq2Seq) framework (Sutskever et al., 2014), which is originally applied for Neural Machine Translation (NMT). They aim at maximizing the probability of generating a response given an input query, and generally use the *maximum likelihood estimation* (MLE) as their objective function. However, various problems occur when Seq2Seq models are used for dialogue generation tasks. One of the most important problems is that such models are inclined to generate generic and dull responses (e.g., I don't know), rather than meaningful and specific answers (Sordoni et al., 2015; Serban et al., 2016; Li et al., 2016a,c; Kannan et al., 2016; Li et al., 2017; Xie, 2017; Wei et al., 2017; Mou et al., 2017).

Until now, it has attracted increasing studies to address the issue of generating generic response. For example, Li et al. (2016a) used the mutual information theory to reconstruct MLE, but this model is easy to generate ungrammatical outputs. They further proposed a fast diverse decoding approach (Li et al., 2016b), which modifies the beam search to re-rank meaningful responses into higher positions. Similar works explore different ways to encourage response diversity for picking less generic responses in the decoding search (Vijayakumar et al., 2016; Li and Jurafsky, 2016). In the reinforcement learning framework (Li et al., 2016c), the reward function used in the decoding considers the ease of answering, which is measured by a distance towards a set of 8 generic responses. Thus, it can also alleviate the problem of generating generic responses to some extent. Lison and Bibauw (2017) proposed to add a weighting model to learn the "quality" of the query and response pair, but it relies heavily on additional inputs. All these works tried to add extra optimized terms in the encoding or decoding modules in Seq2Seq, making the training or prediction more complicated.

In this work, we consider the reason why Seq2Seq often generates generic responses by analyzing the MLE objective function directly. We notice that multiple responses are often associated with one single input query. As shown in Figure 1, the relationship between queries and responses is much looser in conversation models than that in NMT, since the space of possible responses is much

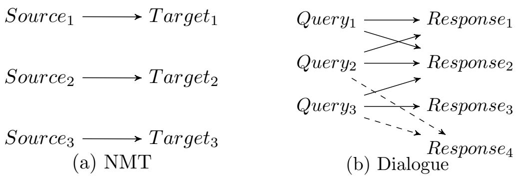
larger than the space of possible translations for a given sentence. On one hand, the information of these responses is only required to be relevant to the input query but usually differs from it. On the other hand, a query accepts large semantic diversity among its responses. Hence, it is a *1*-to-*n* relationship between a query and its responses (Vinyals and Le, 2015; Zhou et al., 2017). Meanwhile, we can see there is a *m*-to-*n* relationship between all queries and responses in the training corpus. Then, we find that MLE, which learns a *1*-to-*1* mapping in response generation, naturally puts more emphasis on optimizing the frequent patterns. Thus, the converged local optimum is easy to output these patterns or their combinations, leading to generic responses.



(a) NMT (b) Dialogue

Figure 1: An illustration of the differences between NMT and dialogue generation. *Response*$_4$ is the potential cases that are not collected in corpus.

Inspired by this observation, we propose a statistical re-weighting method which modifies MLE by re-weighting the multiple responses for each query such that MLE will not be dominated by the frequent patterns or their combinations. The proposed method calculates the weights of a response with the consideration of two statistical features: similarity frequency and sentence length. Our model is simple and efficient to optimize without adding additional terms into the original Seq2Seq objective function. We validate the performance of our proposed method on a large Chinese dialogue corpus. Results show that it can improve the acceptance rate of the generated responses and significantly suppress the number of generic responses.

2 Proposed Method

Standard Seq2Seq models for NMT and dialogue generation aim at estimating the conditional probability $p(\mathbf{y}|\mathbf{x})$ where $\mathbf{x} = (x_1, \ldots, x_T)$ is an input sequence and $\mathbf{y} = (y_1, \ldots, y_{T'})$ is its corresponding output sequence whose length $T^{'}$ may differ from T. During training, we learn all the model parameters $\boldsymbol{\theta}$ by summing the negative log likelihood of each sample pair $(\mathbf{x}, \mathbf{y})$ in the training corpus $\mathbb{C}$:

$$\begin{aligned} \ell(\mathbf{x}, \mathbf{y}, \boldsymbol{\theta}) &= -\sum_{t=1}^{T'} \log p(y_t|\mathbf{x}, \mathbf{y}_{[t-1]}; \boldsymbol{\theta}), && (1) \\ \mathcal{L}(\mathbb{C}, \boldsymbol{\theta}) &= \sum_{(\mathbf{x},\mathbf{y})\in\mathbb{C}} \ell(\mathbf{x}, \mathbf{y}, \boldsymbol{\theta}). && (2) \end{aligned}$$

Recall that generic responses are those that are safe and universal for many queries and thus frequently appear in the training corpus. Hence, if we have two responses of $\mathbf{x}$ in which one is generic and the other one contains more meaningful content, using $\mathcal{L}(\mathbb{C}, \boldsymbol{\theta})$ in Eq. 1 will put the same emphasis on optimizing each of their loss terms. Therefore, $\mathcal{L}(\mathbb{C}, \boldsymbol{\theta})$ contains a large amount of patterns from the generic responses, thus it is not surprised to see that the trained models are stuck into local optimum that are inclined to generate these patterns or their combinations.

Based on this observation, we argue that a good loss function of Seq2Seq for dialogue generation should not be dominated by the patterns from generic responses. Here, we propose a re-weighting method for responses of a query $\mathbf{x}$. Specifically, $\ell(\mathbf{x}, \mathbf{y}, \boldsymbol{\theta})$ in Eq. 1 is modified to be:

$$\ell_w(\mathbf{x}, \mathbf{y}, \boldsymbol{\theta}) = w(\mathbf{y}|\mathbf{x})\ell(\mathbf{x}, \mathbf{y}, \boldsymbol{\theta}), \qquad (3)$$

where $w(\mathbf{y}|\mathbf{x}) \in (0, 1]$ is a soft weight for a response $\mathbf{y}$ of a query $\mathbf{x}$. In the implementation, we make the normalization of this loss at the mini-batch level for better computational efficiency. Hence, the loss of Eq. 2 for a mini-batch $\mathcal{L}(\mathbb{B}, \boldsymbol{\theta})$ takes the form:

$$\mathcal{L}(\mathbb{B}, \boldsymbol{\theta}) = \frac{\sum_{\mathbf{x},\mathbf{y}\in\mathbb{B}} \ell_w(\mathbf{x}, \mathbf{y}, \boldsymbol{\theta})}{\sum_{\mathbf{x},\mathbf{y}\in\mathbb{B}} w(\mathbf{y}|\mathbf{x})}. \qquad (4)$$

We summarize two common properties for the responses:

- Responses with the patterns of frequently appearing in the training corpus tend to be generic. Here, the patterns refer to both the whole sentence or n-grams which can be described by similarities among responses.
- Very short and long responses should be avoid. Owing to the MLE objective function, the Seq2Seq frameworks are inclined to generate short responses that are universal replies. While long responses usually contain more specific information which may not be generalized to most conversation scenarios. Hence,

high-quality responses tend to be with moderate length.

We propose an estimator by considering these two properties:

$$w(\mathbf{y}|\mathbf{x}, \mathbb{R}, \mathbb{C}) = \frac{\Phi(\mathbf{y})}{\max_{\mathbf{r}\in\mathbb{R}}\{\Phi(\mathbf{r})\}}, \tag{5}$$

where $\mathbb{R}$ denotes all collected responses of $\mathbf{x}$ in $\mathbb{C}$. For each response, the estimator gives a weight by:

$$\Phi(\mathbf{y}) = \alpha\mathcal{E}(\mathbf{y}) + \beta\mathcal{F}(\mathbf{y}). \tag{6}$$

Here, $\mathcal{E}(\mathbf{y})$ and $\mathcal{F}(\mathbf{y})$ correspond to the mentioned two properties respectively:

- $\mathcal{E}(\mathbf{y}) = e^{-af(\mathbf{y})}$, where $f(\mathbf{y})$ is a function related to the frequency of response $\mathbf{y}$. It could be formulated as

  $$f(\mathbf{y}) = \max\{0, \text{Count}(D(\mathbf{y}, \mathbf{y}_j) \geq \tau) - b\} \quad \forall j \in |\mathbb{C}|,$$

  where $D(\cdot)$ refers to the similarity between two sentences, a is a scale factor, b is bias and $\tau \in [0, 1]$ is a threshold specifying the similarity that two responses will be considered identical. For instance, it could be the simplest strictly matching, which is used in our experiments. Other methods like cosine distance of TF-IDF (token or n-grams) can also be applied, but may encounter computational issues for large corpus. A response with a higher frequency will be assigned with a smaller $\mathcal{E}(\mathbf{y})$.

- $\mathcal{F}(\mathbf{y}) = e^{-c||\mathbf{y}|-|\hat{\mathbf{y}}||}$, where $|\mathbf{y}|$ denotes the number of tokens in $\mathbf{y}$, $|\hat{\mathbf{y}}| = \frac{1}{|\mathbb{C}|}\sum_{\mathbf{r}\in\mathbb{C}}|\mathbf{r}|$ refers to the average length of responses in the total training corpus, and c is a scale factor. Here, the "moderate length" is set to the average length of responses of the total training corpus. In practice, we have tried to use long responses (longer than average length) to fine-tune the Seq2Seq model. Though it slightly increases the average length of generated responses, the generated responses suffer from more ungrammatical and influent issues. Hence, if a response is too short or long, it will receive a low score of $\mathcal{F}(\mathbf{y})$.

Mentioned hyper-parameters $\{\alpha, \beta, a, b, \tau, c\}$ are constant values in the following experiments, which are set to $\{0.5, 0.5, 0.33, 3, 1.0, 0.33\}$. When we performed our experiments, we tried several hyper-parameter settings and found that our method is not sensitive to different hyper-parameters and achieves stable results in general. Hence, we do not spend many efforts to specifically tune these hyper-parameters.

Response (frequency/length)	$w(\mathbf{y}\|\mathbf{x})$	$\mathcal{E}(\mathbf{y})$	$\mathcal{F}(\mathbf{y})$
一直单身 (70/2) Single till now.	0.047	0.014	0.066
求交往 (173/2) Would you like to have a date with me?	0.039	0.000	0.066
等你看到别人甜蜜就知道一个人的痛苦了 (2/13) Once seeing the happy lovers, you will feel sad.	0.769	1.000	0.560
应该还在哭吧 (1/5) You may be crying now.	0.665	1.000	0.176
单身狗的自我安慰 (2/4) Morale-boosting of singles.	0.622	1.000	0.128
我也是这么觉得 (30/6) I think so.	0.149	0.052	0.248
单身不好,单身23年,孤单太久了 (1/10) Given being single for 23 years, it's not so good.	1.000	1.000	0.924
多么心塞的领悟 (1/4) What a painful understanding!	0.623	1.000	0.128

Table 1: Weights of the responses for a query "其实单身也挺好的 (It's pretty good to be single)".

To validate that our design function in Eq. 5 and Eq. 6 are effective to weight the responses, Table 1 shows the weights of 8 responses for a query "其实单身也挺好的 (It's pretty good to be single)". As can be seen, the weights are reasonable, in which the higher-ranked responses are more informative ones with low similarity frequency and moderate length.

3 Experiments

3.1 Corpus and Evaluation

We crawl conversation pairs from some popular Chinese social media websites[1], and select 7M high-quality pairs as our training corpus. Conventional metrics such as BLEU (Papineni et al., 2002) and perplexity, are improper to be used for response generation tasks. Following previous works (Li et al., 2016c, 2017), we apply human annotations. We randomly sample 500 queries (not used in training) as our test samples, and recruit 3 annotators to evaluate each generated response from two aspects:

- *Fluency*: 0 (unreadable), 1 (readable but with some grammar mistakes), 2 (fluent);
- *Relevance*: 0 (not relevant at all), 1 (relevant at a distant level), 2 (relevant, including the

---

[1] Weibo: `www.weibo.com`, Baidu Tieba: `tieba.baidu.com`, and Zhihu: `www.zhihu.com`

generic responses), 3 (relevant as well as interesting).

Acceptance is then automatically calculated as a metric reflecting whether the response is acceptable to real users. A response will be assigned 1 when it gets *Fluency*$\geq$1 and *Relevance*$\geq$2, otherwise it will be assigned 0.

We implement our baseline Seq2Seq model using its standard objective function in Eq. 1 with two LSTM layers for encoding/decoding and a standard beam search with a beam size of 5 (the best setting), termed as *Seq2Seq*. We also compare several Seq2Seq variants:

- *Seq2Seq-RS*: training with a subset by randomly sampling only one from the multiple responses for each query;
- *Seq2Seq-MMI*: applying the maximum mutual information (Li et al., 2016a) (only the MMI-bidi);
- *Seq2Seq-DD*: applying the diverse decoding algorithm (Li et al., 2016b);
- *Ours-RW*: calculating weights via our reweighting method proposed in Section 2. Without applying any other tricks, we implement three versions of our method by using $\mathcal{E}(\cdot)$ only, $\mathcal{F}(\cdot)$ only, a linear combination of $\mathcal{E}(\cdot)$ and $\mathcal{F}(\cdot)$ in Eq 6, termed as *Ours-RW*$_{\{\text{E,F,EF}\}}$.

3.2 Results and Discussion

Human annotation results are shown in Table 2. Several observations can be made. First, *Seq2Seq-RS* performs slightly worse than the baseline model. This means that it does not work to simply discard a large amount of training data to construct a 1-to-1 query-response subset for training. Second, *Seq2Seq-MMI* not only provides no improvement for the baseline but also inclines to generate generic response. Third, *Seq2Seq-DD* obtains higher relevance and acceptance scores than the baseline, which shows its effectiveness by re-ranking more meaningful responses into higher positions in beam search. Fourth, our method achieves the best performance on almost all metrics. When we use strictly matched frequency of each response, *Ours-RW*$_{\text{E}}$ does not perform better than the baseline model because that the percentage of responses with frequency higher than 3 is about 0.5% in our training corpus. However, it still enhances the performance in *Ours-RW*$_{\text{EF}}$, which performs the best and increases the acceptance of the baseline model from 0.42 to 0.55. This validates that the properties about similarity frequency and sentence length play important roles in generating better responses.

Model	Evaluation Metrics		
	Fluency	Relevance	Acceptance
Seq2Seq	1.96±3.8e-5	1.31±5.3e-3	0.42±4.7e-4
Seq2Seq-RS	**1.97**±8.1e-5	1.30±2.1e-3	0.42±9.9e-4
Seq2Seq-MMI	1.94±7.2e-5	1.19±4.0e-3	0.41±1.9e-4
Seq2Seq-DD	1.86±2.8e-3	1.40±1.5e-2	0.49±2.4e-3
Ours-RW$_{\text{E}}$	1.95±1.9e-4	1.30±5.1e-3	0.42±4.2e-4
Ours-RW$_{\text{F}}$	**1.97**±1.5e-4	1.47±2.1e-3	0.51±6.3e-4
Ours-RW$_{\text{EF}}$	1.96±8.3e-5	**1.59**±1.9e-2	**0.55**±4.4e-3

Table 2: Human annotation results.

Specifically, the average percentage of the generated responses that are assigned to relevance rating 2 (relevant, including the generic responses) and 3 (relevant as well as interesting) are presented in Table 4. It shows that our method achieves higher relevance score owing to generating more high-quality responses with rating 3.

To validate that our method is effective to reduce the number of generated generic responses, we calculated the *distinct-1* and *distinct-2* (Li et al., 2016a) for the compared methods respectively, which are the number of distinct unigrams and bigrams divided by total number of generated words respectively. As shown in Table 5, *Ours-RW*$_{\text{EF}}$ achieves the best performance on the two metrics. This indicates that our model often outputs more meaningful and relevant responses than the other compared methods.

We further randomly sample another 100K queries (not used in training) and use the various models to generate responses. We compare the frequencies of several common generic responses appearing in the generated results, as shown in Table 6. It shows that our method can significantly reduce the number of generic responses. For instance, we reduce about 75% of the case “我也不知道 (I don’t know, either.)” and 77% of the case “我也想知道 (I want to know, too)” to be generated.

4 Conclusion

In this paper, we propose a statistical re-weighting method to weight multiple responses differently and optimize the MLE objective function. The weight of each response is calculated based on

two terms according to the similarity frequency and its length. Experiments show that our approach improves the performance over the baseline models and reduces the number of generated generic responses significantly. It indicates that mismatching issue of objective function can be alleviated through such similar re-weighting methods, by which current encoder-decoder architectures can take full use of the *m*-to-*n* training corpus and model the dialogue generation tasks better.

Training Millions of Personalized Dialogue Agents

Abstract

Current dialogue systems are not very engaging for users, especially when trained end-to-end without relying on proactive reengaging scripted strategies. Zhang et al. (2018) showed that the engagement level of end-to-end dialogue models increases when conditioning them on text personas providing some personalized back-story to the model. However, the dataset used in (Zhang et al., 2018) is synthetic and of limited size as it contains around 1k different personas. In this paper we introduce a new dataset providing 5 million personas and 700 million persona-based dialogues. Our experiments show that, at this scale, training using personas still improves the performance of end-to-end systems. In addition, we show that other tasks benefit from the wide coverage of our dataset by fine-tuning our model on the data from (Zhang et al., 2018) and achieving state-of-the-art results.

1 Introduction

End-to-end dialogue systems, based on neural architectures like bidirectional LSTMs or Memory Networks (Sukhbaatar et al., 2015) trained directly by gradient descent on dialogue logs, have been showing promising performance in multiple contexts (Wen et al., 2016; Serban et al., 2016; Bordes et al., 2016). One of their main advantages is that they can rely on large data sources of existing dialogues to learn to cover various domains without requiring any expert knowledge. However, the flip side is that they also exhibit limited engagement, especially in chit-chat settings: they lack consistency and do not leverage proactive engagement strategies as (even partially) scripted chatbots do.

Zhang et al. (2018) introduced the PERSONA-CHAT dataset as a solution to cope with this issue. This dataset consists of dialogues between pairs of agents with text profiles, or *personas*, attached to each of them. As shown in their paper, conditioning an end-to-end system on a given persona improves the engagement of a dialogue agent. This paves the way to potentially end-to-end personalized chatbots because the personas of the bots, by being short texts, could be easily edited by most users. However, the PERSONA-CHAT dataset was created using an artificial data collection mechanism based on Mechanical Turk. As a result, neither dialogs nor personas can be fully representative of real user-bot interactions and the dataset coverage remains limited, containing a bit more than 1k different personas.

In this paper, we build a very large-scale persona-based dialogue dataset using conversations previously extracted from REDDIT[1]. With simple heuristics, we create a corpus of over 5 million personas spanning more than 700 million conversations. We train persona-based end-to-end dialogue models on this dataset. These models outperform their counterparts that do not have access to personas, confirming results of Zhang et al. (2018). In addition, the coverage of our dataset seems very good since pre-training on it also leads to state-of-the-art results on the PERSONA-CHAT dataset.

2 Related work

With the rise of end-to-end dialogue systems, personalized trained systems have started to appear. Li et al. (2016) proposed to learn latent variables representing each speaker's bias/personality in a dialogue model. Other classic strategies include extracting explicit variables from structured knowledge bases or other symbolic sources as in (Ghazvininejad et al., 2017; Joshi et al., 2017; Young et al., 2017). Still, in the context of per-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2775–2779
Brussels, Belgium, October 31 - November 4, 2018.

sonal chatbots, it might be more desirable to condition on data that can be generated and interpreted by the user itself such as text rather than relying on some knowledge base facts that might not exist for everyone or a great variety of situations. PERSONA-CHAT (Zhang et al., 2018) recently introduced a dataset of conversations revolving around human habits and preferences. In their experiments, they showed that conditioning on a text description of each speaker's habits, their *persona*, improved dialogue modeling.

In this paper, we use a pre-existing REDDIT data dump as data source. REDDIT is a massive online message board. Dodge et al. (2015) used it to assess chit-chat qualities of generic dialogue models. Yang et al. (2018) used response prediction on REDDIT as an auxiliary task in order to improve prediction performance on natural language inference problems.

3 Building a dataset of millions of persona-based dialogues

Our goal is to learn to predict responses based on a persona for a large variety of personas. To that end, we build a dataset of examples of the following form using data from REDDIT:

- Persona: [*"I like sport"*, *"I work a lot"*]
- Context: *"I love running."*
- Response: *"Me too! But only on weekends."*

The persona is a set of sentences representing the personality of the responding agent, the context is the utterance that it responds to, and the response is the answer to be predicted.

3.1 Preprocessing

As in (Dodge et al., 2015), we use a preexisting dump of REDDIT that consists of 1.7 billion comments. We tokenize sentences by padding all special characters with a space and splitting on whitespace characters. We create a dictionary containing the 250k most frequent tokens. We truncate comments that are longer than 100 tokens.

3.2 Persona extraction

We construct the persona of a user by gathering all the comments they wrote, splitting them into sentences, and selecting the sentences that satisfy the following rules: (i) each sentence must contain between 4 and 20 words or punctuation marks, (ii) it contains either the word *I* or *my*, (iii) at least one verb, and (iv) at least one noun, pronoun or adjective.

To handle the quantity of data involved, we limit the size of a persona to N sentences for each user. We compare four different setups for persona creation. In the *rules* setup, we select up to N random sentences that satisfy the rules above. In the *rules + classifier* setup, we filter with the rules then score the resulting sentences using a bag-of-words classifier that is trained to discriminate PERSONA-CHAT persona sentences from random comments. We manually tune a threshold on the score in order to select sentences. If there are more than N eligible persona sentences for a given user, we keep the highest-scored ones. In the *random from user* setup, we randomly select sentences uttered by the user while keeping the sentence length requirement above (we ignore the other rules). The *random from dataset* baseline refers to random sentences from the dataset. They do not necessarily come from the same user. This last setup serves as a control mechanism to verify that the gains in prediction accuracy are due to the user-specific information contained in personas.

In the example at the beginning of this section, the response is clearly consistent with the persona. There may not always be such an obvious relationship between the two: the discussion topic may not be covered by the persona, a single user may write contradictory statements, and due to errors in the extraction process, some persona sentences may not represent a general trait of the user (e.g. *I am feeling happy today*).

3.3 Dataset creation

We take each pair of successive comments in a thread to form the context and response of an example. The persona corresponding to the response is extracted using one of the methods of Section 3.2. We split the dataset randomly between training, validation and test. Validation and test sets contain 50k examples each. We extract personas using training data only: test set responses cannot be contained explicitly in the persona.

In total, we select personas covering 4.6m users in the rule-based setups and 7.2m users in the random setups. This is a sizable fraction of the total 13.2m users of the dataset; depending on the persona selection setup, between 97 and 99.4 % of the training set examples are linked to a persona.

4 End-to-end dialogue models

We model dialogue by next utterance retrieval (Lowe et al., 2016), where a response is picked among a set of candidates and not generated.

4.1 Architecture

The overall architecture is depicted in Fig. 1. We encode the persona and the context using separate modules. As in Zhang et al. (2018), we combine the encoded context and persona using a 1-hop memory network with a residual connection, using the context as query and the set of persona sentences as memory. We also encode all candidate responses and compute the dot-product between all those candidate representations and the joint representation of the context and the persona. The predicted response is the candidate that maximizes the dot product.

We train by passing all the dot products through a softmax and maximizing the log-likelihood of the correct responses. We use mini-batches of training examples and, for each example therein, all the responses of the other examples of the same batch are used as negative responses.

4.2 Context and response encoders

Both context and response encoders share the same architecture and word embeddings but have different weights in the subsequent layers. We train three different encoder architectures.

Bag-of-words applies two linear projections separated by a $\tanh$ non-linearity to the word embeddings. We then sum the resulting sentence representation across all positions in the sentence and divide the result by $\sqrt{n}$ where n is the length of the sequence.

LSTM applies a 2-layer bidirectional LSTM. We use the last hidden state as encoded sentence.

Transformer is a variation of an End-to-end Memory Network (Sukhbaatar et al., 2015) introduced by Vaswani et al. (2017). Based solely on attention mechanisms, it exhibited state-of-the-art performance on next utterance retrieval tasks in dialogues (Yang et al., 2018). Here we use only its encoding module. We subsequently average the resulting representation across all positions in the sentence, yielding a fixed-size representation.

		hits@k		
	Persona	k=1	k=3	k=10
IR Baseline	No	5.6	9.9	19.5
BOW	No	51.7	64.7	77.9
BOW	Yes	53.9	67.9	81.9
LSTM	No	63.1	75.6	87.3
LSTM	Yes	66.3	79.5	90.6
Transformer	No	69.1	80.7	90.7
Transformer	Yes	**74.4**	**85.6**	**94.2**

Table 1: Test results when classifying the correct answer among a total of 100 possible answers.

4.3 Persona encoder

The persona encoder encodes each persona sentence separately. It relies on the same word embeddings as the context encoder and applies a linear layer on top of them. We then sum the representations across the sentence.

We deliberately choose a simpler architecture than the other encoders for performance reasons as the number of personas encoded for each batch is an order of magnitude greater than the number of training examples. Most personas are short sentences; we therefore expect a bag-of-words representation to encode them well.

5 Experiments

We train models on the persona-based dialogue dataset described in Section 3.3 and we evaluate its accuracy both on the original task and when transferring onto PERSONA-CHAT.

5.1 Experimental details

We optimize network parameters using Adamax with a learning rate of $8e{-}4$ on mini-batches of size 512. We initialize embeddings with FastText word vectors and optimize them during learning.

REDDIT LSTMs use a hidden size of 150; we concatenate the last hidden states for both directions and layers, resulting in a final representation of size 600. Transformer architectures on reddit use 4 layers with a hidden size of 300 and 6 attention heads, resulting in a final representation of size 300. We use Spacy for part-of-speech tagging in order to verify the persona extraction rules. We distribute the training by splitting each batch across 8 GPUs; we stop training after 1 full epoch, which takes about 3 days.

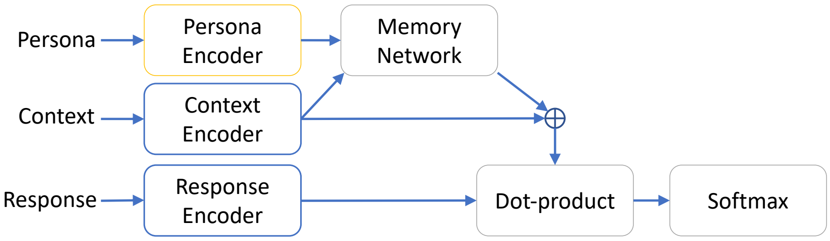

Figure 1: Persona-based network architecture.

Context (Persona)	*Predicted Answer*
Where do you come from?	
(I was born in London.)	*I'm from London, studying in Scotland.*
(I was born in New York.)	*I'm from New York.*
What do you do?	
(I am a doctor.)	*I am a sleep and respiratory therapist.*
(I am an engineer.)	*I am a software developer.*

Table 2: Sample predictions from the best model. In all selected cases the persona consists of a single sentence. The answer is constrained to be at most 10 tokens and is retrieved among 1M candidates sampled randomly from the training set.

PERSONA-CHAT We used the revised version of the dataset where the personas have been rephrased, making it a harder task. The dataset being only a few thousands samples, we had to reduce the architecture to avoid overfitting for the models trained purely on PERSONA-CHAT. 2 layers, 2 attention heads, a dropout of 0.2 and keeping the size of the word embeddings to 300 units yield the highest accuracy on the validation set.

IR Baseline As basic baseline, we use an information retrieval (IR) system that ranks candidate responses according to a TF-IDF weighted exact-match similarity with the context alone.

5.2 Results

Impact of personas We report the accuracy of the different architectures on the reddit task in Table 1. Conditioning on personas improves the prediction performance regardless of the encoder architecture. Table 2 gives some examples of how the persona affects the predicted answer.

Influence of the persona extraction In Table 3, we report precision results for several persona extraction setups. The *rules* setup improves the results somewhat, however adding the persona classifier actually degrades the results. A possible interpretation is that the persona classifier is trained only on the PERSONA-CHAT revised personas, and that this selection might be too narrow and lack diversity. Increasing the maximum persona size also improves the prediction performance.

N	Persona selection	hits@1
0	–	69.1
20	rules + classifier	70.7
20	rules	71.3
100	rules + classifier	72.5
100	rules	**74.4**
100	random from user	73.8
100	random from dataset	66.9

Table 3: Retrieval precision on the REDDIT test set using a Transformer and different persona selection systems. N: maximum number of sentences per persona.

Transfer learning We compare the performance of transformer models trained on REDDIT and on PERSONA-CHAT on both datasets. We report results in Table 4. This architecture provides a strong improvement over the results of (Zhang et al., 2018), jumping from 35.4% hits@1 to 42.1%. Pretraining the model on REDDIT and then fine-tuning on PERSONA-CHAT pushes this score to 60.7%, largely improving the state of the art. As expected, fine-tuning on PERSONA-CHAT reduces the performance on REDDIT. However, directly testing on PERSONA-CHAT the model trained on REDDIT without fine-tuning yields a very low result. This could be a consequence of a discrepancy

	Validation set	
Training set	PERSONA-CHAT	REDDIT

REDDIT	25.6	**74.4**
FT-PC	**60.7**	65.5
IR Baseline	20.7	5.6
(Zhang et al., 2018)	35.4	–

Table 4: hits@1 results for the best found Transformer architecture on different test sets. FT-PC: REDDIT-trained model fine-tuned on the PERSONA-CHAT training set. To be comparable to the state of the art on each dataset, results on PERSONA-CHAT are computed using 20 candidates, while results on REDDIT use 100.

between the style of personas of the two datasets.

6 Conclusion

This paper shows how to create a very large dataset for persona-based dialogue. We show that training models to align answers both with the persona of their author and the context improves the predicting performance. The trained models show promising coverage as exhibited by the state-of-the-art transfer results on the PERSONA-CHAT dataset. As pretraining leads to a considerable improvement in performance, future work could be done fine-tuning this model for various dialog systems. Future work may also entail building more advanced strategies to select a limited number of personas for each user while maximizing the prediction performance.

Abstract

Dialogue state tracking is the core part of a spoken dialogue system. It estimates the beliefs of possible user's goals at every dialogue turn. However, for most current approaches, it's difficult to scale to large dialogue domains. They have one or more of following limitations: (a) Some models don't work in the situation where slot values in ontology changes dynamically; (b) The number of model parameters is proportional to the number of slots; (c) Some models extract features based on hand-crafted lexicons. To tackle these challenges, we propose StateNet, a *universal* dialogue state tracker. It is independent of the number of values, shares parameters across all slots, and uses pre-trained word vectors instead of explicit semantic dictionaries. Our experiments on two datasets show that our approach not only overcomes the limitations, but also significantly outperforms the performance of state-of-the-art approaches.

1 Introduction

A task-oriented spoken dialogue system (SDS) is a system that can continuously interact with a human to accomplish a predefined task through speech. It usually consists of three modules: input, output, and control. The control module is also referred to as *dialogue management* (Young et al., 2010; Yu et al., 2014). It has two missions: dialogue state tracking (DST) and decision making. At each dialogue turn, a state tracker maintains the internal state of the system based on the information received from the input module. Then a machine action is chosen based on the dialogue state according to a dialogue policy to direct the dialogue (Chen et al., 2018).

The dialogue state is an encoding of the machine's understanding of the whole conversation. Traditionally, it is usually factorized into three distinct components (Young et al., 2013): the user's *goal*, the user's action, and the dialogue history. Among them, the user's goal is most important, which is often simply represented by *slot-value* pairs. In this paper, we focus on the tracking of the user's goal.

Recently, the dialogue state tracking challenges (DSTCs) (Williams et al., 2013; Henderson et al., 2014a,d) are organized to provide shared tasks for comparing DST algorithms. A various of models are proposed, e.g. rule-based models (Wang and Lemon, 2013; Sun et al., 2014a; Yu et al., 2015, 2016; Sun et al., 2016b), generative statistical models (Thomson and Young, 2010; Young et al., 2010, 2013), and discriminative statistical models (Lee and Eskenazi, 2013; Lee, 2013; Sun et al., 2014b; Xie et al., 2015; Sun et al., 2016a; Xie et al., 2018). And the state-of-the-art one is the deep learning-based approach. However, most of these models have some limitations. First, some models can only work on a fixed domain *ontology*, i.e. the slots and values are defined in advance, and can't change dynamically. However, this is not flexible in practice (Xu and Hu, 2018). For example, in the tourist information domain, new restaurants or hotels are often added, which results in the change of the ontology. Second, in many approaches the models for every slot are different. Therefore, the number of parameters is proportional to the number of slots. Third, some models extract features based on text *delexicalisation* (Henderson et al., 2014b), which depends on predefined semantic dictionaries. In large scale domains, it's hard to manually construct the semantic dictionaries for all slots and values (Mrkšić et al., 2017).

To tackle these challenges, here we propose a *universal* dialogue state tracker, StateNet. For each state slot, StateNet generates a fixed-length representation of the dialogue history, and then compares the distances between this representation and the value vectors in the candidate set for making prediction. The set of candidate values

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2780–2786
Brussels, Belgium, October 31 - November 4, 2018.

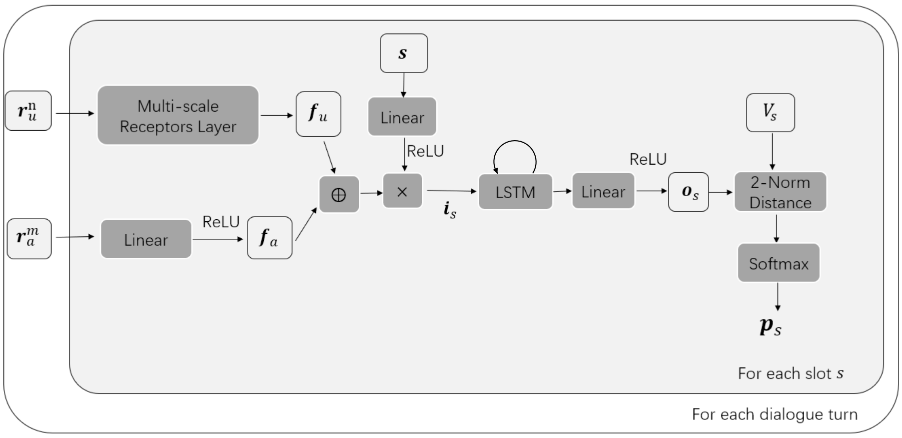

Figure 1: General model architecture of StateNet.

can change dynamically. StateNet only needs the following three parts of the data: (1) the original ASR information (or the transcript) of the user utterance; (2) the information of the machine act; (3) the literal names of the slots and the values. The manually-tagging of the user utterance is not needed as a part of the data. StateNet shares parameters among all slots, through which we can not only transfer knowledge among slots but also reduce the number of parameters.

2 StateNet: A Universal Dialogue State Tracker

For each dialogue turn, StateNet takes the multiple n-gram user utterance representation, $\mathbf{r}_u^n$, the n-gram machine act representation, $\mathbf{r}_a^n$, the value set, $\mathcal{V}_s$, and the word vector of the slot, $\mathbf{s}$, as the input. Then StateNet applies the Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) to track the inner dialogue states among the dialogue turns. And for each slot, StateNet outputs a corresponding probability distribution, $\mathbf{p}_s$, over the set of possible values, $\mathcal{V}_s$, at each of the dialogue turn,

$$\mathbf{p}_s = \text{StateNet}(\mathbf{r}_u^n, \mathbf{r}_a^n, \mathbf{s}, \mathcal{V}_s).$$

The general model architecture is shown in Figure 1.

2.1 User Utterance Representation

At the t-th dialogue turn, the user utterance, U_t, may consist of l number of words, u_i, with their corresponding word vectors, $\mathbf{u}_i$, $(1 \le i \le l)$. The user utterance may also have its corresponding m-best ASR hypotheses with the normalized confidence scores (Chen et al., 2017), q_j,$(1 \le j \le m)$. In this case, we can calculate the weighted word vectors, $\mathbf{u}'_i$,

$$\mathbf{u}'_i = \sum_{j=1}^{m} q_j \mathbf{u}_{i,j},$$

where $\mathbf{u}_{i,j}$ represents the word vector $\mathbf{u}_i$ presented at the j-th ASR hypothesis, and the zero vectors are padded at the end of all the hypotheses that are shorter than the longest one to have a same length of the utterance.

Based on the weighted word vectors generalizing the information from the ASR hypothesis, we can then construct the n-gram weighted word vectors, as proposed by Mrkšić et al. (2017),

$$\mathbf{u'}_i^n = \mathbf{u}'_i \oplus ... \oplus \mathbf{u}'_{i+n-1},$$

where $\oplus$ is the concatenation operator between the word vectors.

An n-gram user utterance representation is then constructed through a sum of the n-gram weighted word vectors,

$$\mathbf{r}_u^n = \sum_{i=1}^{l-n+1} \mathbf{u'}_i^n.$$

2.2 Multi-scale Receptors Layer

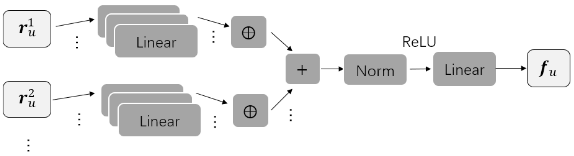

Figure 2: Multi-scale Receptors Layer.

For each gram k of the user utterance representation, $\mathbf{r}_u^k$, $(1 \le k \le n)$, the Multi-scale Receptors Layer has c number of linear neural networks (with the same number of neurons, N_c). Each of them takes the representation as input and is expected to work as the specialized receptor to amplify the signals from some of the word vectors in the utterance representation,

$$\hat{\mathbf{r}}_u^k = \oplus_{j=1}^{c}(\mathbf{W}_k^j \mathbf{r}_u^k + \mathbf{b}_k^j),$$

where $\mathbf{W}_k^j$ means the weight of the j-th linear layer, $\mathbf{b}_k^j$ means the corresponding bias, and $\oplus$ is the concatenation operator between the neurons of these linear layers. Note that each receptor does not necessarily has to be a single linear neural network and can be sophisticated with multiple layers and non-linearity for better detection performance. Here we only use the linear layer to provide a baseline of this kind of structure design.

These c number of linear layers (or receptors) for different grams (or scales) of the representation $\hat{\mathbf{r}}_u^k$ is then summed together to be layer-normalized (Ba et al., 2016). After that, the ReLU activation function is applied, followed by a linear layer with the size N_c that maps all the receptors to a user feature vector, $\mathbf{f}_u$,

$$\mathbf{f}_u = \text{Linear}(\text{ReLU}(\text{LayerNorm}(\sum_{k=1}^{n} \hat{\mathbf{r}}_u^k))).$$

2.3 Machine Act Representation

We represent the machine act in the m order n-gram of bag of words, $\mathbf{r}_a^m$, based on the vocabularies generalized from the machine acts in the training set of a given data set. The machine act feature, $\mathbf{f}_a$, is then simply generated through a linear layer of size N_c with the ReLU activation function,

$$\mathbf{f}_a = \text{ReLU}(\text{Linear}(\mathbf{r}_a^m)).$$

2.4 Slot Information Decoding

Since a slot, e.g. *area* or *food*, is usually indicated as a word or a short word group, then it can be represented as a single word vector (with multiple word vectors summed together), $\mathbf{s}$. A single linear layer with the size $2N_c$ is applied to the word vector $\mathbf{s}$, followed by the ReLU non-linear layer,

$$\mathbf{f}_s = \text{ReLU}(\text{Linear}(\mathbf{s})).$$

The turn-level feature vector, $\mathbf{i}_s$, is then generated through a point-wise multiplication $\otimes$ between the slot feature and the concatenation of the user feature and the machine act feature,

$$\mathbf{i}_s = \mathbf{f}_s \otimes (\mathbf{f}_u \oplus \mathbf{f}_a).$$

In this way, the turn-level feature vector is intended to amplify the large magnitude signals that are from both the user and machine act feature vector and the slot feature vector.

2.5 Fixed-length Value Prediction

Given the turn-level feature vector, $\mathbf{i}_s$, we can now track the dialogue state throughout the dialogue turns by LSTM. For the current turn t, the LSTM takes the $\mathbf{i}_s$ and the previous hidden state, $\mathbf{q}_{t-1}$, as the input. We can then obtain a fixed-length value prediction vector, $\mathbf{o}_s$, whose length is equal to N_w, i.e. the dimension of the word vectors which are fed into the model,

$$\mathbf{o}_s = \text{ReLU}(\text{Linear}(\text{LSTM}(\mathbf{i}_s, \mathbf{q}_{t-1}))),$$

where the linear layer has N_w neurons. In this way, the prediction of the model is independent of the number of the given values, so it is possible for the model to perform parameter sharing among each of the slots. The fixed-length prediction can somehow be interpreted as a *word vector* that is ready for the calculation of the similarity between the prediction and the true value label.

2.6 2-Norm Distance

For a specific semantic slot, since there may be no corresponding value in a given dialogue turn, thus we always add a literally "none" value to the value set for the model to track this state. For the evaluation of the similarity between the prediction and the value, we calculate the 2-Norm distance between the prediction vector and each of the word vectors of the values in the value set. Softmax function is performed with respect to all the negative relative distances to give a distribution of probabilities for the values, $v_i \in \mathcal{V}_s$,

$$p_s(v_i) = \text{Softmax}(-||\mathbf{o}_s - \mathbf{v}_i||),$$

where $\mathbf{v}_i$ is the representation vector of v_i. If the slot value v_i consists of more than one word, $\mathbf{v}_i$ will then be the summation of all corresponding word vectors. When training the model, we minimize the Cross-Entropy (CE) loss between the output probabilities and the given label.

StateNet requires the user utterance, the semantic slots, and slot values to be able to be expressed in words and have their corresponding word vectors. We use the fixed word embedding for every word, and do not fine-tune the word embeddings in the model. Since the word embeddings are distributed on a fixed-dimension vector space and hold rich semantic information, StateNet may have the ability to track the dialogue state for any new slot or value, as long as the corresponding word embedding can be found. This is the reason why we call the StateNet a *universal* dialogue state tracker.

3 Experiments

Experiments are conducted to assess the performance on joint goal. Two datasets are used by us for training and evaluation. One is the second Dialogue State Tracking Challenge (**DSTC2**) dataset (Henderson et al., 2014a), and the other is the second version of Wizard-of-Oz (**WOZ 2.0**) dataset (Wen et al., 2017). Both of them are the conversations between users and a machine system. The user's goal is to find a suitable restaurant around Cambridge. The ontology of these two datasets is identical, which is composed of three informable slots: *food, pricerange* and *area*. The main difference between them is that in WOZ 2.0, users typed instead of using speech directly. This means the users can use far more sophisticated language than they can in the DSTC2, which is a big challenge for the language understanding ability of the model. Thus, it allows WOZ 2.0 to be more indicative of the model's actual performance since it is immune to ASR errors.

Based on the model structure as described in Section 2, we implement three kinds of dialogue state tracker. The difference among them lies in the utilization of parameter sharing and parameter initialization.

- `StateNet`: It doesn't have shared parameters among different slots. In other words, three models for three slots are trained separately using RMSProp optimizer, learning rate set to 0.0005. And its parameters are not initialized with any pre-trained model.
- `StateNet_PS`: Parameter sharing is conducted among three slots. For each slot in a batch, we infer the model with the slot information and the same dialogue information. The losses are calculated based on the corresponding value set. After each slot is inferred, we back-propagate all the losses and do the optimization. So we just train one model in total using RMSProp optimizer, learning rate set to 0.0005. As a result, the amount of model parameters is one third of that of `StateNet`, which means `StateNet_PS` can significantly save the memory usage during inferring.
- `StateNet_PSI`: Parameter sharing is conducted within this model, same as `StateNet_PS`, but its parameters are initialized with a pre-trained model. For pre-training, we only allow the model to track one single slot and make predictions on its value set. After the training ends, we save the model parameters and use them to initialize the model parameters for the training of the multi-slot tracking. The pre-trained model with the best performance on the validation set is selected for initialization. Here, we choose the *food* slot for pre-training since `StateNet` has the lowest prediction accuracy on the *food* slot. `StateNet_PSI` is trained using Adam optimizer and learning rate is set to 0.001. Since the model has obtained the basic knowledge from the pre-trained model, then a more aggressive learning process is preferred. Adam with a higher learning rate can help a lot compared to RMSProp optimizer.

The hyperparameters are identical for all three models, $N_c = 128, N_w = 300, n = 2, m = 3$. We use $c = 4$ for the number of the receptors for each slot, where the number is determined through the grid search. The word embeddings used by us is the *semantically specialised* Paragram-SL999 vectors (Wieting et al., 2015) with the dimension of 300, which contain richer semantic contents compared to other kinds of word embeddings. Implemented with the MXNet deep learning framework of Version 1.1.0, the model is trained with a batch size of 32 for 150 epochs on a single NVIDIA GTX 1080Ti GPU.

The results in Table 1 show the effectiveness of parameter sharing and initialization. `StateNet_PS` outperforms `StateNet`, and `StateNet_PSI` performs best among all 3 models. It is because the parameter sharing can not only prevent the model diverging from the right learning process but also transfer necessary knowledge among different slots. And the parameter initialization provides the model with the opportunity to gain some basic while essential semantic information at the very beginning since the *food* slot is the most important and difficult one. Besides, `StateNet_PSI` beats all the mod-

els reported in the previous literature, whether the model with delexicalisation (Henderson et al., 2014b,c; Rastogi et al., 2017) or not (Mrkšić et al., 2017; Perez and Liu, 2017; Xu and Hu, 2018; Ramadan et al., 2018; Zhong et al., 2018).

Initialization	Joint Acc. DSTC2	Joint Acc. WOZ 2.0
food	**75.5**	**88.9**
pricerange	73.6	88.2
area	73.5	87.8

Table 2: Joint goal accuracy on DSTC2 and WOZ 2.0 of `StateNet_PSI` using different pre-trained models based on different single slot.

We also test `StateNet_PSI` with different pre-trained models, as shown in Table 2. The fact that the *food* initialization has the best performance verifies our selection of the slot with the worst performance for pre-training. This is because the good performance on joint goal requires a model to make correct predictions on all of the slots. A slot on which the model has the worst accuracy, i.e. the most difficult slot, will dramatically limit the overall model performance on the metric of the joint goal accuracy. Thus, the initialization with a model pre-trained on the most difficult slot can improve the performance of the model on its weakness slot and boost the joint goal accuracy, while the initialization of a strength slot may not help much for the overall accuracy but in turn causes the over-fitting problem of the slot itself.

4 Conclusion

In this paper, we propose a novel dialogue state tracker that has the state-of-the-art accuracy as well as the following three advantages: 1) the model does not need manually-tagged user utterance; 2) the model is scalable for the slots that need tracking, and the number of the model parameters will not increase as the number of the slots increases, because the model can share parameters among different slots; 3) the model is independent of the number of slot values, which means for a given slot, the model can make the prediction on a new value as long as we have the corresponding word vector of this new value. If there are a great number of values for a certain slot, to reduce the computational complexity, we can utilize a fixed-size candidate set (Rastogi et al., 2017), which dynamically changes as the dialogue goes on. Experiment results demonstrate the effectiveness of parameter sharing & initialization.

Our future work is to evaluate the performance of our models in the scenario where there are new slots and more unobserved slot values, and to evaluate the domain-transferring ability of our models.

Abstract

Task oriented dialog systems typically first parse user utterances to semantic frames comprised of intents and slots. Previous work on task oriented intent and slot-filling work has been restricted to one intent per query and one slot label per token, and thus cannot model complex compositional requests. Alternative semantic parsing systems have represented queries as logical forms, but these are challenging to annotate and parse. We propose a hierarchical annotation scheme for semantic parsing that allows the representation of compositional queries, and can be efficiently and accurately parsed by standard constituency parsing models. We release a dataset of 44k annotated queries [1], and show that parsing models outperform sequence-to-sequence approaches on this dataset.

1 Introduction

Intelligent personal assistants are now ubiquitous, but modeling the semantics of complex compositional natural language queries remains challenging. Typical systems classify the *intent* of a query (e.g. `GET_DIRECTIONS`) and tag the necessary slots (e.g. `San Francisco`) (Mesnil et al., 2013; Liu and Lane, 2016). It is difficult for such representations to adequately represent nested queries such as *"Driving directions to the Eagles game"*, which is composed of `GET_DIRECTIONS` and `GET_EVENT` intents. We explore a hierarchical representation for such queries, which dramatically improves the expressive power while remaining accurate and efficient to annotate and parse (see Figure 1).

We introduce a Task Oriented Parsing (TOP) representation for intent-slot based dialog systems. This hierarchical representation is expressive enough to capture the semantics of complex nested queries, but is easier to annotate and parse than alternative representations such as logical forms or dependency graphs. We show empirically that our representation is expressive enough to model the vast majority of human-generated requests in two domains.

A key advantage of our representation is that it has a structure similar to standard constituency parses, allowing us to easily adapt algorithms developed for phrase structure parsing for inference. In particular, we use linear-time Recurrent Neural Network Grammars (RNNG) (Dyer et al., 2016) and show that the inductive bias provided by this model significantly improves the accuracy compared to strong sequence-to-sequence (seq2seq) models based on CNNs, LSTMs and Transformers.

Our contributions in this paper are:

1. A hierarchical semantic representation for task oriented dialog systems that can model compositional and nested queries.
2. A publicly available dataset of 44k requests annotated with our representation. We show that our representation has very high coverage of these requests, and that inter-annotator agreement is high.
3. We show that the representation is learnable by standard algorithms. In particular, we show that the RNNG parsing model outperforms seq2seq baselines.

2 Representation

Designing semantic annotation schemes requires trade-offs between how expressive the representation is on one hand, and how easily can it be annotated, parsed, and executed on the other. Most existing annotations for task oriented dialog systems have fallen on the extremes of non-recursive intent and slot tagging, such as in the ATIS dataset (Mes-

Brussels, Belgium, October 31 - November 4, 2018.

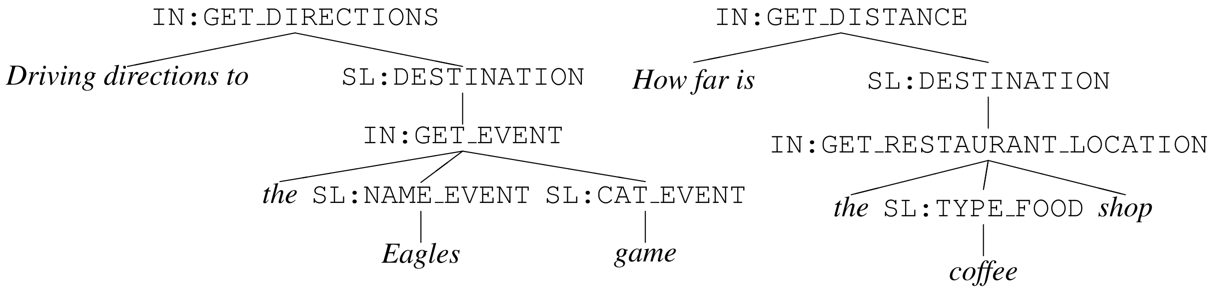

Figure 1: Example TOP annotations of utterances. Intents are prefixed with `IN:` and slots with `SL:`. In a traditional intent-slot system, the `SL:DESTINATION` could not have an intent nested inside it.

nil et al., 2013; Liu and Lane, 2016), and full logical forms (Zettlemoyer and Collins, 2012).

We introduce a hierarchical representation, similar to a constituency syntax tree, with words as terminals. Non-terminals are either *intents* or *slots*, and the root node is an intent. We allow intents to be nested inside a slot, resulting in the ability to compose requests and call multiple APIs. Using this compositional tree representation, we can enable answering compositional queries over multiple domains.

We introduce the following constraints in our representation: 1. The top level node must be an intent, 2. An intent can have tokens and/or slots as children, 3. A slot can have either tokens as children or one intent as a child.

Executing queries such as those in Figure 1 is straightforward because of the explicit tagging of the outer location slot: first we fetch 'the Eagles game' event (or the relevant coffee shop), extract the location, and pass it as the destination slot to the navigation domain intent.

Compositional queries are frequent. In our dataset of crowd-sourced utterances, we found that 30% could not be adequately represented with traditional intent-slot tagging.[2] This shows that more expressive representations are often necessary.

While our representation is capable of modeling many complex queries, some utterances are beyond its scope. For example, in *Set an alarm at 8 am for Monday and Wednesday*, *8 am* needs to be associated with both *Monday* and *Wednesday* which would require graph-structured representations. However, we found that just 0.3% of our dataset would require a more expressive representation to model adequately.[3] More expressive representations, such as dependency graphs or logical forms, would only bring marginal gains but would add significant challenges for annotation and learning.

Together, these results suggest that our tree-structured approach offers a useful compromise between traditional intent-slot tagging and logical forms, by providing very high coverage of queries while avoiding the complexities of annotating and learning more expressive representations.

In summary, our representation has the following attractive properties:

- **Expressiveness** Compared to traditional intent-slot annotations, it can express complex hierarchical queries, improving coverage of queries by 30%. We found that more general representations are required for only 0.3% of queries.
- **Easy Annotation** Annotating our representation simply requires labeling spans of a sentence, which is much more straightforward than alternatives such as creating a logical form for the sentence, or an arbitrary dependency graph. This fact allows us to quickly create a large dataset.
- **Efficient and Accurate Parsing** Since our representation closely resembles syntactic trees, we can easily re-use models from the large literature on constituency parsing.

---

[2] In our dataset, 35% of queries have depth >2, which means that the traditional intent-slot tagging systems would not have been able to annotate or predict these annotations. In addition, to avoid the depth-based statistic being influenced by our label set specification, we manually performed analysis of 100 samples that showed that 30% of the queries required compositional representation.

[3] Utterances that could not be annotated with the label sets and corresponding instructions were marked as 'unsupported' (9.14% of the dataset), including the ones that needed more expressive representation than a tree. Analysis of a random sample of 120 unsupported utterances shows that only four instances cannot be supported because of the tree representation constraint, estimating that there are only 0.3% queries that would require a more general (e.g graph-based) representation.

- **Execution** Our approach can be seen as a simple generalization of traditional dialog systems, meaning that existing infrastructure can easily be adapted to execute the intents.

3 Dataset

We asked crowdsourced workers to generate natural language sentences that they would ask a system that could assist in navigation and event queries. These requests were then labeled by two annotators. If these annotations weren't identical then we adjudicated with a third annotator. If all three annotators disagreed then we discarded the utterance and its annotations. 63.40% of utterances were resolved with 2 annotations and 94.09% were resolved after getting 3 annotations. We also compared percentage of utterances that were resolved after 2 annotations for depth ≤ 2 (traditional slot filling) and for depth > 2 (compositional): 68.87% vs 62.03%, noting that the agreement rate is similar.

We collected a total of 44783 annotations with 25 intents and 36 slots, randomly split into 31279 training, 4462 validation and 9042 test utterances. The dataset has utterances that are focused on navigation, events, and navigation to events.

The median (mean) depth of the trees is 2 (2.54), and the median (mean) length of the utterances is 8 (8.93) tokens. 35% of trees have depth more than 2. The dataset has 4646 utterances that contain both navigation and event intents. Figure 2 shows the distribution of instances in the full dataset over the utterance length and tree depth.

4 Models

We experiment with two types of models: standard sequence-to-sequence learning models, and a model adapted from syntactic parsing, Recurrent Neural Network Grammars (Dyer et al., 2016) (RNNG). RNNG is a top-down transition-based parser and was originally proposed for parsing syntax trees and language modeling. We trained the RNNG parser discriminatively and not generatively to reduce training time of the model. While sequence-to-sequence learning can model arbitrary sequence transduction, we hypothesize that parsing models like RNNG, which can only output well-formed trees, will give better inductive bias and flexibility for predicting compositional and cross-domains scenarios on the fly, particularly for domains with less training data available.

We briefly review the RNNG model – The parse tree is constructed using a sequence of transitions, or 'actions'. The transitions are defined as a set of SHIFT, REDUCE, and the generation of intent and slot labels. SHIFT action *consumes* an input token (that is, adds the token as a child of the right most 'open' sub-tree node) and REDUCE *closes* a sub-tree. The third set of actions is generating non-terminals – the slot and intent labels. Note that at each step, there are only a subset of valid actions. For examples, if all the input tokens have been added to the tree, the only valid action is REDUCE.

5 Experiments and Results

Baselines

We compared RNNG with implementations of sequence-to-sequence models using CNNs (Gehring et al., 2017), LSTMs (Wiseman and Rush, 2016) and Transformer networks (Vaswani et al., 2017) in fairseq[4].

Metrics

We used three metrics to evaluate the systems. **Exact match** accuracy is defined as the number of utterances whose full trees are correctly predicted. The second metric is a commonly used scoring method for syntactic parsing – **labeled bracketing** F_1 scores (Black et al., 1991) (called F_1 henceforth). We used the pre-terminals as well in the calculations. One downside of this metric is that it only considers the token spans for a given non-terminal but not the internal structure. Tree substructures are rather important for task completion. Thus, we introduce a third metric, **Tree-Labeled** (TL) F_1, which compares the sub-tree structure for a non-terminal, instead of just the token span. Exact match accuracy is the strictest metric and F_1 is the least strict metric. **Tree Validity** is the percentage of predictions which formed valid trees (via bracket matching).

Preprocessing and Hyperparameters

We used the same preprocessing of unknown words as used in (Dyer et al., 2016) and mapped numbers to a constant. We used pre-trained GloVe embeddings (Pennington et al., 2014) and tuned hyperparameters on the validation set.

- **RNNG** - We used 2-layer 164-unit LSTM with a bidirectional LSTM compositional

seq2seq-Transformer	72.20	86.60	87.09	86.11	78.54	78.99	78.19	99.55

Table 1: Performance (in percentage) of RNNG and seq2seq models based on LSTMs, CNNs, and Transformer networks. The CNN and LSTM models were trained with a Limited Output Token Vocabulary (LOTV) of just a single element.

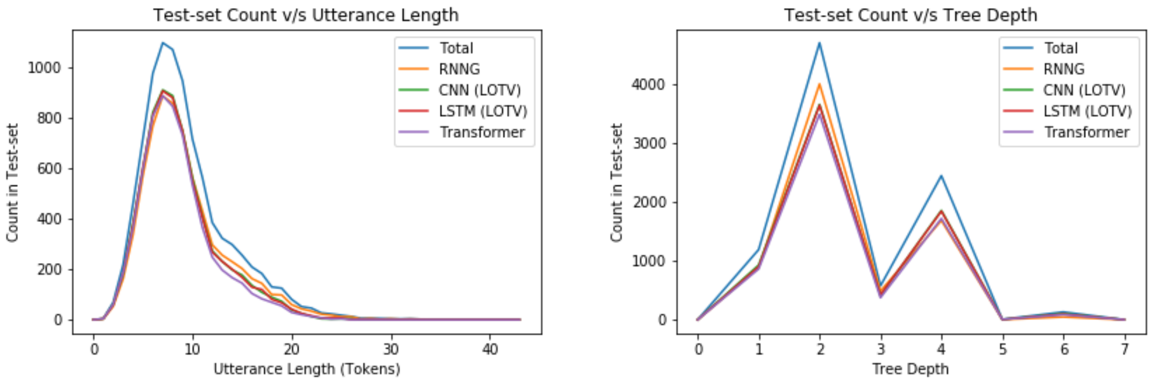

Figure 3: Exact match statistics of the different models on the testset

function, trained with a learning rate of 0.0004, weight decay of 0.00004, dropout of 0.34 with Adam optimizer for 1 epoch with 16 workers using Hogwild updates.

- **seq2seq CNN** - We used 3x3 convolutions (9 layers of 512 units, 4 units of 1024 units), followed by 1x1 convolutions (2 layers of 2048 units) with attention, trained with initial learning rate of 0.9, dropout of 0.2, gradient clipping of 0.1 with NAG optimizer for 30 epochs, inferred with beam size 5.
- **seq2seq Transformer** - We used 3 layers of 4 FFN attention heads of embedding dimension 512, trained with initial learning rate of 0.01, dropout of 0.2, gradient clipping of 5 with Adam optimizer for 50 epochs, inferred with beam size 5.
- **seq2seq LSTM** - We used 1-layer 256 unit LSTMs with attention, trained with initial learning rate of 0.7, dropout of 0.2, gradient clipping of 0.1 with NAG optimizer for 40 epochs, inferred with beam size 5.

Results

The experimental results in Table 1 and Figure 3 show that existing approaches for syntactic parsing, such as RNNG, perform well for this task, achieving perfect outputs on over 75% of queries. RNNG performs better than sequence-to-sequence models, especially in predicting exact trees, which is important for task completion. We present results for the CNN and LSTM models with an output terminal token vocabulary of just a single element (LOTV), which performed better than the regular token vocabulary (exact match accuracy of 75.63% and 68.39%, respectively). We believe LOTV makes the models focus on learning to predict the tree structure rather than to reproduce the input tokens. But we observed that this vocabulary reduction resulted in significantly poorer performance for the Transformer model.

Below we discuss how varying the beam size during inference affects accuracy. The seq2seq results in Table 1 are accuracy for the top prediction when a beam of size 5 was run and the RNNG results are for greedy inference. For RNNG, the accuracy of top prediction did not change much when a beam of size 5 was run. We also measured how often the correct tree annotation was in the top k predictions for the models when a beam of size k was run during inference, called as *Top-k*. For RNNG, *Top-3* was 90.21 and *Top-5* was 92.48, compared to 78.51 for k=1. For seq2seq-CNN, the *Top-3* score was 88.08 and *Top-5* score was 90.21. For seq2seq-LSTM, *Top-3* was 86.55 and *Top-5* was 88.76. We note that *Top-5* is substantially higher than the accuracy of the top prediction. These top-k predictions could be used by a hypothesis ranker downstream, which can take into account agent capabilities.

We also experimented with more minimal representations of the RNNG model (Kuncoro et al., 2017). Removing the actions LSTM dropped Exact match score slightly to 78.08. Separately, removing the stack LSTM dropped it to 75.31. Removing the buffer LSTM caused a unusable decrease to 13.78.

While sequence-to-sequence models have shown strong parsing performance when trained on very large amounts of data (Vinyals et al., 2015); in our setting the inductive bias provided by the RNNG model is crucial to achieving high performance. The model has several useful biases, such as guaranteeing a well-formed output tree, and shortening the dependencies between intents and their slots.

A further advantage of RNNG is that inference has linear time complexity, whereas seq2seq models are quadratic because attention is recomputed at every time step.

6 Related Work

Many annotation schemes have previously been proposed for representing the semantics of natural language. We briefly compare our method with these.

Most work on task oriented dialog systems has focused on identifying a single user intent and then filling the relevant slots – for example, the representations used on the ATIS dataset (Mesnil et al., 2013; Liu and Lane, 2016; Zhu and Yu, 2017) and in the Dialog State Tracking Challenge (Williams et al., 2016). We showed that hierarchical representations with nested intents can improve coverage of requests in our domains.

The semantic parsing literature has focused on representing language with logical forms (Liang, 2016; Zettlemoyer and Collins, 2012; Kwiatkowski et al., 2010). Logical forms are more expressive than our representation, as they are less tightly coupled to the input query, and can be executed directly. However, logical forms are difficult to annotate and no large-scale datasets are available.

While we used a tree-structured representation, others have used arbitrary graphs, such as Abstract Meaning Representation (Banarescu et al., 2013) and Alexa Meaning Representation (Fan et al., 2017). These approaches can represent complex constructions that are beyond the scope of our approach, but with significantly challenging parsing (Artzi et al., 2015). We showed that such cases are very rare in our data.

7 Conclusions

Drawing on ideas from slot-filling and semantic parsing, we introduce a hierarchical generalization of traditional intents and slots that allows the representation of complex nested queries, leading to 30% higher coverage of user requests. We show that the representation can be annotated with high agreement. We are releasing a large dataset of annotated utterances at `http://fb.me/semanticparsingdialog`. The representation allows the use of existing constituency parsing algorithms, resulting in higher accuracy than sequence-to-sequence models.

The glass ceiling in NLP

Natalie Schluter
Department of Computer Science
IT University
Copenhagen, Denmark
natschluter@itu.dk

Abstract

In this paper, we provide empirical evidence based on a rigourously studied mathematical model for bi-populated networks, that a glass ceiling within the field of NLP has developed since the mid 2000s.

1 Introduction

The *glass ceiling* is a powerful metaphor for the unethical, invisible, and yet virtually impenetrable barrier that prevents highly achieving women and minorities from obtaining equal access to senior career opportunities. The existence of a glass ceiling is well documented both in STEM[1] and specifically in Computer Science (Moss-Racusin et al., 2012; Shen, 2013; Larivière et al., 2013; Van der Lee and Ellemers, 2015; Way et al., 2016, for example). To date there has been no published study on this topic for the field of NLP.

In most countries, Computer Science has long been struggling to support female researchers sufficiently: female representation in Computer Science is not only disproportional to the population, but it is lower than the average STEM field. Moreover, as opposed to STEM fields in general, the proportion of women in Computer Science has been on a marked decline for the past two decades (Sax et al., 2017; Williams et al., 2017), placing the entire the tech field in a diversity crisis today.

The discussion of gender representation or even the existence of a glass ceiling is rather more complex for NLP due to its fundamental interdisciplinarity especially across the fields of Linguistics, Computer Science, and Statistics. That is, much mainstream research in NLP follows trends that are heavily situated in one of the main subdisciplines. Can we witness any emergent glass ceiling for female researchers in the wake of an increasing concentration on deep learning engineering techniques applied to NLP problems? What about the preceding Machine Learning wave from the mid 2000s? In this paper we answer this question in the affirmative.

We acquired a gender-annotated co-author dataset covering arguably the most central ACL publication venues for the past 52 years. We carry out basic data analysis over this dataset and the bi-populated (female and male researcher) mentor-mentee network derived from it. We make the following concerning empirical observations:

1. **There is a growing mentor gender gap.** There is a growing disparity between the proportions of female and male NLP researchers who achieve mentor status, with a higher proportion of male researchers becoming mentors, especially since the mid 2000s.
2. **There is a significant time gap to mentor status across genders.** Female NLP researchers must wait a considerable time longer to achieve mentor status than their male colleagues.
3. **In-gender mentorship correlates with future success.** Female NLP researchers who take a male supervisor will have greater difficulty in becoming a mentor than if they take a female supervisor, on average.
4. **Homophily is on the rise.** There is consistently increasing homophily in our field–the preference to establish in-gender mentor-mentee relationships.

Following this analysis, we employ Avin et al. (2015)'s rigorously studied conditions for power inequality and the glass-ceiling effect for complex systems data structured like ours to show that these empirical observations indicate quite precisely **the existence of a glass ceiling effect for the field of NLP**.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2793–2798
Brussels, Belgium, October 31 - November 4, 2018.

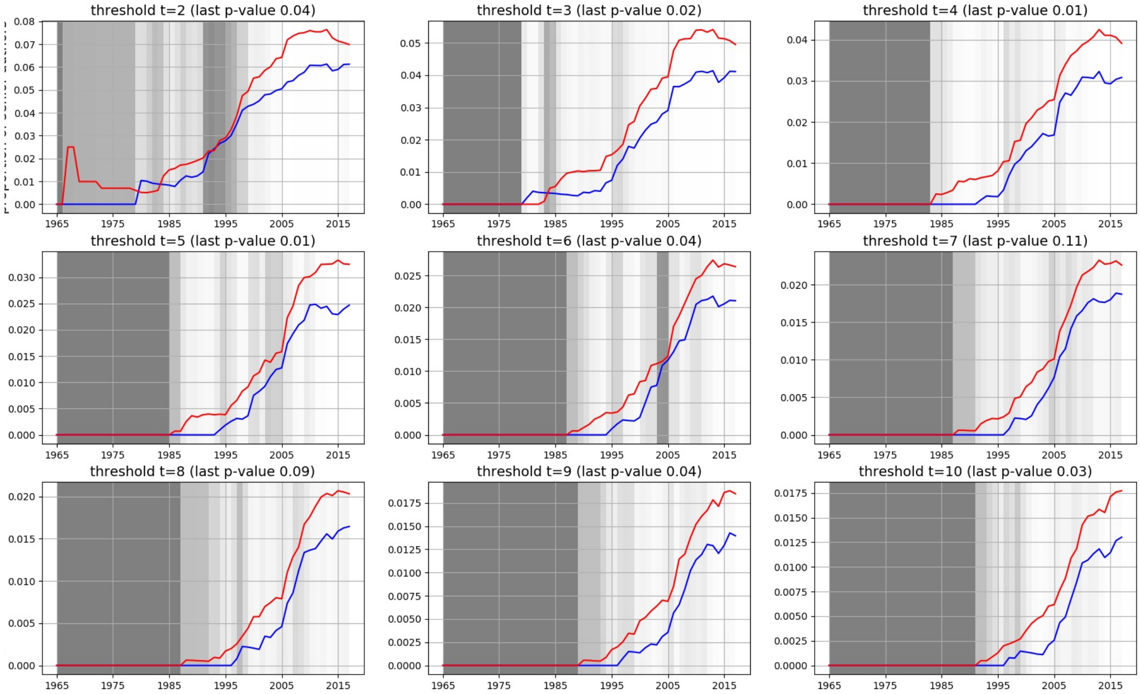

Figure 1: Proportion of male (red line) and female (blue line) mentors from 1966 to 2017, for different thresholds of "mentor seniority". A disparity in these proportions has been increasing since the 1990s, which follows the general field of Computer Science. The whiter the background the more significant the difference in proportions for the corresponding year, with the p-value for 2017 in the title.

2 Acquiring a gender-annotated mentor-mentee network

We scraped all meta-information available from the ACL Anthology[2] for arguably the most central publication venues in NLP. This includes all papers from CoNLL, EACL, TACL, CL, ACL, EMNLP, COLING, ANLP, NAACL, *Sem/SemEval from 1965 to 2017: 19,552 papers in total.

We carried out some normalisation of the author names scraped by lower-casing, normalising for order (first name then last name), removing middle initials and title abbreviations, and removing accents and punctuation, collapsing the extracted list of 18,437 author names to a list of 17,232 author names. Following this, we applied several gendered first-name lists to automatically annotate a large portion of the author names with gender.[3] This resulted in 13,435 automatically annotated author names. Of the remaining 3797 unannotated names, we automatically label as 'unknown' all author names with only an initial standing for the first name, effectively filtering out a further 565 author names. The remaining 3232 author names were annotated by the current authors by manually inspecting the results of Google Image queries for the full name.

The resulting dataset spans 52 years and includes 17,232 authors, of which we labeled 10,382 as male, 5,227 as female and 1,623 whose gender we could not identify. In what remains of our study, we discard these latter authors. This leaves a total of 15,609 researchers.

Power in academia. In our study, we need to account for mentor status–a type of seniority and power. As in many other fields, in NLP it is customary for mentors to take the last-authorship position of papers. Though there can be exceptions to this custom, the assumption of mentor last-authorship is simple, and with this large dataset, we believe it provides a robust approximation of mentorship in the absence of other more precise indications like centralised supervision logs. This method was also adopted by Avin et al. (2015).

We use the assumption of mentor last-authorship to provide an empirical definition of a mentor in our dataset. We say that after t last-authored papers for some threshold $t \in \{1, \ldots, 10\}$, and excluding all sole-author papers,

---

[2] `http://www.aclweb.org/anthology`

[3] The lists are discussed in the appendix.

a researcher is considered to hold *mentor standing with seniority threshold* t.

We model the interactions between researchers by creating the bi-populated (for female and male populations) mentor-mentee network. The network's nodes therefore are researchers and there is an edge between two co-authors of a paper in our dataset if and only if one of the co-authors is the last author. This leaves a mentor-mentee network with 14248 nodes, 25211 edges, and average degree 3.539. This network allows us to observe whether the current system of mentor-mentee relationships entails a glass ceiling effect in the modeled community. We now present the results of this analysis.

3 Evidence of a rising gender gap

We provide some basic empirical evidence which could be indicative of the presence of a glass ceiling effect in NLP. In Section 4, we then prove that there is indeed a glass ceiling.

3.1 Growing mentor standing disparity

A researcher who has achieved some seniority is generally eligible to become a mentor and supervise students. As such, the rise to becoming a mentor is a measurable criterion of success for a researcher in academia. Concretely, in some countries, the mentor role is reserved for permanent/tenured faculty (for example, in Denmark). Therefore a barrier to mentor standing for females can lead to an important under-representation of women. This under-representation in turn may perpetuate itself through the lower availability of same-gender advisors for female students, which we show to be of central importance for rising NLP researchers (in Section 3.3).

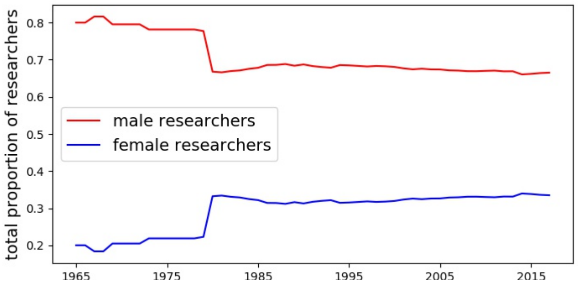

Figure 2: The proportion of female researchers (blue line) in NLP has been gradually increasing since 1965, but seems to be leveling off at around 33.5%, with a very slight decrease since 2014. A corresponding decrease is observed for male NLP researchers (red line).

For thresholds of "mentor seniority" $t \in \{2, \ldots, 10\}$ we examined the proportion of mentors with respect to the pool of researchers of the same gender over time from 1966 to today. Figure 1 shows the resulting time series. Across all thresholds, we observe that the proportion of male supervisors with respect to the total number of male researchers is increasing faster than the proportion of female supervisors within the general pool of female researchers. In fact, the discrepancy between these two proportions seems to slowly close until the early-to-mid 2000s after which it steadily increases again. And in almost all cases this difference in proportions develops into a statistically significant difference (with a 1-sided z-test for proportions, and p-value 0.05). This is despite there being no corresponding development in mentor-mentee proportions as shown in Figure 2.

3.2 Time to seniority gap

We further investigate the subset of female researchers who achieved mentor standing, and compare their difficulty in doing so with that of the respective pool of male researchers. One measurable factor from our dataset is time. Isolating a substantially larger delay to achieving mentor standing for female researchers is one way to use our dataset to measure the difficulty in transitioning female researchers from mentee to mentor standing. We consider the average time it takes to achieve mentor standing between the two populations. For consecutive periods of two years, we compute the average number of years for researchers to achieve mentor standing at threshold $t \in \{2, \ldots, 10\}$. We provide a visualisation of the results in Figure 3. We do a two sample t-test to expose the statistical significance in the non-equality of the respective means. We observe that across all thresholds for mentor standing, female researchers are substantially more delayed than male researchers in becoming mentors. For the most recent numbers, the result is most significant where there is the most data, at seniority $t = 3$, with p-level 0.04. However we note the general whitening of the plots (indicating statistical significance) after the mid-2000s.

3.3 The effects of in-gender supervision

The availability of female mentors been has shown to correlate with mentees' future success–in particular, females in Chemistry who are mentored by

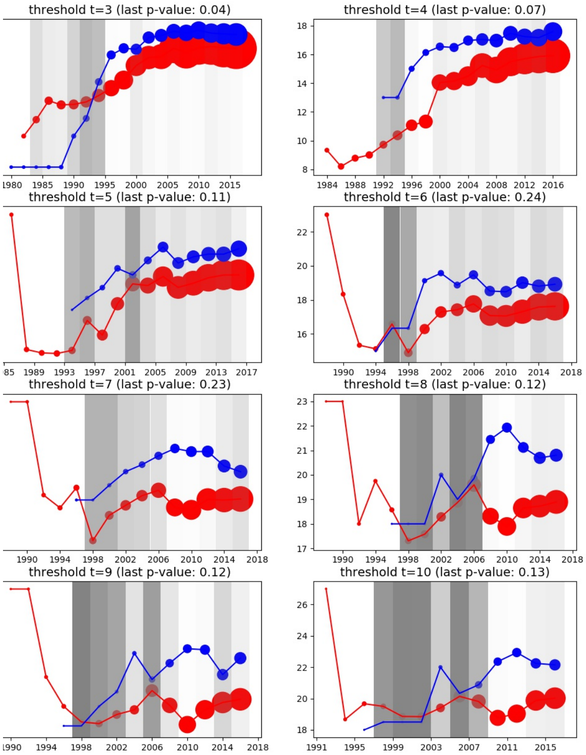

Figure 3: The average time it takes in years, across the past 52 years, for female researchers (blue line) and male researchers (red line) to achieve mentor status in the NLP field. The more significant the difference in means, the whiter the background. The relative number of data points for each year and gender are indicated by the size of the scatter points (blue for females and red for males). The last recorded p-level for each seniority threshold is provided in the corresponding plot's title.

	mentor					
	male	female	male	female	male	female
mentee	$t = 2$		$t = 3$		$t = 4$	
male	12.26	5.69	6.98	4.21	4.95	3.29
female	7.29	10.73	4.96	6.12	3.69	4.11
	$t = 5$		$t = 6$		$t = 7$	
male	3.91	2.72	3.25	2.4	2.64	1.99
female	2.83	3.08	2.31	2.47	2.01	2.1
	$t = 8$		$t = 9$		$t = 10$	
male	2.26	1.74	2.03	1.58	1.85	1.46
female	1.8	1.87	1.61	1.65	1.38	1.4

Table 1: Probabilities (as % here) that a mentee of the row gender, supervised by a mentor of the column gender will achieve mentor standing, for various thresholds t.

female supervisors are considerably more likely to become faculty themselves (Gaule and Piacentini, 2018). In Table 1 we observe a similar trend for in-gender mentorship. In particular, female researchers who have female mentors are much more likely to become mentors themselves. This is a particular problem if, as Sections 3.1 and 3.2 show, the proportion of female NLP mentors is not increasing at the same rate as that of male NLP researchers, possibly due in part to the added delay in achieving mentor status for women. Indeed this delay in access, perpetuated due to the lack of in-gender supervision, can be the result of a glass ceiling in NLP. In the next section we investigate the likelihood of such a glass ceiling.

4 The glass ceiling effect in NLP

In order to understand better how the population of female researchers in NLP can be increasing, but the growth level of seniority/mentor standing still falls significantly below that of the male population and that this gap is widening, we turn to an investigation of power inequality and the glass ceiling effect.

First three key observations can be made of the mentor-mentee network introduced in Section 2 vis-à-vis three well-accepted mechanisms of observed human behavior.

(O1) **Minority-majority partition.** Figure 2 shows the resulting proportion of male and female researchers in NLP through the 52 years. Our network displays a minority-majority partition: the proportion of females has hovered around 33.5% for the past decade now.

(O2) **Homophily** is the is the tendency of individuals to associate with people similar to them.

Easley and Kleinberg (2010) provide the following test for homophily. Given the proportions of male and female ended edges in the network, we should be able to calculate the approximate proportion of mixed edges (the probability that we select a mixed-gendered edge at random). If the true fraction is significantly below the expected amount, the network is exhibiting homophily. Figure 4 shows that homophily is a consistently worsening problem in the NLP community. All numbers are significant with p-value virtually 0 (1-sided z-test for proportions). Note that the plot includes error bars, which are so small they are not visible.

(O3) **The "rich-get-richer" feedback mechanism** describes and explains the process of wealth concentration, by which the future distribution of wealth is predictable from empirical data based on the current wealth distribution.

In our network, the degree of a node captures its level of social wealth: people may try to connect more often to people who already have many connections, either in order to profit from their social wealth or because they are more visible in the network. In our NLP mentor-mentee network, the average degree for male researcher nodes is 3.356, while for females it is 3.186. Hence our mentor-mentee network exhibits a "rich-get-richer" mechanism in favour of male researchers.

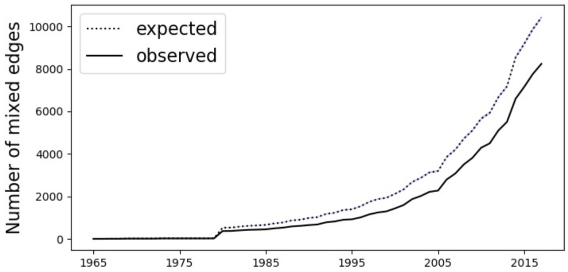

Figure 4: Evidence of ever-increasing homophily. The expected number of mixed-gender interactions is higher than the observed.

The biased preferential attachment model. Avin et al. (2015) extend Barabási and Albert (1999)'s preferential attachment model that was originally based on the "rich-get-richer" feedback mechanism to a *biased preferential attachment model* of mentor-mentee dynamics, $G(n, f, p)$, where there further is (1) a minority-majority partition (the proportion of female nodes is less than half, $f < \frac{1}{2}$) and (2) homophily. The model works as follows, instantiated to our context. Over time, a sequence of bi-populated mentor-mentee networks is constructed, $G_t = (V_t, E_t)$, like the one described in Section 2. $V_t = F_t \cup M_t$ is the set of G_t's nodes, and E_t its edges, where $F_t(M_t)$ is the set of female (male) nodes. G_0 is the empty graph. At each time $t > 0$ a mentee enters the network. The mentee is a female with probability f and a male with probability $m = 1 - f$. Assuming a rich-get-richer mechanism, the mentee chooses a potential mentor according to that mentor's importance in the network: with probability $\frac{\delta_t(u)}{\sum_{v \in V_t} \delta_t(v)}$ where $\delta_t(v)$ is the degree of $v \in V_t$. If this supervision is in-gender, then a relation (edge) is established. However if genders differ, then the relation (edge) is established according to the probability of homophily (p); otherwise (with probability $(1 - p)$) it is rejected and the mentee must restart the process of finding a mentor. Once an advisor for the mentee has been found, t increments to the next time step.

We now introduce definitions and the main theorem established by (Avin et al., 2015) for conditions of the existence of power inequality and a glass ceiling effect in bi-populated networks. Then we empirically check for these conditions in our NLP mentor-mentee network for the main result.

Power inequality definition. The sequence of mentor-mentee networks G_t is said to exhibit a *power inequality effect* for females if the average power of a female node is strictly bounded by the power of a male node: i.e., $\lim_{t \to \infty} \frac{\frac{1}{|F_t|} \sum_{v \in F_t} \delta_t(v)}{\frac{1}{|M_t|} \sum_{v \in M_t} \delta_t(v)} < 1$.

Tail and moment glass ceiling definitions. Let $\text{top}_k(F_t)$ ($\text{top}_k(M_t)$) denote the number of female (male) nodes that have degree of at least k in G_t– this is the group of scholars whose wealth in relations in the network is at level at least k; this wealth of relations is a form of power. The glass ceiling effect for the minority of females describes a process by which the proportion of access to this wealth of relations is limited for females but not for males. Formally, the sequence G_t is said to exhibit a *tail glass ceiling effect* for the female nodes (the minority) if there exists an increasing sequence k_t such that $\lim_{t \to \infty} \text{top}_{k_t}(M_t) = \infty$ and $\lim_{t \to \infty} \frac{\text{top}_{k_t}(F_t)}{\text{top}_{k_t}(M_t)} = 0$. G_t exhibits a *moment glass ceiling* g for the female nodes, if $g = \lim_{t \to \infty} \frac{\frac{1}{|F_t|} \sum_{v \in F_t} \delta_t(v)^2}{\frac{1}{|M_t|} \sum_{v \in M_t} \delta_t(v)^2}$. And if $g = 0$, G_t has a *strong glass ceiling effect*.

The main result: Power inequality and glass ceiling. Avin et al. (2015) proved that if $0 < f < \frac{1}{2}$ and $0 < p < 1$, then for $G(n, f, p)$ produced by the biased preferential attachment model, $G(n, f, p)$ exhibits both power inequality and a tail and strong glass ceiling effects. In observations (O2) and (O3), we identified the conditions $f = 0.335 < 0.5$ and the existence of homophily (i.e., $0 < p < 1$) in our NLP mentor-mentee network. We have therefore shown there to exist power inequality and a glass ceiling in NLP.

5 Concluding remarks

Given our study of the mentee-mentor network for NLP, we have shown that there is a glass ceiling for female researchers in NLP that has taken a hold of the field since the mid-2000s.

Reducing Gender Bias in Abusive Language Detection

Ji Ho Park, Jamin Shin, Pascale Fung
Centre for Artificial Intelligence Research (CAiRE)
Hong Kong University of Science and Technology
`{jhpark, jmshinaa}@connect.ust.hk`, `pascale@ece.ust.hk`

Abstract

Abusive language detection models tend to have a problem of being biased toward identity words of a certain group of people because of imbalanced training datasets. For example, "You are a good *woman*" was considered "sexist" when trained on an existing dataset. Such model bias is an obstacle for models to be robust enough for practical use. In this work, we measure gender biases on models trained with different abusive language datasets, while analyzing the effect of different pre-trained word embeddings and model architectures. We also experiment with three bias mitigation methods: (1) debiased word embeddings, (2) gender swap data augmentation, and (3) fine-tuning with a larger corpus. These methods can effectively reduce gender bias by 90-98% and can be extended to correct model bias in other scenarios.

1 Introduction

Automatic detection of abusive language is an important task since such language in online space can lead to personal trauma, cyber-bullying, hate crime, and discrimination. As more and more people freely express their opinions in social media, the amount of textual contents produced every day grows almost exponentially, rendering it difficult to effectively moderate user content. For this reason, using machine learning and natural language processing (NLP) systems to automatically detect abusive language is useful for many websites or social media services.

Although many works already tackled on training machine learning models to automatically detect abusive language, recent works have raised concerns about the robustness of those systems. Hosseini et al. (2017) have shown how to easily cause false predictions with adversarial examples in Google's API, and Dixon et al. (2017) show that classifiers can have unfair biases toward certain groups of people.

We focus on the fact that the representations of abusive language learned in only supervised learning setting may not be able to generalize well enough for practical use since they tend to overfit to certain words that are neutral but occur frequently in the training samples. To such classifiers, sentences like "You are a good woman" are considered "sexist" probably because of the word "woman."

This phenomenon, called *false positive bias*, has been reported by Dixon et al. (2017). They further defined this model bias as unintended, "a model contains unintended bias if it performs better for comments containing some particular identity terms than for comments containing others."

Such model bias is important but often unmeasurable in the usual experiment settings since the validation/test sets we use for evaluation are already biased. For this reason, we tackle the issue of measuring and mitigating unintended bias. Without achieving certain level of generalization ability, abusive language detection models may not be suitable for real-life situations.

In this work, we address model biases specific to gender identities (gender bias) existing in abusive language datasets by measuring them with a generated unbiased test set and propose three reduction methods: (1) debiased word embedding, (2) gender swap data augmentation, (3) fine-tuning with a larger corpus. Moreover, we compare the effects of different pre-trained word embeddings and model architectures on gender bias.

2 Related Work

So far, many efforts were put into defining and constructing abusive language datasets from different sources and labeling them through crowd-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2799–2804
Brussels, Belgium, October 31 - November 4, 2018.

sourcing or user moderation (Waseem and Hovy, 2016; Waseem, 2016; Founta et al., 2018; Wulczyn et al., 2017). Many deep learning approaches have been explored to train a classifier with those datasets to develop an automatic abusive language detection system (Badjatiya et al., 2017; Park and Fung, 2017; Pavlopoulos et al., 2017). However, these works do not explicitly address any model bias in their models.

Addressing biases in NLP models/systems have recently started to gain more interest in the research community, not only because fairness in AI is important but also because bias correction can improve the robustness of the models. Bolukbasi et al. (2016) is one of the first works to point out the gender stereotypes inside word2vec (Mikolov et al., 2013) and propose an algorithm to correct them. Caliskan et al. (2017) also propose a method called Word Embedding Association Test (WEAT) to measure model bias inside word embeddings and finds that many of those pretrained embeddings contain problematic bias toward gender or race. Dixon et al. (2017) is one of the first works that point out existing "unintended" bias in abusive language detection models. Kiritchenko and Mohammad (2018) compare 219 sentiment analysis systems participating in SemEval competition with their proposed dataset, which can be used for evaluating racial and gender bias of those systems. Zhao et al. (2018) shows the effectiveness of measuring and correcting gender biases in coreference resolution tasks. We later show how we extend a few of these works into ours.

3 Datasets

3.1 Sexist Tweets (`st`)

This dataset consists of tweets with sexist tweets collected from Twitter by searching for tweets that contain common terms pertaining to sexism such as "feminazi." The tweets were then annotated by experts based on criteria founded in critical race theory. The original dataset also contained a relatively small number of "racist" label tweets, but we only retain "sexist" samples to focus on gender biases. Waseem and Hovy (2016); Waseem (2016), the creators of the dataset, describe "sexist" and "racist" languages as specific subsets of abusive language.

Name	Size	Positives (%)	μ	σ	max
`st`	18K	33%	15.6	6.8	39
`abt`	60K	18.5%	17.9	4.6	65

Table 1: Dataset statistics. μ, σ, max are mean, std.dev, and maximum of sentence lengths

3.2 Abusive Tweets (`abt`)

Recently, Founta et al. (2018) has published a large scale crowdsourced abusive tweet dataset with 60K tweets. Their work incrementally and iteratively investigated methods such as boosted sampling and exploratory rounds, to effectively annotate tweets through crowdsourcing. Through such systematic processes, they identify the most relevant label set in identifying abusive behaviors in Twitter as $\{None, Spam, Abusive, Hateful\}$ resulting in 11% as 'Abusive,' 7.5% as 'Hateful', 22.5% as 'Spam', and 59% as 'None'. We transform this dataset for a binary classification problem by concatenating 'None'/'Spam' together, and 'Abusive'/'Hateful' together.

4 Measuring Gender Biases

4.1 Methodology

Gender bias cannot be measured when evaluated on the original dataset as the test sets will follow the same biased distribution, so normal evaluation set will not suffice. Therefore, we generate a separate *unbiased test set* for each gender, male and female, using the identity term template method proposed in Dixon et al. (2017).

The intuition of this template method is that given a pair of sentences with only the identity terms different (ex. "He is happy" & "She is happy"), the model should be able to generalize well and output same prediction for abusive language. This kind of evaluation has also been performed in *SemEval 2018: Task 1 Affect In Tweets* (Kiritchenko and Mohammad, 2018) to measure the gender and race bias among the competing systems for sentiment/emotion analysis.

Using the released code[1] of Dixon et al. (2017), we generated 1,152 samples (576 pairs) by filling the templates with common gender identity pairs (ex. male/female, man/woman, etc.). We created templates (Table 2) that contained both neutral and offensive nouns and adjectives inside the vocabu-

---

[1] `https://github.com/conversationai/unintended-ml-bias-analysis`

Example Templates
You are a *(adjective) (identity term).*
(verb) (identity term).
Being *(identity term)* is *(adjective)*
I am *(identity term)*
I hate *(identity term)*

Table 2: Example of templates used to generated an unbiased test set.

Type	Example Words
Offensive	disgusting, filthy, nasty, rude, horrible, terrible, awful, worst, idiotic, stupid, dumb, ugly, etc.
Non-offensive	help, love, respect, believe, congrats, hi, like, great, fun, nice, neat, happy, good, best, etc.

Table 3: Example of offensive and non-offensive verbs & adjectives used for generating the unbiased test set.

lary (See Table 3) to retain balance in neutral and abusive samples.

For the evaluation metric, we use 1) AUC scores on the original test set (Orig. AUC), 2) AUC scores on the unbiased generated test set (Gen. AUC), and 3) the false positive/negative equality differences proposed in Dixon et al. (2017) which aggregates the difference between the overall false positive/negative rate and gender-specific false positive/negative rate. False Positive Equality Difference (FPED) and False Negative Equality Difference (FNED) are defined as below, where $T = \{male, female\}$.

$$FPED = \sum_{t \in T} |FPR - FPR_t|$$

$$FNED = \sum_{t \in T} |FNR - FNR_t|$$

Since the classifiers output probabilities, equal error rate thresholds are used for prediction decision.

While the two AUC scores show the performances of the models in terms of accuracy, the equality difference scores show them in terms of fairness, which we believe is another dimension for evaluating the model's generalization ability.

4.2 Experimental Setup

We first measure gender biases in `st` and `abt` datasets. We explore three neural models used in previous works on abusive language classification: Convolutional Neural Network (CNN) (Park and Fung, 2017), Gated Recurrent Unit (GRU) (Cho et al., 2014), and Bidirectional GRU with self-attention (α-GRU) (Pavlopoulos et al., 2017), but with a simpler mechanism used in Felbo et al. (2017). Hyperparameters are found using the validation set by finding the best performing ones in terms of original AUC scores. These are the used hyperparameters:

1. CNN: Convolution layers with 3 filters with the size of [3,4,5], feature map size=100, Embedding Size=300, Max-pooling, Dropout=0.5
2. GRU: hidden dimension=512, Maximum Sequence Length=100, Embedding Size=300, Dropout=0.3
3. α-GRU: hidden dimension=256 (bidirectional, so 512 in total), Maximum Sequence Length=100, Attention Size=512, Embedding Size=300, Dropout=0.3

We also compare different pre-trained embeddings, `word2vec` (Mikolov et al., 2013) trained on Google News corpus, `FastText` (Bojanowski et al., 2017)) trained on Wikipedia corpus, and randomly initialized embeddings (*random*) to analyze their effects on the biases. Experiments were run 10 times and averaged.

Model	Embed.	Orig. AUC	Gen. AUC	FNED	FPED
CNN	random	.881	.572	.261	.249
	fasttext	**.906**	.620	.323	.327
	word2vec	**.906**	.635	.305	.263

Table 4: Results on `st`. False negative/positive equality differences are larger when pre-trained embedding is used and CNN or α-RNN is trained

4.3 Results & Discussions

Tables 4 and 5 show the bias measurement experiment results for `st` and `abt`, respectively. As expected, pre-trained embeddings improved task performance. The score on the unbiased generated test set (Gen. ROC) also improved since word embeddings can provide prior knowledge of words.

However, the equality difference scores tended to be larger when pre-trained embeddings were

Model	Embed.	Orig. AUC	Gen. AUC	FNED	FPED

α-GRU	random	.927	.914	.008	.039
	fasttext	**.956**	.998	.014	.005
	word2vec	.955	**.999**	.012	.026

Table 5: Results on `abt`. The false negative/positive equality difference is significantly smaller than the `st`

used, especially in the `st` dataset. This confirms the result of Bolukbasi et al. (2016). In all experiments, direction of the gender bias was towards female identity words. We can infer that this is due to the more frequent appearances of female identities in "sexist" tweets and lack of negative samples, similar to the reports of Dixon et al. (2017). This is problematic since not many NLP datasets are large enough to reflect the true data distribution, more prominent in tasks like abusive language where data collection and annotation are difficult.

On the other hand, `abt` dataset showed significantly better results on the two equality difference scores, of at most 0.04. Performance in the generated test set was better because the models successfully classify abusive samples regardless of the gender identity terms used. Hence, we can assume that `abt` dataset is less gender-biased than the `st` dataset, presumably due to its larger size, balance in classes, and systematic collection method.

Interestingly, the architecture of the models also influenced the biases. Models that "attend" to certain words, such as CNN's max-pooling or α-GRU's self-attention, tended to result in higher false positive equality difference scores in `st` dataset. These models show effectiveness in catching not only the discriminative features for classification, but also the "unintended" ones causing the model biases.

5 Reducing Gender Biases

We experiment and discuss various methods to reduce gender biases identified in Section 4.3.

Table 6: Results of bias mitigation methods on `st` dataset. 'O' indicates that the corresponding method is applied. See Section 5.3 for more analysis.

5.1 Methodology

Debiased Word Embeddings (DE) (Bolukbasi et al., 2016) proposed an algorithm to correct word embeddings by removing gender stereotypical information. All the other experiments used pretrained word2vec to initialized the embedding layer but we substitute the pretrained word2vec with their published embeddings to verify their effectiveness in our task.

Gender Swap (GS) We augment the training data by identifying male entities and swapping them with equivalent female entities and vice-versa. This simple method removes correlation between gender and classification decision and has proven to be effective for correcting gender biases in coreference resolution task (Zhao et al., 2018).

Bias fine-tuning (FT) We propose a method to use transfer learning from a less biased corpus to reduce the bias. A model is initially trained with a larger, less-biased source corpus with a same or similar task, and fine-tuned with a target corpus with a larger bias. This method is inspired by the fact that model bias mainly rises from the imbalance of labels and the limited size of data samples. Training the model with a larger and less biased dataset may regularize and prevent the model from over-fitting to the small, biased dataset.

5.2 Experimental Setup

Debiased word2vec Bolukbasi et al. (2016) is compared with the original *word2vec* (Mikolov et al., 2013) for evaluation. For gender swapping data augmentation, we use pairs identified through crowd-sourcing by Zhao et al. (2018).

After identifying the degree of gender bias of each dataset, we select a source with less bias and a target with more bias. Vocabulary is extracted from training split of both sets. The model is first trained by the source dataset. We then remove final softmax layer and attach a new one initialized for training the target. The target is trained with a slower learning rate. Early stopping is decided by the valid set of the respective dataset.

Based on this criterion and results from Section 4.3, we choose the `abt` dataset as source and `st` dataset as target for bias fine-tuning experiments.

5.3 Results & Discussion

Table 6 shows the results of experiments using the three methods proposed. The first rows are the baselines without any method applied. We can see from the second rows of each section that debiased word embeddings alone do not effectively correct the bias of the whole system that well, while gender swapping significantly reduced both the equality difference scores. Meanwhile, fine-tuning bias with a larger, less biased source dataset helped to decrease the equality difference scores and greatly improve the AUC scores from the generated unbiased test set. The latter improvement shows that the model significantly reduced errors on the unbiased set in general.

To our surprise, the most effective method was applying both debiased embedding and gender swap to GRU, which reduced the equality differences by 98% & 89% while losing only 1.5% of the original performance. We assume that this may be related to the influence of "attending" model architectures on biases as discussed in Section 4.3. On the other hand, using the three methods together improved both generated unbiased set performance and equality differences, but had the largest decrease in the original performance.

All methods involved some performance loss when gender biases were reduced. Especially, fine-tuning had the largest decrease in original test set performance. This could be attributed to the difference in the source and target tasks (abusive & sexist). However, the decrease was marginal (less than 4%), while the drop in bias was significant. We assume the performance loss happens because mitigation methods modify the data or the model in a way that sometimes deters the models from discriminating important "unbiased" features.

6 Conclusion & Future Work

We discussed model biases, especially toward gender identity terms, in abusive language detection. We found out that pre-trained word embeddings, model architecture, and different datasets all can have influence. Also, we found our proposed methods can reduce gender biases up to 90-98%, improving the robustness of the models.

As shown in Section 4.3, some classification performance drop happens when mitigation methods. We believe that a meaningful extension of our work can be developing bias mitigation methods that maintain (or even increase) the classification performance and reduce the bias at the same time. Some previous works (Beutel et al.; Zhang et al., 2018) employ adversarial training methods to make the classifiers unbiased toward certain variables. However, those works do not deal with natural language where features like gender and race are latent variables inside the language. Although those approaches are not directly comparable to our methods, it would be interesting to explore adversarial training to tackle this problem in the future.

Although our work is preliminary, we hope that our work can further develop the discussion of evaluating NLP systems in different directions, not merely focusing on performance metrics like accuracy or AUC. The idea of improving models by measuring and correcting gender bias is still unfamiliar but we argue that they can be crucial in building systems that are not only ethical but also practical. Although this work focuses on gender terms, the methods we proposed can easily be extended to other identity problems like racial and to different tasks like sentiment analysis by following similar steps, and we hope to work on this in the future.

SafeCity: Understanding Diverse Forms of Sexual Harassment Personal Stories

Sweta Karlekar **Mohit Bansal**
UNC Chapel Hill
{swetakar, mbansal}@cs.unc.edu

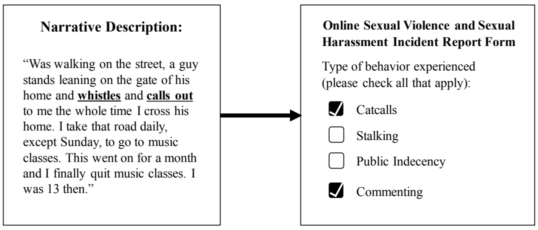
Abstract

With the recent rise of #MeToo, an increasing number of personal stories about sexual harassment and sexual abuse have been shared online. In order to push forward the fight against such harassment and abuse, we present the task of automatically categorizing and analyzing various forms of sexual harassment, based on stories shared on the online forum SafeCity. For the labels of groping, ogling, and commenting, our single-label CNN-RNN model achieves an accuracy of 86.5%, and our multi-label model achieves a Hamming score of 82.5%. Furthermore, we present analysis using LIME, first-derivative saliency heatmaps, activation clustering, and embedding visualization to interpret neural model predictions and demonstrate how this helps extract features that can help automatically fill out incident reports, identify unsafe areas, avoid unsafe practices, and 'pin the creeps'.

1 Introduction

The hashtag #MeToo[1] has been prevalent on various social media platforms as a campaign centered around sharing stories of sexual harassment in an act of solidarity with other victims and spreading awareness of a widespread and endemic issue. With vast amounts of personal stories on the internet, it is important that we make scientific use of this data to push these movements forward and enable real-world change. Manually sorting and comprehending the information shared in these stories is an arduous task, and the power of natural language processing (NLP) can serve as the missing link between online activism and real change.

We present several neural NLP models that allow us to automatically classify, aggregate, and analyze vast amounts of harassment data found on social media, becoming an effective tool for spreading awareness, increasing understanding, and allowing faster action. This large-scale automatic categorization, summarization, and analysis of personal abuse stories can help activist groups enlighten the public and advocate for social change in a timely manner.



Narrative Description:

"Was walking on the street, a guy stands leaning on the gate of his home and **whistles** and **calls out** to me the whole time I cross his home. I take that road daily, except Sunday, to go to music classes. This went on for a month and I finally quit music classes. I was 13 then."

Online Sexual Violence and Sexual Harassment Incident Report Form

Type of behavior experienced (please check all that apply):

☑ Catcalls
☐ Stalking
☐ Public Indecency
☑ Commenting

Figure 1: Task of sexual harassment story classification to help fill online incident reports.

We present single-label and multi-label classification of diverse forms of sexual harassment present in abuse stories shared online through the forum SafeCity, a crowd-sourcing platform for personal stories of sexual harassment and abuse. Each story includes one or more tagged forms of sexual harassment, along with a description of the occurrence. For example, the description "*My college was nearby. This happened all the time. Guys passing comments, staring, trying to touch. Frustrating*" is positive for three classes: commenting, ogling/staring, and touching/groping.

We use CNN-RNN architectures (with character-level CNN embeddings and bidirectional RNNs) to classify the three forms of sexual harassment mentioned above using both single- and multi-label setups. Our models achieve strong performances of 80-86% on these setups. This automatic classification of different forms of sexual harassment can help victims and authorities to partially automate and speed up the process of filling online sexual violence reporting forms (see Figure 1), which usually requires the victim to detail each form of sexual harassment that took place. The act of partially filling out the report

Brussels, Belgium, October 31 - November 4, 2018.

(by our classifier) in itself makes it more likely for the victim to file a report. A study by the Bureau of Justice found that victims who report sexual assault are more likely to seek medical treatment for injuries, which also allows for more immediate prosecution and a better chance of finding DNA evidence to convict the offender (Rennison, 2002). Further, it can also be used to fulfill the need to automatically categorize and summarize large numbers of online testimonials describing or reporting sexual harassment.

Next, in order to further utilize these stories as an important tool for harassment understanding and to help prevent similar situations from happening to others, we present interpretability analysis of our neural classification results in the forms of LIME analysis, first-derivative saliency heatmaps, activation clustering, and t-SNE embedding visualization. We show how these analysis techniques hold promise as avenues for future work and can potentially provide insightful clues towards building (1) a tool to analyze the most common circumstances around each distinct form of harassment to provide more detailed and accurate safety advice, (2) a map of unsafe areas to help others avoid dangerous spaces, and 3) an unofficial sex offender registry that marks frequently-mentioned offenders to warn potential victims. This paper seeks to provide an avenue to utilize the millions of stories shared on social media describing instances of sexual harassment, including #MeToo, #WhyILeft, and #YesAllWomen. With this task and analysis, we hope that these stories can be used to prevent future sexual harassment.

2 Related Work

Analyzing personal sexual harassment stories from online social forums is fairly unexplored, to the best of our knowledge. However, recent works in a similar vein include detecting the presence of domestic abuse stories on social media sites (Schrading et al., 2015a; Schrading, 2015; Schrading et al., 2015b). In more distantly related work, NLP has been used for various socially-driven tasks, such as detecting the presence of cyberbullying or incivility (Ziegele et al., 2018; Founta et al., 2018; Chen et al., 2012; Zhao et al., 2016; Agrawal and Awekar, 2018; Van Hee et al., 2018), and detecting and providing aid for signs of depression or suicidal thoughts (Pestian et al., 2010; Yazdavar et al., 2017; Stepanov et al., 2017; Fitzpatrick et al., 2017).

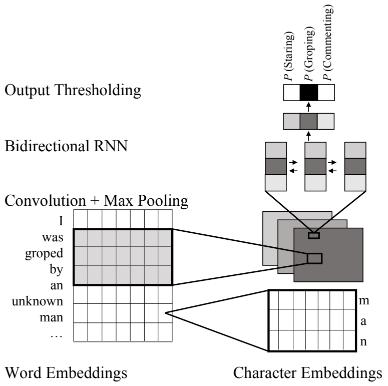

Figure 2: Multi-label CNN-RNN model with CNN-based character embeddings and bidirectional RNNs.

3 Classification Models

For our single-label binary classification task, the two output classes can be [commenting, non-commenting], [ogling, non-ogling], or [groping, non-groping]. For our multi-label scenario, there are a total of 8 combinations (true or false for three types of sexual harassment), including a label for none of the three classes present in the description.

CNN: For each input description, an embedding and convolutional layer are applied. This is followed by a max-pooling layer (Collobert et al., 2011). Filters of varying window sizes are applied to each window of word vectors, the result of which is then passed through a softmax layer to produce probabilities over the output classes.

LSTM-RNN: As CNNs are not designed to capture sequential relationships (Pascanu et al., 2014), we adopted an RNN model that consisted of word vectors fed into LSTM layer, the final state of which was fed into a fully-connected layer. The result is passed through a softmax layer to output the probability over all output classes.

CNN-RNN: As both models have strengths and weaknesses, we experimented with a hybrid architecture in which our LSTM-RNN model after the embedding layer is laid on top of our CNN model before the max-pooling (related to Zhou et al. (2015)). For single-label models, the final fully-connected layer is fed into a softmax to give final output probabilities.

Multi-Label Classification We also present multi-label classification (Boutell et al., 2004; Tsoumakas and Katakis, 2006; Katakis et al., 2008), which allows for models to predict multiple categories simultaneously for the same input. We further utilized CNN-based character embeddings in addition to word embeddings, and also employed bidirectional RNNs (see Figure 2). The outputs of the final fully-connected layer (F) are fed into a sigmoid function. The classification for each category (C) are seen as positive (1) if the output is above threshold *t* and negative (0) if the output is below threshold *t*, a hyperparameter, giving the equation: $C = \mathbb{1}(\sigma(F) \geq t)$.

4 Experimental Setup

4.1 Dataset

SafeCity[2] is, to the best of our knowledge, the largest publicly-available online forum for reporting sexual harassment. Its motto is "pin the creeps". Victims of sexual harassment share personal stories, with the objective of spreading awareness of ongoing sexual harassment and showcasing location-based trends. The language styles of SafeCity forums are very diverse, and therefore can potentially be used for a variety of test cases, such as emails or tweets.

Each of the 9,892 stories includes a description of the incident, the location, and tagged forms of harassment, with all identifying information removed. SafeCity has explicitly given us permission to use this data. The dataset[3] contains descriptions of text submitted by forum users, along with tags of 13 forms of sexual harassment. We chose the top three most dense categories—groping/touching, staring/ogling, and commenting—to use as our dataset, as the others were more sparse. Each description may fall into none, some, or all of the categories.

4.2 Evaluation

The single-label models were evaluated using accuracy. The multi-label models were evaluated using exact match ratio and Hamming score (calculated as the complement of Hamming loss). Hamming loss was used as detailed by Tsoumakas and Katakis (2006). Hamming loss (y) is equal to 1 over $|D|$ (number of multi-label samples), multiplied by the sum of the symmetric differences between the predictions (Z) and the true labels (Y), divided by the number of labels (L), giving $y = \frac{1}{|D|} \sum_{i=1}^{|D|} \frac{|Y_i \Delta Z_i|}{|L|}$.

CNN	53.7	80.2
RNN	57.1	81.5
CNN-RNN	59.2	82.3
CNN-RNN (bidirec + char)	**62.0**	**82.5**

Table 2: Multi-label classification results.

4.3 Training Details

All models have vocabulary size of $10,000$, and use AdamOptimizer (Kingma and Ba, 2015) with a learning rate of $1e^{-4}$. All gradient norms are clipped to 2.0 (Pascanu et al., 2013; Graves, 2013). For each model, the hyperparameters are tuned using the development set.

CNN We use a 2-D CNN. Filter sizes of [3, 4, 5] are used with 128 filters per filter size. Batch size is set to 128, and a dropout (Srivastava et al., 2014) of 0.80 is applied.

LSTM Our LSTM has 2 layers with 60 hidden units. Batch size is 64 with a dropout of 0.75.

CNN-LSTM Our CNN-LSTM model consists of an LSTM on top of a CNN. The CNN has 100 filters per filter size of [3, 4, 5]. Embedding dimensions of 300 are used. An LSTM with 300 hidden units is used. For the character level embeddings, we use an additional CNN with 100 filters per filter size of [3, 4, 5]. Bidirectional RNNs of 300 units are used.

5 Results

See Table 1 for single-label results on the selected harassment categories, where CNN-RNN was the best performing model compared to several non-neural and neural baselines. See Table 2 for multi-label classification results, where the Hamming score for the multi-label CNN-RNN model is 82.5%, showing potential for real-world use as well as substantial future research scope.

6 Analysis

We provide various visualization techniques to analyze our models. Each of these techniques employs a different approach and offers new information or supports previous findings.

Harassment Type	Observed t-SNE Cluster
Groping	abusively, encounter, talk, underage, surrounded, embarrassed
Ogling	boobs, leering, disturbing, gestures, voyeur, visually, gestures
Commenting	shameful, vulgar, inappropriately, indecent, invites, stalked, strong

Table 3: Relevant word clusters found via t-SNE word embedding clustering.

6.1 Word Embedding Visualization

We selected seed words that corresponded to class labels and found the nearest neighbors of each seed word's vector by reducing the dimensionality of the word embeddings using t-SNE (see Table 3) (Maaten and Hinton, 2008). This form of visualization not only ensures that our model has learned appropriate word embeddings, but also demonstrates that each form of sexual harassment has a unique and distinct context. Furthermore, this shows that our model learns related words and concepts for each type of harassment.

6.2 LIME Analysis

LIME analysis (Ribeiro et al., 2016), or Local Interpretable Model-Agnostic Explanation, interprets the local reasoning of a model around an instance. Results of LIME (ξ) are found by taking the minimum of $\mathcal{L}$, which is the measure of how unfaithful the interpretable model (g) is to approximating the probability that an input (x) belongs to a certain class (f) in the locally defined area (π_x) summed with complexity measures Ω, giving $\xi(x) = argmin\ \mathcal{L}(f, g, \pi_x) + \Omega(g)$. In Figure 3 (left), the words "touch", "man", and the collective words "indecently till pushed away" are the most important to the local classification of "groping". Furthermore, the word "metro" has importance in the classification, suggesting that this may be a frequent location in which groping takes place. In Figure 3 (middle), the words with the most importance are "comments" and "staring", indicating that ogling may coincide with commenting very frequently. In Figure 3 (right), the words "ogling", "sexual", and "commenting" had the most importance, which further supports the notion that ogling and commenting often occur together. As verified by the data, ogling and commenting together is more common than ogling alone.

6.3 First Derivative Saliency

Saliency heatmaps (Simonyan et al., 2014; Li et al., 2016) illustrate which words of an input have the biggest impact on the final classification by taking the gradient of the final scores outputted by the neural network (S) with respect to the embedding (E), given the true label (L), giving $\frac{\partial S_L(E)}{\partial E}$. While LIME analysis and first derivative saliency are both used to find word-level contributions, first derivative saliency is model-dependent and gives reasoning behind classification based on the whole model, in contrast to the locally-faithful, model-agnostic LIME analysis technique.

In Figure 4 (left), the word "commenting" and the words "one boy" have the most influence on the classification. The influence of the word "lighting" indicates poor lighting is often present in situations where sexual harassment takes place. In Figure 4 (middle), the classification of "commenting" was most influenced by the word "commenting", followed by the word "age". This suggests the possibility of using descriptors of offenders as a classification tool. Figure 4 (right) is an incorrectly classified example. We see that the word "body", followed by "language", had the most influence on the classification of this example as “commenting”. Our model identifies synonyms and hyponyms like the word “language” in relation to the category of commenting. However, the true label was “non-commenting”, as the word was not used in a context of sexual language, but rather as “vague language” and “body language”.

6.4 Activation Clustering

Activation clustering (Girshick et al., 2014; Aubakirova and Bansal, 2016) accesses the activation values of all n neurons and treats the activation values per input as coordinates in n-dimensional space. K-means clustering was performed to group activation clusters and find common themes in these reports. Activation clustering is distinct from both LIME analysis and first derivative saliency in that it finds patterns and clusterings at a description-level.

Circumstances of Harassment: One of the clusters was classified as “ogling”: {*‘a group of boys was standing near us and were making weird expressions and as we moved away they started following’; ‘a group of guys lurking around the theater...’*}. Another cluster was classified as “commenting”: {*’a group of men were standing who commented on every girl who passed by the’, ’a group of boys were standing there... as we started moving one of them commented on us’*} Both of these clusters contained examples describing circumstances of the harassment, following the pattern of “a group of boys/men were standing/lurking and...” It can be inferred that certain forms of sexual harassment are more likely to happen with large groups of men. Activation clustering can identify the circumstances of harassment, helping potential victims to be better prepared.

Location and Time of Harassment: Some clusters contain examples that point to specific locations of harassment, e.g., a groping cluster: {*‘i was in the bus and there was this man who purposely fell on me and touched me inappropriately’; ‘while traveling in a crowded bus most of the time men try to grind their intimate part over my body’; ‘i was in the bus when a man standing tried to put his d**k on my hand’*}. Specific locations can also be found: {*‘the gurgaon sohna road is very unsafe at night especially if you are alone with no street lights’; ‘kurla station really gets scary at night once i was trying to get a train from kurla station around 10’; ‘mathura highway , not enough lights on the way during nights so is not safe for a individual to journey’*}. Notice that the second cluster examples also contain the word “night”. With data that contains more specific locations or times of day, activation clusters can serve as an automatic way to map out unsafe areas based on location and time of day.

Identifying Offenders: Examples from another groping cluster include: {*‘...her step father abused her physically for a year’; ‘one of the girl of about 6 years got raped by her own father’; ‘it happened at my house my brother harassed me and also misbehaved with me one night its been six months’*}. This shows that clusters can point to common relationships or titles for offenders. This phenomenon can be presumed to happen with names of offenders as well. If many reports have been filed around this offender, clusters will form around his/her name. Instead of a case of “he said, she said”, activation clustering provides an avenue towards “he said, they said”, as clusters form when multiple reports have been filed around the same name.

The main purpose of our visualization techniques is to explain what the black-box deep learning models are learning, such as locations, offenders, or times of day. With more detailed data in the future, we may be able to uncover more nuanced circumstances behind harassment.

7 Conclusion

We presented the novel task of identifying various forms of sexual harassment in personal stories. Our accurate multi-label classification models illustrate the plausibility of automatically filling out incident reports. Using visualization techniques, we found circumstances surrounding forms of harassment and the possibility of automatically identifying safe areas and repeat offenders. In future work, we hope to experiment with the transferability of our model to other datasets to encompass the diverse mediums through which these personal stories are shared. Honoring the courage that these victims demonstrated in sharing their stories online, we use these descriptions not only to help summarize online testimonials and provide more detailed safety advice, but also to help others report similar occurrences to hopefully prevent future sexual harassment from occurring.

Learning multiview embeddings for assessing dementia

Abstract

As the incidence of Alzheimer's Disease (AD) increases, early detection becomes crucial. Unfortunately, datasets for AD assessment are often sparse and incomplete. In this work, we leverage the multiview nature of a small AD dataset, DementiaBank, to learn an embedding that captures different modes of cognitive impairment. We apply generalized canonical correlation analysis (GCCA) to our dataset and demonstrate the added benefit of using multiview embeddings in two downstream tasks: identifying AD and predicting clinical scores. By including multiview embeddings, we obtain an F1 score of 0.82 in the classification task and a mean absolute error of 3.42 in the regression task. Furthermore, we show that multiview embeddings can be obtained from other datasets as well.

1 Introduction

Alzheimer's disease (AD) is a neurodegenerative progressive disease whose symptoms include memory loss, disorientation, and behavioral issues (Ballard et al., 2011). In 2017, 5.7 million Americans were living with AD, and the disease accounted for $11.4 billion in healthcare costs in the United States (Alzheimer's Association, 2018). AD is diagnosed through clinician-administered questionnaires, such as the Mini-Mental State Examination (MMSE), which assigns a score between 0 and 30 based on responses to questions testing memory, recall, and orientation (Folstein et al., 1975). For context, a MMSE score of 23 and below is associated with cognitive decline.

AD affects language and some of its symptoms include difficulties in word-finding and changes in the voice. Detecting these subtle changes can help identify AD at an early stage. Indeed, many studies have applied a combination of natural language processing and machine learning techniques to detect AD. On the DementiaBank (DB) dataset, which includes audio files and corresponding transcripts of participants completing a picture description task, Wankerl et al. (2017) employed an n-gram based approach to classify between participants with and without AD. On the same dataset, Fraser et al. (2015) extracted an extensive list of lexicosyntactic features from the transcripts and identified participants with AD with an accuracy of 81%. More recently, Hernández-Domínguez et al. (2018) looked at the information content units of the pictures and compared them to healthy population-specific references to achieve an F-score of 0.81.

Predicting clinical scores is a harder task and is more common in image processing, where researchers make use of brain scans. For example, Huang et al. (2016) used MRI scans from 805 subjects and relied on the longitudinal aspect of their dataset to predict MMSE scores. Specific to the DB dataset, Yancheva et al. (2015) extracted linguistic features and used a bivariate dynamic Bayes net to represent the longitudinal nature of the data, and obtained a mean absolute error (MAE) of 3.83. Focusing on subjects with larger samples of data yielded a MAE of 2.91.

In instances where multiple views of the same data are available, it makes sense to learn a vector representation (an embedding) that encapsulates the different sources of information. Benton et al. (2016) used different representations of their data (e.g., bag-of-words, word vectors) to learn multiview embeddings for Twitter users, and obtained promising results when evaluating their embeddings in downstream prediction tasks.

In this work, we leverage the multiview nature of DB to learn an embedding for each user. We evaluate the utility of the multiview embedding in two downstream tasks: classification of AD vs non-AD participants, and clinical score prediction.

2 Methods

2.1 Dataset

We use the DementiaBank (DB) corpus (Becker et al., 1994), which consists of adults aged 44 and older, assigned to either the *'Dementia'* ($N = 167$) or *'Healthy'* ($N = 97$) group based on a battery of neuropsychological tests and on their medical histories. In DB, participants performed the "Cookie Theft" picture description task from the Boston Diagnostic Aphasia Examination (Goodglass and Kaplan, 1983), in which they verbally describe the contents of a picture. Additionally, participants in the *'Dementia'* group completed the category fluency (i.e., naming words belonging to a given category), letter fluency (i.e., naming words that start with a given letter), sentence construction, and story recall tasks. The picture description and both fluency tasks were professionally transcribed and annotated with instances of filled pauses. Previous experiments in the literature on DB have been limited to the picture description task, most likely because the other tasks are not available for all participants.

2.2 Linguistic features

From transcripts of the picture description, category fluency and letter fluency tasks, we extract 565 linguistic features[1]. We compute lexical features (e.g., the mean number of syllables per word, the vocabulary richness as measured by the type-token-ratio[2]), semantic features (e.g., the mean specificity of words as measured by their depth in WordNet[3]), and syntactic features (e.g., the proportion of various parts-of-speech tags, such as nouns and adjectives). We also automatically extract various subjective measures, such as the mean imageability (i.e., a word's ability to evoke a mental image) and the mean age-of-acquisition of words using norms derived from the Bristol (Stadthagen-Gonzalez and Davis, 2006) and Gilhoolie-Logie (Gilhooly and Logie, 1980) norms. Finally, we train an LDA model of 100 topics (Blei et al., 2003) using a Wikipedia snapshot, and compute the topic probabilities for each transcript.

2.3 Learning a multiview embedding

We apply generalized canonical correlation analysis (GCCA) to our dataset to obtain a multiview embedding. We use GCCA as described by Benton et al. 2016 to learn linear transformations U_j which project different views of our data into the embedding G. In our experiments, we consider the following views of DB: linguistic features of the picture description, category fluency and letter fluency tasks, and demographic information.

Given $X \in \mathbb{R}^{d \times N}$, $X' \in \mathbb{R}^{d' \times N'}$, where N is the total number of data points, N' is the total number of data points for which all views J are available, and d and d' are the dimensions of X and X'; let X_j and X'_j denote views j of X and X'. Here, $j \in \{PD, CAT, LET, DEM\}$, which correspond to the picture description, category fluency, and letter fluency linguistic features, and demographic information, respectively.

1. We use GCCA to learn U_j from X'_{PD}, X'_{CAT}, X'_{LET}, X'_{DEM}, such that:
$$\underset{U_j, G'}{\text{minimize}} \sum_{j \in J} ||G' - U_j^T X'_j||_F^2$$
$U_j \in \mathbb{R}^{d_j \times k}$, $G' \in \mathbb{R}^{k \times N'}$.
2. We compute $G = U_{PD}^T X_{PD}$. Since $U_{PD} \in \mathbb{R}^{d_{PD} \times k}$ and $X_{PD} \in \mathbb{R}^{d_{PD} \times N}$, then $G \in \mathbb{R}^{k \times N}$.
3. We concatenate G to a subset of the picture description linguistic features, X^*_{PD}, to obtain $C = (X^*_{PD}, G)$, where $C \in \mathbb{R}^{(k + d^*_{PD}) \times N}$.
4. We use the augmented set of features C for two downstream tasks: AD classification and clinical score prediction.

3 Results

We run all experiments with 10-fold cross validation and test various settings of k, the dimension of the multiview embedding.

3.1 GCCA and classification

We select the top n linguistic features, ordered through a one-way ANOVA and concatenate them with multiview embeddings of size k. The $n + k$ features are then given as input to a random forest

---

[1] The code to extract these is being made available at `https://github.com/SPOClab-ca/COVFEFE`.

[2] The type-token ratio is obtained by dividing the number of types (i.e., the total number of *different* words) by the number of tokens (i.e., the total number of words).

[3] WordNet (Miller, 1995) is a lexical database which groups English words into collections of synonyms. The database is ordered from most generic (e.g., "plant") to most specific (e.g., "rose").

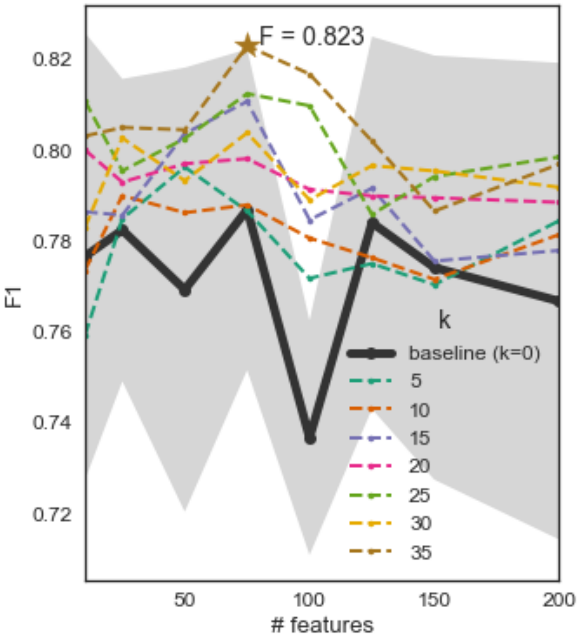

Figure 1: Classification of *'Dementia'* vs *'Healthy'* participants in DB. We report the F1 score as we increase the number of significant features used in our random forest classifier. The dark black line denotes the baseline (i.e., no GCCA) with the shaded grey region corresponding to the standard deviations, and the colored dotted lines denote experiments with multiview embeddings of size k.

classifier with 100 decision trees, and we report the F1 scores in Figure 1. Our best classification result ($F1 = 0.823 \pm 0.032$) is achieved with a multiview embedding of size $k = 35$ using the best $n = 75$ linguistic features. Adding GCCA embeddings improves classification results: an ANOVA test reveals a significant difference between F1 results with and without GCCA ($F = 15.85$, $p = 0.00018$), and a post-hoc Tukey's honest significant difference test reveals that F1 scores are significantly higher in experiments using GCCA embeddings ($p = 0.00018$).

Next, we look at multiview embeddings generated from different combinations of DB views, and report our F1 scores in Table 1 for embeddings of size $k = 35$ and using the top $n = 75$ features. Adding multiview embeddings always improves classification, and we obtain our best results by learning an embedding from the picture description and category fluency views.

3.2 GCCA and regression

Views	**F1**
None (baseline)	*0.782* (0.042)
$X'_{PD}, X'_{CAT}, X'_{LET}, X'_{DEM}$	0.811 (0.045)
$X'_{PD}, X'_{CAT}, X'_{LET}$	0.817 (0.037)
$X'_{PD}, X'_{LET}, X'_{DEM}$	0.815 (0.043)
$X'_{PD}, X'_{CAT}, X'_{DEM}$	0.818 (0.042)
X'_{PD}, X'_{CAT}	**0.824** (0.052)
X'_{PD}, X'_{LET}	0.805 (0.055)
X'_{PD}, X'_{DEM}	0.816 (0.057)

Table 1: Classification results with GCCA applied on different views of DB. We report the different views used to learn our multiview embedding and the resulting F1 scores (with standard deviation in parenthesis) on 10-fold cross-validation experiments. X' denotes the data points for which all views are present (i.e., the data used to learn multiview embeddings), and the subscripts PD, CAT, LET, DEM are used to represent the following views: picture description text features, category fluency text features, letter fluency text features, and demographic information.

To predict MMSE scores, we select the top n best features, ordered through a continuous one-way ANOVA, and concatenate them with our multiview embedding of size k. The $n + k$ features are then given as input to a linear regression model and we report the mean absolute error (MAE). 10-fold cross-validation results are given in Figure 2. Our lowest MAE of 3.412 ± 0.300 was obtained using a GCCA embedding of size $k = 5$ and retaining the top $n = 75$ linguistics features. Adding multiview embeddings yields the best results, but an ANOVA test reveals no significant difference ($F = 0.41$, $p = 0.53$).

3.3 Learning a multiview embedding from another dataset

We then perform the same experiments as described in sections 3.1 and 3.2, but we learn our U_{PD} linear projection matrix with a different dataset. We use *Talk2Me*[4], an online language assessment from the University of Toronto, in which participants use the web to complete a variety of language tasks, including the picture description task, the vocabulary task, the Winograd task (Levesque et al., 2011), and the word fluency task (including both category and letter fluency). For all tasks in *Talk2Me*, we transcribe the audio recordings using the Kaldi open-source automatic speech recognition engine (Povey et al., 2011), and extract the same set of text features as in Section 2.2. Next, we apply GCCA to learn a

---

[4] `https://www.cs.toronto.edu/talk2me`

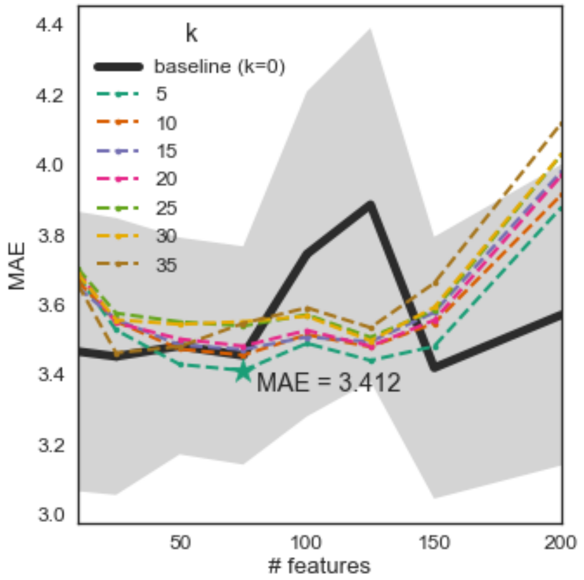

Figure 2: Clinical score prediction. We report the mean absolute error (lower is better) in predicting MMSE score as we increase the number of significant features used in our linear regression model. The black line denotes the baseline (i.e., no GCCA) with the shaded grey region corresponding to the standard deviations, and the colored dotted lines denote experiments with multiview embeddings of size k.

multiview embedding from the following views: picture description, story recall, vocabulary, fluency, and image naming tasks, and demographics.

As in previous experiments, we concatenate the multiview embedding with the DB picture description linguistic features, and use these to classify AD participants and to predict MMSE scores. In the regression task, the GCCA features from *Talk2Me* greatly hinder performance. The best result we obtain with *Talk2Me* multiview embeddings is an MAE of 3.929 ± 1.37. In classification, we observe improvements, as shown in Figure 3, and obtain an F1 of 0.793 ± 0.052. However, an ANOVA test reveals no significant difference with multiview embeddings ($F = 0.45$, $p = 0.50$).

4 Discussion

In our experiments, we use GCCA to learn a multiview embedding and augment our existing set of features. The multiview embedding consists of a vector representation which encapsulates information from various sources of information (i.e., the picture description task, the category and letter fluency tasks, and demographic data). We hypothesize that the additional information contained in this embedding would be useful in downstream

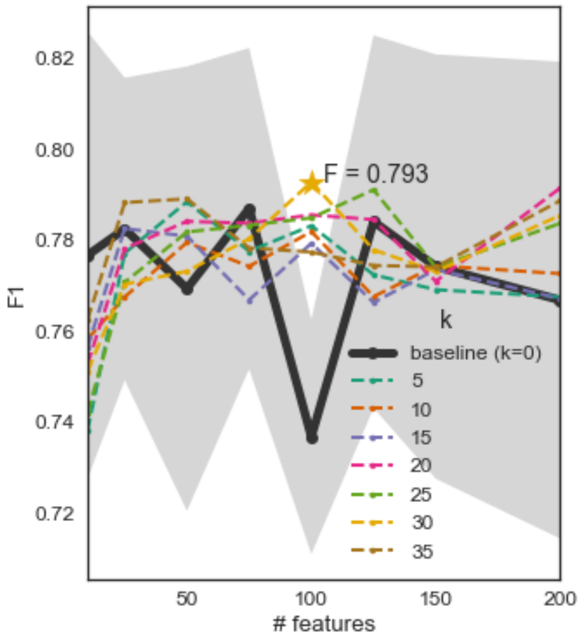

Figure 3: Classification task using multiview embeddings learned from the *Talk2Me* dataset. We report the F1 scores as we increase the number of significant features. The black line denotes the baseline (i.e., no GCCA) with the shaded grey region corresponding to the standard deviations, and the dotted colored lines denote experiments with multiview embeddings of size k obtained through GCCA on *Talk2Me* views.

tasks such as classification and regression. Indeed, the multiview embedding obtained from DB improves AD detection and clinical score prediction. Similarly, we also observe an improvement in classification when using a multiview embedding learned from a normative dataset.

Our results are better in the classification task than in the regression task, since the MMSE score is mainly used as a screening tool (i.e., determining if a person has AD or not) and has restricted sensitivity, especially for identifying milder stages of AD (Trzepacz et al., 2015).

5 Conclusion

We have shown that we can make use of the multiview aspect of a small dataset such as DB to learn a multiview embedding. This embedding can subsequently be used to improve models for classification and regression. In our experiments, multiview embeddings allowed the use of both the category and letter fluency data in DB, even though they were only available for the *'Dementia'* participants. Benefits are also possible using secondary datasets to learn multiview embeddings.

Extracting acoustic features – such as pause ratio, pitch, and Mel-frequency cepstral coefficients (MFCCs) – and treating them as an additional view is part of our future work. Furthermore, we will look into other secondary datasets as well as different approaches of obtaining multiview embeddings. While GCCA allows for an arbitrary number of views, it is limited in that it only learns linear projections to the embedding space. A possible alternative is deep generalized canonical correlation analysis (DGCCA), which makes use of neural networks to learn non-linear mappings to the embedding space (Benton et al., 2017).

Abstract

We present a corpus that encompasses the complete history of conversations between contributors to Wikipedia, one of the largest online collaborative communities. By recording the intermediate states of conversations—including not only comments and replies, but also their modifications, deletions and restorations—this data offers an unprecedented view of online conversation. This level of detail supports new research questions pertaining to the process (and challenges) of large-scale online collaboration. We illustrate the corpus' potential with two case studies that highlight new perspectives on earlier work. First, we explore how a person's conversational behavior depends on how they relate to the discussion's venue. Second, we show that community moderation of toxic behavior happens at a higher rate than previously estimated. Finally the reconstruction framework is designed to be language agnostic, and we show that it can extract high quality conversational data in both Chinese and English.

1 Introduction

Compared to large-scale collections of conversations from social media (Felbo et al., 2017; Luo et al., 2012; Zhang et al., 2017; Tan et al., 2016) or news comments (Napoles et al., 2017), Wikipedia talk pages offer a unique perspective into goal-oriented discussions between thousands of volunteer contributors coordinating to write the largest online encyclopedia. Talk page data already underpins research on social phenomena such as conversational behavior (Danescu-Niculescu-Mizil et al., 2012, 2013), disputes (Wang and Cardie, 2014b), antisocial behavior (Wulczyn et al., 2017; Zhang et al., 2018) and collaboration (Kittur et al., 2007; Halfaker et al., 2009). However, the scope of such studies has so far been limited by a view of the conversation that is incomplete in two crucial ways: first, it only captures a subset of all discussions; and second, it only accounts for the final form of each conversation, which frequently differs from the interlocutors experience as the conversation develops.

In this paper, we undertake the challenge of reconstructing a complete and structured history of the conversational process in Wikipedia talk pages, containing detailed information about all the interlocutors' actions, such as adding and replying to comments, modifying or deleting them. To this end, we devise a methodology for identifying and structuring these actions, while also addressing the challenges spurring from the inconsistent formatting and the raw scale of existing records. This results in the largest public dataset of goal-oriented conversations, *WikiConv*, spanning five languages. The largest component of this dataset is based on the English Wikipedia, and contains roughly 91 million conversations consisting of 212 million conversational actions taking place in 24 million talk pages.

By including details about how each conversation evolved, this corpus provides an unprecedented view into the conversational process, as ex-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2818–2823
Brussels, Belgium, October 31 - November 4, 2018.

perienced by the interlocutors. In fact, we find that about 40% of discussion activity would be missed by approaches that do not consider comment modifications and deletions, and even more is missed when only considering the (final) static snapshots of conversations. Furthermore, a manual review of the English Wikipedia portion of the dataset reveals that 98% of the reply structure is recovered correctly and 98% of the interlocutor's actions are categorized correctly.

Since the reconstruction pipeline does not rely on any language specific heuristics, we also apply it to Chinese, German, Greek and Russian Wikipedia Talk page archives, in addition to those from English Wikipadia. A manual review of the conversations obtained from the Chinese Wikipedia Talk pages shows a similarly high reconstruction accuracy with that obtained from the English Wikipedia, suggesting that it is reasonable to apply the reconstruction pipeline to different languages. To encourage further validation, refinements and updates, we have open sourced the code and published the datasets.[1]

Finally, we present two case studies illustrating how the corpus can bring new insights into previously observed phenomena. We first analyze the conversational behavior of a subset of English Wikipedia contributors across the entire range of talk pages, and show that their levels of linguistic coordination vary according to where the conversation takes place. Second, we investigate the toxicity of deleted comments, and show that community moderation of undesired behavior takes place at a much higher rate than previously estimated.

2 Further Related Work

Past efforts aimed at characterizing conversations on Wikipedia talk pages have either focused on snapshots of discussion threads (Danescu-Niculescu-Mizil et al., 2012; Prabhakaran and Rambow, 2016; Wang and Cardie, 2014b,a), or have considered text segments in talk page history as incremental comments, ignoring conversational turns and reply structures within these conversations (Wulczyn et al., 2017). The limitations of these approaches can be seen in Figure 2, where, if we limit our analysis to only a snapshot of the final state of the conversation, we miss the abusive comment introduced in revision 3 and removed in revision 4, and thus miss an important part of the experience of the participants. In fact, this "hidden" activity accounts for one third of all actions taken on talk pages in English Wikipedia.

The closest dataset to our work is Bender et al. (2011) which introduces the Authority and Alignment in Wikipedia discussions corpus (AAWD), containing 365 talk page discussions. While acknowledging the complexity of conversational behaviors on Wikipedia talk pages, the AAWD work falls short of providing data on the deletions and follow-up changes to existing comments. Beyond addressing this shortcoming, the dataset we introduce in this paper is many orders of magnitude larger, containing 91 million conversations in English Wikipedia alone.

3 Conversation Reconstruction

Technically, comments are added to Wikipedia talk pages the same way content is added to article pages: contributors simply edit the markdown of any part of the talk page without relying on any functionality specialized for structuring the conversations. Figure 1 gives an example of the discussion interface and the resulting rendered conversation. Each edit results in a revision of the whole page that is permanently stored in a public historical record.[3] Because conversations on Wikipedia have no 'official' underlying structure, and instead are organized using indentation markup and other ad hoc visual cues, computational heuristics are necessary to interpret conversational structure.

Actions. We model the conversational structure of

Table 1: **Summary statistics and reconstruction accuracy for the English and Chinese Wikipedia talk page corpora.** These statistics exclude actions that result in empty content after markup cleaning (e.g., purely formatting edits).

interactions as a graph of *actions*, as illustrated in Figure 2. Actions are categorized into five *types*:

- *Creation*: the start of a conversation thread based on a markup section heading being added (e.g. Action 1 in Figure 2).
- *Addition*: the addition of a new comment to a thread (e.g. Actions 2 and 3).
- *Modification*: modification of an existing comment (e.g. Action 5); with the original specified as the Parent-id.
- *Deletion*: the removal of a comment or heading (e.g. Action 4) where the Parent-id specifies the comment or heading's most recent action.
- *Restoration*: a revert specifies the deleted action being undone as the Parent-id.

All action types except thread creations, thread deletions and thread restorations also include a ReplyTo-id indicating the target of the reply.

From Page Revisions to Actions. Our reconstruction pipeline is a Python program written for Google Cloud Dataflow (also known as Apache Beam)[4] that operates on pages in parallel and on the revisions of each page sequentially in temporal order.

Due to the large scale of Wikipedia data, we use external sorting for pages that contains too many revisions to fit in a Dataflow worker's memory.

---

[4] `cloud.google.com/dataflow/`

When the number of revisions is too large for a Dataflow worker's local disk, the computation is performed in stages, a few years at a time.

Given the sorted set of a page-revisions, token-level diffs between sequential revisions are computed using a longest common sequence (LCS) algorithm.[5] Each sequential diff is then decomposed into the set of atomic conversation *actions* attributed to the user who submitted the page revision. During the sequential processing of a page's revisions, two data structures are maintained: each comment's current character offset, and a list of deleted comments. The comment offsets are used to interpret the difference between modification actions (edits within the bounds of an existing action) and additions; the deleted comments are used to identify restoration of comments.

We store the most recent 100 deleted comments between 10 to 1000 characters long, for each page. This is used to compute when a comment is restored by looking up deleted comments in a trie. The token length lower bound parameter avoids short commonly added comments—like "Thanks!"—from being interpreted as restorations. The upper bound ensures that occasional very long deleted comments are skipped, to bound Dataflow workers' memory usage.

Finally, reconstructed actions are processed using *mwparserfromhell* [6] to clean the MediaWiki formating. Note that, since arbitrary page changes are allowed, some actions cannot be processed by the parser (about 1 in 200,000); in such cases, an action's raw MediaWiki markup is stored.

Table 1 shows summary statistics of the final dataset on English and Chinese Wikipedia. The version of the raw data dumps processed were retrieved on July 1st 2018.

4 Evaluation of Reconstruction Quality

We evaluate the quality of the automatic reconstruction by manually verifying a randomly drawn subset of (at least) 100 examples from each action category. For each action we verify the accuracy of (1) the assigned action type, (2) the token-level boundary of the comment, (3) the ReplyTo relation and (4) the action's Parent relation.

We conduct the evaluation for both English and Chinese data (Table 1). With over 98% of actions classified correctly in both languages, the dataset exhibits a high annotation quality given its scale and detail. From the error cases in the English data, 10% result from limitations in the current technologies for HTML parsing and LCS matching. User behavior that we could interpret but is not yet captured by our algorithm, such as moving ongoing conversations to another talk pages accounts for another 24%. The remaining errors were from edits that we were unable to interpret. By open sourcing the reconstruction code, we encourage further refinements.

5 Case Studies

We now briefly present two studies on English Wikipedia that highlight the importance of (1) collecting the full history of Wikipedia across all pages and (2) capturing the various types of interactions.

Linguistic Coordination. Danescu-Niculescu-Mizil et al. (2012) studied language coordinations (i.e., in a conversation between a and b, to what degree is b systematically adopting a's language patterns when replying to a) on a conversational corpus derived from $5,657$ *User Talk pages*: those associated with, and managed by, a specific user. The study showed that social status mediates the amount of linguistic coordination, with contributors imitating more the linguistic style of those with higher status in the community.

We now show that the coordination pattern of the page owners in the previous dataset differs significantly based on where the conversation takes place. We compare each contributor's coordination patterns on their own user talk page to patterns exhibited on talk pages of other contributors, as well as to those on article talk pages—talk pages associated with a Wikipedia article. To avoid confounding different populations (and fall into the trap of Simpson's paradox), we only include in the comparison users that had a sufficient amount of contributions across all three venues. Figure 3 shows the three aggregated coordination values computed by applying the methodology of the original paper on 4 million addition actions that occurred before 2012.

Our results show with significant difference ($p < 0.001$ calculated by one-way ANOVA) that contributors coordinate the least when replying on other users' talk pages, and most on their own talk page. This leads us to speculate a new hypothesis: contributors have a different perception of status

or respect on their own page than on others. Such questions, which require more thorough investigation that depends on observing how contributors interact across different discussion venues, can be studied using the WikiConv corpus.

Moderation of toxic behavior. Wulczyn et al. (2017) measured prevalence of personal attacks in a Wikipedia talk page corpus, and evaluated the fraction of attacks that moderators follow up on with a block or warning (17.9%). However, because there was no structured history of comment deletion, the authors were unable to measure the rate at which toxic comments are moderated through deletion. Using the more complete datasets provided by WikiConv we show that the fraction of problematic comments moderated by Wikipedians is significantly higher than their initial estimate suggests.

We used the Perspective API[7] to score the toxicity of all addition and creation actions (which we refer to as "comments" here).[8] Each comment is further classified as toxic or non-toxic according to the equal error rate threshold, following the methodology of (Wulczyn et al., 2017), where false positives are offset by false negatives. The threshold is calculated by on the human labels in the Kaggle Toxicity dataset of Wikipedia comments [9]. Classification at this threshold yields 86% precision and 84% recall.

We used the same method to labeled comments with the *severe toxic* model. Figure 3 shows the fraction of comments deleted by Wikipedians who are not the author of the comment for different lengths of time; distinguishing between comments labeled as toxic, severely toxic, and the background distribution. The key results here are that nearly 33% of toxic comments are removed within a day; And over 82% of severely toxic comments are deleted within a day. This complements results previously reported by Wulczyn et al. (2017), accounting for an additional type of community moderation that is revealed using the detailed information about the history of the conversation provided by our corpus.

6 Conclusion and Future Work

We introduced a pipeline that extracts the complete conversational history of Wikipedia talk pages at a level of detail that was not previously available. We applied this pipeline to Wikipedia in multiple languages and evaluated its quality on the English and Chinese Talk page corpora, obtaining a high reconstruction accuracy for both the Chinese and English datasets (9̃8%). This level of detail and completeness opens avenues for new research, as well as revisiting and extending existing work on online conversational and collaboration behavior. For example, while in our use cases we have focused on contributors deleting toxic comments, one could seek to understand why and when an editor is deleting or rewording their own comments. Beyond refining the heuristics and parsing methods used in our reconstruction pipeline, and reducing the time needed to update the corpus, a significant remaining challenge is to capture conversations that happen across page boundaries.

7 Acknowledgement

We thank Thomas Ristenpart, Andreas Veit for proof reading; Ben Vitale for many helpful discussions on building the pipeline; and all those who helped us find bugs and discussed the challenges throughout. This project is supported in part by NSF grant CNS-1558500.

Marginal Likelihood Training of BiLSTM-CRF for Biomedical Named Entity Recognition from Disjoint Label Sets

Nathan Greenberg, Trapit Bansal, Patrick Verga, and Andrew McCallum
College of Information and Computer Sciences
University of Massachusetts Amherst
{ngreenberg, tbansal, pat, mccallum}@cs.umass.edu

Abstract

Extracting typed entity mentions from text is a fundamental component to language understanding and reasoning. While there exist substantial labeled text datasets for multiple *subsets* of biomedical entity types—such as genes and proteins, or chemicals and diseases—it is rare to find large labeled datasets containing labels for all desired entity types together. This paper presents a method for training a single CRF extractor from multiple datasets with disjoint or partially overlapping sets of entity types. Our approach employs marginal likelihood training to insist on labels that are present in the data, while filling in "missing labels". This allows us to leverage all the available data within a single model. In experimental results on the Biocreative V CDR (chemicals/diseases), Biocreative VI ChemProt (chemicals/proteins) and MedMentions (19 entity types) datasets, we show that joint training on multiple datasets improves NER F1 over training in isolation, and our methods achieve state-of-the-art results.

1 Introduction

Identifying entities in text is a vital component in language understanding, facilitating knowledge base construction (Riedel et al., 2013), question answering (Bordes et al., 2015), and search. Identifying these entities are particularly important in biomedical data. While large scale Named Entity Recognition (NER) datasets exist in news and web data (Tjong Kim Sang and De Meulder, 2003; Hovy et al., 2006), biomedical NER datasets are typically smaller and contain only one or two types per dataset. Ultimately, we would like to identify all entity types present across the union of the label sets during inference while leveraging all the available annotations to train our models.

While one may train a single model across the union of all the datasets available, this training procedure assumes that all labels (from the union of the tag set) are correctly annotated in every training instance – which is incorrect. On the other hand, training separate models on each available dataset does not take advantage of shared statistical strength from the multiple sources of information, and requires resolution of the conflicting predictions output by the different models.

To remedy these problems, we propose methods to train a joint model across the multiple tag-sets of the different datasets, sharing statistical strength by using a single feature encoder across datasets while respecting the incompleteness of the labels during training. Thus, our single model can take full advantage of all the available annotated resources and predict the full set of relevant types given a piece of text.

In experiments on three datasets, we show our methods outperform models that do not consider the incomplete annotations. We also show that jointly training on multiple datasets improves performance further and achieves state-of-the-art performance on the Biocreative V CDR dataset.

2 Model

Our models build on state-of-the-art NER systems (Lample et al., 2016) based on bi-directional Long Short Term Memory (BiLSTM) feature extractors fed into a conditional random field (CRF).

The data consists of input sequence of tokens $\mathbf{x} = \{x_1, \ldots, x_T\}$ where each token is a sequence of characters $x_t = \{c_1, \ldots, c_{K_t}\}$. The output consists of labels for each token in the sequence $\mathbf{y} = \{y_1, \ldots, y_T\}$. Labeling is done using the BILOU tagging scheme, following previous observations that it outperforms the BIO tagging scheme (Ratinov and Roth, 2009). We have D such datasets of input tokens and output labels.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2824–2829
Brussels, Belgium, October 31 - November 4, 2018.

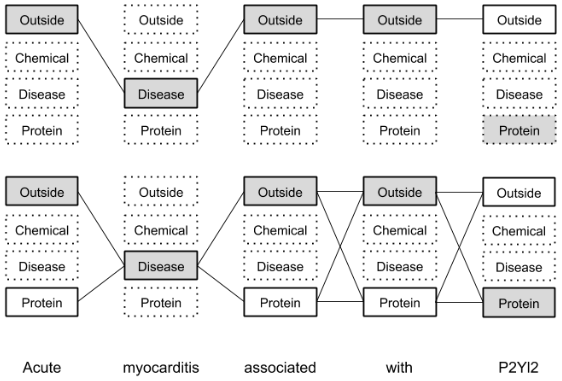

Figure 1: Training example where one label set contains Chemical/Protein and the other contains Chemical/Disease. Here Chemical and Disease annotations are given and Outside is ambiguous. Tokens labeled as Outside could potentially be either Outside or Protein (top). The shaded labels are the gold labels. The EM CRF marginalizes over all potential sequences (bot).

2.1 Feature Encoder BiLSTM

Our model takes a sequence of tokens from a single abstract as input. Tokens are generated using byte-pair encodings (BPE) (Gage, 1994; Sennrich et al., 2016), which have recently been shown to be effective for tokenization of biological texts by addressing the issue of rare or out-of-vocabulary tokens (Verga et al., 2018). BPE starts from white space tokenization and breaks down the tokens further. Because all of the evaluations are on the span level rather than the token level, the use of BPE does not impact any numerical performance. Each token t produced from BPE is mapped to a d dimensional word embedding w.

Character level features have been shown to improve NER accuracy (Lafferty et al., 2001; Lample et al., 2016; Passos et al., 2014). We encode characters in a word using another BiLSTM, similar to Lample et al. (2016), and obtain a character based embedding for every word by concatenating the last hidden state of the forward and backward character LSTM. We concatenate this character based embedding with the d-dimensional word embedding and input it to the word-level BiLSTM. This feature representation is then projected to the label dimension L using a linear layer, giving a matrix of scores $[f_{il}]$ where f_{il} is the score for predicting label $l \in [L]$ for token $i \in [T]$.

2.2 Conditional Random Field (CRF)

BiLSTM-CRF models used for named entity recognition add a CRF layer (Lafferty et al., 2001) on the output representations from the BiLSTM model described. The CRF layer scores all possible labelings to give a probability of the correct label sequence under the model. Given an input sequence of tokens $\mathbf{x} = \{x_1, \ldots, x_T\}$ and the output matrix of scores $[f_{il}]$, the score for an output labeling $\mathbf{y} = \{y_1, \ldots, y_T\}$ is given by: $s(\mathbf{x}, \mathbf{y}) = \sum_{t=1}^{T} \left(A_{y_{t-1}, y_t} + f_{t, y_t}\right)$, where A is an $L \times L$ matrix of parameters for transitioning between output labels. The CRF then generates the likelihood for the correct labeling by normalizing this score over all possible output labelings:

$$\log P(\mathbf{y}|\mathbf{x}) = s(\mathbf{x}, \mathbf{y}) - \underset{y'}{\text{logsumexp}}\, s(\mathbf{x}, \mathbf{y}') \quad (1)$$

The log normalization term here is: $\underset{y'}{\text{logsumexp}}\, s(\mathbf{x}, \mathbf{y}') = \log \sum_{y'} \exp s(\mathbf{x}, \mathbf{y}')$ where the sum goes over all possible labelings y' of the sequence and is computed efficiently using dynamic programming (Lafferty et al., 2001).

2.3 Tagging Multiple Datasets

One way to tag multiple datasets is to concatenate all the datasets with all the output labels and train a single BiLSTM-CRF model. However, this assumes that each text snippet is completely annotated across the label sets, which is not true. We now discuss two models which do not make this assumption.

2.3.1 Multiple CRFs

We first propose one simple method to get around the assumption of complete annotation – train separate CRFs for the label set of each dataset. In particular, to share statistical strengths on the input tokens, we share the BiLSTM feature encoder across the datasets but use separate CRF layers for each of the datasets. This is a multi-task learning model (Caruana, 1998) and is expected to perform better than the naive model as it no longer makes the strict assumption of complete annotation (by using separate CRFs), and shares statistical strength across datasets. However, given a new abstract to tag, this model will generate multiple possible labelings from the different CRFs. Moreover, the labelings output by the different CRFs may be inconsistent, and how to combine these multiple labelings is not obvious. We propose and evaluate a simple heuristic procedure for merging the outputs of the different CRF predictions. Whenever the different CRF predictions disagree on a span of tokens, we choose the prediction from the CRF that has higher marginal probability of predicting that span of tokens (Alg. 1 in supplementary).

2.3.2 EM Marginal CRF

We also propose an alternative principled approach that does not require a heuristic merging process. In order to label D datasets with some disjoint labels, we only consider the probability of the "observed labels" and allow the "unobserved" tokens to be free. Thus, when tagging dataset $i \in [D]$, we treat the non-entity tokens as potentially taking any entity type label from any of the other datasets as well as the 'O' label.

For a particular input $\mathbf{x}$ of length T from a dataset $i \in [D]$ with label set S_i, let $\mathbf{y}$ be the gold output label. Let $E \subset [T]$ be the index of tokens with any entity type label in S_i and $N \subset [T]$ be the index of tokens with 'O' label, and let $\mathbf{y}_E$ be the output sequence corresponding to indices in E, and similarly $\mathbf{y}_N$ be the output sequence for indices in N. Then, from (1), we get the likelihood $P_i(\mathbf{y_E} \cup \mathbf{y_N}|\mathbf{x})$, and a naive CRF trained on the concatenation of all the data will maximize this probability. However, since we cannot make the complete annotation assumption, we should instead maximize only the marginal probability of the observed entities on the dataset i, $P_i(\mathbf{y_E}|\mathbf{x})$, allowing $\mathbf{y_N}$ to take any values from the labels of the *other* datasets: $\cup_{j \neq i}^{D} S_j$. Thus,

$$\log P_i(\mathbf{y_E}|\mathbf{x}) = \log \sum_{\mathbf{y_N} \in \cup_{j \neq i} S_j} P_i(\mathbf{y_E}, \mathbf{y_N}|\mathbf{x})$$

$$\log P_i(\mathbf{y_E}|\mathbf{x}) = \underset{\mathbf{y_N} \in \cup_{j \neq i} S_j}{\text{logsumexp}}\, s(\mathbf{x}, \mathbf{y}_E, \mathbf{y}_N) - \log Z$$

where $\log Z$ is the log normalization term which is the same as in (1). Note that since the normalization term is the same here as for a standard CRF, we can still use the same dynamic programming algorithm as for a regular CRF to compute this $\log Z$. Now, in order to compute the first term, we note that it is similar to the computation required to compute $\log Z$ – whereas $\log Z$ is obtained by summing over all possible output sequences, this term is obtained by summing over all possible output sequences which have indices in E fixed to the correct label and indices in N taking values from $\cup_{j \neq i} S_j$. Thus, this can be computed using the same dynamic programming algorithm (Tsuboi et al., 2008), and the implementation of training this model is compatible with modern automatic differentiation libraries.

3 Experimental Results

We perform experiments on two benchmark Biocreative datasets as well as the recently introduced MedMentions data (Murty et al., 2018). Our experiments consider three types of models. The **single CRF** model naively concatenates all training datasets together and assumes complete labeling, **multi CRF** has a single Bi-LSTM feature encoder with a separate CRF for each dataset (Section 2.3.1), and **EM CRF** has a single feature encoder and a single CRF trained with EM marginalization (Section 2.3.2). For full dataset statistics and specific implementation details see supplementary material.

3.1 Biocreative V / VI

Biocreative V Chemical Disease Relation (CDR): consists of 1,500 titles and abstracts from PubMed, human annotated with chemical and disease mentions (Li et al., 2016), and has been used in previous NER evluations (Fries et al., 2017; Leaman and Lu, 2016). **Biocreative VI ChemProt (CP)**: consists of 2,432 PubMed titles and abstracts, and contains human annotated mentions of both chemicals and proteins (Krallinger et al., 2017)[1].

Our results are shown in Table 1. The top portion of the table shows models trained on single datasets, and the bottom portion shows models trained on both CDR and CP. Comparing the top and bottom portions of the table, we can see that models trained on both CP and CDR outperform training on either in isolation. Further, we see in the bottom section that our EM CRF outperforms the single CRF model and is generally better than the multi CRF model.

3.2 Adding Additional Data

Weakly Labeled data The addition of weakly labeled data has been used recently to improve the performance of relation extraction systems (Peng et al., 2016; Verga et al., 2018). In these approaches, titles and abstracts from PubMed are annotated using Pubtator, a state of the art entity tagging and linking/normalization system (Wei et al., 2013). We use the same weakly labeled data from Verga et al. (2018).

Results when adding in the additional weakly labeled data is shown in Table 2. Our models

improve further, outperforming the state-of-the-art TaggerOne model (Leaman and Lu, 2016).

3.3 MedMentions

MedMentions (Murty et al., 2018) is a recently introduced large dataset of PubMed abstracts containing entity linked mentions of many different semantic types. We used this data to create an artificially extreme example where two training sets contain 9 and 10 entity types each. The two type sets are fully disjoint (further details in supplementary).

In Table 3, we see that the single CRF model performs very poorly in this extreme setting due to the large amount of missing annotations. The multi CRF and EM CRF both perform well and come close to the performance of a single CRF trained on the full data, which is approximately twice as much annotated data.

Model	P	R	F1
single CRF	65.0	24.3	35.3
multi CRF	62.5	50.9	56.1
EM CRF	59.7	54.2	**56.8**
Full single CRF	60.5	58.3	59.4

Table 3: MedMentions results. Full single CRF is trained on the full set of annotations. Other models are trained on the two disjoint training sets.

4 Related Work

Until recently, feature engineered machine learning models were the highest performing approaches to NER (Ratinov and Roth, 2009; Passos et al., 2014). More recently, neural network based approaches have become state-of-the-art (Lample et al., 2016; Strubell et al., 2017; Peters et al., 2017). In BioNLP, many highest performing systems still use engineered features fed into a CRF (Wei et al., 2015; Leaman et al., 2015; Leaman and Lu, 2016). In addition to the two datasets we explored in this work, there are several other popular bio NER datasets for chemicals (Krallinger et al., 2015), species (Wang et al., 2010), diseases

(Doğan et al., 2014), and genes (Tanabe et al., 2005).

In concurrent work, Wang et al. (2018) train a model very similar to our multi-CRF model on multiple biological NER datasets with non-fully overlapping labels. Additionally, they experiment with different ways of sharing the parameters of the BiLSTM encoder. We believe this work is complementary to ours, and in many ways deals with a simpler subset of the tasks we address. Wang et al. assumes complete labeling in each of their datasets, and does not attempt to merge the final results of the multiple CRFS. On the other hand, we focus on the problem of cohesively labeling a dataset with the joint set of the different label sets, either directly through the EM model or by the merging process of the multi-CRF model.

Our method of training via marginal likelihood is the same as Tsuboi et al. (2008), who trained CRF models for Japanese word segmentation and POS tagging where only partial annotations of sentences are available. In comparison, we use the marginal likelihood training in conjunction with state-of-the art deep learning models for NER and use it to tag across multiple disjoint labels sets.

5 Conclusions and Future Work

We've introduced a method for training NER models on multiple datasets containing disjoint label sets. We show experimentally that this joint training improves performance and that our EM CRF methods outperform models using a single CRF.

One interesting problem that our models do not account for is the existence of overlapping and non-continuous entity spans. Particularly when annotating using disjoint label sets, a token could belong to multiple entity spans from different label sets. We are interested in investigating this problem in future work.

Adversarial training for multi-context joint entity and relation extraction

Abstract

Adversarial training (AT) is a regularization method that can be used to improve the robustness of neural network methods by adding small perturbations in the training data. We show how to use AT for the tasks of entity recognition and relation extraction. In particular, we demonstrate that applying AT to a general purpose baseline model for jointly extracting entities and relations, allows improving the state-of-the-art effectiveness on several datasets in different contexts (i.e., news, biomedical, and real estate data) and for different languages (English and Dutch).

1 Introduction

Many neural network methods have recently been exploited in various natural language processing (NLP) tasks, such as parsing (Zhang et al., 2017), POS tagging (Lample et al., 2016), relation extraction (dos Santos et al., 2015), translation (Bahdanau et al., 2015), and joint tasks (Miwa and Bansal, 2016). However, Szegedy et al. (2014) observed that intentional small scale perturbations (i.e., adversarial examples) to the input of such models may lead to incorrect decisions (with high confidence). Goodfellow et al. (2015) proposed adversarial training (AT) (for image recognition) as a regularization method which uses a mixture of clean and adversarial examples to enhance the robustness of the model. Although AT has recently been applied in NLP tasks (e.g., text classification (Miyato et al., 2017)), this paper — to the best of our knowledge — is the first attempt investigating regularization effects of AT in a joint setting for two related tasks.

We start from a baseline joint model that performs the tasks of named entity recognition (NER) and relation extraction at once. Previously proposed models (summarized in Section 2) exhibit several issues that the neural network-based baseline approach (detailed in Section 3.1) overcomes: (i) our model uses automatically extracted features without the need of external parsers nor manually extracted features (see Gupta et al. (2016); Miwa and Bansal (2016); Li et al. (2017)), (ii) all entities and the corresponding relations within the sentence are extracted at once, instead of examining one pair of entities at a time (see Adel and Schütze (2017)), and (iii) we model relation extraction in a multi-label setting, allowing multiple relations per entity (see Katiyar and Cardie (2017); Bekoulis et al. (2018a)). The core contribution of the paper is the use of AT as an extension in the training procedure for the joint extraction task (Section 3.2).

To evaluate the proposed AT method, we perform a large scale experimental study in this joint task (see Section 4), using datasets from different contexts (i.e., news, biomedical, real estate) and languages (i.e., English, Dutch). We use a strong baseline that outperforms all previous models that rely on automatically extracted features, achieving state-of-the-art performance (Section 5). Compared to the baseline model, applying AT during training leads to a consistent additional increase in joint extraction effectiveness.

2 Related work

Joint entity and relation extraction: Joint models (Li and Ji, 2014; Miwa and Sasaki, 2014) that are based on manually extracted features have been proposed for performing both the named entity recognition (NER) and relation extraction subtasks at once. These methods rely on the availability of NLP tools (e.g., POS taggers) or manually designed features leading to additional complexity. Neural network methods have been exploited to overcome this feature design issue and usually involve RNNs and CNNs (Miwa and Bansal,

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2830–2836
Brussels, Belgium, October 31 - November 4, 2018.

2016; Zheng et al., 2017). Specifically, Miwa and Bansal (2016) as well as Li et al. (2017) apply bidirectional tree-structured RNNs for different contexts (i.e., news, biomedical) to capture syntactic information (using external dependency parsers). Gupta et al. (2016) propose the use of various manually extracted features along with RNNs. Adel and Schütze (2017) solve the simpler problem of entity classification (EC, assuming entity boundaries are given), instead of NER, and they replicate the context around the entities, feeding entity pairs to the relation extraction layer. Katiyar and Cardie (2017) investigate RNNs with attention without taking into account that relation labels are not mutually exclusive. Finally, Bekoulis et al. (2018a) use LSTMs in a joint model for extracting just one relation at a time, but increase the complexity of the NER part. Our baseline model enables simultaneous extraction of multiple relations from the same input. Then, we further extend this strong baseline using adversarial training.

Adversarial training (AT) (Goodfellow et al., 2015) has been proposed to make classifiers more robust to input perturbations in the context of image recognition. In the context of NLP, several variants have been proposed for different tasks such as text classification (Miyato et al., 2017), relation extraction (Wu et al., 2017) and POS tagging (Yasunaga et al., 2018). AT is considered as a regularization method. Unlike other regularization methods (i.e., dropout (Srivastava et al., 2014), word dropout (Iyyer et al., 2015)) that introduce random noise, AT generates perturbations that are variations of examples easily misclassified by the model.

3 Model

3.1 Joint learning as head selection

The baseline model, described in detail in Bekoulis et al. (2018b), is illustrated in Fig. 1. It aims to detect (i) the type and the boundaries of the entities and (ii) the relations between them. The input is a sequence of tokens (i.e., sentence) $w = w_1, ..., w_n$. We use character level embeddings to implicitly capture morphological features (e.g., prefixes and suffixes), representing each character by a vector (embedding). The character embeddings are fed to a bidirectional LSTM (BiLSTM) to obtain the character-based representation of the word. We also use pre-trained word embeddings.

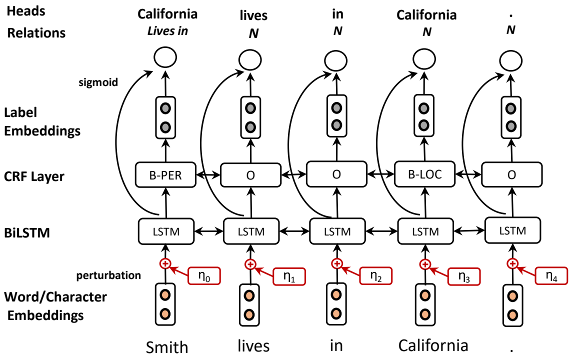

Figure 1: Our model for joint entity and relation extraction with adversarial training (AT) comprises (i) a word and character embedding layer, (ii) a BiLSTM layer, (iii) a CRF layer and (iv) a relation extraction layer. In AT, we compute the worst-case perturbations η of the input embeddings.

Word and character embeddings are concatenated to form the final token representation, which is then fed to a BiLSTM layer to extract sequential information.

For the **NER task**, we adopt the BIO (Beginning, Inside, Outside) encoding scheme. In Fig. 1, the B-*PER* tag is assigned to the beginning token of a 'person' (*PER*) entity. For the prediction of the entity tags, we use: (i) a softmax approach for the entity classification (EC) task (assuming entity boundaries given) or (ii) a CRF approach where we identify both the *type* and the boundaries for each entity. During decoding, in the softmax setting, we greedily detect the entity *types* of the tokens (i.e., independent prediction). Although independent distribution of *types* is reasonable for EC tasks, this is not the case when there are strong correlations between neighboring tags. For instance, the BIO encoding scheme imposes several constraints in the NER task (e.g., the B-*PER* and I-*LOC* tags cannot be sequential). Motivated by this intuition, we use a linear-chain CRF for the NER task (Lample et al., 2016). For decoding, in the CRF setting, we use the Viterbi algorithm. During training, for both EC (softmax) and NER tasks (CRF), we minimize the cross-entropy loss $\mathcal{L}_{\text{NER}}$. The entity tags are later fed into the relation extraction layer as label embeddings (see Fig. 1), assuming that knowledge of the entity *types* is beneficial in predicting the relations between the involved entities.

We model the **relation extraction task** as a multi-label head selection problem (Bekoulis et al., 2018b; Zhang et al., 2017). In our model, each word w_i can be involved in multiple relations with other words. For instance, in the example illustrated in Fig. 1, "Smith" could be involved not only in a *Lives in* relation with the token "California" (head) but also in other relations simultaneously (e.g., *Works for, Born In* with some corresponding tokens). The goal of the task is to predict for each word w_i, a vector of heads $\hat{y}_i$ and the vector of corresponding relations $\hat{r}_i$. We compute the score $s(w_j, w_i, r_k)$ of word w_j to be the head of w_i given a relation label r_k using a single layer neural network. The corresponding probability is defined as: $\mathbb{P}(w_j, r_k \mid w_i; \theta) = \sigma(s(w_j, w_i, r_k))$, where $\sigma(.)$ is the sigmoid function. During training, we minimize the cross-entropy loss $\mathcal{L}_{\text{rel}}$ as:

$$\sum_{i=0}^{n}\sum_{j=0}^{m} -\log \mathbb{P}(y_{i,j},\, r_{i,j} \mid w_i; \theta) \tag{1}$$

where m is the number of associated heads (and thus relations) per word w_i. During decoding, the most probable heads and relations are selected using threshold-based prediction. The final objective for the joint task is computed as $\mathcal{L}_{\text{JOINT}}(w;\theta) = \mathcal{L}_{\text{NER}} + \mathcal{L}_{\text{rel}}$ where θ is a set of parameters. In the case of multi-token entities, only the last token of the entity can serve as head of another token, to eliminate redundant relations. If an entity is not involved in any relation, we predict the auxiliary "N" relation label and the token itself as head.

3.2 Adversarial training (AT)

We exploit the idea of AT (Goodfellow et al., 2015) as a regularization method to make our model robust to input perturbations. Specifically, we generate examples which are variations of the original ones by adding some noise at the level of the concatenated word representation (Miyato et al., 2017). This is similar to the concept introduced by Goodfellow et al. (2015) to improve the robustness of image recognition classifiers. We generate an adversarial example by adding the worst-case perturbation η_{adv} to the original embedding w that maximizes the loss function:

$$\eta_{adv} = \underset{\|\eta\|\leq\epsilon}{\operatorname{argmax}}\, \mathcal{L}_{\text{JOINT}}(w+\eta; \hat{\theta}) \tag{2}$$

where $\hat{\theta}$ is a copy of the current model parameters. Since Eq. (2) is intractable in neural networks, we use the approximation proposed in Goodfellow et al. (2015) defined as: $\eta_{adv} = \epsilon g / \|g\|$, with $g = \nabla_w \mathcal{L}_{\text{JOINT}}(w;\hat{\theta})$, where ϵ is a small bounded norm treated as a hyperparameter. Similar to Yasunaga et al. (2018), we set ϵ to be $\alpha\sqrt{D}$ (where D is the dimension of the embeddings). We train on the mixture of original and adversarial examples, so the final loss is computed as: $\mathcal{L}_{\text{JOINT}}(w;\hat{\theta}) + \mathcal{L}_{\text{JOINT}}(w+\eta_{adv};\hat{\theta})$.

4 Experimental setup

We evaluate our models on four datasets, using the code as available from our github codebase.[1] Specifically, we follow the 5-fold cross-validation defined by Miwa and Bansal (2016) for the ACE04 (Doddington et al., 2004) dataset. For the CoNLL04 (Roth and Yih, 2004) EC task (assuming boundaries are given), we use the same splits as in Gupta et al. (2016); Adel and Schütze (2017). We also evaluate our models on the NER task similar to Miwa and Sasaki (2014) in the same dataset using 10-fold cross validation. For the Dutch Real Estate Classifieds, DREC (Bekoulis et al., 2017) dataset, we use train-test splits as in Bekoulis et al. (2018a). For the Adverse Drug Events, ADE (Gurulingappa et al., 2012), we perform 10-fold cross-validation similar to Li et al. (2017). To obtain comparable results that are not affected by the input embeddings, we use the embeddings of the previous works. We employ early stopping in all of the experiments. We use the Adam optimizer (Kingma and Ba, 2015) and we fix the hyperparameters (i.e., α, dropout values, best epoch, learning rate) on the validation sets. The scaling parameter α is selected from $\{5\text{e}{-2}, 1\text{e}{-2}, 1\text{e}{-3}, 1\text{e}{-4}\}$. Larger values of α (i.e., larger perturbations) lead to consistent performance decrease in our early experiments. This can be explained from the fact that adding more noise can change the content of the sentence as also reported by Wu et al. (2017).

We use three types of evaluation, namely: (i) *S(trict)*: we score an entity as correct if both the entity boundaries and the entity *type* are correct (ACE04, ADE, CoNLL04, DREC), (ii) *B(oundaries)*: we score an entity as correct if only the entity boundaries are correct while the entity *type* is not taken into account (DREC) and (iii) *R(elaxed)*: a multi-token entity is considered correct if at least one correct *type* is assigned to the tokens comprising the entity, assuming that the

Table 1: Comparison of our method with the state-of-the-art in terms of F_1 score. The proposed models are: (i) baseline, (ii) baseline EC (predicts only entity classes) and (iii) baseline (EC) + AT (regularized by AT). The ✓and ✗ symbols indicate whether the models rely on external NLP tools. We include different evaluation types (*S*, *R* and *B*).

boundaries are known (CoNLL04), to compare to previous works. In all cases, a relation is considered as correct when both the relation *type* and the argument entities are correct.

5 Results

Table 1 shows our experimental results. The name of the dataset is presented in the first column while the models are listed in the second column. The proposed models are the following: (i) *baseline*: the baseline model shown in Fig. 1 with the CRF layer and the sigmoid loss, (ii) *baseline EC*: the proposed model with the softmax layer for EC, (iii) *baseline (EC) + AT*: the baseline regularized using AT. The final three columns present the F_1 results for the two subtasks and their average performance. Bold values indicate the best results among models that use only automatically extracted features.

For ACE04, the baseline outperforms Katiyar and Cardie (2017) by ∼2% in both tasks. This improvement can be explained by the use of: (i) multi-label head selection, (ii) CRF-layer and (iii) character level embeddings. Compared to Miwa and Bansal (2016), who rely on NLP tools, the baseline performs within a reasonable margin (less than 1%) on the joint task. On the other hand, Li et al. (2017) use the same model for the ADE biomedical dataset, where we report a 2.5% overall improvement. This indicates that NLP tools are not always accurate for various contexts. For the CoNLL04 dataset, we use two evaluation settings. We use the *relaxed* evaluation similar to Gupta et al. (2016); Adel and Schütze (2017) on the EC task. The baseline model outperforms the state-of-the-art models that do not rely on manually extracted features (>4% improvement for both tasks), since we directly model the whole sentence, instead of just considering pairs of entities. Moreover, compared to the model of Gupta et al. (2016) that relies on complex features, the baseline model performs within a margin of 1% in terms of overall F_1 score. We also report NER results on the same dataset and improve overall F_1 score with ∼1% compared to Miwa and Sasaki (2014), indicating that our automatically extracted features are more informative than the hand-crafted ones. These automatically extracted features exhibit their performance improvement mainly due to the shared LSTM layer that learns to automatically generate feature representations of entities and their corresponding relations within a single model. For the DREC dataset, we use two evaluation methods. In the *boundaries* evaluation, the baseline has an improvement of ∼3% on both tasks compared to Bekoulis et al. (2018a), whose quadratic scoring layer complicates NER.

Table 1 and Fig. 2 show the effectiveness of the adversarial training on top of the baseline model. In all of the experiments, AT improves the predictive performance of the baseline model in the joint setting. Moreover, as seen in Fig. 2, the performance of the models using AT is closer to maximum even from the early training epochs. Specifically, for ACE04, there is an improvement in both tasks as well as in the overall F_1 performance (0.4%). For CoNLL04, we note an improvement in the overall F_1 of 0.4% for the EC and 0.8% for the NER tasks, respectively. For the DREC dataset, in both settings, there is an overall improvement of ∼1%. Figure 2 shows that from the first epochs, the model obtains its maximum performance on the DREC validation set. Finally, for ADE, our AT model beats the baseline F_1 by 0.7%.

Our results demonstrate that AT outperforms the neural baseline model consistently, considering our experiments across multiple and more diverse datasets than typical related works. The im-

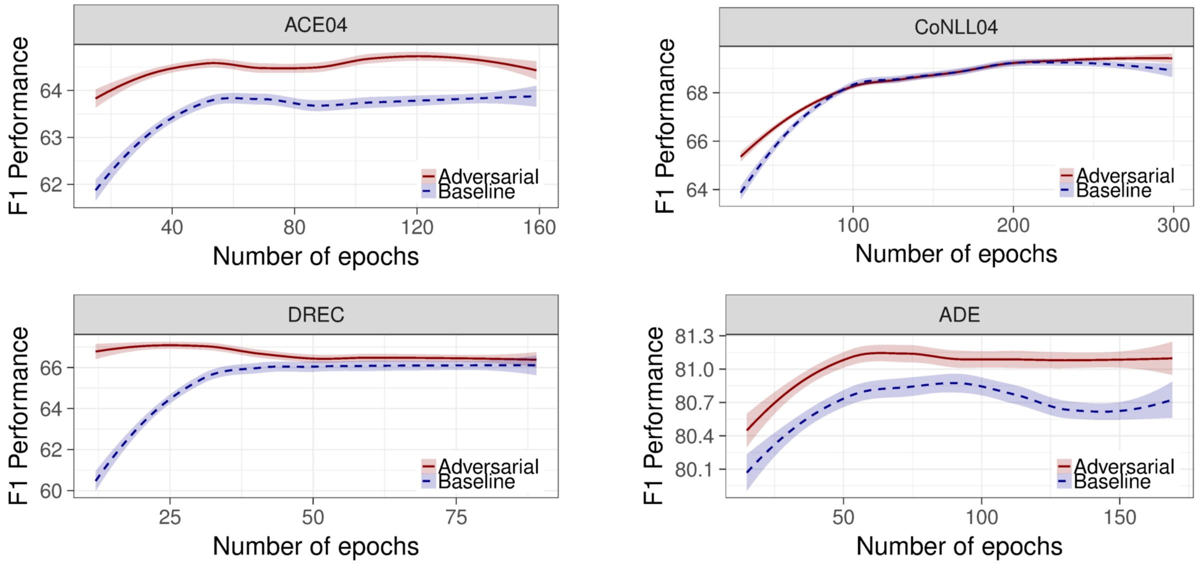

Figure 2: F_1 performance of the baseline and the AT models on the validation sets from 10-30 epochs onwards depending on the dataset. The smoothed lines (obtained by LOWESS smoothing) model the trends and the 95% confidence intervals.

provement of AT over our baseline (depending on the dataset) ranges from ∼0.4% to ∼0.9% in terms of overall F_1 score. This seemingly small performance increase is mainly due to the limited performance benefit for the NER component, which is in accordance with the recent advances in NER using neural networks that report similarly small gains (e.g., the performance improvement in Ma and Hovy (2016) and Lample et al. (2016) on the CoNLL-2003 test set is 0.01% and 0.17% F_1 percentage points, while in the work of Yasunaga et al. (2018), a 0.07% F_1 improvement on CoNLL-2000 using AT for NER is reported). However, the relation extraction performance increases by ∼1% F_1 scoring points, except for the ACE04 dataset. Further, as seen in Fig. 2, the improvement for CoNLL04 is particularly small on the evaluation set. This may indicate a correlation between the dataset size and the benefit of adversarial training in the context of joint models, but this needs further investigation in future work.

6 Conclusion

We proposed to use adversarial training (AT) for the joint task of entity recognition and relation extraction. The contribution of this study is twofold: (i) investigation of the consistent effectiveness of AT as a regularization method over a multi-context baseline joint model, with (ii) a large scale experimental evaluation. Experiments show that AT improves the results for each task separately, as well as the overall performance of the baseline joint model, while reaching high performance already during the first epochs of the training procedure.

Abstract

We propose a model for tagging unstructured texts with an arbitrary number of terms drawn from a tree-structured vocabulary (i.e., an ontology). We treat this as a special case of sequence-to-sequence learning in which the decoder begins at the root node of an ontological tree and recursively elects to expand child nodes as a function of the input text, the current node, and the latent decoder state. In our experiments the proposed method outperforms state-of-the-art approaches on the important task of automatically assigning MeSH terms to biomedical abstracts.

1 Introduction

We consider the task of multilabel text annotation, where labels are drawn from an ontology. We are motivated by problems in biomedical NLP (Zweigenbaum et al., 2007; Demner-Fushman et al., 2016). Specifically, scientific abstracts in this domain are typically associated with multiple Medical Subject Heading (MeSH) terms. MeSH is a controlled, hierarchically structured vocabulary that facilitates semantic labeling of texts at varying levels of granularity. This in turn supports semantic indexing of biomedical literature, thus facilitating improved search and retrieval.[1]

At present, MeSH annotation is largely performed manually by highly skilled annotators employed by the National Library of Medicine (NLM). Automating this annotation task is thus highly desirable, and there have been considerable efforts to do so. The BIOASQ[2] challenge, in particular, concerns MeSH annotation, and competitive systems have emerged from this in past years (Liu et al., 2014; Tsoumakas et al., 2013); these constitute baseline approaches in the present work.

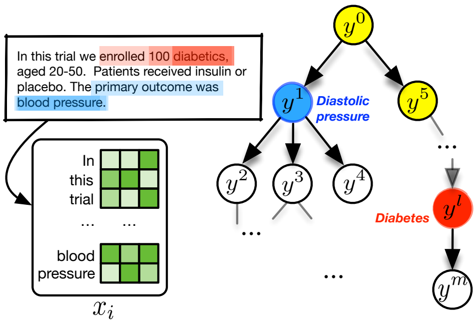

Figure 1: Illustration of the proposed Neural Tree Decoding (NTD) model. Input text is encoded, and a decoder then conditionally traverses the label tree to select all relevant nodes to apply, with node-wise attention induced over the input text.

More generally, MeSH annotation is a specific instance of multi-label classification, which has received substantial attention in general (Elisseeff and Weston, 2002; Fürnkranz et al., 2008; Read et al., 2011; Bhatia et al., 2015; Daumé III et al., 2017; Chen et al., 2017; Jernite et al., 2016). Our work differs from these prior efforts in that MeSH tagging involves *structured* multi-label classification: the label space is a tree[3] in which nodes represent nested semantic concepts, and the specificity of these increases with depth.

Past efforts in multi-label classification have considered hierarchical and tree-based approaches for tagging (Jernite et al., 2016; Beygelzimer et al., 2009; Daumé III et al., 2017), but these have not assumed a *given* structured label space; instead, these efforts have attempted to *induce* trees to improve inference efficiency. By contrast, we propose to explicitly capitalize on a known output structure codified here by the target ontology from which tags are drawn. We realize this by recursively traversing the tree to make (conditional) bi-

---

[1] This problem also resembles tagging clinical notes with ICD codes (Mullenbach et al., 2018).

[2] `http://bioasq.org/`

[3] Technically, MeSH comprises multiple trees, but we join these by insertion of an overarching root node.

nary tag application predictions.

The contribution of this work is a neural sequence-to-sequence (*seq2seq*) model (Bahdanau et al., 2014) for structured multi-label classification. Our approach entails encoding the input text to be tagged using an RNN, and then *decoding into the ontological output space*. This involves a tree traversal beginning at the root of the tree. At each step, the decoder decides whether to 'expand' children as a function of a hidden state vector, node embeddings, and induced attention weights over the input text. This approach is schematized in Figure 1. Expanded nodes are added to the predicted tag set. This process is repeated recursively until either leaf nodes are reached or no children are selected for expansion. This neural tree decoding (NTD) model outperforms state-of-the-art models for MeSH tagging.

2 Model

Overview. Our model is an instance of an encoder-decoder architecture. For the encoder, we adopt a standard Gated Recurrent Unit (GRU) network (Cho et al., 2014a), which yields hidden states for the tokens comprising an input document. The decoder network consumes these outputs and begins at the root of the ontological tree. It induces an attention distribution over encoder states, which is used together with the current decoder state vector to inform which (if any) of its immediate children are applicable to the input text (Figure 1). This decoding process proceeds recursively for all children deemed relevant. Below we provide more in-depth technical detail regarding the constituent modules.

The encoder (ENC) consumes as input a raw sequence of words, here composing an abstract. These are passed through an embedding layer, producing a sequence of word embeddings x (for clarity we omit a document index here), which are then passed through a GRU (Cho et al., 2014b) to obtain a sequence of hidden vectors $h = \{h_0, \cdots, h_{|x|-1}\}$, where $h_t = \text{GRU}(x_t, h_{t-1})$.

These are then passed to our neural tree decoder, which is responsible for tagging the encoded text with an arbitrary number of terms from the label tree, i.e., sequences in the structured output space. This module traverses the label space top-down, beginning at the root, thus exploiting the concept hierarchy codified by the tree structure.

At each step in the decoding process, the decoder will be positioned at a particular node in the tree n. Children — immediate descendents — of this node are then considered for expansion in turn, based on a hidden state vector s_n, and a context vector c_n. Both of these are initialized to zero vectors and recursively updated during traversal, i.e., as nodes are selected for expansion (and hence added to the predicted tag set). More specifically, the context vector that informs the decision to expand node v in the label hierarchy from its parent node n is a weighted sum of the encoder hidden states h, where weights reflect induced attention over inputs, conditioned on n. That is:

$$c_n = \sum_j \alpha_{nj} h_j \tag{1}$$

where

$$\alpha_{nj} = \frac{exp\{a(s_n, h_j)|\theta_n\}}{\sum_l exp\{a(s_n, h_l)|\theta_n\}} \tag{2}$$

and a is a simple multi-layer perceptron (MLP), with node-specific parameters θ_n. Here both sums range over the length of the input text.

Given c_n, we then estimate the probability that child label v is applicable to the current input text as a function of the decoder state vector (s_n), the current context vector (c_n) and the decoder parameters. In particular, this is realized via a standard linear layer with sigmoid activations, parameterized by a weight matrix W comprising independent weight vectors for each output node v. Thus the score for a particular output node v is $\sigma(W_v \cdot [s_n, c_n])$, where W_v denotes the weight vector for output node v.

Pseudocode for the training and decoding procedures are presented in Algorithm 1. In the NODELOSS function, n denotes a particular node. The set of hidden vectors induced by the encoder (corresponding to the inputs) are denoted by h, s is the hidden state of the decoder, and y is the reference label (this encodes a path in the output tree). We assume the decoder, DEC, consumes input representations, a node index and a hidden state and yields a context vector for n, c_n and an updated state vector s_n; in our case the latter is implemented via a GRU. The advantage of using an RNN during decoding is that this allows the exploitation of learned, distributed hidden representations of partial tree paths, which inform node-wise attention and subsequent predictions.

Algorithm 1 RecursiveTreeDecoding

```
function NodeLoss($n$, $h$, $s$, $y$)
    $l_n \leftarrow 0$
    $c_n, s_n \leftarrow$ DEC($h$, $n$, $s$)
    for each child $v \in$ children($n$) do
        $\hat{y}_v \leftarrow \sigma(W_v \cdot [s_n, c_n])$
        $p_v \leftarrow \propto$ depth in tree
        $B_v \sim$ Ber($p_v$)
        if $B_v$ then
            $l_n \leftarrow l_n + \mathcal{L}(\hat{y}_v, y)$
        if $\hat{y}_v > \tau$ then
            $l_n \leftarrow l_n$ + NodeLoss($v$, $h$, $s_n$, $y$)
    return $l_n$

function Train($x$, $y$, $\alpha$, epochs)
    $\theta \leftarrow$ INIT($\theta$)
    $e \leftarrow 0$
    while $e <$ epochs do
        for each instance $x_i \in x$ do
            $h_i \leftarrow$ ENC($x_i$)
            $s_0 \leftarrow \mathbf{0}$
            $l_i \leftarrow$ NodeLoss(ROOT, $h_i$, $s_0$, $y_i$)
            $\Delta\theta \leftarrow$ BACKPROP($l_i$)
            $\theta \leftarrow \theta + \alpha\Delta\theta$
        $e \leftarrow e + 1$
    return $\theta$
```

Incurring loss for all nodes along the path specified by y would place a disproportionate amount of emphasis on correctly applying terms that are 'higher' in the ontology, as loss will be propagated for the initial predictions concerning the application of these and then also, due to recursive application, for all of their children (and so on). Thus we only incur (and hence backpropagate) loss for a node v stochastically, according to a Bernoulli distribution B with parameter p_v. We set p_v to be proportional to the depth of node v in the tree such that we are likely to incur larger loss for deeper (rarely occurring) nodes. We operationalize this as: $p_v = \mathit{min}(1, 0.5 + \frac{m}{f_v})$, where m is the count corresponding to the least frequently observed node in the training corpus and f_v is the count for node v. In Section 4 we demonstrate the benefit of this approach.

At train time we use *teacher forcing* (Williams and Zipser, 1989) during decoding. That is, we revert the model back to the correct (training) tree subsequence when it goes off-course, and continue decoding from there. We have elided this detail from the pseudocode for clarity.

3 Experimental setup

Below we describe experimental details concerning our implementation, datasets and baselines. Code and data to reproduce our results is available at `https://github.com/gauravsc/NTD`.

3.1 Implementation Details

We limited the vocabulary to the $50,000$ most frequent words. Word embeddings were initialized to pre-trained vectors induced via word2vec, trained over a large set of abstracts indexed on PubMed.[4] Ontology node embeddings were pre-trained using DeepWalk (Perozzi et al., 2014), fit over PubMed.

3.2 Dataset

Our dataset comprises abstracts of articles describing randomized controlled trials (RCTs) from PubMed along with their MeSH terms. The MeSH annotations were manually applied by professionals at the National Library of Medicine (NLM). The label space underlying MeSH terms is codified by a publicly available ontology.[5]

We split this dataset into disjoint sets for training/development and final evaluation (Table 1). We further separated the former into train, validation and development test subsets, to refine our approach. For our final evaluation we used a held-out set of 10,000 abstracts that were not seen in any way during model development and/or hyper-parameter tuning. We performed extensive hyper-parameter tuning for the baseline models to ensure fair comparison; details regarding this tuning are provided in the Appendix.

3.3 Baselines

We compare our proposed approach to three baselines, including two prior winners of the annual BioASQ challenge, which includes an automated MeSH annotation task. However, it is important to note that we used a different (and considerably smaller) dataset in the current work, as compared to the corpus used in the BioASQ challenge.

LSSI (Tsoumakas et al., 2013) use an approach that involves predicting both the number of terms and which to apply to a given abstract. They use linear models for both tasks, which operate over TF-IDF representations of abstracts. Specifically, they train a regressor to predict k, the number of MeSH terms to be applied to an abstract. Simultaneously, a binary linear SVM is trained independently for each MeSH term appearing in the train set. At test time, these SVMs provide scores for each term and the top $\hat{k}$ terms are applied, where $\hat{k}$ is the estimate from the aforementioned regressor.

Table 2: Results on the held-out test dataset. SD refers to *semantic distance*, defined in Eq. 3.

UIUC (Liu et al., 2014) uses a learning-to-rank model to identify the top MeSH terms for an abstract from a candidate set of terms, which is obtained from the nearest neighbours of the abstract. Additionally, one SVM classifier is trained for each of the MeSH terms (similar to the above approach), and scores for each are used to obtain additional terms to be added to the candidate set. In the end, a threshold (tuned on the validation set) is used to select the final set of terms to be assigned.

Finally, we consider a deep multilabel classification model **DML** (Rios and Kavuluru, 2015) that takes as input unstructured abstracts and activates the output nodes corresponding to the relevant MeSH terms. In brief, embedded tokens are fed through a CNN to induce a vector representation, which is then passed on to the dense output layer. Finally, this is passed through a sigmoid activation function. Note that this model exploits the same pre-trained word embeddings as our model does.

3.4 Evaluation metrics

We first evaluate model performance via output node-wise precision, recall and F1 measure. However, these metrics are overly strict in the sense that a model will be penalized equally for all mistakes, regardless of whether they are nearby or far from the target in the label tree. This is problematic because whether to apply a specific MeSH term or its immediate parent may be somewhat subjective in practice. To quantify this, and to explore the extent to which explicitly decoding into the target label space yields improved predictions, we also consider a measure that we refer to as *semantic distance* (SD):

$$\text{SD} = \frac{1}{|\mathcal{Y}|} \sum_{u \in \mathcal{Y}} \min_{v \in \hat{\mathcal{Y}}} \mathit{dist}(u, v) \qquad (3)$$

where $\mathcal{Y}$ and $\hat{\mathcal{Y}}$ are the sets of target and predicted terms respectively, and *dist* is a function that returns the shortest distance between two nodes in the label ontology tree. The idea is that this penalizes less for 'near misses'. Thus if a model fails to apply a particular tag t, but does apply one near to t in the label tree, then it is penalized less.[6] We hypothesize that our model will improve results markedly with respect to this metric, given our exploitation of the tree structure.

As in the case of recall, SD can be 'gamed': one can achieve a perfect score by predicting that all nodes apply to a given abstract. Thus this is only meaningful alongside complementary metrics like F1.

4 Results

Results on the test set (which was completely held out during development) are reported in Table 2. The proposed Neural Tree Decoding model with stochastic backpropagation (NTD-s) bests the most competitive baseline (LSSI) in F1 score by over 2 points.

To explore the effect of backpropagating loss from nodes in proportion to their depth in the ontology, we also include results for a deterministic variant that does not do this, NTD-d. This version does not perform as well, demonstrating the utility of the proposed training approach.

The metrics reported thus far do not account of the structure in the output space. We thus additionally report results with respect to the the semantic distance (SD) metric (Eq. 3). We observe a marked performance increase of $\sim$21% over the best performing baseline. This is intuitive given that we are explicitly decoding into the label tree structure, and demonstrates the ability of our model to learn the ontological structure, thereby predicting semantically appropriate terms.

---

[6] This metric is equivalent to the sum of two metrics ("divergent path to gold standard" and "divergent path to prediction") defined in (Perotte et al., 2013).

5 Conclusions, Discussion & Limitations

We developed a neural attentive sequence tree decoding model for structured multilabel classification where labels are drawn from a known ontology. The proposed method can decode an input text into a tree of labels, effectively using the structure in the output space. We demonstrated that this model outperformed SOTA approaches for the important task of tagging biomedical abstracts with Medical Subject Heading (MeSH) terms on a modestly sized training corpus. Code and data to reproduce these results are available at `https://github.com/gauravsc/NTD`.

One limitation of our model is that it is comparatively slow, due to having to traverse the tree structure during decoding. Prediction speed may not be a major issue in practice, as articles on PubMed could be batch tagged nightly as they arrive. However, slow decoding also means lengthy training (see Appendix, section A.2 for details). For this reason we have here used a modest training set of ∼20k abstracts, which is smaller than corpora used in prior work on this task. Given the relative expressiveness of our model, we expect it to benefit substantially from additional training data, moreso than the simpler baseline architectures. But at present this is only a conjecture.

In future work we thus hope to apply this model to larger datasets, and to address the efficiency issue. Concerning the latter, sibling subtrees may be traversed in parallel, conditioned on the hidden state of their parent. Another promising direction would be to move to convolutional encoder and decoder architectures, designing the latter in a way similarly capitalizes on the label space tree structure.

Abstract

We propose a simple deep neural model for nested named entity recognition (NER). Most NER models focused on flat entities and ignored nested entities, which failed to fully capture underlying semantic information in texts. The key idea of our model is to enumerate all possible regions or spans as potential entity mentions and classify them with deep neural networks. To reduce the computational costs and capture the information of the contexts around the regions, the model represents the regions using the outputs of shared underlying bidirectional long short-term memory. We evaluate our exhaustive model on the GENIA and JNLPBA corpora in biomedical domain, and the results show that our model outperforms state-of-the-art models on nested and flat NER, achieving 77.1% and 78.4% respectively in terms of F-score, without any external knowledge resources.

1 Introduction

Named entity recognition (NER) is a task of finding entities with specific semantic types such as *Protein*, *Cell*, and *RNA* in text. NER is generally treated as a sequential labeling task, where each token is tagged with a label that corresponds to its surrounding entity. However, when entities overlap or are nested within one another, treating the task as a sequential labeling task becomes difficult because an individual token can be included in several entities and defining a label for each token can be difficult. For example, in the following phrase from the GENIA corpus (Kim et al., 2004), four levels of nested entities occur and the token "*IL-2*" is a *Protein* on its own, and it is also a part of two other *Protein*s and one *DNA*.

[[[[*IL-2*]^{Protein} *receptor*]^{Protein} *(IL-2R) alpha chain*]^{Protein} *gene*]^{DNA}

NER has drawn considerable attention as the first step towards many natural language processing (NLP) applications including relation extraction (Miwa and Bansal, 2016), event extraction (Feng et al., 2016), co-reference resolution (Fragkou, 2017; Stone and Arora, 2017), and entity linking (Gupta et al., 2017). Much work on NER, however, has ignored nested entities and instead chosen to focus on the non-nested entities, which are also referred to as flat entities. Only a few studies target the nested named entity recognition (Muis and Lu, 2017; Lu and Roth, 2015; Finkel and Manning, 2009).

Recent successes in neural networks have shown impressive performance gains on flat named entity recognition in several domains (Lample et al., 2016; Ma and Hovy, 2016; Gridach, 2017; Strubell et al., 2017). Such models achieve state-of-the-art results without requiring any hand crafted features or external knowledge resources. In contrast, fewer approaches have emphasized the nested entity recognition problem. Existing approaches to nested NER (Shen et al., 2003; Alex et al., 2007; Finkel and Manning, 2009; Lu and Roth, 2015; Xu et al., 2017; Muis and Lu, 2017) are mostly feature-based and thus suffer from heavy feature engineering. In this paper, we present a novel neural exhaustive model that reasons over all the regions within a specified maximum size. The model represents each region using the outputs of bidirectional long short-term memory (LSTM) by combining the boundary representation of a region and inside representation that simply treats all the tokens in a region equally by taking the average of LSTM outputs corresponding to tokens inside the region. It then classifies regions into their entity types or non-entity. Unlike the existing model that relies on token-level labels, our model directly employs an entity type as the label of a region. The model

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2843–2849
Brussels, Belgium, October 31 - November 4, 2018.

does not rely on any external knowledge resources or NLP tools like part-of-speech taggers. We evaluated our model on the GENIA and JNLPBA corpora in the biomedical domain and the model achieved 77.1% and 78.4% respectively in terms of F-score, which are the new state-of-the-art performances on the corpora.

2 Neural Exhaustive Model

The proposed model exhaustively considers all possible regions in a sentence using a single neural network; we thus call the model neural exhaustive model. Our model is built upon a shared bidirectional LSTM layer. The model enumerates all possible regions or spans that can include all the nested entities. It then represent the regions by using the outputs of the LSTM layer and detect the entities from the regions. The number of possible regions depend on the predefined maximum size. In this section, we describe the architecture of our neural exhaustive model in detail, which is summarized in Figure 1.

2.1 Word Representation

We represent each word by concatenating word embeddings and character-based word representations. Pre-trained word embeddings are used to initialize word embeddings (Chiu et al., 2016). For the character-based word representations, we encode the character-level information of each word following the successes of Ma and Hovy (2016) and Lample et al. (2016) that utilized character embeddings for the flat NER task. The embedding of each character in a word is randomly initialized. We feed the sequence of character embeddings comprising a word to a bidirectional LSTM layer and concatenate the forward and backward output representations to obtain the word representations.

2.2 Exhaustive Combination using LSTM

Given an input sentence sequence $X = \{x_1, x_2, ...x_n\}$, where x_i denotes the i-th word and n denotes the number of words in the sentence sequence, the distributed embeddings of words and characters are fed into a bidirectional LSTM layer that computes the hidden vector sequence in forward $\overrightarrow{\mathbf{h}} = \left\{\overrightarrow{\mathbf{h}_1}, \overrightarrow{\mathbf{h}_2}, \ldots, \overrightarrow{\mathbf{h}_n}\right\}$ and backward $\overleftarrow{\mathbf{h}} = \left\{\overleftarrow{\mathbf{h}_1}, \overleftarrow{\mathbf{h}_2}, \ldots, \overleftarrow{\mathbf{h}_n}\right\}$ manners. We concatenate the forward and backward outputs as $\mathbf{h}_i = \left[\overrightarrow{\mathbf{h}_i}; \overleftarrow{\mathbf{h}_i}\right]$, where $[;]$ denotes concatenation.

With the LSTM output $\mathbf{h}_i$, our exhaustive model shares the underlying representations of all possible regions by exhaustive combination. We generate all possible regions with the sizes less than or equal to the maximum region size L. We use a $region(i, j)$ to represent the region from i to j inclusive, where $1 \leq i < j \leq n$ and $j - i < L$.

2.3 Region Representation and Classification

We represent the region by separating the region into the boundary and inside representations. The boundary representation is important to capture the contexts surrounding the region. We simply rely on the outputs of the bidirectional LSTM layer corresponding to the boundary words of a target region for this purpose. For the inside representation, we simply average the outputs of the bidirectional LSTM layer in the region to treat them equally. We include the outputs for the boundary words to guarantee that the inside representation has corresponding outputs. In summary, we obtain the representation $\mathbf{R}(i, j)$ of the $region(i, j)$ as follows:

$$\mathbf{R}(i, j) = \left[\mathbf{h}_i; \frac{1}{j - i + 1} \sum_{k=i}^{j} \mathbf{h}_k; \mathbf{h}_j\right]. \qquad (1)$$

We then feed the representation of each segmented region to a rectified linear unit (ReLU) as an activation function. Finally, the output of the activation layer is passed to a softmax output layer to classify the region into a specific entity type or non-entity.

The exhaustive model represents all possible regions based on maximum entity length and classify all of them. The overall number of classifications for each sentence in the exhaustive model is in $O(lmn)$, where l is a total number of words in the sentence, m is the maximum entity length and n is the total number of possible entity types. Finkel and Manning (2009) and Alex et al. (2007) proposed featured-based approaches for handling nested NER. The time complexity of their models are expensive, i.e., cubic in the number of the words in the sentence. The exhaustive approach is fast since we run the LSTM once and the classifications can be performed in parallel on the combinations created from the LSTM outputs.

The exhaustive model classify each region independently unlike word-level taggers. This makes the model flexible so that it can incorporate

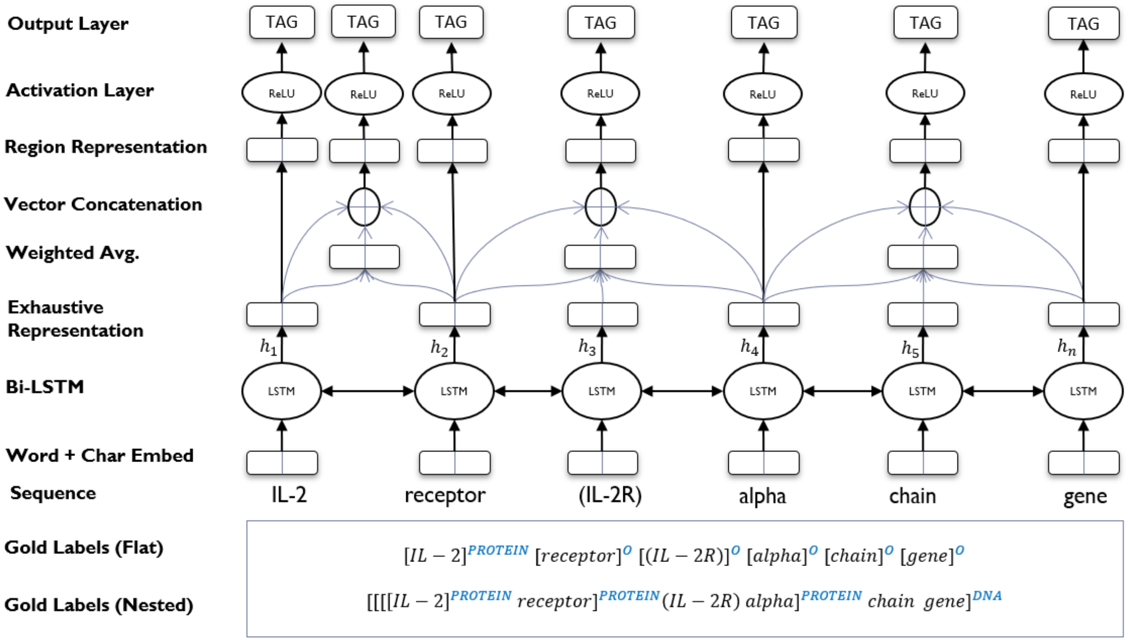

Figure 1: Architecture of the proposed neural exhaustive model. The model considers all possible regions up to a maximum size, but we depict here only a small subset for brevity. "*IL-2*", "*IL-2 receptor*", "*IL-2 receptor (IL-2R) alpha*", and "*IL-2 receptor (IL-2R) alpha chain gene*" are nested entities.

phrase-level dictionary information directly and we can tune biases for each type unlike CRF. We leave this evaluation to our future work.

3 Experimental Settings

We evaluated our exhaustive model on GENIA[1] (Kim et al., 2003) and JNLPBA[2] (Kim et al., 2004) datasets to provide empirical evidence for the effectiveness of our model both in nested and flat NER. Table 1 shows the statistics of GENIA dataset.

Our model was implemented in Chainer[3] deep learning framework. We employed pre-trained word embeddings that were trained on MEDLINE abstracts (Chiu et al., 2016), which included 200-dimensional embeddings of 2,231,686 vocabulary. We used ADAM (Kingma and Ba., 2015) for learning with a mini-batch size of 100. We used the same hyper-parameters in all the experiments; we set the dimension of word embedding to 200, the dimension of character embedding to 25, the hidden layer size to 200, the gradient clipping to 5, and the ADAM hyper-parameters to its default values (Kingma and Ba., 2015).

evaluate our model. We also compared the performances for single-token v.s. multi-token entities and top-level v.s. nested entities.

4 Results and Discussions

4.1 Nested NER

Table 2 shows the comparison of our model with several previous state-of-the nested NER models on the test dataset. Our model outperforms the state-of-the-art models in terms of F-score. Our results on Table 2 is based on bidirectional LSTM with character embeddings and the maximum region size is 10.

Table 3 describes the performances of our model on different entity levels on the test dataset. The model performs well on multi-token and top-level entities. This is interesting because they are often considered difficult for sequential labeling models.

Table 4 shows the performances on the five entity types on the test dataset. We here show the performance by Finkel and Manning (2009) (F&M) for the reference. Our system performs better than their model except for the *RNA* type.

4.2 Ablation Tests

We show the differences in the performance on the development dataset to compare the possible scenarios of the proposed approach and to report the importance of each component in our exhaustive model.

Label	P(%)	R(%)	F(%)	F&M F(%)

Boundary+Inside*	93.5	67.6	78.2

Table 6: Performance of our model with different model architectures on the development dataset. $\star$ indicates results using character embeddings.

Label	P(%)	R(%)	F(%)
DNA	95.2	56.8	71.4
RNA	96.1	61.4	75.2
cell line	86.2	44.1	58.8
cell type	96.7	61.5	75.3
protein	97.1	72.2	82.6
overall	96.4	66.8	78.4

Table 7: Categorical and overall performances of the JNLPBA test dataset.

Table 5 shows the coverage ratio and the performance with different maximum region sizes. Since the average entity mention length of GENIA dataset is less than 4, the system can cover almost all the entities for the maximum sizes of 6 or more. The longer maximum region size is desirable to cover all the mentions, but it requires more computational costs. Fortunately, the performance did not degrade with the long maximum region size, despite the fact that it introduces more out-of-entity regions.

Ablations on character embeddings in Table 6 also show the importance of character embeddings. It also shows that both the boundary information and the inside information, i.e., average of the embeddings in a region, are necessary to improve the performance.

4.3 Flat NER

We evaluated our model on JNLPBA as a flat dataset, where nested and discontinuous entities are removed. Table 7 shows the performances of our model on JNLPBA dataset. We compared our result with the state-of-the-art result of Gridach (2017) which achieved 75.8% in F-score, where our model obtained 78.4% in terms of F-score.

5 Related Work

Interests in nested NER detection have increased in recent years, but it is still the case that NER models deals with only one flat level at a time. Zhou et al. (2004) detected nested entities in a bottom-up way. They detected the innermost flat entities and then found other NEs containing the flat entities as substrings using rules derived from the detected entities. The authors reported an improvement of around 3% in the F-score under certain conditions on the GENIA corpus (Collier et al., 1999). Katiyar and Cardie (2018) proposed a neural network-based approach that learns hypergraph representation for nested entities using features extracted from a recurrent neural network (RNN). The authors reported that the model outperformed the existing state-of-the-art feature-based approaches.

Recent studies show that the conditional random fields (CRFs) can significantly produce higher tagging accuracy in flat (Athavale et al., 2016) or nested (stacking flat NER to nested representation) (Son and Minh, 2017) NERs. Ju et al. (2018) proposed a novel neural model to address nested entities by dynamically stacking flat NER layers until no outer entities are extracted. A cascaded CRF layer is used after the LSTM output in each flat layer. The authors reported that the model outperforms state-of-the-art results by achieving 74.5% in terms of F-score. Finkel and Manning (2009) proposed a tree-based representation to represent each sentence as a constituency tree of nested entities. All entities were treated as phrases and represented as subtrees following the whole tree structure and used a CRF-based approach driven by entity-level features to detect nested entities. We demonstrate that the performance can be improved significantly without CRFs, by training an exhaustive neural model that learns which regions are entity mentions and how to best classify the regions.

6 Conclusion

This paper presented a neural exhaustive model that considers all possible regions exhaustively for nested NER. The model obtains the representation of each region from an underlying shared LSTM layer, and it represents the region by concatenating boundary representations of the region and inside representation that averages embeddings of words in the region. It then classifies the region into its entity type or non-entity. The model does not depend on any external NLP tools. In the experiment, we show that our model learns to detect nested named entities from the generated mention candidates of all possible regions. Our exhaustive model outperformed existing models with a significant margin in terms of F-score in both flat and nested NER.

For future work, we would like to investigate the use of region-level information. We also consider modeling the dependencies between regions.

Abstract

Conventional wisdom is that hand-crafted features are redundant for deep learning models, as they already learn adequate representations of text automatically from corpora. In this work, we test this claim by proposing a new method for exploiting handcrafted features as part of a novel hybrid learning approach, incorporating a feature auto-encoder loss component. We evaluate on the task of named entity recognition (NER), where we show that including manual features for part-of-speech, word shapes and gazetteers can improve the performance of a neural CRF model. We obtain a F_1 of 91.89 for the CoNLL-2003 English shared task, which significantly outperforms a collection of highly competitive baseline models. We also present an ablation study showing the importance of auto-encoding, over using features as either inputs or outputs alone, and moreover, show including the autoencoder components reduces training requirements to 60%, while retaining the same predictive accuracy.

1 Introduction

Deep neural networks have been proven to be a powerful framework for natural language processing, and have demonstrated strong performance on a number of challenging tasks, ranging from machine translation (Cho et al., 2014b,a), to text categorisation (Zhang et al., 2015; Joulin et al., 2017; Liu et al., 2018b). Not only do such deep models outperform traditional machine learning methods, they also come with the benefit of not requiring difficult feature engineering. For instance, both Lample et al. (2016) and Ma and Hovy (2016) propose end-to-end models for sequence labelling task and achieve state-of-the-art results.

Orthogonal to the advances in deep learning is the effort spent on feature engineering. A representative example is the task of named entity recognition (NER), one that requires both lexical and syntactic knowledge, where, until recently, most models heavily rely on statistical sequential labelling models taking in manually engineered features (Florian et al., 2003; Chieu and Ng, 2002; Ando and Zhang, 2005). Typical features include POS and chunk tags, prefixes and suffixes, and external gazetteers, all of which represent years of accumulated knowledge in the field of computational linguistics.

The work of Collobert et al. (2011) started the trend of feature engineering-free modelling by learning internal representations of compositional components of text (e.g., word embeddings). Subsequent work has shown impressive progress through capturing syntactic and semantic knowledge with dense real-valued vectors trained on large unannotated corpora (Mikolov et al., 2013a,b; Pennington et al., 2014). Enabled by the powerful representational capacity of such embeddings and neural networks, feature engineering has largely been replaced with taking off-the-shelf pre-trained word embeddings as input, thereby making models fully end-to-end and the research focus has shifted to neural network architecture engineering.

More recently, there has been increasing recognition of the utility of linguistic features (Li et al., 2017; Chen et al., 2017; Wu et al., 2017; Liu et al., 2018a) where such features are integrated to improve model performance. Inspired by this, taking NER as a case study, we investigate the utility of hand-crafted features in deep learning models, challenging conventional wisdom in an attempt to refute the utility of manually-engineered features. Of particular interest to this paper is the work by Ma and Hovy (2016) where they

Brussels, Belgium, October 31 - November 4, 2018.

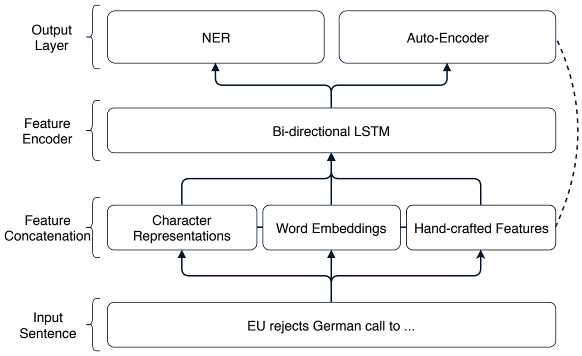

Figure 1: Main architecture of our neural network. Character representations are extracted by a character-level CNN. The dash line indicates we use an auto-encoder loss to reconstruct hand-crafted features.

introduce a strong end-to-end model combining a bi-directional Long Short-Term Memory (Bi-LSTM) network with Convolutional Neural Network (CNN) character encoding in a Conditional Random Field (CRF). Their model is highly capable of capturing not only word- but also character-level features. We extend this model by integrating an auto-encoder loss, allowing the model to take hand-crafted features as input and re-construct them as output, and show that, even with such a highly competitive model, incorporating linguistic features is still beneficial. Perhaps the closest to this study is the works by Ammar et al. (2014) and Zhang et al. (2017), who show how CRFs can be framed as auto-encoders in unsupervised or semi-supervised settings.

With our proposed model, we achieve strong performance on the CoNLL 2003 English NER shared task with an F_1 of 91.89, significantly outperforming an array of competitive baselines. We conduct an ablation study to better understand the impacts of each manually-crafted feature. Finally, we further provide an in-depth analysis of model performance when trained with varying amount of data and show that the proposed model is highly competent with only 60% of the training set.

2 Methodology

In this section, we first outline the model architecture, then the manually crafted features, and finally how they are incorporated into the model.

2.1 Model Architecture

We build on a highly competitive sequence labelling model, namely Bi-LSTM-CNN-CRF, first introduced by Ma and Hovy (2016). Given an input sequence of $\mathbf{x} = \{x_1, x_2, \ldots, x_T\}$ of length T, the model is capable of tagging each input with a predicted label $\hat{y}$, resulting in a sequence of $\hat{\mathbf{y}} = \{\hat{y}_1, \hat{y}_2, \ldots, \hat{y}_T\}$ closely matching the gold label sequence $\mathbf{y} = \{y_1, y_2, \ldots, y_T\}$. Here, we extend the model by incorporating an auto-encoder loss taking hand-crafted features as in/output, thereby forcing the model to preserve crucial information stored in such features and allowing us to evaluate the impacts of each feature on model performance. Specifically, our model, referred to as Neural-CRF+AE, consists of four major components: (1) a character-level CNN (char-CNN); (2) a word-level bi-directional LSTM (Bi-LSTM); (3) a conditional random field (CRF); and (4) an auto-encoder auxiliary loss. An illustration of the model architecture is presented in Figure 1.

Char-CNN. Previous studies (Santos and Zadrozny, 2014; Chiu and Nichols, 2016; Ma and Hovy, 2016) have demonstrated that CNNs are highly capable of capturing character-level features. Here, our character-level CNN is similar to that used in Ma and Hovy (2016) but differs in that we use a ReLU activation (Nair and Hinton, 2010).[1]

Bi-LSTM. We use a Bi-LSTM to learn contextual information of a sequence of words. As inputs to the Bi-LSTM, we first concatenate the pre-trained embedding of each word $\boldsymbol{w}_i$ with its character-level representation $\boldsymbol{c}_{w_i}$ (the output of the char-CNN) and a vector of manually crafted features $\boldsymbol{f}_i$ (described in Section 2.2):

$$\overrightarrow{\boldsymbol{h}}_i = \overrightarrow{\mathrm{LSTM}}(\overrightarrow{\boldsymbol{h}}_{i-1}, [\boldsymbol{w}_i; \boldsymbol{c}_{w_i}; \boldsymbol{f}_i]) \qquad (1)$$

$$\overleftarrow{\boldsymbol{h}}_i = \overleftarrow{\mathrm{LSTM}}(\overleftarrow{\boldsymbol{h}}_{i+1}, [\boldsymbol{w}_i; \boldsymbol{c}_{w_i}; \boldsymbol{f}_i])\,, \qquad (2)$$

where $[;]$ denotes concatenation. The outputs of the forward and backward pass of the Bi-LSTM is then concatenated $\boldsymbol{h}_i = [\overrightarrow{\boldsymbol{h}}_i; \overleftarrow{\boldsymbol{h}}_i]$ to form the output of the Bi-LSTM, where dropout is also applied.

CRF. For sequence labelling tasks, it is intuitive and beneficial to utilise information carried between neighbouring labels to predict the best sequence of labels for a given sentence. Therefore,

---

[1] While the hyperbolic tangent activation function results in comparable performance, the choice of ReLU is mainly due to faster convergence.

y	B-ORG	O	B-PER	O	O	B-LOC	O

Table 1: Example sentence (top), showing the different types of linguistic features used in this work as additional inputs and auxiliary outputs (middle), and its labelling (bottom).

we employ a conditional random field layer (Lafferty et al., 2001) taking as input the output of the Bi-LSTM $\boldsymbol{h}_i$. Training is carried out by maximising the log probability of the gold sequence: $\mathcal{L}_{CRF} = \log p(\mathbf{y}|\mathbf{x})$ while decoding can be efficiently performed with the Viterbi algorithm.

Auto-encoder loss. Alongside sequence labelling as the primary task, we also deploy, as auxiliary tasks, three auto-encoders for reconstructing the hand-engineered feature vectors. To this end, we add multiple independent fully-connected dense layers, all taking as input the Bi-LSTM output $\boldsymbol{h}_i$ with each responsible for reconstructing a particular type of feature: $\hat{\boldsymbol{f}}_i^t = \sigma(\boldsymbol{W}^t\boldsymbol{h}_i)$ where σ is the sigmoid activation function, t denotes the type of feature, and $\boldsymbol{W}^t$ is a trainable parameter matrix. More formally, we define the auto-encoder loss as:

$$\mathcal{L}_{AE}^t = \sum_{i=0}^{T} \text{XEntropy}(\boldsymbol{f}_i^t, \hat{\boldsymbol{f}}_i^t)\,. \tag{3}$$

Model training. Training is carried out by optimising the joint loss:

$$\mathcal{L} = \mathcal{L}_{CRF} + \sum_t \lambda^t \mathcal{L}_{AE}^t\,, \tag{4}$$

where, in addition to $\mathcal{L}_{CRF}$, we also add the auto-encoder loss, weighted by λ^t. In all our experiments, we set λ^t to 1 for all ts.

2.2 Hand-crafted Features

We consider three categories of widely used features: (1) POS tags; (2) word shape; and (3) gazetteers and present an example in Table 1. While POS tags carry syntactic information regarding sentence structure, the word shape feature focuses on a more fine-grained level, encoding character-level knowledge to complement the loss of information caused by embedding lookup, such as capitalisation. Both features are based on the implementation of spaCy.[2] For the gazetteer feature, we focus on *PERSON* and *LOCATION* and compile a list for each. The *PERSON* gazetteer is collected from U.S. census 2000, U.S. census 2010 and DBpedia whereas GeoNames is the main source for *LOCATION*, taking in both official and alternative names. All the tokens on both lists are then filtered to exclude frequently occurring common words.[3] Each category is converted into a one-hot sparse feature vector $\boldsymbol{f}_i^t$ and then concatenated to form a multi-hot vector $\boldsymbol{f}_i = [\boldsymbol{f}_i^{\text{POS}}; \boldsymbol{f}_i^{\text{shape}}; \boldsymbol{f}_i^{\text{gazetteer}}]$ for the i-th word. In addition, we also experimented with including the label of the incoming dependency edge to each word as a feature, but observed performance deterioration on the development set. While we still study and analyse the impacts of this feature in Table 3 and Section 3.2, it is excluded from our model configuration (not considered as part of $\boldsymbol{f}_i$ unless indicated otherwise).

3 Experiments

In this section, we present our experimental setup and results for name entity recognition over the CoNLL 2003 English NER shared task dataset (Tjong Kim Sang and De Meulder, 2003).

3.1 Experimental Setup

Dataset. We use the CoNLL 2003 NER shared task dataset, consisting of 14,041/3,250/3,453 sentences in the training/development/test set respectively, all extracted from Reuters news articles during the period from 1996 to 1997. The dataset is annotated with four categories of name entities: *PERSON, LOCATION, ORGANIZATION* and *MISC*. We use the `IOBES` tagging scheme, as previous study have shown that this scheme provides a modest improvement to the model performance (Ratinov and Roth, 2009; Chiu and Nichols, 2016; Lample et al., 2016; Ma and Hovy, 2016).

---

[2] `https://spacy.io/`

[3] Gazetteer data is included in the code release.

Model configuration. Following the work of Ma and Hovy (2016), we initialise word embeddings with GloVe (Pennington et al., 2014) (300-dimensional, trained on a 6B-token corpus). Character embeddings are 30-dimensional and randomly initialised with a uniform distribution in the range $[-\sqrt{\frac{3}{dim}}, +\sqrt{\frac{3}{dim}}]$. Parameters are optimised with stochastic gradient descent (SGD) with an initial learning rate of $\eta = 0.015$ and momentum of 0.9. Exponential learning rate decay is applied every 5 epochs with a factor of 0.8. To reduce the impact of exploding gradients, we employ gradient clipping at 5.0 (Pascanu et al., 2013).

We train our models on a single GeForce GTX TITAN X GPU. With the above hyper-parameter setting, training takes approximately 8 hours for a full run of 40 epochs.

Evaluation. We measure model performance with the official CoNLL evaluation script and report span-level named entity F-score on the test set using early stopping based on the performance on the validation set. We report average F-scores and standard deviation over 5 runs for our model.

Baseline. In addition to reporting a number of prior results of competitive baseline models, as listed in Table 2, we also re-implement the Bi-LSTM-CNN-CRF model by Ma and Hovy (2016) (referred to as Neural-CRF in Table 2) and report its average performance.

3.2 Results

The experimental results are presented in Table 2. Observe that Neural-CRF+AE, trained either on the training set only or with the addition of the development set, achieves substantial improvements in F-score in both settings, superior to all but one of the benchmark models, highlighting the utility of hand-crafted features incorporated with the proposed auto-encoder loss. Compared against the Neural-CRF, a very strong model in itself, our model significantly improves performance, showing the positive impact of our technique for exploiting manually-engineered features. Although Peters et al. (2018) report a higher F-score using their ELMo embedding technique, our approach here is orthogonal, and accordingly we would expect a performance increase if we were to incorporate their ELMo representations into our model.

Ablation Study To gain a better understanding of the impacts of each feature, we perform an ablation study and present the results in Table 3. We observe performance degradation when eliminating POS, word shape and gazetteer features, showing that each feature contributes to NER performance beyond what is learned through deep learning alone. Interestingly, the contribution of gazetteers is much less than that of the other features, which is likely due to the noise introduced in the matching process, with many incorrectly identified false positives.

Including features based on dependency tags into our model decreases the performance slightly. This might be a result of our simple implementation (as illustrated in Table 1), which does not include dependency direction, nor parent-child relationships.

Next, we investigate the impact of different means of incorporating manually-engineered features into the model. To this end, we experiment with three configurations with features as: (1) input only; (2) output only (equivalent to multi-task learning); and (3) both input and output (Neural-CRF+AE) and present the results in Table 4. Simply using features as either input or output only improves model performance slightly, but insignificantly so. It is only when features are incorporated with the proposed auto-encoder loss do we observe a significant performance boost.

+ output	94.69 (± 0.22)	91.23 (± 0.19)
+ input & output∗	**94.87** (± 0.21)	**91.89** (± 0.23)

Table 4: Average performance of Neural-CRF with different features configurations over 5 runs with standard deviation. Note that + input & output = Neural-CRF+AE. ∗ indicates statistical significance on the test set against Neural-CRF by two-sample Student's t-test at level $\alpha = 0.05$.

Training Requirements Neural systems typically require a large amount of annotated data. Here we measure the impact of training with varying amount of annotated data, as shown in Figure 2. Wtih the proposed model architecture, the amount of labelled training data can be drastically reduced: our model, achieves comparable performance against the baseline Neural-CRF, with as little as 60% of the training data. Moreover, as we increase the amount of training text, the performance of Neural-CRF+AE continues to improve.

Hyperparameters Three extra hyperparameters are introduced into our model, controlling the weight of the autoencoder loss relative to the CRF loss, for each feature type. Figure 3 shows the effect of each hyperparameter on test performance. Observe that setting $\lambda_i = 1$ gives strong performance, and that the impact of the gazetteer is less marked than the other two feature types. While increasing λ is mostly beneficial, performance drops if the λs are overly large, that is, the auto-encoder loss overwhelms the main prediction task.

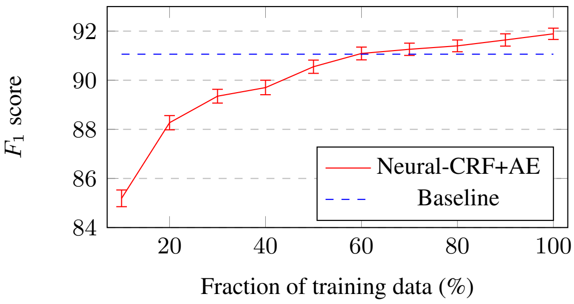

Figure 2: Comparing the Neural-CRF+AE (red solid line) trained with varying amounts of data vs. a Neural-CRF baseline (blue dashed line), trained on the full training set. Performance averaged over 5 runs, and error bars show ± 1 std.dev.

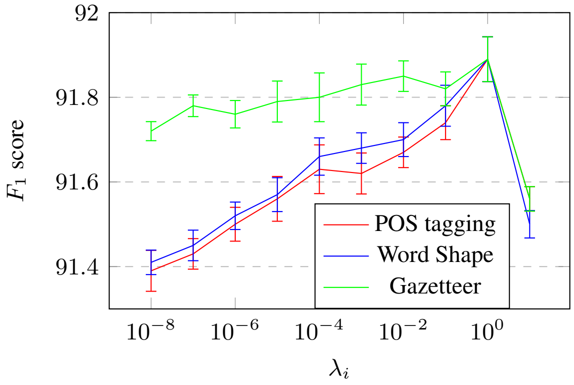

Figure 3: Effect of hyperparameter values on model performance. Each curve shows the effect of λ_i, for feature type i, with all other $\lambda_j = 1$, $j \neq i$. Performance averaged over 5 runs, and error bars show ± 1 variance.

4 Conclusion

In this paper, we set out to investigate the utility of hand-crafted features. To this end, we have presented a hybrid neural architecture to validate this hypothesis extending a Bi-LSTM-CNN-CRF by incorporating an auto-encoder loss to take manual features as input and then reconstruct them. On the task of named entity recognition, we show significant improvements over a collection of competitive baselines, verifying the value of such features. Lastly, the method presented in this work can also be easily applied to other tasks and models, where hand-engineered features provide key insights about the data.

Abstract

Pre-trained word embeddings and language model have been shown useful in a lot of tasks. However, both of them cannot directly capture word connections in a sentence, which is important for dependency parsing given its goal is to establish dependency relations between words. In this paper, we propose to implicitly capture word connections from unlabeled data by a word ordering model with self-attention mechanism. Experiments show that these implicit word connections do improve our parsing model. Furthermore, by combining with a pre-trained language model, our model gets state-of-the-art performance on the English PTB dataset, achieving 96.35% UAS and 95.25% LAS.

1 Introduction

Dependency parsing is a fundamental task for language processing which aims to establish syntactic relations between words in a sentence. Graph-based models (McDonald et al., 2005; McDonald and Pereira, 2006; Carreras, 2007; Koo and Collins, 2010) and transition-based models (Nivre, 2008; Zhang and Nivre, 2011) are the most successful solutions to the challenge.

Recently, neural network methods have been successfully introduced into dependency parsing. Deep feed-forward neural network models (Chen and Manning, 2014; Pei et al., 2015; Weiss et al., 2015) are proposed firstly. It alleviates the heavy burden of feature engineering. LSTM networks (Hochreiter and Schmidhuber, 1997) are then applied to dependency parsing (Dyer et al., 2015; Cross and Huang, 2016; Wang and Chang, 2016; Kiperwasser and Goldberg, 2016; Dozat and Manning, 2016) due to its ability to capture contextual information. Generative neural network models (Dyer et al., 2016; Smith et al., 2017; Choe and Charniak, 2016) also show promising parsing performance.

Different from Machine Translation task where massive sets of labeled data could be easily obtained, parsing performance is limited by the relatively small size of available treebank. Vinyals et al. (2015) and Weiss et al. (2015) adopt an approach of tri-training to augment the labeled data. They generate large quantities of parse trees by parsing unlabeled data with two existing parsers and selecting only the sentences for which the two parsers produced the same trees. However, the trees produced this way have noise[1] and tend to be short sentences, since it is easier for different parsers to get consistent results.

Pre-trained neural networks are another methods to take advantage of unlabeled data. Pre-trained word embeddings (Mikolov et al., 2013) and language model (Józefowicz et al., 2016; Peters et al., 2017, 2018) have been shown useful in modelling NLP tasks since word embeddings could capture word semantic information and language model could capture contextual information at the sentence level. However, connections between words in the sentence cannot be directly captured by word embeddings or language model, which are crucial for dependency parsing given its goal is to establish dependency relations between words. In this paper, we propose to implicitly model word connections by a word ordering model. The purpose of word ordering model is to generate a well-formed sentence given a bag of words. We human could make sentences easily from unordered words since we have syntactic knowledge, thus a model generating well-formed sentences from the bag of words encodes syntactic information. In addition, word ordering task allows us to use self-attention mechanism

to model connections between words in the sentence. Different from the tri-training approach, our approach takes advantage of implicit word connections learned by self-attended word ordering model in an unsupervised way.

Experiments show that pre-trained word ordering model significantly improves our dependency parsing model. Ablation tests also show self-attention mechanism is critical. Moreover, by combining word ordering model and language model, our graph-based dependency parsing model achieves SOTA performance on the English Penn Treebank (Marcus et al., 1993) with 96.35% UAS and 95.25% LAS.
