Concretely, because the encoding and decoding stages are decoupled, the encoder is not aware of the target language while generating it. Thus, we can take an encoded intermediate representation of a sentence and translate it to any target language. This is because, in this case, the intermediate representation is independent of any target language. This makes for a stronger argument that the intermediate representation produced by our encoder could be approaching a universal interlingua, more so than methods that are aware of the target language when they perform encoding.

3.1 Parameter Generator Network

We refer to the functions $g^{(enc)}$ and $g^{(dec)}$ as *parameter generator networks*. Even though our proposed NMT framework does not rely on a specific choice for $g^{(enc)}$ and $g^{(dec)}$, here we describe the functional form we used for our experiments. Our goal is to provide a simple form that works, and for which we can reason about. For this reason, we decided to define the parameter generator networks as simple linear transforms, similar to the factored adaptation model of Michel and Neubig (2018), which was only applied to the bias terms of the output softmax:

$$g^{(enc)}(\mathbf{l_s}) \triangleq \mathbf{W^{(enc)}} \mathbf{l_s}, \tag{1}$$

$$g^{(dec)}(\mathbf{l_t}) \triangleq \mathbf{W^{(dec)}} \mathbf{l_t}, \tag{2}$$

where $\mathbf{l_s}, \mathbf{l_t} \in \mathbb{R}^{\mathbf{M}}$, $\mathbf{W^{(enc)}} \in \mathbb{R}^{\mathbf{P^{(enc)}} \times \mathbf{M}}$, $\mathbf{W^{(dec)}} \in \mathbb{R}^{\mathbf{P^{(dec)}} \times \mathbf{M}}$, M is the language embedding size, $P^{(enc)}$ is the number of parameters of the encoder, and $P^{(dec)}$ is the number of parameters of the decoder.

Another way to interpret this model is that it imposes a low-rank constraint on the parameters. As opposed to our approach, in the base case of using multiple pairwise models to perform multilingual translation, each model has $P = P^{(enc)} + P^{(dec)}$ learnable parameters for its encoder and decoder. Given that the models are pairwise, for L languages, we have a total of $L(L-1)$ learnable parameter vectors of size P. On the other hand, using our contextual parameter generator we have a total of L vectors of size M (one for each language), and a single matrix of size $P \times M$. Then, the parameters of the encoder and the decoder, for a single language pair, are defined as a linear combination of the M columns of that matrix.

Controlled Parameter Sharing. We can further control parameter sharing by observing that the encoder/decoder parameters often have some "natural grouping". For example, in the case of recurrent neural networks we may have multiple weight matrices, one for each layer, as well as attention-related parameters. Based on this observations, we now propose a way to control how much information is shared across languages. The language embeddings need to represent all of the language-specific information and thus may need to be large in size. However, when computing the parameters of each group, only a small part of that information is relevant. Let $\theta^{(enc)} = \{\theta_j^{(enc)}\}_{j=1}^{G}$ and $\theta_j^{(enc)} \in \mathbb{R}^{P_j^{(enc)}}$, where G denotes the number of groups. Then, we define:

$$\theta_j^{(enc)} \triangleq \mathbf{W_j^{(enc)}} \mathbf{P_j^{(enc)}} \mathbf{l_s}, \tag{3}$$

where $\mathbf{W_j^{(enc)}} \in \mathbb{R}^{P_j^{(enc)} \times M'}$ and $\mathbf{P_j^{(enc)}} \in \mathbb{R}^{M' \times M}$, with $M' < M$ (and similarly for the decoder parameters). We can see now that $\mathbf{P_j^{(enc)}}$ is used to extract the relevant information (size M') for parameter group j, from the larger language embedding (size M). This allows us to control the parameter sharing across languages in the following way: if we want to increase the number of per-language parameters (i.e., the language embedding size) we can increase M while keeping M' small enough so that the total number of parameters does not explode. This would not have been possible without the proposed low-rank approximation for $\mathbf{W}^{(\mathbf{enc})}$, that uses the parameter grouping information.

Alternative Options. Given that our proposed approach does not depend on the specific choice of the parameter generator network, it might be interesting to design models that use side-information about the languages that are being used (such as linguistic information about language families and hierarchies). This is outside the scope of this paper, but may be an interesting future direction.

3.2 Semi-Supervised and Zero-Shot Learning

The proposed parameter generator also enables semi-supervised learning via back-translation. Concretely, monolingual data can be used to train the shared encoder/decoder networks to translate a sentence from some language to itself (similar to the idea of auto-encoders by Vincent et al. (2008)). This is possible and can help learning because of the fact that many of the learnable parameters are shared across languages.

Furthermore, zero-shot translation, where the model translates between language pairs for which it has seen no explicit training data, is also possible. This is because the same per-language parameters are used to translate to and from a given language, irrespective of the language at the other end. Therefore, as long as we train our model using some language pairs that involve a given language, it is possible to learn to translate in any direction involving that language.

3.3 Potential for Adaptation

Let us assume that we have trained a model using data for some set of languages, $\ell_1, \ell_2, \dots, \ell_m$. If we obtain data for some new language ℓ_n, we do not have to retrain the whole model from scratch. In fact, we can fix the parameters that are shared across all languages and only learn the embedding for the new language (along with the relevant word embeddings if not using a shared vocabulary). Assuming that we had a sufficient number of languages in the beginning, this may allow us to obtain reasonable translation performance for the new language, with a minimal amount of training.[3]

3.4 Number of Parameters

For the base case of using multiple pairwise models to perform multilingual translation, each model has $P + 2WV$ parameters, where $P = P^{(enc)} + P^{(dec)}$, W is the word embedding size, and V is the vocabulary size per language (assumed to be the same across languages, without loss of generality). Given that the models are pairwise, for L languages, we have a total of $L(L-1)(P + 2WV) = \mathcal{O}(L^2P + 2L^2WV)$ learnable parameters. For our approach, using the linear parameter generator network presented in Section 3.1, we have a total of $\mathcal{O}(PM + LWV)$ learnable parameters. Note that the number of encoder/decoder parameters has no dependence on L now, meaning that our model can easily scale to a large number of languages.

4 Experiments

In this section, we describe our experimental setup along with our results and key observations.

Setup. For all our experiments we use as the base NMT model an encoder-decoder network which uses a bidirectional LSTM for the encoder, and a two-layer LSTM with the attention model of Bahdanau et al. (2015) for the decoder. The word embedding size is set to 512. This is a common baseline model that achieves reasonable performance and we decided to use it as-is, without tuning any of its parameters, as extensive hyperparameter search is outside the scope of this paper.

During training, we use a label smoothing factor of 0.1 (Wu et al., 2016) and the AMSGrad optimizer (Reddi et al., 2018) with its default parameters in TensorFlow, and a batch size of 128 (due to GPU memory constraints). Optimization was stopped when the validation set BLEU score was maximized. The order in which language pairs are used while training was as follows: we always first sample a language pair (uniformly at random), and then sample a batch for that pair (uniformly at random).[4] During inference, we employ beam search with a beam size of 10 and the length normalization scheme of (Wu et al., 2016). We want to emphasize that we did not run experiments with other architectures or configurations, and thus this architecture was not chosen because it was favorable to our method, but rather because it was a frequently mentioned baseline in existing literature.

All experiments were run on a machine with a single Nvidia V100 GPU, and 24 GBs of system memory. Our most expensive experiment took about 10 hours to complete, which would

---

[3] This is due to the small number of parameters that need to be learned in this case. To put this into perspective, in most of our experiments we used language embeddings of size 8.

[4] We did not observe any "forgetting" effect, because we keep "re-visiting" all language pairs throughout training. It would be interesting to explore other sampling schemes, but it is outside the scope of this paper.

Table 1: Comparison of our proposed approach (shaded rows) with the base pairwise NMT model (PNMT) and the Google multilingual NMT model (GML) for the IWSLT-15 dataset. The *Percent Parallel* row shows what portion of the parallel corpus is used while training; the rest is being used only as monolingual data. Results are shown for the BLEU and Meteor metrics. CPG* represents the same model as CPG, but trained without using auto-encoding training examples. The best score in each case is shown in **bold**.

cost about $25 on a cloud computing service such as Google Cloud or Amazon Web Services, thus making our results reproducible, even by independent researchers.

Experimental Settings. The goal of our experiments is to show how, by using a simple modification of this model, (i) we can achieve significant improvements in performance, while at the same time (ii) being more data and computation efficient, and (iii) enabling support for zero-shot translation. To that end, we perform three types of experiments:

1. Supervised: In this experiment, we use full parallel corpora to train our models. Plain pairwise NMT models (PNMT) are compared to the same models modified to use our proposed decoupled parameter generator. We use two variants: (i) one which does not use auto-encoding of monolingual data while training (CPG*), and (ii) one which does (CPG). Please refer to Section 3.2 for more details.
2. Low-Resource: Similar to the supervised experiments except that we limit the size of the parallel corpora used in training. However, for GML and CPG the full monolingual corpus is used for auto-encoding training.
3. Zero-Shot: In this experiment, our goal is to evaluate how well a model can learn to translate between language pairs that it has not seen while training. For example, a model trained using parallel corpora between English and German, and English and French, will be evaluated in translating from German to French. PNMT can perform zero-shot translation in this setting using pivoting. This means that, in the previous example, we would first translate from German to English and then from English to French (using two pairwise models for a single translation). However, pivoting is prone to error propagation incurred when chaining multiple imperfect translations. The proposed CPG

Table 2: Comparison of our proposed approach (shaded rows) with the base pairwise NMT model (PNMT) and the Google multilingual NMT model (GML) for the IWSLT-17 dataset. Results are shown for the BLEU metric only because Meteor does not support `It`, `Nl`, and `Ro`. CPG^8 represents CPG using language embeddings of size 8. The "$_{C4}$" subscript represents the low-rank version of CPG for controlled parameter sharing (see Section 3.1), using rank 4, etc. The best score in each case is shown in **bold**.

models inherently support zero-shot translation and require no pivoting.

For the experiments using the CPG model without controlled parameter sharing, we use language embeddings of size 8. This is based merely on the fact that this is the largest model size we could fit on one GPU. Whenever possible, we compare against PNMT, GML by Johnson et al. (2017),[5] and other state-of-the-art results.

Datasets. We use the following datasets:

- IWSLT-15: Used for supervised and low-resource experiments only (this dataset does not support zero-shot learning). We report results for Czech (`Ch`), English (`En`), French (`Fr`), German (`De`), Thai (`Th`), and Vietnamese (`Vi`). This dataset contains ~90,000-220,000 training sentence pairs (depending on the language pair), ~500-900 validation pairs, and ~1,000-1,300 test pairs.
- IWSLT-17: Used for supervised and zero-shot experiments. We report results for Dutch (`Nl`), English (`En`), German (`De`), Italian (`It`), and Romanian (`Ro`). This dataset contains ~220,000 training sentence pairs (for all language pairs except for the zero-shot ones), ~900 validation pairs, and ~1,100 test pairs.

Data Preprocessing. We preprocess our data using a modified version of the Moses tokenizer (Koehn et al., 2007) that correctly handles escaped HTML characters. We also perform some Unicode character normalization and cleaning. While training, we only consider sentences up to length 50. For both datasets, we generate a per-language vocabulary consisting of the most frequently occurring words, while ignoring words that appear less than 5 times in the whole corpus, and capping the vocabulary size to 20,000 words.

Results. Our results for the IWSLT-15 experiments are shown in Table 1. It is clear that our approach consistently outperforms both the corresponding pairwise model and GML. Furthermore, its advantage grows larger in the low-resource setting (up to 5.06 BLEU score difference, or a 2.4× increase), which is expected due to the extensive parameter sharing in our model. For this dataset, there exist some additional published state-of-the-art results not shown in Tables 1 and 2. Huang et al. (2018) report a BLEU score of 28.07 for the `En→Vi` task, while our model is able to achieve a score of **29.03**. Furthermore, Ha et al. (2016) report a BLEU score of 25.87 for the

---

[5] We use our own implementation of `GML` in order to obtain a fair comparison, in terms of the whole MT pipeline. We have modified it to use the same per-language vocabularies that we use for our approaches, as the proposed shared BPE vocabulary fails to perform well for the considered datasets.

`En→De` task, while our model is able to achieve a score of **26.77**.[6] Our results for the IWSLT-17 experiments are shown in Table 2.[7] Again, our method consistently outperforms both PNMT and GML, in both the supervised and the zero-shot settings. Furthermore, the results indicate that our model performance is robust to different sizes of the language embeddings and the choice of M' for controllable parameter sharing. It only underperforms in the degenerate case where $M' = 1$. It is also worth noting that, in the fully supervised setting, GML, the current state-of-the-art in the multilingual setting, underperforms the pairwise models.

The presented results provide evidence that our proposed approach is able to significantly improve performance, without requiring extensive tuning.

Language Embeddings. An important aspect of our model is that it learns language embeddings. In Figure 2 we show pairwise cosine distances between the learned language embeddings for our fully supervised experiments. There are some interesting patterns that indicate that the learned language embeddings are reasonable. For example, we observe that German (`De`) and Dutch (`Nl`) are most similar for the IWSLT-17 dataset, with Italian (`It`) and Romanian (`Ro`) coming second. Furthermore, Romanian and German are the furthest apart for that dataset. These relationships agree with linguistic knowledge about these languages and the families they belong to. We see similar patterns in the IWSLT-15 results but we focus on IWSLT-17 here, because it is a larger, better quality, dataset with more supervised language pairs. These results are encouraging for analyzing such embeddings to discover relationships between languages that were previously unknown. For example, perhaps surprisingly, French (`Fr`) and Vietnamese (`Vi`) appear to be significantly related for the IWSLT-15 dataset results. This is likely due to French influence in Vietnamese because to the occupation of Vietnam by France during the 19th and 20th centuries (Marr, 1981).

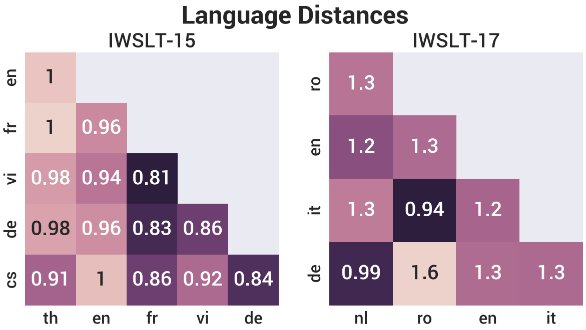

Figure 2: Pairwise cosine distance for all language pairs in the IWSLT-15 and IWSLT-17 datasets. **Darker** colors represent more similar languages.

4.1 Implementation and Reproducibility

Along with this paper we are releasing an implementation of our approach and experiments as part of a new Scala framework for machine translation.[8] It is built on top of TensorFlow Scala (Platanios, 2018) and follows the modular NMT design (described in Section 2.1) that supports various NMT models, including our baselines (e.g., Johnson et al. (2017)). It also contains data loading and preprocessing pipelines that support multiple datasets and languages, and is more efficient than other packages (e.g., `tf-nmt`[9]). Furthermore, the framework supports various vocabularies, among which we provide a new implementation for the byte-pair encoding (BPE) algorithm (Sennrich et al., 2016b) that is 2 to 3 orders of magnitude faster than the released one.[10] All experiments presented in this paper were performed using version `0.1.0` of the framework.

5 Related Work

Interlingual translation (Richens, 1958) has been the object of many research efforts. For a long time, before the move to NMT, most practical machine translation systems only focused on individual language pairs. Since the success of end-to-end NMT approaches such as the encoder-decoder framework (Sutskever et al., 2014; Bahdanau et al., 2015; Cho et al., 2014), recent work has tried to extend the framework to multi-lingual translation. An early approach was Dong et al. (2015) who performed one-to-many translation with a separate attention mechanism for each decoder. Luong et al. (2016) extended this idea with a focus on multi-task learning and multiple encoders and decoders, operating in a single shared vector space. The same architecture is used in

---

[6] We were unable to find reported state-of-the-art results for the rest of the language pairs.

[7] Note that, our results for IWSLT-17 are not comparable to those of the official challenge report (Cettolo et al., 2017), as we use less training data, a smaller baseline model, and our evaluation pipeline potentially differs. However, the numbers presented for all methods in this paper are comparable, as they were all obtained using the same baseline model and evaluation pipeline.

[8] `https://github.com/eaplatanios/symphony-mt`

[9] `https://github.com/tensorflow/nmt`

[10] `https://github.com/rsennrich/subword-nmt`

(Caglayan et al., 2016) for translation across multiple modalities. Zoph and Knight (2016) flipped this idea with a many-to-one translation model, however requiring the presence of a multi-way parallel corpus between all the languages, which is difficult to obtain. Lee et al. (2017) used a single character-level encoder across multiple languages by training a model on a many-to-one translation task. Closest to our work are more recent approaches, already described in Section 2 (Firat et al., 2016a; Johnson et al., 2017; Ha et al., 2016), that attempt to enforce different kinds of parameter sharing across languages.

Parameter sharing in multilingual NMT naturally enables semi-supervised and zero-shot learning. Unsupervised learning has been previously explored with key ideas such as back-translation (Sennrich et al., 2016a), dual learning (He et al., 2016), common latent space learning (Lample et al., 2018), etc. In the vein of multilingual NMT, Artetxe et al. (2018) proposed a model that uses a shared encoder and multiple decoders with a focus on unsupervised translation. The entire system uses cross-lingual embeddings and is trained to reconstruct its input using only monolingual data. Zero-shot translation was first attempted in (Firat et al., 2016b) who performed zero-zhot translation using their pre-trained multi-way multilingual model, fine-tuning it with pseudo-parallel data generated by the model itself. This was recently extended using a teacher-student framework (Chen et al., 2017). Later, zero-shot translation without any additional steps was attempted in (Johnson et al., 2017) using their shared encoder-decoder network. An iterative training procedure that leverages the duality of translations directly generated by the system for zero-shot learning was proposed by Lakew et al. (2017). For extremely low resource languages, Gu et al. (2018) proposed sharing lexical and sentence-level representations across multiple source languages with a single target language. Closely related is the work of Cheng et al. (2016) who proposed the joint training of source-to-pivot and pivot-to-target NMT models.

Ha et al. (2018) are probably the first to introduce a similar idea to that of having one network (called a *hypernetwork*) generate the parameters of another. However, in that work, the input to the hypernetwork are structural features of the original network (e.g., layer size and index). Al-Shedivat et al. (2017) also propose a related method where a neural network generates the parameters of a linear model. Their focus is mostly on interpretability (i.e., knowing which features the network considers important). However, to our knowledge, there is no previous work which proposes having a network generate the parameters of another deep neural network (e.g., a recurrent neural network), using some well-defined context based on the input data. This context, in our case, is the language of the input sentences to the translation model, along with the target translation language.

6 Conclusion and Future Directions

We have presented here a novel *contextual parameter generation* approach to neural machine translation. Our resulting system, which outperforms other state-of-the-art systems, uses a standard pairwise encoder-decoder architecture. However, it differs from earlier approaches by incorporating a component that generates the parameters to be used by the encoder and the decoder for the current sentence, based on the source and target languages, respectively. We refer to this novel component as the *contextual parameter generator*. The benefit of this approach is that it dramatically improves the ratio of the number of parameters to be learned, to the number of training examples available, by leveraging shared structure across different languages. Thus, our approach does not require any extra machinery such as back-translation, dual learning, pivoting, or multilingual word embeddings. It rather relies on the simple idea of *treating language as a context within which to encode/decode*. We also showed that the proposed approach is able to achieve state-of-the-art performance without requiring any tuning. Finally, we performed a basic analysis of the learned language embeddings, which showed that cosine distances between the learned language embeddings reflect well known similarities among language pairs such as German and Dutch.

In the future, we want to extend the concept of the contextual parameter generator to more general settings, such as translating between different modalities of data (e.g., image captioning). Furthermore, based on the discussion of Section 3.3, we hope to develop an adaptable, never-ending learning (Mitchell et al., 2018) NMT system.

Acknowledgments

We would like to thank Otilia Stretcu, Abulhair Saparov, and Maruan Al-Shedivat for the useful feedback they provided in early versions of this paper. This research was supported in part by AFOSR under grant FA95501710218.

Science Park 904, 1098 XH Amsterdam, The Netherlands
{m.fadaee,c.monz}@uva.nl

Abstract

Neural Machine Translation has achieved state-of-the-art performance for several language pairs using a combination of parallel and synthetic data. Synthetic data is often generated by back-translating sentences randomly sampled from monolingual data using a reverse translation model. While back-translation has been shown to be very effective in many cases, it is not entirely clear why. In this work, we explore different aspects of back-translation, and show that words with high prediction loss during training benefit most from the addition of synthetic data. We introduce several variations of sampling strategies targeting difficult-to-predict words using prediction losses and frequencies of words. In addition, we also target the contexts of difficult words and sample sentences that are similar in context. Experimental results for the WMT news translation task show that our method improves translation quality by up to 1.7 and 1.2 BLEU points over back-translation using random sampling for German→English and English→German, respectively.

1 Introduction

Neural machine translation (NMT) using a sequence-to-sequence model has achieved state-of-the-art performance for several language pairs (Bahdanau et al., 2015; Sutskever et al., 2014; Cho et al., 2014). The availability of large-scale training data for these sequence-to-sequence models is essential for achieving good translation quality.

Previous approaches have focused on leveraging monolingual data which is available in much larger quantities than parallel data (Lambert et al., 2011). Gulcehre et al. (2017) proposed two methods, shallow and deep fusion, for integrating a neural language model into the NMT system. They observe improvements by combining the scores of a neural language model trained on target monolingual data with the NMT system.

Sennrich et al. (2016a) proposed back-translation of monolingual target sentences to the source language and adding the synthetic sentences to the parallel data. In this approach a reverse model trained on parallel data is used to translate sentences from target-side monolingual data into the source language. This *synthetic* parallel data is then used in combination with the actual parallel data to re-train the model. This approach yields state-of-the-art results even when large parallel data are available and has become common practice in NMT (Sennrich et al., 2017; García-Martínez et al., 2017; Ha et al., 2017).

While back-translation has been shown to be very effective to improve translation quality, it is not exactly clear why it helps. Generally speaking, it mitigates the problem of overfitting and fluency by exploiting additional data in the target language. An important question in this context is how to select the monolingual data in the target language that is to be back-translated into the source language to optimally benefit translation quality. Pham et al. (2017) experimented with using domain adaptation methods to select monolingual data based on the cross-entropy between the monolingual data and in-domain corpus (Axelrod et al., 2015) but did not find any improvements over random sampling as originally proposed by Sennrich et al. (2016a). Earlier work has explored to what extent data selection of parallel corpora can benefit translation quality (Axelrod et al., 2011; van der Wees et al., 2017), but such selection techniques have not been investigated in the context of back-translation.

In this work, we explore different aspects of the back-translation method to gain a better understanding of its performance. Our analyses show that the quality of the synthetic data acquired with

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 436–446
Brussels, Belgium, October 31 - November 4, 2018.

a reasonably good model has a small impact on the effectiveness of back-translation, but the ratio of synthetic to real training data plays a more important role. With a higher ratio, the model gets biased towards noises in synthetic data and unlearns the parameters completely. Our findings show that it is mostly words that are difficult to predict in the target language that benefit from additional back-translated data. These are the words with high prediction loss during training when the translation model converges. We further investigate these difficult words and explore alternatives to random sampling of sentences with a focus on increasing occurrences of such words.

Our proposed approach is twofold: identifying difficult words and sampling with the objective of increasing occurrences of these words, and identifying contexts where these words are difficult to predict and sample sentences similar to the difficult contexts. With targeted sampling of sentences for back-translation we achieve improvements of up to 1.7 BLEU points over back-translation using random sampling.

2 Back-Translation for NMT

In this section, we briefly review a sequence-to-sequence NMT system and describe our experimental settings. We then investigate different aspects and modeling challenges of integrating the back-translation method into the NMT pipeline.

2.1 Neural Machine Translation

The NMT system used for our experiments is an encoder-decoder network with recurrent architecture (Luong et al., 2015). For training the NMT system, two sequences of tokens, $X = [x_1, \ldots, x_n]$ and $Y = [y_1, \ldots, y_m]$, are given in the source and target language, respectively.

The source sequence is the input to the encoder which is a bidirectional long short-term memory network generating a representation $\mathbf{s}_n$. Using an attention mechanism (Bahdanau et al., 2015), the attentional hidden state is:

$$\widetilde{\mathbf{h}}_t = \tanh(\mathbf{W}_c[\mathbf{c}_t; \mathbf{h}_t])$$

where $\mathbf{h}_t$ is the target hidden state at time step t and $\mathbf{c}_t$ is the context vector which is a weighted average of $\mathbf{s}_n$.

The decoder predicts each target token y_t by computing the probability:

$$p(y_t|y_{<t}, \mathbf{s}_n) = \mathrm{softmax}(\mathbf{W}_o\widetilde{\mathbf{h}}_t)$$

For the token y_t, the conditional probability $p(y_t|y_{<t}, \mathbf{s}_n)$ during training quantifies the difficulty of predicting that token in the context $y_{<t}$. The prediction loss of token y_t is the negative log-likelihood of this probability.

During training on a parallel corpus $\mathbb{D}$, the cross-entropy objective function is defined as:

$$\mathcal{L} = \sum_{(X,Y)\in\mathbb{D}} \sum_{i=1}^{m} -\log p(y_i|y_{<i}, \mathbf{s}_n)$$

The objective of this function is to improve the model's estimation of predicting target words given the source sentence and the target context.

The model is trained end-to-end by minimizing the negative log likelihood of the target words.

2.2 Experimental Setup

For the translation experiments, we use English↔German WMT17 training data and report results on newstest 2014, 2015, 2016, and 2017 (Bojar et al., 2017).

As NMT system, we use a 2-layer attention-based encoder-decoder model implemented in OpenNMT (Klein et al., 2017) trained with embedding size 512, hidden dimension size 1024, and batch size 64. We pre-process the training data with Byte-Pair Encoding (BPE) using 32K merge operations (Sennrich et al., 2016b).

We compare the results to Sennrich et al. (2016a) by back-translating random sentences from the monolingual data and combine them with the parallel training data. We perform the random selection and re-training 3 times and report the averaged outcomes for the 3 models. In all experiments the sentence pairs are shuffled before each epoch.

We measure translation quality by single-reference case-sensitive BLEU (Papineni et al., 2002) computed with the `multi-bleu.perl` script from Moses.

2.3 Size of the Synthetic Data in Back-Translation

One selection criterion for using back-translation is the ratio of real to synthetic data. Sennrich et al. (2016a) showed that higher ratios of synthetic data leads to decreases in translation performance.

In order to investigate whether the improvements in translation performance increases with higher ratios of synthetic data, we perform three experiments with different sizes of synthetic data.

	Size	2014	2015	2016	2017
Baseline	4.5M	26.7	27.6	32.5	28.1
+ synthetic (1:1)	9M	28.7	29.7	36.3	30.8
+ synthetic (1:4)	23M	29.1	30.0	36.9	31.1
+ synthetic (1:10)	50M	22.8	23.6	29.2	23.9

Table 1: German→English translation quality (BLEU) of systems with different ratios of *real:syn* data.

Figure 1 shows the perplexity as a function of training time for different sizes of synthetic data. One can see that all systems perform similarly in the beginning and converge after observing increasingly more training instances. However, the model with the ratio of (1:10) synthetic data gets increasingly biased towards the noisy data after 1M instances. Decreases in performance with more synthetic than real data is also inline with findings of Poncelas et al. (2018).

Comparing the systems using ratios of (1:1) and (1:4), we see that the latter achieves lower perplexity during training. Table 1 presents the performance of these systems on the German→English translation task. The BLEU scores show that the translation quality does not improve linearly with the size of the synthetic data. The model trained on (1:4) real to synthetic ratio of training data achieves the best results, however, the performance is close to the model trained on (1:1) training data.

2.4 Direction of Back-Translation

Adding monolingual data in the target language to the training data has the benefit of introducing new context and improving the fluency of the translation model. The automatically generated translations in the source language while being erroneous, introduce new context for the source words and will not affect the translation model significantly.

Monolingual data is available in large quantities for many languages. The decision of the direction of back-translation is subsequently not based on the monolingual data available, but on the advantage of having more fluent source or target sentences.

Lambert et al. (2011) show that adding synthetic source and real target data achieves improvements in traditional phrase-based machine translation (PBMT). Similarly in previous works in NMT, back-translation is performed on monolingual data in the target language.

	Size	2014	2015	2016	2017
Baseline	4.5M	21.2	23.3	28.0	22.4
+ synthetic tgt	9M	22.4	25.3	29.8	23.7
+ synthetic src	9M	24.0	26.0	30.7	24.8

Table 2: English→German translation quality (BLEU) of systems using forward and reverse models for generating synthetic data.

We perform a small experiment to measure whether back-translating from source to target is also beneficial for improving translation quality. Table 2 shows that in both directions the performance of the translation system improves over the baseline. This is in contrast to the findings of Lambert et al. (2011) for PBMT systems where they show that using synthetic target data does not lead to improvements in translation quality.

Still, when adding monolingual data in the target language the BLEU scores are slightly higher than when using monolingual data in the source language. This indicates the moderate importance of having fluent sentences in the target language.

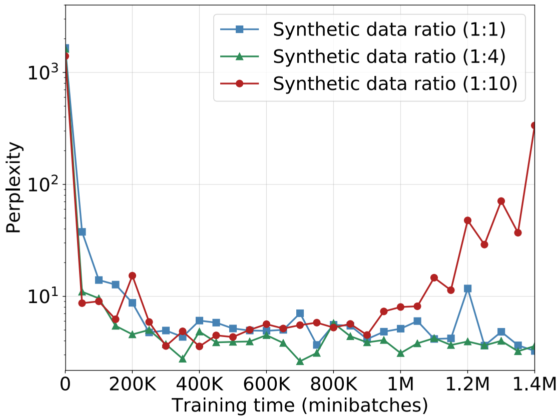

Figure 1: Training plots for systems with different ratios of $(real : syn)$ training data, showing perplexity on development set.

2.5 Quality of the Synthetic Data in Back-Translation

One selection criterion for back-translation is the quality of the synthetic data. Khayrallah and Koehn (2018) studied the effects of noise in the training data on a translation model and discovered that NMT models are less robust to many types of noise than PBMT models. In order for the NMT model to learn from the parallel data, the data should be fluent and close to the manually generated translations. However, automatically generating sentences using back-translation is not as accurate as manual translations.

	Size	2014	2015	2016	2017
Baseline	2.25M	24.3	24.9	29.5	25.6
+ synthetic	4.5M	26.0	26.9	32.2	27.5
+ ground truth	4.5M	26.7	27.6	32.5	28.1

Table 3: German→English translation quality (BLEU).

To investigate the *oracle gap* between the performance of manually generated and back-translated sentences, we perform a simple experiment using the existing parallel training data. In this experiment, we divide the parallel data into two parts, train the reverse model on the first half of the data and use this model to back-translate the second half. The manually translated sentences of the second half are considered as ground truth for the synthetic data.

Table 3 shows the BLEU scores of the experiments. As to be expected, re-training with additional parallel data yields higher performance than re-training with additional synthetic data. However, the differences between the BLEU scores of these two models are surprisingly small. This indicates that performing back-translation with a reasonably good reverse model already achieves results that are close to a system that uses additional manually translated data. This is inline with findings of Sennrich et al. (2016a) who observed that the same monolingual data translated with three translation systems of different quality and used in re-training the translation model yields similar results.

3 Back-Translation and Token Prediction

In the previous section, we observed that the reverse model used to back-translate achieves results comparable to manually translated sentences. Also, there is a limit in learning from synthetic data, and with more synthetic data the model unlearns its parameters completely.

In this section, we investigate the influence of the sampled sentences on the learning model. Fadaee et al. (2017) showed that targeting specific words during data augmentation improves the generation of these words in the right context. Specifically, adding synthetic data to the training data has an impact on the prediction probabilities of individual words. In this section, we further examine the effects of the back-translated synthetic data on the prediction of target tokens.

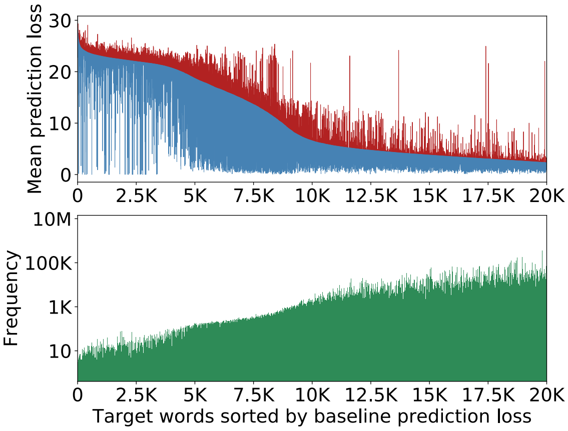

Figure 2: Top: Changes in mean token prediction loss after re-training with synthetic data sorted by mean prediction loss of the baseline system. Decreases and increases in values are marked blue and red, respectively. Bottom: Frequencies (log) of target tokens in the baseline training data.

As mentioned in Section 2.1, the objective function of training an NMT system is to minimize $\mathcal{L}$ by minimizing the prediction loss $-\log p(y_t|y_{<t}, \mathbf{s}_n)$ for each target token in the training data. The addition of monolingual data in the target language improves the estimation of the probability $p(Y)$ and consequently the model generates more fluent sentences.

Sennrich et al. (2016a) show that by using back-translation, the system with target-side monolingual data reaches a lower perplexity on the development set. This is expected since the domain of the monolingual data is similar to the domain of the development set. To investigate the model's accuracy independent from the domains of the data, we collect statistics of the target token prediction loss during training.

Figure 2 shows changes of token prediction loss when training converges and the weights are verging on being stable. The values are sorted by mean token prediction loss of the system trained on real parallel data.

We observe an effect similar to distributional smoothing (Chen and Goodman, 1996): While prediction loss increases slightly for most tokens, the largest decrease in loss occurs for tokens with high prediction loss values. This indicates that by randomly sampling sentences for back-translation, the model improves its estimation of tokens that were originally more difficult to predict, i.e., tokens that had a high prediction loss. Note that we compute the token prediction loss in just one pass over the training corpus with the final model and as a result it is not biased towards the order of the data.

This finding motivates us to further explore sampling criteria for back-translation that contribute considerably to the parameter estimation of the translation model. We propose that by oversampling sentences containing difficult-to-predict tokens we can maximize the impact of using the monolingual data. After translating sentences containing such tokens and including them in the training data, the model becomes more robust in predicting these tokens.

In the next two sections, we propose several methods of using the target token prediction loss to identify the most rewarding sentences for back-translating and re-training the translation model.

4 Targeted Sampling for Difficult Words

One of the main outcomes of using synthetic data is better estimation of words that were originally difficult to predict as measured by their high prediction losses during training. In this section, we propose three variations of how to identify these words and perform sampling to target these words.

Algorithm 1 Sampling for difficult words

Input: Difficult tokens $\mathfrak{D} = \{y_i\}_{i=1}^{D}$, monolingual corpus $\mathbb{M}$, number of required samples N
Output: Sampled sentences $S = \{S_i\}_{i=1}^{N}$ where each sentence S_i is sampled from $\mathbb{M}$

```
procedure DIFFSAMPLING ($\mathfrak{D}, \mathbb{M}, N$):
    Initialize $S = \{\}$
    repeat
        Sample $S_c$ from $\mathbb{M}$
        for all tokens $y$ in $S_c$ do
            if $y \in \mathfrak{D}$ then
                Add $S_c$ to $S$
    until $|S| = N$
    return $S$
```

4.1 Token Frequency as a Feature of Difficulty

Figure 2 shows that the majority of tokens with high mean prediction losses have low frequencies in the training data. Additionally, the majority of decreases in prediction loss after adding synthetic sentence pairs to the training data occurs with less frequent tokens.

Note that these tokens are not necessarily *rare* in the traditional sense; in Figure 2 the $10k$ less frequent tokens in the target vocabulary benefit most from back-translated data.

Sampling new contexts from monolingual data provides context diversity proportional to the token frequencies and less frequent tokens benefit most from new contexts. Algorithm 1 presents this approach where the list of difficult tokens is defined as:

$$\mathfrak{D} = \{\forall y_i \in V_t \colon freq(y_i) < \eta\}$$

V_t is the target vocabulary and η is the frequency threshold for deciding on the difficulty of the token.

4.2 Difficult Words with High Mean Prediction Losses

In this approach, we use the mean losses to identify difficult-to-predict tokens. The mean prediction loss $\hat{\ell}(y)$ of token y during training is defined as follows:

$$\hat{\ell}(y) = \frac{1}{n_y} \sum_{n=1}^{N} \sum_{t=1}^{|Y^n|} - \log p(y_t^n | y_{<t}^n, \mathbf{s}_n) \delta(y_t^n, y)$$

where n_y is the number of times token y is observed during training, i.e., the token frequency of y, N is the number of sentences in the training data, $|Y^n|$ is the length of target sentence n, and $\delta(y_t^n, y)$ is the Kronecker delta function, which is 1 if $y_t^n = y$ and 0 otherwise.

By specifically providing more sentences for difficult words, we improve the model's estimation and decrease the model's uncertainty in prediction. During sampling from the monolingual data, we select sentences that contain difficult words.

Algorithm 1 presents this approach where the list of difficult tokens is defined as:

$$\mathfrak{D} = \{\forall y_i \in V_t \colon \hat{\ell}(y_i) > \mu\}$$

V_t is the vocabulary of the target language and μ is the threshold on the difficulty of the token.

	De-En				En-De

Table 4: German↔English translation quality (Bleu). Experiments marked † are averaged over 3 runs. MeanPredLoss and Freq are difficulty criteria based on mean token prediction loss and token frequency respectively. MeanPredLoss + stdPredLoss is experiments favoring tokens with skewed prediction losses. Preserve PredLoss ratio preserves the ratio of the distribution of difficult contexts.

4.3 Difficult Words with Skewed Prediction Losses

By using the mean loss for target tokens as defined above, we do not discriminate between differences in prediction loss for occurrences in different contexts. This lack of discrimination can be problematic for tokens with high loss variations. For instance, there can be a token with ten occurrences, out of which two have high and eight have low prediction loss values.

We hypothesize that if a particular token is easier to predict in some contexts and harder in others, the sampling strategy should be context sensitive, allowing to target specific contexts in which a token has a high prediction loss. In order to distinguish between tokens with a skewed and tokens with a more uniform prediction loss distribution, we use both mean and standard deviation of token prediction losses to identify difficult tokens.

Algorithm 1 formalizes this approach where the list of the difficult tokens is defined as:

$$\mathfrak{D} = \{\forall y_i \in V_t \colon \hat{\ell}(y_i) > \mu \wedge \sigma(\ell(y_i)) > \rho\}$$

$\hat{\ell}(y_i)$ is the mean and $\sigma(\ell(y_i))$ is the standard deviation of prediction loss of token y_i, V_t is the vocabulary list of the target language, and μ and ρ are the thresholds for deciding on the difficulty of the token.

4.4 Preserving Sampling Ratio of Difficult Occurrences

Above we examined the mean of prediction loss for each token over all occurrences, in order to identify difficult-to-predict tokens. However, the uncertainty of the model in predicting a difficult token varies for different occurrences of the token: one token can be easy to predict in one context, and hard in another. While the sampling step in the previous approaches targets these tokens, it does not ensure that the distribution of sampled sentences is similar to the distribution of problematic tokens in difficult contexts.

Algorithm 2 Sampling with ratio preservation

```
Input: Difficult tokens and the corresponding sentences in the bitext $\mathfrak{D} = \{y_t, Y_{y_t} = [y_1, \ldots, y_t, \ldots, y_m]\}$, monolingual corpus $\mathbb{M}$, number of required samples $N$
Output: Sampled sentences $S = \{S_i\}_{i=1}^{N}$ where each sentence $S_i$ is sampled from $\mathbb{M}$
procedure PredLossRatioSampling($\mathfrak{D}, \mathbb{M}, N$):
    Initialize $S = \{\}$
    $H(y_t) = \frac{N \times |(y_t, \cdot) \in \mathfrak{D}|}{|(y_\cdot, \cdot) \in \mathfrak{D}|}$
    repeat
        Sample $S_c$ from $\mathbb{M}$
        for all tokens $y$ in $S_c$ do
            if $|y \in S| < H(y)$ then
                Add $S_c$ to $S$
    until $|S| = N$
    return $S$
```

To address this issue, we propose an approach where we target the number of times a token occurs in difficult-to-predict contexts and sample sentences accordingly, thereby ensuring the same ratio as the distribution of difficult contexts. If token y_1 is difficult to predict in two contexts and token y_2 is difficult to predict in four contexts, the number of sampled sentences containing y_2 is double the number of sampled sentences containing y_1. Algorithm 2 formalizes this approach.

4.5 Results

We measure the translation quality of various models for German→English and English→German translation tasks. The results of the translation experiments are presented in Table 4. As baseline we compare our approach to Sennrich et al. (2016a). For all experiments we sample and back-translate sentences from the monolingual data, keeping a one-to-one ratio of back-translated versus original data (1:1).

We set the hyperparameters μ, ρ, and η to 5, 10, and 5000 respectively. The values of the hyperparameters are chosen on a small sample of the parallel data based on the token loss distribution.

As expected using random sampling for back-translation improves the translation quality over the baseline. However, all targeted sampling variants in turn outperform random sampling. Specifically, the best performing model for German→English, MEANPREDLOSS, uses the mean of prediction loss for the target vocabulary to oversample sentences including these tokens.

For the English→German experiments we obtain the best translation performance when we preserve the prediction loss ratio during sampling.

We also observe that even though the model targeting tokens with skewed prediction loss distributions (MEANPREDLOSS + STDPREDLOSS) improves over random selection of sentences, it does not outperform the model using only mean prediction losses.

5 Context-Aware Targeted Sampling

In the previous section, we proposed methods for identifying difficult-to-predict tokens and performed targeted sampling from monolingual data. While the objective was to increase the occurrences of difficult tokens, we ignored the context of these tokens in the sampled sentences.

Arguably, if a word is difficult to predict in a given context, providing more examples of the same or similar context can aid the learning process. In this section, we focus on the context of difficult-to-predict words and aim to sample sentences that are similar to the corresponding difficult context.

The general algorithm is described in Algorithm 3. In the following sections, we discuss different definitions of the local context (line 7 and line 9) and similarity measures (line 10) in this algorithm, and report the results.

5.1 Definition of Local Context

Prediction loss is a function of the source sentence and the target context. One reason that a token has high prediction loss is that the occurrence of the word is a deviation from what occurs more frequently in other occurrences of the context in the training data. This indicates an infrequent event, in particular a rare sense of the word, a domain that is different from other occurrences of the word, or an idiomatic expression.

<table>
<tr><td><i>source</i></td><td>wer glaube, dass das ende, sobald sie in Deutschland ank|ä|men, ir|re, erzählt B|ahr.</td></tr>
<tr><td><i>reference</i></td><td>if you think that this stops as soon as they arrive in Germany, you'd be wrong, says B|ahr.</td></tr>
<tr><td><i>NMT output</i></td><td>who believe that the end, as soon as they go to Germany, tells B|risk.</td></tr>
</table>

Table 5: An example from the synthetic data where the word *B|ahr* is incorrectly translated to *B|risk*. Subword unit boundaries are marked with '|'.

We identify *pairs* of tokens and sentences from parallel data where in each pair the NMT model assigns high prediction loss to the token in the given context. Note that a token can occur several times in this list, since it can be considered as difficult-to-predict in different sentences.

We propose two approaches to define the local context of the difficult token:

Neighboring tokens A straightforward way is to use positional context: tokens that precede and follow the target token, typically in a window of w tokens to each side. For sentence S containing a difficult token at index i the *context* function in Algorithm 3 is:

$$context(S, i) = [S^{i-w}, \ldots, S^{i-1}, S^{i+1}, \ldots, S^{i+w}]$$

where S^j is the token at index j in sentence S.

<table>
<tr><td><i>Sentence from bitext containing difficult token:</i></td></tr>
<tr><td>He attended Stan|ford University, where he double maj|ored in Spanish and History.</td></tr>
<tr><td><i>Sampled sentences from monolingual data:</i></td></tr>
<tr><td>– The group is headed by Aar|on K|ush|ner, a Stan|ford University gradu|ate who formerly headed a gre|eting card company.

– Joe Grund|fest, a professor and a colleague at Stan|ford Law School, outlines four reasons why the path to the IP|O has become so steep for asp|iring companies.</td></tr>
</table>

Table 6: Results of targeted sampling for the difficult subword unit *'Stan'*.

Neighboring subword units In our analysis of prediction loss during training, we observe that several tokens that are difficult to predict are indeed subword units. Current state-of-the-art NMT systems apply BPE to the training data to address large vocabulary challenges (Sennrich et al., 2016b).

By using BPE the model generalizes common subword units towards what is more frequent in the training data. This is inherently useful since it allows for better learning of less frequent words. However, a side effect of this approach is that at times the model generates subword units that are not linked to any words in the source sentence.

As an example, in Table 5 German source and English reference translation show this problem. The word *B|ahr* consisting of two subword units is incorrectly translated into *B|risk*.

We address the insufficiency of the context for subword units with high prediction losses by targeting these tokens in sentence sampling.

Algorithm 3 formalizes this approach in sampling sentences from the monolingual data. For a sentence S containing a difficult subword at index i, the context function is defined as:

$$context(S, i) = [\ldots, S^{i-1}, S^{i+1}, \ldots]$$

where every token S^j in the local context is a subword unit and part of the same word as S^i. Table 6 presents examples of sampled sentences for the difficult subword unit *'Stan'*.

Sentence from bitext containing difficult word:
Bud|dy Hol|ly was part of the first group induc|ted into the **Rock** and R|oll Hall of F|ame on its formation in 1986.
Sampled sentences from monolingual data:
– A 2008 **Rock** and R|oll Hall of F|ame induc|t|ee, Mad|onna is ran|ked by the Gu|inn|ess Book of World Rec|ords as the top-selling recording artist of all time. – The **Rock** and R|oll Hall of Fam|ers gave birth to the California rock sound. – The winners were chosen by 500 voters, mostly musicians and other music industry veter|ans, who belong to the **Rock** and R|oll Hall of F|ame Foundation.

Table 7: Results of context-aware targeted sampling for the difficult token *'Rock'*

5.2 Similarity of the Local Contexts

In context-aware targeted sampling, we compare the context of a sampled sentence and the difficult context in the parallel data and select the sentence if they are *similar*. In the following, we propose two approaches for quantifying the similarities.

Algorithm 3 Sampling with context

```
Input: Difficult tokens and the corresponding sentences in the bitext $\mathfrak{D} = \{y_t, Y_{y_t} = [y_1, \ldots, y_t, \ldots, y_m]\}$, monolingual corpus $\mathbb{M}$, context function $context$, number of required samples $N$, similarity threshold $s$
Output: Sampled sentences $S = \{S_i\}_{i=1}^{N}$ where each sentence $S_i$ is sampled from $\mathbb{M}$
procedure CNTXTSAMPLING($\mathfrak{D}, \mathbb{M}, context, N, s$):
    Initialize $S = \{\}$
    repeat
        Sample $S_c$ from $\mathbb{M}$
        for all tokens $y_t$ in $S_c$ do
            if $y_t \in \mathfrak{D}$ then
                $C_m \leftarrow context(S_c, \text{indxof}(S_c, y_t))$
                for all $Y_{y_t}$ do
                    $C_p \leftarrow context(Y_{y_t}, \text{indxof}(Y_{y_t}, y_t))$

                    if $\text{Sim}(C_m, C_p) > s$ then
                        Add $S_c$ to $S$
    until $|S| = N$
    return $S$
```

Matching the local context In this approach we aim to sample sentences containing the difficult token, matching the exact context to the problematic context. By sampling sentences that match in a local window with the problematic context and differ in the rest of the sentence, we have more instances of the difficult token for training.

Algorithm 3 formalizes this approach where the similarity function is defined as:

$$\text{Sim}(C_m, C_p) = \frac{1}{c} \sum_{i=1}^{c} \delta(C_m^i, C_p^i)$$

C_m and C_p are the contexts of the sentences from monolingual and parallel data respectively, and c is the number of tokens in the contexts.

Word representations Another approach to sampling sentences that are similar to the problematic context is to weaken the matching assumption. Acquiring sentences that are similar in subject and not match the exact context words allows for lexical diversity in the training data. We use embeddings obtained by training the Skipgram model (Mikolov et al., 2013) on monolingual data to calculate the similarity of the two contexts.

For this approach we define the similarity function in Algorithm 3 as:

$$\text{Sim}(C_m, C_p) = cos(\mathbf{v}(C_m), \mathbf{v}(C_p))$$

where $\mathbf{v}(C_m)$ and $\mathbf{v}(C_p)$ are the averaged embeddings of the tokens in the contexts.

Table 8: German↔English translation quality (Bleu). Experiments marked † are averaged over 3 runs. PredLoss is the contextual prediction loss and MeanPredLoss is the average loss. token and Sword are context selection definitions from neighboring tokens and subword units respectively. Note that token includes both subword units and full words. emb is computing context similarities with token embeddings and match is comparing the context tokens.

Table 7 presents examples of sampled sentences for the difficult word *rock*. In this example, the context where the word *'Rock'* has high prediction loss is about the *music genre* and not the most prominent sense of the word, *stone*. Sampling sentences that contain this word in this particular context provides an additional signal for the translation model to improve parameter estimation.

5.3 Results

The results of the translation experiments are given in Table 8. In these experiments, we set the hyperparameters s and w to 0.75 and 4, respectively. Comparing the experiments with different similarity measures, match and emb, we observe that in all test sets we achieve the best results when using word embeddings. This indicate that for targeted sampling, it is more beneficial to have diversity in the context of difficult words as opposed to having the exact ngrams.

When using embeddings as the similarity measure, it is worth noting that with a context of size 4 the model performs very well but fails when we increase the window size to include the whole sentence.

The experiments focusing on subword units (sword) achieve improvements over the baselines, however they perform slightly worse than the experiments targeting tokens (token).

The best Bleu scores are obtained with the mean of prediction loss as difficulty criterion (meanPredLoss) and using word representations to identify the most similar contexts. We observe that summarizing the distribution of the prediction losses by its mean is more beneficial than using individual losses. Our results motivate further explorations of using context for targeted sampling sentences for back-translation.

6 Conclusion

In this paper we investigated the effective method of back-translation for NMT and explored alternatives to select the monolingual data in the target language that is to be back-translated into the source language to improve translation quality.

Our findings showed that words with high prediction losses in the target language benefit most from additional back-translated data.

As an alternative to random sampling, we proposed targeted sampling and specifically targeted words that are difficult to predict. Moreover, we used the contexts of the difficult words by incorporating context similarities as a feature to sample sentences for back-translation. We discovered that using the prediction loss to identify weaknesses of the translation model and providing additional synthetic data targeting these shortcomings improved the translation quality in German↔English by up to 1.7 Bleu points.

Abstract

With great practical value, the study of Multi-domain Neural Machine Translation (NMT) mainly focuses on using mixed-domain parallel sentences to construct a unified model that allows translation to switch between different domains. Intuitively, words in a sentence are related to its domain to varying degrees, so that they will exert disparate impacts on the multi-domain NMT modeling. Based on this intuition, in this paper, we devote to distinguishing and exploiting word-level domain contexts for multi-domain NMT. To this end, we jointly model NMT with monolingual attention-based domain classification tasks and improve NMT as follows: 1) Based on the sentence representations produced by a domain classifier and an adversarial domain classifier, we generate two gating vectors and use them to construct domain-specific and domain-shared annotations, for later translation predictions via different attention models; 2) We utilize the attention weights derived from target-side domain classifier to adjust the weights of target words in the training objective, enabling domain-related words to have greater impacts during model training. Experimental results on Chinese-English and English-French multi-domain translation tasks demonstrate the effectiveness of the proposed model. Source codes of this paper are available on Github https://github.com/DeepLearnXMU/WDCNMT.

1 Introduction

In recent years, neural machine translation (NMT) has achieved great advancement (Nal and Phil, 2013; Sutskever et al., 2014; Bahdanau et al., 2015). However, two difficulties are encountered in the practical applications of NMT. On the one hand, training a NMT model for a specific domain requires a large quantity of parallel sentences in such domain, which is often not readily available. Hence, the much more common practice is to construct NMT models using mixed-domain parallel sentences. In this way, the domain-shared translation knowledge can be fully exploited. On the other hand, the translated sentences often belong to multiple domains, thus requiring a NMT model general to different domains. Since the textual styles, sentence structures and terminologies in different domains are often remarkably distinctive, whether such domain-specific translation knowledge is effectively preserved could have a direct effect on the performance of the NMT model. Therefore, how to simultaneously exploit the exclusive and shared translation knowledge of mixed-domain parallel sentences for multi-domain NMT remains a challenging task.

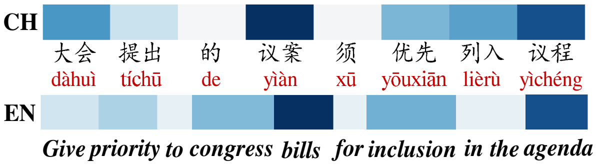

Figure 1: Word-level correlation heat map to *Laws* domain for a Chinese(CH)-English(EN) parallel sentence.

To tackle this problem, recently, researchers have carried out many constructive and in-depth studies (Kobus et al., 2016; Zhang et al., 2016; Pryzant et al., 2017; Farajian et al., 2017). However, most of these studies mainly focus on the utilization of domain contexts as a whole in NMT, while ignoring the discrimination of domain contexts at finer-grained level. In each sentence, some words are closely associated with its domain, while others are domain-independent. Intuitively, these two kinds of words play differ-

Brussels, Belgium, October 31 - November 4, 2018.

ent roles in multi-domain NMT, nevertheless, they are not being distinguished by the current models. Take the sentence shown in Figure 1 for example. The Chinese words “‘大会”(congress), “议案”(bills), “列入”(inclusion), and “议程”(agenda) are frequently used in *Laws* domain and imply the *Laws* style of the sentence, while other words in this sentence are common in all domains and they mainly indicate the semantic meaning of the sentence. Thus, it is reasonable to distinguish and encode these two types of words separately to capture domain-specific and domain-shared contexts, allowing the exclusive and shared knowledge to be exploited without any interference from the other. Meanwhile, the English words “*priority*”,“*government*”, “*bill*” and “*agenda*” are also closely related to *Laws* domain. To preserve the domain-related text style and idioms in generated translations, it is also reasonable for our model to pay more attention to these domain-related words than the others during model training. On this account, we believe that it is significant to distinguish and explore word-level domain contexts for multi-domain NMT.

In this paper, we propose a multi-domain NMT model with word-level domain context discrimination. Specifically, we first jointly model NMT with monolingual attention-based domain classification tasks. In source-side domain classification and adversarial domain classification tasks, we perform two individual attention operations on source-side annotations to generate the domain-specific and domain-shared vector representations of source sentence, respectively. Meanwhile, an attention operation is also placed on target-side hidden states to implement target-side domain classification. Then, we improve NMT with the following two approaches:

(1) According to the sentence representations produced by source-side domain classifier and adverisal domain classifier, we generate two gating vectors for each source annotation. With these two gating vectors, the encoded information of source annotation is selected automatically to construct domain-specific and domain-shared annotations, both of which are used to guide translation predictions via two attention mechanisms;

(2) Based on the attention weights of the target words from target-side domain classifier, we employ word-level cost weighting strategy to refine our model training. In this way, domain-specific target words will be assigned greater weights than others in the objective function of our model.

Our work demonstrates the benefits of separate modeling of the domain-specific and domain-shared contexts, which echoes with the successful applications of the multi-task learning based on shared-private architecture in many tasks, such as discourse relation recognition (Liu et al., 2017b), word segmentation (Chen et al., 2017b), text classification (Liu et al., 2017a), and image classification (Liu et al., 2016). Overall, the main contributions of our work are summarized as follows:

- We propose to construct domain-specific and domain-shared source annotations from initial annotations, of which effects are respectively captured for translation predictions.
- We propose to adjust the weights of target words in the training objective of NMT according to their relevance to different domains.
- We conduct experiments on large-scale multi-domain Chinese-English and English-French datasets. Experimental results demonstrate the effectiveness of our model.

2 Model

Figure 2 illustrates the architecture of our model, which includes a neural encoder equipped with a domain classifier and an adversarial domain classifier, and a neural decoder with two attention models and a target-side domain classifier.

2.1 Neural Encoder

As shown in the lower part of Figure 2, our encoder leverages the sentence representations produced by these two classifiers to construct domain-specific and domain-shared annotations from initial ones, preventing the exclusive and shared translation knowledge from interfering with each other. In our encoder, the input sentence $\mathbf{x}$=$x_1, x_2, ..., x_N$ are first mapped to word vectors and then fed into a bidirectional GRU (Cho et al., 2014) to obtain $\overrightarrow{\mathbf{h}}=\overrightarrow{h}_1, \overrightarrow{h}_2, ..., \overrightarrow{h}_N$ and $\overleftarrow{\mathbf{h}}=\overleftarrow{h}_1, \overleftarrow{h}_2, ..., \overleftarrow{h}_N$ in the left-to-right and right-to-left directions, respectively. These two sequences are then concatenated as $h_i = \{\overrightarrow{h}_i^\top, \overleftarrow{h}_i^\top\}^\top$ to form the word-level semantic representation of the input sentence.

Domain Classifier and Adversarial Domain Classifier. With annotations $\{h_i\}_{i=1}^N$, we employ

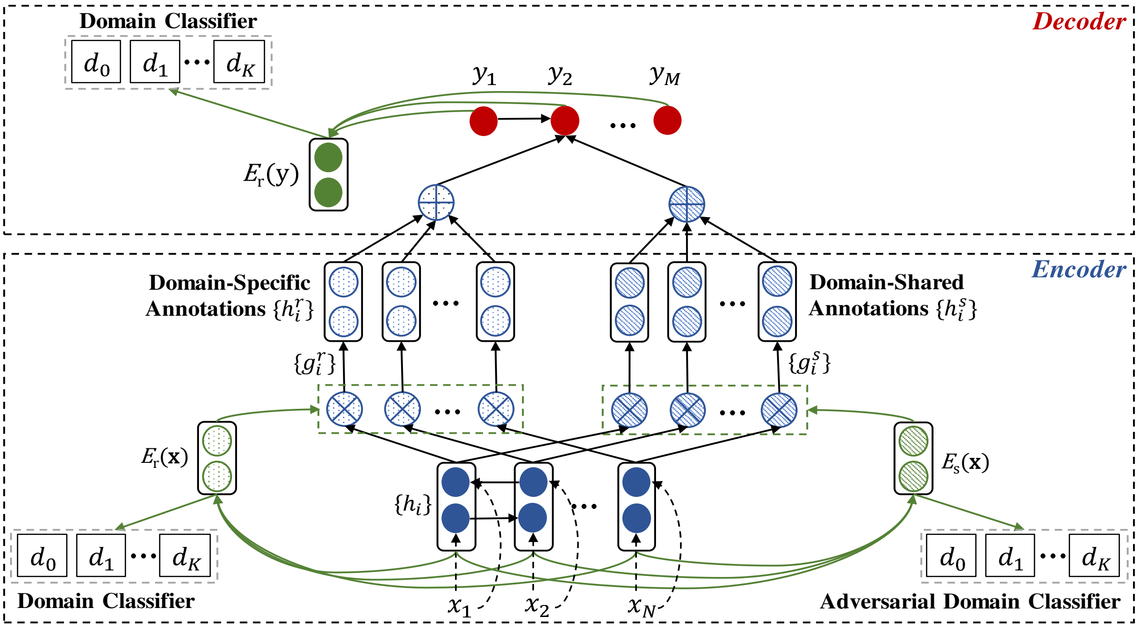

Figure 2: The architecture illustration of our model. Note that our two source-side domain classifiers are used to produce domain-specific and domain-shared annotations, respectively, and our target-side domain classifier is only used during model training.

two attention-like aggregators to generate the semantic representations of sentence $\mathbf{x}$, denoted by the vectors $E_r(\mathbf{x})$ and $E_s(\mathbf{x})$, respectively. Based on these two vectors, we employ the same neural network to model two classifiers with different context modeling objectives:

One is a domain classifier that aims to distinguish different domains in order to generate domain-specific source-side contexts. It is trained using the objective function $\mathcal{J}^s_{dc}(\mathbf{x};\boldsymbol{\theta}^s_{dc})$ = log $p(d|\mathbf{x};\boldsymbol{\theta}^s_{dc})$, where d is the domain tag of $\mathbf{x}$ and $\boldsymbol{\theta}^s_{dc}$ is its parameter set. The other is an adversarial domain classifier capturing source-side domain-shared contexts. To this end, we train it using the following adversarial loss functions:

$$\mathcal{J}^{s1}_{adc}(\mathbf{x};\boldsymbol{\theta}^{s1}_{adc}) = \log p(d|\mathbf{x};\boldsymbol{\theta}^{s1}_{adc},\boldsymbol{\theta}^{s2}_{adc}), \quad (1)$$

$$\mathcal{J}^{s2}_{adc}(\mathbf{x};\boldsymbol{\theta}^{s2}_{adc}) = H(p(d|\mathbf{x};\boldsymbol{\theta}^{s1}_{adc},\boldsymbol{\theta}^{s2}_{adc})), \quad (2)$$

where $H(p(\cdot))$=$-\sum_{k=1}^{K} p_k(\cdot)\log\, p_k(\cdot)$ is an entropy of distribution $p(\cdot)$ with K domain labels, $\boldsymbol{\theta}^{s1}_{adc}$ and $\boldsymbol{\theta}^{s2}_{adc}$ denote the parameters of softmax layer and the generation layer of $E_s(\mathbf{x})$ in this classifier, respectively. By this means, $E_r(\mathbf{x})$ and $E_s(\mathbf{x})$ are expected to encode the domain-specific and domain-shared semantic representations of $\mathbf{x}$, respectively. It should be noted that our utilization of domain classifiers is similar to adversarial training used in (Pryzant et al., 2017) which injects domain-shared contexts into annotations. However, by contrast, we introduce domain classifier and adversarial domain classifier simultaneously to distinguish different kinds of contexts for NMT more explicitly.

Here we describe only the modeling procedure of the domain classifier, while it is also applicable to the adversarial domain classifier. Specifically, $E_r(\mathbf{x})$ is defined as follows:

$$E_r(\mathbf{x}) = \sum_{i=1}^{N} \alpha_i h_i, \quad (3)$$

$$\text{where} \quad \alpha_i = \frac{exp(e_i)}{\sum_{i'}^{N} exp(e_{i'})},$$

$$e_i = (v_a)^\top \tanh(W_a h_i),$$

and v_a and W_a are the relevant attention parameters. Then, we feed $E_r(\mathbf{x})$ into a fully connected layer with *ReLU* function (Ballesteros et al., 2015), and then pass its output through a *softmax* layer to implement domain classification

$$p(\cdot|\mathbf{x};\boldsymbol{\theta}^s_{dc})$$
$$= softmax(W^{s\top}_{dc}\ ReLU(E_r(\mathbf{x})) + b^s_{dc}), \quad (4)$$

where W^s_{dc} and b^s_{dc} are softmax parameters.

Domain-Specific and Domain-Shared Annotations. Since domain-specific and domain-shared contexts have different effects on NMT, and thus should be distinguished and separately captured by NMT model. Specifically, we first leverage the sentence representations $E_r(\mathbf{x})$ and $E_s(\mathbf{x})$ to generate two gating vectors, g_i^r and g_i^s, for annotation h_i in the following way:

$$g_i^r = sigmoid(W_{gr}^{(1)}E_r(\mathbf{x}) + W_{gr}^{(2)}h_i + b_{gr}), \tag{5}$$

$$g_i^s = sigmoid(W_{gs}^{(1)}E_s(\mathbf{x}) + W_{gs}^{(2)}h_i + b_{gs}), \tag{6}$$

where W_{gr}^*, W_{gs}^*, b_{gr} and b_{gs} denote the relevant matrices and bias, respectively. With these two vectors, we construct domain-specific and domain-shared annotations h_i^r and h_i^s from h_i:

$$h_i^r = g_i^r \odot h_i, \tag{7}$$

$$h_i^s = g_i^s \odot h_i. \tag{8}$$

2.2 Neural Decoder

The upper half of Figure 2 illustrates the architecture of our decoder. In particular, with the attention weights of target words from the domain classifier, we employ word-level cost weighting strategy to refine model training.

Formally, our decoder applies a nonlinear function $g(*)$ to define the conditional probability of translation $\mathbf{y}$=$y_1, y_2, ..., y_M$:

$$p(\mathbf{y}|\mathbf{x}) = \prod_{j=1}^{M} p(y_j|\mathbf{x}, y_{<j}) = \prod_{j=1}^{M} g(y_{j-1}, s_j, c_j^r, c_j^s), \tag{9}$$

where the vector s_j denotes the GRU hidden state. It is updated as

$$s_j = GRU(s_{j-1}, y_{j-1}, c_j^r, c_j^s). \tag{10}$$

Here the vectors c_j^r and c_j^s represent the domain-specific and domain-shared contexts, respectively.

Domain-Specific and Domain-Shared Context Vectors. When generating y_j, we define c_j^r as a weighted sum of the domain-specific annotations $\{h_i^r\}$:

$$c_j^r = \sum_{i=1}^{N} \frac{\exp(e_{j,i}^r)}{\sum_{i'=1}^{N}\exp(e_{j,i'}^r)} \cdot h_i^r, \tag{11}$$

$$\text{where} \quad e_{j,i}^r = a(s_{j-1}, h_i^r),$$

and $a(*)$ is a feedforward neural network. Meanwhile, we produce c_j^s from the domain-shared annotations $\{h_i^s\}$ as in Eq. 11. By introducing c_j^r and c_j^s into s_j, our decoder is able to distinguish and simultaneously exploit two types of contexts for translation predictions.

Domain Classifier. We equip our decoder with a domain classifier with parameters $\boldsymbol{\theta_{tdc}}$, which maximizes the training objective i.e., $\mathcal{J}_{dc}^t(\mathbf{y}; \boldsymbol{\theta_{dc}^t}) = log\ p(d|\mathbf{y}; \boldsymbol{\theta_{dc}^t})$. To do this, we also apply attention operation to produce the domain-aware semantic representation $E_r(\mathbf{y})$ of $\mathbf{y}$,

$$E_r(\mathbf{y}) = \sum_{j=1}^{M} \beta_j s_j, \tag{12}$$

$$\text{where} \quad \beta_j = \frac{\exp(e_j)}{\sum_{j'}^{M}\exp(e_{j'})},$$

$$e_j = (v_b)^\top \tanh(W_b s_j),$$

and v_b and W_b are the related parameters. Likewise, we stack a domain classifier on top of $E_r(\mathbf{y})$. Note that this classifier is only used in model training to infer attention weights of target words. These weights measure their semantic relevance to different domains and can be utilized to adjust their cost weights in NMT training objective.

NMT Training Objective with Word-Level Cost Weighting. Formally, we define the objective function of NMT as follows:

$$\mathcal{J}_{nmt}(\mathbf{x}, \mathbf{y}; \boldsymbol{\theta_{nmt}})$$

$$= \sum_{j=1}^{M}(1 + \beta_j)\log p(y_j|\mathbf{x}, y_{<j}; \boldsymbol{\theta_{nmt}}), \tag{13}$$

where β_j is the attention weight of y_j obtained by Eq. (12), and $\boldsymbol{\theta_{nmt}}$ denotes the parameter set of NMT. By this scaling strategy, domain-specific words are emphasized with a bonus, while domain-shared words are updated as usual.

Please note that scaling costs with a multiplicative scalar essentially changes the magnitude of parameter update but without changing its direction (Chen et al., 2017a). Besides, although our scaling strategy is similar to the cost weighting proposed by Chen et al. (2017a), our approach differs from it in two aspects: First, we employ word-level cost weighting rather than sentence-level one to refine NMT training; Second, our approach is less time-consuming for multi-domain NMT.

2.3 Overall Training Objective

Given a mixed-domain training corpus $\mathcal{D} = \{(\mathbf{x}, \mathbf{y}, d)\}$, we train the proposed model according to the following objective function:

$$
\begin{aligned}
\mathcal{J}(\mathcal{D};\boldsymbol{\theta}) = \sum_{(\mathbf{x},\mathbf{y},d)\in\mathcal{D}} & \{\mathcal{J}_{nmt}(\mathbf{x},\mathbf{y};\boldsymbol{\theta_{nmt}}) \\
& + \mathcal{J}^{s}_{dc}(\mathbf{x};\boldsymbol{\theta^{s}_{dc}}) + \mathcal{J}^{t}_{dc}(\mathbf{y};\boldsymbol{\theta^{t}_{dc}}) \\
& + \mathcal{J}^{s1}_{adc}(\mathbf{x};\boldsymbol{\theta^{s1}_{adc}}) + \lambda \cdot \mathcal{J}^{s2}_{adc}(\mathbf{x};\boldsymbol{\theta^{s2}_{adc}})\}
\end{aligned} \quad (14)
$$

where $\mathcal{J}_{nmt}(*)$, $\mathcal{J}^{s}_{dc}(*)$, $\mathcal{J}^{t}_{dc}(*)$ and $\mathcal{J}^{s*}_{adc}(*)$ are the objective functions of NMT, source-side domain classifier, target-side domain classifier, and source-side adversarial domain classifier, respectively, $\boldsymbol{\theta}$=$\{\boldsymbol{\theta_{nmt}}, \boldsymbol{\theta^{s}_{dc}}, \boldsymbol{\theta^{t}_{dc}}, \boldsymbol{\theta^{s1}_{adc}}, \boldsymbol{\theta^{s2}_{adc}}\}$, and λ is the hyper-parameter for adversarial learning.

Particularly, to ensure encoding accuracy of domain-shared contexts, we follow Chen et al. (2017b) to adopt an alternative two-phase strategy in training, where we alternatively optimize $\mathcal{J}(\mathcal{D};\boldsymbol{\theta})$ with $\boldsymbol{\theta^{s1}_{adc}}$ and $\{\boldsymbol{\theta}\text{-}\boldsymbol{\theta^{s1}_{adc}}\}$ respectively fixed at a time.

3 Experiment

To investigate the effectiveness of our model, we conducted multi-domain translation experiments on Chinese-English and English-French datasets.

3.1 Setup

Datasets. For Chinese-English translation, our data comes from UM-Corpus (Tian et al., 2014) and LDC[1]. To ensure data quality, we chose only the parallel sentences with domain label *Laws*, *Spoken*, and *Thesis* from UM-Corpus, and the LDC bilingual sentences related to *News* domain as our dataset. We used randomly selected sentences from UM-Corpus and LDC as development set, and combined the test set of UM-Corpus and randomly selected sentences from LDC to construct our test set. For English-French translation, we conducted experiments on the datasets of OPUS corpus[2], containing sentence pairs from *Medical*, *News*, and *Parliamentary* domains. We also divided these datasets into training, development and test sets. Table 1 provides the statistics of the corpora used in our experiments.

We performed word segmentation on Chinese sentences using *Stanford Segmenter*[3], and tokenized English and French sentences using *MOSES* script[4]. Then, we employed *Byte Pair Encoding* (Sennrich et al., 2016) to convert all words into subwords. The translation quality was evaluated by case-sensitive BLEU (Papineni et al., 2002).

Task	Domain	Train	Dev	Test

Contrast Models. Since our model is essentially a standard attentional NMT model enhanced with **w**ord-level **d**omain **c**ontexts, we refer to it as **+WDC**. We compared it with the following models, namely:

- **OpenNMT**[5]. A famous open-source NMT system used widely in the NMT community trained on mix-domain training set.
- **DL4NMT-single** (Bahdanau et al., 2015). A reimplemented attentional NMT trained on a single domain dataset.
- **DL4NMT-mix** (Bahdanau et al., 2015). A reimplemented attentional NMT trained on mix-domain training set.
- **DL4NMT-finetune** (Luong and Manning, 2015). A reimplemented attentional NMT which is first trained using out-of-domain training corpus and then fine-tuned using in-domain dataset.
- **+Domain Control (+DC)** (Kobus et al., 2016). It directly introduces embeddings of source domain tag to enrich annotations of encoder.
- **+Multitask Learning (+ML1)** (Dong et al., 2015). It adopts a multi-task learning framework that shares encoder representation and separates the decoder modeling of different domains.
- **+Multitask Learning (+ML2)** (Pryzant et al., 2017). This model jointly trains

[3] https://nlp.stanford.edu/

[4] http://www.statmt.org/moses/

[5] http://opennmt.net/.

NMT with domain classification via multi-task learning.

- **+Adversarial Discriminative Mixing (+ADM)** (Pryzant et al., 2017). It employs adversarial training to achieve the domain adaptation in NMT.

- **+Target Token Mixing (+TTM)** (Pryzant et al., 2017). This model is similar to +DC, with the only difference that it enriches source annotations by adding target-side domain tag rather than source-side one.

Note that our model uses two annotation sequences, thus we also compared it with the aforementioned models with two times of hidden state size ($2\times hd$). To further examine the effectiveness of the proposed components in our model, we also provided the performance of the following variants of our model:

- **+WDC(S)**. It only exploits the source-side word-level domain contexts for multi-domain NMT.

- **+WDC(T)**. It only employ word-level cost weighting on the target side to refine the model training.

Implementation Details. Following the common practice, we only used the training sentences within 50 words to efficiently train NMT models. Thus, 85.40% and 88.96% of the Chinese-English and English-French parallel sentences were covered in our experiments. In addition, we set the vocabulary size for Chinese-English and English-French as 32,000 and 32,000, respectively. In doing so, our vocabularies covered 99.97% Chinese words and 99.99% English words of the Chinese-English corpus, and almost 100% English words and 99.99% French words of the English-French corpus, respectively.

We applied *Adam* (Kingma and Ba, 2015) to train models and determined the best model parameters based on the model performance on development set. The used hyper-parameter were set as follows: β_1 and β_2 of Adam as 0.9 and 0.999, word embedding dimension as 500, hidden layer size as 1000, learning rate as 5×10^{-4}, batch size as 80, gradient norm as 1.0, dropout rate as 0.1, and beamsize as 10. Other settings were set following (Bahdanau et al., 2015).

Model	**Laws**	**Spoken**	**Thesis**	**News**

Table 2: Overall Evaluation of the Chinese-English translation task. $2\times hd$ = two times of hidden state size.

3.2 Results on Chinese-English Translation

We first determined the optimal hyper-parameter λ (see Eq. (14)) on the development set. To do this, we gradually varied λ from 0.1 to 1.0 with an increment of 0.1 in each step. Since our model achieved the best performance when λ=0.1, hence, we set λ=0.1 for all experiments thereafter.

Table 2 shows the overall experimental results. Using almost the same hyper-parameters, our reimplemented DL4NMT outperforms OpenNMT in all domains, demonstrating that our baseline is competitive in performance. Moreover, on all test sets of different domains, our model significantly outperforms other contrast models no matter which hyper-parameters they use. Furthermore, we arrive at the following conclusions:

First, our model surpasses DL4NMT-single, DL4NMT-mix and DL4NMT-finetune, all of which are commonly used in domain adaptation for NMT. Please note that DL4NMT-finetune requires multiple adapted NMT models to be constructed, while ours is a unified one that works well in all domains.

Second, compared with +DC, +ML2 and +ADM which all exploit source-side domain contexts for multi-domain NMT, our +WDC(S) still

(a) An Example Sentence in *Laws* Domain

(b) An Example Sentence in *Thesis* Domain

Figure 3: The correlation heat map of the gating vectors(blue/green) to domain-specific/domain-shared annotations in two example sentences. Note that domain-specific words "澳门"(Macao), "立法会"(Legislative Council), "产生"(Formation), "办法"(Method), "封闭"(Seal), "计算"(Calculation), "实验" (Experiment) are strengthened by g_i^r, while most of the domain-shared words "的"(of) and "与"(and) are focused by g_i^s.

exhibits better performance. This is because that these models focus on one aspect of domain contexts, while our model considers both domain-specific and domain-shared contexts on the source side.

Third, +WDC(T) also outperforms DL4NMT, revealing that it is reasonable and effective to emphasize domain-specific words in model training..

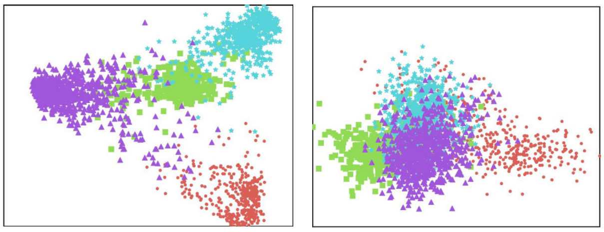
Last, +WDC achieves the best performance when compared with both +WDC(S) and +WDC(T). Therefore, we believe that word-level domain contexts on the both sides are complementary to each other, and utilizing them simultaneously is beneficial to multi-domain NMT.

3.3 Experimental Analysis

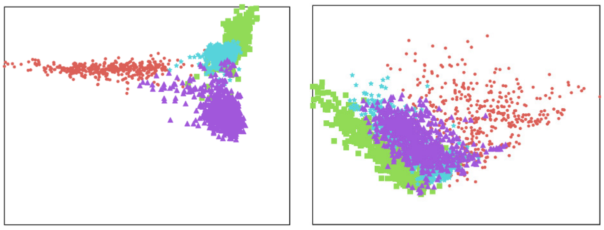
Furthermore, we conducted several visualization experiments to empirically analyze the individual effectiveness of the added model components.

3.3.1 Visualizations of Gating Vectors

We first visualized the gating vectors g_i^r and g_i^s to quantify their effects on extracting domain-specific and domain-shared contexts from initial source-side annotations. Since both g_i^r and g_i^s are high dimension vectors, which are difficult to be visualized directly, we followed Li et al. (2016) and Zhou et al. (2017) to visualize their individual contributions to the final output, which can be approximated by their first derivatives.



(a) Sentence Representation E_r(x) **(b) Sentence Representation E_s(x)**



(c) Average of Sentence Annotations $\{h_i^r(x)\}$ **(d) Average of Sentence Annotations $\{h_i^s(x)\}$**

Figure 4: The visualization of the sentence representations and their corresponding average annotations, where the triangle-shaped(purple), circle-shaped(red), square-shaped(green) and pentagonal-shaped(blue) points denote *News*, *Laws*, *Spoken* and *Thesis* sentences, respectively.

Figure 3 shows the first derivative heat maps for two example sentences in *Laws* and *Thesis* domain, respectively. We can observe that without any loss of semantic meanings from source sentences, most of the domain-specific words are strengthened by g_i^r, while most of the domain-shared words, especially function words, are focused by g_i^s. This result is consistent with our expectation for the function of two gating vectors.

3.3.2 Visualizations of Sentence Representations and Annotations

Furthermore, we applied the *hypertools* (Heusser et al., 2018) to visualize the sentence representations $E_r(\mathbf{x})$ and $E_s(\mathbf{x})$, and the domain-specific and domain-shared annotation sequences $\{h_i^r\}_{i=1}^N$ and $\{h_i^s\}_{i=1}^N$. Here we represent each annotation sequence with its average vector in the figure.

As shown in Figure 4 (a) and (b), the sentence representation vectors and the average annotation vectors of different domains are clearly distributed in different regions. By contrast, their distributions are much more concentrated in Figure 4 (c) and (d). Thus, we conclude that our model is able to distinctively learn domain-specific and domain-shared contexts. Moreover, from Figure 4 (b), we observe that the sentence representation vectors of *Laws* domain does not completely coincide with

Table 4: Overall Evaluation on the English-French translation task.

those of the other domains, this may be caused by the more formal and consistent sentence styles in *Laws* domain.

3.3.3 Illustrations of Domain-Specific Target Words

Lastly, for each domain, we presented the top ten target words with the highest weights learned by our target-side domain classifier. To do this, we calculated the average attention weight of each word in the training corpus as its corresponding domain weight.

As is clearly shown in Table 3 that most listed target words are closely related to their domains. This result validates the aforementioned hypothesis that some words are domain-dependent while others are domain-independent, and our target-side domain classifier is capable of distinguishing them with different attention weights.

3.4 Results on English-French Translation

Likewise, we determined the optimal λ=0.1 on the development set. Table 4 gives the results of English-French multi-domain translation. Similar to the previous experimental result in Section 3.2, our model continues to achieve the best performance compared to all contrast models using two different hidden state size settings, which demonstrates again that our model is effective and general to different language pairs in multi-domain NMT.

4 Related Work

In this work, we study on multi-domain machine translation in the field of domain adaptation for machine translation, which has attracted great attention since SMT (Clark et al., 2012; Huck et al., 2015; Sennrich et al., 2013). As for NMT, the dominant strategies for domain adaptation generally fall into two categories:

The first category is to transfer out-of-domain knowledge to in-domain translation. The conventional method is *fine-tuning*, which first trains the model on out-of-domain dataset and then fine-tunes it on in-domain dataset (Luong and Manning, 2015; Zoph et al., 2016; Servan et al., 2016). Freitag and Al-Onaizan (2016) proceeded further by ensembling the fine-tuned model with the original one. Chu et al. (2017) fine-tuned the model using the mix of in-domain and out-of-domain training corpora. From the perspective of data selection, Chen et al. (2017a) scaled the top-level costs of NMT system according to each training sentence's similarity to the development set. Wang et al. (2017a) explored the data selection strategy based on sentence embeddings for NMT domain adaptation. Moreover, Wang et al. (2017b) further proposed several sentence and domain weighting methods with a dynamic weight learning strategy. However, these approaches usually only perform well on target domain while being highly time consuming in transferring translation knowledge to all the constitute domains.

The second category is to directly use a mixed-domain training corpus to construct NMT model for the translated sentences derived from different domains. In this aspect, Kobus et al. (2016) incorporated domain information into NMT by appending a domain indicator token to each source sequence. Similarly, Johnson et al. (2016) added an artificial token to the input sequence to indicate the required target language. Contrastingly, Farajian et al. (2017) utilized the similarity between each test sentence and the training instances to dynamically set the hyper-parameters of the learning algorithm and update the generic model on the fly. Pryzant et al. (2017) proposed three novel models: *discriminative mixing* that jointly models NMT with domain classification, *adversarial discriminative mixing*, and *target token mixing* which appends a domain token to the target sequence. Sajjad et al. (2017) explored data concatenation, model stacking, data selection and multi-model ensemble to train multi-domain NMT. By exploiting domain as a tag or a feature, Tars and Fishel (2018) treated text domains as distinct languages in order to use multi-lingual approaches when implementing multi-domain NMT. Inspired by topic-based SMT, some researchers resorted to incorporating topical contexts into NMT. Chen et al. (2016) used the topic information of input sentence as an additional input to decoder. Zhang et al. (2016) enhanced the word representation by adding its topic embedding. However, these methods require to have explicit document boundaries between training data, which unfortunately do not exist in most datasets.

Overall, our work is related to the second type of approach with (Pryzant et al., 2017) and (Chen et al., 2017a) most related to ours. Unlike (Pryzant et al., 2017) applying adversarial training to only capture domain-shared translation knowledge, we further exploit domain-specific translation knowledge for multi-domain NMT. Also, in sharp contrast to (Chen et al., 2017a), our model not only exploits the source-side word-level domain contexts differently, but also employs a word-level cost weighting strategy for multi-domain NMT.

5 Conclusion and Future Work

In this work, we have explored how to utilize word-level domain contexts for multi-domain NMT. By jointly modeling NMT and domain classification tasks, we utilize the sentence representations of source-side domain classifier and adversarial domain classifier to construct domain-specific and domain-shared source annotations, which are then exploited by decoder. Moreover, using the attentional weights of target-side domain classifier, we adjust the weights of target words in the training objective to refine model training. Experimental results and in-depth analyses demonstrate the effectiveness of the proposed model.

In the future, we would like to extend the proposed word-level cost weighting strategy to source words. Besides, our method is also general to other NMT models. Therefore, we plan to apply our method to the NMT with complex architectures, for example, lattice-to-sequence NMT (Su et al., 2017), hierarchy-to-sequence NMT (Su et al., 2018), NMT with context-aware encoder (Zhang et al., 2017) and Transformer (Vaswani et al., 2017) and so on.

Abstract

We introduce a novel discriminative latent-variable model for the task of bilingual lexicon induction. Our model combines the bipartite matching dictionary prior of Haghighi et al. (2008) with a state-of-the-art embedding-based approach. To train the model, we derive an efficient Viterbi EM algorithm. We provide empirical improvements on six language pairs under two metrics and show that the prior theoretically and empirically helps to mitigate the hubness problem. We also demonstrate how previous work may be viewed as a similarly fashioned latent-variable model, albeit with a different prior.[1]

1 Introduction

Is there a more fundamental bilingual linguistic resource than a dictionary? The task of bilingual lexicon induction seeks to create a dictionary in a data-driven manner directly from monolingual corpora in the respective languages and, perhaps, a small seed set of translations. From a practical point of view, bilingual dictionaries have found uses in a myriad of NLP tasks ranging from machine translation (Klementiev et al., 2012) to cross-lingual named entity recognition (Mayhew et al., 2017). In this work, we offer a probabilistic twist on the task, developing a novel discriminative latent-variable model that outperforms previous work.

Our proposed model is a bridge between current state-of-the-art methods in bilingual lexicon induction that take advantage of word embeddings, e.g., the embeddings induced by Mikolov et al. (2013b)'s skip-gram objective, and older ideas in the literature that build explicit probabilistic models for the task. We propose a discriminative probability model, inspired by Irvine and Callison-Burch (2013), infused with the bipartite matching dictionary prior of Haghighi et al. (2008). However, like more recent approaches (Artetxe et al., 2017), our model operates directly over pretrained word embeddings, induces a joint cross-lingual embedding space, and scales to large vocabulary sizes. To train our model, we derive a generalized expectation-maximization algorithm (EM; Neal and Hinton, 1998) and employ an efficient matching algorithm.

Empirically, we experiment on three standard and three extremely low-resource language pairs. We evaluate intrinsically, comparing the quality of the induced bilingual dictionary, as well as analyzing the resulting bilingual word embeddings themselves. The latent-variable model yields gains over several previous approaches across language pairs. It also enables us to make implicit modeling assumptions explicit. To this end, we provide a reinterpretation of Artetxe et al. (2017) as a latent-variable model with an IBM Model 1–style (Brown et al., 1993) dictionary prior, which allows a clean side-by-side analytical comparison. Viewed in this light, the difference between our approach and Artetxe et al. (2017), the strongest baseline, is whether one-to-one alignments or one-to-many alignments are admitted between the words of the languages' respective lexicons. Thus, we conclude that our hard constraint on one-to-one alignments is primarily responsible for the improvements over Artetxe et al. (2017).

2 Background: Bilingual Lexicon Induction and Word Embeddings

Bilingual lexicon induction[2] is the task of finding word-level translations between the lexicons of two languages. For instance, the German word *Hund* and the English word *dog* are roughly semantically

---

[∗] The first two authors contributed equally.

[1] The code used to run the experiments is available at `https://github.com/sebastianruder/latent-variable-vecmap`.

[2] For the purposes of this paper, we use bilingual lexicon and (bilingual) dictionary synonymously. On the other hand, unmodified lexicon always refers to a word list in a single language.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 458–468
Brussels, Belgium, October 31 - November 4, 2018.

equivalent, so the pair *Hund–dog* should be an entry in a German–English bilingual lexicon. The task itself comes in a variety of flavors. We consider a version of the task that only relies on *monolingual* corpora in the tradition of Rapp (1995) and Fung (1995). In other words, the goal is to produce a bilingual lexicon primarily from unannotated raw text in each of the respective languages. Importantly, we avoid reliance on bitext, i.e. corpora with parallel sentences that are known translations of each other, e.g., EuroParl (Koehn, 2005). The bitext assumption is quite common in the literature; see Ruder et al. (2018, Table 2) for a survey. Additionally, we will assume the existence of a small seed set of word-level translations obtained from a dictionary; we also experiment with seed sets obtained from heuristics that do not rely on the existence of linguistic resources.

2.1 Graph-Theoretic Formulation

To ease the later exposition, we will formulate the task graph-theoretically. Let ℓ_{src} denote the source language and ℓ_{trg} the target language. Suppose the source language ℓ_{src} has n_{src} word types in its lexicon V_{src} and ℓ_{trg} has n_{trg} word types in its lexicon V_{trg}. We will write $v_{src}(i)$ for the i^{th} word type in ℓ_{src} and $v_{trg}(i)$ for the i^{th} word type in ℓ_{trg}. We can view the elements of V_{src} and V_{trg} as sets of vertices in a graph. Now consider the bipartite set of vertices $V = V_{trg} \cup V_{src}$. In these terms, a bilingual lexicon is just a bipartite graph $G = (E, V)$ and, thus, the task of bilingual lexicon induction is a combinatorial problem: the search for a 'good' edge set $E \subseteq V_{trg} \times V_{src}$. We depict such a bipartite graph in Figure 1. In §3, we will operationalize the notion of 'goodness' by assigning a weight w_{ij} to each possible edge between V_{trg} and V_{src}.

When the edge set E takes the form of a **matching**, we will denote it as $\mathbf{m}$.[3] In general, we will be interested in partial matchings, where many vertices have no incident edges. We will write $\mathcal{M}$ for the set of all partial matchings on the bipartite graph G. The set of vertices in V_{trg} (respectively V_{src}) with no incident edges will be termed $\mathbf{u}_{trg}$ (respectively $\mathbf{u}_{src}$). Note that for any matching $\mathbf{m}$, we have the identity $\mathbf{u}_{trg} = V_{trg} \setminus \{i : (i, j) \in \mathbf{m}\}$.

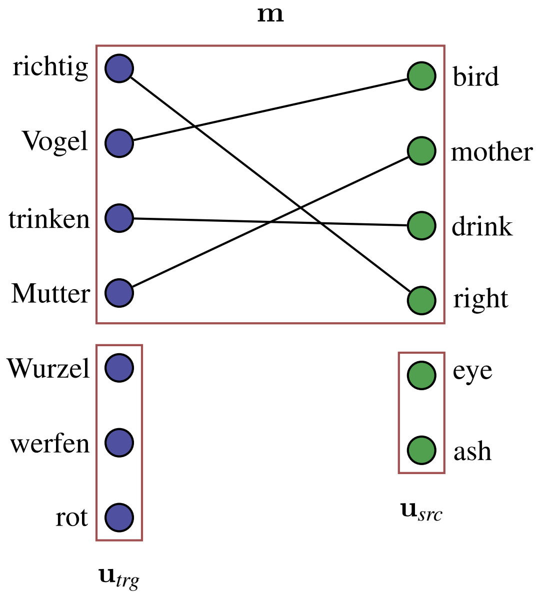

Figure 1: Partial lexicons of German and English shown as a bipartite graph. German is the target language and English is the source language. The $n_{trg} = 7$ German words are shown in blue and the $n_{src} = 6$ English words are shown in green. A bipartite matching $\mathbf{m}$ between the two sets of vertices is also depicted. The German nodes in $\mathbf{u}_{trg}$ are unmatched.

2.2 Word Embeddings

Word embeddings will also play a key role in our model. For the remainder of the paper, we will assume we have access to d-dimensional embeddings for each language's lexicon—for example, those provided by a standard model such as skip-gram (Mikolov et al., 2013b). Notationally, we define the real matrices $S \in \mathbb{R}^{d \times n_{src}}$ and $T \in \mathbb{R}^{d \times n_{trg}}$. Note that in this formulation $s_i \in \mathbb{R}^d$, the i^{th} column of S, is the word embedding corresponding to $v_{src}(i)$. Likewise, note that $t_i \in \mathbb{R}^d$, the i^{th} column of T, is the word embedding corresponding to $v_{trg}(i)$.

3 A Latent-Variable Model

The primary contribution of this paper is a novel latent-variable model for bilingual lexicon induction. The latent variable will be the edge set E, as discussed in §2.1. Given pretrained embeddings for the source and target languages, arranged into the matrices S and T, we define the density

$$p(T \mid S) := \sum_{\mathbf{m} \in \mathcal{M}} p(T \mid S, \mathbf{m}) \cdot p(\mathbf{m}) \quad (1)$$

where, recall from §2, $\mathcal{M}$ is the set of all bipartite matchings on the graph G and $\mathbf{m} \in \mathcal{M}$ is an individual matching. Note that, then, $p(\mathbf{m})$ is a

---

[3] A matching is an edge set where none of the edges share common vertices (West, 2000).

distribution over all bipartite matchings on G such as the matching shown in Figure 1. We will take $p(\mathbf{m})$ to be fixed as the uniform distribution for the remainder of the exposition, though more complicated distributions could be learned, of course. We further define the distribution

$$p_\theta(T \mid S, \mathbf{m}) := \prod_{(i,j)\in\mathbf{m}} p(t_i \mid s_j) \cdot \prod_{i\in\mathbf{u}_{\mathit{trg}}} p(t_i) \quad (2)$$

Recall we write $(i, j) \in \mathbf{m}$ to denote an edge in the matching. Furthermore, for notational simplicity, we have dropped the dependence of $\mathbf{u}_{\mathit{trg}}$ on $\mathbf{m}$. (Recall $\mathbf{u}_{\mathit{trg}} = V_{\mathit{trg}} \setminus \{i : (i, j) \in \mathbf{m}\}$). Next, we define the two densities present in equation (2) as Gaussians:

$$\begin{aligned} p_\theta(t \mid s) &:= \mathcal{N}(\Omega\, s, I) && (3)\\ &\propto \exp ||t - \Omega\, s||_2^2 \\ p_\theta(t) &:= \mathcal{N}(\mu, I) && (4) \end{aligned}$$

Given a fixed matching $\mathbf{m}$, we may create matrices $S_\mathbf{m} \in \mathbb{R}^{d\times|\mathbf{m}|}$ and $T_\mathbf{m} \in \mathbb{R}^{d\times|\mathbf{m}|}$ such that the rows correspond to word vectors of matched vertices (translations under the matching $\mathbf{m}$). Now, after some algebra, we see that we can rewrite $\prod_{(i,j)\in\mathbf{m}} p(t_i \mid s_i)$ in matrix notation:

$$\begin{aligned} p_\theta(T_\mathbf{m} \mid S_\mathbf{m}, \mathbf{m}) &= \prod_{(i,j)\in\mathbf{m}} p(t_i \mid s_j) && (5)\\ &\propto \prod_{(i,j)\in\mathbf{m}} \exp ||t_i - \Omega\, s_j||_2^2 \\ &= \exp \sum_{(i,j)\in\mathbf{m}} ||t_i - \Omega\, s_j||_2^2 \\ &= \exp ||T_\mathbf{m} - \Omega\, S_\mathbf{m}||_F^2 && (6) \end{aligned}$$

where $\Omega \in \mathbb{R}^{d\times d}$ is an orthogonal matrix of parameters to be learned. The result of this derivation, equation (6), will become useful during the discussion of parameter estimation in §4.

We define the model's parameters, to be optimized, as $\theta = (\Omega, \mu)$.

Modeling Assumptions and their Limitations In the previous section, we have formulated the induction of a bilingual lexicon as the search for an edge set E, which we treat as a latent variable that we marginalize out in equation (2). Specifically, we assume that E is a partial matching. Thus, for every $(i, j) \in \mathbf{m}$, we have $t_i \sim \mathcal{N}(\Omega\, s_j, I)$, that is, the embedding for $v_{\mathit{trg}}(i)$ is assumed to have been drawn from a Gaussian centered around the embedding for $v_{\mathit{src}}(j)$, after an orthogonal transformation. This gives rise to two modeling assumptions, which we make explicit: (i) There exists a single source for every word in the target lexicon *and* that source cannot be used more than once.[4] (ii) There exists an orthogonal transformation, after which the embedding spaces are more or less equivalent.

Assumption (i) may be true for related languages, but is likely false for morphologically rich languages that have a many-to-many relationship between the words in their respective lexicons. We propose to ameliorate this using a rank constraint that only considers the top n most frequent words in both lexicons for matching in §6. In addition, we experiment with priors that express different matchings in §7.

As for assumption (ii), previous work (Xing et al., 2015; Artetxe et al., 2017) has achieved some success using an orthogonal transformation; recently, however, Søgaard et al. (2018) demonstrated that monolingual embedding spaces are not approximately isomorphic and that there is a complex relationship between word form and meaning, which is only inadequately modeled by current approaches, which for example cannot model polysemy. Nevertheless, we will show that imbuing our model with these assumptions helps empirically in §6, giving them practical utility.

Why it Works: The Hubness Problem Why should we expect the bipartite matching prior to help, given that we know of cases when multiple source words *should match a target word*? One answer is because the bipartite prior helps us obviate the **hubness problem**, a common issue in word-embedding-based bilingual lexicon induction (Dinu et al., 2015). The hubness problem is an intrinsic problem of high-dimensional vector spaces where certain vectors will be *universal* nearest neighbors, i.e. they will be the nearest neighbor to a disproportionate number of other vectors (Radovanović et al., 2010). Thus, if we allow one-to-many alignments, we will find the embeddings of certain elements of V_{src} acting as hubs, i.e. the model will pick them to generate a disproportionate number of target embeddings, which reduces the quality of the embedding space.[5]

Another explanation for the positive effect of the

---

[4] This is true by the definition of a matching.

[5] In §5, we discuss the one-to-many alignment used in several of our baseline systems.

Algorithm 1 Viterbi EM for our latent-variable model

```
repeat
    // Viterbi E-Step
    $\mathbf{m}^\star \leftarrow \text{argmax}_{\mathbf{m}\in\mathcal{M}} \log p_\theta(\mathbf{m} \mid S, T)$
    $\mathbf{u}^\star_{trg} \leftarrow V_{trg} \setminus \{i : (i,j) \in \mathbf{m}^\star\}$
    // M-Step
    $U\Sigma V^\top \leftarrow \text{SVD}\left(T_{\mathbf{m}^\star} S^\top_{\mathbf{m}^\star}\right)$
    $\Omega^\star \leftarrow UV^\top$
    $\mu^\star \leftarrow {}^1\!/\!_{|\mathbf{u}^\star_{trg}|} \cdot \sum_{i\in\mathbf{u}^\star_{trg}} t_i$
    $\theta \leftarrow (\Omega^\star, \mu^\star)$
until converged
```

one-to-one alignment prior is its connection to the Wasserstein distance and computational optimal transport (Villani, 2008). Concurrent work (Grave et al., 2018) similarly has found the one-to-one alignment prior to be beneficial.

4 Parameter Estimation

We will conduct parameter estimation through Viterbi EM. We describe first the E-step, then the M-step. Viterbi EM estimates the parameters by alternating between the two steps until convergence. We give the complete pseudocode in Algorithm 1.

4.1 Viterbi E-Step

The E-step asks us to compute the posterior of latent bipartite matchings $p(\mathbf{m} \mid S, T)$. Computation of this distribution, however, is intractable as it would require a *sum* over all bipartite matchings, which is #P-hard (Valiant, 1979). Tricks from combinatorial optimization make it possible to *maximize* over all bipartite matchings in polynomial time. Thus, we fall back on the Viterbi approximation for the E-step (Brown et al., 1993; Samdani et al., 2012). The derivation will follow Haghighi et al. (2008). In order to compute

$$\mathbf{m}^\star = \underset{\mathbf{m}\in\mathcal{M}}{\text{argmax}} \log p_\theta(\mathbf{m} \mid S, T) \tag{7}$$

we construct a fully connected bipartite graph $G = (E, V_{src} \cup V_{trg})$, where $E = V_{src} \times V_{trg}$. We weight each arc $(i, j) \in E$ with the weight between the projected source word and target word embeddings: $w_{ij} = \log p(t_i \mid s_j) - \log p(t_i) = ||t_i - \Omega\, s_j||_2^2 - ||t_i - \mu||_2^2$, where the normalizers of both Gaussians cancel as both have the same covariance matrix, i.e., I. Note that in the case where the t_i and the s_j are of length 1, that is, $||t_i||_2 = ||s_j||_2 = 1$, and $\mu = \mathbf{0}$, we recover cosine distance between the vectors up to an additive constant as orthogonal matrices preserve length (the constant is always -1 as $||t_i||_2 = 1$). We may ignore this constant during the E-step's combinatorial optimization. Note the optimal partial matching will contain no edges with weight $w_{ij} < 0$. For this reason, we remove such edges from the bipartite graph. To find the maximal *partial* bipartite matching on G to compute $\mathbf{m}^\star$, we employ an efficient algorithm as detailed in the next section.

Finding a Maximal Bipartite Matching We frame finding an optimal one-to-one alignment between n_{src} source and n_{trg} words as a combinatorial optimization problem, specifically, a linear assignment problem (LAP; Bertsimas and Tsitsiklis, 1997). In its original formulation, the LAP requires assigning a number of agents (source words) to a number of tasks (target words) at a cost that varies based on each assignment. An optimal solution assigns each source word to exactly one target word and vice versa at minimum cost. The Hungarian algorithm (Kuhn, 1955) is one of the most well-known approaches for solving the LAP, but runs in $O((n_{src} + n_{trg})^3)$. This works for smaller vocabulary sizes,[6] but is prohibitive for matching cross-lingual word embeddings with large vocabularies for real-world applications.[7]

For each source word, most target words, however, are unlikely candidates for alignment. We thus propose to consider only the top k most similar target words for alignment with every source word. We sparsify the graph by weighting the edges for all other words with $-\infty$. The remaining weights w_{ij} are chosen as discussed above. We employ a version of the Jonker-Volgenant algorithm (Jonker and Volgenant, 1987; Volgenant, 1996), which has been optimized for LAP on sparse graphs, to find the maximum-weight matching $\mathbf{m}^\star$ on G.[8]

4.2 M-Step

Next, we will describe the M-step. Given an optimal matching $\mathbf{m}^\star$ computed in §4.1, we search for a matrix $\Omega \in \mathbb{R}^{d\times d}$. We additionally enforce the constraint that Ω is a real orthogonal matrix, i.e., $\Omega^\top\Omega = I$. Previous work (Xing et al., 2015;

---

[6] Haghighi et al. (2008) use the Hungarian algorithm to find a matching between 2000 source and target language words.

[7] For reference, in §6, we learn bilingual lexicons between embeddings of 200,000 source and target language words.

[8] After acceptance to EMNLP 2018, Edouard Grave pointed out that Sinkhorn propagation (Adams and Zemel, 2011; Mena et al., 2018) may have been a computationally more effective manner to deal with the latent matchings.

Artetxe et al., 2017) found that the orthogonality constraint leads to noticeable improvements.

Our M-step optimizes two objectives independently. First, making use of the result in equation (6), we optimize the following:

$$\begin{aligned}\log p(T_{\mathbf{m}^\star} \mid S_{\mathbf{m}^\star}, \mathbf{m}^\star) \quad (8)\\ = ||T_{\mathbf{m}^\star} - \Omega\, S_{\mathbf{m}^\star}||_F^2 + C\end{aligned}$$

with respect to Ω subject to $\Omega^\top \Omega = I$. (Note we may ignore the constant C during the optimization.) Second, we optimize the objective

$$\log \prod_{i \in \mathbf{u}_{trg}} p(t_i) = \sum_{i \in \mathbf{u}_{trg}} ||t_i - \mu||_2^2 + D \quad (9)$$

with respect to the mean parameter μ, which is simply an average. Note, again, we may ignore the constant D during optimization.

Optimizing equation (8) with respect to Ω is known as the orthogonal Procrustes problem (Schönemann, 1966; Gower and Dijksterhuis, 2004) and has a closed form solution that exploits the singular value decomposition (Horn and Johnson, 2012). Namely, we compute $U\Sigma V^\top = T_{\mathbf{m}}^\top S_{\mathbf{m}}$. Then, we directly arrive at the optimum: $\Omega^\star = UV^\top$. Optimizing equation (9) can also been done in closed form; the point which minimizes distance to the data points (thereby maximizing the log-probability) is the centroid: $\mu^\star = {}^1\!/\!_{|\mathbf{u}_{trg}|} \cdot \sum_{i \in \mathbf{u}_{trg}} t_i$.

5 Reinterpretation of Artetxe et al. (2017) as a Latent-Variable Model

The self-training method of Artetxe et al. (2017), our strongest baseline in §6, may also be interpreted as a latent-variable model in the spirit of our exposition in §3. Indeed, we only need to change the edge-set prior $p(\mathbf{m})$ to allow for edge sets other than those that are matchings. Specifically, a matching enforces a one-to-one alignment between types in the respective lexicons. Artetxe et al. (2017), on the other hand, allow for one-to-many alignments. We show how this corresponds to an alignment distribution that is equivalent to IBM Model 1 (Brown et al., 1993), and that Artetxe et al. (2017)'s self-training method is actually a form of Viterbi EM.

To formalize Artetxe et al. (2017)'s contribution as a latent-variable model, we lay down some more notation. Let $\mathcal{A} = \{1, \ldots, n_{src} + 1\}^{n_{trg}}$, where we define $(n_{src} + 1)$ to be `none`, a distinguished symbol indicating unalignment. The set $\mathcal{A}$ is to be interpreted as the set of all one-to-many alignments $\mathbf{a}$ on the bipartite vertex set $V = V_{trg} \cup V_{src}$ such that $a_i = j$ means the i^{th} vertex in V_{trg} is aligned to the j^{th} vertex in V_{src}. Note that $a_i = (n_{src} + 1) = \texttt{none}$ means that the i^{th} element of V_{trg} is unaligned. Now, by analogy to our formulation in §3, we define

$$\begin{aligned} p(T \mid S) &:= \sum_{\mathbf{a} \in \mathcal{A}} p(T \mid S, \mathbf{a}) \cdot p(\mathbf{a}) && (10)\\ &= \sum_{\mathbf{a} \in \mathcal{A}} \prod_{i=1}^{n_{trg}} p(t_i \mid s_{a_i}, a_i) \cdot p(a_i) && (11)\\ &= \prod_{i=1}^{n_{trg}} \sum_{a_i=1}^{n_{src}+1} p(t_i \mid s_{a_i}, a_i) \cdot p(a_i) && (12)\end{aligned}$$

The move from equation (11) to equation (12) is the dynamic-programming trick introduced in Brown et al. (1993). This reduces the number of terms in the expression from exponentially many to polynomially many. We take $p(\mathbf{a})$ to be a uniform distribution over all alignments with no parameters to be learned.

Artetxe et al. (2017)'s Viterbi E-Step In the context of Viterbi EM, it means the max over $\mathcal{A}$ will decompose additively s

$$\max_{\mathbf{a} \in \mathcal{A}} \log p(\mathbf{a} \mid S, T) = \sum_{i=1}^{n_{trg}} \max_{1 \le a_i \le (n_{src}+1)} \log p(a_i \mid S, T)$$

thus, we can simply find $\mathbf{a}^\star$ component-wise as follows:

$$a_i^\star = \underset{1 \le a_i \le (n_{src}+1)}{\operatorname{argmax}} \log p(a_i \mid t_i, s_{a_i}) \quad (13)$$

Artetxe et al. (2017)'s M-step The M-step remains unchanged from the exposition in §3 with the exception that we fit Ω given matrices $S_{\mathbf{a}}$ and $T_{\mathbf{a}}$ formed from a one-to-many alignment $\mathbf{a}$, rather than a matching $\mathbf{m}$.

Why a Reinterpretation? The reinterpretation of Artetxe et al. (2017) as a probabilistic model yields a clear analytical comparison between our method and theirs. The only difference between the two is the constraint on the bilingual lexicon that the model is allowed to induce.

6 Experiments

We first conduct experiments on bilingual dictionary induction and cross-lingual word similarity on three standard language pairs, English–Italian, English–German, and English–Finnish.

Table 2: Spearman correlations on English–Italian and English–German cross-lingual word similarity datasets.

6.1 Experimental Details

Datasets For bilingual dictionary induction, we use the English–Italian dataset by Dinu et al. (2015) and the English–German and English–Finnish datasets by Artetxe et al. (2017). For cross-lingual word similarity, we use the RG-65 and WordSim-353 cross-lingual datasets for English–German and the WordSim-353 cross-lingual dataset for English–Italian by Camacho-Collados et al. (2015).

Monolingual Embeddings We follow Artetxe et al. (2017) and train monolingual embeddings with word2vec, CBOW, and negative sampling (Mikolov et al., 2013a) on a 2.8 billion word corpus for English (ukWaC + Wikipedia + BNC), a 1.6 billion word corpus for Italian (itWaC), a 0.9 billion word corpus for German (SdeWaC), and a 2.8 billion word corpus for Finnish (Common Crawl).

Seed dictionaries Following Artetxe et al. (2017), we use dictionaries of 5,000 words, 25 words, and a numeral dictionary consisting of words matching the `[0-9]+` regular expression in both vocabularies.[9] In line with Søgaard et al. (2018), we additionally use a dictionary of identically spelled strings in both vocabularies.

Implementation details Similar to Artetxe et al. (2017), we stop training when the improvement on the average cosine similarity for the induced dictionary is below 1×10^{-6} between succeeding iterations. Unless stated otherwise, we induce a dictionary of 200,000 source and 200,000 target words as in previous work (Mikolov et al., 2013c; Artetxe et al., 2016). For optimal 1:1 alignment, we have observed the best results by keeping the top $k = 3$ most similar target words. If using a rank constraint, we restrict the matching in the E-step to the top 40,000 words in both languages.[10] Finding an optimal alignment on the $200{,}000 \times 200{,}000$ graph takes about 25 minutes on CPU;[11] with a rank constraint, matching takes around three minutes.

Baselines We compare our approach with and without the rank constraint to the original bilingual mapping approach by Mikolov et al. (2013c). In addition, we compare with Zhang et al. (2016) and Xing et al. (2015) who augment the former with an orthogonality constraint and normalization and an orthogonality constraint respectively. Finally, we compare with Artetxe et al. (2016) who add dimension-wise mean centering to Xing et al. (2015), and Artetxe et al. (2017).

Both Mikolov et al. (2013c) and Artetxe et al. (2017) are special cases of our famework and comparisons to these approaches thus act as an ablation study. Specifically, Mikolov et al. (2013c) does not

---

[9] The resulting dictionaries contain 2772, 2148, and 2345 entries for English–{Italian, German, Finnish} respectively.

[10] We validated both values with identical strings using the 5,000 word lexicon as validation set on English–Italian.

[11] Training takes a similar amount of time as (Artetxe et al., 2017) due to faster convergence.

employ orthogonal Procrustes, but rather allows the learned matrix Ω to range freely. Likewise, as discussed in §5, Artetxe et al. (2017) make use of a Viterbi EM style algorithm with a different prior over edge sets.[12]

6.2 Results

We show results for bilingual dictionary induction in Table 1 and for cross-lingual word similarity in Table 2. Our method with a 1:1 prior outperforms all baselines on English–German and English–Italian.[13] Interestingly, the 1:1 prior by itself fails on English–Finnish with a 25 word and numerals seed lexicon. We hypothesize that the prior imposes too strong of a constraint to find a good solution for a distant language pair from a poor initialization. With a better—but still weakly supervised—starting point using identical strings, our approach finds a good solution. Alternatively, we can mitigate this deficiency effectively using a rank constraint, which allows our model to converge to good solutions even with a 25 word or numerals seed lexicon. The rank constraint generally performs similarly or boosts performance, while being about 8 times faster. All approaches do better with identical strings compared to numerals, indicating that the former may be generally suitable as a default weakly-supervised seed lexicon.

On cross-lingual word similarity, our approach yields the best performance on WordSim-353 and RG-65 for English–German and is only outperformed by Artetxe et al. (2017) on English–Italian Wordsim-353.

7 Analysis

Vocabulary sizes The beneficial contribution of the rank constraint demonstrates that in similar languages, many frequent words will have one-to-one matchings, while it may be harder to find direct matches for infrequent words. We would thus expect the latent variable model to perform better if we only learn dictionaries for the top n most frequent words in both languages. We show results for our approach in comparison to the baselines in Figure 2 for English–Italian using a 5,000 word seed lexicon across vocabularies consisting of different numbers n of the most frequent words[14].

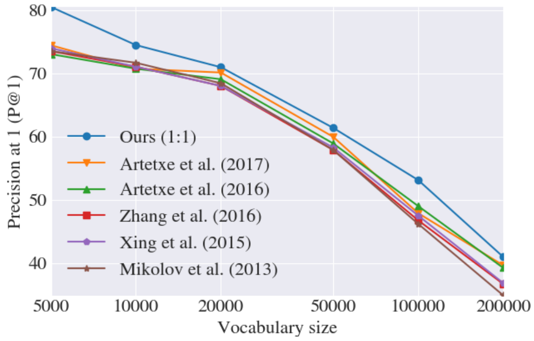

Figure 2: Bilingual dictionary induction results of our method and baselines for English–Italian with a 5,000 word seed lexicon across different vocabulary sizes.

The comparison approaches mostly perform similar, while our approach performs particularly well for the most frequent words in a language.

Different priors An advantage of having an explicit prior as part of the model is that we can experiment with priors that satisfy different assumptions. Besides the 1:1 prior, we experiment with a 2:2 prior and a 1:2 prior. For the 2:2 prior, we create copies of the source and target words V'_{src} and V'_{trg} and add these to our existing set of vertices $V' = (V_{trg} + V'_{trg}, V_{src} + V'_{src})$. We run the Viterbi E-step on this new graph G' and merge matched pairs of words and their copies in the end. Similarly, for the 1:2 prior, which allows one source word to be matched to two target words, we augment the vertices with a copy of the source words V'_{src} and proceed as above. We show results for bilingual dictionary induction with different priors across different vocabulary sizes in Figure 3.

The 2:2 prior performs best for small vocabulary sizes. As solving the linear assignment problem for larger vocabularies becomes progressively more challenging, the differences between the priors become obscured and their performance converges.

Hubness problem We analyze empirically whether the prior helps with the hubness problem. Following Lazaridou et al. (2015), we define the *hubness* $N_k(y)$ at k of a target word y as follows:

$$N_k(y) = |\{x \in Q \mid y \in NN_k(x, G)\}| \qquad (14)$$

where Q is a set of query source language words and $NN_k(x, G)$ denotes the k nearest neighbors

---

[12] Other recent improvements such as symmetric reweighting (Artetxe et al., 2018) are orthogonal to our method, which is why we do not explicitly compare to them here.

[13] Note that results are not directly comparable to (Conneau et al., 2018) due to the use of embeddings trained on different monolingual corpora (WaCKy vs. Wikipedia).

[14] We only use the words in the 5,000 word seed lexicon that are contained in the n most frequent words. We do not show results for the 25 word seed lexicon and numerals as they are not contained in the smallest n of most frequent words.

Table 4: Bilingual dictionary induction results for English-{Turkish, Bengali, Hindi} and Estonian-Finnish.

of x in the graph G.[15] In accordance with Lazaridou et al. (2015), we set $k = 20$ and use the words in the evaluation dictionary as query terms. We show the target language words with the highest hubness using our method and Artetxe et al. (2017) for English–German with a 5,000 seed lexicon and the full vocabulary in Table 3.[16]

Hubs are fewer and occur less often with our method, demonstrating that the prior—to some extent—aids with resolving hubness. Interestingly, compared to Lazaridou et al. (2015), hubs seem to occur less often and are more meaningful in current cross-lingual word embedding models.[17] For instance, the neighbors of 'gleichgültigkeit' all relate to indifference and words appearing close to 'luis' or 'jorge' are Spanish names. This suggests that the prior might also be beneficial in other ways, e.g. by enforcing more reliable translation pairs for subsequent iterations.

Low-resource languages Cross-lingual embeddings are particularly promising for low-resource languages, where few labeled examples are typically available, but are not adequately reflected in current benchmarks (besides the English–Finnish language pair). We perform experiments with our method with and without a rank constraint and Artetxe et al. (2017) for three truly low-resource language pairs, English–{Turkish, Bengali, Hindi}. We additionally conduct an experiment for Estonian-Finnish, similarly to Søgaard et al. (2018). For all languages, we use fastText embeddings (Bojanowski et al., 2017) trained on Wikipedia, the evaluation dictionaries provided by Conneau et al. (2018), and a seed lexicon based on identical strings to reflect a realistic use case. We note that English does not share scripts with Bengali and Hindi, making this even more challenging. We show results in Table 4.

Surprisingly, the method by Artetxe et al. (2017) is unable to leverage the weak supervision and fails to converge to a good solution for English-Bengali and English-Hindi.[18] Our method without a rank constraint significantly outperforms Artetxe et al. (2017), while particularly for English-Hindi the rank constraint dramatically boosts performance.

Error analysis To illustrate the types of errors the model of Artetxe et al. (2017) and our method with a rank constraint make, we query both of them with words from the test dictionary of Artetxe et al.

---

[15] In other words, the hubness of a target word measures how often it occurs in the neighborhood of the query terms.

[16] We verified that hubs are mostly consistent across runs and similar across language pairs.

[17] Lazaridou et al. (2015) observed mostly rare words with N_{20} values of up to 50 and many with $N_{20} > 20$.

[18] One possible explanation is that Artetxe et al. (2017) particularly rely on numerals, which are normalized in the fastText embeddings.

Query	Gold	Artetxe et al. (2017)	Ours

Table 5: Example translations for German-English.

(2017) in German and seek their nearest neighbours in the English embedding space. P@1 over the German-English test set is 36.38 and 39.18 for Artetxe et al. (2017) and our method respectively. We show examples where nearest neighbours of the methods differ in Table 5.

Similar to Kementchedjhieva et al. (2018), we find that morphologically related words are often the source of mistakes. Other common sources of mistakes in this dataset are names that are translated to different names and nearly synonymous words being predicted. Both of these sources indicate that while the learned alignment is generally good, it is often not sufficiently precise.

8 Related work

Cross-lingual embedding priors Haghighi et al. (2008) first proposed an EM self-learning method for bilingual lexicon induction, representing words with orthographic and context features and using the Hungarian algorithm in the E-step to find an optimal 1:1 matching. Artetxe et al. (2017) proposed a similar self-learning method that uses word embeddings, with an implicit one-to-many alignment based on nearest neighbor queries. Vulić and Korhonen (2016) proposed a more strict one-to-many alignment based on symmetric translation pairs, which is also used by Conneau et al. (2018). Our method bridges the gap between early latent variable and word embedding-based approaches and explicitly allows us to reason over its prior.

Hubness problem The hubness problem is an intrinsic problem in high-dimensional vector spaces (Radovanović et al., 2010). Dinu et al. (2015) first observed it for cross-lingual embedding spaces and proposed to address it by re-ranking neighbor lists. Lazaridou et al. (2015) proposed a max-marging objective as a solution, while more recent approaches proposed to modify the nearest neighbor retrieval by inverting the softmax (Smi, 2017) or scaling the similarity values (Conneau et al., 2018).

9 Conclusion

We have presented a novel latent-variable model for bilingual lexicon induction, building on the work of Artetxe et al. (2017). Our model combines the prior over bipartite matchings inspired by Haghighi et al. (2008) and the discriminative, rather than generative, approach inspired by Irvine and Callison-Burch (2013). We show empirical gains on six language pairs and theoretically and empirically demonstrate the application of the bipartite matching prior to solving the hubness problem.

Abstract

Unsupervised word translation from non-parallel inter-lingual corpora has attracted much research interest. Very recently, neural network methods trained with adversarial loss functions achieved high accuracy on this task. Despite the impressive success of the recent techniques, they suffer from the typical drawbacks of generative adversarial models: sensitivity to hyper-parameters, long training time and lack of interpretability. In this paper, we make the observation that two sufficiently similar distributions can be aligned correctly with iterative matching methods. We present a novel method that first aligns the second moment of the word distributions of the two languages and then iteratively refines the alignment. Extensive experiments on word translation of European and Non-European languages show that our method achieves better performance than recent state-of-the-art deep adversarial approaches and is competitive with the supervised baseline. It is also efficient, easy to parallelize on CPU and interpretable.

1 Introduction

Inferring word translations between languages is a long-standing research task. Earliest efforts concentrated on finding parallel corpora in a pair of languages and inferring a dictionary by force alignment of words between the two languages. An early example of this approach is the translation achieved using the Rosetta stone.

However, if most languages share the same expressive power and are used to describe similar human experiences across cultures, they should share similar statistical properties. Exploiting statistical properties of letters has been successfully employed by substitution crypto-analysis since at least the 9th century. It seems likely that one can learn to map between languages statistically, by considering the word distributions. As one specific example, it is likely that the set of elements described by the most common words in one language would greatly overlap with those described in a second language.

Another support for the plausibility of unsupervised word translation came with the realization that when words are represented as vectors that encode co-occurrences, the mapping between two languages is well captured by an affine transformation (Mikolov et al., 2013b). In other words, not only that one can expect the most frequent words to be shared, one can also expect the representations of these words to be similar up to a linear transformation.

A major recent trend in unsupervised learning is the use of Generative Adversarial Networks (GANs) presented by Goodfellow et al. (2014), in which two networks provide mutual training signals to each other: the generator and the discriminator. The discriminator plays an adversarial role to a generative model and is trained to distinguish between two distributions. Typically, these distributions are labeled as "real" and "fake", where "fake" denotes the generated samples.

In the context of unsupervised translation (Conneau et al., 2017; Zhang et al., 2017a,b), when learning from a source language to a target language, the "real" distribution is the distribution of the target language and the "fake" one is the mapping of the source distribution using the learned mapping. Such approaches have been shown recently to be very effective when employed on top of modern vector representations of words.

In this work, we ask whether GANs are necessary for achieving the level of success recently demonstrated for unsupervised word translation. Given that the learned mapping is simple and that the concepts described by the two languages are similar, we suggest to directly map every word

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 469–478
Brussels, Belgium, October 31 - November 4, 2018.

in one language to the closest word in the other. While one cannot expect that all words would match correctly for a random initialization, some would match and may help refine the affine transformation. Once an improved affine transformation is recovered, the matching process can repeat.

Naturally, such an iterative approach relies on a good initialization. For this purpose we employ two methods. First, an initial mapping is obtained by matching the means and covariances of the two distributions. Second, multiple solutions, which are obtained stochastically, are employed.

Using multiple stochastic solutions is crucial for languages that are more distant, e.g., more stochastic solutions are required for learning to translate between English and Arabic, in comparison to English and French. Evaluating multiple solutions relies on the ability to automatically identify the true matching without supervision and we present an unsupervised reconstruction-based criterion for determining the best stochastic solution.

Our presented approach is simple, has very few hyper-parameters, and is trivial to parallelize. It is also easily interpretable, since every step of the method has a clear goal and a clear success metric, which can also be evaluated without the ground truth bilingual lexicon. An extensive set of experiments shows that our much simpler and more efficient method is more effective than the state-of-the-art GAN based method.

2 Related Work

The earlier contributions in the field of word translation without parallel corpora were limited to finding matches between a small set of carefully selected words and translations, and relied on co-occurrence statistics (Rapp, 1995) or on similarity in the variability of the context before and after the word (Fung, 1995). Finding translations of larger sets of words was made possible in follow-up work by incorporating a seed set of matching words that is either given explicitly or inferred based on words that appear in both languages or are similar in edit distance due to a shared etymology (Fung and Yee, 1998; Rapp, 1999; Schafer and Yarowsky, 2002; Koehn and Knight, 2002; Haghighi et al., 2008; Irvine and Callison-Burch, 2013; Xia et al., 2016; Artetxe et al., 2017).

For example, Koehn and Knight (2002) matched English with German. Multiple heuristics were suggested based on hand crafted rules, including similarity in spelling and word frequency. A weighted linear combination is employed to combine the heuristics and the matching words are identified in a greedy manner. Haghighi et al. (2008) modeled the problem of matching words across independent corpora as a generative model, in which cross-lingual links are represented by latent variables, and employed an iterative EM method.

Another example that employs iterations was presented by Artetxe et al. (2017). Similarly to our method, this method relies on word vector embeddings, in their case the word2vec method (Mikolov et al., 2013a). Unlike our method, their method is initialized using seed matches.

Our core method incorporates a circularity term, which is also used in (Xia et al., 2016) for the task of NMT and later on in multiple contributions in the field of image synthesis (Kim et al., 2017; Zhu et al., 2017). This term is employed when learning bidirectional transformations to encourages samples from either domain to be mapped back to exactly the same sample when translated to the other domain and back. Since our transformations are linear, this is highly related to employing orthogonality as done in (Xing et al., 2015; Smith et al., 2017; Conneau et al., 2017) for the task of weakly or unsupervised word vector space alignment. Conneau et al. (2017) also employ a circularity term, but unlike our use of it as part of the optimization's energy term, there it is used for validating the solution and selecting hyperparameters.

Very recently, Zhang et al. (2017a,b); Conneau et al. (2017) have proposed completely unsupervised solutions. All three solutions are based on GANs. The methods differ in the details of the adversarial training, in the way that model selection is employed to select the best configuration and in the way in which matching is done after the distributions are aligned by the learned transformation.

Due to the min-max property of GANs, methods which rely on GANs are harder to interpret, since, for example, the discriminator D could focus on a combination of local differences between the distributions. The reliance on a discriminator also means that complex weight dependent metrics are implicitly used, and that these metrics evolve dynamically during training.

Our method does not employ GANs. Alternatives to GANs are also emerging in other domains. For example, generative methods were trained by iteratively fitting random ("noise") vectors by Bojanowski et al. (2017); In the recent image translation work of Chen and Koltun (2017), distinguishability between distribution of images was measured using activations of pretrained networks, a practice that is referred to as the "perceptual loss" (Johnson et al., 2016).

3 Non-Adversarial Word Translation

We present an approach for unsupervised word translation consisting of multiple parts: (i) Transforming the word vectors into a space in which the two languages are more closely aligned, (ii) Mini-Batch Cycle iterative alignment. There is an optional final stage of batch-based finetuning.

Let us define two languages $\mathcal{X}$ and $\mathcal{Y}$, each containing a set of N_X and N_Y words represented by the feature vectors $x_1..x_{N_X}$ and $y_1..y_{N_Y}$ respectively. Our objective is to find the correspondence function $f(n)$ such that for every x_n, $f(n)$ yields the index of the $\mathcal{Y}$ word that corresponds to the word x_n. If a set of possible correspondences is available for a given word, our objective is to predict one member of this set. In this unsupervised setting, no training examples of $f(n)$ are given.

3.1 Approximate Alignment with PCA

Each language consists of a set of words each parameterized by a word vector. A popular example of a word embedding method is FastText (Bojanowski et al., 2016), which uses the internal word co-occurrence statistics for each language. These word vectors are typically not expected to be aligned between languages and since the alignment method we employ is iterative, a good initialization is key.

Let us motivate our approach by a method commonly used in 3D point cloud matching. Let A be a set of 3D points and TA be the same set of points with a rotated coordinate system. Assuming non-isotropic distributions of points, transforming each set of points to its principle axes of variations (using PCA) will align the two point clouds. As noted by Daras et al. (2012), PCA-based alignment is common in the literature of point cloud matching.

Word distributions are quite different from 3D point clouds: They are much higher dimensional, and it is not obvious a priori that different languages present different "views" of the same "object" and share exactly the same axes of variation. The success of previous results, e.g. (Conneau et al., 2017), to align word vectors between languages using an orthonormal transformation does give credence to this approach. Our method relies on the assumption that many language pairs share some principle axes of variation. The empirical success of PCA initialization in this work supports this assumption.

For each language $[\mathcal{X}, \mathcal{Y}]$, we first select the N most frequent word vectors. In our implementation, we use $N = 5000$ and employ FastText vectors of dimension $D = 300$. We project the word vectors, after centering, to the top p principle components (we use $p = 50$).

3.2 Mini-Batch Cycle Iterative Closest Point

Although projecting to the top principle axes of variation would align a rotated non-isotropic point cloud, it does not do so in the general case. This is due to languages having different word distributions and components of variation.

We therefore attempt to find a transformation T that will align every word x_i from language $\mathcal{X}$ to a word $y_{f(i)}$ in language $\mathcal{Y}$. The objective is therefore to minimize:

$$\underset{T}{\operatorname{argmin}} \sum_i \min_{f(i)} |y_i - Tx_{f(i)}| \tag{1}$$

Eq. 1 is difficult to optimize directly and various techniques have been proposed for its optimization. One popular method used in 3D point cloud alignment is Iterative Closest Point (ICP). ICP solves Eq. 1 iteratively in two steps.

1. For each y_j, find the nearest Tx_i. We denote its index by $f_y(j) = i$
2. Optimize for T in $\sum_j \|y_j - Tx_{f_y(j)}\|$

In this work, we use a modified version of ICP which we call Mini-Batch Cycle ICP (MBC-ICP). MBC-ICP learns transformations T_{xy} for $\mathcal{X} \rightarrow \mathcal{Y}$ and T_{yx} for $\mathcal{Y} \rightarrow \mathcal{X}$. We include cycle-constraints ensuring that a word x transformed to the $\mathcal{Y}$ domain and back is unchanged (and similarly for every $\mathcal{Y} \rightarrow \mathcal{X} \rightarrow \mathcal{Y}$ transformation). The strength of the cycle constraints is parameterized by λ (we have $\lambda = 0.1$). We compute the nearest neighbor matches at the beginning of each epoch, and then optimize transformations T_{yx} and T_{xy} using mini-batch SGD with mini-batch size 128. Mini-batch rather than full-batch optimization greatly increases the success of the method. Experimental comparisons can be seen in the results section. Note we only compute the nearest neighbors at the beginning of each epoch, rather than for each mini-batch due to the computational expense.

Every iteration of the final MBC-ICP algorithm therefore becomes:

1. For each y_j, find the nearest $T_{xy}x_i$. We denote its index by $f_y(j)$
2. For each x_i, find the nearest $T_{yx}y_j$. We denote its index by $f_x(i)$
3. Optimize T_{xy} and T_{yx} using mini-batch SGD for a single epoch of $\{x_i\}$ and $\{y_j\}$ on: $\sum_j \|y_j - T_{xy}x_{f_y(j)}\| + \sum_i \|x_i - T_{yx}y_{f_x(i)}\| + \lambda \sum_i \|x_i - T_{yx}T_{xy}x_i\| + \lambda \sum_j \|y_j - T_{xy}T_{yx}y_j\|$

A good initialization is important for ICP-type methods. We therefore begin with the projected data in which the transformation is assumed to be relatively small and initialize transformations T_{xy} and T_{yx} with the identity matrix. We denote this step PCA-MBC-ICP.

Once PCA-MBC-ICP has generated the correspondences functions $f_x(i)$ and $f_y(j)$, we run a MBC-ICP on the original $300D$ word vectors (no PCA). We denote this step: RAW-MBC-ICP. We initialize the optimization using $f_x(i)$ and $f_y(j)$ learned before, and proceed with MBC-ICP. At the end of this stage, we recover transformations $\bar{T}_{xy}$ and $\bar{T}_{yx}$ that transform the $300D$ word vectors from $\mathcal{X} \rightarrow \mathcal{Y}$ and $\mathcal{Y} \rightarrow \mathcal{X}$ respectively.

Reciprocal pairs: After several iterations of MBC-ICP, the estimated transformations become quite reliable. We can therefore use this transformation to identify the pairs that are likely to be correct matches. We use the reciprocity heuristic: For every word $y \in \mathcal{Y}$ we find the nearest transformed word from the set $\{T_{xy}x | x \in X\}$. We also find the nearest neighbors for the $\mathcal{Y} \rightarrow \mathcal{X}$ transformation. If a pair of words is matched in both $\mathcal{X} \rightarrow \mathcal{Y}$ and $\mathcal{Y} \rightarrow \mathcal{X}$ directions, the pair is denoted reciprocal. During RAW-MBC-ICP, we use only reciprocal pairs, after the 50th epoch (this parameter is not sensitive).

In summary: we run PCA-MBC-ICP on the $5k$ most frequent words after transformation to principle components. The resulting correspondences $f_x(i)$ and $f_y(j)$ are used to initialize a RAW-MBC-ICP on the original 300D data (rather than PCA), using reciprocal pairs. The output of the method are transformation matrices T_{xy} and T_{yx}.

3.3 Fine-tuning

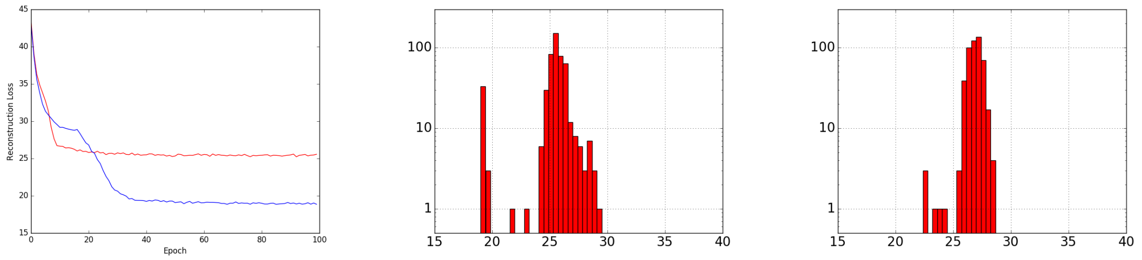
MBC-ICP is able to achieve very competitive performance without any further finetuning or use of large corpora. GAN-based methods on the other hand require iterative finetuning (Conneau et al., 2017; Hoshen and Wolf, 2018) to achieve competitive performance. To facilitate comparison with such methods, we also add a variant of our method with identical finetuning to (Conneau et al., 2017). As we show in the results section, fine-tuning European languages typically results in small improvements in accuracy (1-2%) for our method, in comparison to 10-15% for the previous work. Following (Xing et al., 2015; Conneau et al., 2017), fine-tuning is performed by running the Procrustes method iteratively on the full vocabulary of 200k words, initialized with the final transformation matrix from MBC-ICP. The Procrustes method uses SVD to find the optimal orthonormal matrix between $\mathcal{X}$ and $\mathcal{Y}$ given approximate matches. The new transformation is used to finetune the approximate matches. We run 5 iterations of successive transformation and matching estimation steps.

3.4 Matching Metrics

Although we optimize the nearest neighbor metric, we found that in accordance with (Conneau et al., 2017), neighborhood retrieval methods such as Inverted Soft-Max (ISF) (Smith et al., 2017) and Cross-domain Similarity Local Scaling (CSLS) improve final retrieval performance. We therefore evaluate using CSLS. The similarity between a word $x \in \mathcal{X}$ and a word $y \in \mathcal{Y}$ is computed as $2\cos(T_{xy}x, y) - r(T_{xy}x) - r(y)$, where $r(.)$ is the average cosine similarity between the word and its 10-NN in the other domain.

4 Multiple Stochastic Solutions

Our approach utilizes multiple stochastic solutions, to provide a good initialization for the MBC-ICP algorithm. There are two sources of stochasticity in our system: (i) The randomized nature of the PCA algorithm (it uses random matrices (Liberty et al., 2007)) (ii) The order of the training samples (the mini-batches) when training the transformations.



(a) (b) (c)

Figure 1: (a) Evolution of reconstruction loss as a function of epoch number for successful (Blue) and unsuccessful runs (Red). (b) The final reconstruction loss distribution for En-Fr. (c) A similar histogram for En-Ar.

The main issue faced by unsupervised learning in the case of multiple solutions, is either (i) choosing the best solution in case of a fixed parallel run budget, or (ii) finding a good stopping criterion if attempting to minimize the number of runs serially.

We use the reconstruction cost as an unsupervised metrics for measuring convergence of MBC-ICP. Specifically, we measure how closely every $x \in \mathcal{X}$ and $y \in \mathcal{Y}$ is reconstructed by a transformed word from the other domain.

$$\sum_j \|y_j - T_{xy} x_{f_y(j)}\| + \sum_i \|x_i - T_{yx} y_{f_x(i)}\| \quad (2)$$

Although for isotropic distributions this has many degenerate solutions, empirically we find that values that are significantly lower than the median almost always correspond to a good solution.

The optimization profile of MBC-ICP is predictable and easily lends itself for choosing effective termination criteria. The optimization profile of a successfully converged and non-converging runs are presented in Fig. 1(a). The reconstruction loss clearly distinguish between the converged and non-converging runs. Fig. 1(b,c) presents the distribution of final reconstruction costs for 500 different runs for En-Fr and En-Ar.

5 Experiments

We evaluated our method extensively to ensure that it is indeed able to effectively and efficiently perform unsupervised word translation. As a strong baseline, we used the code and datasets from the MUSE repository by Conneau et al. (2017)[1]. Care was taken in order to make sure that we report these results as fairly as possible: (1) the results from the previous work were copied as is, except for En-It, where our runs indicated better baseline results. (2) For languages not reported, we ran the code with multiple options and report the best results obtained. One crucial option for GAN was whether to center the data or not. From communication with the authors we learned that, in nearly all non-European languages, centering the data is crucial. For European languages, not centering gave better results. For Arabic, centering helps in one direction but is very detrimental in the other. In all such cases, we report the best baseline result per direction. (3) For the supervised baseline, we report both the results from the original paper (in Tab. 1) and the results post Procrustes finetuning, which are better (Tab. 2). (4) Esperanto is not available in the MUSE repository at this time. We asked the authors for the data and will update the paper once available. Currently we are able to say (without the supervision data) that our method converges on En-Eo and Eo-En.

The evaluation concentrated on two aspects of the translation: (i) Word Translation Accuracy measured by the fraction of words translated to a correct meaning in the target language, and (ii) Runtime of the method.

We evaluated our method against the best methods from (Conneau et al., 2017). The supervised baseline method learns an alignment from 5k supervised matches using the Procrustes method. The mapping is then refined using the Procrustes method and CSLS matching on 200k unsupervised word vectors in the source and target languages. The unsupervised method proposed by (Conneau et al., 2017), uses generative adversarial domain mapping between the word vectors of the 50k most common words in each language. The mapping is then refined using the same procedure that is used in the supervised baseline.

A comparison of the word translation accura-

---

[1] https://github.com/facebookresearch/MUSE

cies before finetuning can be seen in Tab. 1. Our method significantly outperforms the method of (Conneau et al., 2017) on all of the evaluated European language pairs. Additionally, for these languages, our method performs comparably to the supervised baseline on all pairs except En-Ru for which supervision seems particularly useful. The same trends are apparent for simple nearest neighbors and CSLS although CSLS always performs better. For non-European languages, none of the unsupervised methods succeeds on all languages. We found that the GAN baseline fails on Farsi, Hindu, Bengali, Vietnamese and one direction of Japanese and Indonesian while our method does not succeed on Chinese, Japanese and Vietnamese. We conclude that the methods have complementary strengths, our method doing better on more languages. On languages where both methods succeed, MBC-ICP tends to do much better.

We present a comparison between the methods after finetuning and using the CSLS metric in Tab. 2. All methods underwent the same finetuning procedure. We can see that our method still outperforms the GAN method and is comparable to the supervised baseline on European languages. Another observation is that on most European language pairs, finetuning only makes a small difference for our method (1-2%). An unaligned vocabulary of 7.5k is sufficient to achieve most of the accuracy. This is in contrast with the GAN, that benefits greatly from finetuning on 200k words. Non-European language and English pairs are typically more challenging, finetuning helps much more for all unsupervised methods.

It is interesting to examine the languages on which each method could not converge. They typically fall into geographical and semantic clusters. The GAN method failed on Arabic and Hebrew, Hindu, Farsi and Bengali. Whereas our method failed on Japanese and Chinese. We suspect that different statistical properties favor each method.

We also compare the different methods in terms of training time required by the method. We emphasize that our method is trivially parallelizable, simply by splitting the random initializations between workers. The run time of each solution of MBC-ICP is 47 seconds on CPU. The run time of all solutions can therefore be as low as a single run, at linear increase in compute resources. As it runs on CPU, parallelization is not expensive. The average number of runs required for convergence depends on the language pair (see below, Fig. 2). We note that our method learns translations for both languages at the same time.

Table 1: Comparison of word translation accuracy (%) - without finetuning. Bold: best unsupervised method.

*Failed to converge

The current state-of-the-art baseline by (Conneau et al., 2017) requires around 3000 seconds on the GPU. It is not obvious how to parallelize such a method efficiently. It requires about 30 times longer to train than our method (with parallelization) and is not practical on a multi-CPU platform. The optional refinement step requires about 10 minutes. The performance increase of refinement for our method are typically quite modest and can be be skipped at the cost of 1-2% in accuracy, the GAN however requires finetuning to obtain competitive results. Another obvious advan-

tage is that our method does not require a GPU.

Implementation: We used 100 iterations for the PCA-MBC-ICP stage on 50 PCA word vectors. This was run in parallel over 500 stochastic solutions. We selected the solution with the smallest unsupervised reconstitution criterion. This solution was used to initialize RAW-MBC-PCA, which we run for 100 iterations on the raw word vectors. The latter 50 iterations of RAW-MBC-ICP were carried out with only reciprocal pairs contributing to the optimization. Results were typically not sensitive to hyper-parameter choice, although longer optimization generally resulted in better performance.

Table 3: En-Es accuracy with and without PCA

Method	En-Es	Es-En
No PCA	0.0%	0.0%
With 300 PCs	0.0%	0.0%
With 50 PCs	**82.2%**	**83.8%**

Table 4: Fraction of converging runs per stochasticity.

Method	En-Es	En-Ar
No randomization	0.0%	0.0%
Randomized Ordering	0.0%	0.0%
Randomized PCA	9.8%	0.0%
Randomized Ordering + PCA	**16.8%**	**1.2%**

Ablation Analyses There are three important steps for the convergence of the ICP step: (i) PCA, (ii) Dimensionality reduction, (iii) Multiple stochastic solutions. In Tab. 3 we present the ablation results on the En-Es pair with PCA and no dimensionality reduction, with only the top 50 PCs and without PCA at all (best run out of 500 chosen using the unsupervised reconstruction loss). We can observe that the convergence rate without PCA and with PCA but without dimensionality reduction is much lower than with PCA, the best run without PCA has not succeeded in obtaining a good translation. This provides evidence that both PCA and dimensionality reduction are essential for the success of the method.

We experimented with the different factors of randomness between runs, to understand the causes of diversity allowing for convergence in the more challenging language pairs (such as En-Ar). We performed the following four experiments: i. Fixing PCA and Batch Ordering. ii. Fixing all data batches to have the same ordering in all runs, iii. Fix the PCA bases of all runs, iv. Let both PCA and batch ordering vary between runs.

Tab. 4 compares the results on En-Es and En-Ar for the experiments described above. It can be seen that using both sources of stochasticity is usually better. Although there is some probability the PCA will result in aligned principle components between the two languages, this usually does not happen and therefore using stochastic PCA is highly beneficial.

Convergence Statistics In Fig. 2 we present the statistics for all language pairs with Procrustes-ICP (P-ICP) vs MBC-ICP. In P-ICP, we first calculate the matches for the vocabulary, and then perform a batch estimate of the transformation using the P-ICP method (starting from PCA word

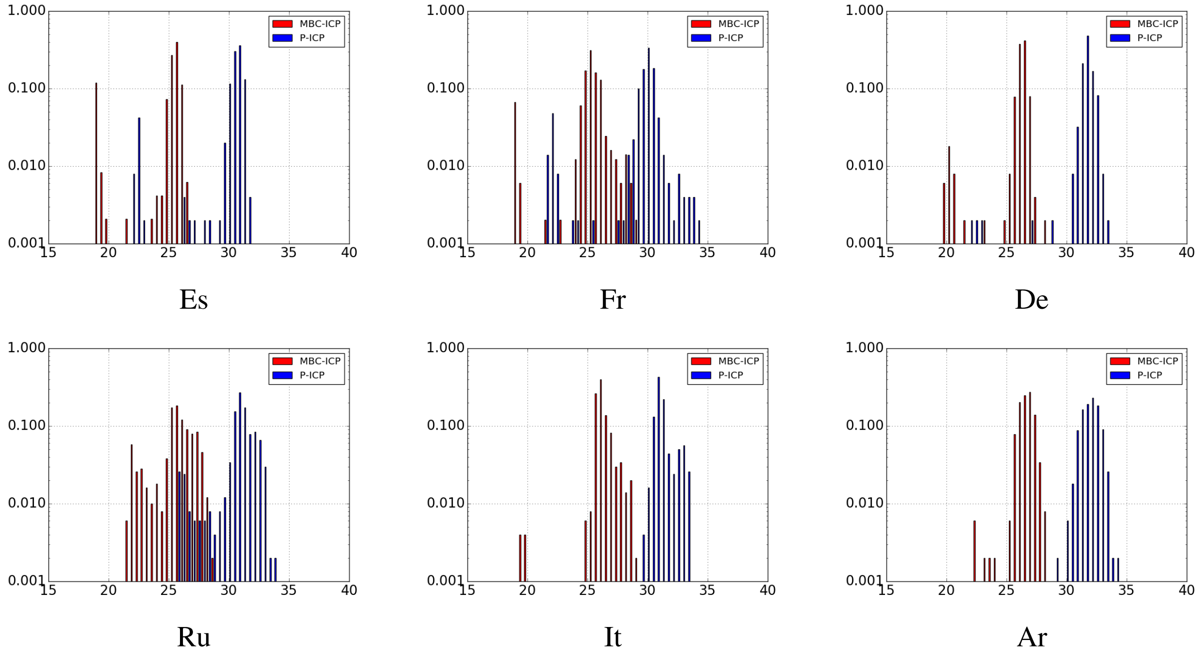

Figure 2: Histograms of the Reconstruction metric across 500 ICP runs for MBC-ICP (Red) and P-ICP (Blue). The comparison is shown for En-Es, En-Fr, En-De, En-Ru, En-It, En-Ar. On average MBC-ICP converges to much better minima. We can observe that MBC-ICP has many more converging runs than P-ICP. In fact for En-It and En-Ar, P-ICP does not converge even once in 500 runs.

vectors and T_{xy} initialized at identity). The only source of stochasticity in P-ICP is the PCA where in MBC-ICP the order of mini-batches provides further stochasticity. Adding random noise to the mapping initialization was not found to help. Each plot shows the histogram in log space for the number of runs that achieved unsupervised reconstruction loss within the range of the bin. The converged runs with lower reconstruction values typically form a peak which is quite distinct from the non-converged runs allowing for easy detection of converged runs. The rate of convergence generally correlates with our intuition for distance between languages (En-Ar much lower than En-Fr), although there are exceptions.

MBC-ICP converges much better than P-ICP: For the language pairs with a wide convergence range (En-Es, En-Fr, En-Ru) we can see that MBC-ICP converged on many more runs than P-ICP. For the languages with a narrow convergence range (En-Ar, En-It), P-ICP was not able to converge at all. We therefore conclude that the mini-batch update and batch-ordering stochasticity increase the convergence range and is important for effective unsupervised matching.

6 Conclusions

We have presented an effective technique for unsupervised word-to-word translation. Our method is simple and non-adversarial. We showed empirically that our method outperforms current state-of-the-art GAN methods in terms of pre and post finetuning word translation accuracy. Our method runs on CPU and is much faster than current methods when using parallelization. This will enable researchers from labs that do not possess graphical computing resources to participate in this exciting field. The proposed method is interpretable, i.e. every stage has an intuitive loss function with an easy to understand objective.

It is interesting to consider the relative performance between language pairs. Typically more related languages yielded better performance than more distant languages (but note that Indonesian performed better than Russian when translated to English). Even more interesting is contrasting the better performance of our method on West and South Asian languages, and GAN's better performance on Chinese.

Overall, our work highlights the potential benefits of considering alternatives to adversarial methods in unsupervised learning.

Semi-Autoregressive Neural Machine Translation

Chunqi Wang[*] **Ji Zhang** **Haiqing Chen**

Abstract

Existing approaches to neural machine translation are typically autoregressive models. While these models attain state-of-the-art translation quality, they are suffering from low parallelizability and thus slow at decoding long sequences. In this paper, we propose a novel model for fast sequence generation — the semi-autoregressive Transformer (SAT). The SAT keeps the autoregressive property in global but relieves in local and thus are able to produce multiple successive words in parallel at each time step. Experiments conducted on English-German and Chinese-English translation tasks show that the SAT achieves a good balance between translation quality and decoding speed. On WMT'14 English-German translation, the SAT achieves 5.58× speedup while maintaining 88% translation quality, significantly better than the previous non-autoregressive methods. When produces two words at each time step, the SAT is almost lossless (only 1% degeneration in BLEU score).

1 Introduction

Neural networks have been successfully applied to a variety of tasks, including machine translation. The encoder-decoder architecture is the central idea of neural machine translation (NMT). The encoder first encodes a source-side sentence $\mathbf{x} = x_1 \dots x_m$ into hidden states and then the decoder generates the target-side sentence $\mathbf{y} = y_1 \dots y_n$ from the hidden states according to an autoregressive model

$$p(y_t | y_1 \dots y_{t-1}, \mathbf{x})$$

Recurrent neural networks (RNNs) are inherently good at processing sequential data. Sutskever et al. (2014); Cho et al. (2014) successfully applied RNNs to machine translation. Bahdanau et al. (2014) introduced attention mechanism into the encoder-decoder architecture and greatly improved NMT. GNMT (Wu et al., 2016) further improved NMT by a bunch of tricks including residual connection and reinforcement learning.

The sequential property of RNNs leads to its wide application in language processing. However, the property also hinders its parallelizability thus RNNs are slow to execute on modern hardware optimized for parallel execution. As a result, a number of more parallelizable sequence models were proposed such as ConvS2S (Gehring et al., 2017) and the Transformer (Vaswani et al., 2017). These models avoid the dependencies between dif-

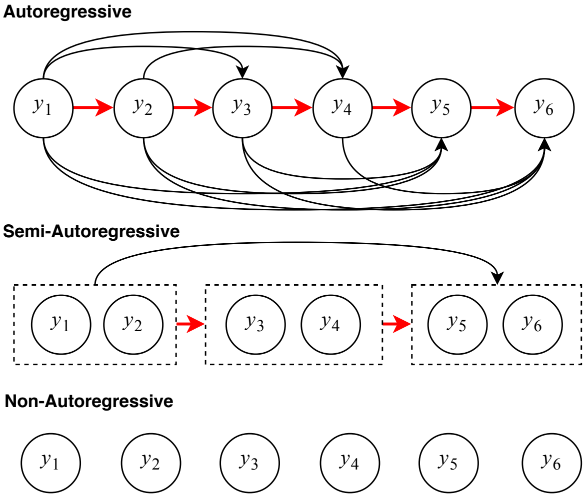

Figure 1: The different levels of autoregressive properties. Lines with arrow indicate dependencies. We mark the longest dependency path with bold red lines. The length of the longest dependency path decreases as we relieve the autoregressive property. An extreme case is *non-autoregressive*, where there is no dependency at all.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 479–488
Brussels, Belgium, October 31 - November 4, 2018.

ferent positions in each layer thus can be trained much faster than RNN based models. When inference, however, these models are still slow because of the autoregressive property.

A recent work (Gu et al., 2017) proposed a non-autoregressive NMT model that generates all target-side words in parallel. While the parallelizability is greatly improved, the translation quality encounter much decrease. In this paper, we propose the semi-autoregressive Transformer (SAT) for faster sequence generation. Unlike Gu et al. (2017), the SAT is semi-autoregressive, which means it keeps the autoregressive property in global but relieves in local. As the result, the SAT can produce multiple successive words in parallel at each time step. Figure 1 gives an illustration of the different levels of autoregressive properties.

Experiments conducted on English-German and Chinese-English translation show that compared with non-autoregressive methods, the SAT achieves a better balance between translation quality and decoding speed. On WMT'14 English-German translation, the proposed SAT is 5.58× faster than the Transformer while maintaining 88% of translation quality. Besides, when producing two words at each time step, the SAT is almost lossless.

It is worth noting that although we apply the SAT to machine translation, it is not designed specifically for translation as Gu et al. (2017); Lee et al. (2018). The SAT can also be applied to any other sequence generation task, such as summary generation and image caption generation.

2 Related Work

Almost all state-of-the-art NMT models are autoregressive (Sutskever et al., 2014; Bahdanau et al., 2014; Wu et al., 2016; Gehring et al., 2017; Vaswani et al., 2017), meaning that the model generates words one by one and is not friendly to modern hardware optimized for parallel execution. A recent work (Gu et al., 2017) attempts to accelerate generation by introducing a non-autoregressive model. Based on the Transformer (Vaswani et al., 2017), they made lots of modifications. The most significant modification is that they avoid feeding the previously generated target words to the decoder, but instead feeding the source words, to predict the next target word. They also introduced a set of latent variables to model the *fertilities* of source words to tackle the multimodality problem in translation. Lee et al. (2018) proposed another non-autoregressive sequence model based on iterative refinement. The model can be viewed as both a latent variable model and a conditional denoising autoencoder. They also proposed a learning algorithm that is hybrid of lower-bound maximization and reconstruction error minimization.

The most relevant to our proposed semi-autoregressive model is (Kaiser et al., 2018). They first autoencode the target sequence into a shorter sequence of discrete latent variables, which at inference time is generated autoregressively, and finally decode the output sequence from this shorter latent sequence in parallel. What we have in common with their idea is that we have not entirely abandoned autoregressive, but rather shortened the autoregressive path.

A related study on realistic speech synthesis is the parallel WaveNet (Oord et al., 2017). The paper introduced *probability density distillation*, a new method for training a parallel feed-forward network from a trained WaveNet (Van Den Oord et al., 2016) with no significant difference in quality.

There are also some work share a somehow simillar idea with our work: character-level NMT (Chung et al., 2016; Lee et al., 2016) and chunk-based NMT (Zhou et al., 2017; Ishiwatari et al., 2017). Unlike the SAT, these models are not able to produce multiple tokens (characters or words) each time step. Oda et al. (2017) proposed a bit-level decoder, where a word is represented by a binary code and each bit of the code can be predicted in parallel.

3 The Transformer

Since our proposed model is built upon the Transformer (Vaswani et al., 2017), we will briefly introduce the Transformer. The Transformer uses an encoder-decoder architecture. We describe the encoder and decoder below.

3.1 The Encoder

From the source tokens, learned embeddings of dimension d_{model} are generated which are then modified by an additive positional encoding. The positional encoding is necessary since the network does not leverage the order of the sequence by recurrence or convolution. The authors use additive encoding which is defined as:

$$PE(pos, 2i) = sin(pos/10000^{2i/d_{model}})$$
$$PE(pos, 2i+1) = cos(pos/10000^{2i/d_{model}})$$

where pos is the position of a word in the sentence and i is the dimension. The authors chose this function because they hypothesized it would allow the model to learn to attend by relative positions easily. The encoded word embeddings are then used as input to the encoder which consists of N blocks each containing two layers: (1) a multi-head attention layer, and (2) a position-wise feed-forward layer.

Multi-head attention builds upon scaled dot-product attention, which operates on a query Q, key K and value V:

$$Attention(Q, K, V) = softmax(\frac{QK^T}{\sqrt{d_k}})V$$

where d_k is the dimension of the key. The authors scale the dot product by $1/\sqrt{d_k}$ to avoid the inputs to softmax function growing too large in magnitude. Multi-head attention computes h different queries, keys and values with h linear projections, computes scaled dot-product attention for each query, key and value, concatenates the results, and projects the concatenation with another linear projection:

$$H_i = Attention(QW_i^Q, KW_i^K, VW_i^V)$$
$$MultiHead(Q, K, V) = Concat(H_1, \dots H_h)$$

in which $W_i^Q, W_i^K \in \mathbb{R}^{d_{model} \times d_k}$ and $W_i^V \in \mathbb{R}^{d_{model} \times d_v}$. The attention mechanism in the encoder performs attention over itself ($Q = K = V$), so it is also called self-attention.

The second component in each encoder block is a position-wise feed-forward layer defined as:

$$FFN(x) = max(0, xW_1 + b_1)W_2 + b_2$$

where $W_1 \in \mathbb{R}^{d_{model} \times d_{ff}}$, $W_2 \in \mathbb{R}^{d_{ff} \times d_{model}}$, $b_1 \in \mathbb{R}^{d_{ff}}$, $b_2 \in \mathbb{R}^{d_{model}}$.

For more stable and faster convergence, residual connection (He et al., 2016) is applied to each layer, followed by layer normalization (Ba et al., 2016). For regularization, dropout (Srivastava et al., 2014) are applied before residual connections.

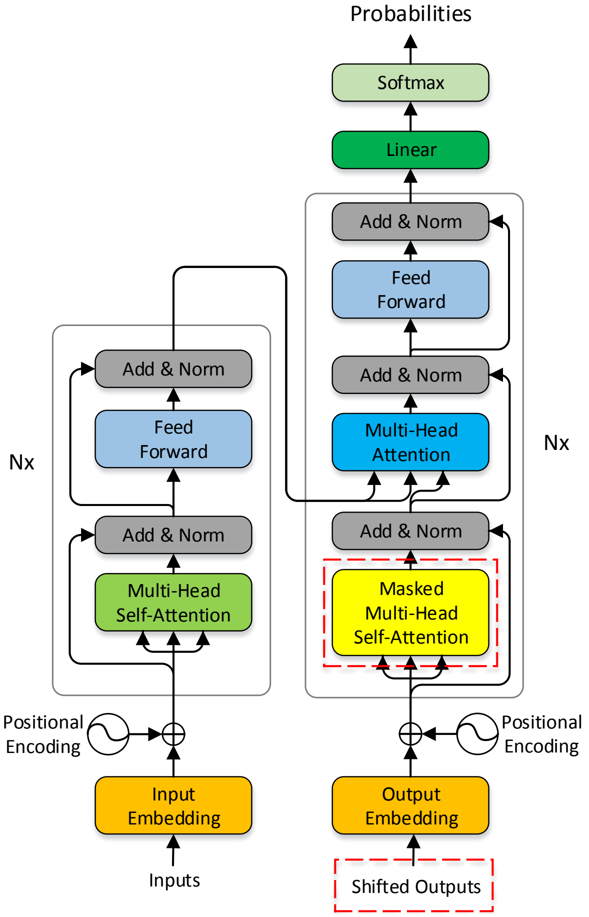

Figure 2: The architecture of the Transformer, also of the SAT, where the red dashed boxes point out the different parts of these two models.

3.2 The Decoder

The decoder is similar with the encoder and is also composed by N blocks. In addition to the two layers in each encoder block, the decoder inserts a third layer, which performs multi-head attention over the output of the encoder.

It is worth noting that, different from the encoder, the self-attention layer in the decoder must be masked with a causal mask, which is a lower triangular matrix, to ensure that the prediction for position i can depend only on the known outputs at positions less than i during training.

4 The Semi-Autoregressive Transformer

We propose a novel NMT model—the Semi-Autoregressive Transformer (SAT)—that can produce multiple successive words in parallel. As shown in Figure 2, the architecture of the SAT is almost the same as the Transformer, except some modifications in the decoder.

4.1 Group-Level Chain Rule

Standard NMT models usually factorize the joint probability of a word sequence $y_1 \dots y_n$ according to the word-level chain rule

$$p(y_1 \dots y_n|\mathbf{x}) = \prod_{t=1}^{n} p(y_t|y_1 \dots y_{t-1}, \mathbf{x})$$

resulting in decoding each word depending on all previous decoding results, thus hindering the parallelizability. In the SAT, we extend the standard word-level chain rule to the group-level chain rule.

We first divide the word sequence $y_1 \dots y_n$ into consecutive groups

$$G_1, G_2, \dots, G_{[(n-1)/K]+1} =$$
$$y_1 \cdots y_K, y_{K+1} \cdots y_{2K}, \dots, y_{[(n-1)/K]\times K+1} \cdots y_n$$

where $[\cdot]$ denotes floor operation, K is the group size, and also the indicator of parallelizability. The larger the K, the higher the parallelizability. Except for the last group, all groups must contain K words. Then comes the group-level chain rule

$$p(y_1 \dots y_n|\mathbf{x}) = \prod_{t=1}^{[(n-1)/K]+1} p(G_t|G_1 \dots G_{t-1}, \mathbf{x})$$

This group-level chain rule avoids the dependencies between consecutive words if they are in the same group. With group-level chain rule, the model no longer produce words one by one as the Transformer, but rather group by group. In next subsections, we will show how to implement the model in detail.

4.2 Long-Distance Prediction

In autoregressive models, to predict y_t, the model should be fed with the previous word y_{t-1}. We refer it as *short-distance prediction*. In the SAT, however, we feed y_{t-K} to predict y_t, to which we refer as *long-distance prediction*. At the beginning of decoding, we feed the model with K special symbols <s> to predict $y_1 \dots y_K$ in parallel. Then $y_1 \dots y_K$ are fed to the model to predict $y_{K+1} \dots y_{2K}$ in parallel. This process will continue until a terminator </s> is generated. Figure 3 gives illustrations for both short and long-distance prediction.

4.3 Relaxed Causal Mask

In the Transformer decoder, the causal mask is a lower triangular matrix, which strictly prevents earlier decoding steps from peeping information from later steps. We denote it as *strict causal mask*. However, in the SAT decoder, strict causal mask is not a good choice. As described in the previous subsection, in long-distance prediction, the model predicts y_{K+1} by feeding with y_1. With strict causal mask, the model can only access to y_1 when predict y_{K+1}, which is not reasonable since $y_1 \dots y_K$ are already produced. It is better to allow the model to access to $y_1 \dots y_K$ rather than only y_1 when predict y_{K+1}.

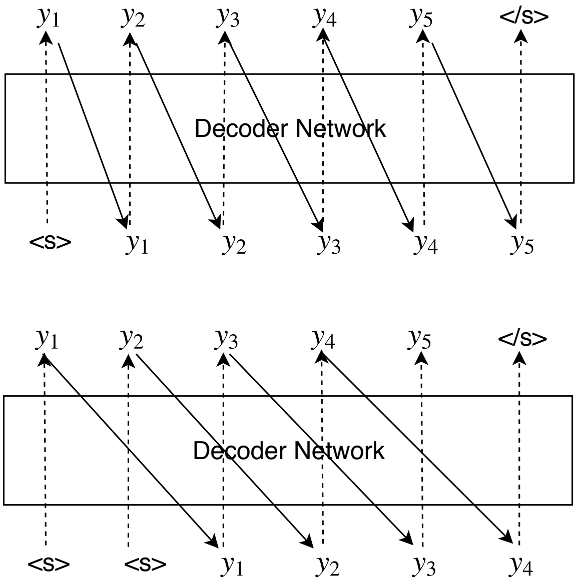

Figure 3: Short-distance prediction (top) and long-distance prediction (bottom).

Therefore, we use a coarse-grained lower triangular matrix as the causal mask that allows peeping later information in the same group. We refer to it as *relaxed causal mask*. Given the target length n and the group size K, relaxed causal mask $M \in \mathbb{R}^{n\times n}$ and its elements are defined below:

$$M[i][j] = \begin{cases} 1 & \text{if } j < ([(i-1)/K]+1) \times K \\ 0 & \text{other} \end{cases}$$

For a more intuitive understanding, Figure 4 gives a comparison between strict and relaxed causal mask.

4.4 The SAT

Using group-level chain rule instead of word-level chain rule, long-distance prediction instead of short-distance prediction, and relaxed causal

$$\begin{bmatrix} 1 & \mathbf{0} & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & \mathbf{0} & 0 & 0 \\ 1 & 1 & 1 & 1 & 0 & 0 \\ 1 & 1 & 1 & 1 & 1 & \mathbf{0} \\ 1 & 1 & 1 & 1 & 1 & 1 \end{bmatrix} \quad \begin{bmatrix} 1 & \mathbf{1} & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & \mathbf{1} & 0 & 0 \\ 1 & 1 & 1 & 1 & 0 & 0 \\ 1 & 1 & 1 & 1 & 1 & \mathbf{1} \\ 1 & 1 & 1 & 1 & 1 & 1 \end{bmatrix}$$

Figure 4: Strict causal mask (left) and relaxed causal mask (right) when the target length $n = 6$ and the group size $K = 2$. We mark their differences in bold.

Model	Complexity	Acceleration
Transformer	$N(a+b)$	1
SAT (beam search)	$\frac{N}{K}a + Nb$	$K(\frac{a+b}{a+Kb})$
SAT (greedy search)	$\frac{N}{K}(a+b)$	K

Table 1: Theoretical complexity and acceleration of the SAT. a denotes the time consumed on the decoder network (calculating a distribution over the target vocabulary) each time step and b denotes the time consumed on search (searching for top scores, expanding nodes and pruning). In practice, a is usually much larger than b since the network is deep.

mask instead of strict causal mask, we successfully extended the Transformer to the SAT. The Transformer can be viewed as a special case of the SAT, when the group size $K = 1$. The non-autoregressive Transformer (NAT) described in Gu et al. (2017) can also be viewed as a special case of the SAT, when the group size K is not less than maximum target length.

Table 1 gives the theoretical complexity and acceleration of the model. We list two search strategies separately: beam search and greedy search. Beam search is the most prevailing search strategy. However, it requires the decoder states to be updated once every word is generated, thus hinders the decoding parallelizability. When decode with greedy search, there is no such concern, therefore the parallelizability of the SAT can be maximized.

5 Experiments

We evaluate the proposed SAT on English-German and Chinese-English translation tasks.

5.1 Experimental Settings

Datasets For English-German translation, we choose the corpora provided by WMT 2014 (Bojar et al., 2014). We use the newstest2013 dataset for development, and the newstest2014 dataset for test. For Chinese-English translation, the corpora we use is extracted from LDC[1]. We chose the NIST02 dataset for development, and the NIST03, NIST04 and NIST05 datasets for test. For English and German, we tokenized and segmented them into subword symbols using byte-pair encoding (BPE) (Sennrich et al., 2015) to restrict the vocabulary size. As for Chinese, we segmented sentences into characters. For English-German translation, we use a shared source and target vocabulary. Table 2 summaries the two corpora.

	Sentence Number	Vocab Size	
		Source	Target
EN-DE	4.5M	36K	36K
ZH-EN	1.8M	9K	34K

Table 2: Summary of the two corpora.

Baseline We use the base Transformer model described in Vaswani et al. (2017) as the baseline, where $d_{model} = 512$ and $N = 6$. In addition, for comparison, we also prepared a lighter Transformer model, in which two encoder/decoder blocks are used ($N = 2$), and other hyper-parameters remain the same.

Hyperparameters Unless otherwise specified, all hyperparameters are inherited from the base Transformer model. We try three different settings of the group size K: $K = 2$, $K = 4$, and $K = 6$. For English-German translation, we share the same weight matrix between the source and target embedding layers and the pre-softmax linear layer. For Chinese-English translation, we only share weights of the target embedding layer and the pre-softmax linear layer.

Search Strategies We use two search strategies: beam search and greedy search. As mentioned in Section 4.4, these two strategies lead to different parallelizability. When beam size is set to 1, greedy search is used, otherwise, beam search is used.

Knowledge Distillation Knowledge distillation (Hinton et al., 2015; Kim and Rush, 2016) describes a class of methods for training a smaller *student* network to perform better by learning from a larger *teacher* network. For NMT, Kim and Rush (2016) proposed a sequence-level knowledge distillation method. In this work, we apply this method to train the SAT using a pre-trained

Table 3: Results on English-German translation. Latency is calculated on a single NVIDIA TITAN Xp without batching. For comparison, we also list results reported by Gu et al. (2017); Kaiser et al. (2018); Lee et al. (2018). Note that Gu et al. (2017); Lee et al. (2018) used PyTorch as their platform, but we and Kaiser et al. (2018) used TensorFlow. Even on the same platform, implementation and hardware may not exactly be the same. Therefore, it is not fair to directly compare BLEU and latency. A fairer way is to compare performance degradation and speedup, which are calculated based on their own baseline.

autoregressive Transformer network. This method consists of three steps: (1) train an autoregressive Transformer network (the *teacher*), (2) run beam search over the training set with this model and (3) train the SAT (the *student*) on this new created corpus.

Initialization Since the SAT and the Transformer have only slight differences in their architecture (see Figure 2), in order to accelerate convergence, we use a pre-trained Transformer model to initialize some parameters in the SAT. These parameters include all parameters in the encoder, source and target word embeddings, and pre-softmax weights. Other parameters are initialized randomly. In addition to accelerating convergence, we find this method also slightly improves the translation quality.

Training Same as Vaswani et al. (2017), we train the SAT by minimize cross-entropy with label smoothing. The optimizer we use is Adam (Kingma and Ba, 2015) with $\beta_1 = 0.9$, $\beta_2 = 0.98$ and $\varepsilon = 10^{-9}$. We change the learning rate during training using the learning rate funtion described in Vaswani et al. (2017). All models are trained for 10K steps on 8 NVIDIA TITAN Xp with each minibatch consisting of about 30k tokens. For evaluation, we average last five checkpoints saved with an interval of 1000 training steps.

Evaluation Metrics We evaluate the translation quality of the model using BLEU score (Papineni et al., 2002).

Implementation We implement the proposed SAT with *TensorFlow* (Abadi et al., 2016). The code and resources needed for reproducing the results are released at `https://github.com/chqiwang/sa-nmt`.

5.2 Results on English-German

Table 3 summaries results of English-German translation. According to the results, the translation quality of the SAT gradually decreases as K increases, which is consistent with intuition. When K = 2, the SAT decodes 1.51× faster than the Transformer and is almost lossless in translation quality (only drops 0.21 BLEU score). With K = 6, the SAT can achieve 2.98× speedup while the performance degeneration is only 8%.

When using greedy search, the acceleration becomes much more significant. When K = 6, the decoding speed of the SAT can reach about 5.58× of the Transformer while maintaining 88%

Model	b=1	b=16	b=32	b=64
Transformer	346ms	58ms	53ms	56ms
SAT, K=2	229ms	38ms	32ms	32ms
SAT, K=4	149ms	24ms	21ms	20ms
SAT, K=6	116ms	20ms	17ms	16ms

Table 4: Time needed to decode one sentence under various batch size settings. A single NVIDIA TIAN Xp is used in this test.

Model	K=1	K=2	K=4	K=6
Latency	1384ms	607ms	502ms	372ms

Table 5: Time needed to decode one sentence on CPU device. Sentences are decoded one by one without batching. K=1 denotes the Transformer.

of translation quality. Comparing with Gu et al. (2017); Kaiser et al. (2018); Lee et al. (2018), the SAT achieves a better balance between translation quality and decoding speed. Compared to the lighter Transformer (N = 2), with K = 4, the SAT achieves a higher speedup with significantly better translation quality.

In a real production environment, it is often not to decode sentences one by one, but batch by batch. To investigate whether the SAT can accelerate decoding when decoding in batches, we test the decoding latency under different batch size settings. As shown in Table 4, the SAT significantly accelerates decoding even with a large batch size.

It is also good to know if the SAT can still accelerate decoding on CPU device that does not support parallel execution as well as GPU. Results in Table 5 show that even on CPU device, the SAT can still accelerate decoding significantly.

5.3 Results on Chinese-English

Table 6 summaries results on Chinese-English translation. With K = 2, the SAT decodes 1.69× while maintaining 97% of the translation quality. In an extreme setting where K = 6 and beam size = 1, the SAT can achieve 6.41× speedup while maintaining 83% of the translation quality.

5.4 Analysis

Effects of Knowledge Distillation As shown in Figure 5, sequence-level knowledge distillation is very effective for training the SAT. For larger K, the effect is more significant. This phenomenon is echoing with observations by Gu et al. (2017); Oord et al. (2017); Lee et al. (2018). In addition, we tried word-level knowledge distillation (Kim and Rush, 2016) but only a slight improvement was observed.

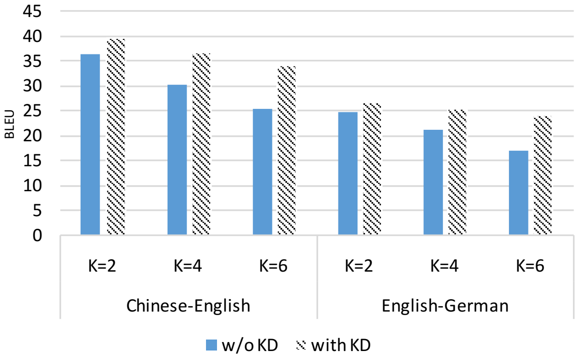

Figure 5: Performance of the SAT with and without sequence-level knowledge distillation.

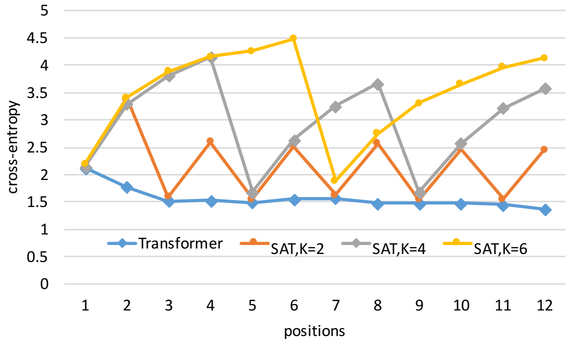

Figure 6: Position-wise cross-entropy for various models on English-German translation.

Position-Wise Cross-Entropy In Figure 6, we plot position-wise cross-entropy for various models. To compare with the baseline model, the results in the figure are from models trained on the original corpora, i.e., without knowledge distillation. As shown in the figure, position-wise cross-entropy has an apparent periodicity with a period of K. For positions in the same group, the position-wise cross-entropy increase monotonously, which indicates that the long-distance dependencies are always more difficult to model than short ones. It suggests the key to further improve the SAT is to improve the ability of modeling long-distance dependencies.

Case Study Table 7 lists three sample Chinese-English translations from the development set. As shown in the table, even when producing K = 6 words at each time step, the model can still gen-

Table 7: Three sample Chinese-English translations by the SAT and the Transformer. We mark repeated words or phrases by red font and underline.

erate fluent sentences. As reported by Gu et al. (2017), instances of repeated words or phrases are most prevalent in their non-autoregressive model. In the SAT, this is also the case. This suggests that we may be able to improve the translation quality of the SAT by reducing the similarity of the output distribution of adjacent positions.

6 Conclusion

In this work, we have introduced a novel model for faster sequence generation based on the Transformer (Vaswani et al., 2017), which we refer to as the semi-autoregressive Transformer (SAT). Combining the original Transformer with group-level chain rule, long-distance prediction and relaxed causal mask, the SAT can produce multiple consecutive words at each time step, thus speedup decoding significantly. We conducted experiments on English-German and Chinese-English translation. Compared with previously proposed non-autoregressive models (Gu et al., 2017; Lee et al., 2018; Kaiser et al., 2018), the SAT achieves a better balance between translation quality and decoding speed. On WMT'14 English-German translation, the SAT achieves 5.58× speedup while maintaining 88% translation quality, significantly better than previous methods. When producing two words at each time step, the SAT is almost lossless (only 1% degeneration in BLEU score).

In the future, we plan to investigate better methods for training the SAT to further shrink the performance gap between the SAT and the Transformer. Specifically, we believe that the following two directions are worth study. First, use object function beyond maximum likelihood to improve the modeling of long-distance dependencies. Second, explore new method for knowledge distillation. We also plan to extend the SAT to allow the use of different group sizes K at different positions, instead of using a fixed value.

Abstract

An effective method to improve neural machine translation with monolingual data is to augment the parallel training corpus with back-translations of target language sentences. This work broadens the understanding of back-translation and investigates a number of methods to generate synthetic source sentences. We find that in all but resource poor settings back-translations obtained via sampling or noised beam outputs are most effective. Our analysis shows that sampling or noisy synthetic data gives a much stronger training signal than data generated by beam or greedy search. We also compare how synthetic data compares to genuine bitext and study various domain effects. Finally, we scale to hundreds of millions of monolingual sentences and achieve a new state of the art of 35 BLEU on the WMT'14 English-German test set.

1 Introduction

Machine translation relies on the statistics of large parallel corpora, i.e. datasets of paired sentences in both the source and target language. However, bitext is limited and there is a much larger amount of monolingual data available. Monolingual data has been traditionally used to train language models which improved the fluency of statistical machine translation (Koehn, 2010).

In the context of neural machine translation (NMT; Bahdanau et al. 2015; Gehring et al. 2017; Vaswani et al. 2017), there has been extensive work to improve models with monolingual data, including language model fusion (Gulcehre et al., 2015, 2017), back-translation (Sennrich et al., 2016a) and dual learning (Cheng et al., 2016; He et al., 2016a). These methods have different advantages and can be combined to reach high accuracy (Hassan et al., 2018).

We focus on back-translation (BT) which operates in a semi-supervised setup where both bilingual and monolingual data in the target language are available. Back-translation first trains an intermediate system on the parallel data which is used to translate the target monolingual data into the source language. The result is a parallel corpus where the source side is *synthetic* machine translation output while the target is genuine text written by humans. The synthetic parallel corpus is then simply added to the real bitext in order to train a final system that will translate from the source to the target language. Although simple, this method has been shown to be helpful for phrase-based translation (Bojar and Tamchyna, 2011), NMT (Sennrich et al., 2016a; Poncelas et al., 2018) as well as unsupervised MT (Lample et al., 2018a).

In this paper, we investigate back-translation for neural machine translation at a large scale by adding hundreds of millions of back-translated sentences to the bitext. Our experiments are based on strong baseline models trained on the public bitext of the WMT competition. We extend previous analysis (Sennrich et al., 2016a; Poncelas et al., 2018) of back-translation in several ways. We provide a comprehensive analysis of different methods to generate synthetic source sentences and we show that this choice matters: sampling from the model distribution or noising beam outputs outperforms pure beam search, which is typically used, by 1.7 BLEU on average across several test sets. Our analysis shows that synthetic data based on sampling and noised beam search provides a stronger training signal than synthetic data based on argmax inference. We also study how adding synthetic data compares to adding real bitext in a controlled setup with the surprising finding that synthetic data can sometimes match the accuracy of real bitext. Our best setup achieves 35 BLEU on the WMT'14 English-German test set by rely-

ing only on public WMT bitext as well as 226M monolingual sentences. This outperforms the system of DeepL by 1.7 BLEU who train on large amounts of high quality non-benchmark data. On WMT'14 English-French we achieve 45.6 BLEU.

2 Related work

This section describes prior work in machine translation with neural networks as well as semi-supervised machine translation.

2.1 Neural machine translation

We build upon recent work on neural machine translation which is typically a neural network with an encoder/decoder architecture. The encoder infers a continuous space representation of the source sentence, while the decoder is a neural language model conditioned on the encoder output. The parameters of both models are learned jointly to maximize the likelihood of the target sentences given the corresponding source sentences from a parallel corpus (Sutskever et al., 2014; Cho et al., 2014). At inference, a target sentence is generated by left-to-right decoding.

Different neural architectures have been proposed with the goal of improving efficiency and/or effectiveness. This includes recurrent networks (Sutskever et al., 2014; Bahdanau et al., 2015; Luong et al., 2015), convolutional networks (Kalchbrenner et al., 2016; Gehring et al., 2017; Kaiser et al., 2017) and transformer networks (Vaswani et al., 2017). Recent work relies on attention mechanisms where the encoder produces a sequence of vectors and, for each target token, the decoder attends to the most relevant part of the source through a context-dependent weighted-sum of the encoder vectors (Bahdanau et al., 2015; Luong et al., 2015). Attention has been refined with multi-hop attention (Gehring et al., 2017), self-attention (Vaswani et al., 2017; Paulus et al., 2018) and multi-head attention (Vaswani et al., 2017). We use a transformer architecture (Vaswani et al., 2017).

2.2 Semi-supervised NMT

Monolingual target data has been used to improve the fluency of machine translations since the early IBM models (Brown et al., 1990). In phrase-based systems, language models (LM) in the target language increase the score of fluent outputs during decoding (Koehn et al., 2003; Brants et al., 2007). A similar strategy can be applied to NMT (He et al., 2016b). Besides improving accuracy during decoding, neural LM and NMT can benefit from deeper integration, e.g. by combining the hidden states of both models (Gulcehre et al., 2017). Neural architecture also allows multi-task learning and parameter sharing between MT and target-side LM (Domhan and Hieber, 2017).

Back-translation (BT) is an alternative to leverage monolingual data. BT is simple and easy to apply as it does not require modification to the MT training algorithms. It requires training a target-to-source system in order to generate additional synthetic parallel data from the monolingual target data. This data complements human bitext to train the desired source-to-target system. BT has been applied earlier to phrase-base systems (Bojar and Tamchyna, 2011). For these systems, BT has also been successful in leveraging monolingual data for domain adaptation (Bertoldi and Federico, 2009; Lambert et al., 2011). Recently, BT has been shown beneficial for NMT (Sennrich et al., 2016a; Poncelas et al., 2018). It has been found to be particularly useful when parallel data is scarce (Karakanta et al., 2017).

Currey et al. (2017) show that low resource language pairs can also be improved with synthetic data where the source is simply a copy of the monolingual target data. Concurrently to our work, Imamura et al. (2018) show that sampling synthetic sources is more effective than beam search. Specifically, they sample multiple sources for each target whereas we draw only a single sample, opting to train on a larger number of target sentences instead. Hoang et al. (2018) and Cotterell and Kreutzer (2018) suggest an iterative procedure which continuously improves the quality of the back-translation and final systems. Niu et al. (2018) experiment with a multilingual model that does both the forward and backward translation which is continuously trained with new synthetic data.

There has also been work using source-side monolingual data (Zhang and Zong, 2016). Furthermore, Cheng et al. (2016); He et al. (2016a); Xia et al. (2017) show how monolingual text from both languages can be leveraged by extending back-translation to dual learning: when training both source-to-target and target-to-source models jointly, one can use back-translation in both directions and perform multiple rounds of BT. A similar idea is applied in unsupervised NMT (Lample et al., 2018a,b). Besides monolingual data, various approaches have been introduced to benefit from parallel data in other language pairs (Johnson et al., 2017; Firat et al., 2016a,b; Ha et al., 2016; Gu et al., 2018).

Data augmentation is an established technique in computer vision where a labeled dataset is supplemented with cropped or rotated input images. Recently, generative adversarial networks (GANs) have been successfully used to the same end (Antoniou et al., 2017; Perez and Wang, 2017) as well as models that learn distributions over image transformations (Hauberg et al., 2016).

3 Generating synthetic sources

Back-translation typically uses beam search (Sennrich et al., 2016a) or just greedy search (Lample et al., 2018a,b) to generate synthetic source sentences. Both are approximate algorithms to identify the maximum a-posteriori (MAP) output, i.e. the sentence with the largest estimated probability given an input. Beam is generally successful in finding high probability outputs (Ott et al., 2018a).

However, MAP prediction can lead to less rich translations (Ott et al., 2018a) since it always favors the most likely alternative in case of ambiguity. This is particularly problematic in tasks where there is a high level of uncertainty such as dialog (Serban et al., 2016) and story generation (Fan et al., 2018). We argue that this is also problematic for a data augmentation scheme such as back-translation. Beam and greedy focus on the head of the model distribution which results in very regular synthetic source sentences that do not properly cover the true data distribution.

As alternative, we consider sampling from the model distribution as well as adding noise to beam search outputs. First, we explore unrestricted sampling which generates outputs that are very diverse but sometimes highly unlikely. Second, we investigate sampling restricted to the most likely words (Graves, 2013; Ott et al., 2018a; Fan et al., 2018). At each time step, we select the k most likely tokens from the output distribution, renormalize and then sample from this restricted set. This is a middle ground between MAP and unrestricted sampling.

As a third alternative, we apply noising Lample et al. (2018a) to beam search outputs. Adding noise to input sentences has been very beneficial for the autoencoder setups of (Lample et al., 2018a; Hill et al., 2016) which is inspired by denoising autoencoders (Vincent et al., 2008). In particular, we transform source sentences with three types of noise: deleting words with probability 0.1, replacing words by a filler token with probability 0.1, and swapping words which is implemented as a random permutation over the tokens, drawn from the uniform distribution but restricted to swapping words no further than three positions apart.

4 Experimental setup

4.1 Datasets

The majority of our experiments are based on data from the WMT'18 English-German news translation task. We train on all available bitext excluding the ParaCrawl corpus and remove sentences longer than 250 words as well as sentence-pairs with a source/target length ratio exceeding 1.5. This results in 5.18M sentence pairs. For the back-translation experiments we use the German monolingual newscrawl data distributed with WMT'18 comprising 226M sentences after removing duplicates. We tokenize all data with the Moses tokenizer (Koehn et al., 2007) and learn a joint source and target Byte-Pair-Encoding (BPE; Sennrich et al., 2016) with 35K types. We develop on newstest2012 and report final results on newstest2013-2017; additionally we consider a held-out set from the training data of 52K sentence-pairs.

We also experiment on the larger WMT'14 English-French task which we filter in the same way as WMT'18 English-German. This results in 35.7M sentence-pairs for training and we learn a joint BPE vocabulary of 44K types. As monolingual data we use newscrawl2010-2014, comprising 31M sentences after language identification (Lui and Baldwin, 2012). We use newstest2012 as development set and report final results on newstest2013-2015.

The majority of results in this paper are in terms of case-sensitive tokenized BLEU (Papineni et al., 2002) but we also report test accuracy with detokenized BLEU using sacreBLEU (Post, 2018).

4.2 Model and hyperparameters

We re-implemented the Transformer model in pytorch using the fairseq toolkit.[1] All experiments

---

[1] Code available at `https://github.com/pytorch/fairseq`

are based on the Big Transformer architecture with 6 blocks in the encoder and decoder. We use the same hyper-parameters for all experiments, i.e., word representations of size 1024, feed-forward layers with inner dimension 4096. Dropout is set to 0.3 for En-De and 0.1 for En-Fr, we use 16 attention heads, and we average the checkpoints of the last ten epochs. Models are optimized with Adam (Kingma and Ba, 2015) using $\beta_1 = 0.9$, $\beta_2 = 0.98$, and $\epsilon = 1e-8$ and we use the same learning rate schedule as Vaswani et al. (2017). All models use label smoothing with a uniform prior distribution over the vocabulary $\epsilon = 0.1$ (Szegedy et al., 2015; Pereyra et al., 2017). We run experiments on DGX-1 machines with 8 Nvidia V100 GPUs and machines are interconnected by Infiniband. Experiments are run on 16 machines and we perform 30K synchronous updates. We also use the NCCL2 library and the torch distributed package for inter-GPU communication. We train models with 16-bit floating point operations, following Ott et al. (2018b). For final evaluation, we generate translations with a beam of size 5 and with no length penalty.

5 Results

Our evaluation first compares the accuracy of back-translation generation methods (§5.1) and analyzes the results (§5.2). Next, we simulate a low-resource setup to experiment further with different generation methods (§5.3). We also compare synthetic bitext to genuine parallel data and examine domain effects arising in back-translation (§5.4). We also measure the effect of upsampling bitext during training (§5.5). Finally, we scale to a very large setup of up to 226M monolingual sentences and compare to previous research (§5.6).

5.1 Synthetic data generation methods

We first investigate different methods to generate synthetic source translations given a back-translation model, i.e., a model trained in the reverse language direction (Section 5.1). We consider two types of MAP prediction: greedy search (greedy) and beam search with beam size 5 (beam). Non-MAP methods include unrestricted sampling from the model distribution (sampling), restricting sampling to the k highest scoring outputs at every time step with $k = 10$ (top10) as well as adding noise to the beam outputs (beam+noise). Restricted sampling is a middle-ground between beam search and unrestricted sampling, it is less likely to pick very low scoring outputs but still preserves some randomness. Preliminary experiments with top5, top20, top50 gave similar results to top10.

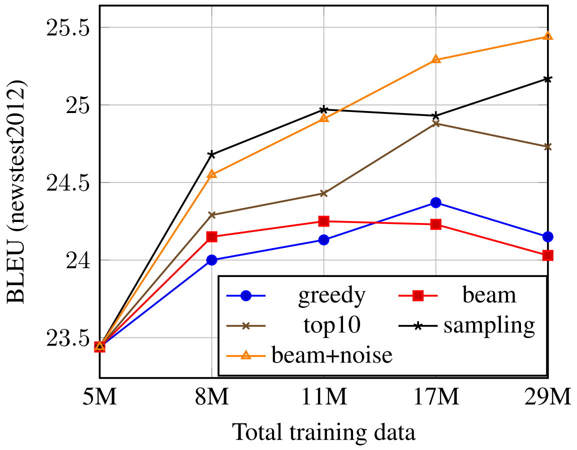

Figure 1: Accuracy of models trained on different amounts of back-translated data obtained with greedy search, beam search ($k = 5$), randomly sampling from the model distribution, restricting sampling over the ten most likely words (top10), and by adding noise to the beam outputs (beam+noise). Results based on newstest2012 of WMT English-German translation.

We also vary the amount of synthetic data and perform 30K updates during training for the bitext only, 50K updates when adding 3M synthetic sentences, 75K updates for 6M and 12M sentences and 100K updates for 24M sentences. For each setting, this corresponds to enough updates to reach convergence in terms of held-out loss. In our 128 GPU setup, training of the final models takes 3h 20min for the bitext only model, 7h 30min for 6M and 12M synthetic sentences, and 10h 15min for 24M sentences. During training we also sample the bitext more frequently than the synthetic data and we analyze the effect of this in more detail in §5.5.

Figure 1 shows that sampling and beam+noise outperform the MAP methods (pure beam search and greedy) by 0.8-1.1 BLEU. Sampling and beam+noise improve over bitext-only (5M) by between 1.7-2 BLEU in the largest data setting. Restricted sampling (top10) performs better than beam and greedy but is not as effective as unrestricted sampling (sampling) or beam+noise.

test sets (newstest2013-2017). Sampling and beam+noise perform roughly equal and we adopt sampling for the remaining experiments.

5.2 Analysis of generation methods

The previous experiment showed that synthetic source sentences generated via sampling and beam with noise perform significantly better than those obtained by pure MAP methods. Why is this?

Beam search focuses on very likely outputs which reduces the diversity and richness of the generated source translations. Adding noise to beam outputs and sampling do not have this problem: Noisy source sentences make it harder to predict the target translations which may help learning, similar to denoising autoencoders (Vincent et al., 2008). Sampling is known to better approximate the data distribution which is richer than the argmax model outputs (Ott et al., 2018a). Therefore, sampling is also more likely to provide a richer training signal than argmax sequences.

To get a better sense of the training signal provided by each method, we compare the loss on the training data for each method. We report the cross entropy loss averaged over all tokens and separate the loss over the synthetic data and the real bitext data. Specifically, we choose the setup with 24M synthetic sentences. At the end of each epoch we measure the loss over 500K sentence pairs sub-sampled from the synthetic data as well as an equally sized subset of the bitext. For each generation method we choose the same sentences except for the bitext which is disjoint from the synthetic data. This means that losses over the synthetic data are measured over the *same* target tokens because the generation methods only differ in the source sentences. We found it helpful to upsample the frequency with which we observe the bitext compared to the synthetic data (§5.5) but we do not upsample for this experiment to keep conditions as similar as possible. We assume that when the training loss is low, then the model can easily fit the training data without extracting much learning signal compared to data which is harder to fit.

Figure 2 shows that synthetic data based on

source	Diese gegenstzlichen Auffassungen von Fairness liegen nicht nur der politischen Debatte zugrunde.
reference	These competing principles of fairness underlie not only the political debate.

sample	*Mr President,* these contradictory interpretations of fairness are not based solely on the political debate.
top10	Those conflicting interpretations of fairness are not solely at the heart of the political debate.
beam+noise	conflicting BLANK interpretations BLANK are of not BLANK based on the political debate.

Table 3: Example where sampling produces inadequate outputs. ”Mr President,” is not in the source. BLANK means that a word has been replaced by a filler token.

greedy or beam is much easier to fit compared to data from sampling, top10, beam+noise and the bitext. In fact, the perplexity on beam data falls below 2 after only 5 epochs. Except for sampling, we find that the perplexity on the training data is somewhat correlated to the end-model accuracy (cf. Figure 1) and that all methods except sampling have a lower loss than real bitext.

These results suggest that synthetic data obtained with argmax inference does not provide as rich a training signal as sampling or adding noise. We conjecture that the regularity of synthetic data obtained with argmax inference is not optimal. Sampling and noised argmax both expose the model to a wider range of source sentences which makes the model more robust to reordering and substitutions that happen naturally, even if the model of reordering and substitution through noising is not very realistic.

Next we analyze the richness of synthetic outputs and train a language model on real human text and score synthetic source sentences generated by beam search, sampling, top10 and beam+noise. We hypothesize that data that is very regular should be more predictable by the language model and therefore receive low perplexity. We eliminate a possible domain mismatch effect between the language model training data and the synthetic data by splitting the parallel corpus into three non-overlapping parts:

1. On 640K sentences pairs, we train a back-translation model,
2. On 4.1M sentence pairs, we take the source side and train a 5-gram Kneser-Ney language model (Heafield et al., 2013),
3. On the remaining 450K sentences, we apply the back-translation system using beam, sampling and top10 generation.

For the last set, we have genuine source sentences as well as synthetic sources from different generation techniques. We report the perplexity of our language model on all versions of the source data in Table 2. The results show that beam outputs receive higher probability by the language model compared to sampling, beam+noise and real source sentences. This indicates that beam search outputs are not as rich as sampling outputs or beam+noise. This lack of variability probably explains in part why back-translations from pure beam search provide a weaker training signal than alternatives.

Closer inspection of the synthetic sources (Table 3) reveals that sampled and noised beam outputs are sometimes not very adequate, much more so than MAP outputs, e.g., sampling often introduces target words which have no counterpart in the source. This happens because sampling sometimes picks highly unlikely outputs which are harder to fit (cf. Figure 2).

5.3 Low resource vs. high resource setup

The experiments so far are based on a setup with a large bilingual corpus. However, in resource poor settings the back-translation model is of much lower quality. Are non-MAP methods still more effective in such a setup? To answer this question, we simulate such setups by sub-sampling the training data to either 80K sentence-pairs or 640K sentence-pairs and then add synthetic data from sampling and beam search. We compare these smaller setups to our original 5.2M sentence bitext configuration. The accuracy of the

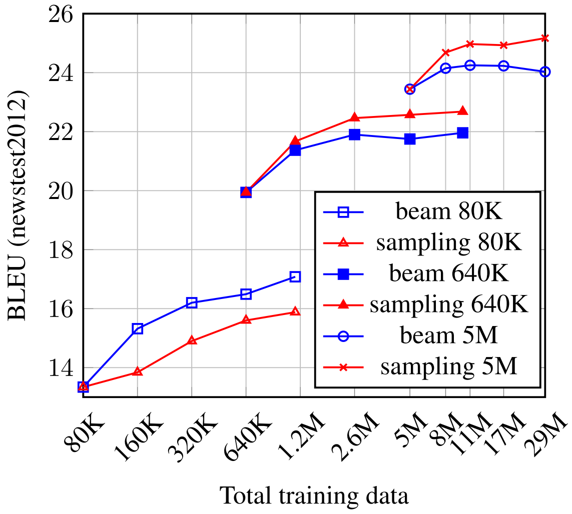

Figure 3: BLEU when adding synthetic data from beam and sampling to bitext systems with 80K, 640K and 5M sentence pairs.

German-English back-translation systems steadily increases with more training data: On newstest2012 we measure 13.5 BLEU for 80K bitext, 24.3 BLEU for 640K and 28.3 BLEU for 5M.

Figure 3 shows that sampling is more effective than beam for larger setups (640K and 5.2M bitexts) while the opposite is true for resource poor settings (80K bitext). This is likely because the back-translations in the 80K setup are of very poor quality and the noise of sampling and beam+noise is too detrimental for this brittle low-resource setting. When the setup is very small the very regular MAP outputs still provide useful training signal while the noise from sampling becomes harmful.

5.4 Domain of synthetic data

Next, we turn to two different questions: How does real human bitext compare to synthetic data in terms of final model accuracy? And how does the domain of the monolingual data affect results?

To answer these questions, we subsample 640K sentence-pairs of the bitext and train a back-translation system on this set. To train a forward model, we consider three alternative types of data to add to this 640K training set. We either add:

- the remaining parallel data (bitext),
- the back-translated target side of the remaining parallel data (BT-bitext),
- back-translated newscrawl data (BT-news).

The back-translated data is generated via sampling. This setup allows us to compare synthetic data to genuine data since BT-bitext and bitext share the same target side. It also allows us to estimate the value of BT data for domain adaptation since the newscrawl corpus (BT-news) is pure news whereas the bitext is a mixture of europarl and commoncrawl with only a small news-commentary portion. To assess domain adaptation effects, we measure accuracy on two held-out sets:

- newstest2012, i.e. pure newswire data.
- a held-out set of the WMT training data (valid-mixed), which is a mixture of europarl, commoncrawl and the small news-commentary portion.

Figure 4 shows the results on both validation sets. Most strikingly, BT-news performs almost as well as bitext on newstest2012 (Figure 4a) and improves the baseline (640K) by 2.6 BLEU. BT-bitext improves by 2.2 BLEU, achieving 83% of the improvement with real bitext. This shows that synthetic data can be nearly as effective as real human translated data when the domains match.

Figure 4b shows the accuracy on valid-mixed, the mixed domain valid set. The accuracy of BT-news is not as good as before since the domain of the BT data and the test set do not match. However, BT-news still improves the baseline by up to 1.2 BLEU. On the other hand, BT-bitext matches the domain of valid-mixed and improves by 2.7 BLEU. This trails the real bitext by only 1.3 BLEU and corresponds to 67% of the gain achieved with real human bitext.

In summary, synthetic data performs remarkably well, coming close to the improvements achieved with real bitext for newswire test data, or trailing real bitext by only 1.3 BLEU for valid-mixed. In absence of a large parallel corpus for news, back-translation therefore offers a simple, yet very effective domain adaptation technique.

5.5 Upsampling the bitext

We found it beneficial to adjust the ratio of bitext to synthetic data observed during training. In particular, we tuned the rate at which we sample data from the bitext compared to synthetic data. For example, in a setup of 5M bitext sentences and 10M synthetic sentences, an upsampling rate of 2 means that we double the frequency at which we

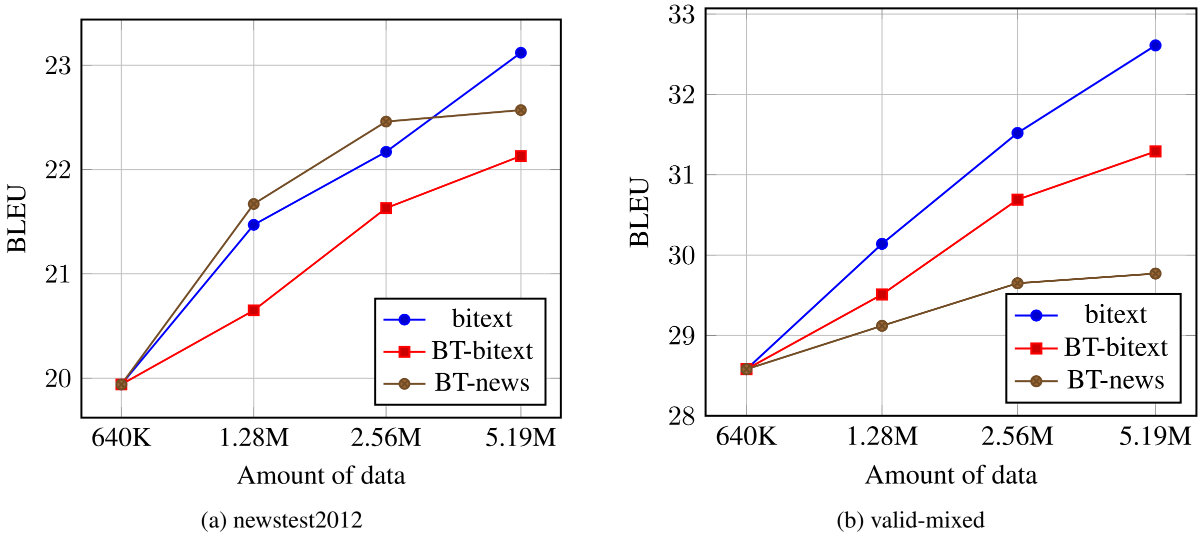

Figure 4: Accuracy on (a) newstest2012 and (b) a mixed domain valid set when growing a 640K bitext corpus with (i) real parallel data (bitext), (ii) a back-translated version of the target side of the bitext (BT-bitext), (iii) or back-translated newscrawl data (BT-news).

visit bitext, i.e. training batches contain on average an equal amount of bitext and synthetic data as opposed to 1/3 bitext and 2/3 synthetic data.

Figure 5 shows the accuracy of various upsampling rates for different generation methods in a setup with 5M bitext sentences and 24M synthetic sentences. Beam and greedy benefit a lot from higher rates which results in training more on the bitext data. This is likely because synthetic beam and greedy data does not provide as much training signal as the bitext which has more variation and is harder to fit. On the other hand, sampling and beam+noise require no upsampling of the bitext, which is likely because the synthetic data is already hard enough to fit and thus provides a strong training signal (§5.2).

5.6 Large scale results

To confirm our findings we experiment on WMT'14 English-French translation where we show results on newstest2013-2015. We augment the large bitext of 35.7M sentence pairs by 31M newscrawl sentences generated by sampling. To train this system we perform 300K training updates in 27h 40min on 128 GPUs; we do not upsample the bitext for this experiment. Table 4 shows tokenized BLEU and Table 5 shows detokenized BLEU.[2] To our knowledge, our baseline is the best reported result in the literature for newstest2014, and back-translation further improves upon this by 2.6 BLEU (tokenized).

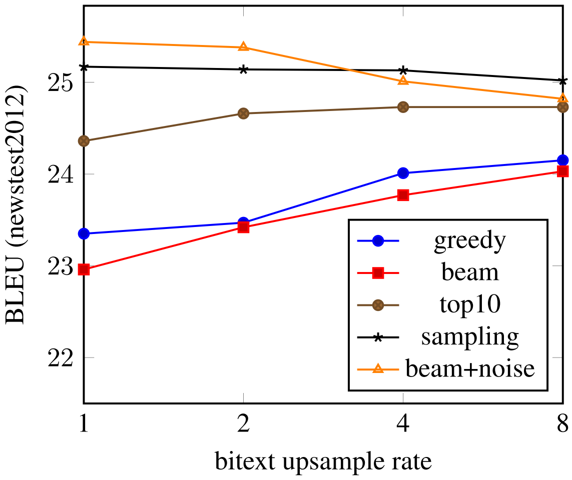

Figure 5: Accuracy when changing the rate at which the bitext is upsampled during training. Rates larger than one mean that the bitext is observed more often than actually present in the combined bitext and synthetic training corpus.

Finally, for WMT English-German we train on all 226M available monolingual training sentences and perform 250K updates in 22.5 hours on 128 GPUs. We upsample the bitext with a rate of 16 so that we observe every bitext sentence

16 times more often than each monolingual sentence. This results in a new state of the art of 35 BLEU on newstest2014 by using only WMT benchmark data. For comparison, DeepL, a commercial translation engine relying on high quality bilingual training data, achieves 33.3 tokenized BLEU .[4] Table 6 summarizes our results and compares to other work in the literature. This shows that back-translation with sampling can result in high-quality translation models based on benchmark data only.

6 Conclusions and future work

Back-translation is a very effective data augmentation technique for neural machine translation. Generating synthetic sources by sampling or by adding noise to beam outputs leads to higher accuracy than argmax inference which is typically used. In particular, sampling and noised beam outperforms pure beam by 1.7 BLEU on average on newstest2013-2017 for WMT English-German translation. Both methods provide a richer training signal for all but resource poor setups. We also find that synthetic data can achieve up to 83% of the performance attainable with real bitext. Finally, we achieve a new state of the art result of 35 BLEU on the WMT'14 English-German test set by using publicly available benchmark data only.

In future work, we would like to investigate an end-to-end approach where the back-translation model is optimized to output synthetic sources that are most helpful to the final forward model.

Abstract

Generating the English transliteration of a name written in a foreign script is an important and challenging step in multilingual knowledge acquisition and information extraction. Existing approaches to transliteration generation require a large (>5000) number of training examples. This difficulty contrasts with transliteration *discovery*, a somewhat easier task that involves picking a plausible transliteration from a given list. In this work, we present a bootstrapping algorithm that uses constrained discovery to improve generation, and can be used with as few as 500 training examples, which we show can be sourced from annotators in a matter of hours. This opens the task to languages for which large number of training examples are unavailable. We evaluate transliteration generation performance itself, as well the improvement it brings to cross-lingual candidate generation for entity linking, a typical downstream task. We present a comprehensive evaluation of our approach on nine languages, each written in a unique script.[1]

1 Introduction

Transliteration is the process of transducing names from one writing system to another (e.g., ओबामा in Devanagari to *Obama* in Latin script) while preserving their pronunciation (Knight and Graehl, 1998; Karimi et al., 2011). In particular, *back-transliteration* from foreign languages to English has applications in multilingual knowledge acquisition tasks including named entity recognition (Darwish, 2013) and information retrieval (Virga and Khudanpur, 2003). Two tasks feature prominently in the transliteration literature: *generation* (Knight and Graehl, 1998) which involves producing an appropriate transliteration for a given word in an open-ended way, and *discovery* (Sproat et al., 2006; Klementiev and Roth, 2008) which involves selecting an appropriate transliteration for a word from a list of candidates. This work develops transliteration generation approaches for low-resource languages.

Existing transliteration generation models require supervision in the form of source-target name pairs (≈5-10k), which are often collected from names in Wikipedia inter-language links (Irvine et al., 2010). However, most languages that use non-Latin scripts are under-represented in terms of such resources. Table 1 illustrates this issue, and the extra coverage one can achieve by extending to low-resource languages. A model that requires 50k name pairs as supervision can only support 6 languages, while one that just needs 500 could support 56. For a model to be widely applicable, it must function in low-resource settings.

# Name Pairs in Wikipedia		Languages	Scripts
$> 50,000$		6	5
$> 10,000$		18	14
$> 5,000$	*Previous Work*	24	15
$> 1,000$		45	22
> 500	*Our Approach*	56	23
> 0		93	30

Table 1: Cumulative number of person name pairs in Wikipedia inter-language links. While previous approaches for transliteration generation were applicable to only 24 languages (spanning 15 scripts), our approach is applicable to 56 languages (23 scripts). When counting scripts we exclude variants (e.g., all Cyrillic scripts and variants count as one).

We propose a new bootstrapping algorithm that uses a weak generation model to guide discovery of good transliterations, which in turn aids future bootstrapping iterations.[2] By carefully controlling the interaction of discovery and the generation model via constrained inference, we show

---

[1] code at `github.com/shyamupa/hma-translit`.

[2] All generative approaches are also capable of discovery, by using the posterior $P(y \mid x)$ to select the most likely candidate transliteration, while the opposite is not true.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 501–511
Brussels, Belgium, October 31 - November 4, 2018.

how to bootstrap a generation model using a dictionary of names in English, a list of words in the foreign script, and little initial supervision (≈500 name pairs). To the best of our knowledge, ours is the first work to accomplish transliteration generation in such a low-resource setting.

We demonstrate the practicality of our approach in truly low-resource scenarios and downstream applications through two case studies. First, in §8.1 we show that one can obtain the initial supervision from a *single* human annotator within a few hours for two languages – Armenian and Punjabi. This is a realistic scenario where language access is limited to a single native informant. Second, in §8.2 we show that our approach benefits a typical downstream application, namely candidate generation for cross-lingual entity linking, by improving recall on two low-resource languages – Tigrinya and Macedonian. We also present an analysis (§7) of the inherent challenges of transliteration, and the trade-off between native (i.e., source) and foreign (i.e., target) vocabulary.

2 Related Work

We briefly review the limitations of existing generation and discovery approaches, and provide an overview of how our work addresses them.

Transliteration Generation (Haizhou et al., 2004; Jiampojamarn et al., 2009; Ravi and Knight, 2009; Jiampojamarn et al., 2010; Finch et al., 2015, *inter alia*) requires generous amount of name pairs (≈5-10k) in order to learn to map words in the source script to the target script. While some approaches (Irvine et al., 2010; Tsai and Roth, 2018) use Wikipedia inter-language links to identify name pairs for supervision, a truly low-resource language (like Tigrinya) is likely to have limited Wikipedia presence as well.

Transliteration Discovery (Sproat et al., 2006; Chang et al., 2009) is considerably easier than generation, owing to the smaller search space. However, discovery often uses features derived from resources that are unavailable for low-resource languages, like comparable corpora (Sproat et al., 2006; Klementiev and Roth, 2008).

A key limitation of discovery is the assumption that the correct transliteration(s) is in the list of candidates $\mathcal{N}$. Since discovery models always pick *something* from $\mathcal{N}$, they can produce false positives, if no correct transliteration is present in $\mathcal{N}$. To overcome this, it is prudent to develop generation models which can handle input for which the transliteration does not belong in $\mathcal{N}$.

Our Work We show that a weak generation model can be iteratively improved using constrained discovery. In particular, our work uses a weak generation model to discover new training pairs, using constraints to drive the bootstrapping. Our generation model is inspired by the success of sequence to sequence generation models (Sutskever et al., 2014; Bahdanau et al., 2015) for string transduction tasks like inflection and derivation generation (Faruqui et al., 2016; Cotterell et al., 2017; Aharoni and Goldberg, 2017; Makarov et al., 2017). Our bootstrapping framework can be viewed as an instance of constraint driven learning (Chang et al., 2007, 2012).

3 Transliteration Generation with Hard Monotonic Attention - Seq2Seq(HMA)

We view generation as a string transduction task and use a sequence to sequence (Seq2Seq) generation model that uses *hard monotonic attention* (Aharoni and Goldberg, 2017), henceforth referred to as Seq2Seq(HMA). During generation, Seq2Seq(HMA) directly models the *monotonic* source-to-target sequence alignments, using a pointer that attends to a *single* input character at a time. Monotonic attention is a natural fit for transliteration because even though the number of characters needed to represent a sound in the source and target language vary, the sequence of sounds is presented in the same order.[3] We review Seq2Seq(HMA) below, and describe how it can be applied to transliteration generation.

Encoding Input Word Let Σ_f be the source alphabet and Σ_e be the English alphabet. Let $x = (x_1, x_2, \cdots, x_n)$ denote an input word where each character $x_i \in \Sigma_f$. The characters are first encoded using a embedding matrix $\mathbf{W} \in \mathbb{R}^{|\Sigma_f| \times d}$ to get character embeddings $\boldsymbol{x}_1, \boldsymbol{x}_2, \cdots, \boldsymbol{x}_n$ where each $\boldsymbol{x}_i \in \mathbb{R}^d$. These embeddings are fed into a bidirectional RNN encoder to generate encoded vectors $\boldsymbol{h}_1, \boldsymbol{h}_2, \cdots, \boldsymbol{h}_n$ where each $\boldsymbol{h}_i \in \mathbb{R}^{2k}$, and k is the size of output vector of the forward (and backward) encoder. The encoded vectors $\boldsymbol{h}_1, \boldsymbol{h}_2, \cdots, \boldsymbol{h}_n$ are then fed into the decoder.

---

[3] Many Indic scripts, that sometimes write vowels before the consonants they are pronounced after, seem to violate this claim, but Unicode representations of these scripts actually preserve the consonant-vowel order.

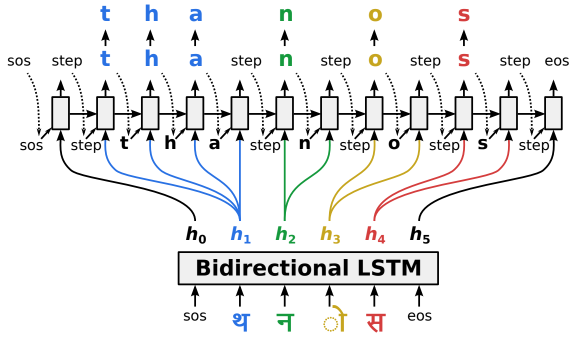

Figure 1: Transliteration using Seq2Seq transduction with Hard Monotonic Attention, or Seq2Seq(HMA). The figure shows how decoding proceeds for transliterating “थनोस” to “thanos”. During decoding, the model attends to a source character (e.g.,थ shown in blue) and outputs target characters (t, h, a) until a *step* action is generated, which moves the attention position forward by one character (to न), and so on.

Monotonic Decoding with Hard Attention Figure 1 illustrates the decoding process. The decoder RNN generates a sequence of actions $\{s_1, s_2, \cdots\}$, such that each $s_i \in \Sigma_e \cup \{step\}$. The *step* action controls an attention position a, attending on input character x_a, with encoded vector $\boldsymbol{h}_a$. Each action s_i is embedded into $\boldsymbol{s}_i \in \mathbb{R}^d$ using a output embedding matrix $\mathbf{A} \in \mathbb{R}^{(|\Sigma_e|+1)\times d}$. At any time during decoding, the decoder uses its last hidden state, the embedding of the previous action $\boldsymbol{s}_i$ and the encoded vector $\boldsymbol{h}_a$ of the current attended position to generate the next action s_{i+1}. If the generated action is *step*, the decoder increments the attention position by one. This ensures that the decoding is monotonic, as the attention position can only move forward or stay at the same position during generation. We use `Inference`(G, x) to refer to the above decoding process for a trained generation model G and input word x.

Training requires the oracle action sequence $\{s_i\}$ for input $x_{1:n}$ that generates the correct transliteration $y_{1:m}$. The oracle sequence is generated using the train name pairs and Algorithm 1 in Aharoni and Goldberg (2017), with the character-level alignment between $x_{1:n}$ and $y_{1:m}$ being generated using the algorithm in Cotterell et al. (2016).

Inference Strategies We describe an unconstrained and a constrained inference strategy to select the best transliteration $\hat{y}$ from a beam $\{y_i\}_{i=1}^k$ of transliteration hypotheses, sorted in descending order by likelihood. The constrained strategy use a name dictionary $\mathcal{N}$, to guide the inference. These strategies are applicable to any generation model.

- **Unconstrained (U)** selects the most likely item y_1 in the beam as $\hat{y}$.
- **Dictionary-Constrained (DC)** selects the highest scoring hypothesis that is present in $\mathcal{N}$, and defaults to y_1 if none are in $\mathcal{N}$.

It is tempting to disallow the model from generating hypotheses which are not in the dictionary $\mathcal{N}$. However, dictionaries are always incomplete, and restricting the search to generate from $\mathcal{N}$ inevitably leads to incorrect predictions if the correct transliteration is not in $\mathcal{N}$. This is essentially the same as the problem inherent to discovery models.

Other Strategies in Previous Work A related constrained inference strategy was proposed by Lin et al. (2016), who use a entity linking system (Wang et al., 2015) to correct and re-rank hypotheses, using any available context to aid hypothesis correction. Our constrained inference strategy is much simpler, requiring only a name dictionary $\mathcal{N}$. We experimentally show that our approach outperforms that of Lin et al. (2016).

4 Low-Resource Bootstrapping

Low-resource languages will have a limited number of name pairs for training a generation model. To learn a good generation model in this setting, we propose a new bootstrapping algorithm, that uses *constrained discovery* to mine name pairs to re-train the generation model. Our algorithm requires a small (≈500) seed list of name pairs $\mathcal{S}$ for supervision, a dictionary $\mathcal{N}$ containing names in English, and a list of words $\mathcal{V}_f$ in the foreign script.

Below we describe our algorithm and the constraints used to guide discovery of new name pairs.

4.1 The Bootstrapping Algorithm

Algorithm 1 shows the pseudo-code of the bootstrapping procedure. We initialize a weak generation model G_0 using a seed list of name pairs $\mathcal{S}$ (line 1). At iteration t, the current generation model G_t produces the top-k transliteration hypotheses $\{y_i\}_{i=1}^k$ for each word $x \in \mathcal{V}_f$ (line 5). A source word and hypothesis pair (x, y_i), is added to the set of mined name pairs $\mathcal{B}$ if they satisfy a set of discovery constraints (described below) (line 8). A new generation model G_{t+1} is trained for the next iteration using the union of the seed list $\mathcal{S}$ and the mined name pairs $\mathcal{B}$ (line 12). $\mathcal{B}$ is purged after every iteration (line 3) to prevent G_{t+1} from being influenced by possibly incorrect name pairs mined in

Algorithm 1 Bootstrapping a Transliteration Generation Model via Constrained Discovery

```
Input:
    English name dictionary $\mathcal{N}$; Seed training pairs $\mathcal{S}$;
    Vocabulary in the target language $\mathcal{V}_f$.
Hyper-parameters:
    initial minimum length threshold $L_0^{min}$;
    minimum likelihood threshold $\delta^{min}$;
    length ratio tolerance $\epsilon$.
Output: Generation model $G_T$
$G_0 = \texttt{train}(\mathcal{S})$                    ▷ init. generation model.
while not converged do

    for $x$ in $\mathcal{V}_f$ do
        $\{y_i\}_{i=1}^{k} = \text{argtop}_k\ \texttt{Inference}(G_t, x)$
        for $y_i$ in $\{y_i\}_{i=1}^{k}$ do
            if $(x, y_i)$ satisfies constraints in §4.2 then
                $\mathcal{B} = \mathcal{B} \cup \{(x, y_i)\}$   ▷ add to mined set.
            end if
        end for
    end for
    $G_{t+1} = \texttt{train}\ (\mathcal{S} \cup \mathcal{B})$
    $L_{t+1}^{min} = L_t^{min} - 1$                     ▷ reduce length threshold.
    $t = t + 1$                                         ▷ track iteration
end while
```

earlier iterations. The algorithm converges when accuracy@1 stops increasing on a development set. We note that our bootstrapping approach is applicable to any transliteration generation model.

To ensure that high quality name pairs are added to the mined set $\mathcal{B}$ during bootstrapping, we use the following discovery constraints.

4.2 Discovery Constraints

A word-transliteration pair (x, y) is added to the set of mined pairs $\mathcal{B}$, only if all the following constraints are satisfied,

1. $y \in \mathcal{N}$. i.e., y belongs in the dictionary.
2. $\text{P}(y \mid x) > \delta^{min}$. The model is sufficiently confident about the transliteration.
3. The ratio of lengths $\frac{|y|}{|x|}$ should be close to the average ratio estimated from $\mathcal{S}$ (Matthews, 2007). We encode this using the constraint $|\frac{|y|}{|x|} - r(\mathcal{S})| \leq \epsilon$, where ϵ is a tunable tolerance and $r(\mathcal{S})$ is the average ratio in $\mathcal{S}$.
4. $|y| > L_t^{min}$. We found that false positives were more likely to be short hypotheses in early iterations. As the model improves with each iteration, L_t^{min} is lowered to allow more new pairs to be mined.

We note that our bootstrapping algorithm can be formulated as an instance of constraint driven learning (Chang et al., 2007, 2012).

5 Experimental Setup

Unless otherwise specified, we evaluate all generation models using the best model prediction $\hat{y}$ using acc@1 against the reference transliteration y^*.

Training and Evaluation Dataset We use the train and development sets from the Named Entities Workshop 2015 (Duan et al., 2015) (NEWS2015) for Hindi (hi), Kannada (kn), Bengali (bn), Tamil (ta) and Hebrew (he) as our train and evaluation set.[4] The size of the train set was ∼12k, 10k, 14k, 10k and 10k respectively, and all evaluation sets were ∼1k.

For the low resource experiments, we subsample 500 examples from each train set in the NEWS2015 dataset using five random seeds and report the averaged results. We also set aside a 1k name pairs from the corresponding NEWS2015 train set of each language as development data. The foreign script portion of the remaining train data is used as $\mathcal{V}_f$ in the bootstrapping algorithm.

Model and Tuning Details We implemented Seq2Seq(HMA) using PyTorch.[5] We used 50 dimensional character embeddings, and single layer GRU (Cho et al., 2014) encoder with 20 hidden states for all experiments. The Adam (Kingma and Ba, 2014) optimizer was used with default hyperparameters, a learning rate of 0.001, a batch size of 1, and maximum of 20 iterations in all experiments. Beam search used a width of 10. For low-resource experiments, all bootstrapping parameters were tuned on the development data set aside above. L_0^{min} is chosen from $\{10, 15, 20, 25\}$.

Name Dictionary We use a name dictionary of 1.05 million names constructed from the English Wikipedia (dump dated 05/20/2017) by taking the list of title tokens in Wikipedia sorted by frequency, and removing tokens which appears only once.

5.1 Comparisons

We compare with the following generation models:

P&R (Pasternack and Roth, 2009) A probabilistic transliteration generation approach that learns latent alignments between substrings in the source and the target words. The model is trained to score all possible segmentation and their alignments, using an EM-like algorithm.

---

[4] Test set was not available since shared task concluded.

[5] github.com/pytorch

DirecTL+ (Jiampojamarn et al., 2009) A HMM-like discriminative string transduction model that predicts the output transliteration using many-to-many alignments between the source word and target transliteration. Following Jiampojamarn et al. (2009), we use the m2m-aligner (Jiampojamarn et al., 2007) to generate the many-to-many alignments, and the public implementation of DirecTL+ to train models.[6]

RPI-ISI (Lin et al., 2016) A transliteration approach that uses a language-independent entity linking system (Wang et al., 2015) to jointly correct and re-rank the hypotheses produced by the generation model. We compare to both the unconstrained inference (U) approach and the entity linking constrained inference (+EL) approach.

Seq2Seq w/ Att A sequence to sequence generation model which uses soft attention as described in (Bahdanau et al., 2015). This model does not enforce monotonicity at inference time, and serves as direct comparison for Seq2Seq(HMA).

6 Experiments

This section aims to analyze: **(a)** how effective is Seq2Seq(HMA) for transliteration generation when provided all available supervision (§6.1)? and **(b)** how effective is the bootstrapping algorithm in the low-resource setting when only 500 examples are available (§6.2)?

6.1 Full Supervision Setting

We compare Seq2Seq(HMA) with previous approaches when provided all available supervision, to see how it fares under standard evaluation.

Results in the unconstrained inference (U) setting (Table 2 top 5 rows) shows Seq2Seq(HMA), denoted by "Ours", outperforms previous approaches on Hindi, Kannada, and Bengali, with almost 3-4% gains. Improvements over the Seq2Seq with Attention (Seq2Seq w/ Att) model demonstrate the benefit of imposing the monotonicity constraint in the generation model. On Tamil and Hebrew, Seq2Seq(HMA) is at par with the best approaches, with negligible gap (∼0.3) in scores. Overall, we see that Seq2Seq(HMA) can achieve better (and sometimes competitive) scores than state-of-the-art approaches in full supervision settings. When comparing approaches which use constrained inference (Table 2, rows 6 and 7), we see that using dictionary-constrained inference (as in Ours(DC)) is more effective than using a entity-linking model for re-ranking (RPI-ISI + EL).

Lang. → **Approach ↓**	hi	kn	bn	ta	he	Avg.
Full Supervision Setting (5-10k examples)						
Seq2Seq w/ Att (U)	35.5	33.4	46.1	17.2	20.3	30.5
P&R (U)	37.4	31.6	45.4	**20.2**	18.7	30.7
DirecTL+ (U)	38.9	34.7	48.4	19.9	16.8	31.7
RPI-ISI (U)	40.3	29.8	49.4	**20.2**	21.5	32.2
Ours(U)	**42.8**	**38.9**	**52.4**	**20.5**	**23.4**	**35.6**
Approaches Using Constrained Inference						
RPI-ISI + EL	44.8	37.6	52.0	**29.0**	**37.2**	40.1
Ours(DC)	**51.8**	**43.3**	**56.6**	28.0	36.1	**43.2**
Low-Resource Setting (500 examples)						
Seq2Seq w/ Att (U)	17.0	13.6	14.5	6.0	9.5	12.1
P&R (U)	21.1	16.6	34.2	9.4	13.0	18.9
DirecTL+ (U)	26.6	25.3	35.5	11.8	10.7	22.0
Ours(U)	29.1	27.7	37.7	11.5	16.2	24.4
Ours(U) + Boot.	**40.1**	**35.1**	**50.3**	**17.8**	**22.8**	**33.2**

Table 2: Comparing different approaches on the NEWS 2015 dataset using acc@1 as the evaluation metric. "Ours" denotes the Seq2Seq(HMA) model, with (.) denoting the inference strategy. Numbers for RPI-ISI are from Lin et al. (2016).

6.2 Low-Resource Setting

In Table 2 (rows under "Low-Resource Setting"), we evaluate different models in a low-resource setting when provided only 500 name pairs as supervision. Results are averaged over 5 different random sub-samples of 500 examples.

The results clearly demonstrate that all generation models suffer a drop in performance when provided limited training data. Note that models like Seq2Seq with Attention suffer a larger drop than those which enforce monotonicity, suggesting that incorporating monotonicity into the inference step in the low-resource setting is essential. After bootstrapping our weak generation model using Algorithm 1, the performance improves substantially (last row in Table 2). On almost all languages, the generation model improves by at least 6%, with performance for Hindi and Bengali improving by more than 10%. Bootstrapping results for the languages are within 2-4% of the best model trained with all available supervision.

To better analyze the progress of the transliteration model during bootstrapping, we plot the accuracy@1 of the current transliteration model after each bootstrapping iteration for each of the languages (solid lines in Figure 2). For reference, we also show the best performance for a gener-

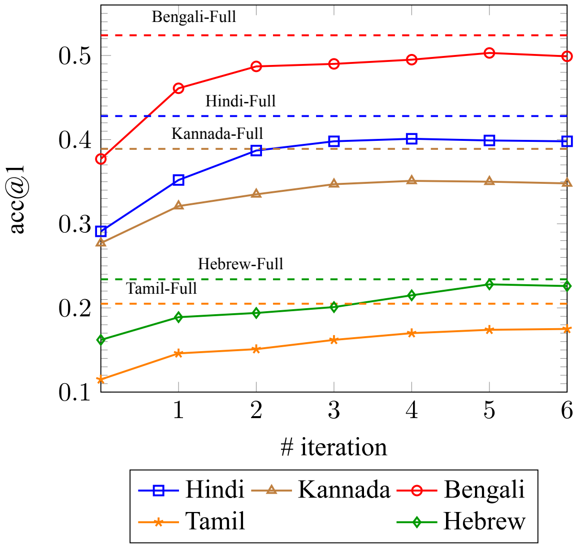

Figure 2: Plot showing acc@1 after each bootstrapping iteration for Hindi, Kannada, Bengali, Tamil and Hebrew, starting with only 500 training pairs as supervision. For comparison, the acc@1 of a model trained with all available supervision is also shown (respective dashed lines, marked X-Full).

ation model using all available supervision from §6.1 (dotted horizontal lines in Figure 2). From Figure 2, we can see that almost after 5 bootstrapping iterations, the generation model attains competitive performance to respective state-of-the-art models trained with full supervision.

6.3 Error Analysis

Though our model is state of the art, it does present a few weaknesses. We have found that the dictionary sometimes misleads the model during constrained inference. For example, the correct transliteration "vidyul" of the Hindi विद्युल, is not present in the dictionary, but another hypothesis "vidul" is. Another issue comes from the proportion of native (i.e., from the source language) and foreign (i.e., from English or other languages) names in the training data. It is usually not the case that the source and target scripts have the same transliteration rules. For example, य in Hindi might represent *ya* in English or Hindi names, but *ja* in German. Similarly, while अ should be *a* in Hindi names, it could be any of a few vowels in English. The NEWS2015 dataset does not report a native/foreign ratio, but by our estimation, it is about 70/30 for each language. This native and foreign names dichotomy are some of the inherent challenges in transliteration, that we discuss in detail in the next section.

7 Challenges Inherent to Transliteration

The fact that all models in Table 2 perform well or poorly on the same languages suggests that most of the observed performance variation is the result of factors *intrinsic* to the specific languages. Here we analyze some challenges that are inherent to the transliteration task, and explain why the performance ceiling is well under 100% for all languages, and lower for languages like Tamil and Hebrew than the others.

7.1 Source and Target-Specific Issues

Source-Driven Some transliteration errors are due to ambiguities in the source scripts. For instance, the Tamil script uses a single character to denote {*ta*, *da*, *tha*, *dha*}, a single character for {*ka*, *ga*, *kha*, *gha*}, etc., while the rest of the Indian scripts have unique characters for each of these. Thus, names like *Har**t**ley* and *Har**d**ley* are entirely indistinguishable in Tamil but are distinguishable in the other scripts. We illustrate this problem by transliterating back and forth between Tamil and Hindi. When transliterating Hindi→Tamil, the model achieves an accuracy of 31%, which drops to 15% when transliterating Tamil→Hindi, suggesting that the Tamil script is more ambiguous.

The Hebrew script also introduces error because it tends to omit vowels or write them ambiguously, leaving the model to guess between plausible choices. For example, the word מלך could be transliterated *melech* "king" just as easily as *malach* "he ruled." When Hebrew does write vowels, it reuses consonant letters, again ambiguously. For example, ה can be used to express *a* or *e*, so שמונה can be either *shmona* or *shmone* "eight masculine/feminine". The script also does not reliably distinguish *b* from *v* or *p* from *f*, among others.

All languages run into problems when they are faced with writing sounds that they do not natively distinguish. For example, Hindi does not make a distinction between *w* and *v*, so both *vest* and *west* are written as वेस्ट in its script.

These script-specific deficiencies explains why all models struggle on Tamil and Hebrew relative to the others. These issues cannot be completely resolved without memorizing individual source-target pairs and leveraging context.

Target-Driven Some errors arise from the challenges presented by target script (here Latin script for English). To handle English's notoriously convoluted orthography, a model has to infer silent let-

	Native	Foreign	Ratio
Hindi	45.1	31.4	1.44
Bengali	63.1	20.1	3.14
Kannada	42.6	23.1	1.84
Tamil	24.3	05.2	4.67

Table 3: Acc@1 for native and foreign words for four languages (§7.2). Ratio is native performance relative to foreign.

ters, decide whether to use *f* or *ph* for /f/; use *k*, *c*, *ck*, *ch*, or *q* for /k/, and so on. The problem is made worse because English is not the only language that uses Latin script. For example, German names like *Schmidt* should be written with *sch* instead of *sh*, and for French names like *Margot* and *Margeau* (which are pronounced the same), we have to resort to memorization. The arbitrariness extends into borrowings from the source languages as well. For example, the Indian name *Bangalore* is written with a silent-*e*, and the name *Lakshadweep* contains *ee*, instead of the expected *i*.

7.2 Disparity between Native and Foreign

All these issues come together to create a performance disparity between *native* names, which are well-integrated into the source language etymologically (Indian names like *Jasodhara* or *Ramanathan* for Hindi), and *foreign* names (French *Grenoble* or Japanese *Honshu* for Hindi), which are not. The above datasets include an unspecified mix of native and foreign names. This is a problem since any model must learn essentially separate transliteration schemes for each.

To quantify the effect of this, we annotate native and foreign names in the test split of the four Indian languages, and evaluate performance for both categories. Table 3 shows that our model performs significantly better on native names for all the languages. A possible reason for is that the source scripts were designed for writing native names (e.g., Tamil script lacks separate {*ta*, *da*, *tha*, *dha*} characters because the Tamil language does not distinguish these sounds). Furthermore, foreign names have a wide variety of origins with their own conventions as discussed in §7.1. The performance gap is proportionally greatest for Tamil, likely due to its script.

8 Case Studies

In this section, we evaluate the practical utility of our approach in low-resource settings and for downstream applications through two case studies. We first show that obtaining an adequate seed list is possible with a few hours of manual annotation (§8.1) from a *single* human annotator. We then show the positive impact that our approach has on a downstream task, by evaluating its contribution to candidate generation for Tigrinya and Macedonian entity linking (§8.2).

Language	Monolingual Corpus	Vocabulary
Punjabi	Corpus ILCI-II♠	30k
Armenian	TED♣	50k
Tigrinya	Habit Project♦	225k
Macedonian	TED♣	60k

♦=`habit-project.eu/wiki/TigrinyaCorpus`,
♠=`tdil-dc.in`,
♣=`github.com/ajinkyakulkarni14/TED-Multilingual-Parallel-Corpus`

Table 4: Corpora used for obtaining foreign vocabulary $\mathcal{V}_f$ for bootstrapping in the case studies in §8.1 and §8.2.

8.1 Manual Annotation

The manual annotation exercises simulate a low-resource setting with only a single human annotator is available. We judge the usability of the annotations by training models on them and evaluating the models on test sets of 1000 names each, obtained from Wikipedia inter-language links. For bootstrapping experiments, we use the corpora shown in Table 4 to obtain foreign vocabulary $\mathcal{V}_f$.

Languages Studied We investigate performance on two languages: Armenian and Punjabi.

Spoken in Armenia and Turkey, Armenian is an Indo-European language with no close relatives. It has Eastern and Western dialects with different spelling conventions. Armenian Wikipedia is primarily written in the Eastern dialect, while our annotator was a native Western speaker.[7]

Punjabi is an Indic language from Northwest India and Pakistan that is closely related to Hindi. Our annotator grew up primarily speaking Hindi.

Annotation Guidelines Annotators were given two tasks. First, they were asked to write two names and their English transliterations for each letter in the source script: one beginning with the letter and another containing it elsewhere. (e.g. "**J**ulia" and "Ben**j**amin" for the letter "j" if the source were English). The is done to ensure good coverage over the alphabet. Next, annotators were shown a list of English words and were asked to

---

[7] The annotator produced Western Armenian which was mechanically mapped to "Eastern" by swapping five Armenian character pairs: ղ/տ, պ/բ , ք/կ , ձ/ծ, ճ/ջ

Lang. → **Approach** ↓	Punjabi	Armenian
Ours(U)	33.4	49.9
Ours(U) + Bootstrapping	44.5	55.8
Annotation Time (hours)	5	4

Table 5: Acc@1 using human annotated seed set and bootstrapping the Seq2Seq(HMA) model. Both languages perform well relative to the other languages investigated so far. Both annotation sub-tasks took roughly the same time.

provide plausible transliteration(s) into the target script. The list had a mix of recognizable foreign (e.g., *Clinton*, *Helsinki*) and native names (e.g., *Sarkessian*, *Yerevan* for Armenian).

We collected about 600 and 500 annotated pairs respectively for Armenian and Punjabi. Table 5 shows that the performance of the models trained on the annotated data is comparable to that on the standard test corpora for other languages. This show that our approach is robust to human inconsistencies and regional spelling variations, and that obtaining an adequate seed list is possible with just a few hours of manual annotation.

8.2 Candidate Generation (CG)

Since transliteration is an intermediate step in many downstream multilingual information extraction tasks (Darwish, 2013; Kim et al., 2012; Jeong et al., 1999; Virga and Khudanpur, 2003; Chen et al., 2006), it is possibly to gauge its performance extrinsically by the impact it has on such tasks. We use the task of *candidate generation* (CG), which is a key step in cross-lingual entity linking.

The goal of cross-lingual entity linking (McNamee et al., 2011; Tsai and Roth, 2016; Upadhyay et al., 2018) is to ground spans of text written in any language to an entity in a knowledge base (KB). For instance, grounding **[Chicago]** in the following German sentence to `Chicago_(band)`.[8]

[Chicago] *wird in Woodstock aufzutreten.*

The role of CG in cross-lingual entity linking is to create a set of plausible entities given a string while ensuring the correct KB entity belongs to that set. For the above German sentence, it would provide a list of possible KB entities for the string *Chicago*: `Chicago_(band)`, `Chicago_(city)`, `Chicago_(font)`, etc., so that entity linking can select the band. Foreign scripts pose an additional challenge for CG because they must be transliterated before they are passed on to candidate generation. For instance, any mention of "Chicago" in Amharic must first be transliterated from **ቺካጎ**.

Most approaches for CG use Wikipedia inter-language links to generate the lists of candidates (Tsai and Roth, 2016). While recent approaches such as Tsai and Roth (2018) have resorted to name translation for CG, they require over 10k examples for languages written in non-Latin scripts, which is prohibitive for low-resource languages with little Wikipedia presence.

Candidate Generation with Transliteration We evaluate the extent to which our approach improves recall of a naive CG baseline that generates candidates by performing exact name match. For each span of text to be linked (or *query mention*), we first check if the naive name matching strategy finds any candidates in the KB. If none are found, the query mention is back-transliterated to English, and at most 20 candidates are generated using a inverted-index from English names to KB entities. The evaluation metric is recall@20, i.e., if the gold KB entity is in the top 20 candidates. We use Tigrinya and Macedonian as our test languages.

Tigrinya is a South Semitic language related to Amharic, written in the Ethiopic script, and spoken primarily in Eritrea and northern Ethiopia. The Tigrinya Wikipedia has <200 articles, so we use inter-language links (∼7.5k) from the Amharic Wikipedia instead to extract 1k name pairs for the seed set. We use the monolingual corpus in Table 4 for bootstrapping and evaluate on the *unsequestered set* provided under the NIST LoReHLT evaluation, containing 4,630 query mentions.

The Ethiopic script is an alphasyllabary, where each character is consonant-vowel pair. For example, the character **መ** is *mä*, **ሚ** with a tail is *mi*, and **ሞ** with a line is *mo*. With 26 consonants and 8 vowels, this leads to a set of >200 characters creating a sparsity problem since each character has its own Unicode code point. However, the code points are organized so that they can be automatically split[9] into unique consonant and vowel codes *without explicitly understanding the script*. We assign arbitrary ASCII codes to each consonant and vowel so that **መ**/*mä* becomes "D 1" and **ሞ**/*mo* becomes "D 6." This consonant-vowel splitting (CV-split) reduces the number of unique input characters to 55.

---

[8] Translation: Chicago will perform at Woodstock.

[9] Consonant = Unicode / 8; Vowel = Unicode % 8

Approach	Recall@20
Tigrinya	
Name match (baseline)	31.4
Ours	35.6
Ours (CV-split)	41.3
Ours (CV-split) + Bootstrapping	**46.2**
Macedonian	
Name match (baseline)	33.6
Ours	72.2
Ours + Bootstrapping	**76.8**

Table 6: Comparing candidate recall@20 for different approaches on Tigrinya and Macedonian. CV-split refers to consonant-vowel splitting. Using our transliteration generation model with bootstrapping yields the highest recall, improving significantly over a name match baseline.

Macedonian is a South Slavic language closely related to the languages of the former Yugoslavia and written in a local variant of the Cyrillic alphabet similar to Serbian's. We use the Macedonian test set constructed by McNamee et al. (2011) containing 1956 query mentions. A seed set of 1k name pairs was obtained from the inter-language Wikipedia links for Macedonian, and the monolingual corpus from Table 4 is used for bootstrapping.

Candidate Generation Results Table 6 shows the results for the two languages. For Tigrinya, candidate generation with transliteration improves on the baseline by 4.2%. Splitting the characters (CV-split) gives another 5.7%, and adding bootstrapping gives 4.9% more. Our approach yields an overall 14.8% improvement in recall over the baseline, showing that we can effectively exploit the little available supervision by bootstrapping. Macedonian yields more dramatic results, where transliteration provides 38.6% improvement (more than double the baseline), with bootstrapping providing another 4.6%. The differences between Tigrinya and Macedonian is likely due both to their test sets, corpora and writing systems.

9 Conclusion and Future Work

We presented a new transliteration generation model, namely Seq2Seq(HMA), and a new bootstrapping algorithm that can iteratively improve a weak generation model using constrained discovery. The model presented here achieves state-of-the-art results on typical training set sizes, and more importantly, works well in a low-resource setting with the aid of the bootstrapping algorithm. The key benefit of the bootstrapping approach is that it can "recover" most of the performance lost in the low-resource setting when little supervision is available by training with a smaller seed set, an English name dictionary, and a list of unannotated words in the target script. Additionally, our bootstrapping algorithm admits any generation model, giving it wide applicability. Through case studies, we showed that collecting an adequate seed list is practical with a few hours of annotation. The benefit of incorporating our transliteration approach in a downstream task, namely candidate generation, was also demonstrated. Finally, we discussed some of the inherent challenges of learning transliteration and the deficits of existing training sets.

There are several interesting directions for future work. Performing model combination, either by developing hybrid transliteration models (Nicolai et al., 2015) or by ensembling (Finch et al., 2016), can further improve low resource transliteration. Jointly leveraging similarities between related languages, such as writing systems or phonetic properties (Kunchukuttan et al., 2018), also shows promise for low-resource settings. Our analysis suggests value in revisiting "transliteration in context" approaches (Goto et al., 2003; Hermjakob et al., 2008), especially for languages like Hebrew. We would also like to expand on the analyses provided in §7 which uncover challenges inherent to the transliteration task, particularly the impact of the native/foreign distinction in the train and test data, the difficulties posed by specific scripts or pairs of scripts, and how these impact both back- and forward-transliteration. Recent work from Merhav and Ash (2018) suggests many useful analyses that we would like to incorporate.

NORMA: Neighborhood Sensitive Maps for Multilingual Word Embeddings

Ndapa Nakashole
Computer Science and Engineering
University of California, San Diego
La Jolla, CA 92093
nnakashole@eng.ucsd.edu

Abstract

Inducing multilingual word embeddings by learning a linear map between embedding spaces of different languages achieves remarkable accuracy on related languages. However, accuracy drops substantially when translating between distant languages. Given that languages exhibit differences in vocabulary, grammar, written form, or syntax, one would expect that embedding spaces of different languages have different structures especially for distant languages. With the goal of capturing such differences, we propose a method for learning neighborhood sensitive maps, NORMA. Our experiments show that NORMA outperforms current state-of-the-art methods for word translation between distant languages.

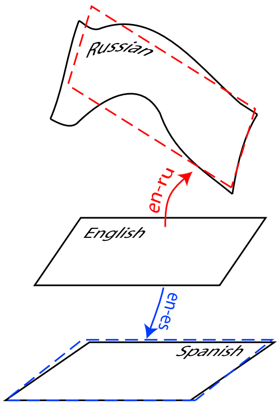

Figure 1: **Bottom:** By learning a linear map between embedding spaces of related languages, e.g., en-es, current methods achieve high accuracy on word translation. **Top:** For distant language pairs, e.g., en-ru, where differences are larger, word translation accuracy substantially degrades.

1 Introduction

The success of monolingual word embeddings has sparked interest in multilingual word embeddings. The goal is to learn word vectors where similar words have similar vector representations regardless of their language. Multilingual word embeddings are playing an increasingly prominent role in machine translation (Zou et al., 2013; Lample et al., 2018; Artetxe et al., 2018b). In addition, they are a promising avenue for cross-lingual model transfer (Guo et al., 2015; Täckström et al., 2012).

A prominent approach to learning multilingual word embeddings is to induce a mapping function between embedding spaces of different languages. However, there is a key assumption behind learning such a mapping function: that the embedding spaces of different languages exhibit similar structures (Mikolov et al., 2013a). Evidence that this assumption holds has mostly been through extrinsic evaluation metrics such as word translation accuracy. A notable exception is (Mikolov et al., 2013a), who showed empirical evidence on animals and numbers. Embeddings corresponding to a few numbers and animals in English and Spanish were projected down to two dimensions using PCA, and then manually rotated to accentuate similarity. Despite showing only these two concepts for two related languages, this work concluded that embedding spaces of different languages exhibit similar geometric arrangements. Additionally, work in this line of inquiry has continued to develop methods based on this assumption (Artetxe et al., 2018a; Conneau et al., 2018). Given that languages differ along dimensions such as vocabulary, grammar, written form, and syntax, one would expect that embedding spaces of different languages exhibit different structures. Indeed, recent work showed that assumptions of isomorphism and linearity do not hold (Søgaard et al., 2018; Nakashole and Flauger, 2018)

While these assumptions do not substantially affect accuracy when translating between related

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 512–522
Brussels, Belgium, October 31 - November 4, 2018.

languages, this is not the case for distant languages, see Figure 1. There is no established quantitative metric for measuring distances between languages. Language trees trace the evolution of languages but do not provide similarity scores. (Chiswick and Miller, 2005) learned similarity scores of 43 different languages to English by measuring how well Americans could learn a given language in a fixed period of time. Low scores on a standardized proficiency test were taken to indicate a large distance between the language and English. According to their scores, Japanese and Chinese are the most distant from English, Russian has a middle score, and French, Portuguese, Dutch, as expected, have some of the highest scores.

Additionally, linguists and psychologists have long studied the question of how language affects the way we think (Birner, 1999; Boroditsky, 2011). This influence would arise due to different languages organizing concepts differently.

We would like to model some aspects of the structural differences of languages when learning mapping functions between embedding spaces. To this end, we propose to learn neighborhood sensitive maps. We can, in principle, achieve neighborhood sensitive maps by training non-linear functions. However, training non-linear functions, in particular deep neural networks for this problem is difficult to optimize for this zero-shot (Lazaridou et al., 2015) learning problem, as we show in our experiments. Prior work alludes to similar observations(Mikolov et al., 2013a). For example, (Conneau et al., 2018) found that using non-linear mapping functions made training unstable[1].

In summary, our contributions are as follows:

- We propose a method for learning neighborhood sensitive maps, NORMA, which learns a single mapping function but in a departure from prior work, it *discovers neighborhoods*. NORMA avoids learning multiple mapping functions, thus enabling parameter sharing among neighborhoods. This is a more efficient use of training data than if we were to train multiple mapping functions for different neighborhoods as is done in (Zou et al., 2013).
- The neighborhoods are learned jointly while learning to translate, and we show that they are *interpretable*.
- Our experiments show that for word translation between distant languages, NORMA substantially outperforms methods that achieve the best performance when translating between related languages.
- Additionally, in the related language setting, we show that on rare words NORMA substantially outperforms state-of-the-art methods.

2 Related Work

The common approach to learning cross embedding space mapping functions is: first monolingual word embeddings for each language are trained independently; and second, a mapping function is learned, using supervised or unsupervised methods. The resulting mapping function enables translating words from the source to the target language.

Map Induction Methods. The earliest and simplest approach is to use a regularized least squares loss to induce a linear map $\mathbf{M}$ as follows: $\hat{\mathbf{M}} = \arg\min_{\mathbf{M}} ||\mathbf{MX} - \mathbf{Y}||_F + \lambda||\mathbf{M}||$, here $\mathbf{X}$ and $\mathbf{Y}$ are matrices that contain word embedding vectors for the source and target language (Mikolov et al., 2013a; Dinu et al., 2014; Vulic and Korhonen, 2016). Improved results were obtained by imposing an orthogonality constraint on $\mathbf{M}$ (Xing et al., 2015; Smith et al., 2017). Another loss function used in prior work is the max-margin loss, which has been shown to significantly outperform the least squares loss (Lazaridou et al., 2015; Nakashole and Flauger, 2017).

Another approach is to use canonical correlation analysis (CCA) to map two languages to a shared embedding space (Haghighi et al., 2008; Faruqui and Dyer, 2014; Lu et al., 2015; Ammar et al., 2016).

Most of the prior methods can be characterized as a series of linear transformations. In particular, (Artetxe et al., 2018a) propose a framework to differentiate prior methods in terms of which transformations they perform: embedding normalization, whitening, re-weighting, de-whitening, and dimensionality reduction.

Work on phrase translation proposed to induce many local maps that are individually trained (Zhao et al., 2015) on local neighborhoods. In

---

[1] https://openreview.net/forum?id=H196sainb

contrast, our approach trains a single function while taking into account neighborhood sensitivity. Our underlying motivation of neighborhood sensitivity is similar in spirit to the use of locally linear embeddings for nonlinear dimensionality reduction (Roweis and Saul, 2000).

Forms of Supervision. The methods we have described so far fall under supervised learning. In the supervised setting, a seed dictionary (5k word pairs is a typical size) is used to induce the mapping function. In (Artetxe et al., 2017) a semi-supervised approach is explored, whereby the method alternates between learning the map and generating an increasingly large dictionary. Completely unsupervised methods have recently been proposed using adversarial training (Barone, 2016; Zhang et al., 2017; Conneau et al., 2018). However, the underlying methods for learning the mapping function are similar to prior work such as (Xing et al., 2015). The limitations and strengths of unsupervised methods are detailed in (Søgaard et al., 2018)

Although in our our experiments we work in the supervised setting, NORMA can work with any form of supervision.

Translation Retrieval Methods. The most commonly used way to obtain a translation t of a source language word s is nearest neighbor retrieval, given by: $t = \arg\max_t \cos(\mathbf{M}x_s, y_t)$. Alternative retrieval methods have been proposed, such as the inverted nearest neighbor retrieval(Dinu et al., 2014), inverted softmax (Smith et al., 2017) and Cross-Domain Similarity Local Scaling (CSLS) (Conneau et al., 2018). Since we are interested in evaluating the quality of mapping functions, our experiments use standard nearest neighbor retrieval for all methods.

3 Local Maps in Embedding Space

Is it useful for maps to be neighborhood sensitive? To study this question we carried out experiments comparing performance of neighborhood-specific maps to global maps. A thorough analysis of this kind was carried out in our prior work (Nakashole and Flauger, 2018)

We created neighborhoods by first selecting the embeddings of a few words associated with specific topics such as diseases, or cities. We then added all nearby words, which are words whose cosine similarity to any of the selected words is $>=$0.5 [2]. We used three language pairs for local vs global map translation experiments: English to German, English to Portuguese, and English to Swedish. The neighborhoods and their train/test splits are:
$en - de$: medication(3,415/500), cities(2,083/500), and animals(990/500);
$en - pt$: diseases(1,670/300), chemicals(1,279/300), and names(1,986/300);
$en - sv$: flowers(1,537/200), insects(1,271/200), and names(1,416/200). The training and test data was obtained from subsets of Facebook AI MUSE lexicons[3]

For each of the neighborhoods, we evaluated translation accuracy both when using a locally trained map and when using a globally trained map. The difference is that the locally trained map is only trained using training data from the neighborhood, whereas the global map is trained using training data from the neighborhood but also from all other neighborhoods and more (˜10000 word pairs). That is, the training data for global maps is a superset of the local training data.

We trained all maps using linear transformations. As we will show in our experiments, optimizing neural network mapping functions for this problem fails. This is a similar observation to prior work (Mikolov et al., 2013a; Conneau et al., 2018)[1]. More details on models and experimental settings are described in Sections 4 and 5.

Figure 2 shows that for various neighborhoods, translation accuracy is higher when we train neighborhood-specific maps than one single global map. These results are similar to (Zou et al., 2013) who then trained many local maps. While we could also proceed to train many local maps, this requires identifying optimal neighborhoods. It also requires gathering sufficient training data for each of the neighborhoods independently. In our proposed method, NORMA, we avoid learning multiple maps, creating a single map, while modeling neighborhood information and promoting parameter sharing.

Overall, the results in Figure 2 are an indicator neighborhood sensitivity in maps is useful. This would particularly be useful for distant languages

---

[2] We found a 0.5 cutoff to be a good compromise between neighborhood purity, and size. However, our final method (Section 4) on which all our comparison experiments were based, automatically discovers neighborhoods based on ideas from sparse coding.

[3] https://github.com/facebookresearch/MUSE

where a single global map that is linear might not suffice since the underlying embedding structure for distant languages might differ more than those of related languages as depicted in Figure 1.

4 Model

In this section we introduce our model for learning neighborhood sensitive maps, NORMA. Our approach jointly discovers neighborhoods while learning to translate.

4.1 Reconstructive Neighborhood Discovery

Inspired by work on sparse coding (Lee et al., 2007), we discover neighborhoods by learning a reconstructive dictionary. We would like to learn a dictionary of neighborhoods on the source language side. To learn this dictionary, we set up a reconstruction objective, where for any given word embedding $x_i \in \mathbb{R}^d$, where d is the dimensionality of the word embeddings, we want to reconstruct x_i using a linear combination of K neighborhoods. Let $\mathbf{D} \in \mathbb{R}^{K \times d}$ be the neighborhood matrix, each row of $\mathbf{D}$ represents a d-dimensional vector which can be interpreted as representing the center of the neighborhood. Let $\mathbf{X} \in \mathbb{R}^{N \times d}$ be a set of N embedding vectors corresponding to words in the source language vocabulary[4]. We can learn a reconstructive dictionary of K neighborhoods with the following objective:

$$\mathbf{D}, \mathbf{V} = \arg\min_{\mathbf{D},\mathbf{V}} ||\mathbf{X} - \mathbf{VD}||_2^2 \qquad (1)$$

$\mathbf{D} \in \mathbb{R}^{K \times d}$ is the learned dictionary of neighborhoods, $K > d$ and thus the dictionary is overcomplete; $\mathbf{V} \in \mathbb{R}^{N \times K}$ are the learned neighborhood membership weights for $\mathbf{X}$. While we use the squared loss, other loss functions can be used (Lee et al., 2007). To encourage neighborhoods to be different from each other, one can impose an orthogonality constraint : $||\mathbf{DD}^T - \mathbf{I}||$ where $\mathbf{I}$ is the identity matrix. The reconstruction error with an orthogonality penalty is:

$$R(\theta) = ||\mathbf{X} - \mathbf{VD}||_2^2 + \lambda ||\mathbf{DD}^T - \mathbf{I}|| \qquad (2)$$

Where λ is a hyperparameter which controls the contribution of the orthogonality constraint to the reconstruction error.

4.2 Joint Neighborhood Discovery and Translation

Our approach ties neighborhood discovery to the word translation task. First, we obtain neighborhood 'factorized' representations by multiplying the input vector $\mathbf{X}$ by the dictionary of neighborhoods:

$$\mathbf{X}_{\mathcal{N}} = \mathbf{XD}^T,$$

where $\mathbf{X}_{\mathcal{N}} \in \mathbb{R}^{N \times K}$. Here again N refers to words in the source language vocabulary, English in the case of $en - de$ translation. And K is the number of neighborhoods.

Second, we obtain an intermediate representation of the input, which contains both the original input $\mathbf{X}$ and the neighborhood 'factorized' representations of the input $\mathbf{X}_{\mathcal{N}}$, through vector concatenation as follows:

$$\mathbf{X}_{\mathcal{I}} = [\mathbf{X}_{\mathcal{N}}; \mathbf{X}],$$

where $\mathbf{X}_{\mathcal{I}} \in \mathbb{R}^{N \times (K+d)}$.

To get the final representation of the input, we project $\mathbf{X}_{\mathcal{I}}$ into a low-dimensional vector of the same size as the original input:

$$\mathbf{X}_{\mathcal{F}} = \mathbf{X}_{\mathcal{I}} \mathbf{W}_f,$$

where $\mathbf{W}_f \in \mathbb{R}^{(K+d) \times d}$ is a set of learned parameters. And $\mathbf{X}_{\mathcal{F}} \in \mathbb{R}^{N \times d}$ is the resulting final representation.

We use these neighborhood sensitive representation $\mathbf{X}_{\mathcal{F}}$ as the input for learning the mapping function $\mathbf{W}$, instead of the original $\mathbf{X}$. We explore different ways for learning the mapping $\mathbf{W}$: first a linear mapping, and second, a single layer neural network with a leaky rectified linear unit (leaky ReLU[5]) non-linearity and a highway layer (Srivastava et al., 2015). As we will show in our experiments, training neural networks with more layers fails on this zero-shot learning problem.

For the linear map, the translation $\hat{y}_i$ is given by:

$$\hat{y}_i^{linear} = \mathbf{W} x_{\mathcal{F}_i} \qquad (3)$$

where $x_{\mathcal{F}_i} \in \mathbf{X}_{\mathcal{F}}$ is the neighborhood sensitive representation of x_i.

For the neural network map, using a single layer neural network, and a highway layer, the transla-

---

[4] Since the vocabulary size can be very large, in our experiments, we work in batches of N=50

[5] It outperformed other non-linearities such as $tanh$ in our initial experiments.

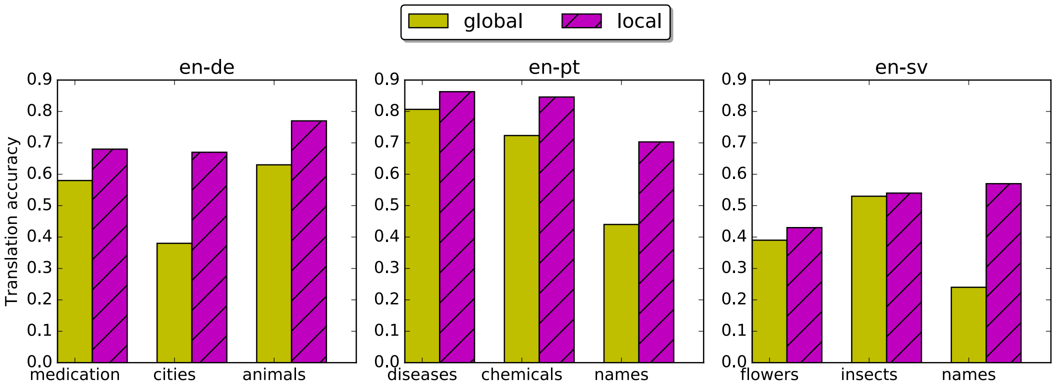

Figure 2: Accuracy of globally vs locally trained mapping functions for various neighborhoods on $en-de$, $en-pt$, and $en-sv$ translation.

tion $\hat{y}_i$ is given by:

$$h_i = \sigma_1(x_{\mathcal{F}_i}\mathbf{W})$$
$$t_i = \sigma_2(x_{\mathcal{F}_i}\mathbf{W^t})$$
$$\hat{y}_i^{nn} = t_i \times h_i + (1.0 - t_i) \times x_{\mathcal{F}_i} \qquad (4)$$

where σ_1 is a non-linearity. We use a leaky-ReLU non-linearity. σ_2 is the sigmoid function. $\mathbf{W^t}$ is another set of parameters in addition to $\mathbf{W}$.

4.3 Objective Function

We use the max-margin loss function to learn the parameters of the model:

$$L(\theta) = \sum_{i=1}^{m}\sum_{j\neq i}^{k} \max\Big(0, \gamma + d(y_i, \hat{y}_i^g) - d(y_j, \hat{y}_i^g)\Big), \qquad (5)$$

Where y_i is the true label; $\hat{y}_i^g$ is the prediction, which is either $\hat{y}_i^{linear}$ or $\hat{y}_i^{nn}$. The goal of the max-margin loss function is to rank correct training data pairs (x_i, y_i) higher than incorrect pairs (x_i, y_j) with a margin of at least γ. The margin γ is a hyper-parameter and the incorrect labels, y_j are selected randomly such that $j \neq i$. k is the number of incorrect examples per training instance, and $d(x, y) = (x-y)^2$ is the distance measure.

The joint neighborhood discovery and word translation objective is given by:

$$J(\theta) = L(\theta) + R(\theta) \qquad (6)$$

The neighborhood discovery part of the objective, $R(\theta)$, does not depend on availability of supervised data and only requires monolingual data on the source language side. Thus, we can discover neighborhoods in an unsupervised manner on a large set of monolingual word embeddings, then initialize using this pre-trained D which is then jointly optimized with the translation part of the objective $L(\theta)$. Importantly, this also means that our method can work with unsupervised methods for learning mapping functions such as those using adversarial training (Barone, 2016; Conneau et al., 2018).

5 Experimental Evaluation

In this section, we study the following questions: How does NORMA compare to state-of-the-art methods for learning mapping functions between embedding spaces of different languages? We study this question in three settings: when translating between distant languages, when translating between related languages, and lastly, when translating between related languages but on rare words. Additionally, we ask the following question: are the neighborhoods learned by NORMA meaningful?

To study these questions, we carried out experiments on word translation from English to two distant languages, a Slavic language (Russian), and a Sino-Tibetan language (Chinese). In addition, we carried out experiments on word translation between related languages (English, French, German and Portuguese).

Data and Experimental Setup. The Facebook AI MUSE[3] project (Conneau et al., 2018) provides train/test data for bilingual dictionaries of various language pairs, we use this data in our experiments. The MUSE dictionaries consist of

Method	Slavic & Sino-Tibetan

ADJECTIVE	10% /34.4	11% /38.7	10% /56.1	9% /76.9	10% /71.3

Table 2: Part-of-Speech (POS) distributions of the MUSE test sets. Listed are the top 3 parts of speech, which account for ˜90% of the test data for all language pairs. X% /Y means the POS tag makes up X% of the test set, with accuracy Y.

5,000/1,500 word pairs for train/test data. Unless specified, we use the train/test split provided by MUSE. Development sets: the MUSE dictionaries that we used are very large. They contain over 100,000 entries for most language pairs, we tuned our models on data that was not part of the train and test sets.

We obtained pre-trained word embeddings from FastText (Bojanowski et al., 2017). In Equation 2, we did not find it helpful to encourage neighborhoods to be different, thus we set $\lambda = 0$. We set the margin γ in Equation 5 to be $\gamma = 0.4$. For the dictionary of neighborhoods D in Equation 1, we set the number of neighborhoods $K = 2,000$[6]. We use $N = 50$ batch size. We estimate model parameters using stochastic gradient descent.

Methods Under Comparison. We compare variations of NORMA to several previously proposed methods for generating mapping functions. The methods compared are: (Artetxe et al., 2018a; Conneau et al., 2018; Smith et al., 2017; Xing et al., 2015; Lazaridou et al., 2015; Faruqui and Dyer, 2014; Mikolov et al., 2013a). More detailed descriptions of these prior methods can be found in the related work section.

Our primary goal is to evaluate the quality of maps produced. While a number of prior work proposed various approaches for retrieval, which have been shown to improve accuracy by a few points, we compare all methods using the same retrieval method, nearest neighbor. Thus, for (Conneau et al., 2018), we report the results for the variant of their method called: *adv - Refine - NN*.

---

[6] We carried out experiments using different neighborhood sizes, and consistently found $K \approx 2000$ to outperform other choices.

5.1 English to Slavic and Sino Tibetan

State-of-the-art methods have mostly focused word translation evaluation on English to Latin languages or other nearby languages. (Artetxe et al., 2018a) performed experiments on en-es, en-de, en-it and en-fi, where concepts might still be organized in a relatively similar way. In (Conneau et al., 2018), the adversarial training method proposed was evaluated on Chinese, Russian, and Esperanto, but thorough comparison experiments to prior work on word translation were only performed on English to Italian.

We carried out en-ru and en-zh comparison experiments, and present the results in the second and third columns of Table 1. The two state-of-of-the art methods (Artetxe et al., 2018a) and (Conneau et al., 2018) are significantly outperformed by NorMA-Linear. On English to Russian, NorMA-Linear achieves 50.33 precision 1, outperforming both (Artetxe et al., 2018a) (Conneau et al., 2018), as well as other methods. On English to Chinese, NorMA-Linear achieves 43.37 precision 1, again ahead of other methods. The best performing variant of our method is NorMA-Linear. The neural networks with more than a single layer prove difficult to optimize for this problem, and produce accuracy of 0. This could be because the problem of cross-embedding space mapping is a zero-shot learning problem, which is much more difficult to train than a supervised problem, the setting in which deep learning methods have thrived so far.

5.2 English to Related Languages

We show experiments on English to related languages in the last three columns of Table 1. On these languages, indeed the most recently proposed methods (Artetxe et al., 2018a; Conneau et al., 2018) produce the best performing maps. However, NorMA-Linear is only 2-3 points behind these methods. This in contrast to English to Chinese where both (Artetxe et al., 2018a) and (Conneau et al., 2018) are behind NorMA - Linear, by more than 10 points.

A promising line of future work is to get NorMA-Linear to bridge the 2-3 point gap on related languages by exploring a best of both worlds approach, combining neighborhood sensitivity with the methods that achieve superior performance on nearby languages.

	en-pt	
	RARE	MUSE

Lazaridou et al 2015	48.00	72.27

Table 3: Performance for en-pt on rare words (RARE), and the en-pt MUSE dataset, which as shown in Figure 3 contains a lot of frequent words.

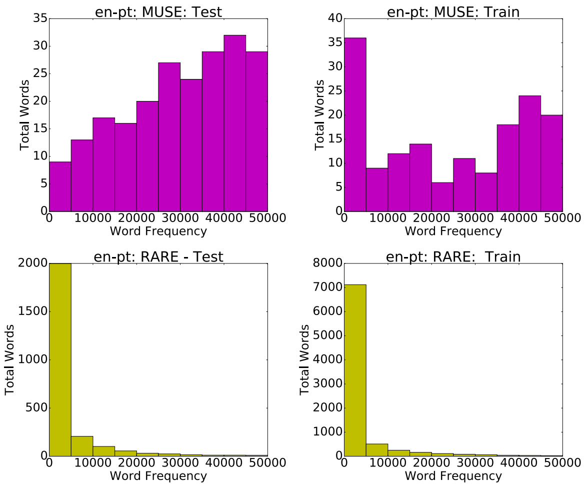

Figure 3: Top: Frequency distribution of MUSE dictionary test and train sets for en-pt. Bottom: Frequency distribution of the RARE words dataset.

5.3 Accuracy by Part-of-Speech

We assigned each word its majority part-of-speech by tagging the ClueWeb[7] corpus, which contains over 500 million webpages. We then evaluated translation precision of NorMA-Linear stratified by part-of-speech. The results are shown in Table 5 We found that, nouns and verbs make up about 80 percent of the MUSE test dictionaries, followed by adjectives (˜10%). We found that while nouns and verbs make up a large chunk of the test data, nouns are translated with much higher accuracy than verbs, except for English to Chinese. This finding will serve as a guide for future improvements to our method.

5.4 English to Languages: Rare Words

We analyzed the frequency distribution of the MUSE dictionaries. To get word frequency infor-

Neighborhood			
51	134	162	7
drugs zonisamide cocaine ritalin hospitalized pheniprazine overdose disorientation focusyn alfaxalone	criminally judicature prosecutory derogation restitutionary derogative jailable extradition sodomy crimes	chuanyao chuanyan zhiang thanong qiangbing pengpeng nguyan yuning liheng thanong	khoisan bantu sepedi otjiherero ndebeles hereros otjinene shona hutu witotoan

Table 4: Sample neighborhoods discovered by NORMA during en-de translation: 51 appears to represent drugs, 132: justice and crime; 162: Asian names, 7 : African names.

mation, we processed documents in the ClueWeb[7] corpus and recorded word occurrence frequency. We discovered that the MUSE dictionaries contain a lot of frequent words. The top half of Figure 3 shows frequency counts of the en-pt MUSE test dictionary. For readability we only show bins up to occurrence frequency of 50,000. We see that only about 50/1500 in the MUSE en-pt test data are infrequent, the rest are frequent words, occurring more than 10,000 times in the ClueWeb corpus.

We therefore created another test set for en-pt from the rest of the MUSE data which is not part of the train or test data, with the goal of creating a train/test of rare words. The bottom half of Figure 3 is a plot of frequency counts of train and test data for these rare words.

We then compared variations of NORMA to the best performing method on English to related languages, which is (Artetxe et al., 2018a). The comparison was done both on the regular MUSE test dataset for en-pt and the rare word dataset for en-pt. Since our method uses a max-margin loss much like (Lazaridou et al., 2015), we also compare to (Lazaridou et al., 2015).

Table 3 shows that NORMA-Linear outperforms (Artetxe et al., 2018a) by over 10 points on the RARE words dataset. On the regular MUSE dictionary, (Artetxe et al., 2018a) is ahead by about 5 points. On RARE, (Lazaridou et al., 2015) is behind NORMA-Linear by 9 points, whereas on the MUSE dictionary performance of (Lazaridou et al., 2015) and NORMA-Linear is about the same.

5.5 Neighborhood Interpretability

NORMA jointly discovers neighborhoods while learning to translate words. We now ask if the discovered neighborhoods semantically make sense. We can answer this question since each neighborhood vector can be seen as a "center" vector representing the words in the neighborhood. Thus we can consider words whose cosine similarity to the neighborhood vector is greater than some threshold, to be members of that neighborhood. As we mentioned, we found that setting the total number of neighborhoods to be discovered to $K = 2,000$ provided the best results. Of these 2,000 we show some of them in Table 4 obtained when training $en - de$. For each neighborhood, we show 10 words that appear among the top 100 words of that neighborhood. It can be seen that the neighborhoods represent some kind of "topics". For example, neighborhood number 51 appears to represent drugs, and drug-related concepts; number 132 contains justice and crime-related concepts; number 162 contains mostly Asian concepts and names, number 7 contains mostly African and names. We can see that the granularity of neighborhoods and their specificity varies.

6 Conclusions

We propose neighborhood sensitive maps for learning multilingual word embeddings, NORMA. Our method is motivated by the fact that languages differ along dimensions such as vocabulary, grammar, written form, and syntax, and therefore one would expect that embedding spaces of different languages exhibit different structures especially for distant languages.

Our method jointly discovers neighborhoods while learning to translate words. Experimental evaluation showed that NORMA substantially outperforms state-of-the-art (SOTA) methods on distant languages, while only being a few points behind on related languages. A promising line of future work is to explore a best of both worlds approach, combining neighborhood sensitivity with the methods that achieve superior performance on nearby languages.

Adaptive Multi-pass Decoder for Neural Machine Translation

Xinwei Geng **Xiaocheng Feng** **Bing Qin**[*] **Ting Liu**
Harbin Institute of Technology, China
`{xwgeng, xcfeng, qinb, tliu}@ir.hit.edu.cn`

Abstract

Although end-to-end neural machine translation (NMT) has achieved remarkable progress in the recent years, the idea of adopting multi-pass decoding mechanism into conventional NMT is not well explored. In this paper, we propose a novel architecture called *adaptive multi-pass decoder*, which introduces a flexible multi-pass polishing mechanism to extend the capacity of NMT via reinforcement learning. More specifically, we adopt an extra policy network to automatically choose a suitable and effective number of decoding passes, according to the complexity of source sentences and the quality of the generated translations. Extensive experiments on Chinese-English translation demonstrate the effectiveness of our proposed adaptive multi-pass decoder upon the conventional NMT with a significant improvement about 1.55 BLEU.

1 Introduction

In the past several years, end-to-end neural machine translation (NMT) (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2014) has attracted increasing attention from both academic and industry communities. Compared with conventional statistical machine translation (SMT) (Brown et al., 1993; Koehn et al., 2003), which needs to explicitly model latent structures, NMT adopts a unified *encoder-decoder* framework to directly transform a source sentence into a target sentence. Furthermore, the introduction of attention mechanism (Bahdanau et al., 2014) enhances the capability of NMT in capturing long-distance dependencies.

Recently, a number of authors have endeavored to adopt the polishing mechanism into NMT. Similar to human cognitive process for writing a good paper, their models first create a complete draft and then polish it based on global understanding of the whole draft (Niehues et al., 2016; Chatterjee et al., 2016; Zhou et al., 2017; Xia et al., 2017; Junczys Dowmunt and Grundkiewicz, 2017) . Moreover, Zhang et al. (2018) introduces a backward decoder to better exploit the right-to-left target-side contexts. Generally these methods employ two separate decoders to accomplish the polishing task.

Although these polishing mechanism-based approaches demonstrate their effectiveness with two-pass decoding, the idea of multi-pass decoding is not well explored for NMT. Motivated by it, we first propose a novel multi-pass decoder to perform the translation procedure with a fixed number of decoding passes, referred to as decoding depth. According to the preliminary results, just as expected, multi-pass decoding really benefit to most translations. However, in some cases, the more decoding passes perhaps lead to the poor translation. For example in Table 1, the 3rd-pass de-

Brussels, Belgium, October 31 - November 4, 2018.

coding achieves a better result compared to 1st- and 2nd-pass decoding. Nevertheless, a drastic decrease arises, when we perform the 4th-pass decoding. Therefore, it's necessary to introduce a flexible multi-pass decoding, which has the ability to adaptively choose the suitable decoding passes.

Towards above goal, we further propose a novel framework called *adaptive multi-pass decoder* to automatically choose a proper decoding depth using reinforcement learning. Our model considers multi-pass decoding as a sequential decision making process, where continuing decoding or halt is chosen at each step. An extra policy network is employed to learn to automatically choose to continue next pass decoding or halt via reinforcement learning. For the purpose of making accurate and effective choices, the policy network employs recurrent neural network to capture the complexity of source sentence as well as the difference between the consecutive generated translations. Extensive experiments on Chinese-English translation show the proposed adaptive multi-pass decoder is capable of choosing a suitable decoding depth and significantly improves translation performance over conventional NMT model.

2 Background

Given a source sentence $\mathbf{x} = x_1, \dots, x_m, \dots, x_M$ and a target sentence $\mathbf{y} = y_1, \dots, y_n, \dots, y_N$, end-to-end neural machine translation directly models translation probability word by word as a single, large neural network:

$$P(\mathbf{y}|\mathbf{x};\theta) = \prod_{n=1}^{N} P(\mathbf{y_n}|\mathbf{x}, \mathbf{y}_{<n};\theta) \tag{1}$$

where θ is a set of model parameters and $\mathbf{y}_{<n}$ denotes a partial translation. Prediction of n-th word is generally made in an *encoder-decoder* framework:

$$P(\mathbf{y}_n|\mathbf{x}, \mathbf{y}_{<n};\theta) = g(\mathbf{y}_{n-1}, \mathbf{s}_n, \mathbf{c}_n) \tag{2}$$

where $g(\cdot)$ is a non-linear function, $\mathbf{y}_{n-1}$ denotes the previously generated word, $\mathbf{s}_n$ is n-th decoding hidden state, and $\mathbf{c}_n$ is a context vector for generating n-th target word. The decoder state $\mathbf{s}_n$ is computed by RNNs as follows:

$$\mathbf{s}_n = f(\mathbf{s}_{n-1}, \mathbf{y}_{n-1}, \mathbf{c}_n) \tag{3}$$

where $f(\cdot)$ is an activation function. Actually it's found gated RNN alternatives such as LSTM (Hochreiter and Schmidhuber, 1997) or GRU (Cho et al., 2014) often achieve better performance than vanilla ones. $\mathbf{c}_n$ is a dynamic vector that selectively summarizes certain parts of source sentence at each decoding step:

$$\mathbf{c}_n = \sum_{m=1}^{M} \alpha_{n,m}\mathbf{h}_m \tag{4}$$

where $\alpha_{m,n}$ measures how well $\mathbf{x}_m$ and $\mathbf{y}_n$ are aligned, calculated by attention model (Bahdanau et al., 2014; Luong et al., 2015), and $\mathbf{h}_m$ is the encoder hidden state of the m-th source word. For the purpose of capturing both forward and backward contexts, bidirectional RNN (Schuster and Paliwal, 1997) is often employed as the encoder which converts the source sentence into an annotation sequence $\mathbf{h} = \{\mathbf{h}_1, \dots, \mathbf{h}_m, \dots, \mathbf{h}_M\}$, where $\mathbf{h}_m = [\overrightarrow{\mathbf{h}}_m, \overleftarrow{\mathbf{h}}_m]$ captures information about m-th word with respect to the preceding and following words in the source sentence respectively.

Although the introduction of RNNs as a decoder has resulted in substantial improvements in terms of translation quality, simultaneously it imposes a serious restriction on the capability of *encoder-decoder* framework caused by the structure of RNNs. That is, when the RNN decoder generates the t-th word $\mathbf{y}_t$ in decoding phase, only $\mathbf{y}_{<t}$ can be utilized, while the possible words $\mathbf{y}_{>t}$ are directly neglected. Thus, it's difficult to capture global information especially the ungenerated words for the current dominant RNN decoder without new significant innovation. Under the premise of preserving the original structure, a promising alternative to address the aforementioned issue is to incorporate with auxiliary neural networks to extend the RNN decoder.

Towards above goal, polishing mechanism-based methods first capture the global information through a complete draft created by SMT or NMT, and then take it as input to finally generate a translation. Compared with conventional NMT, polishing mechanism-based methods make a more accurate prediction at each time-step due to the extra global understanding, resulting in more fluent and grammatically correct translation. While these approaches have demonstrated the effectiveness, previous approaches follow pre-defined routes to perform the decoding procedure, not considering choosing a suitable decoding depth for the complexity of source sentences completely.

Therefore, it's important to develop a novel framework for making an accurate and effective choice about which decoding depth is appropriate for the source sentence.

3 Adaptive Multi-pass Decoder

In this section, we present an adaptive multi-pass decoder for neural machine translation, as illustrated in Figure 1. It could choose a proper decoding depth, depending on the complexity of the source sentence. As shown in Figure 1, our model includes three major components: an encoder to summarize source sentences with parameter set θ_e, a multi-pass decoder for multi-pass decoding with parameter set θ_d, and a policy network to choose a suitable depth with parameter set θ_p. The encoder of our model is identical to that of the dominant NMT which is modeled using a bidirectional RNN. Please refer to Bahdanau et al. (2014) for more details. We will elaborate the *multi-pass decoder* and *policy network* for adaptive multi-pass decoding in the following subsections.

3.1 Multi-pass Decoder

The multi-pass decoder is extended from the one of the dominant NMT model to leverage the target-side context. Similar to the dominant NMT model, our multi-pass decoder also performs the decoding under the semantic guide of source-side context captured by the encoder, whereas more importantly and differently, the global understanding through the target-side context provided by last pass decoding, is able to strongly assist our model to produce a better translation.

Given the source-side and target-side contexts separately captured by the encoder and last pass decoding, the multi-pass decoder learns to generate next target word, based on previous generated words. Using the multi-pass decoder with parameter set θ_d, we calculate the conditional probability of the translation $\hat{\mathbf{y}}^l$ at the l-th decoding pass as follows:

$$\begin{aligned}
&P(\hat{\mathbf{y}}^l|\mathbf{x},\hat{\mathbf{y}}^{l-1};\theta_e,\theta_d)\\
&=\prod_{n=1}^{N_l} P(\hat{\mathbf{y}}^l_n|\mathbf{x},\hat{\mathbf{y}}^l_{<n},\hat{\mathbf{y}}^{l-1};\theta_e,\theta_d)\\
&=\prod_{n=1}^{N_l} g^{dec}(\hat{\mathbf{y}}^l_{n-1},\mathbf{s}^{l,dec}_n,\mathbf{c}^{l,enc}_n,\mathbf{c}^{l,dec}_n) \qquad (5)
\end{aligned}$$

where $g^{dec}(\cdot)$ is a non-linear function, and $\mathbf{s}^{l,dec}_n$ denotes the n-th decoding state within the l-th decoding pass. N_l indicates the length of generated translation at the l-th decoding pass. The decoding state $\mathbf{s}^{l,dec}_n$ is obtained by RNNs as follows:

$$\mathbf{s}^{l,dec}_n = f^{dec}(\mathbf{s}^{l,dec}_{n-1},\hat{\mathbf{y}}^l_{n-1},\mathbf{c}^{l,enc}_n,\mathbf{c}^{l,dec}_n) \qquad (6)$$

where $f^{dec}(\cdot)$ is the GRU activation function. $\mathbf{c}^{l,enc}_n$ and $\mathbf{c}^{l,dec}_n$ denote source-side and target-side contexts at the n-th time step within the l-th decoding pass, respectively. It should be noted that when the multi-pass decoder performs the first decoding, there doesn't exist any generated translation. To address this case, the first-pass target-side context $\mathbf{c}^{1,dec}$ is set to zero.

Among the aforementioned contexts, $\mathbf{c}^{l,enc}_n$ is obtained as the weighted sum of the source-side hidden states $\{\mathbf{h}_m\}$, while we take the target-side hidden states $\{\mathbf{s}^{l-1,dec}_n\}$ produced by last pass decoding as input to compute $\mathbf{c}^{l,dec}_n$. Similar to the dominant NMT model, we adopt the attention model (Bahdanau et al., 2014; Luong et al., 2015) to calculate the weights, which indicate the alignment probability. We assume that $attn^{enc}$ denotes the encoder-decoder attention model, which takes the source annotations $\{\mathbf{h}_m\}$ as input, while $attn^{dec}$ are introduced to calculate the weight which measures how well the decoding state $\mathbf{s}^{l,dec}$ attends the last-pass hidden states $\{\mathbf{s}^{l-1,dec}_n\}$.

Assuming $\mathbf{s}^a$ indicates the decoding state, which attends the annotations $\{\mathbf{s}^b_k\}$ with a length K, our attention model calculates the context vector $\mathbf{s}^c$ as follows:

$$\mathbf{s}^c = \sum_{k=1}^{K} \alpha_k \mathbf{s}^b_k \qquad (7)$$

$$\alpha_k = \frac{\exp(e_k)}{\sum_{k'=1}^{K}\exp(e_{k'})} \qquad (8)$$

$$e_k = (v_a)^T \tanh(W_a\mathbf{s}^a + U_a\mathbf{s}^b_k) \qquad (9)$$

where v_a, W_a and U_a are the parameters of attention model.

Given a training $(\mathbf{x},\mathbf{y})$, the translation route can be demonstrated as: $\mathbf{x}\rightarrow\hat{\mathbf{y}}^1\rightarrow\ldots\rightarrow\hat{\mathbf{y}}^l\rightarrow\ldots\rightarrow\hat{\mathbf{y}}^{L(\mathbf{x},\mathbf{y})-1}\rightarrow\mathbf{y}$.The intermediate translations $\{\hat{\mathbf{y}}^l\}$ are generated by decoding. Given a training corpus $D=\{\mathbf{x},\mathbf{y}\}$, we define the object function using cross-entropy at last pass decoding as follows:

$$\begin{aligned}
J^{dec}(\theta_e,\theta_d) = -\frac{1}{|D|}\operatorname*{arg\,min}_{\theta_e,\theta_d}\sum_{(\mathbf{x},\mathbf{y})\in D}\\
\{\log P(\mathbf{y}|\mathbf{x},\hat{\mathbf{y}}^{L(\mathbf{x},\mathbf{y})-1};\theta_e,\theta_d)\} \qquad (10)
\end{aligned}$$

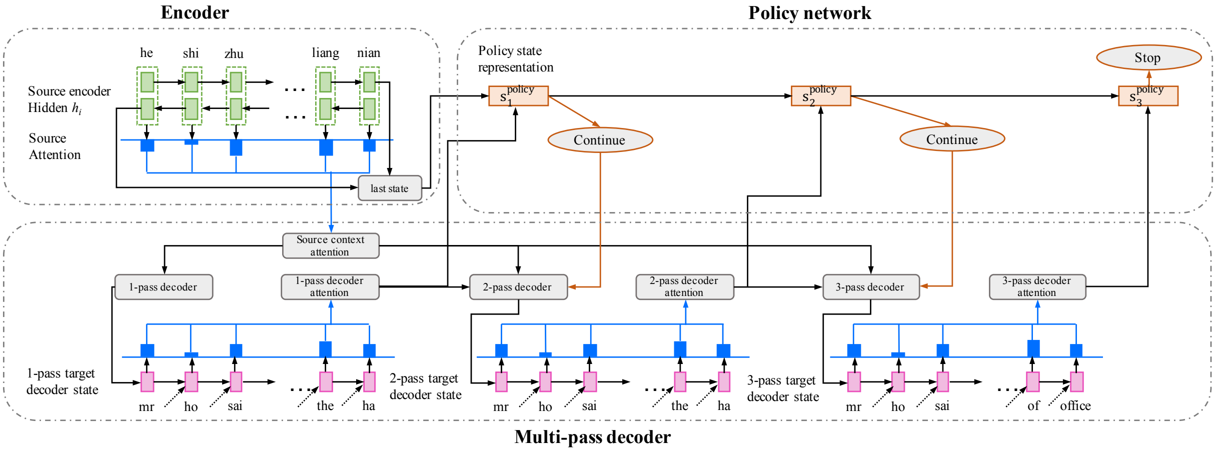

Figure 1: The architecture of our *adaptive multi-pass decoder*. Given the annotation sequence produced by the encoder, a policy network is adopted to choose a suitable action from the set $\{Continue, Stop\}$, which indicates continuing next pass decoding, or halt respectively. Different from the conventional decoder which only obtains the source-side context with the source attention model $attn^{enc}$, our multi-pass decoder also captures the target-side context of last-pass decoding with decoder attention model $attn^{dec}$. The policy network also use $attn^{policy}$ to collect useful information from the multi-pass decoding to choose an accurate and effective action to generate a good translation. Note that in this work the same parameters set of decoder and the corresponding attention is shared among different decoding passes. For this figure, we demonstrate a translation procedure with 3-pass decoding controlled by adaptive multi-pass decoder.

where $P(\mathbf{y}|\mathbf{x}, \hat{\mathbf{y}}^{L_{(\mathbf{x},\mathbf{y})}-1}; \theta_e, \theta_d)$ is conditional probability computed by multi-pass decoder. $L_{(\mathbf{x},\mathbf{y})}$ indicates the decoding depth for the instance $(\mathbf{x}, \mathbf{y})$. For effectiveness, note that all the intermediate translations $\{\hat{\mathbf{y}}^l\}$ are generated by greedy search in training and testing phase.

3.2 Policy Network

The multi-pass decoding can be converted into sequential decision making process, in which a policy is adopted to choose next pass decoding or halt. It's expected to automatically choose an accurate and effective decoding depth to generate a good translation. For example, if the source sentence is exhausted to obtain the corresponding translation such as the long sentences, we assume more decoding passes are needed to improve the translation, while only one pass decoding is enough to tackle the simple case.

Our main idea is to use reinforcement learning to control the decoding depth. We parameterize the available action $\mathbf{a}_l \in \{Continue, Stop\}$, where $Continue$ and $Stop$ indicate continuing next decoding pass and halt respectively, by a policy network $\pi(\mathbf{a}_l|\mathbf{s}_l^{policy}; \theta_p)$, where $\mathbf{s}_l^{policy}$ represents the policy state at the l-th decoding pass. For the purpose of making a better choice about the decoding depth and direction, it's necessary to consider whether or not the source sentence is easy to obtain a good translation and compared with the last pass decoding, whether the quality of translation can be improved. Thus, supervised by this guideline, the policy state $\mathbf{s}_l^{policy}$ is calculated by GRU to model the difference between the consecutive two decoding passes as follows:

$$\mathbf{s}_l^{policy} = f^{policy}(\mathbf{s}_{l-1}^{policy}, m_l) \tag{11}$$

where f^{policy} is the activation function, and m_l captures the useful information with respect to the policy network at the l-th decoding pass. In this work, we use the attention models $attn^{policy}$ to collect the decoding progress, denoted as m_l of the l-th decoding pass. In order to take account of the complexity of source sentence itself, the initial policy state $\mathbf{s}_0^{policy}$ is computed by $\mathbf{s}_0^{policy} = \tanh(W_{init}\mathbf{h}_M)$, where $\mathbf{h}_M$ is last state source annotations, and W_{init} is the parameters of initializing the policy state. Finally, we take the policy state $\mathbf{s}_l^{policy}$ as input to calculate the policy as follows:

$$\pi(\mathbf{a}_l|\mathbf{s}_l^{policy}; \theta_p) = softmax(W_p\mathbf{s}_l^{policy} + b_p) \tag{12}$$

where W_p and b_p are the parameters of the policy network. In this work we use REINFORCE algorithm (Williams, 1992), which is an instance of a broader class of algorithms called policy gradient methods (Sutton and Barto, 1998), to learn the parameter set θ_p such that the sequence of actions

$\mathbf{a} = \{\mathbf{a}_1, \ldots, \mathbf{a}_l, \ldots, \mathbf{a}_{L_{(\mathbf{x},\mathbf{y})}}\}$ maximizes the total expected reward. The expected reward for an instance is defined as:

$$J^{policy}(\theta_p) = \mathbb{E}_{\pi(\mathbf{a}|\mathbf{s}^{policy};\theta_p)} r(\hat{\mathbf{y}}^{L_{(\mathbf{x},\mathbf{y})}}) \quad (13)$$

where $r(\hat{\mathbf{y}}^{L_{(\mathbf{x},\mathbf{y})}})$ is the reward at the $L_{(\mathbf{x},\mathbf{y})}$-th decoding pass. In this work, we use BLEU (Papineni et al., 2002) of the final translation $\hat{\mathbf{y}}^{L_{(\mathbf{x},\mathbf{y})}}$ generated by greedy search as input to compute our reward as follows:

$$r(\hat{\mathbf{y}}^{L_{(\mathbf{x},\mathbf{y})}}) = \text{BLEU}(\hat{\mathbf{y}}^{L_{(\mathbf{x},\mathbf{y})}}, \mathbf{y}) \quad (14)$$

4 Experiments

In this section, we describe experimental settings and report empirical results.

4.1 Setup

We evaluated the proposed *adaptive multi-pass decoder* on Chinese-English translation task. The evaluation metric was case-insensitive BLEU (Papineni et al., 2002) calculated by the `multi-bleu.perl`[1] script. The training corpus[2] consisted of 1.25M bilingual sentences with 27.9M Chinese words and 34.5M English words. We used the NIST 2002 (MT02) as the validation set for hyper-parameter optimization and model selection, and NIST 2003 (MT03), 2004 (MT04), 2005 (MT05) and 2006 (MT06) as test sets.

To effectively train the NMT model, we trained each model with sentences of length up to 50 words. Besides, we limited vocabulary size to 30K for both languages and map all the out-of-vocabulary words in the Chinese-English corpus to a special token UNK. We applied *Rmsprop* (Graves, 2013) to train models and selected the best model parameters according to the model performance on the development set. During this procedure, we set the following hyper-parameters: word embedding dimension as 620, hidden layer size as 1000, learning rate as 5×10^{-4}, batch size as 80, gradient norm as 1.0, and dropout rate as 0.3.

In the experiments, we compared our approach against the following state-of-the-art SMT and NMT systems:

1. *Moses*[3]: an open source phrase-based translation system with default configuration and a 4-gram language model trained on the target portion of training data. Note that we used all data to train MOSES (Koehn et al., 2007).

2. *RNNSearch*: a variant of the attention-based NMT system (Bahdanau et al., 2014) with slight changes from dl4mt tutorial[4].

3. *Deliberation Network*[5]: a re-implementation of attention-based NMT system with two independent left-to-right decoders (Xia et al., 2017). The first-pass decoder is identical to one of RNNSearch to generate a draft translation, while the second-pass decoder polishes it with an extra attention over the first pass decoder. The second-pass decoder is integrated with the first-pass decoder via reinforcement learning.

4. *ABDNMT*: As a comparison with the Deliberation Network, ABDNMT utilizes first-pass backward decoder to generate a translation with greedy search, and the second-pass forward decoder refines it with attention model (Zhang et al., 2018). For fairness, we replace the first-pass backward decoder with a forward decoder.

We set the beam size of all above-mentioned models as 10 in our work. Deliberation Network and ABDNMT were initialized with the pre-trained RNNSearch as Xia et al. (2017) and Zhang et al. (2018) described. Our multi-pass decoder was also initialized with RNNSearch and other parameters were randomly initialized from a uniform distribution on $[-0.1, 0.1]$. Besides, for effectiveness, we set the maximum decoding depth of our adaptive multi-pass decoder as 5.

4.2 Results on Chinese-English Translation

The experimental results of our model and baseline models on Chinese-English machine translation datasets are depicted in Table 2 .

Adaptive multi-pass decoder	96.01M	180	**41.42**	**38.39**	**41.43**	**38.54**	37.86	**39.05**

Table 2: Evaluation of the NIST Chinese-English translation task. The BLEU scores are case-insensitive. "Params" denotes the number the parameters in each model. The "Speed" denotes the generation speed in seconds on the development set. RNNSearch is an attention-based neural machine translation model(Bahdanau et al., 2014) with one-pass left-to-right decoding. RNNSearch(R2L) is a variant of RNNSearch with one-pass right-to-left decoding. As a comparison, Deliberation Network (Xia et al., 2017) and ABDNMT (Zhang et al., 2018) involve two independent decoders to adopt polishing mechanism to extend the ability of conventional NMT. Deliberation Network utilizes two left-to-right decoders coupled with reinforcement learning. However, ABDNMT exploits a backward decoder to perform first-pass right-to-left decoding. {2,3,4,5}-pass decoder utilizes our multi-pass decoder with a fixed number of decoding passes. Furthermore, adaptive multi-pass decoder involves a policy network to enhance our multi-pass decoder to choose a proper decoding depth.

Parameters RNNSearch, Deliberation Network and ABDNMT have 83.99M, 125.16M and 122.86M parameters, respectively. And the parameter size of our {2,3,4,5}-pass decoder and adaptive multi-pass decoder are about 87.81M and 96.01M, respectively.

Fixed Decoding Depth {2,3,4,5}-pass decoders perform the left-to-right decoding by the multi-pass decoder with a fixed number of decoding passes. In contrast to the related machine translation systems, our fixed number-pass decoder significantly outperforms Moses and RNNSearch by 7.53 and 1.05 BLEU points at least, as Table 2 presents. More importantly, our proposed multi-pass decoder obtains much better performance with an increase of only 3.82M parameters over RNNSearch. As a comparison with Deliberation Network involves two-pass decoding, the multi-pass decoder has a minimum increase of 0.24 BLEU score. Nevertheless, our multi-pass decoder proves its effectiveness due to the less parameters consumption of 37.35M in contrast to Deliberation Network. These results verify our hypothesis that the more decoding passes can polish the generated output to improve the translation quality. The underlying reason is that the attention component $attn^{dec}$ within our multi-pass decoder can capture the extra target-side contexts to obtain a global understanding to assist the translation procedure.

Towards the effect of the decoding depth set {2,3,4,5}, our multi-pass decoders obtain the approximate results, but the whole curve of BLEU is on an upward trend. Specifically, the multi-pass decoder with decoding depth 5 achieves the best performance with 38.64 BLEU, while the one with decoding depth 3 performs the worst among the decoding depth set with 38.55 BLEU. Although the average results of {2,3,4,5}-pass decoder are approximate, the distinction of {2,3,4,5}-pass decoder on NIST03, NIST04, NIST05, NIST06 and NIST08 is not negligible. These results indirectly prove the necessity of flexibility mechanism.

Adaptive Decoding Depth our proposed adaptive multi-pass decoder involves an extra policy network which controls the decoding depth according to the complexity of the source sentence and the differences between the consecutive generated translations. As shown in Table 2, the proposed adaptive multi-pass decoder obtains an improvement about 0.41 to 0.5 BLEU on average over the {2,3,4,5}-pass decoder, which demonstrates the effectiveness of the policy network. Specifically, the adaptive multi-pass decoder outperforms the multi-pass decoder with a fixed decoding depth by 0.69, 0.71, 0.68 and 0.45 BLEU scores on NIST03, NIST04, NIST05 and NIST06 datasets at most. In contrast to the Moses, RNNSearch, Deliberation Network and ABDNMT, the adaptive multi-pass decoder has the corresponding improvement about 8.03, 1.55, 0.74 and 0.34 BLEU points, respectively. More importantly, our adaptive multi-pass decoder outperforms ABDNMT, Deliberation Network model with a decrease of 26.85M, 29.15M parameters.

In order to further demonstrate the effective-

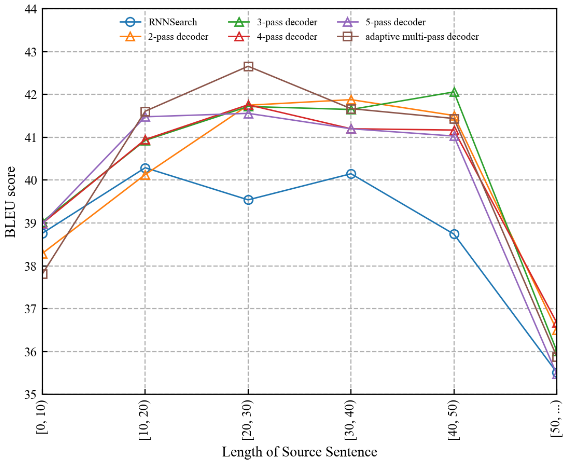

Figure 2: Performance of the generated translations with respect to the lengths of the source sentences on the development dataset.

ness of adaptively choosing the decoding depth, we investigate the ratio of decoding passes consumed by our multi-pass decoder on the development dataset, as shown in Table 3. Our adaptive multi-pass decoder chooses one-pass decoding in a high ratio of 46.57%, while in most about 53.43% cases our model leverages more than one pass decoding to produce a translation. The average decoding depth of our model is calculated as: $(1 \times 46.36\% + 2 \times 20.84\% + 3 \times 13.10\% + 4 \times 13.55\% + 5 \times 6.15\%) = 2.12$. Moreover, our ratio of the samples tends to decrease as the decoding depth rises on a whole. Since time consumption correlates with decoding depth, our adaptive multi-pass decoder proves its superior performance due to fewer parameters and less decoding passes.

Depth	1	2	3	4	5
Ratio(%)	46.57	20.45	13.00	13.60	6.38

Table 3: The ratio of decoding depth chosen by adaptive multi-pass decoder on the development dataset.

Time Consumption Due to the multi-pass decoding mechanism, the major limitation of our proposed multi-pass decoder is time cost. In training phrase, we spend more time training the multi-pass decoder than RNNSearch, Deliberation Network and ABDNMT. However, in testing phrase, as illustrated in Table 2, our adaptive multi-pass decoder spends about 180s completing the entire testing procedure, in comparison with the corresponding 87s, 162s, 132s of RNNSearch, Deliberation Network and ABDNMT, due to the auxiliary policy network. These results are consistent with above conclusion drew according to the decoding depth. Therefore, it's proven the necessity of our proposed auxiliary policy network to choose the decoding depth.

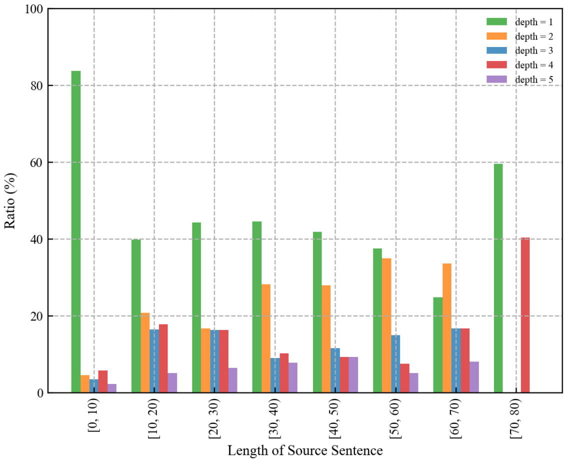

Figure 3: Ratio of decoding depth set {1,2,3,4,5} controlled by our adaptive multi-pass decoder with respect to each length segment of the source sentences on the development dataset.

4.3 Effect of Source Sentence Length

Following Bahdanau et al. (2014), we group sentences of similar lengths together and compute the BLEU score for each group, as shown in Figure 2. Obviously, our proposed adaptive multi-pass decoder outperforms RNNSearch in all length segments. Compared with {2,3,4,5}-pass decoders, our adaptive multi-pass decoder outperforms most even all the multi-pass decoders with fixed decoding depth in the length segments.

For the purpose of investigating the flexibility of policy network, we calculate the ratios of decoding depth set {1,2,3,4,5} on each sentence group with similar length, as illustrated in Figure 3. The ratio of one-pass decoding remains high level on each length segment, but explicitly is dominant on the length segment $[0, 10)$. In contrast, the ratios of remaining decoding depths show upwards trends on a whole. These results indirectly proves that our policy network has the capability of choosing the proper decoding depth. That is, when the source sentence is difficult to be translated such as some long sentences, more decoding passes are consumed to improve the translation quality, while in simple cases such as short source sentences, one-pass decoding is adequate.

4.4 Case Study

To better understand the effectiveness of flexible polishing mechanism adopted by policy network, Table 4 provides a Chinese-English transla-

Table 4: Translation examples at each decoding depth of adaptive multi-pass decoder.

tion example. Our proposed adaptive multi-pass decoder has the ability to polish the generated hypothesis again and again. As shown in Table 4, we force our adaptive multi-pass decoder to perform the multi-pass decoding with fixed depth sets {1,2,3,4,5}. The translation quality has an upwards trend with decoding depth 1 to 3, and the decoding with depth set {4,5} generates the identical translation as the decoding depth 3. Moreover, given the same source sentence, we use the proposed adaptive multi-pass decoder to choose the decoding depth. As expected, our adaptive multi-pass chooses 3-pass decoding which generates best translation and consumes least time, rather than {4,5}-pass decoding. Therefore, these results proves the effectiveness of our adaptive multi-pass decoder.

5 Related Work

In this work, we mainly focus on how to adopt adaptive polishing mechanism into NMT model, which has attracted intensive attention in recent years. We will elaborate polishing mechanism-based methods in the following pages.

The polishing mechanism-based approaches first generate a complete draft, and then improve the quality of it based on the global understanding of the whole draft. A related work is post-editing (Niehues et al., 2016; Chatterjee et al., 2016; Zhou et al., 2017; Junczys Dowmunt and Grundkiewicz, 2017): a source sentence e is first translated to f, and then f is refined by another model. Niehues et al. (2016) used phrase-based statistical machine translation (PBMT) to pre-translate the source sentence into target language, which was taken as input of NMT to generate the final translation. Zhou et al. (2017) combined phrase-based statistical machine translation (PBMT), hierarchical phrase-based statistical machine translation (HPMT) and NMT with a unified architecture, similar to the dominant NMT model. Compared with the dominant NMT model, two attention models were involved to compute the context vectors. Specifically, an attention model is utilized to calculate the context vector for each machine system, while the other attention model obtains the context vector over the all context vectors of machine systems.

In above works, the generating and refining are two separate processes. As a comparison, Xia et al. (2017) proposed deliberation network, which consists of two decoders: a first-pass decoder generates a draft, which is taken as input of second-pass decoder to obtain a better translation. All the components of deliberation network are coupled together and jointly optimized in an end-to-end way via reinforcement learning. Instead of first-pass forward decoder, Zhang et al. (2018) adopted a backward decoder to capture the right-to-left target-side contexts, which is taken as input to assist the second-pass forward decoder to obtain a better translation. Besides, the another difference with deliberation network is the second-pass decoder is integrated with the first-pass decoder without reinforcement learning.

For the purpose of exploring polishing mechanism, our model adopts adaptive multi-pass decoding strategy. Compared with the previous works which consumes no more than two decoding passes, our multi-pass decoder makes an attempt to perform the multi-pass decoding. More importantly, we adopt adaptive decoding depth controlled by policy network to extend the capacity of our multi-pass decoder.

6 Conclusion

In this paper, we propose a novel architecture called *adaptive multi-pass decoder* to adopt polishing mechanism into the NMT model via reinforcement learning. Towards this goal, a novel multi-pass decoder is introduced to generate the translation, conditioned on the source- and target-side contexts. Simultaneously, the multi-pass decoding is supervised by a policy network which learns to choose a suitable action from continuing next pass decoding or halt at each time step to maximize the BLEU of the final translation. As a result, our model has the capability of controlling the decoding depth to generate a better translation. Extensive experiments on Chinese-English translation demonstrate the effectiveness of the proposed adaptive multi-pass decoder.

In this paper, we focus on utilizing multi-pass decoder to polish the translation. Our proposed multi-pass decoder performs the multi-pass decoding mechanism with only forward decoding. One promising direction is to incorporate the backward decoding into our architecture. More specifically, we can extend the policy network to choose the backward decoding except for forward decoding and halting.

Abstract

Although the Transformer translation model (Vaswani et al., 2017) has achieved state-of-the-art performance in a variety of translation tasks, how to use document-level context to deal with discourse phenomena problematic for Transformer still remains a challenge. In this work, we extend the Transformer model with a new context encoder to represent document-level context, which is then incorporated into the original encoder and decoder. As large-scale document-level parallel corpora are usually not available, we introduce a two-step training method to take full advantage of abundant sentence-level parallel corpora and limited document-level parallel corpora. Experiments on the NIST Chinese-English datasets and the IWSLT French-English datasets show that our approach improves over Transformer significantly. [1]

1 Introduction

The past several years have witnessed the rapid development of neural machine translation (NMT) (Sutskever et al., 2014; Bahdanau et al., 2015), which investigates the use of neural networks to model the translation process. Showing remarkable superiority over conventional statistical machine translation (SMT), NMT has been recognized as the new *de facto* method and is widely used in commercial MT systems (Wu et al., 2016). A variety of NMT models have been proposed to map between natural languages such as RNNencdec (Sutskever et al., 2014), RNNsearch (Bahdanau et al., 2015), ConvS2S (Gehring et al., 2017), and Transformer (Vaswani et al., 2017). Among them, the Transformer model has achieved state-of-the-art translation performance. The capability to minimize the path length between long-distance dependencies in neural networks contributes to its exceptional performance.

However, the Transformer model still suffers from a major drawback: it performs translation only at the sentence level and ignores document-level context. Document-level context has proven to be beneficial for improving translation performance, not only for conventional SMT (Gong et al., 2011; Hardmeier et al., 2012), but also for NMT (Wang et al., 2017; Tu et al., 2018). Bawden et al. (2018) indicate that it is important to exploit document-level context to deal with context-dependent phenomena which are problematic for machine translation such as coreference, lexical cohesion, and lexical disambiguation.

While document-level NMT has attracted increasing attention from the community in the past two years (Jean et al., 2017; Kuang et al., 2017; Tiedemann and Scherrer, 2017; Wang et al., 2017; Maruf and Haffari, 2018; Bawden et al., 2018; Tu et al., 2018; Voita et al., 2018), to the best of our knowledge, only one existing work has endeavored to model document-level context for the Transformer model (Voita et al., 2018). Previous approaches to document-level NMT have concentrated on the RNNsearch model (Bahdanau et al., 2015). It is challenging to adapt these approaches to Transformer because they are designed specifically for RNNsearch.

In this work, we propose to extend the Transformer model to take advantage of document-level context. The basic idea is to use multi-head self-attention (Vaswani et al., 2017) to compute the representation of document-level context, which is then incorporated into the encoder and decoder using multi-head attention. Since large-scale document-level parallel corpora are usually hard to acquire, we propose to train sentence-level model parameters on sentence-level paral-

(b)

Figure 1: (a) The original Transformer translation model (Vaswani et al., 2017) and (b) the extended Transformer translation model that exploits document-level context. The newly introduced modules are highlighted in red.

lel corpora first and then estimate document-level model parameters on document-level parallel corpora while keeping the learned original sentence-level Transformer model parameters fixed. Our approach has the following advantages:

1. *Increased capability to capture context*: the use of multi-head attention, which significantly reduces the path length between long-range dependencies, helps to improve the capability to capture document-level context;
2. *Small computational overhead*: as all newly introduced modules are based on highly parallelizable multi-head attention, there is no significant slowdown in both training and decoding;
3. *Better use of limited labeled data*: our approach is capable of maintaining the superiority over the sentence-level counterpart even when only small-scale document-level parallel corpora are available.

Experiments show that our approach achieves an improvement of 1.96 and 0.89 BLEU points over Transformer on Chinese-English and French-English translation respectively by exploiting document-level context. It also outperforms a state-of-the-art cache-based method (Kuang et al., 2017) adapted for Transformer.

2 Approach

2.1 Problem Statement

Our goal is to enable the Transformer translation model (Vaswani et al., 2017) as shown in Figure 1(a) to exploit document-level context.

Formally, let $\mathbf{X} = \mathbf{x}^{(1)}, \dots, \mathbf{x}^{(k)}, \dots, \mathbf{x}^{(K)}$ be a source-language document composed of K source sentences. We use $\mathbf{x}^{(k)} = x_1^{(k)}, \dots, x_i^{(k)}, \dots, x_I^{(k)}$ to denote the k-th source sentence containing I words. $x_i^{(k)}$ denotes the i-th word in the k-th source sentence. Likewise, the corresponding target-language document is denoted by $\mathbf{Y} = \mathbf{y}^{(1)}, \dots, \mathbf{y}^{(k)}, \dots, \mathbf{y}^{(K)}$ and $\mathbf{y}^{(k)} = y_1^{(k)}, \dots, y_j^{(k)}, \dots, y_J^{(k)}$ represents the k-th target sentence containing J words. $y_j^{(k)}$ denotes the j-th word in the k-th target sentence. We assume that $\langle \mathbf{X}, \mathbf{Y} \rangle$ constitutes a *parallel document* and each $\langle \mathbf{x}^{(k)}, \mathbf{y}^{(k)} \rangle$ forms a *parallel sentence*.

Therefore, the document-level translation probability is given by

$$P(\mathbf{Y}|\mathbf{X};\boldsymbol{\theta}) = \prod_{k=1}^{K} P(\mathbf{y}^{(k)}|\mathbf{X}, \mathbf{Y}_{<k};\boldsymbol{\theta}), \qquad (1)$$

where $\mathbf{Y}_{<k} = \mathbf{y}^{(1)}, \dots, \mathbf{y}^{(k-1)}$ is a partial translation.

For generating $\mathbf{y}^{(k)}$, the source document $\mathbf{X}$ can be divided into three parts: (1) the k-th source sentence $\mathbf{X}_{=k} = \mathbf{x}^{(k)}$, (2) the source-side document-level context on the left $\mathbf{X}_{<k} = \mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(k-1)}$, and (3) the source-side document-level context on the right $\mathbf{X}_{>k} = \mathbf{x}^{(k+1)}, \ldots, \mathbf{x}^{(K)}$. As the languages used in our experiments (i.e., Chinese and English) are written left to right, we omit $\mathbf{X}_{>k}$ for simplicity.

We also omit the target-side document-level context $\mathbf{Y}_{<k}$ due to the translation error propagation problem (Wang et al., 2017): errors made in translating one sentence will be propagated to the translation process of subsequent sentences. Interestingly, we find that using source-side document-level context $\mathbf{X}_{<k}$, which conveys the same information with $\mathbf{Y}_{<k}$, helps to compute better representations on the target side (see Table 8).

As a result, the document-level translation probability can be approximated as

$$\begin{aligned} & P(\mathbf{Y}|\mathbf{X};\boldsymbol{\theta}) \\ \approx & \prod_{k=1}^{K} P(\mathbf{y}^{(k)}|\mathbf{X}_{<k}, \mathbf{x}^{(k)}; \boldsymbol{\theta}), \quad (2) \\ = & \prod_{k=1}^{K}\prod_{j=1}^{J} P(y_j^{(k)}|\mathbf{X}_{<k}, \mathbf{x}^{(k)}, \mathbf{y}_{<j}^{(k)}; \boldsymbol{\theta}), \quad (3) \end{aligned}$$

where $\mathbf{y}_{<j}^{(k)} = y_1^{(k)}, \ldots, y_{j-1}^{(k)}$ is a partial translation.

In this way, the document-level translation model can still be defined at the sentence level without sacrificing efficiency except that the source-side document-level context $\mathbf{X}_{<k}$ (or *context* for short) is taken into account.

In the following, we will introduce how to represent the context (Section 2.2), how to integrate the context (Section 2.3), and how to train the model especially when only limited training data is available (Section 2.4).

2.2 Document-level Context Representation

As document-level context often includes several sentences, it is important to capture long-range dependencies and identify relevant information. We use multi-head self-attention (Vaswani et al., 2017) to compute the representation of document-level context because it is capable of reducing the maximum path length between long-range dependencies to $O(1)$ (Vaswani et al., 2017) and determining the relative importance of different locations in the context (Bahdanau et al., 2015). Because of this property, multi-head self-attention has proven to be effective in other NLP tasks such as constituency parsing (Kitaev and Klein, 2018).

As shown in Figure 1(b), we use a self-attentive encoder to compute the representation of $\mathbf{X}_{<k}$. The input to the self-attentive encoder is a sequence of context word embeddings, represented as a matrix. Suppose $\mathbf{X}_{<k}$ is composed of M source words: $\mathbf{X}_{<k} = x_1, \ldots, x_m, \ldots, x_M$. We use $\boldsymbol{x}_m \in \mathbb{R}^{D\times 1}$ to denote the vector representation of x_m that is the sum of word embedding and positional encoding (Vaswani et al., 2017). Therefore, the matrix representation of $\mathbf{X}_{<k}$ is given by

$$\boldsymbol{X}_c = [\boldsymbol{x}_1; \ldots; \boldsymbol{x}_M], \quad (4)$$

where $\boldsymbol{X}_c \in \mathbb{R}^{D\times M}$ is the concatenation of all vector representations of all source contextual words.

The self-attentive encoder is composed of a stack of N_c identical layers. Each layer has two sub-layers. The first sub-layer is a multi-head self-attention:

$$\mathbf{A}^{(1)} = \mathrm{MultiHead}(\boldsymbol{X}_c, \boldsymbol{X}_c, \boldsymbol{X}_c), \quad (5)$$

where $\mathbf{A}^{(1)} \in \mathbb{R}^{D\times M}$ is the hidden state calculated by the multi-head self-attention at the first layer, $\mathrm{MultiHead}(\mathbf{Q}, \mathbf{K}, \mathbf{V})$ is a multi-head self-attention function that takes a query matrix $\mathbf{Q}$, a key matrix $\mathbf{K}$, and a value matrix $\mathbf{V}$ as inputs. In this case, $\mathbf{Q} = \mathbf{K} = \mathbf{V} = \boldsymbol{X}_c$. This is why it is called self-attention. Please refer to (Vaswani et al., 2017) for more details.

Note that we follow Vaswani et al. (2017) to use residual connection and layer normalization in each sub-layer, which are omitted in the presentation for simplicity. For example, the actual output of the first sub-layer is:

$$\mathrm{LayerNorm}(\mathbf{A}^{(1)} + \boldsymbol{X}_c). \quad (6)$$

The second sub-layer is a simple, position-wise fully connected feed-forward network:

$$\mathbf{C}^{(1)} = \Big[\mathrm{FNN}(\mathbf{A}^{(1)}_{\cdot,1}); \ldots; \mathrm{FNN}(\mathbf{A}^{(1)}_{\cdot,M})\Big] \quad (7)$$

where $\mathbf{C}^{(1)} \in \mathbb{R}^{D\times M}$ is the annotation of $\mathbf{X}_{<k}$ after the first layer, $\mathbf{A}^{(1)}_{\cdot,m} \in \mathbb{R}^{D\times 1}$ is the column vector for the m-th contextual word, and $\mathrm{FNN}(\cdot)$ is a position-wise fully connected feed-forward network (Vaswani et al., 2017).

This process iterates N_c times as follows:

$$\mathbf{A}^{(n)} = \mathrm{MultiHead}\Big(\mathbf{C}^{(n-1)}, \mathbf{C}^{(n-1)}, \mathbf{C}^{(n-1)}\Big), \quad (8)$$

$$\mathbf{C}^{(n)} = \Big[\mathrm{FNN}(\mathbf{A}^{(n)}_{\cdot,1}); \ldots; \mathrm{FNN}(\mathbf{A}^{(n)}_{\cdot,M})\Big], \quad (9)$$

where $\mathbf{A}^{(n)}$ and $\mathbf{C}^{(n)}$ ($n = 1, \ldots, N_c$) are the hidden state and annotation at the n-th layer, respectively. Note that $\mathbf{C}^{(0)} = \boldsymbol{X}_c$.

2.3 Document-level Context Integration

We use multi-head attention to integrate $\mathbf{C}^{(N_c)}$, which is the representation of $\mathbf{X}_{<k}$, into both the encoder and the decoder.

2.3.1 Integration into the Encoder

Given the k-th source sentence $\mathbf{x}^{(k)}$, we use $\boldsymbol{x}_i^{(k)} \in \mathbb{R}^{D \times 1}$ to denote the vector representation of the i-th source word $x_i^{(k)}$, which is a sum of word embedding and positional encoding. Therefore, the initial matrix representation of $\mathbf{x}^{(k)}$ is

$$\boldsymbol{X} = [\boldsymbol{x}_1^{(k)}; \ldots; \boldsymbol{x}_I^{(k)}], \tag{10}$$

where $\boldsymbol{X} \in \mathbb{R}^{D \times I}$ is the concatenation of all vector representations of source words.

As shown in Figure 1(b), we follow (Vaswani et al., 2017) to use a stack of N_s identical layers to encode $\mathbf{x}^{(k)}$. Each layer consists of three sub-layers. The first sub-layer is a multi-head self-attention:

$$\mathbf{B}^{(n)} = \mathrm{MultiHead}\Big(\mathbf{S}^{(n-1)}, \mathbf{S}^{(n-1)}, \mathbf{S}^{(n-1)}\Big), \tag{11}$$

where $\mathbf{S}^{(0)} = \boldsymbol{X}$. The second sub-layer is context attention that integrates document-level context into the encoder:

$$\mathbf{D}^{(n)} = \mathrm{MultiHead}\Big(\mathbf{B}^{(n)}, \mathbf{C}^{(N_c)}, \mathbf{C}^{(N_c)}\Big). \tag{12}$$

The third sub-layer is a position-wise fully connected feed-forward neural network:

$$\mathbf{S}^{(n)} = \Big[\mathrm{FNN}(\mathbf{D}_{\cdot,1}^{(n)}); \ldots; \mathrm{FNN}(\mathbf{D}_{\cdot,I}^{(n)})\Big], \tag{13}$$

where $\mathbf{S}^{(n)} \in \mathbb{R}^{D \times I}$ is the representation of the source sentence $\mathbf{x}^{(k)}$ at the n-th layer ($n = 1, \ldots, N_s$).

2.3.2 Integration into the Decoder

When generating the j-th target word $y_j^{(k)}$, the partial translation is denoted by $\mathbf{y}_{<j}^{(k)} = y_1^{(k)}, \ldots, y_{j-1}^{(k)}$. We follow Vaswani et al. (2017) to offset the target word embeddings by one position, resulting in the following matrix representation of $\mathbf{y}_{<j}^{(k)}$:

$$\boldsymbol{Y} = [\boldsymbol{y}_0^{(k)}, \ldots, \boldsymbol{y}_{j-1}^{(k)}], \tag{14}$$

where $\mathbf{y}_0^{(k)} \in \mathbb{R}^{D \times 1}$ is the vector representation of a begin-of-sentence token and $\boldsymbol{Y} \in \mathbb{R}^{D \times j}$ is the concatenation of all vectors.

As shown in Figure 1(b), we follow (Vaswani et al., 2017) to use a stack of N_t identical layers to compute target-side representations. Each layer is composed of four sub-layers. The first sub-layer is a multi-head self-attention:

$$\mathbf{E}^{(n)} = \mathrm{MultiHead}\Big(\mathbf{T}^{(n-1)}, \mathbf{T}^{(n-1)}, \mathbf{T}^{(n-1)}\Big), \tag{15}$$

where $\mathbf{T}^{(0)} = \boldsymbol{Y}$. The second sub-layer is context attention that integrates document-level context into the decoder:

$$\mathbf{F}^{(n)} = \mathrm{MultiHead}\Big(\mathbf{E}^{(n)}, \mathbf{C}^{(N_c)}, \mathbf{C}^{(N_c)}\Big). \tag{16}$$

The third sub-layer is encoder-decoder attention that integrates the representation of the corresponding source sentence:

$$\mathbf{G}^{(n)} = \mathrm{MultiHead}\Big(\mathbf{F}^{(n)}, \mathbf{S}^{(N_s)}, \mathbf{S}^{(N_s)}\Big). \tag{17}$$

The fourth sub-layer is a position-wise fully connected feed-forward neural network:

$$\mathbf{T}^{(n)} = \Big[\mathrm{FNN}(\mathbf{G}_{\cdot,1}^{(n)}); \ldots; \mathrm{FNN}(\mathbf{G}_{\cdot,j}^{(n)}),\Big], \tag{18}$$

where $\mathbf{T}^{(n)} \in \mathbb{R}^{D \times j}$ is the representation at the n-th layer ($n = 1, \ldots, N_t$). Note that $\mathbf{T}^{(0)} = \boldsymbol{Y}$.

Finally, the probability distribution of generating the next target word $y_j^{(k)}$ is defined using a softmax layer:

$$P(y_j^{(k)} | \mathbf{X}_{<k}, \mathbf{x}^{(k)}, \mathbf{y}_{<j}^{(k)}; \boldsymbol{\theta}) \propto \exp(\mathbf{W}_o \mathbf{T}_{\cdot,j}^{(N_t)}) \tag{19}$$

where $\mathbf{W}_o \in \mathbb{R}^{|\mathcal{V}_y| \times D}$ is a model parameter, $\mathcal{V}_y$ is the target vocabulary, and $\mathbf{T}_{\cdot,j}^{(N_t)} \in \mathbb{R}^{D \times 1}$ is a column vector for predicting the j-th target word.

2.3.3 Context Gating

In our model, we follow Vaswani et al. (2017) to use residual connections (He et al., 2016) around each sub-layer to shortcut its input to its output:

$$\mathrm{Residual}(\mathbf{H}) = \mathbf{H} + \mathrm{SubLayer}(\mathbf{H}), \tag{20}$$

where $\mathbf{H}$ is the input of the sub-layer.

While residual connections prove to be effective for building deep architectures, there is one potential problem for our model: the residual connections after the context attention sub-layer might increase the influence of document-level context

$\mathbf{X}_{<k}$ in an uncontrolled way. This is undesirable because the source sentence $\mathbf{x}^{(k)}$ usually plays a more important role in target word generation.

To address this problem, we replace the residual connections after the context attention sub-layer with a *position-wise context gating* sub-layer:

$$\mathrm{Gating}(\mathbf{H}) = \lambda\mathbf{H} + (1-\lambda)\mathrm{SubLayer}(\mathbf{H}). \quad (21)$$

The gating weight is given by

$$\lambda = \sigma(\mathbf{W}_i\mathbf{H} + \mathbf{W}_s\mathrm{SubLayer}(\mathbf{H})), \quad (22)$$

where $\sigma(\cdot)$ is a sigmoid function, $\mathbf{W}_i$ and $\mathbf{W}_s$ are model parameters.

2.4 Training

Given a document-level parallel corpus D_d, the standard training objective is to maximize the log-likelihood of the training data:

$$\hat{\boldsymbol{\theta}} = \underset{\boldsymbol{\theta}}{\mathrm{argmax}} \left\{ \sum_{\langle \mathbf{X},\mathbf{Y}\rangle \in D_d} \log P(\mathbf{Y}|\mathbf{X};\boldsymbol{\theta}) \right\}. \quad (23)$$

Unfortunately, large-scale document-level parallel corpora are usually unavailable, even for resource-rich languages such as English and Chinese. Under small-data training conditions, document-level NMT is prone to underperform sentence-level NMT because of poor estimates of low-frequency events.

To address this problem, we adopt the idea of freezing some parameters while tuning the remaining part of the model (Jean et al., 2015; Zoph et al., 2016). We propose a two-step training strategy that uses an additional sentence-level parallel corpus D_s, which can be larger than D_d. We divide model parameters into two subsets: $\boldsymbol{\theta} = \boldsymbol{\theta}_s \cup \boldsymbol{\theta}_d$, where $\boldsymbol{\theta}_s$ is a set of original sentence-level model parameters (highlighted in blue in Figure 1(b)) and $\boldsymbol{\theta}_d$ is a set of newly-introduced document-level model parameters (highlighted in red in Figure 1(b)).

In the first step, sentence-level parameters $\boldsymbol{\theta}_s$ are estimated on the combined sentence-level parallel corpus $D_s \cup D_d$: [2]

$$\hat{\boldsymbol{\theta}}_s = \underset{\boldsymbol{\theta}_s}{\mathrm{argmax}} \sum_{\langle \mathbf{x},\mathbf{y}\rangle \in D_s \cup D_d} \log P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}_s). \quad (24)$$

Note that the newly introduced modules (highlighted in red in Figure 1(b)) are inactivated in this step. $P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}_s)$ is identical to the original Transformer model, which is a special case of our model.

In the second step, document-level parameters $\boldsymbol{\theta}_d$ are estimated on the document-level parallel corpus D_d only:

$$\hat{\boldsymbol{\theta}}_d = \underset{\boldsymbol{\theta}_d}{\mathrm{argmax}} \sum_{\langle \mathbf{X},\mathbf{Y}\rangle \in D_d} \log P(\mathbf{Y}|\mathbf{X};\hat{\boldsymbol{\theta}}_s,\boldsymbol{\theta}_d). \quad (25)$$

Our approach is also similar to pre-training which has been widely used in NMT (Shen et al., 2016; Tu et al., 2018). The major difference is that our approach keeps $\hat{\boldsymbol{\theta}}_s$ *fixed* when estimating $\boldsymbol{\theta}_d$ to prevent the model from overfitting on the relatively smaller document-level parallel corpora.

3 Experiments

3.1 Setup

We evaluate our approach on Chinese-English and French-English translation tasks. In Chinese-English translation task, the training set contains 2M Chinese-English sentence pairs with 54.8M Chinese words and 60.8M English words. [3] The document-level parallel corpus is a subset of the full training set, including 41K documents with 940K sentence pairs. On average, each document in the training set contains 22.9 sentences. We use the NIST 2006 dataset as the development set and the NIST 2002, 2003, 2004, 2005, 2008 datasets as test sets. The development and test sets contain 588 documents with 5,833 sentences. On average, each document contains 9.9 sentences.

In French-English translation task, we use the IWSLT bilingual training data (Mauro et al., 2012) which contains 1,824 documents with 220K sentence pairs as training set. For development and testing, we use the IWSLT 2010 development and test sets, which contains 8 documents with 887 sentence pairs and 11 documents with 1,664 sentence pairs respectively. The evaluation metric for both tasks is case-insensitive BLEU score as calculated by the *multi-bleu.perl* script.

In preprocessing, we use byte pair encoding (Sennrich et al., 2016) with 32K merges to segment words into sub-word units for all languages. For the original Transformer model and our extended model, the hidden size is set to 512 and the

---

[2] It is easy to create a sentence-level parallel corpus from D_d.

[3] The training set consists of sentence-level parallel corpora LDC2002E18, LDC2003E07, LDC2003E14, news part of LDC2004T08 and document-level parallel corpora LDC2002T01, LDC2004T07, LDC2005T06, LDC2005T10, LDC2009T02, LDC2009T15, LDC2010T03.

filter size is set to 2,048. The multi-head attention has 8 individual attention heads. We set $N = N_s = N_t = 6$. In training, we use Adam (Kingma and Ba, 2015) for optimization. Each mini-batch contains approximately 24K words. We use the learning rate decay policy described by Vaswani et al. (2017). In decoding, the beam size is set to 4. We use the length penalty (Wu et al., 2016) and set the hyper-parameter α to 0.6. We use four Tesla P40 GPUs for training and one Tesla P40 GPU for decoding. We implement our approach on top of the open-source toolkit THUMT (Zhang et al., 2017). [4]

3.2 Effect of Context Length

We first investigate the effect of context length (i.e., the number of preceding sentences) on our approach. As shown in Table 1, using two preceding source sentences as document-level context achieves the best translation performance on the development set. Using more preceding sentences does not bring any improvement and increases computational cost. This confirms the finding of Tu et al. (2018) that long-distance context only has limited influence. Therefore, we set the number of preceding sentences to 2 in the following experiments. [5]

3.3 Effect of Self-Attention Layer Number

Table 2 shows the effect of self-attention layer number for computing representations of document-level context (see Section 2.2) on translation quality. Surprisingly, using only one self-attention layer suffices to achieve good performance. Increasing the number of self-attention layers does not lead to any improvements. Therefore, we set N_c to 1 for efficiency.

3.4 Comparison with Previous Work

In Chinese-English translation task, we compare our approach with the following previous methods:

1. (Wang et al., 2017): using a hierarchical RNN to integrate document-level context into the RNNsearch model. They use a document-level parallel corpus containing 1M sentence pairs. Table 3 gives the BLEU scores reported in their paper.

2. (Kuang et al., 2017): using a cache which stores previous translated words and topical words to incorporate document-level context into the RNNsearch model. They use a document-level parallel corpus containing 2.8M sentence pairs. Table 3 gives the BLEU scores reported in their paper.

3. (Vaswani et al., 2017): the state-of-the-art NMT model that does not exploit document-level context. We use the open-source toolkit THUMT (Zhang et al., 2017) to train and evaluate the model. The training dataset is our sentence-level parallel corpus containing 2M sentence pairs.

4. (Kuang et al., 2017)*: adapting the cache-based method to the Transformer model. We implement it on top of the open-source toolkit THUMT. We also use the same training data (i.e., 2M sentence pairs) and the same two-step training strategy to estimate sentence- and document-level parameters separately.

As shown in Table 3, using the same data, our approach achieves significant improvements over the original Transformer model (Vaswani et al., 2017) ($p < 0.01$). The gain on the concatenated test set (i.e., "All") is 1.96 BLEU points. It also outperforms the cache-based method (Kuang et al., 2017) adapted for Transformer significantly ($p < 0.01$), which also uses the two-step training strategy. Table 4 shows that our model also outperforms Transformer by 0.89 BLEU points on French-English translation task.

---

[4] `https://github.com/thumt/THUMT`

[5] If there is no preceding sentence, we simply use a single begin-of-sentence token.

Method	Model	MT06	MT02	MT03	MT04	MT05	MT08	All

this work	Transformer	**49.69**	**50.96**	**50.21**	**49.73**	**49.46**	**39.69**	**47.93**

Table 3: Comparison with previous works on Chinese-English translation task. The evaluation metric is case-insensitive BLEU score. (Wang et al., 2017) use a hierarchical RNN to incorporate document-level context into RNNsearch. (Kuang et al., 2017) use a cache to exploit document-level context for RNNsearch. (Kuang et al., 2017)* is an adapted version of the cache-based method for Transformer. Note that "MT06" is not included in "All".

Method	Dev	Test
Transformer	29.42	35.15
this work	**30.40**	**36.04**

Table 4: Comparison with Transformer on French-English translation task. The evaluation metric is case-insensitive BLEU score.

	>	=	<
Human 1	24%	45%	31%
Human 2	20%	55%	25%
Human 3	12%	52%	36%
Overall	19%	51%	31%

Table 5: Subjective evaluation of the comparison between the original Transformer model and our model. ">" means that Transformer is better than our model, "=" means equal, and "<" means worse.

3.5 Subjective Evaluation

We also conducted a subjective evaluation to validate the benefit of exploiting document-level context. All three human evaluators were asked to compare the outputs of the original Transformer model and our model of 20 documents containing 198 sentences, which were randomly sampled from the test sets.

Table 5 shows the results of subjective evaluation. Three human evaluators generally made consistent judgements. On average, around 19% of Transformer's translations are better than that of our model, 51% are equal, and 31% are worse. This evaluation confirms that exploiting document-level context helps to improve translation quality.

3.6 Evaluation of Efficiency

We evaluated the efficiency of our approach. It takes the original Transformer model about 6.7 hours to converge during training and the training speed is 41K words/second. The decoding speed is 872 words/second. In contrast, it takes our model about 7.8 hours to converge in the second step of training. The training speed is 31K words/second. The decoding speed is 364 words/second.

Method	Training	Decoding
Transformer	41K	872
this work	31K	364

Table 6: Evaluation of training and decoding speed. The speed is measured in terms of word/second (wps).

Therefore, the training speed is only reduced by 25% thanks to the high parallelism of multi-head attention used to incorporate document-level context. The gap is larger in decoding because target words are generated in an autoregressive way in Transformer.

3.7 Effect of Two-Step Training

Table 7 shows the effect of the proposed two-step training strategy. The first two rows only use sentence-level parallel corpus to train the original Transformer model (see Eq. 24) and achieve BLEU scores of 39.53 and 45.97. The third row only uses the document-level parallel corpus to directly train our model (see Eq. 23) and achieves a BLEU score of 36.52. The fourth and fifth rows use the two-step strategy to take advantage of both sentence- and document-level parallel corpora and achieve BLEU scores of 40.22 and 47.93, respectively.

We find that document-level NMT achieves much worse results than sentence-level NMT (i.e., 36.52 vs. 39.53) when only small-scale document-level parallel corpora are available. Our two-step training method is capable of addressing this problem by exploiting sentence-level corpora, which

sent.	doc.	MT06	MT02	MT03	MT04	MT05	MT08	All

Table 7: Effect of two-step training. "sent." denotes sentence-level parallel corpus and "doc." denotes document-level parallel corpus.

Integration	MT06	MT02	MT03	MT04	MT05	MT08	All
none	48.09	48.63	47.54	47.79	48.34	38.31	45.97
encoder	48.88	50.30	49.34	48.81	49.75	39.55	47.51
decoder	49.10	50.31	49.83	49.35	49.29	39.07	47.48
both	49.69	50.96	50.21	49.73	49.46	39.69	47.93

Table 8: Effect of context integration. "none" means that no document-level context is integrated, "encoder" means that the document-level context is integrated only into the encoder, "decoder" means that the document-level context is integrated only into the decoder, and "both" means that the context is integrated into both the encoder and the decoder.

Gating	MT06	MT02	MT03	MT04	MT05	MT08	All
w/o	49.33	50.56	49.74	49.29	50.11	39.02	47.55
w/	49.69	50.96	50.21	49.73	49.46	39.69	47.93

Table 9: Effect of context gating.

leads to significant improvements across all test sets.

3.8 Effect of Context Integration

Table 8 shows the effect of integrating document-level context to the encoder and decoder (see Section 2.3). It is clear that integrating document-level context into the encoder (Eq. 12) brings significant improvements (i.e., 45.97 vs. 47.51). Similarly, it is also beneficial to integrate document-level context into the decoder (Eq. 16). Combining both leads to further improvements. This observation suggests that document-level context does help to improve Transformer.

3.9 Effect of Context Gating

As shown in Table 9, we also validated the effectiveness of context gating (see Section 2.3.3). We find that replacing residual connections with context gating leads to an overall improvement of 0.38 BLEU point.

3.10 Analysis

We use an example to illustrate how document-level context helps translation (Table 10). In order to translate the source sentence, NMT has to disambiguate the multi-sense word "*yundong*", which is actually impossible without the document-level context. The exact meaning of "*rezhong*" is also highly context dependent. Fortunately, the sense of "*yundong*" can be inferred from the word "*saiche*" (car racing) in the document-level context and "*rezhong*" is the antonym of "*yanjuan*" (tired of). This example shows that our model learns to resolve word sense ambiguity and lexical cohesion problems by integrating document-level context.

4 Related Work

Developing document-level models for machine translation has been an important research direction, both for conventional SMT (Gong et al., 2011; Hardmeier et al., 2012; Xiong et al., 2013a,b; Garcia et al., 2014) and NMT (Jean et al., 2017; Kuang et al., 2017; Tiedemann and Scherrer, 2017; Wang et al., 2017; Maruf and Haffari, 2018; Bawden et al., 2018; Tu et al., 2018; Voita et al., 2018).

Most existing work on document-level NMT has focused on integrating document-level context into the RNNsearch model (Bahdanau et al.,

Context	*· · ·ziji ye yinwei queshao jingzheng duishou er dui* ***saiche*** *youxie* ***yanjuan*** *shi· · ·*
Source	*wo rengran feichang* ***rezhong*** *yu zhexiang* ***yundong****.*
Reference	I'm still very **fond of** the **sport**.
Transformer	I am still very **enthusiastic about** this **movement**.
Our work	I am still very **keen on** this **sport**.

Table 10: An example of Chinese-English translation. In the source sentence, "*yundong*" (sport or political movement) is a multi-sense word and "*rezhong*" (fond of) is an emotional word whose meaning is dependent on its context. Our model takes advantage of the words "*saiche*" (car racing) and "*yanjuan*" (tired of) in the document-level context to translate the source words correctly.

2015). These approaches can be roughly divided into two broad categories: computing the representation of the full document-level context (Jean et al., 2017; Tiedemann and Scherrer, 2017; Wang et al., 2017; Maruf and Haffari, 2018; Voita et al., 2018) and using a cache to memorize most relevant information in the document-level context (Kuang et al., 2017; Tu et al., 2018). Our approach falls into the first category. We use multi-head attention to represent and integrate document-level context.

Voita et al. (2018) also extended Transformer to model document-level context, but our work is different in modeling and training strategies. The experimental part is also different. While Voita et al. (2018) focus on anaphora resolution, our model is able to improve the overall translation quality by integrating document-level context.

5 Conclusion

We have presented a method for exploiting document-level context inside the state-of-the-art neural translation model Transformer. Experiments on Chinese-English and French-English translation tasks show that our method is able to improve over Transformer significantly. In the future, we plan to further validate the effectiveness of our approach on more language pairs.

MTNT: A Testbed for Machine Translation of Noisy Text

Paul Michel and **Graham Neubig**
Language Technologies Institute
Carnegie Mellon University
`{pmichel1,gneubig}@cs.cmu.edu`

Abstract

Noisy or non-standard input text can cause disastrous mistranslations in most modern Machine Translation (MT) systems, and there has been growing research interest in creating noise-robust MT systems. However, as of yet there are no publicly available parallel corpora of with naturally occurring noisy inputs and translations, and thus previous work has resorted to evaluating on synthetically created datasets. In this paper, we propose a benchmark dataset for Machine Translation of Noisy Text (MTNT), consisting of noisy comments on Reddit[1] and professionally sourced translations. We commissioned translations of English comments into French and Japanese, as well as French and Japanese comments into English, on the order of 7k-37k sentences per language pair. We qualitatively and quantitatively examine the types of noise included in this dataset, then demonstrate that existing MT models fail badly on a number of noise-related phenomena, even after performing adaptation on a small training set of in-domain data. This indicates that this dataset can provide an attractive testbed for methods tailored to handling noisy text in MT.[2]

1 Introduction

#nlproc is actualy f*ing hARD tbh 😂

This handcrafted sentence showcases several types of noise that are commonly seen on social media: abbreviations (“#nlproc”), typographical errors (“actualy”), obfuscated profanities (“f*ing”), inconsistent capitalization (“hARD”), Internet slang (“tbh” for “to be honest”) and emojis (😂). Although machine translation has achieved significant quality improvements over the past few years due to the advent of Neural Machine Translation (NMT) (Kalchbrenner and Blunsom; Sutskever et al., 2014; Bahdanau et al., 2014; Wu et al., 2016), systems are still not robust to noisy input like this (Belinkov and Bisk, 2018; Khayrallah and Koehn). For example, Google Translate[3] translates the above example into French as:

#nlproc est en train de f * ing dur hb

which translates back into English as “#nlproc is in the process of [f * ing] hard hb”. This shows that noisy input can lead to erroneous translations that can be misinterpreted or even offensive.

Noise in social media text is a known issue that has been investigated in a variety of previous work (Eisenstein; Baldwin et al.). Most recently, Belinkov and Bisk (2018) have focused on the difficulties that character based NMT models have translating text with character level noise within individual words (from scrambling to simulated human errors such as typos or spelling/conjugation errors). This is a good first step towards noise-robust NMT systems, but as we demonstrate in §2, word-by-word replacement or scrambling of characters doesn’t cover all the idiosyncrasies of language on the Internet.

At this point, despite the obvious utility of creating noise-robust MT systems, and the scientific challenges contained therein, there is currently a bottleneck in that there is no standard open benchmark for researchers and developers of MT systems to test the robustness of their models to these and other phenomena found in noisy text on the Internet. In this work, we introduce MTNT, a new, realistic dataset aimed at testing robustness of MT systems to these phenomena. The dataset contains naturally created noisy source

sentences with professionally sourced translations both in a pair of typologically close languages (English and French) and distant languages (English and Japanese). We collect noisy comments from the Reddit online discussion website (§3) in English, French and Japanese, and ask professional translators to translate to and from English, resulting in approximately 1000 test samples and from 6k to 36k training samples in four language pairs (English-French (`en-fr`), French-English (`fr-en`), English-Japanese (`en-ja`) and Japanese-English (`ja-en`)). In addition, we release additional small monolingual corpora in those 3 languages to both provide data for semi-supervised adaptation approaches as well as noisy Language Modeling (LM) experiments. We test standard translation models (§5) and language models (§6) on our data to understand their failure cases and to provide baselines for future work.

2 Noise and Input Variations in Language on the Internet

2.1 Examples from Social Media Text

The term "noise" can encompass a variety of phenomena in natural language, with variations across languages (*e.g.* what is a typo in logographic writing systems?) and type of content (Baldwin et al.). To give the reader an idea of the challenges posed to MT and Natural Language Processing (NLP) systems operating on this kind of text, we provide a non-exhaustive list of types of noise and more generally input variations that deviate from standard MT training data we've encountered in Reddit comments:

- **Spelling/typographical errors**: "across" → "accross", "receive" → "recieve", "could have" → "could of", "temps" → "tant", "除く" → "覗く"
- **Word omission/insertion/repetition**: "je n'aime pas" → "j'aime pas","je pense" → "moi je pense"
- **Grammatical errors**: "a ton of" → "a tons of", "There are fewer people" → "There are less people"
- **Spoken language**: "want to" → "wanna", "I am" → "I'm", "je ne sais pas" → "chais pas", "何を笑っているの" → "何わろてんねん",
- **Internet slang**: "to be honest" → "tbh", "shaking my head" → "smh", "mort de rire" → "mdr", "笑" → "w"/"草"
- **Proper nouns** (with or without correct capitalization): "Reddit"→ "reddit"
- **Dialects**: African American Vernacular English, Scottish, Provençal, Québécois, Kansai, Tohoku...
- **Code switching**: "This is so cute" → "This is so kawaii", "C'est trop conventionel" → "C'est trop mainstream", "現在捏造中…" → "Now 捏造ing..."
- **Jargon**: on Reddit: "upvote", "downvote", "sub", "gild"
- **Emojis and other unicode characters**: ❤️,😀,😂,😍,😡, 😘, 😭
- **Profanities/slurs** (sometimes masked) "f*ck", "m*rde" …

2.2 Is Translating Noisy Text just another Adaptation Problem?

To a certain extent, translating noisy text is a type of *adaptation*, which has been studied extensively in the context of both Statistical Machine Translation (SMT) and NMT (Axelrod et al.; Li et al.; Luong and Manning, 2015; Chu et al.; Miceli Barone et al.; Wang et al.; Michel and Neubig, 2018). However, it presents many differences with previous domain adaptation problems, where the main goal is to adapt from a particular topic or style. In the case of noisy text, it will not only be the case that a particular word will be translated in a different way than it is in the general domain (e.g. as in the case of "sub"), but also that there will be increased lexical variation (e.g. due to spelling or typographical errors), and also inconsistency in grammar (e.g. due to omissions of critical words or mis-usage). The sum of these differences warrants that noisy MT be treated as a separate instance than domain adaptation, and our experimental analysis in 5.4 demonstrates that even after performing adaptation, MT systems still make a large number of noise-related errors.

3 Collection Procedure

We first collect noisy sentences in our three languages of interest, English, French and Japanese.

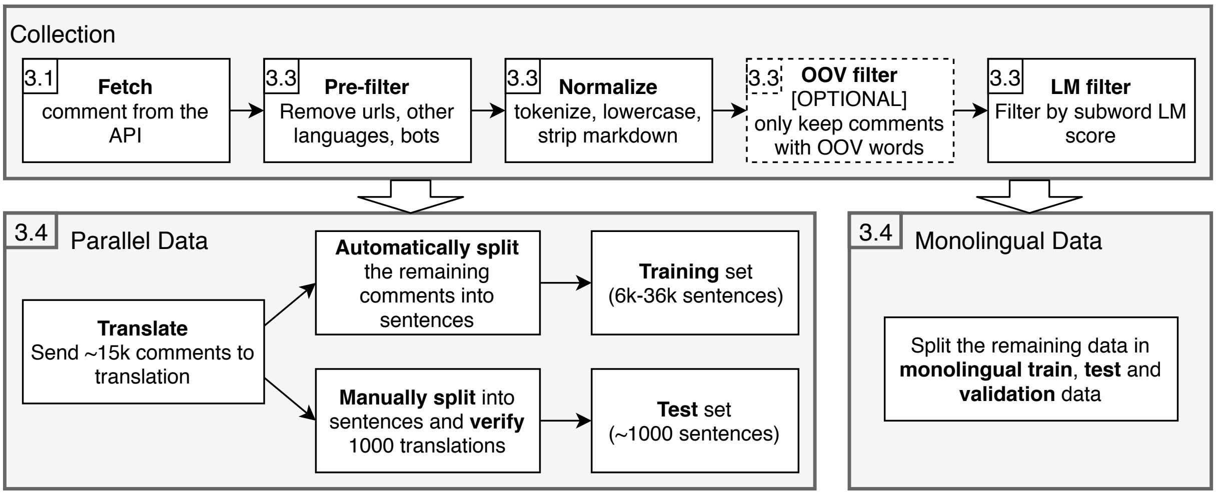

Figure 1: Summary of our collection process and the respective sections addressing them. We apply the same procedure for each language.

We refer to Figure 1 for an overview of the data collection and translation process.

We choose Reddit as a source of data because (1) its content is likely to exhibit noise, (2) some of its sub-communities are entirely run in different languages, in particular, English, French and Japanese, and (3) Reddit is a popular source of data in curated and publicly distributed NLP datasets (Tan et al.). We collect data using the public Reddit API. [4]

Note that the data collection and translation is performed at the comment level. We split the parallel data into sentences as a last step.

3.1 Data Sources

For each language, we select a set of communities ("subreddits") that we know contain many comments in that language:

English: Since an overwhelming majority of the discussions on Reddit are conducted in English, we don't restrict our collection to any community in particular.

French: `/r/france`, `/r/quebec` and `/r/rance`. The first two are among the biggest French speaking communities on Reddit. The third is a humor/sarcasm based offspring of `/r/france`.

Japanese: `/r/newsokur`, `/r/bakanewsjp`, `/r/newsokuvip`, `/r/lowlevelaware` and `/r/steamr`. Those are the biggest Japanese speaking communities, with over 2,000 subscribers.

We collect comments made during the 03/27/2018-03/29/3018 time period for English, 09/2018-03/2018 for French and 11/2017-03/2018 for Japanese. The large difference in collection time is due to the variance in comment throughput and relative amount of noise between the languages.

3.2 Contrast Corpora

Not all comments found on Reddit exhibit noise as described in Section 2. Because we would like to focus our data collection on noisy comments, we devise criteria that allow us to distinguish potentially noisy comments from clean ones. Specifically, we compile a *contrast* corpus composed of clean text that we can compare to, and find potentially noisy text that differs greatly from the contrast corpus. Given that our final goal is MT robust to noise, we prefer that these contrast corpora consist of the same type of data that is often used to train NMT models. We select different datasets for each language:

English: The English side of the preprocessed parallel training data provided for the German-English WMT 2017 News translation task,[5] as provided on the website. This amounts to ≈ 5.85 million sentences.

---

[4] In particular, we use this implementation: `praw.readthedocs.io/en/latest`, and our complete code is available at `http://www.cs.cmu.edu/~pmichel1/mtnt/`.

[5] `http://www.statmt.org/wmt17/translation-task.html`

French: The entirety of the French side of the parallel training data provided for the English-French WMT 2015 translation task.[6] This amounts to ≈ 40.86 million sentences.

Japanese: We aggregate three small/medium sized MT datasets: KFTT (Neubig, 2011), JESC (Pryzant et al.) and TED talks (Cettolo et al., 2012), amounting to $\approx$ 4.19 million sentences.

3.3 Identifying Noisy Comments

We now describe the procedure used to identify comments containing noise.

Pre-filtering First, we perform three pre-processing to discard comments that do not represent natural noisy text in the language of interest:

1. Comments containing a URL, as detected by a regular expression.
2. Comments where the author's username contains "bot" or "AutoModerator". This mostly removes automated comments from bots.
3. Comments in another language: we run `langid.py`[7] (Lui and Baldwin) and discard comments where $p(\text{lang} \mid \text{comment}) > 0.5$ for any language other than the one we are interested in.

This removes cases that are less interesting, i.e. those that could be solved by rule-based pattern matching or are not natural text created by regular users in the target language. Our third criterion in particular discards comments that are blatantly in another language while still allowing comments that exhibit code-switching or that contain proper nouns or typos that might skew the language identification. In preliminary experiments, we noticed that these criteria 14.47, 6.53 and 7.09 % of the collected comments satisfied the above criteria respectively.

Normalization After this first pass of filtering, we pre-process the comments before running them through our noise detection procedure. We first strip Markdown[8] syntax from the comments. For English and French, we normalize the punctuation, lowercase and tokenize the comments using the Moses tokenizer. For Japanese, we simply lowercase the alphabetical characters in the comments. Note that this normalization is done for the purpose of noise detection only. The collected comments are released without any kind of pre-processing. We apply the same normalization procedure to the contrast corpora.

Unknown words In the case of French and English, a clear indication of noise is the presence of out-of-vocabulary words (OOV): we record all lowercased words encountered in our reference corpus described in Section 3.2 and only keep comments that contain at least one OOV. Since we did not use word segmentation for the Japanese reference corpus, we found this method not to be very effective to select Japanese comments and therefore skipped this step.

Language model scores The final step of our noise detection procedure consists of selecting those comments with a low probability under a language model trained on the reference monolingual corpus. This approach mirrors the one used in Moore and Lewis and Axelrod et al. to select data similar to a specific domain using language model perplexity as a metric. We search for comments that have a low probability under a sub-word language model for more flexibility in the face of OOV words. We segment the contrast corpora with Byte-Pair Encoding (BPE) using the sentencepiece[9] implementation. We set the vocabulary sizes to $1,000$, $1,000$ and $4,000$ for English, French and Japanese respectively. We then use a 5-gram Kneser-Ney smoothed language model trained using `kenLM`[10] (Heafield et al.) to calculate the log probability, normalized by the number of tokens for every sentence in the reference corpus. Given a reddit comment, we compute the normalized log probability of each of its lines under our subword language model. If for any line this score is below the 1st percentile of scores in the reference corpus, the comment is labeled as noisy and saved.

3.4 Creating the Parallel Corpora

Once enough data has been collected, we isolate $15,000$ comments in each language by the follow-

	#samples	#src tokens	#trg tokens
`en-fr`	1,020	15,919	18,445
`fr-en`	1,022	16,662	16,038
`en-ja`	1,002	11,040	20,008
`ja-en`	1,020	23,997	33,429

Table 1: Test set numbers.

ing procedure:

- Remove all duplicates. In particular, this handles comments that might have been scraped twice or automatic comments from bots.
- To further weed out outliers (comments that are too noisy, *e.g.* ASCII art, wrong language. . . or not noisy enough), we discard comments that are on either end of the distribution of normalized LM scores within the set of collected comments. We only keep comments whose normalized score is within the 5-70 percentile for English (resp. 5-60 for French and 10-70 for Japanese). These numbers are chosen by manually inspecting the data.
- Choose $15,000$ samples at random.

We then concatenate the title of the thread where the comment was found to the text and send everything to an external vendor for manual translations. Upon reception of the translations, we noticed a certain amount of variation in the quality of translations, likely because translating social media text, with all its nuances, is difficult even for humans. In order to ensure the highest quality in the translations, we manually filter the data to segment the comments into sentences and weed out poor translations for our test data. We thereby retain around $1,000$ sentence pairs in each direction for the final test set.

We gather the samples that weren't selected for the test sets to be used for training or fine-tuning models on noisy data. We automatically split comments into sentences with a regular expression detecting sentence delimiters, and then align the source and target sentences. Should this alignment fail (*i.e.* the source comment contains a different number of sentences than the target comment after automatic splitting), we revert back to providing the whole comment without splitting. For the training data, we do not verify the correctness of translations as closely as for the test data. Finally, we isolate $\approx$ 900 samples in each direction to serve as validation data.

	#samples	#src tokens	#trg tokens
`en-fr`	36,058	841k	965k
`fr-en`	19,161	661k	634k
`en-ja`	5,775	281k	506k
`ja-en`	6,506	172k	128k

Table 2: Training sets numbers.

	#samples	#src tokens	#trg tokens
`en-fr`	852	16,957	18,948
`fr-en`	886	41,578	46,886
`en-ja`	852	40,124	46,886
`ja-en`	965	25,010	23,289

Table 3: Validation sets numbers.

Information about the size of the data can be found in Table 1, 2 and 3 for the test, training and validation sets respectively. We tokenize the English and French data with the Moses (Koehn et al.) tokenizer and the Japanese data with Kytea (Neubig et al., 2011) before counting the number of tokens in each dataset.

3.5 Monolingual Corpora

After the creation of the parallel train and test sets, a large number of unused comments remain in each language, which we provide as monolingual corpora. This additional data has two purposes: first, it serves as a resource for in-domain training using semi-supervised methods relying on monolingual data (e.g. Cheng et al.; Zhang and Zong). Second, it provides a language modeling dataset for noisy text in three languages.

We select $3,000$ comments at random in each dataset to form a validation set to be used to tune hyper-parameters, and provide the rest as training data. The data is provided with one comment per line. Newlines within individual comments are replaced with spaces. Table 4 contains information

		#samples	#tok	#char
`en`	train	81,631	3,99M	18,9M
	dev	3,000	146k	698k

	MTNT	**0.269**	**1.527**	**0.156**	0.036

Table 5: Numbers, per 100 tokens, of quantifiable noise occurrences. For each language and category, the dataset with the highest amount of noise is highlighted.

on the size of the datasets. As with the parallel MT data, we provide the number of tokens after tokenization with the Moses tokenizer for English and French and Kytea for Japanese.

4 Dataset Analysis

In this section, we investigate the proposed data to understand how different categories of noise are represented and to show that our test sets contain more noise overall than established MT benchmarks.

4.1 Quantifying Noisy Phenomena

We run a series of tests to count the number of occurrences of some of the types of noise described in Section 2. Specifically we pass our data through spell checkers to count spelling and grammar errors. Due to some of these tests being impractical to run on a large scale, we limit our analysis to the test sets of MTNT.

We use slightly different procedures depending on the tools available for each language. We test for spelling and grammar errors in English data using Grammarly[11], an online resource for English spell-checking. Due to the unavailability of an equivalent of Grammarly in French and Japanese, we test for spelling and grammar error using the integrated spell-checker in Microsoft Word 2013[12]. Note that Word seems to count proper nouns as spelling errors, giving higher numbers of spelling errors across the board in French as compared to English.

For all languages, we also count the number of profanities and emojis using custom-made lists and regular expressions[13]. In order to compare results across datasets of different sizes, we report all counts per 100 words.

The results are recorded in the last row of each section in Table 5. In particular, for the languages with a segmental writing system, English and French, spelling errors are the dominant type of noise, followed by grammar error. Unsurprisingly, the former are much less present in Japanese.

4.2 Comparison to Existing MT Test Sets

Table 5 also provide a comparison with the relevant side of established MT test sets. For English and French, we compare our data to newstest2014[14] and newsdiscusstest2015[15] test sets. For Japanese, we compare with the test sets of the datasets described in Section 3.2.

Overall, MTNT contains more noise in all metrics but one (there are more profanities in JESC, a Japanese subtitle corpus). This confirms that MTNT indeed provides a more appropriate benchmark for translation of noisy or non-standard text.

Compared to synthetically created noisy test sets (Belinkov and Bisk, 2018) MTNT contains less systematic spelling errors and more varied types of noise (*e.g.* emojis and profanities) and is thereby more representative of naturally occurring noise.

5 Machine Translation Experiments

We evaluate standard NMT models on our proposed dataset to assess its difficulty. Our goal is not to train state-of-the art models but rather to test standard off-the-shelf NMT systems on our data, and elucidate what features of the data make it difficult.

5.1 Model Description

All our models are implemented in DyNet (Neubig et al., 2017) with the XNMT toolkit (?). We use approximately the same setting for all language pairs: the encoder is a bidirectional LSTM with 2 layers, the attention mechanism is a multi layered perceptron and the decoder is a 2 layered LSTM. The embedding dimension is 512, all other dimensions are 1024. We tie the target word embeddings and the output projection weights (Press and Wolf). We train with Adam (Kingma and Ba, 2014) with XNMT's default hyper-parameters, as well as dropout (with probability 0.3). We used BPE subwords to handle OOV words. Full configuration details as well as code to reproduce the baselines is available at `https://github.com/pmichel31415/mtnt`.

5.2 Training Data

We train our models on standard MT datasets:

- en ↔ fr: Our training data consists in the europarl-v7[16] and news-commentary-v10[17] corpora, totaling 2,164,140 samples, 54,611,105 French tokens and 51,745,611 English tokens (non-tokenized). We use the newsdiscussdev2015[14] dev set from WMT15 as validation data and evaluate the model on the newsdiscusstest2015[15] and newstest2014[14] test sets.

- en ↔ ja: We concatenate the respective train, validation and test sets of the three corpora mentioned in 3.2. In particular we detokenize the Japanese part of each dataset to make sure that any tokenization we perform will be uniform (in practice we remove ASCII spaces). This amounts to 3,900,772 training samples (34,989,346 English tokens without tokenization). We concatenate the dev sets associated with these corpora to serve as validation data and evaluate on each respective test set separately.

	`en-fr`	`fr-en`
newstest2014	33.52	28.93
newsdiscusstest2015	33.03	30.76
MTNT	21.77	23.27
MTNT (+tuning)	29.73	30.29
	`en-ja`	`ja-en`
TED	14.51	13.25
KFTT	20.82	20.77
JESC	15.77	18.00
MTNT	9.02	6.65
MTNT (+tuning)	12.45	9.82

Table 6: BLEU scores of NMT models on the various datasets.

5.3 Results

We use `sacreBLEU`[18], a standardized BLEU score evaluation script proposed by Post (2018), for BLEU evaluation of our benchmark dataset. It takes in detokenized references and hypotheses and performs its own tokenization before computing BLEU score. We specify the `intl` tokenization option. In the case of Japanese text, we run both hypothesis and reference through KyTea before computing BLEU score. We strongly encourage that evaluation be performed in the same manner in subsequent work, and will provide both scripts and an evaluation web site in order to facilitate reproducibility.

Table 6 lists the BLEU scores for our models on the relevant test sets in the two language pairs, including the results on MTNT.

5.4 Analysis

To better understand the types of errors made by our model, we count the n-grams that are over- and under- generated with respect to the reference translation. Specifically, we compare the count ratios of all 1- to 3-grams in the output and in the reference and look for the ones with the highest (over-generated) and lowest (under-generated) ratio.

We find that in English, the model under-generates the contracted form of the negative ("do not"/"don't") or of auxiliaries ("That is"/"I'm").

Table 7: Comparison of our model’s output before and after fine-tuning in `fr-en`.

Similarly, in French, our model over generates “de votre” (where “votre” is the formal 2nd person plural for “your”) and “n’ai pas” which showcases the “ne […] pas” negation, often dropped in spoken language. Conversely, the informal second person “tu” is under-generated, as is the informal and spoken contraction of “cela”, “ça”. In Japanese, the model under-generates, among others, the informal personal pronoun 俺 (“ore”) or the casual form だ (“da”) of the verb です (“desu”, to be). In `ja-en` the results are difficult to interpret as the model seems to produce incoherent outputs (*e.g.* “no, no, no…”) when the NMT system encounters sentences it has not seen before. The full list of n-grams with the top 5 and bottom 5 count ratios in each language pair is displayed in Table 8.

Table 8: Over and under generated n-grams in our model’s output for `en-fr`

5.5 Fine-Tuning

Finally, we test a simple domain adaptation method by fine-tuning our models on the training data described in Section 3.4. We perform one epoch of training with vanilla SGD with a learning rate of 0.1 and a batch size of 32. We do not use the validation data at all. As evidenced by the results in the last row of Table 6, this drives BLEU score up by 3.17 to 7.96 points depending on the language pair. However large this increase might be, our model still breaks on very noisy sentences. Table 7 shows three examples in `fr-en`. Although our model somewhat improves after fine-tuning, the translations remain inadequate in all cases. In the third case, our model downright fails to produce a coherent output. This shows that despite improving BLEU score, naive domain adaptation by fine-tuning doesn’t solve the problem of translating noisy text.

6 Language Modeling Experiments

In addition to our MT experiments, we report character-level language modeling results on the monolingual part of our dataset. We use the data described in Section 3.5 as training and validation sets. We evaluate the trained model on the source side of our `en-fr`, `fr-en` and `ja-en` test sets for English, French and Japanese respectively.

We report results for two models: a Kneser-Ney smoothed 6-gram model (implemented with KenLM) and an implementation of the AWD-LSTM proposed in (Merity et al., 2018)[19]. We report the Bit-Per-Character (bpc) counts in table 9.

---

[19] `https://github.com/salesforce/awd-lstm-lm`

	6-gram		AWD LSTM	
	dev	test	dev	test

Japanese	5.003	5.497	4.801	5.225

Table 9: Language modeling scores

We intend these results to serve as a baseline for future work in language modeling of noisy text in either of those three languages.

7 Related work

Handling noisy text has received growing attention among various language processing tasks due to the abundance of user generated content on popular social media platforms (Crystal, 2001; Herring, 2003; Danet and Herring, 2007). These contents are considered as noisy when compared to news corpora which have been the main data source for language tasks (Baldwin et al.; Eisenstein). They pose several unique challenges because they contain a larger variety of linguistic phenomena that are absent in the news domain and that lead to degraded quality when applying an model to out-of-domain data (Ritter et al.; Luong and Manning, 2015). Additionally, they are live examples of the Cmabrigde Uinervtisy (Cambridge University) effect, where state-of-the-art models become brittle while human's language processing capability is more robust (Sakaguchi et al., 2017; Belinkov and Bisk, 2018).

Efforts to address these challenges have been focused on creating in-domain datasets and annotations (Owoputi et al.; Kong et al.; Blodgett et al., 2017), and domain adaptation training (Luong and Manning, 2015). In MT, improvements were obtained for SMT (Formiga and Fonollosa). However, the specific challenges for neural machine translation have not been studied until recently (Belinkov and Bisk, 2018; Sperber et al.; Cheng et al., 2018). The first provides empirical evidence of non-trivial quality degradation when source sentences contain natural noise or synthetic noise within words, and the last two explore data augmentation and adversarial approaches of adding noise efficiently to training data to improve robustness.

Our work also contributes to recent advances in evaluating neural machine translation quality with regard to specific linguistic phenomena, such as manually annotated test sentences for English to French translation, in order to identify errors due to specific linguistic divergences between the two languages (Isabelle et al.), or automatically generated test sets to evaluate typical errors in English to German translation (Sennrich). Our contribution distinguishes itself from this previous work and other similar initiatives (Peterson, 2011) by providing an open test set consisting of naturally occurring text exhibiting a wide range of phenomena related to noisy input text from contemporaneous social media.

8 Conclusion

We proposed a new dataset to test MT models for robustness to the types of noise encountered in natural language on the Internet. We contribute parallel training and test data in both directions for two language pairs, English ↔ French and English ↔ Japanese, as well as monolingual data in those three languages. We show that this dataset contains more noise than existing MT test sets and poses a challenge to models trained on standard MT corpora. We further demonstrate that these challenges cannot be overcome by a simple domain adaptation approach alone. We intend this contribution to provide a standard benchmark for robustness to noise in MT and foster research on models, dataset and evaluation metrics tailored for this specific problem.

SimpleQuestions Nearly Solved:
A New Upperbound and Baseline Approach

Michael Petrochuk[*†] **Luke Zettlemoyer**[*]

{mikep5, lsz}@cs.washington.edu

Abstract

The SimpleQuestions dataset is one of the most commonly used benchmarks for studying single-relation factoid questions. In this paper, we present new evidence that this benchmark can be nearly solved by standard methods. First, we show that ambiguity in the data bounds performance at 83.4%; many questions have more than one equally plausible interpretation. Second, we introduce a baseline that sets a new state-of-the-art performance level at 78.1% accuracy, despite using standard methods. Finally, we report an empirical analysis showing that the upperbound is loose; roughly a quarter of the remaining errors are also not resolvable from the linguistic signal. Together, these results suggest that the SimpleQuestions dataset is nearly solved.

1 Introduction

We present new evidence that the SimpleQuestions benchmark (Bordes et al., 2015) can be nearly solved by standard methods. First, we show that ambiguity in the data bounds performance; there are often questions have more than one equally plausible interpretation. Second, we introduce a baseline that sets a new state-of-the-art performance level, despite using standard methods. Finally, we report an empirical analysis showing that the upperbound is loose.

The simple questions task involves mapping an English question (e.g. "Who wrote Gulliver's travels?") to an analogous Freebase (Bollacker et al., 2008) query, used to answer the question. The query consists of a Freebase relation (e.g. /film/film/story_by) and subject (e.g. 090s_0 [gulliver's travels]). To understand how we might bound performance on the SimpleQuestions dataset, our first contribution in this paper, consider the following examples:

a. who wrote gulliver's travels?
(film/film/story_by, 090s_0 [gulliver's travels, TV miniseries])

b. Name a character from gullivers travels.
(book/book/characters, 0btc7 [gulliver's travels])

In example (a) the phrase "Gulliver's travels" is mapped to a TV miniseries, while in (b) it is mapped to a book. This introduces an unintended ambiguity, since either mapping is equally plausible for both examples (i.e. both books and TV miniseries have authors and characters). We introduce a method for automatically identifying many such ambiguities in the data, for both the entities and relations, and show that performance is upperbounded at 83.4%.

Our second main contribution is a baseline that sets a new state-of-the-art performance level, despite using standard methods. Our approach includes (1) a CRF used to tag the mention of the subject in a question and (2) a BiLSTM used to classify the Freebase relation. Despite its simplicity, this approach achieves 78.1% accuracy for predicting Freebase subject-relation queries, surpassing all previous models.

Finally, we present an empirical error analysis of this model which shows the upperbound is loose and that there is likely not much more than 4% of performance to be gained with future work on the data. Together, these results suggest that the SimpleQuestions dataset is nearly solved. Our code and pretrained models are available at `github.com/PetrochukM/Simple-Question-Answering`.

2 Background

Single-relation factoid questions (simple questions) are common in many settings (e.g. Microsoft's search query logs (Yih et al., 2014) and WikiAnswers web questions (Fader et al., 2013)). The SimpleQuestions dataset is one of the most

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 554–558
Brussels, Belgium, October 31 - November 4, 2018.

commonly used benchmarks for studying such questions.

The Freebase knowledge graph (KG) provides the facts for answering the questions in the SimpleQuestions dataset. It includes 3 billion triples of the form (subject, relation, object) (e.g. [04b5zb_ (Fires Creek), location/location/containedby, 0f80hy (Nantahala National Forest)]). We denote such triples as (s, r, o).

The SimpleQuestions task is to rewrite questions into subject-relation pairs of the form (subject, relation), denoted in this paper as (s, r). Each pair defines a graph query that can be used to answer the corresponding natural language question. The subject is a Freebase object with a identifier called an MID (e.g. 04b5zb_). Freebase objects also typically include one or more string aliases (e.g. MID 04b5zb_ is named "Fires Creek"), which we will use later when computing our upper bounds. The relation is an object property (e.g. location/location/containedby) defined by the Freebase ontology. For example, the question "which forest is fires creek in" corresponds with the subject-relation pair (04b5zb_ [Fires Creek], location/location/containedby). Finally, the SimpleQuestions task is evaluated on subject-relation pair accuracy.

The SimpleQuestions dataset provides a set of 108,442 simple questions; each question is accompanied by a ground truth triple (s, r, o). This dataset also provides two subsets of Freebase: FB2M and FB5M.[1]

3 Dataset Ambiguity and Upperbound

The ambiguity in the SimpleQuestions dataset likely comes from the way the data was created. Annotators were shown a single Freebase triple and asked to write a question. For example, given any of the following triples:

- (0btc7 [Gulliver's Travels, Book], book/written_work/author, o3_dj [Dean Swift])
- (06znpjr [Gulliver's Travels, American film], film/film/written_by, 03whnyn [Nicholas Stroller])
- (06znpjr [Gulliver's Travels, American film], film/film/story_by, o3_dj [Dean Swift])

Subject	Description
0btc7	Gulliver's Travels (Book)
090s_0	**Gulliver's Travels (TV miniseries)**
06znpjr	Gulliver's Travels (American film)
02py9bj	Gulliver's Travels (French film)

Table 1: FB2M entities with the alias "gulliver's travels"

Relation	Count
book/written_work/author	132
film/film/written_by	67
film/film/story_by	**9**
...	...

Table 2: SimpleQuestions dataset abstract predicate "who wrote e?" relation count

The annotator might reasonably contribute the question "who wrote gulliver's travels?" However, adding all of these pairs to the data is problematic. Systems are evaluated on producing the correct subject-relation pair, and cannot learn a deterministic mapping that would get these three examples correct. In this section, we present a simple heuristic method for finding many such instances of ambiguity, and use it to upper bound performance on this benchmark.

3.1 Approach

Given an example question q with the ground truth (s, r, o), our goal is to determine the set of all other subject-relation pairs that are equally supported by the text in q.

We first determine a string alias a for the subject by matching a phrase in q with a Freebase alias for s, in our example yielding "gulliver's travels". For 97% of questions q, some string alias a exactly matched a question q phrase. We then find all other Freebase entities that share this alias a and add them to a set S, in our example S is the subject column of Table 1.

We define an abstract predicate p (e.g. "who wrote e?") as q with alias a abstracted. We determine the set of potential relations R as the relations p co-occurs with in the SimpleQuestions dataset, in our example R is the relation column of Table 2.

Finally, if there exists a subject-relation pair $(s, r) \in KG$ such that $r \in R \wedge s \in S$ we de-

---

[1] The FB2M and FB5M subsets of Freebase KG can complete 7,188,636 and 7,688,234 graph queries respectively; therefore, the FB5M subset is 6.9% larger than the FB2M subset. More previous research has cited FB2M numbers than FB5M; therefore, we report our numbers on FB2M.

fine that as an accurate semantic interpretation of q. q is unanswerable if there exists multiple valid subject-relation pairs (s, r). In our example above, the question is unanswerable because of the many different subject, relation pairs that co-occur with "gulliver's travels" and "who wrote e?"

3.2 Results

We find that 33.9% of examples in the SimpleQuestions dataset are unanswerable. In these cases, we can predict a majority baseline (i.e. always guess the most commonly seen Freebase entity or relation), yielding an upperbound of 85.2%.

Finally, we also found that 1.8% of example questions were noisy. For example, "Which book is written about?" does not reference the corresponding ground truth subject 01n7q (california). We also consider these examples unanswerable, yielding a final upperbound of 83.4%.

4 Baseline Model

Our second main contribution is a baseline that sets a new state-of-the-art performance level, despite using standard methods. Our approach includes (1) a CRF tagger to determine the subject alias, and (2) a BiLSTM to classify the relation.

4.1 Approach

Given a question q (e.g. "who wrote gulliver's travels?") our model must predict the corresponding subject-relation pair (s, r). We predict (s, r) with a pipeline that first runs top-k subject recognition and then relation classification.

We make use of two learned distributions. The subject recognition model $P(a|q)$ ranges over text spans A within the question q, in our example A includes the correct subject "gulliver's travels". This distribution is modeled with a CRF, as defined in more detail below. The relation classification model $P(r|q, a)$ will be used to select a Freebase relation r that matches q. The distribution ranges over all relations in Freebase that co-occur with a subject that is named a. It is modeled with an LSTM, that encodes q, again as defined in more detail below.

Given these distributions, we predict the final subject-relation pair (s, r) as follows. First, we determine the most likely subject alias a according to $P(a|q)$ that also matches a subject alias in the KG. We define set S as all Freebase entities named a, in our example S is the subject column of Table 1. Second, we define all potential relations R such that $\forall(s, r) \in KG\{r \in R \wedge s \in S\}$. Using the relation classification model $p(r|q, a)$, we predict the most likely relation $r_{max} \in R$.

Now, the answer candidates are subject-relation pairs such that $(s, r_{max}) \in KG\{r \in R \wedge s \in S\}$. In our example question, if r_{max} is film/film/story_by then S includes both subjects 06znpjr (Gullivers Travels, American film) and 02py9bj (Gullivers Travels, French film). Because there is no explicit linguistic signal to disambiguate this choice, we pick the subject that co-occurs most often with r_{max} in Freebase.

4.2 Model Details

Our approach requires two models, in this section we cover training and configuring these models.

Top-K Subject Recognition We model top-k subject recognition $P(a|q)$ using a linear-chain conditional random field tagger (CRF) with a conditional log likelihood loss objective. k candidates are inferred with the top-k Viterbi algorithm.

Our model is trained on a dataset of questions each with their corresponding subject alias span delimited with IO tagging. The gold standard subject alias spans are determined by heuristically matching a phrase in the question with a Freebase alias for the subject.

All hyperparameters are hand tuned and then a limited set are further tuned with grid search to increase validation accuracy. In total we evaluated at most 100 hyperparameter configurations. The word embeddings are initialized with GloVe (Pennington et al., 2014) and frozen. Adam (Kingma and Ba, 2014), initialized with a learning rate of 0.001, is employed to optimize the model weights. Finally, we halve the learning rate if the validation accuracy has not improved in 3 epochs.

Relation Classification The relation classification distribution $P(r|q, a)$ is modeled with a one layer BiLSTM batchnorm softmax classifier. The BiLSTM encodes an abstract predicate string (e.g. "who wrote e?"), as described in Section 4.1. The last LSTM output vector is provided as input to an output block consisting of batch normalization, ReLU, and softmax.

All hyperparameters are hand tuned and then a limited set are further tuned with Hyperband (Li et al., 2017) to increase validation accuracy. Hyperband is allowed at most 30 epochs per model

Previous Work	**Acc.**

Table 3: Summary of past results on the SimpleQuestions benchmark along with the neural models employed. Note that an "&" indicates multiple neural models.

and a total of 1000 epochs. In total we evaluated at most 500 hyperparameter configurations. The word embeddings are initialized with FastText (Bojanowski et al., 2017) and frozen. We use the AMSGrad variant of Adam (Reddi et al., 2018), initialized with an learning rate of 0.001. Finally, we double the batch size (Smith et al., 2017) if the validation accuracy has not improved in 3 epochs.

4.3 Results

Finally, we present our results on the SimpleQuestions test set.

SimpleQuestions Task Our model achieves 78.1% accuracy on the SimpleQuestions test set, a new state-of-the-art without ensembling or data augmentation (Table 3). These results suggest that relatively standard architectures work well when carefully tuned, and approach the level set by our upper bound earlier in the paper. This further confirms the results of Mohammed et al. 2017.

Further Qualitative Analysis We also analyze the remaining errors, to point toward directions for future work.

In Section 3, we showed that questions can provide equal evidence for multiple subject-relation pairs. To remove this ambiguity, we count any of these options as correct, and our performance jumps to 91.5%.

The remaining 8.5% error comes from a number of sources. First, we find that 1.9% of examples were incorrect due to noise, as described in Section 3. To better understand the remaining 6.5% gap, we do an empirical error analysis on a sample of 50 negative examples.

First we found that for 14 of 50 cases the question provided equal linguistic evidence for both the ground truth options and the predicted subject-relation pair, similar to the dataset ambiguity found in Section 3, suggesting that our upper bound is loose. We note that Section 3 did not cover all possible question-subject-relation pair ambiguities. The approach relied on exact string matching to discover ambiguity; therefore, missing other paraphrases. For example, the abstract predicate "what classification is e" had more examples than "what classification is **the** e" allowing our approach to programmatically define more subject-relation pair ambiguities for the former predicate than the latter.

The remaining 36 of 50 cases were linguistic mistakes by our model. Among the 36 cases, we identified these error cases:

- **Low Shot** (16 of 36) The relation label was seen in the training data less than 10 times.
- **Span Identification** (14 of 36) The subject span was incorrectly labeled.
- **Noise** (2 of 36) The question did not make grammatical sense.

Together, this error analysis shows that the upperbound is loose. There is likely not much more than 4% of performance to be gained with future work on the data.

5 Conclusions and Future Work

The SimpleQuestions dataset is one of the most commonly used benchmarks for studying single-relation factoid questions. In this paper, we presented new evidence to suggest that this benchmark can be nearly solved by standard methods. These results suggest there is likely not much more than 4% to be gained with future work on the data.

Finally, other KG (e.g. Freebase) query datasets should consider providing a set of correct subject-relation pairs when there is ambiguity in the linguistic input.

---

[1] Türe and Jojic 2017 reported a 86.8% accuracy but we and Mohammed et al. 2017 have not been able to replicate their results. Wang et al. 2017 scored 77.5% but removed 0.5% of the test examples.

Phrase-Indexed Question Answering:
A New Challenge for Scalable Document Comprehension

Abstract

We formalize a new modular variant of current question answering tasks by enforcing complete independence of the document encoder from the question encoder. This formulation addresses a key challenge in machine comprehension by requiring a standalone representation of the document discourse. It additionally leads to a significant scalability advantage since the encoding of the answer candidate *phrases* in the document can be pre-computed and *indexed* offline for efficient retrieval. We experiment with baseline models for the new task, which achieve a reasonable accuracy but significantly underperform unconstrained QA models. We invite the QA research community to engage in Phrase-Indexed Question Answering (PIQA, *pika*) for closing the gap. The leaderboard is at: `nlp.cs.washington.edu/piqa`

1 Introduction

Extractive question answering (QA) is the task of selecting an answer phrase (span) to a question given an evidence document. Due to the easiness of evaluation (compared to generative QA) and the fine-grainess of the answer (compared to sentence-level QA), it has become one of the most popular QA tasks, driven by massive new datasets such as SQuAD (Rajpurkar et al., 2016) and TriviaQA (Joshi et al., 2017). Current QA models heavily rely on explicitly learning the interaction between the evidence document and the question using neural attention mechanisms (Wang and Jiang, 2017; Xiong et al., 2017; Seo et al., 2017; Lee et al., 2016, *inter alia*), in which the model is fully aware of the question before or as it reads the document. As a result, despite significant advances, they have not led to the standalone representation of document discourse which is nevertheless a key goal of research in reading comprehension. Furthermore, QA models that condition the document representation on a question have the practical scalability downside that the entire model should be re-applied on the same document for every question.

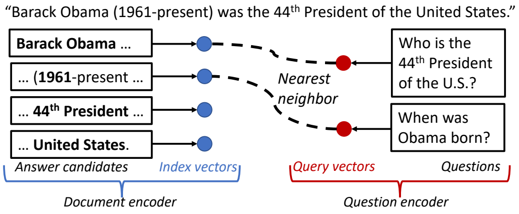

Figure 1: PIQA task for a short context sentence.

In this paper, we formalize a modular variant of the QA task, Phrase Indexed Question Answering (PIQA), that enforces complete independence between document encoder and question encoder (Figure 1). In PIQA, all documents are processed independently of any question to generate *phrase index vectors* (blue nodes in the figure) for each answer candidate (left boxes in the figure). Similarly, the questions are independently mapped to *query vectors* (red nodes in figure). Then, at inference time, the answer is obtained by retrieving the nearest indexed phrase vector to the query vector. Hence the algorithms aimed at tackling PIQA have the inherent benefit of modularity and scalability compared to current QA systems.

The task setup is analogous to how documents or sentences are retrieved in modern search engines via similarity search algorithms (Shrivastava and Li, 2015). Nevertheless, there is a key distinction that search engines index each *document* by its *content*, while PIQA requires one to index each *phrase* in documents by its *context*.

We formally define the PIQA problem and provide baseline models for the new task. Our experiments show that the constraint introduced

by PIQA leads to meaningful standalone document representations and practical scalability advantage, demonstrating the significance of the new task. Moreover, there is still a large gap between the baselines and the unconstrained state of the art, showing that the task is yet far from being solved. We have set up a leaderboard[1] for PIQA challenge and invite the research community to participate. We currently support SQuAD and plan to expand to other datasets as well.

2 Related Work

Reading comprehension. Massive reading comprehension question answering datasets (Hermann et al., 2015; Hill et al., 2016; Dhingra et al., 2017; Dunn et al., 2017) have driven a large number of successful neural approaches (Kadlec et al., 2016; Hu et al., 2017, *inter alia*). Choi et al. (2017); Chen et al. (2017); Clark and Gardner (2017); Min et al. (2018) tackled large-scale QA by using a fast, coarse model (e.g. TF-IDF) to retrieve few documents or sentences and then using a slower, accurate model to obtain the answer. Salant and Berant (2018) proposed to minimize (but not prohibit) the influence of question when modeling the document. Similarly to ours, Lee et al. (2016) proposed to explicitly learn the representation for each answer candidate (phrase) in the document, but it was conditioned (dependent) on the question.

Sentence retrieval. A closely related task to ours is that of retrieving a sentence/paragraph in a corpus that answers the question (Tay et al., 2017). A comprehensive survey for neural approaches in information retrieval literature is discussed in Mitra and Craswell (2017). We note that our problem is focused on phrasal answer extraction, which presents a unique challenge over sentence retrieval—the need for *context-based* representation as opposed to the *content-based* representation in the sentence-retrieval literature.

Language representation. Recently there has been a growing interest in developing natural language representations that can be transferred across tasks (Vendrov et al., 2016; Wieting et al., 2016; Conneau et al., 2017, *inter alia*). In particular, SNLI (Bowman et al., 2015) and MultiNLI (Williams et al., 2017) encourage architectures that first encode the hypothesis and the premise independently before a comparator neural network is applied. Our proposed problem shares similar traits but has a stronger constraint that only inner product comparison is allowed and one needs to model phrases instead of complete sentences.

3 Phrase-Indexed Question Answering

Extractive question answering is the task of obtaining the answer $\hat{a}$ to a question $Q = \{q_1 \dots q_n\}$ given an evidence document $D = \{d_1 \dots d_m\}$, where the answer $\hat{a} = (s, e)$ indicates the start and end of a span in the document. The task is often formulated as learning the probabilistic distribution of the answer given the question and the document. In existing literature (Section 2), the distribution is mainly featurized by $\Pr(a|Q, D) \propto \exp(F_\theta(Q, D, a))$ where F_θ could be any real-valued scoring function parameterized by θ. Once θ is learned, the prediction $\hat{a}$ is obtained by

$$\hat{a} = \operatorname*{argmax}_a F_\theta(Q, D, a). \tag{1}$$

So far, most competitive designs of $F_\theta(Q, D, a)$ make use of attention connections between the words in Q and D. As a result, these models cannot yield a query independent representation of the document D. It is subsequently not possible to independently assess the document understanding capability of the model. Furthermore, $F_\theta(Q, D, a)$ needs to be re-computed for the entire document for every new question. We believe that this inefficiency precludes all current models as the candidates for end-to-end QA systems.

We propose a new task—Phrase-Indexed Question Answering (PIQA)—that addresses these issues. We enforce the *decomposability* of F_θ into two exclusive functions $G_\theta(Q), H_\theta(D, a) \in \mathbb{R}^k$. The answer distribution is then modeled by $\Pr(a|Q, D) \propto \exp(G_\theta(Q) \bullet H_\theta(D, a))$, where $\bullet$ is the inner product. The prediction is obtained by

$$\hat{a} = \operatorname*{argmax}_a G_\theta(Q) \bullet H_\theta(D, a). \tag{2}$$

In this setting, the document encoder H_θ learns models the document independently of the question. Successful question answering models that follow the structure of PIQA will have two important advantages over current QA models: full document comprehension and scalablity.

Full document comprehension. Language understanding ability is widely associated with learning a good standalone representation of text (or its

---

[1] `nlp.cs.washington.edu/piqa`

components such as phrases) independent of the end task (Bowman et al., 2015). Under PIQA constraints, the document encoder H_θ learns the representation of the answer candidate phrases a in the document D independent of the question. In order to correctly answer questions, these phrase representations (index vectors) need to correctly encode their meaning with respect to their context. Therefore, PIQA constraint enforces evaluating research in document comprehension and phrase representation learning.

Scalability. Models that adhere to the PIQA constraint only need to be run once for each document, regardless of the number of questions asked. To answer a question, the model then just needs to encode the question and compare it to each of the answer candidates via the inner product in Equation 2. Implemented naively, computing a single inner product for each answer candidate is more efficient than building a new document encoding; after the documents are pre-encoded, Equation 2 is $O(k)$ time per word where k is the vector size (most neural models require $O(k^2)$ per word for matrix multiplications).

More importantly, PIQA also permits an approximate solution in sublinear time using asymmetric locality-sensitive hashing (aLSH) (Shrivastava and Li, 2014, 2015), through which Equation 2 can be approximated for N answer candidates with $O(kN^\rho \log N)$ time, where $\rho < 1$ is a function of the approximation factor and the properties of the hash functions. We argue that this type of approach will be essential for the development of real world QA systems, where the number of potential answers N is extremely large.

4 Baseline Models

We introduce several baselines for PIQA that are motivated by related literature.

For all (neural) baselines, we represent the words in D and Q with one of three embedding mechanisms: CharCNN (Kim, 2014) + GloVe (Pennington et al., 2014), and ELMo (Peters et al., 2018). We follow the majority of the related literature and apply bidirectional LSTMs (Hochreiter and Schmidhuber, 1997) to these embeddings to build the context-aware representations of the document $\mathbf{D} = \{\mathbf{d}_1 \ldots \mathbf{d}_m\}$ and question $\mathbf{Q} = \{\mathbf{q}_1 \ldots \mathbf{q}_n\}$, where the forward & backward LSTM outputs are concatenated to get a single word representation, i.e. $\mathbf{d}_i, \mathbf{q}_i \in \mathbb{R}^{2k}$ where k is the hidden state size of LSTMs.

PIQA disallows cross-attention between document and question. However, we can still benefit from self-attention, which has become crucial for machine translation (Vaswani et al., 2017) and QA (Huang et al., 2018; Yu et al., 2018). In all of our baselines, each variable-length question is collapsed into a fixed length vector via the sum $\mathbf{q}^{\mathrm{SA}} = \sum_i u_i \mathbf{q}_i$ where $\mathbf{u} = \{u_1 \ldots u_n\}$ is a vector containing a single weight for each word in the question. Similarly, we experiment with document side self attention to represent each document word $\mathbf{d}_j$ as a weighted sum of itself and all neighboring words $\mathbf{d}_j^{\mathrm{SA}} = \sum_i h_i^j \mathbf{d}_j$. The weight vectors $\mathbf{u}$ and $\mathbf{h}^j$ are calculated as

$$\mathbf{u} = \mathrm{softmax}_i(\mathbf{w}^\top \mathbf{q}_i)$$
$$\mathbf{h}^j = \mathrm{softmax}_i(R_\theta(\mathbf{D}, j)^\top K_\theta(\mathbf{D}, i))$$

where R_θ, and K_θ are trainable neural networks with the same ouptut size, and $\mathbf{w} \in \mathbb{R}^{2k}$ is a trainable weight vector. We use independent BiLSTMs with hidden state size k (i.e. the output size is $2k$) to model both R_θ and K_θ. That is, $R_\theta(\mathbf{D}, j)$ is the j-th output of BiLSTM on top of $\mathbf{D}$, and we similarly define K_θ with unshared parameters.

For all (neural) baselines, the question is represented using the concatenation of two copies of $\mathbf{q}^{\mathrm{SA}}$, one that should have high inner product with the vector for the answer's start span and another that should have high inner product with the vector for the answer's end. Thus, Equation 2's $G_\theta(Q) = [\mathbf{q}_s^{\mathrm{SA}}, \mathbf{q}_e^{\mathrm{SA}}]$ where the subscripts s (start) and e (end) imply that different sets of parameters were used. Now we define several baselines.

LSTM baseline. An answer candidate $a = (s, e)$ is represented using the LSTM outputs at its endpoints: from Equation 2, $H_\theta(D, (s, e)) = [\mathbf{d}_s, \mathbf{d}_e] \in \mathbb{R}^{4k}$ and $G_\theta(Q) = [\mathbf{q}_s^{\mathrm{SA}}, \mathbf{q}_e^{\mathrm{SA}}] \in \mathbb{R}^{4k}$.

LSTM+SA baseline. The LSTM outputs are augmented with the endpoint representations that come out of the document's self-attention (SA): $H_\theta(D, (s, e)) = [\mathbf{d}_s, \mathbf{d}_s^{\mathrm{SA}}, \mathbf{d}_e, \mathbf{d}_e^{\mathrm{SA}}] \in \mathbb{R}^{8k}$ and $G_\theta(Q) = [\mathbf{q}_{s1}^{\mathrm{SA}}, \mathbf{q}_{s2}^{\mathrm{SA}}, \mathbf{q}_{e1}^{\mathrm{SA}}, \mathbf{q}_{e2}^{\mathrm{SA}}] \in \mathbb{R}^{8k}$.

TF-IDF. We lastly include a purely TF-IDF-based model, where each answer candidate phrase is associated with a bag of neighbor words within a distance of 7. Then the BOW vector is normalized via TF-IDF and indexed. When the query comes in, its TF-IDF vector is queried on the indexed phrases to yield the answer.

Constraint	Model	F1 (%)	EM (%)
PI	TF-IDF	15.0	3.9
	LSTM	57.2	46.8
	LSTM+SA	59.8	49.0
	LSTM+ELMo	60.9	50.9
	LSTM+SA+ELMo	62.7	52.7
None	Rajpurkar et al. (2016)	51.0	40.0
	Yu et al. (2018)	89.3	82.5

Table 1: Performance on SQuAD dev set with the PIQA constraint (top), and without the constraint (bottom). See Section 4 for the description of the terms.

For training the (neural) models, we minimize the negative log probability of getting the correct answer: the loss function for each example (D, Q, a^*) is $L(\theta) = -\log \Pr(a^*|D, Q)$ where a^* is the correct answer.

5 Experiments

We impose the independence restrictions from PIQA on the Stanford Question Answering Dataset[2]. We only consider answer spans with length ≤ 7. We use the hidden state size (k) of 128, which results in a 512D ($4k$) and 1024D ($8k$) vector for each phrase in LSTM and LSTM+SA, respectively. The default embedding model is CharCNN concatenated with 200D GloVe, with an option to append ELMo vectors following the same setup for SQuAD experiments discussed in Peters et al. (2018). We use a batch size of 64 and train for 20 epochs with the default Adam optimizer (Kingma and Ba, 2015), and take the best model on the validation set during training.

Results. Table 1 shows the results for the PIQA baselines (top) and the unconstrained state of the art (bottom). First, the TF-IDF model performs poorly, which signifies the limitations of traditional document retrieval models for the task. Second, we note that the addition of self-attention makes a significant impact on results, improving F1 by 2.6%. Next, we see that adding ELMo gives 3.7% and 2.9% improvement on F1 for LSTM and LSTM+SA models, respectively. Lastly, the best PIQA baseline model is 11.7% higher than the first (unconstrained) baseline model (Rajpurkar et al., 2016) and 26.6% lower than the state of the art (Yu et al., 2018). This gives us a reasonable starting point of the new task and a significant gap to close for future work.

Table 2: Most similar phrase pairs from disjoint sets of documents. Bold print is the phrase, and non-bold is its context.

Phrase representations. Since PIQA models encode all answer candidates into the same space, we expect similar answer candidates to have high inner products with one another. Table 2 shows pairs of answer candidates that come from different documents in SQuAD, but that have similar encodings (high inner product). We observe that phrase representations learned through the PIQA task capture different interesting characteristics of the phrases. In all three rows, we can see that the phrase pairs seem to fit into natural categories: national, or multi-national organizational constructs; mechanical engines; and mechanical properties, respectively. This suggests that the model has learned interesting typing information above the word level. The second and third rows also indicate that the model has learned a rich representation of context. This is particularly obvious in the third row where the two phrases are lexically dissimilar, but preceded by the similar contexts *'primarily accomplished through'* and *'directly derived from'*. We believe that this analysis, while not complete, points toward exciting future lines of work in learning highly contextualized phrase representations through question answering.

Scalability. PIQA can also gain massive execution time speedups once the documents are pre-encoded: in our simple benchmark on a consumer-grade CPU and NumPy (for LSTM+SA model, 1024D vectors), one can easily perform exact search over 1 million document words per second. BiDAF (Seo et al., 2017), an open-sourced and relatively light QA model reaching 77.5% F1 (66.5% EM), can process less than 1k document words per second with an equivalent computing power (after pre-encoding the document as much as possible), which is more than 1,000x slower.[3]

---

[2] PIQA paradigm can be also extended to other extractive QA datasets.

[3] The difference will be even higher with a dedicated similarity search package such as Faiss (Johnson et al., 2017) or approximate search (Section 3).

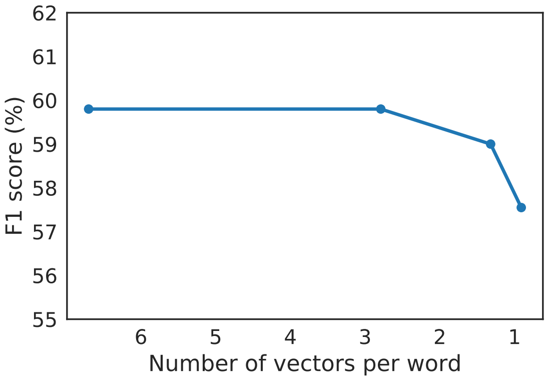

Figure 2: F1 score versus number of vectors per word for LSTM+SA. Answer candidates have been filtered with varying threshold on an independent classifier learned on the candidate representations.

It is also important to consider the memory cost for storing a vector representation of each of the answer candidates. We train an independent single-layer perceptron classifier that predicts whether the phrase encoding is likely to be a good one. By varying a threshold on the score assigned by this classifier, we can filter answer candidates prior to storage. Figure 2 illustrates the trade-off between accuracy and memory (measured in mean number of vectors per document word) resulting from this filtering procedure for the LSTM+SA model. We observe that 1.3 vectors (candidates) per word on average reaches $> 98\%$ of the model's F1 accuracy. This is equivalent to 5.2 KB per word with 1024D (4 KB) float vectors, or around 15 TB for the entire English Wikipedia (3 billion words). Future work will also involve creating a better classifier (i.e. improving the trade-off curve in Figure 2) for determining which phrase vectors to store.

6 Conclusion and Future Work

We introduced Phrase-Indexed Question Answering (PIQA), a new variant of the extractive question answering task that requires documents and question encoded completely independently and that they only interact each other via inner product. We argued that building a question-agnostic document encoder for question answering should be an important consideration for those in the QA community with the research goal of learning a model that reads and comprehends documents. Furthermore, the imposed constraint of the task implies a sublinear scalability benefit. Given that SQuAD models have recently outperformed humans, PIQA formulation motivates a new challenge for which we hope that the community's effort gradually closes the gap between our constrained baselines and the unconstrained models.

Ranking Paragraphs for Improving Answer Recall in Open-Domain Question Answering

Jinhyuk Lee, Seongjun Yun, Hyunjae Kim, Miyoung Ko and **Jaewoo Kang***

Abstract

Recently, open-domain question answering (QA) has been combined with machine comprehension models to find answers in a large knowledge source. As open-domain QA requires retrieving relevant documents from text corpora to answer questions, its performance largely depends on the performance of document retrievers. However, since traditional information retrieval systems are not effective in obtaining documents with a high probability of containing answers, they lower the performance of QA systems. Simply extracting more documents increases the number of irrelevant documents, which also degrades the performance of QA systems. In this paper, we introduce Paragraph Ranker which ranks paragraphs of retrieved documents for a higher answer recall with less noise. We show that ranking paragraphs and aggregating answers using Paragraph Ranker improves performance of open-domain QA pipeline on the four open-domain QA datasets by 7.8% on average.

1 Introduction

With the introduction of large scale machine comprehension datasets, machine comprehension models that are highly accurate and efficient in answering questions given raw texts have been proposed recently (Seo et al., 2016; Xiong et al., 2016; Wang et al., 2017c). While conventional machine comprehension models were given a paragraph that always contains an answer to a question, some researchers have extended the models to an open-domain setting where relevant documents have to be searched from an extremely large knowledge source such as Wikipedia (Chen et al., 2017; Wang et al., 2017a). However, most of the open-domain QA pipelines depend on traditional information retrieval systems which use TF-IDF rankings (Chen et al., 2017; Wang et al., 2017b). Despite the efficiency of the traditional retrieval systems, the documents retrieved and ranked at the top by such systems often do not contain answers to questions. However, simply increasing the number of top ranked documents to find answers also increases the number of irrelevant documents. The tradeoff between reading more documents and minimizing noise is frequently observed in previous works that defined the N number of top documents as a hyper-parameter to find (Wang et al., 2017a).

In this paper, we tackle the problem of ranking the paragraphs of retrieved documents for improving the answer recall of the paragraphs while filtering irrelevant paragraphs. By using our simple but efficient Paragraph Ranker, our QA pipeline considers more documents for a high answer recall, and ranks paragraphs to read only the most relevant ones. The work closest to ours is that of Wang et al. (2017a). However, whereas their main focus is on re-ranking retrieved sentences to maximize the rewards of correctly answering the questions, our focus is to increase the answer recall of paragraphs with less noise. Thus, our work is complementary to the work of Wang et al. (2017a).

Our work is largely inspired by the field of information retrieval called *Learning to Rank* (Liu et al., 2009; Severyn and Moschitti, 2015). Most learning to rank models consist of two parts: encoding networks and ranking functions. We use bidirectional long short term memory (Bi-LSTM) as our encoding network, and apply various ranking functions proposed by previous works (Severyn and Moschitti, 2015; Tu et al., 2017). Also, as the time and space complexities of ranking paragraphs are much larger than those of ranking sentences (Severyn and Moschitti, 2015), we resort to negative sampling (Mikolov et al., 2013) for an efficient training of our Paragraph Ranker.

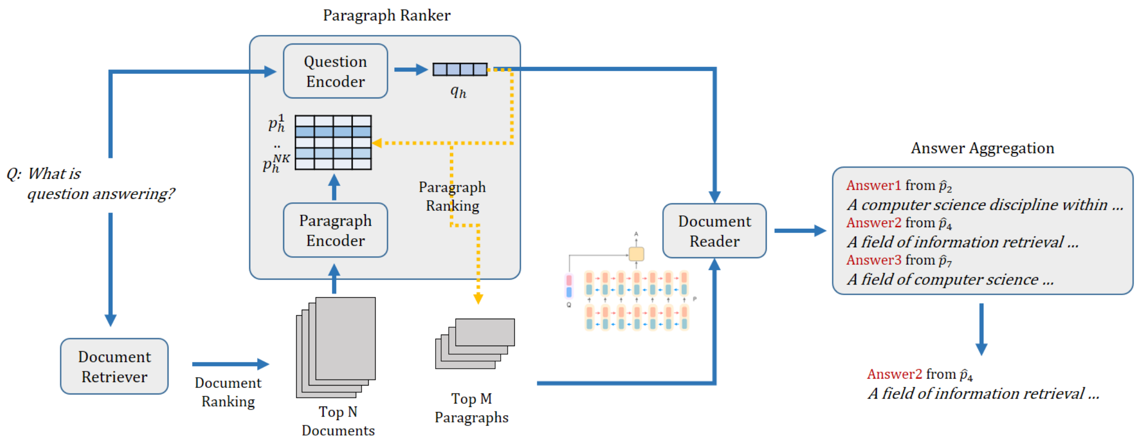

Figure 1: Our proposed open-domain QA pipeline with Paragraph Ranker

Our pipeline with Paragraph Ranker improves the exact match scores on the four open-domain QA datasets by 7.8% on average. Even though we did not further customize Document Reader of DrQA (Chen et al., 2017), the large improvement in the exact match scores shows that future researches would benefit from ranking and reading the more relevant paragraphs. By a qualitative analysis of ranked paragraphs, we provide additional evidence supporting our findings.

2 Open-Domain QA Pipeline

Most open-domain QA systems are constructed as pipelines that include a retrieval system and a reader model. We additionally built Paragraph Ranker that assists our QA pipeline for a better paragraph selection. For the retrieval system and the reader model, we used Document Retriever and Document Reader of Chen et al. (2017).[1] The overview of our pipeline is illustrated in Figure 1.

2.1 Paragraph Ranker

Given N number of documents retrieved from Document Retriever, we assume that each document contains K number of paragraphs on average. Instead of feeding all NK number of paragraphs to Document Reader, we select only M number of paragraphs using Paragraph Ranker. Utilizing Paragraph Ranker, we safely increase N for a higher answer recall, and reduce the number of paragraphs to read by selecting only top ranked paragraphs.

Given the retrieved paragraphs P_i where i ranges from 1 to NK, and a question Q, we encode each paragraph and the question using two separate RNNs such as Bi-LSTM. Representations of each paragraph and the question are calculated as follows:

$$p_h^i = \text{BiLSTM}_p(\text{E}(P_i)) \quad q_h = \text{BiLSTM}_q(\text{E}(Q))$$

where BiLSTM$(\cdot)$ returns the concatenation of the last hidden state of forward LSTM and the first hidden state of backward LSTM. E$(\cdot)$ converts tokens in a paragraph or a question into pretrained word embeddings. We use GloVe (Pennington et al., 2014) for the pretrained word embeddings.

Once each paragraph and the question are represented as p_h^i and q_h, we calculate the probability of each paragraph to contain an answer of the question as follows:

$$p(P_i|Q) = \frac{1}{1 + e^{-s(p_h^i, q_h)}}$$

where we have used similarity function $s(\cdot,\cdot)$ to measure the probability of containing answer to the question Q in the paragraph P_i. While Wang and Jiang (2015) adopted high capacity models such as Match-LSTM for measuring the similarity between paragraphs and questions, we use much simpler scoring functions to calculate the similarity more efficiently. We tested three different scoring functions: 1) the dot product of p_h^i and q_h, 2) the bilinear form ${p_h^i}^T W q_h$, and 3) a multilayer perceptron (MLP) (Severyn and Moschitti, 2015). While utilizing MLP takes much more time than the other two functions, recall of MLP was similar to that of the dot product. Also, as recall of the bilinear form was worse than that of the dot product, we use the dot product as our scoring function.

---

[1] https://github.com/facebookresearch/DrQA

Due to the large size of NK, it is difficult to train Paragraph Ranker on all the retrieved paragraphs.[2] To efficiently train our model, we use a negative sampling of irrelevant paragraphs (Mikolov et al., 2013). Hence, the loss function of our model is as follows:

$$\begin{aligned} J(\Theta) = &- \log p(P_i|Q) \\ &- E_{k \sim p_n}[\log(1 - p(P_k|Q))] \end{aligned}$$

where k indicates indexes of negative samples that do not contain the answer, and Θ denotes trainable parameters of Paragraph Ranker. The distribution of negative samples are defined as p_n. We use the distribution of all the Stanford Question Answering Dataset (SQuAD) (Rajpurkar et al., 2016) training paragraphs as p_n .

Based on the rank of each paragraph from Paragraph Ranker and the rank of source document from Document Retriever, we collect top M paragraphs to read. We combine the ranks by the multiplication of probabilities $p(P_i|Q)$ and $\tilde{p}(D_i|Q)$ to find most relevant paragraphs where $\tilde{p}(D_i|Q)$ denotes TF-IDF score of a source document D_i.

2.2 Answer Aggregation

We feed M paragraphs to Document Reader to extract M answers. While Paragraph Ranker increases the probability of including answers in the top M ranked paragraphs, aggregation step should determine the most probable answer among the M extracted answers. Chen et al. (2017) and Clark et al. (2017) used the unnormalized answer probability from the reader. However, as the unnormalized answer probability is very sensitive to noisy answers, Wang et al. (2017b) proposed a more sophisticated aggregation methods such as coverage-based and strength-based re-rankings.

In our QA pipeline, we incorporate the coverage-based method by Wang et al. (2017b) with paragraph scores from Paragraph Ranker. Although strength-based answer re-ranking showed good performances on some datasets, it is too complex to efficiently re-rank M answers. Given the M candidate answers $[A_1, ..., A_M]$ from each paragraph, we aggregate answers as follows:

$$\begin{aligned} \hat{A} &= \arg\max_{A_i} p(A_i|Q) \\ &= \arg\max_{A_i} \tilde{p}(A_i|P_i, Q)^{\alpha} p(P_i|Q)^{\beta} \tilde{p}(D_i|Q)^{\gamma} \end{aligned} \tag{1}$$

where $\tilde{p}(A_i|P_i, Q)$ denotes the unnormalized answer probability from a reader given the paragraph P_i and the question Q. Importance of each score is determined by the hyperparamters α, β, and γ. Also, we add up all the probabilities of the duplicate candidate answers for the coverage-based aggregation.

3 Experiments

3.1 Datasets

We evaluate our pipeline with Paragraph Ranker on the four open-domain QA datasets. Wang et al. (2017a) termed SQuAD without relevant paragraphs for the open-domain QA as **SQuAD$_{\text{OPEN}}$**, and we use the same term to denote the open-domain setting SQuAD. **CuratedTrec** (Baudiš and Šedivỳ, 2015) was created for TREC open-domain QA tasks. **WebQuestions** (Berant et al., 2013) contains questions from Google Suggest API. **WikiMovies** (Miller et al., 2016) contains questions regarding movies collected from OMDb and the MovieLens database. We pretrain Document Reader and Paragraph Ranker on the SQuAD training set.[3]

3.2 Implementation Details

Paragraph Ranker uses 3-layer Bi-LSTM networks with 128 hidden units. On SQuAD$_{\text{OPEN}}$ and CuratedTrec, we set α, β, and γ of Paragraph Ranker to 1. Due to the different characteristics of questions in WebQuestion and WikiMovies, we find α, β, and γ based on the validation QA pairs of the two datasets. We use $N = 20$ for the number of documents to retrieve and $M = 200$ for the number of paragraphs to read for all the four datasets. We use Adamax (Kingma and Ba, 2014) as the optimization algorithm. Dropout is applied to LSTMs and embeddings with $p = 0.4$.

3.3 Results

In our experiments, **Paragraph Ranker** ranks only paragraphs, and answers are determined by unnormalized scores of the answers. **Paragraph Ranker + Answer Agg.** sums up the unnormalized probabilities of duplicate answers (i.e., $\beta = \gamma = 0$). **Paragraph Ranker + Full Agg.** aggregates answers using Equation 1 with the coverage-based aggregation.

---

[2] $NK \approx 350$ when $N = 5$ in SQuAD QA pairs.

[3] On SQuAD development set, pretrained Document Reader achieves 69.1% EM, and pretrained Paragraph Ranker achieves 96.7% recall on the top 5 paragraph .

	SQuAD$_{\text{OPEN}}$		CuratedTrec		WebQuestions		WikiMovies	
Model	EM	Recall	EM	Recall	EM	Recall	EM	Recall
DrQA (Chen et al., 2017)	27.1	77.8	19.7	86.0	11.8	74.4	24.5	70.3
DrQA + Fine-tune	28.4	-	25.7	-	19.5	-	34.3	-
DrQA + Multitask	29.8	-	25.4	-	20.7	-	36.5	-
R^3 (Wang et al., 2017a)	29.1	-	28.4	-	17.1	-	38.8	-
Par. Ranker	28.5	83.1	26.8	91.4	18.0	70.7	33.4	79.7
Par. Ranker + Answer Agg.	28.9	-	28.2	-	18.4	-	33.9	-
Par. Ranker + Full Agg.	**30.2**	-	**35.4**	-	**19.9**	-	**39.1**	-

Table 1: Open-domain QA results on four QA datasets. Best scores including those of the Multitask model are underlined. Bold texts denote best scores excluding those of the Multitask model.

Question #1	*What position does Von Miller play?* (SQuAD$_{\text{OPEN}}$)
Answer	*linebacker*, *linebacker*, *linebacker*
Doc. Retriever	(Top-1 document) *Ferdinand Miller, from 1875 von Miller ... was an ore caster, ...* *Miller was born and died in Munich. He was the son of the artisan and First ...* *Ferdinand was simultaneously ennobled. Ferdinand's younger brother was the ...*
Par. Ranker	(Top-1 paragraph) *The two teams exchanged field goals ... with a 48-yarder by ...* (Top-2 paragraph) *Luck was strip-sacked by Broncos'* ***linebacker*** *Von Miller ...* (Top-3 paragraph) *Broncos'* ***linebacker*** *Von Miller forced a fumble off RGIII ...*

Table 2: Top ranked paragraphs by Paragraph Ranker based on SQuAD$_{\text{OPEN}}$

In Table 1, we summarize the performance and recall of each model on open-domain QA datasets. We define recall as the probability of read paragraphs containing answers. While Reinforced Reader-Ranker (R^3) (Wang et al., 2017a) performs better than DrQA on the three datasets (SQuAD$_{\text{OPEN}}$, CuratedTrec, WikiMovies), Paragraph Ranker + Full Agg. outperforms both DrQA and R^3. Paragraph Ranker + Full Agg. achieved 3.78%, 24.65%, 2.05%, 0.77% relative improvements in terms of EM on SQuAD$_{\text{OPEN}}$, CuratedTrec, WebQuestion, and WikiMovies, respectively (7.8% on average). It is noticeable that our pipeline with Paragraph Ranker + Full Agg. greatly outperforms DrQA + Multitask in SQuAD$_{\text{OPEN}}$ and CuratedTrec.

3.4 Analysis

In Table 2, we show 3 random paragraphs of the top document returned by Document Retriever, and the top 3 paragraphs ranked by Paragraph Ranker from the top 40 documents. As Document Retriever largely depends on matching of query tokens with document tokens, the top ranked document is usually the document with most tokens matching the query. However, Question 1 includes the polysemy of the word "play" which makes it more difficult for Document Retriever to perform effectively. Our Paragraph Ranker well understands that the question is about a sports player not a musician. The top 1-3 paragraphs for the second question came from the 30th, 7th, and 6th documents, respectively, ranked by Document Retriever. This shows that increasing number of documents to rank helps Paragraph Ranker find more relevant paragraphs.

4 Conclusion

In this paper, we present an open-domain question answering pipeline and proposed Paragraph Ranker. By using Paragraph Ranker, the QA pipeline benefits from increased answer recall from paragraphs to read, and filters irrelevant documents or paragraphs. With our simple Paragraph Ranker, we achieve state-of-the-art performances on the four open-domain QA datasets with large margins. As future works, we plan to further improve Paragraph Ranker based on the researches on learning to rank.

Abstract

In recent years many deep neural networks have been proposed to solve Reading Comprehension (RC) tasks. Most of these models suffer from reasoning over long documents and do not trivially generalize to cases where the answer is not present as a span in a given document. We present a novel neural-based architecture that is capable of extracting relevant regions based on a given question-document pair and generating a well-formed answer. To show the effectiveness of our architecture, we conducted several experiments on the recently proposed and challenging RC dataset 'NarrativeQA'. The proposed architecture outperforms state-of-the-art results (Tay et al., 2018) by 12.62% (ROUGE-L) relative improvement.

1 Introduction

Building Artificial Intelligence (AI) algorithms to teach machines to read and to comprehend text is a long-standing challenge in Natural Language Processing (NLP). A common strategy for assessing these AI algorithms is by treating them as RC tasks. This can be formulated as finding an answer to a question given the document(s) as evidence. Recently, many deep-learning based models (Seo et al., 2017; Xiong et al., 2017; Wang et al., 2017; Shen et al., 2017; Clark and Gardner, 2017) have been proposed to solve RC tasks based on the SQuAD (Rajpurkar et al., 2016) and TriviaQA (Joshi et al., 2017) datasets, reaching human level performance. A common approach in these models is to score and/or extract candidate spans conditioned on a given question-document pair.

Most of these models have limited applicability to real problems for the following reasons. They do not generalize well to scenarios where the answer is not present as a span, or where several discontinuous parts of the document are required to form the answer. In addition, unlike humans, they can not easily skip through irrelevant parts to comprehend long documents (Masson, 1983).

To address the issues above we develop a novel context zoom-in network (ConZNet) for RC tasks, which can skip through irrelevant parts of a document and generate an answer using only the relevant regions of text. The ConZNet architecture consists of two phases. In the first phase we identify the relevant regions of text by employing a reinforcement learning algorithm. These relevant regions are not only useful to generate the answer, but can also be presented to the user as supporting information along with the answer. The second phase is based on an encoder-decoder architecture, which comprehends the identified regions of text and generates the answer by using a residual self-attention network as encoder and a RNN-based sequence generator along with a pointer network (Vinyals et al., 2015) as the decoder. It has the ability to generate better well-formed answers not verbatim present in the document than span prediction models.

Recently, there have been several attempts to adopt condensing documents in RC tasks. Wang et al. (2018) retrieve a relevant paragraph based on the question and predict the answer span. Choi et al. (2017) select sentence(s) to make a summary of the entire document with a feed-forward network and generate an answer based on the summary. Unlike existing approaches, our method has the ability to select relevant regions of text not just based on the question but also on how well regions are related to each other. Moreover, our decoder combines span prediction and sequence generation. This allows the decoder to copy words from the relevant regions of text as well as to generate words from a fixed vocabulary.

We evaluate our model using one of the challenging RC datasets, called 'NarrativeQA', which

Brussels, Belgium, October 31 - November 4, 2018.

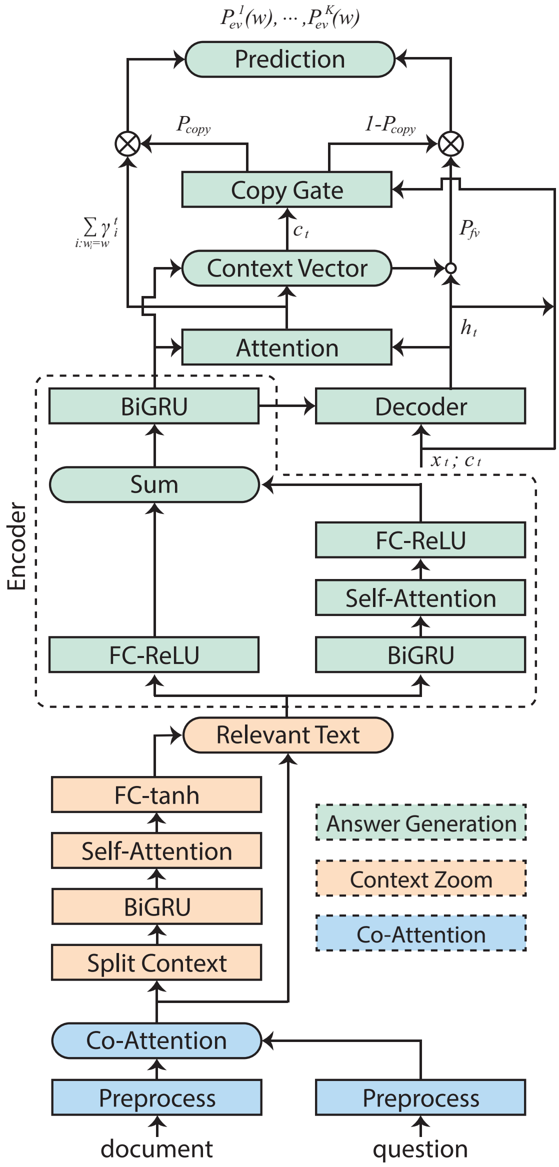

Figure 1: The proposed ConZNet architecture

was released recently by Kočiskỳ et al. (2017). Experimental results show the usefulness of our framework for RC tasks and we outperform state-of-the-art results on this dataset.

2 Proposed Architecture

An overview of our architecture is shown in Figure 1, which consists of two phases. First, the identification of relevant regions of text is computed by the **Co-attention** and **Context Zoom** layers as explained in Sections 2.1 and 2.2. Second, the comprehension of identified regions of text and output generation is computed by **Answer Generation** block as explained in Section 2.3.

2.1 Co-attention layer

The words in the document, question and answer are represented using pre-trained word embeddings (Pennington et al., 2014). These word-based embeddings are concatenated with their corresponding char embeddings. The char embeddings are learned by feeding all the characters of a word into a Convolutional Neural Network (CNN) (Kim, 2014). We further encode the document and question embeddings using a shared bi-directional GRU (Cho et al., 2014) to get context-aware representations.

We compute the co-attention between document and question to get question-aware representations for the document by using tri-linear attention as proposed by Seo et al. (2017). Let d_i be the vector representation for the document word i, q_j be the vector for the question word j, and l_d and l_q be the lengths of the document and question respectively. The tri-linear attention is calculated as

$$a_{ij} = w_d d_i + w_q q_j + w_{dq}(d_i \odot q_j), \qquad (1)$$

where w_d, w_q, and w_{dq} are learnable parameters and $\odot$ denotes the element-wise multiplication.

We compute the attended document word $\tilde{d}_i$ by first computing $\lambda_i = softmax(a_{i:})$ and followed by $\tilde{d}_i = \sum_{j=1}^{l_q} \lambda_{ij} q_j$. Similarly, we compute a question to document attention vector $\tilde{q}$ by first computing $b = softmax(\max(a_{i:}))$ and followed by $\tilde{q} = \sum_{i=i}^{l_d} d_i b_i$. Finally, d_i, $\tilde{d}_i$, $d_i \odot \tilde{d}_i$, $\tilde{d}_i \odot \tilde{q}$ are concatenated to yield a query-aware contextual representation for each word in the document.

2.2 Context Zoom Layer

This layer finds relevant regions of text. We use reinforcement learning to do that, with the goal of improving answer generation accuracy – see Section 2.4.

The *Split Context* operation splits the attended document vectors into sentences or fixed size chunks (useful when sentence tokenization is not available for a particular language). This results in n text regions with each having length l_k, where $l_d = \sum_{k=1}^{n} l_k$. We then get the representations, denoted as z_k, for each text region by running a *BiGRU* and concatenating the last states of the forward and backward GRUs.

The text region representations, z_k, encode how well they are related to the question, and their surrounding context. Generating an answer may depend on multiple regions, and it is important for each text region to collect cues from other regions which are outside of their surroundings. We can compute this by using a *Self-Attention* layer. It is a special case of co-attention where both operands (d_i and q_j) are the text fragment itself, computed by setting $a_{ij} = -\infty$ when $i = j$ in Eq. 1.

These further self-attended text region representations, $\tilde{z}_k$, are passed through a linear layer with *tanh* activation and *softmax* layer as follows:

$$u = tanh(W_c[\tilde{z}_1, \cdots, \tilde{z}_n] + b_c), \tag{2}$$

$$\psi = softmax(u), \tag{3}$$

where ψ is the probability distribution of text regions, which is the evidence used to generate the answer. The policy of the reinforcement learner is defined as $\pi(r|u; \theta_z) = \psi_r$, where ψ_r is the probability of a text region r (agent's action) being selected, u is the environment state as defined in Eq. 2, and θ_z are the learnable parameters. During the training time we sample text regions using ψ, in inference time we follow greedy evaluation by selecting most probable region(s).

2.3 Answer Generation

This component is implemented based on the encoder-decoder architecture of (Sutskever et al., 2014). The selected text regions from the *Context Zoom* layer are given as input to the encoder, where its output is given to the decoder in order to generate the answer.

The encoder block uses residual connected self-attention layer followed by a BiGRU. The selected relevant text regions ($\in \psi_r$) are first passed through a separate BiGRU, then we apply a self-attention mechanism similar to the *Context Zoom* layer followed by a linear layer with ReLU activations. The encoder's output consists of representations of the relevant text regions, denoted by e_i.

The decoder block is based on an attention mechanism (Bahdanau et al., 2015) and a copy mechanism by using a pointer network similar to (See et al., 2017). This allows the decoder to predict words from the relevant regions as well as from the fixed vocabulary. At time step t, the decoder predicts the next word in the answer using the attention distribution, context vector and current word embedding. The attention distribution and context vector are obtained as follows:

$$o_i^t = v^T tanh(W_e e_i + W_h h_t + b_o), \tag{4}$$

$$\gamma^t = softmax(o_i^t), \tag{5}$$

where h_t is hidden state of the decoder, v, W_e, W_h, b_o are learnable parameters. The γ^t represents a probability distribution over words of relevant regions e_i. The context vector is given by $c_t = \sum_i \gamma_i^t e_i$.

	AW	AS/MS
document	659	28/66
question	10	n/a
answer	5	n/a

	NE
Train	32,747
Dev	3,461
Test	10,557

Table 1: NarrativeQA statistics. **AW, AS/MS** are defined as avg. words, avg./max. sentences in the document/question/answer. **NE**: Number of examples.

The probability distribution to predict word w_t from the fixed vocabulary (P_{fv}) is computed by passing state h_t and context vector c_t to a linear layer followed by a softmax function denoted as

$$P_{fv} = softmax(W_v(X_v[h_t, c_t] + b_p) + b_q). \tag{6}$$

To allow decoder to copy words from the encoder sequence, we compute a soft gate (P_{copy}), which helps the decoder to generate a word by sampling from the fixed vocabulary or by copying from a selected text regions (ψ_r). The soft gate is calculated as

$$P_{copy} = \sigma(w_p^T c_t + v_h^T h_t + w_x^T x_t + b_c), \tag{7}$$

where x_t is current word embedding, h_t is hidden state of the decoder, c_t is the context vector, and w_p, v_h, w_x, and b_c are learnable parameters. We maintain a list of out-of-vocabulary (OOV) words for each document. The fixed vocabulary along with this OOV list acts as an extended vocabulary for each document. The final probability distribution (unnormalized) over this extended vocabulary (P_{ev}) is given by

$$P_{ev}(w_t) = (1 - P_{copy})P_{fv}(w_t) + P_{copy} \sum_{i:w_i = w_t} \gamma_i^t. \tag{8}$$

2.4 Training

We jointly estimate the parameters of our model coming from the *Co-attention*, *Context Zoom*, and *Answer Generation* layers, which are denoted as θ_a, θ_z, and θ_g respectively. Estimating θ_a and θ_g is straight-forward by using the cross-entropy objective $J_1(\{\theta_a, \theta_g\})$ and the backpropagation algorithm. However, selecting text regions in the *Context Zoom* layer makes it difficult to estimate θ_z

given their discrete nature. We therefore formulate the estimation of θ_z as a reinforcement learning problem via a policy gradient method. Specifically, we design a reward function over θ_z.

We use mean F-score of ROUGE-1, ROUGE-2, and ROUGE-L (Lin and Hovy, 2003) as our reward function R. The objective function to maximize is the expected reward under the probability distribution of current text regions ψ_r, i.e., $J_2(\theta_z) = E_{p(r|\theta_z)}[R]$. We approximate the gradient $\nabla_{\theta_z} J_2(\theta_z)$ by following the REINFORCE (Williams, 1992) algorithm. To reduce the high variance in estimating $\nabla_{\theta_z} J_2(\theta_z)$ one widely used mechanism is to subtract a baseline value from the reward. It is shown that any number will reduce the variance (Williams, 1992; Zaremba and Sutskever, 2015), here we used the mean of the mini-batch reward b as our baseline. The final objective is to minimize the following equation:

$$J(\theta) = J_1(\{\theta_a, \theta_g\}) - J_2(\theta_z) + \sum_{i=1}^{B} (R^i - b), \quad (9)$$

where, B is the size of mini-batch, and R^i is the reward of example $i \in B$. $J(\theta)$ is now fully differentiable and we use backpropagation to estimate θ.

3 Experimental Results

3.1 Dataset

The NarrativeQA dataset (Kočiskỳ et al., 2017) consists of fictional stories gathered from books and movie scripts, where corresponding summaries and question-answer pairs are generated with the help of human experts and Wikipedia articles. The summaries in NarrativeQA are 4-5 times longer than documents in the SQuAD dataset. Moreover, answers are well-formed by human experts and are not verbatim in the story, thus making this dataset ideal for testing our model. The statistics of NarrativeQA are available in Table 1[1].

3.2 Baselines

We compare our model against reported models in Kočiskỳ et al. (2017) (Seq2Seq, ASR, BiDAF) and the Multi-range Reasoning Unit (MRU) in Tay et al. (2018). We implemented two baseline models (Baseline 1, Baseline 2) with *Context Zoom* layer similar to Wang et al. (2018). In both baselines we replace the span prediction layer with an answer generation layer. In Baseline 1 we use an attention based seq2seq layer without using copy mechanism in the answer generation unit similar to Choi et al. (2017). In Baseline 2 the answer generation unit is similar to our ConZNet architecture.

3.3 Implementation Details

We split each document into sentences using the sentence tokenizer of the NLTK toolkit (Bird and Loper, 2004). Similarly, we further tokenize each sentence, corresponding question and answer using the word tokenizer of NLTK. The model is implemented using Python and Tensorflow (Abadi et al., 2015). All the weights of the model are initialized by Glorot Initialization (Glorot et al., 2011) and biases are initialized with zeros. We use a 300 dimensional word vectors from GloVe (Pennington et al., 2014) (with 840 billion pre-trained vectors) to initialize the word embeddings, which we kept constant during training. All the words that do not appear in Glove are initialized by sampling from a uniform random distribution between [-0.05, 0.05]. We apply dropout (Srivastava et al., 2014) between the layers with keep probability of 0.8 (i.e dropout=0.2). The number of hidden units are set to 100. We trained our model with the AdaDelta (Zeiler, 2012) optimizer for 50 epochs, an initial learning rate of 0.1, and a minibatch size of 32. The hyperparameter 'sample size' (number of relevant sentences) is chosen based on the model performance on the devset.

3.4 Results

Table 2 shows the performance of various models on NarrativeQA. It can be noted that our model with sample size 5 (choosing 5 relevant sentences) outperforms the best ROUGE-L score available so far by 12.62% compared to Tay et al. (2018). The low performance of Baseline 1 shows that the hybrid approach (ConZNet) for generating words from a fixed vocabulary as well as copying words from the document is better suited than span prediction models (Seq2Seq, ASR, BiDAF, MRU).

To validate the importance of finding relevant sentences in contrast to using an entire document for answer generation, we experimented with sample sizes beyond 5. The performance of our model gradually dropped from sample size 7 onwards. This result shows evidence that only a few relevant sentences are sufficient to answer a question.

We also experimented with various sample sizes to see the effect of intra sentence relations for an-

Table 2: Performance of various models on NarrativeQA dataset (SS=sample size ≡ number of relevant sentences)

swer generation. The performance of the model improved dramatically with sample sizes 3 and 5 compared to the sample size of 1. These results show that the importance of selecting multiple relevant sentences for generating an answer. In addition, the low performance of Baseline 2 indicates that just selecting multiple sentences is not enough, they should also be related to each other. This result points out that the self-attention mechanism in the *Context zoom* layer is an important component to identify related relevant sentences.

4 Conclusion

We have proposed a new neural-based architecture which condenses an original document to facilitate fast comprehension in order to generate better well-formed answers than span based prediction models. Our model achieved the best performance on the challenging NarrativeQA dataset. Future work can focus for example on designing an inexpensive preprocess layer, and other strategies for improved performance on answer generation.

Adaptive Document Retrieval for Deep Question Answering

Bernhard Kratzwald and **Stefan Feuerriegel**
Chair of Management Information Systems
ETH Zurich
Zurich, Switzerland
`{bkratzwald, sfeuerriegel}@ethz.ch`

Abstract

State-of-the-art systems in deep question answering proceed as follows: (1) an initial document retrieval selects relevant documents, which (2) are then processed by a neural network in order to extract the final answer. Yet the exact interplay between both components is poorly understood, especially concerning the number of candidate documents that should be retrieved. We show that choosing a static number of documents – as used in prior research – suffers from a noise-information trade-off and yields suboptimal results. As a remedy, we propose an adaptive document retrieval model. This learns the optimal candidate number for document retrieval, conditional on the size of the corpus and the query. We report extensive experimental results showing that our adaptive approach outperforms state-of-the-art methods on multiple benchmark datasets, as well as in the context of corpora with variable sizes.

1 Introduction

Question-answering (QA) systems proceed by following a two-staged process (Belkin, 1993): in a first step, a module for document retrieval selects n potentially relevant documents from a given corpus. Subsequently, a machine comprehension module extracts the final answer from the previously-selected documents. The latter step often involves hand-written rules or machine learning classifiers (c. f. Shen and Klakow, 2006; Kaisser and Becker, 2004), and recently also deep neural networks (e. g. Chen et al., 2017; Wang et al., 2018)

The number of candidate documents n affects the interplay between both document retrieval and machine comprehension component. A larger n improves the recall of document retrieval and thus the chance of including the relevant information. However, this also increases the noise and might adversely reduce the accuracy of answer extraction. It was recently shown that a top-1 system can potentially outperform a system selecting more than one document (Kratzwald and Feuerriegel, 2018). This finding suggests that a static choice of n can result a suboptimal performance.

Contributions. This work analyzes the interplay between document retrieval and machine comprehension inside neural QA systems. We first reason numerically why a fixed choice of n in document retrieval can negatively affect the performance of question answering. We thus propose a novel machine learning model that adaptively selects the optimal n_i for each document retrieval. The resulting system outperforms state-of-the-art neural question answering on multiple benchmark datasets. Notably, the overall size of the corpus affects the optimal n considerably and, as a result, our system evinces as especially superior over a fixed n in settings where the corpus size is unknown or grows dynamically.

2 Related Work

Taxonomy of QA systems. Question answering systems are frequently categorized into two main paradigms. On the one hand, knowledge-based systems draw upon manual rules, ontologies and large-scale knowledge graphs in order to deduce answers (e. g. Berant et al., 2013; Lopez et al., 2007; Unger et al., 2012). On the other hand, QA system incorporate a document retrieval module which selects candidate documents based on a chosen similarity metric, while a subsequent module then processes these in order to extract the answer (e. g. Cao et al., 2011; Harabagiu et al., 2000).

Deep QA. Recently, Chen et al. (2017) developed a state-of-the-art deep QA system, where the

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 576–581
Brussels, Belgium, October 31 - November 4, 2018.

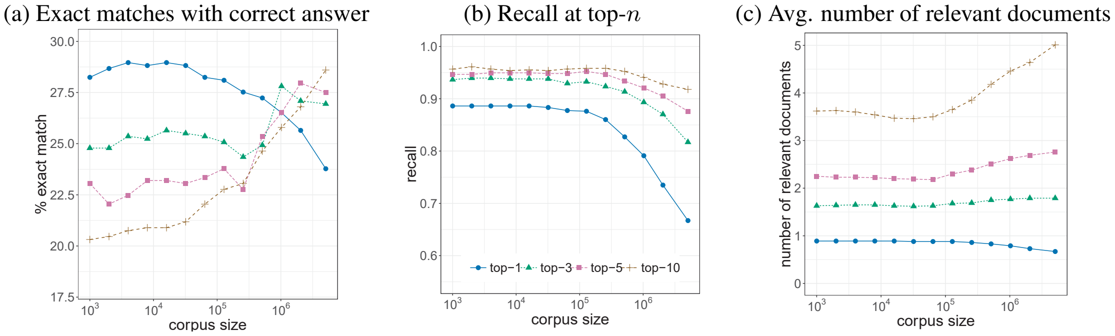

Figure 1: Comparison of how top-n document retrieval affects deep QA. Plot (a) shows the percentage of exact matches with the correct answering, thereby measuring the end-to-end performance of the complete system. Plot (b) gives the recall at top-n, i. e. the fraction of samples where *at least once* the correct answer is returned. Plot (c) depicts the *average number* of documents that contain the ground-truth answer. As a result, the recall lowers with increasing corpus size, yet this not necessarily compromises a top-n system, as it often contains the correct answer more than once.

answer is extracted from the top $n = 5$ documents. This choice stems from computing the dot product between documents and a query vector; with tf-idf weighting of hashed bi-gram counts. Wang et al. (2018) extended this approach by implementing a neural re-ranking of the candidate document, yet keeping the fixed number of n selected documents unchanged. In particular, the interplay between both modules for document retrieval and machine comprehension has not yet been studied. This especially pertains to the number of candidate documents, n, that should be selected during document retrieval.

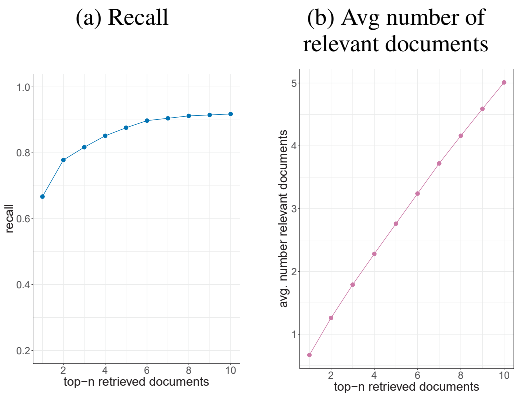
Component interactions. Extensive research has analyzed the interplay of both document retrieval and machine comprehension in the context of knowledge-based systems (c. f. Moldovan et al., 2003) and even retrieval-based systems with machine learning (c. f. Brill et al., 2002). However, these findings do not translate to machine comprehension with deep learning. Deep neural networks consist of a complex attention mechanism for selecting the context-specific answer (Hermann et al., 2015) that has not been available to traditional machine learning and, moreover, deep learning is highly sensitive to settings involving multiple input paragraphs, often struggling with selecting the correct answer (Clark and Gardner, 2017).

3 Noise-Information Trade-Off in Document Retrieval

In the following, we provide empirical evidence why a one-fits-all n can be suboptimal. For this purpose, we run a series of experiments in order to obtain a better understanding of the interplay between document retrieval and machine comprehension modules. That is, we specifically compare the recall of document retrieval to the end-to-end performance of the complete QA system; see Fig. 1. Our experiments study the sensitivity along two dimensions: on the one hand, we change the number of top-n documents that are returned during document retrieval and, on the other hand, we vary the corpus size.

Our experiments utilize the TREC QA dataset as a well-established benchmark for open-domain question answering. It contains 694 question-answer pairs that are answered with the help of Wikipedia. We vary the corpus between a small case (where each question-answer pair contains only one Wikipedia article with the correct answer plus 50 % articles as noise) and the complete Wikipedia dump containing more than five million documents. Our experiments further draw upon the DrQA system (Chen et al., 2017) for question answering that currently stands as a baseline in deep question answering. We further modified it to return different numbers of candidate documents.

Fig. 1 (a) shows the end-to-end performance across different top-n document retrievals as measured by the exact matches with ground truth. For a small corpus, we clearly register a superior performance for the top-1 system. However, we observe a different pattern with increasing corpus size. Fig. 1 (b) and (c) shed light into the underlying reason by reporting how frequently the correct answer is returned and, as the correct an-



(a) Recall

(b) Avg number of relevant documents

Figure 2: Recall (a) and average number of relevant documents (b) for growing top-n configurations and a static corpus size (full Wikipedia dump). While the recall is converging the number of relevant documents keeps growing resulting in a higher density of relevant information.

swer might appear multiple times, how often it is included in the top-n. Evidently, the recall in (b) drops quickly for a top-1 system when augmenting the corpus. Yet it remains fairly stable for a top-n system, due to the fact that it is sufficient to have the correct answer in any of the n documents. According to (c), the correct answer is often more than once returned by a top-n system, increasing the chance of answer extraction.

The above findings result in a noise-information trade-off. A top-1 system often identifies the correct answer for a small corpus, whereas a larger corpus introduces additional noise and thus impedes the overall performance. Conversely, a top-n system accomplishes a higher density of relevant information for a large corpus as the answer is often contained multiple times. This effect is visualized in an additional experiment shown in Fig. 2. We keep the corpus size fixed and vary only n, i.e. the number of retrieved documents. We see the recall converging fast, while the average number of relevant documents keeps growing, leading to a higher density of relevant information. As a result, a top-n system might not be compromised by a declining recall, since it contains the correct answer over-proportionally often. This logic motivates us in the following to introduce an adaptive n_i that optimizes the number of documents retrievals in a top-n system independently for every query q_i.

4 Adaptive Document Retrieval

This section advances deep question answering by developing adaptive methods for document retrieval. Our methods differ from conventional document retrieval in which the number of returned documents is set to a fixed n. Conversely, we actively optimize the choice of n_i for each document retrieval i. Formally, we select n_i between 1 and a maximum τ (e.g. $\tau = 20$), given documents $[d_i^{(1)}, \ldots, d_i^{(\tau)}]$. These entail further scores denoting the relevance, i.e. $s_i = [s_i^{(1)}, \ldots, s_i^{(\tau)}]^T$ with normalization s.t. $\sum_j s_i^{(j)} = 1$. The scoring function is treated as a black-box and thus can be based on simple tf-idf similarity but also complex probabilistic models.

4.1 Threshold-Based Retrieval

As a naïve baseline, we propose a simple threshold-based heuristic. That is, n_i is determined such that the cumulative confidence score reaches a fixed threshold $\theta \in (0, 1]$. Formally, the number n_i of retrieved documents is given by

$$n_i = \max_k \sum_{j=1}^{k} s_i^{(j)} < \theta. \qquad (1)$$

In other words, the heuristic fills up documents until surpassing a certain confidence threshold. For instance, if the document retrieval is certain that the correct answer must be located within a specific document, it automatically selects fewer documents.

4.2 Ordinal Regression

We further implement a trainable classifier in the form of an ordinal ridge regression which is tailored to ranking tasks. We further expect the cumulative confidence likely to be linear. The classifier then approximates n_i with a prediction y_i that denotes the position of the first relevant document containing the desired answer. As such, we learn a function

$$y_i = f([s_i^{(1)}, \ldots, s_i^{(\tau)}]) = \lceil s_i^T \beta \rceil, \qquad (2)$$

where $\lceil \ldots \rceil$ denotes the ceiling function.

The ridge coefficients are learned through a custom loss function

$$\mathcal{L} = \| \lceil X\beta \rceil - y \|_1 + \lambda \, \| \beta \|_2 \, , \qquad (3)$$

where X is a matrix containing scores of our training samples. In contrast to the classical ridge regression, we introduce a ceiling function and replace the mean squared error by a mean absolute error in order to penalize the difference from the optimal rank. The predicted cut-off $\hat{n}_i$ for document retrieval is then computed for new observations ${s'}_i$ via $\hat{n}_i = \lceil {s'}_i^T \hat{\beta} \rceil + b$. The linear offset b is added in order to ensures that $n_i \leq \hat{n}_i$ holds, i. e. reducing the risk that the first relevant document is not included.

We additionally experimented with non-linear predictors, including random forests and feed-forward neural networks; however; we found no significant improvement that justified the additional model complexity over the linear relationship.

5 Experiments

We first compare our QA system with adaptive document retrieval against benchmarks from the literature. Second, we specifically study the sensitivity of our adaptive approach to variations in the corpus size. All our experiments draw upon the DrQA implementation (Chen et al., 2017), a state-of-the-art system for question answering in which we replaced the default module for document retrieval with our adaptive scheme (but leaving all remaining components unchanged, specifically without altering the document scoring or answer extraction).

For the threshold-based model, we set $\tau = 15$ and the confidence threshold to $\theta = 0.75$. For the ordinal regression approach, we choose $\tau = 20$ and use the original SQuAD train-dev split from the full corpus also as the basis for training across all experiments.

5.1 Overall Performance

In a first series of experiments, we refer to an extensive set of prevalent benchmarks for evaluating QA systems, namely, SQuAD (Rajpurkar et al., 2016), Curated TREC (Baudiš and Šedivý, 2015), WikiMovies (Miller et al., 2016) and WebQuestions (Berant et al., 2013) in order to validate the robustness of our findings. Based on these, we then evaluate our adaptive QA systems against the naïve DrQA system in order to evaluate the relative performance. We included the deep QA system R^3 as an additional, top-scoring benchmark from recent literature (Wang et al., 2018) for better comparability.

Tbl. 1 reports the ratio of exact matches for the different QA systems. The results demonstrate the effectiveness of our adaptive scheme: it yields the best-performing system for three out of four datasets. On top of that, it outperforms the naïve DrQA system consistently across all datasets.

5.2 Sensitivity: Adaptive QA to Corpus Size

We earlier observed that the corpus size affects the best choice of n and we thus study the sensitivity with regard to the size. For this purpose, we repeat the experiments from Section 3 in order to evaluate the performance gain from our adaptive scheme. More precisely, we compare the ordinal regression ($b = 1$) against document retrieval with a fixed document count n.

Fig. 3 shows the end-to-end performance, confirming the overall superiority of our adaptive document retrieval. For instance, the top-1 system reaches a slightly higher rate of exact matches for small corpus sizes, but is ranked last when considering the complete corpus. The high performance of the top-1 system partially originates from the design of the experiment itself, where we initially added *one* correct document per question, which is easy to dissect by adding little additional noise. On the other hand, the top-10 system accomplishes the best performance on the complete corpus, whereas it fails to obtain an acceptable performance for smaller corpus sizes.

To quantify our observations, we use a notation of regret. Formally, let μ_{nm} denote the performance of the top-n system on a corpus of size m. Then the regret of choosing system n at evaluation point m is the difference between the best performing system μ_m^* and the chosen system $r_{nm} = \mu_m^* - \mu_{nm}$. The total regret of system n is computed by averaging the regret over all observations of system n, weighted with the span in-between observations in order to account for the logarithmic intervals. The best top-n system yields a regret of 0.83 and 1.12 respectively, whereas our adaptive control improves it down to 0.70.

5.3 Robustness Check

Experiments so far have been conducted on the DrQA system. To show the robustness of our approach, we repeat all experiments on a different QA system. Different from DrQA, this system operates on paragraph-level information retrieval and

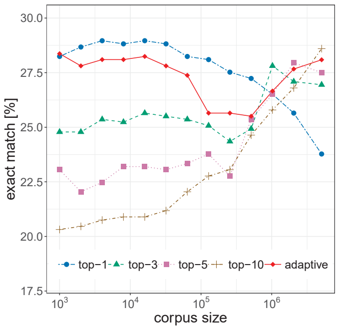


Figure 3: End-to-end performance of adaptive information retrieval over static top-n configurations and a growing corpus.

Top-50 System	27.0	23.5	15.1	24.4
Top-80 System	27.2	25.9	14.9	26.0
Threshold-based ($\theta = 0.75, \tau = 100$)	27.2	**27.1**	15.4	26.3
Ordinal regression ($b = 3, \tau = 250$)	**27.3**	**27.1**	**16.7**	**26.5**

Table 2: End-to-end performance measured in percentages of exact matching answers of a second QA system that operates on paragraph-level information retrieval. We compare two configurations of the system using the top-50 and top-80 ranked paragraphs to extract the answer against our threshold-based approach and regression approach that selects the cutoff within the first 250 paragraphs.

uses cosine similarity to score tf-idf-weighted bag-of-word (unigram) vectors. The reader is a modified version of the DrQA document reader with an additional bi-directional attention layer (Seo et al., 2017). We are testing two different configurations[1] of this system: one that selects the top-50 paragraphs and one that selects the top-80 paragraphs against our approach as shown in Tab. 2. We see that, owed to the paragraph-level information retrieval, the number of top-n passages gains even more importance. Both variations of the system outperform a system without adaptive retrieval, which confirms our findings.

6 Conclusion

Our contribution is three-fold. First, we establish that deep question answering is subject to a noise-information trade-off. As a consequence, the number of selected documents in deep QA should not be treated as fixed, rather it must be carefully tailored to the QA task. Second, we propose adaptive schemes that determine the optimal document count. This can considerably bolster the performance of deep QA systems across multiple benchmarks. Third, we further demonstrate how crucial an adaptive document retrieval is in the context of different corpus sizes. Here our adaptive strategy presents a flexible strategy that can successfully adapt to it and, compared to a fixed document count, accomplishes the best performance in terms of regret.

Reproducibility

Code to integrate adaptive document retrieval in custom QA system and future research is freely available at `https://github.com/bernhard2202/adaptive-ir-for-qa`

Abstract

This paper presents a challenge to the community: Generative adversarial networks (GANs) can perfectly align independent English word embeddings induced using *the same* algorithm, based on distributional information alone; but fails to do so, for two different embeddings algorithms. *Why is that?* We believe understanding why, is key to understand *both* modern word embedding algorithms *and* the limitations and instability dynamics of GANs. This paper shows that (a) in all these cases, where alignment fails, there exists a linear transform between the two embeddings (so algorithm biases do not lead to non-linear differences), and (b) similar effects can not easily be obtained by varying hyper-parameters. One plausible suggestion based on our initial experiments is that the differences in the inductive biases of the embedding algorithms lead to an optimization landscape that is riddled with local optima, leading to a very small basin of convergence, but we present this more as a challenge paper than a technical contribution.

1 Introduction

This paper brings together two fascinating research topics in natural language processing (NLP), namely *understanding the properties of word embeddings* (Mikolov et al., 2013; Mitchell and Steedman, 2015; Mimno and Thompson, 2017) and *unsupervised bilingual dictionary induction* (Conneau et al., 2018; Zhang et al., 2017; Søgaard et al., 2018). In an effort to better understand when unsupervised bilingual dictionary induction is possible, we factored out linguistic differences between languages, and studied English-English alignability (by learning to align English embeddings trained on different samples of the English Wikipedia), when we came across a puzzling phenomena: *English-English can be aligned with almost 100% precision, if you use the same embedding algorithms for the two samples, but not at all (0% precision), if you use different embedding algorithms*. This results suggest that the properties of word embeddings induced by different algorithms challenge unsupervised bilingual dictionary algorithms. Understanding why will enable us to develop more stable adversarial learning algorithms and give us a better understanding of how embedding algorithms differ.

Contributions We are, to the best of our knowledge, the first to study unsupervised alignability of pairs of English word embeddings. We show that unsupervised alignment – specifically the MUSE system (Conneau et al., 2018) – fails when the algorithms used to induce the two embeddings differ, and that this is *not* because there is no linear transformation between the two spaces. We further show that poor initialization, as a result of MUSE initially applying an identity transform to two word embeddings far apart in space, is not the sole reason the discriminator suffers from local optima. Finally, we present an experiment showing what the minimal corpus size is for unsupervised alignment to succeed, in the absence of linguistic differences.

2 Aligning embeddings

2.1 Unsupervised alignment using generative adversarial networks

MUSE (Conneau et al., 2018) uses a vanilla generative adversarial network (GAN) with a linear generator to learn alignments between embedding spaces without supervision. In a two-player game, a discriminator D aims to tell the two language spaces apart, while a generator G aims to map the source language into the target language space, fooling the discriminator. While MUSE achieves impressive results at times, MUSE is highly unstable, e.g., with different initializations precision

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 582–586
Brussels, Belgium, October 31 - November 4, 2018.

scores vary between 0% and 45% for English-Greek (Søgaard et al., 2018).

The parameters of a GAN with a linear generator are (Ω, w). They are obtained by solving the following min-max problem:

$$\min_{\Omega} \max_{w} \mathrm{E}[\log(D_w(X)) + \log(1 - D_w(g_{\Omega}(Z)))] \tag{1}$$

which reduces to

$$\min_{\Omega} JS(P_X \mid P_{\Omega}) \tag{2}$$

Ω is initialized as the identity matrix I.

If G wins the game against an ideal discriminator on a very large number of samples, then F (the source vector space) and ΩE (with E being the target vector space) can be shown to be close in Jensen-Shannon divergence, and thus the model has learned the true distribution. This result, referring to the distributions of the data, p_{data}, and the distribution, p_g, G is sampling from, is from Goodfellow et al. (2014): *If G and D have enough capacity, and at each step of training, the discriminator is allowed to reach its optimum given G, and p_g is updated so as to improve the criterion*

$$E_{\mathbf{x}\sim p_{data}}[\log D_G^*(\mathbf{x})] + E_{\mathbf{x}\sim p_g}[\log(1 - D_G^*(\mathbf{x}))]$$

then p_g converges to p_{data}.

This result relies on a number of assumptions that do not hold in practice. Our generator, which learns a linear transform Ω, has very limited capacity, for example, and we are updating Ω rather than p_g. In practice, therefore, during training, we alternate between k steps of optimizing the discriminator and one step of optimizing the generator. If the GAN-based alignment is not successful, this can thus be a result of two things: Either that G does not have enough capacity, or that D is stuck in a local optimum. Our results in §3 show that the inability to align English-English in the case of different word embedding algorithms is *not* a result of limited capacity, but a result of the GAN being trapped in one of the many local optima of the loss function.

2.2 Supervised alignment using Procrustes Analysis

Procrustes Analysis (Schönemann, 1966) has been commonly used for supervised alignment of word embeddings (Smith et al., 2017; Artetxe et al., 2018). Here, the optimal alignment between two embedding spaces is computed using singular value decomposition of the aligned embeddings in a seed dictionary. Conneau et al. (2018) use Procrustes Analysis to refine an initial seed dictionary learned by the generative adversarial network without supervision. In our supervised experiments, we use 5000 seed words as supervision for learning the alignment between embeddings.

2.3 Geometry of embeddings

Below we summarize some previous findings about the geometry of monolingual embeddings (Mimno and Thompson, 2017), and add some new observations. We discuss five embedding algorithms: SVD on positive PMI matrices (Hyperwords-SVD) (Levy et al., 2015), skip-gram negative sampling applied to co-occurrence matrices (Hyperwords-SGNS) (Levy et al., 2015), continuous bag-of-words (CBOW) (Mikolov et al., 2013a), GloVe (Pennington et al., 2014), and FastText (Bojanowski et al., 2017). To analyze the geometry of our monolingual embeddings in space, we report average inner product to mean vector; see Mimno and Thompson (2017) for details.

Hyperwords-SVD have a small average inner product (0.0032), suggesting they are well-dispersed through space; like Hyperwords-SGNS and standard SGNS (Mimno and Thompson, 2017), they do not exhibit a clear word frequency bias. **Hyperwords-SGNS** vectors also have a small average inner product (0.0002), in contrast with standard SGNS vectors, which are narrowly clustered in a single orthant (Mimno and Thompson, 2017). In line with standard SGNS vectors, the frequency of words has relatively little effect on their inner product, with the exception of the rare words, which have slightly less positive inner products. **CBOW** vectors have a relatively large average inner product (4.2985). The vectors trained by **GloVe** show a clear relationship with word frequency, with low-frequency words opposing the frequency-balanced mean vector. The embeddings are well-dispersed, with an average inner product of 0.0002. Finally, **FastText** vectors have a large, positive inner product with the mean (0.2988), indicating that they are not evenly dispersed through the space, but pointing in roughly the same direction. The FastText vectors exhibit a frequency bias, much like what has been previously observed with GloVe vectors. The differences are the results of the inductive biases of the different embedding algorithms.

3 Experiments

This section presents our data, the hyper-parameters of our embeddings, our experimental protocols, and our results.

3.1 Data

In the following experiments we learn word embeddings on samples of a publicly available Wikipedia dump from March 2018.[1] The data is preprocessed using a publicly available preprocessing script[2], extracting text, removing non-alphanumeric characters, converting digits to text, and lowercasing the text.

3.2 Hyper-parameters

We train 300-dimensional word embeddings using the algorithms' recommended hyperparameter settings, listed in the following:[3] For **Hyperwords-SGNS**, the window size is set to 2 and the subsampling of frequent words and smoothing of the context distribution are disabled. The minimal word count for being in the vocabulary is 100. The same applies for **Hyperwords-SVD**, and the exponent for weighting the eigenvalue matrix is 0.5. For **CBOW**, the window size is set to 8, the number of negative samples is 25, and the subsampling threshold for frequent words is 1e-4. For **GloVe**, the window size is set to 15 and the cutoff parameter x_{max} to 10. Finally, for **FastText**, the window size is 5, the number of negatives samples is 5 and the sampling threshold is 0.0001.

3.3 Main experiments

We train word embeddings using the different embedding algorithms listed in §3.2 on two non-overlapping 10% samples of the English Wikipedia dump (the samples contain 463,576 and 528,556 distinct words, with an overlap in vocabulary of 351,858 words). We learn unsupervised and supervised alignments for embeddings (as described in §2) trained by different algorithms on the same datasplits, and for embeddings trained by the same algorithm on the two different datasplits. For the unsupervised alignments, we use the default parameters of the MUSE system for the adversarial training, i.e. a discriminator with 2 fully connected layers of 2048 units trained over 5 epochs, 1,000,000 iterations per epoch with 5 discriminator steps per iteration and a batch size of 32.

We evaluate the alignments in terms of Precision@1 in the word translation retrieval task for the 1500 test words used by Bojanowski et al. (2017). The results are shown in Table 1[4]. Our main observations are: (a) MUSE learns perfect alignments for embeddings learned by the same algorithm on different data splits. (b) MUSE cannot learn alignments for embeddings learned by different algorithms on the same data splits, even if there exists a linear transformation aligning both sets of embeddings (the supervised algorithm learns perfect alignments). We also verify that MUSE cannot learn to align embeddings from different algorithms *even when induced from the same sample*. As already mentioned, we also ran experiments to check that the failure of MUSE to learn good alignments was not a result of the differences in hyper-parameter settings. §3.4 presents additional experiments with normalization, for control; §3.5 addresses how much data is needed to align independently induced embeddings from the same algorithm. §4 discusses potential answers to why MUSE fails when embeddings are induced using different algorithms.

3.4 Experiments with normalization

The embeddings in the main experiments differ in several ways; see §2. One possible explanation for the inability of MUSE to align embeddings from different algorithms could be that the two embeddings are so far apart in space that the discriminator learns to discriminate between them too quickly. Recall that Ω is initialized as the identity matrix I, which means that the generator initially presents the discriminator with the source embedding as is. This is an effect that has often been observed with GANs (Arjovsky and Bottou, 2017); could this also be the explanation for our results? At a first glance, this seems a possible explanation. The inner products with the mean differ significantly for the five embedding

---

[2] `http://mattmahoney.net/dc/textdata.html`

[3] We also ran experiments with one of the embedding algorithms (FastText) to check if our results were robust across hyper-parameter settings

[4] We report Precision at 1 scores but find that the pattern is the same for Precision at 10, with perfect alignments for embeddings from the same algorithm and 0 scores for alignments between embeddings from different algorithms in the unsupervised experiments.

	Hyperwords-SGNS	Hyperwords-SVD	CBOW	GloVe	FastText
		UNSUPERVISED			
Hyperwords-SGNS	**0.997**

FastText	0.994	0.994	0.999	0.997	

Table 1: Precision at 1 (P@1) for unsupervised GAN alignment with Procrustes refinement (top) and supervised Procrustes analysis for the cases in which unsupervised alignment fails (bottom). Results clearly show that GANs can align two independent embeddings induced by the same algorithm; but not embeddings aligned by different ones. Supervised Procrustes analysis, on the other hand, perfectly aligns the embeddings in both cases.

algorithms (see §2). The only embeddings that have roughly the same directionality are Hyperwords and GloVe, and their centroids are very far apart in cosine space. The cosine similarity of the centroids of the two versions of Hyperwords is -0.006, and the cosine similarity for Hyperwords-SVD and GloVe is 0.019. However, poor initialization as a result of applying the identity transform to very distant word embeddings is not the explanation for the poor performance of MUSE in this set-up: Both sets of Hyperwords embeddings were normalized, but alignment still failed. To verify this holds in general, i.e., that results are not affected by normalization in general, we also ran experiments with the remaining 14 embedding pairs, normalizing and/or centering both embeddings. Results stayed the same: Precision at 1 scores of 0.

3.5 Learning curve

MUSE perfectly aligns independently induced word embeddings induced by the same algorithm. For FastText, it correctly aligns 99.7% of all words in the evaluation lexicon with itself. Our samples are 10% of a publicly available Wikipedia dump, amounting to more than 400 million tokens per sample. English-English alignment is an interesting control experiment for unsupervised bilingual dictionary induction, abstracting away from linguistic differences, and we ran a series of experiments to see how small samples MUSE can align in the absence of linguistic differences. The learning curve is presented in Figure 1.

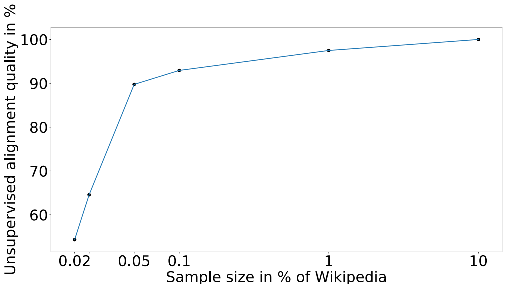

Figure 1: Unsupervised alignment quality for FastText embeddings trained on samples of different sizes, evaluated on 878 words covered by all of the embeddings. The x-axis is log-scaled.

4 Discussion

We have shown that the fact that MUSE cannot align two embedding spaces for English induced by different algorithms (even if using the same corpus), is *not* a result of there not being a linear transformation, and not a result of (lack of) normalization or trivial differences in model hyperparameters. The only explanation left seems to be that the inductive biases of the different algorithms lead to a loss landscape so riddled with local optima that MUSE cannot possible escape them.

To support this hypothesis, compare the loss curves for the MUSE runs aligning embeddings induced with the *same* algorithms (black curves) to the runs aligning embeddings induced with dif-

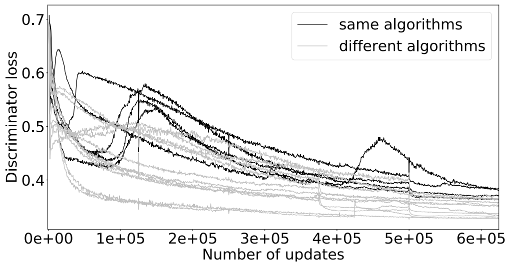

Figure 2: Discriminator losses using the same algorithm for source and target (black curves) or using different algorithms (grey curves).

ferent algorithms, in Figure 2. When the embeddings are induced by the same algorithm, we clearly see the contours of a min-max game, suggesting that the generator and discriminator challenge each other, both contributing to a good alignment. When the embeddings are induced by different algorithms, however, the discriminator quickly drops, with the generator unable to push the discriminator out of a local optimum. *Understanding when biases induce highly non-convex landscapes, and how to make adversarial training less sensitive to such scenarios, remains an open problem, which we think will be key to the success of unsupervised machine translation and related tasks.*

Quantifying Context Overlap for Training Word Embeddings

Yimeng Zhuang, Jinghui Xie, Yinhe Zheng and Xuan Zhu
Samsung Research Institute China - Beijing (SRC-B)
{ym.zhuang, jh.xie, yh.zheng, xuan.zhu}@samsung.com

Abstract

Most models for learning word embeddings are trained based on the context information of words, more precisely first order co-occurrence relations. In this paper, a metric is designed to estimate second order co-occurrence relations based on context overlap. The estimated values are further used as the augmented data to enhance the learning of word embeddings by joint training with existing neural word embedding models. Experimental results show that better word vectors can be obtained for word similarity tasks and some downstream NLP tasks by the enhanced approach.

1 Introduction

In the last decade, the distributed word representation (a.k.a word embedding) has attracted tremendous attention in the field of natural language processing (NLP). Instead of large vectors, such as the one-hot representation, the distributed word representation embeds semantic and syntactic characteristics of words into a low-dimensional space, which makes it popular in NLP applications.

The main idea of most word embedding models follows the distributional hypothesis (Harris, 1954), i.e., the embedding of each word may be inferred using its context. An important model family for distributional word representation learning is built based on the global matrix factorization approach (Deerwester et al., 1990; Lee and Seung, 2001; Srebro et al., 2005; Mnih and Hinton, 2007; Li et al., 2015; Wang and Cohen, 2016), in which a dimensionality reduction over a sparse matrix is performed to capture the statistical information about a corpus in low-dimensional vectors. Another model family is neural word embeddings (Levy and Goldberg, 2014b), some attempts include the famous Neural Probabilistic Language Model (Bengio et al., 2003), SGNS and CBOW (Mikolov et al., 2013a,b), GloVe (Pennington et al., 2014) and their variants (Shazeer et al., 2016; Kenter et al., 2016; Ling et al., 2017; Patel et al., 2017).

Most of these models capture the context information of each word using the co-occurrence matrix. However, the co-occurrence matrix only represents relatively local information, i.e., it describes context associations based on word pairs' co-occurrence counts without considering global context perspective. Besides, the co-occurrence matrix is only an estimation of a corpus, which is only a sample of a language. A mass of related word pairs may not be observed in the corpus, and the latent relations between unobserved word pairs may not be modeled well due to the missing knowledge.

Few attempts are carried out to indirectly deal with unobserved co-occurrence for dense neural word embeddings. SGNS (Mikolov et al., 2013a,b) indirectly addresses this problem through negative sampling. Swivel (Shazeer et al., 2016) improves GloVe by using a "soft hinge" loss to prevent from over-estimating zero co-occurrences. However, the latent relations between unobserved word pairs are not explicitly represented. There are also some works around semantic composition and distributional inference (Mitchell and Lapata, 2008; Erk and Padó, 2008, 2010; Reisinger and Mooney, 2010; Thater et al., 2011; Kartsaklis et al., 2013; Kober et al., 2016) that are explored to address the sparseness problem, but they are not designed for training neural word embeddings.

In this paper, we explore an approach that utilizes context overlap information to dig up more effective co-occurrence relations and propose extensions for GloVe and Swivel to validate the positive impact of introducing context overlap.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 587–593
Brussels, Belgium, October 31 - November 4, 2018.

2 Quantify Context Overlap

In this work, we explore quantifying context overlap based on the observation that to a certain extent the overlap of Point-wise Mutual Information (PMI) (Church and Hanks, 1990) reflects context overlap.

As shown in Figure 1, two separate words may exhibit a particular aspect of interest or be semantically related when the overlap area between their PMI is relatively large.

The calculation of complete PMI-weighted context overlap may be time-consuming when the number of words is large. To make the time complexity affordable, only the context words that have strong lexical association with a target word i are considered:

$$S_i = \{k \in V | PMI(i,k) > h_{PMI}\} \qquad (1)$$

in which V is the vocabulary, h_{PMI} is a threshold which acts as a magnitude to shift PMI, and S_i denotes the set that consists of the context words that have enough large PMI values with the target word i. It is expected that most context information associated with the word i can be captured by its PMI values over S_i. Then, we measure the degree of context overlap (CO) between two target words i, j as a function of their PMI values over the intersection of S_i and S_j, i.e.,

$$CO(i,j) = \sum_{k \in S_i \cap S_j} \min(f(PMI(i,k)), f(PMI(j,k))) \qquad (2)$$

where f is a monotonic mapping function to rectify the data characteristics for certain objective function in word embedding training.

Compared to identity function $f(x) = x$, we find exponential function $f(x) = exp(x)$ works much better in our experiments. For the quantized context overlap, the exponential mapping function results in a similar data distribution as the co-occurrence counts, i.e., few word pairs have extremely large values while most word pairs' values are distributed in a relatively small range.

3 Extend to Existing Models

We consider the original co-occurrence matrix as a description of first order co-occurrence relations, while the quantized context overlap as a description of second order co-occurrence relations (Schütze, 1998), i.e., co-co-occurrences, which is represented by "non-logarithmic PMI-weighted context overlap" in this work. The context overlap between two words can be inferred even when they never co-occur in the corpus. According to our statistics, more than 84% word pairs in the second order co-occurrence matrix are not included in the first order co-occurrence matrix. We expect introducing second order co-occurrence relations may enhance the quality of the word embedding that is originally trained on first order co-occurrence relations. GloVe (Pennington et al., 2014) and Swivel (Shazeer et al., 2016) are extended by joint training with context overlap information in this paper.

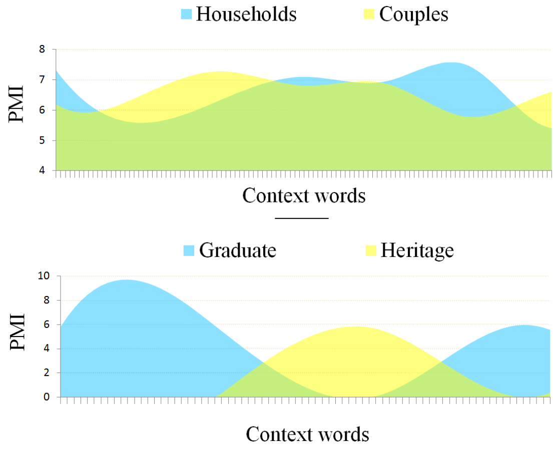

Figure 1: PMI of different words. The x-axis represents a series of context words in a subset of the whole vocabulary, the y-axis denotes PMI values between the target word and context words. (a) The upper part of this figure illustrates the large overlap between semantics related words. (b) The lower part, on the contrary, is an example of relatively unrelated word pair, in which the overlap is relatively small.

GloVe The logarithmic co-occurrence matrix is factorized in GloVe with bias terms, and a weighted least squares loss function is optimized:

$$\mathcal{J}_{GloVe} = \sum_{i,j} \lambda_{ij} (w_i^T \tilde{w}_j + b_i + \tilde{b}_j - \log X_{ij})^2 \qquad (3)$$

where X_{ij} denotes the word-context co-occurrence count between a target word i and a context word j. The model parameters to be learned include $w_i \in \mathbb{R}^d$, $\tilde{w}_j \in \mathbb{R}^d$, b_i and $\tilde{b}_j$, which correspond to target word vector, context word vector, bias terms associated with the target word and the context word, respectively. λ_{ij} is a weight whose value equals to $(\min(X_{ij}, x_{max})/x_{max})^\alpha$.

To extend GloVe, two tasks are trained in parallel during the training process: One is the main task that follows the original GloVe training process as above; Another one is an auxiliary task that tunes word embeddings using context overlap. The parameters of word embeddings are shared in both tasks.

Following GloVe-style loss function, in the auxiliary task, the dot products of word vectors are pushed to estimate logarithmic second order co-occurrence.

$$\mathcal{J}^{(2)}_{GloVe} = \sum_{i,j} \lambda^{(2)}_{ij} (Aw_i^T w_j + b^{(2)}_i + b^{(2)}_j - \log X^{(2)}_{ij})^2 \quad (4)$$

where the superscripts $^{(2)}$ are used to differentiate with the terms in the original GloVe. $X^{(2)}_{ij} = CO(i,j)$ represents context overlap, a word independent learnable scale A is adopted to relieve the potential inconformity between first order and second order co-occurrences. The weight $\lambda^{(2)}_{ij}$ is similar to the original λ_{ij}, but using a different hyperparameter $x^{(2)}_{max}$.

The multi-task (Ruder, 2017) loss function is the weighted sum of the two tasks, i.e., $\mathcal{J} = \mathcal{J}_{GloVe} + \beta \cdot \mathcal{J}^{(2)}_{GloVe}$, where the weight β is a hyperparameter.

Swivel As pointed out by (Levy et al., 2015) , if the bias terms in GloVe are fixed to the logarithmic count of the corresponding word, the dot products of target word vectors and context word vectors are almost equivalent to the approximation of logarithmic PMI matrix with a shift of $\log \sum_{i,j} X_{ij}$. Submatrix-wise Vector Embedding Learner (Swivel) directly reconstructs the PMI matrix by dot product between target vectors and context vectors and deals with unobserved co-occurrences using a "soft hinge" loss function. (Shazeer et al., 2016) details its loss functions and training process. In our extended version, we add a supplementary loss function to handle second order co-occurrences. When the second order co-occurrence $X^{(2)}_{ij}$ is more than zero, the PMI of context overlap is approximated.

$$\frac{1}{2} \lambda^{(2)}_{ij} (Aw_i^T w_j + B - PMI^{(2)}(i,j))^2 \quad (5)$$

in which A, B are word independent learnable scale parameters, and $PMI^{(2)}(i,j)$ is the Pointwise Mutual Information computed on the second order co-occurrence matrix $[X^{(2)}_{ij}]$.

4 Experiments

4.1 Setup

Corpus The training dataset contains 6 billion tokens collected from diversified corpora, including the News Crawl corpus (Chelba et al., 2013), the April 2010 Wikipedia dump (Shaoul, 2010; Lee and Chen, 2017), and a year-2012 subset of the Reddit comment datasets [1].

Preprocessing Following (Lee and Chen, 2017), the Stanford tokenizer is used to process the training corpus, which are split into sentences with characters converted to lower cases. Punctuations are removed.

Parameter Configuration The vocabularies are limited to the 200K most frequent words. Following (Pennington et al., 2014), a decreasing weighting function is adopted to construct the co-occurrence matrix. We use symmetric context window of five words to the left and five words to the right.

For GloVe, recommended parameters in (Pennington et al., 2014) are used. Specifically, we set $\alpha = \frac{3}{4}$, $x_{max} = 100$, initial learning rate as 0.05, 100 iterations. For Swivel, recommended parameters in (Shazeer et al., 2016) are used. The weighting function is $0.1 + 0.25x_{ij}^{0.5}$, each shard is sampled about 100 times. But we set the block size as 4000 so that the vocabulary size can be divided exactly.

For the auxiliary tasks, we tune the hyperparameters on the small News Crawl corpus. And we find that in an appropriate range, the threshold h_{PMI} is not sensitive to the performance. In this paper, h_{PMI}, $x^{(2)}_{max}$ and β are set to $\log 100$, 10000 and 0.2 respectively. Since there is no difference between target vectors and context vectors (except random initialization), in order to keep symmetry, we not only approximate context overlap between target vectors, but also approximate context overlap between context vectors simultaneously. Final vectors are the sum of w and $\tilde{w}$ in both GloVe and Swivel.

4.2 Intrinsic Evaluation

Table 1 shows the evaluation results of word similarity tasks and word analogy tasks. Word similarity is measured as the Spearman's rank correlation ρ between human-judged similarity and cosine distance of word vectors. In word analogy

Table 1: Word similarity and analogy results ($\rho \times 100$ and analogy accuracy). We denote context overlap enhanced method with "+ CO". 300-dimensional embeddings are used. The datasets used include WS353 (Finkelstein et al., 2001), SL999 (Hill et al., 2016), SCWS (Huang et al., 2012), RW (Luong et al., 2013), MEN (Bruni et al., 2014), MT771 (Halawi et al., 2012), and Mikolov's analogy dataset (Mikolov et al., 2013a).

task, the questions are answered over the whole vocabulary through 3CosMul (Levy and Goldberg, 2014a). In addition to GloVe and Swivel, the evaluations of SGNS are also reported for reference. We train SGNS with the word2vec tool, using symmetric context window of five words to the left and five words to the right, and 5 negative samples.

As can be seen from the table, the context overlap information enhanced word embeddings perform better in most word similarity tasks and get higher analogy accuracy in semantic aspect at the cost of syntactic score. The improved semantics performance, to a certain extent, reflects second order co-occurrence relations are more semantic.

4.3 Text Classification

Text classification tasks are conducted on five shared benchmark datasets from (Kim, 2014) including binary classification tasks CR (Hu and Liu, 2004), MR (Pang and Lee, 2005), Subj (Pang and Lee, 2004) and multiple classification tasks TREC (Li and Roth, 2002), SST1 (Socher et al., 2013). Texts are preprocessed following the description of Section 4.1. We train Convolutional Neural Networks (CNN) on top of our static pretrained word vectors following (Kim, 2014). To avoid the high-risk of single-run estimate being false (Melis et al., 2017; Reimers and Gurevych, 2017), average classification accuracies of 20 runs are reported as the final scores. The results are shown in Table 2. As can be seen from the results that the enhanced word embeddings outperform the baselines.

5 Model Analysis

As it is known to all, word frequency plays an important role in the computation of word embeddings (Gittens et al., 2017). Inspired from the graph in (Shazeer et al., 2016), relations between word analogy accuracy and the log mean frequency of the words in analogy questions and answers are plotted on Figure 2. The word embeddings trained by GloVe with or without context overlap information are used here.

Method	CR	MR	SST1	Subj	TREC
GloVe	80.9	76.5	46.9	90.9	89.7
+ CO	$81.7^{\dagger}$	76.4	$47.6^{\dagger}$	$91.4^{\dagger}$	$90.2^{\dagger}$
Swivel	81.7	76.7	47.9	91.4	90.4
+ CO	$82.4^{\dagger}$	76.7	$48.3^{\dagger}$	$91.7^{\dagger}$	90.5
CBOW	80.6	75.3	46.5	89.8	89.6
SGNS	81.6	77.0	48.0	91.2	90.6

Table 2: Text classification results (Acc.%). Pretrained word vectors with 300 dimensions are reported here. Enhanced runs statistically significantly (t-test, p-value < 0.05) different from the GloVe/Swivel baseline runs are marked with a †. The results of CBOW and SGNS are also given for reference.

An obvious semantic performance improvement is observed in the range of low frequency. Our observation of second order co-occurrences may explain this fact. We randomly sample 1 million word pairs, and rank these word pairs in descending order by their quantized context overlap. In all the word pairs, average word frequency is 13934.4. However, it is only 1676.1 in the top 0.1% word pairs, it is 3984.8 in the top 1%, and it is 7904.9 in the top 10%. This may be caused by PMI's bias towards infrequent words, but it illustrates infrequent words carry more information in second order co-occurrence relations.

6 Conclusion

In this paper, we propose an empirical metric to enhance the word embeddings through estimating second order co-occurrence relations using con-

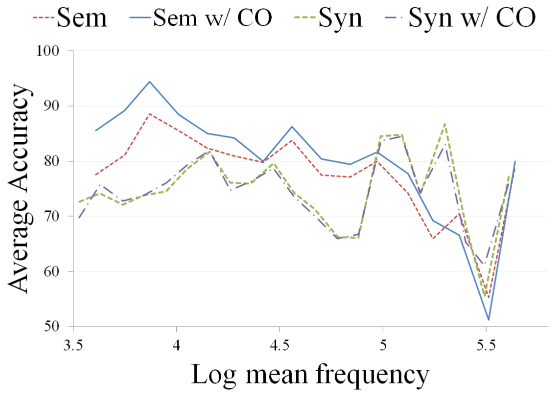

Figure 2: Relations between word analogy accuracy and the log mean frequency.

text overlap. Instead of only local statistical information, context overlap leverages global association distribution to measure word pairs correlation.

The proposed method is easy to extend to existing models, such as GloVe and Swivel, by an auxiliary objective function. The improvement in experimental results helps to validate the positive impact of introducing quantized context overlap.

We have considered the feasibility of enriching SGNS and CBOW with information from context-overlap. However, because of their training mode, we can't remake them in a straightforward way following their "original spirit". When training SGNS and CBOW, the program scans the training text. The target and context words are chosen using a slide window and negative sampling is used. In this process, no co-occurrence matrix is explicitly computed, and we fail to extend it in a united form as we extend GloVe and Swivel. The extensions for GloVe and Swivel can also be used for reference for extending other word embedding approaches that are trained on co-occurrence matrix. The exploration for second order co-occurrence can be traced back to 1990s. We think it is helpful to revive the classical method in a modern, embedding driven way. How to integrate second order co-occurrence information for approaches like SGNS, CBOW should be an interesting future work.

As future works, we suggest further investigating the characteristics of context overlap in diversified ways.

Abstract

Capturing the semantic relations of words in a vector space contributes to many natural language processing tasks. One promising approach exploits lexico-syntactic patterns as features of word pairs. In this paper, we propose a novel model of this pattern-based approach, neural latent relational analysis (NLRA). NLRA can generalize co-occurrences of word pairs and lexico-syntactic patterns, and obtain embeddings of the word pairs that do not co-occur. This overcomes the critical data sparseness problem encountered in previous pattern-based models. Our experimental results on measuring relational similarity demonstrate that NLRA outperforms the previous pattern-based models. In addition, when combined with a vector offset model, NLRA achieves a performance comparable to that of the state-of-the-art model that exploits additional semantic relational data.

1 Introduction

Information on the semantic relations of words is important for many natural language processing tasks, such as recognizing textual entailment, discourse classification, and question answering. There are two main approaches to obtain the distributed relational representations of word pairs.

One is the vector offset method (Mikolov et al., 2013a,b). This approach represents word pairs as the vector offsets of their word embeddings. Another approach exploits lexico-syntactic patterns to obtain word pair representations. As a pioneer work, Turney (2005) introduced latent relational analysis (LRA), based on the *latent relation hypothesis*. It states that word pairs that co-occur in similar lexico-syntactic patterns tend to have similar semantic relations (Turney, 2008b; Turney and Pantel, 2010). LRA is expected to complement the vector offset model because word embeddings do not contain information on lexico-syntactic patterns that connect word pairs in a corpus (Shwartz et al., 2016).

However, LRA cannot obtain the representations of word pairs that do not co-occur in a corpus. Even with a large corpus, observing a co-occurrence of all semantically related word pairs is nearly impossible because of Zipf's law, which states that most content words rarely occur. This data sparseness problem is a major bottleneck of pattern-based models such as LRA.

In this paper, we propose neural latent relational analysis (NLRA) to solve that data sparseness problem. NLRA unsupervisedly learns the embeddings of target word pairs and co-occurring patterns from a corpus. In addition, it jointly learns the mapping from the word embedding space to the word-pair embedding space. By this mapping, NLRA can generalize the co-occurrences of word pairs and patterns, and obtain the relational embeddings for arbitrary word pairs even if they do not co-occur in the corpus.

Our experimental results on the task of measuring relational similarity show that NLRA significantly outperforms LRA, and it can also capture semantic relations of word pairs without co-occurrences. Moreover, we show that combining NLRA and the vector offset model improves the performance and leads to competitive results to those of the state-of-the-art method that exploits additional semantic relational data.

2 Background

2.1 Vector Offset Model

The vector offset model (Mikolov et al., 2013a,b; Levy and Goldberg, 2014) obtains word embeddings from a corpus and represents each word pair (a, b) as the vector offset of their embedding as

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 594–600
Brussels, Belgium, October 31 - November 4, 2018.

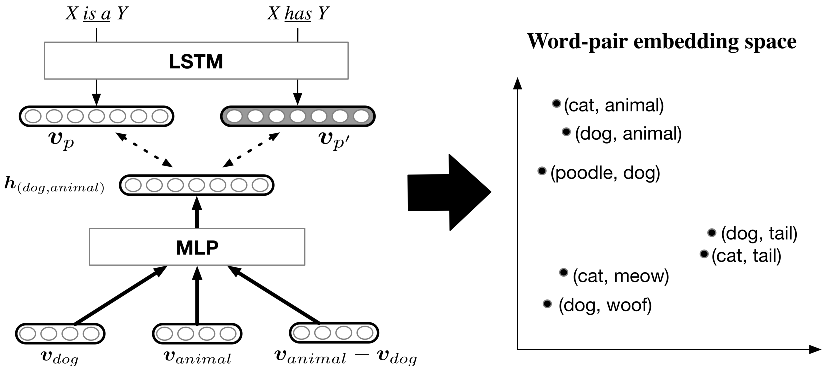

Figure 1: An illustration of NLRA

follows:

$$\boldsymbol{v}_{(a,b)} = \boldsymbol{v}_b - \boldsymbol{v}_a \quad (1)$$

where $\boldsymbol{v}_a$ and $\boldsymbol{v}_b$ are the word embeddings of a and b respectively.

This method regards relational information as the change in multiple topicality dimensions from one word to the other in the word embedding space (Zhila et al., 2013). Meanwhile, it does not contain the information of lexico-syntactic patterns that were shown to capture complementary information with word embeddings in previous studies on the lexical semantic relation detection (Levy et al., 2015; Shwartz et al., 2016).

2.2 Latent Relational Analysis

LRA takes a set of word pairs as input and generates the distributed representations of those word pairs based on their co-occurring patterns.

Given target word pairs $W = \{(a_1, b_1), \ldots, (a_n, b_n)\}$, LRA constructs a list of lexico-syntactic patterns that connect those pairs, such as *is a* or *in the*, from the corpus for each word pair. Then, those patterns are generalized by replacing any or all or none of the intervening words with wildcards. As a feature selection, the generalized patterns generated from many word pairs are used as features. We define the set of these target feature patterns as $C = \{p_1, \ldots, p_m\}$. Then, the $2n \times 2m$ matrix M is constructed. The rows of M correspond to pairs (a_i, b_i) and reversed pairs (b_i, a_i). The columns of M correspond to patterns Xp_iY and swapped patterns Yp_iX, where X and Y are the slots for the words of the word pairs. The value of M_{ij} represents the strength of the association between the corresponding word pair and pattern, which is calculated using weighting methods such as positive pointwise mutual information (PPMI). After these processes, the singular value decomposition (SVD) is applied to M, and the vector $\boldsymbol{v}_{(a,b)}$ is assigned to each word pair (a, b).

Although pattern-based approaches such as LRA have achieved promising results in some semantic relational tasks (Turney, 2008a,b), they have a crucial problem that a co-occurrence of all semantically related word pairs cannot be observed because of Zipf's law, which states that the frequency distribution of words has a long tail. In other words, most words occur very rarely (Hanks, 2009). For the word pairs without co-occurrences, LRA cannot obtain their vector representations.

3 Neural Latent Relational Analysis

We introduce NLRA, based on the latent relation hypothesis. NLRA represents the target word pairs and lexico-syntactic patterns as embeddings. Similar to the skip-gram model (Mikolov et al., 2013a), NLRA updates those representations unsupervisedly, such that the inner products of the word pairs and patterns in which they co-occur in a corpus have high values. Through this learning, the word pairs that co-occur in similar patterns have similar embeddings. Moreover, NLRA can generalize the co-occurrences of the word pairs and patterns by constructing the embeddings of the word pairs from their word embeddings, thus solving the data sparseness problem of word co-occurrences. Therefore, NLRA can provide representations that capture the information of lexico-syntactic patterns even for the word pairs that do not co-occur in a sentence.

Figure 1 is an illustration of our model. NLRA encodes a word pair (a, b) into a dense vector as follows:

$$\boldsymbol{h}_{(a,b)} = MLP([\boldsymbol{v}_a; \boldsymbol{v}_b; \boldsymbol{v}_b - \boldsymbol{v}_a]) \quad (2)$$

where $[\boldsymbol{v}_a; \boldsymbol{v}_b; \boldsymbol{v}_b - \boldsymbol{v}_a]$ is the concatenation of the word embeddings of a and b and their vector offsets; MLP is a multilayer perceptron with nonlinear activation functions.

A pattern p is a sequence of the words $w_1, \ldots, w_k$. The sequence of the corresponding word embeddings $\boldsymbol{w}_1, \ldots, \boldsymbol{w}_k$ are encoded using long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997). Then, the final output vector $\boldsymbol{v}_p$ is used as the pattern embedding.

For unsupervised learning, we use the negative sampling objective (Mikolov et al., 2013a). Given a set of observed triples $(a, b, p) \in D$, where a and b are words such that $(a, b) \in W$, or $(b, a) \in W$ and p is a co-occurring pattern from a corpus, the objective is as follows:

$$\begin{aligned} L &= \sum_{(a,b,p) \in D} \log \sigma(\boldsymbol{v}_p \cdot \boldsymbol{h}_{(a,b)}) \\ &+ \sum_{(a,b,p') \in D'} \log \sigma(-\boldsymbol{v}_{p'} \cdot \boldsymbol{h}_{(a,b)}) \end{aligned} \quad (3)$$

where D' is a set of randomly generated negative samples and σ is the sigmoid function. We sampled 10 negative patterns for each word pair. This objective is maximized using the stochastic gradient descent.

After unsupervised learning, we can obtain word pair representations $\boldsymbol{v}_{(a,b)}$ as follows:

$$\boldsymbol{v}_{(a,b)} = [\boldsymbol{h}_{(a,b)}; \boldsymbol{h}_{(b,a)}] \quad (4)$$

4 Evaluation

4.1 Dataset

In our evaluation, we used the SemEval-2012 Task 2 dataset (Jurgens et al., 2012) for the task of measuring relational similarity. This dataset contains a collection of 79 fine-grained semantic relations. For each relation, there are a few prototypical word pairs and a set of several dozen target word pairs. The task is to rank the target pairs based on the extent to which they exhibit the relation. In our experiment, we calculated the score of a target word pair with the average cosine similarity between it and each prototypical word pair. The models are evaluated in terms of the MaxDiff accuracy and Spearman's correlation. Following previous works (Rink and Harabagiu, 2012; Zhila et al., 2013), we used the test set that includes 69 semantic relations to evaluate the performance.

4.2 Baselines

VecOff. We used the 300-dimensional pre-trained GloVe (Pennington et al., 2014)[1] and represented word pairs as described in Section 2.1.

LRA. We implemented LRA as described in Section 2.2. We set W as the lemmatized word pairs of the dataset. We used the English Wikipedia as a corpus. For each word pair, we searched for patterns of from one to three words. When searching for patterns, the left word and right word adjacent to the patterns were lemmatized to ignore their inflections. Following (Turney, 2008b), we selected C as the top $20|W|$ generalized patterns. Then, M was constructed using PPMI weighting, and its dimensionality was reduced to 300 using SVD.

4.3 Our methods

NLRA. For each word pair in the dataset, co-occurring patterns were extracted from the same corpus in the same manner as with LRA, resulting in D. For word embeddings, we used the same pre-trained GloVe as VecOff. These embeddings were updated during the training. For MLP, we used three affine transformations followed by the batch normalization (Ioffe and Szegedy, 2015) and tanh activation. The size of each hidden layer of the MLP was 300. To encode the patterns, we used LSTM with the 300-dimensional hidden state. The objective was optimized by AdaGrad (Duchi et al., 2011) (whose learning rate was 0.01). We trained the model for 50 epochs.

NLRA+VecOff. This method combines NLRA and VecOff by averaging their score for a target word pair.

4.4 Result and Analysis

Table 1 displays the overall result.

NLRA vs. LRA

First, NLRA outperformed LRA in terms of both the average accuracy and correlation. These differences were statistically significant ($p < 0.01$) with the paired t-test. These results indicate that generalizing patterns with LSTM is better than by using wildcards. Moreover, NLRA can successfully calculate the relational similarity for the word pairs that do not co-occur in the corpus. Table 2 shows an example of the Reference–Express relation, where the middle-score pair *handshake:cordiality*

Table 3: Published results of other models on the SemEval2012 Task 2 dataset.

and the low-score pair *friendliness:wink* have no co-occurring pattern. In these cases, LRA could not obtain the representations of those word pairs nor correctly assign the score. By contrast, NLRA could accomplish both because it could generalize the co-occurrences of word pairs and patterns.

NLRA+VecOff vs. Other Models

Second, NLRA+VecOff outperformed the other models. These differences were statistically significant (the correlation difference between NLRA+Vecoff and NLRA: $p < 0.05$; the other differences: $p < 0.01$). These results indicate that lexico-syntactic patterns and the vector offset of word embeddings capture complementary information for measuring relational similarity. This is inconsistent with the findings of Zhila et al. (2013). That work combined heterogeneous models, such as the vector offset model, pattern-based model, etc., and stated that the pattern-based model was less significant than the vector offset model, based on their ablation study. We believe that this was because their pattern-based model did not generalize patterns with wildcards nor select useful features. Their pattern-based model seemed to suffer from sparse feature space. In our experiment, NLRA helped VecOff, for example, for the Part-Whole relation, Cause Purpose relation, and Space-Time relation, where there seemed to be prototypical patterns indicating those relations. Meanwhile, VecOff helped NLRA for the Attribute relation, where the relational patterns seemed to be diverse. These results showed that the combined model is robust.

4.5 Comparison to other systems

We compared the results of our models to other published results. Table 3 displays those results. Rink and Harabagiu (2012) is the pattern-based model with naive Bayes. Mikolov et al. (2013b), Levy and Goldberg (2014), and Iacobacci et al. (2015) are the vector offset models. Zhila et al. (2013) is the model composed of various features. Turney (2013) extracts the statistical features of two word pairs from a word-context co-occurrence matrix and trains the classifier with additional semantic relational data to assign a relational similarity for two word pairs.

NLRA+VecOff achieved a competitive performance to the state-of-the-art method of Turney (2013). Note that our method learns unsupervisedly and does not exploit additional resources, and the method of Turney (2013) cannot obtain the distributed representation of word pairs.

A work similar to ours, Bollegala et al. (2015), represented lexico-syntactic patterns as the vector offset of co-occurring word pairs and updated the vector offsets of word pairs such that word pairs that co-occur in similar patterns have similar offsets. They evaluated their model on all 79 semantic relations of the dataset and achieved 0.449 accuracy. In their setting, NLRA+VecOff achieved 0.47 accuracy, outperforming their model.

5 Related Work

5.1 Word Pairs and Co-occurring Patterns

Hearst (1992) detected the hypernymy relation of word pairs from a corpus using several handcrafted lexico-syntactic patterns. Turney and Littman (2005) used 64 handcrafted lexico-syntactic patterns as features of word pairs to represent word pairs as vectors. To obtain word-pair embeddings, Turney (2005) extended the method of Turney and Littman (2005) as LRA. Our work is a neural extension of LRA.

Washio and Kato (2018) proposed the method similar to ours in lexical semantic relation detection. Their neural method modeled the co-occurrences of word pairs and dependency paths connecting two words to alleviate the data sparseness problem of pattern-based lexical semantic relation detection. While they assigned randomly initialized embeddings to each dependency path, our work encodes co-occurring patterns with LSTM for better generalization. Jameel et al. (2018) embedded word pairs with the context words occurring around word pairs instead of lexico-syntactic patterns. Their method cannot obtain embeddings of word pairs that do not co-occur in a corpus because they directly assigned embeddings to word pairs. By contrast, NLRA can obtain embeddings for those word pairs.

In another research area, relation extraction, several works have explored an idea similar to the latent relation hypothesis (Riedel et al., 2013; Toutanova et al., 2015; Verga et al., 2017). They factorized a matrix of entity pairs and co-occurring patterns, while they focused on named entity pairs instead of word pairs and did not consider co-occurrence frequencies.

5.2 Relation to Knowledge Graph Embedding

Knowledge graph embedding (KGE) embeds entities and relations in knowledge graph (KG), where entities and relations corresponds to nodes and edges respectively (Nickel et al., 2011; Bordes et al., 2013; Socher et al., 2013; Wang et al., 2014; Lin et al., 2015; Yang et al., 2015; Nickel et al., 2016; Trouillon et al., 2016; Liu et al., 2017; Wang et al., 2017; Ishihara et al., 2018). By considering words and lexico-syntactic patterns as nodes and edges, respectively, a corpus can be viewed as a graph, i.e., corpus graph (CG). Thus, NLRA can be regarded as corpus graph embedding (CGE) models based on the latent relation hypothesis.

Although KGE models can be easily applied to CG, several differences exist between KG and CG. First, the nodes and edges of CG are (sequences of) linguistic expressions, such as tokens, lemmas, phrases, etc. Thus, the nodes and edges of CG might exhibit compositionality and ambiguity, while KG does not have those properties. Second, the edges of CG have weights based on co-occurrence frequencies unlike the edges of KG. Finally, CG might have a large number of edges types while the number of KG edges is at most several thousands. An interesting research direction is exploring models suitable for CGE to capture the property of linguistic expressions and their relations in the embedding space.

6 Conclusion

We presented NLRA, which learns the distributed representation of word pairs capturing semantic relational information through co-occurring patterns encoded by LSTM. This model jointly learns the mapping from the word embedding space into the word-pair embedding space to generalize co-occurrences of word pairs and patterns. Our experiment on measuring relational similarity demonstrated that NLRA outperforms LRA and can successfully solve the data sparseness problem of word co-occurrences, which is a major bottleneck in pattern-based approaches. Moreover, combining the vector offset model and NLRA yielded competitive performance to the state-of-the-art method, though our method relied only on unsupervised learning. This combined model exploits the complementary information of lexico-syntactic patterns and word embeddings.

In our future work, we will apply word-pair embeddings from NLRA to various downstream tasks related to lexical relational information.

Generalizing Word Embeddings using Bag of Subwords

Jinman Zhao, Sidharth Mudgal, Yingyu Liang
Department of Computer Sciences
University of Wisconsin-Madison
`{jz,sidharth,yliang}@cs.wisc.edu`

Abstract

We approach the problem of generalizing pre-trained word embeddings beyond fixed-size vocabularies without using additional contextual information. We propose a subword-level word vector generation model that views words as bags of character n-grams. The model is simple, fast to train and provides good vectors for rare or unseen words. Experiments show that our model achieves state-of-the-art performances in English word similarity task and in joint prediction of part-of-speech tag and morphosyntactic attributes in 23 languages, suggesting our model's ability in capturing the relationship between words' textual representations and their embeddings.

1 Introduction

Word embeddings have been an essential part of neural-network based approaches for natural language processing tasks (Goldberg, 2016). However, many popular word embeddings techniques have a fixed vocabulary (Mikolov et al., 2013; Pennington et al., 2014), i.e., they can only provide vectors over a finite set of common words that appear frequently in a given corpus. Such methods fail to generate vectors for rare words and words not present in the training corpus, but appearing in the test corpus or downstream task texts, raising difficulty for any methods relying on word vectors to efficiently extract useful features from text. This is often referred to as the out-of-vocabulary (OOV) word problem. We aim to address this problem by inferring vectors for OOV words with only access to pre-trained vectors over a fixed vocabulary of common words and the OOV word itself without context.

The motivations come from both linguistics and natural language processing applications. First, from a linguistic view a word can be decomposed into multiple morphemes: stems, affixes, modifiers and etc. This is more often the case for rare words. In some field such as chemistry and agglutinative languages such as Turkish, there exists a systematic way of composing words from morphemes. Some can even be arbitrarily long.

Apart from the explicit and systematic way of making words, we can also observe the ability of a language speaker to infer the meaning of an unseen word. For instance, one can guess that "pre-EMNLP" means "before EMNLP", even without the presence of any context, suggesting that it is part of our implicit linguistic knowledge to infer meaning of an unseen word solely from its lexical form. This observation, together with the morpheme decomposition of many rare words, implies the feasibility of inferring their vectors from those for common words, and also raises the algorithmic question of how to compute them efficiently.

Second, there are many NLP applications where estimating word embeddings of OOV is critical. For instance, in the case of analyzing Twitter data, while there exists pre-trained word embeddings with giant vocabularies trained on massive number of tweets, such as GloVe vectors (Pennington et al., 2014), this would still not cover new words coined by users everyday. In such cases, it is more prudent to extend the available pre-trained vectors trained on very large corpora, so that we can estimate embeddings for OOV words, instead of retraining a new word / subword level embedding model on the new extended data corpus.

OOV words have always been a problem for methods that assume fixed vocabularies. A common workaround is to view all OOV words as a special UNK token and use the same vector for all of them. This would restrict any downstream models from accessing distinct features of those words. Thus, we would like a method to provide vectors that capture semantic and grammatical fea-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 601–606
Brussels, Belgium, October 31 - November 4, 2018.

tures even for OOV words. We also would like such method to maximally rely on the word itself, instead of its context, as contextual information is already used later with sentence level models stacking over word vectors.

To achieve this, we aim to build a word embedding model that generalizes pre-trained word embeddings to OOV words. First, given word embeddings for a fixed vocabulary, our model learns the relationship between the subwords present in each word and its corresponding pre-trained word vector. Then, using the learned subword information, our model can generate word embeddings for any word, regardless if it is OOV or not.

Contribution We propose a simple yet effective subword-level word embedding method that can be efficiently trained given pre-trained word vectors for a limited number of words. Once trained, our embedding model takes the characters n-grams in a word as input and gives its word vector as output.[1]

Our experiments on word similarity tasks in English and POS tagging in a variety of languages suggests that the proposed word embedder is able to mimic and generalize consistently the word vectors from in-vocabulary words to out-of-vocabulary words, and achieves state-of-the-art scores for the tasks compared to previous subword-level word embedders trained under the same setting. This gives evidence that such a simple model is capable of capturing language speaker's morphological knowledge, and also provides an easy way to generate word vectors for rare or unseen (OOV) words with potential application to various natural language processing tasks.

Related work There exist a large body of works that try to incorporate morphological information into word representations, e.g., (Alexandrescu and Kirchhoff, 2006; Luong et al., 2013a; Qiu et al., 2014; Botha and Blunsom, 2014; Cotterell and Schütze, 2015; Soricut and Och, 2015). These approaches typically rely on the morphological decomposition of words. Some other approaches using subword information do not rely on morphological decomposition but requires context information from large text corpus (Schütze, 1993; Santos and Zadrozny, 2014; Ling et al., 2015; Wieting et al., 2016).

In particular, Bojanowski et al. (2017) introduced fastText, a word embedding method enhanced with subword (character n-gram) embeddings. They are able to generate vectors for OOV words, which has been shown useful for text classification (Joulin et al., 2016), but the model is to be trained over large text corpus.

Pinter et al. (2017) use a character-level bidirectional LSTM model called MIMICK, mapping from word strings to word vectors. The idea of using character-level recurrent neural networks (RNNs) for word vectors is not new (Ling et al., 2015; Plank et al., 2016), but as per authors' knowledge, they are by far the only attempt to the exact task of generalizing word vectors from only pre-trained vectors with a fixed vocabulary, i.e. with no access to contextual information.

2 Bag-of-Substring Model

Our Bag-of-Substring (BoS) word vector generation model views a word as a bag of its substrings, or character n-grams. Specifically, we maintain a vector lookup table for each possible substrings (or character n-grams) of length between l_{min} and l_{max}. A word vector is then formed as the average of vectors of all its substrings with lengths in the range. Let Σ be the finite set of characters in the language, $subs_a^b(s) = \{t \text{ is substring of } s : a \leq |t| \leq b\}$ for string $s \in \Sigma^*$ be the set of substrings of s whose length is between a and b inclusive, and $<s>$ be the concatenation of character $<$, string s and character $>$ where $<, > \notin \Sigma$. The BoS embedding for a string/word s can be expressed as

$$\text{BoS}(s; V) = \frac{1}{|\mathcal{S}_{<s>}|} \sum_{t \in \mathcal{S}_{<s>}} v_t, \qquad (1)$$

where $V \in \mathbb{R}^{d \times (|\Sigma|^{l_{min}} + \cdots + |\Sigma|^{l_{max}})}$ are the parameters which stores the embeddings of dimension d for each possible substring of length between l_{min} and l_{max}, v_t is the vector in V indexed by t, $\mathcal{S}_{<s>}$ is a shorthand for $subs_{l_{min}}^{l_{max}}(<s>)$. Special characters $<, > \notin \Sigma$ are used to mark the start and the end of the word and thus help the model to distinguish homographic morphemes that occur at different word parts, e.g. prefixes or suffixes. An example BoS representation for word `infix` is $subs_3^4$(`<infix>`) = {`<in`, `<inf`, `inf`, `infi`, `nfi`, `nfix`, `fix`, `fix>`, `ix>`}.

fastText (Bojanowski et al., 2017) uses the same idea for their word vector generation part. How-

---

[1] The code is available at `https://github.com/jmzhao/bag-of-substring-embedder`.

ever, unlike them, we train the model directly towards pre-trained vectors, instead of via context prediction over text corpora.

Training Given pre-trained vectors for a set of common words, our model views them as targets and is trained to fit these targets. Once the parameters (the vectors v_t for the substrings) are learned, the model can then be used to infer vectors for rare words. Let $U \in \mathbb{R}^{d\times|W|}$ be the target vectors of the same dimension d over finite vocabulary $W \subset \Sigma^*$. Our model is trained by minimizing the overall loss between the generated and the given vectors for each word:

$$\underset{V}{\text{minimize}} \frac{1}{|W|} \sum_{w\in W} l(BoS(w;V), u_w) \qquad (2)$$

where the loss function $l(v,u) = \frac{1}{2}\|v-u\|_2^2$, namely the mean squared loss.

After training, one can use the learned V and Eqn (1) to compute the vector for any given word, even if it is OOV.

Hyperparameters We set the following hyperparameters for all the experiments. For BoS model, $l_{min} = 3$ and $l_{max} = 6$ following Bojanowski et al. (2017). Note that under this setting, $\mathcal{S}_{<s>}$ can never be empty for non-empty string s. For optimization, stochastic gradient descent with learning rate 1 for 100 epochs. The dimension of the word vectors is not a hyperparameters here as it needs to agree with the target vector.

3 Word Similarity

We run experiments to quantitatively evaluate the our model's generalizability towards OOV words.

The word similarity task asks to predict word similarity between a pair of two words. Given a set of pairs of words and gold labels for their similarities, the performance of word embeddings is measured by the correlation between the gold similarities and the similarities induced by the generated embeddings. And we can thus imply how good our model is at generating word vectors. The word similarity here is computed using the cosine distance between the two word vectors, and the correlation is computed using Spearman's ρ.

Datasets We evaluate over Stanford RareWord (RW) introduced by Luong et al. (2013b) and WordSim353 (WS) introduced by Finkelstein et al. (2001). RW consists of less common words so we use it to access our model's ability to generalize word embeddings to OOV words. WS is composed of mostly common words and we use it to test if our subword-level models successfully mimic the target vectors.

	Dim.	# Tokens	RW	WS
Polyglot	64	100k	41(58%)	45(5%)
Google	300	160k	53(11%)	69(1%)

Table 1: Target vectors statistics and word similarity task scores in Spearman's $\rho \times 100$. In parentheses are OOV rates.

Model	Size	Target	RW	WS
EditDist	-	-	18	-2
MIMICK	649KB	Polyglot	14	12
BoS	238MB	Polyglot	36	36
BoS	1.3GB	Google	46	56
fastText	8.0GB	-	48	74

Table 2: Word similarity task results measured in Spearman's $\rho \times 100$.

Target vectors We train our BoS model over the English Polyglot vectors [2] to establish a direct comparison with results from MIMICK (Pinter et al., 2017), and as well as the Google word2vec vectors [3] which are popularly used in NLP tasks. Polyglot (Al-Rfou et al., 2013) is a multilingual NLP dataset, which also provides pre-trained word vectors over each language's corpus with a vocabulary of 100,000 most frequent words. For Google vectors, most of their vocabulary consists of non-words such as URLs and phrases, so we normalize tokens into ASCII characters by taking off all the diacritics and take only tokens consisting of a single word with all lower letters. Statistics of the processed vectors are summarized in Table 1, along with their word similarity task scores (for in-vocabulary words only) and OOV rate over the aforementioned evaluation sets.

Baselines We compare the scores with other subword-level models (fastText and MIMICK) and word similarity induced by non-parametric edit distance (EditDist).

fastText (Bojanowski et al., 2017) uses the same subword-level character n-gram model but is to be trained via context prediction over large text corpora (here English Wikipedia dump [4]). MIM-

[2] `http://polyglot.readthedocs.io/en/latest/Download.html`

[3] `https://code.google.com/archive/p/word2vec/`

[4] `https://fasttext.cc/docs/en/pretrained-vectors.html`

ICK (Pinter et al., 2017) is a character-level bidirectional LSTM word embedder trained against pre-trained word vectors (here Polyglot vectors [5]).

Edit distance is defined between two strings as the smallest number of modifications: adding, deleting and changing one character, needed to turn one string into the other. It can be computed using dynamic programming in $O(|s_1| \times |s_2|)$ time. The word similarity between w_1 and w_2 here is the edit distance normalized by the length of the longer word:

$$s_{EditDist}(w_1, w_2) = -\frac{d_{edit}(w_1, w_2)}{\max(|w_1|, |w_2|)} \quad (3)$$

where d_{edit} is edit distance.

Results Results are summarized in Table 2. When trained over Polyglot vectors, our BoS model works better than EditDist and MIMICK. When trained on Google vectors, the correlation scores are almost as good as those of fastText, the state-of-the-art subword level word embedder. However, unlike fastText, our model does not have access to word contexts in a large text corpus for training. In both cases, the significant differences of scores compared to those of EditDist, suggest that our model indeed learns to capture semantic similarities between words, rather than superficial similarities in spelling.

Comparing to MIMICK, our model is able to fill up 81% (14 to 36 against 41) and 73% (12 to 36 against 45) of the gaps in scores over RW and WS respectively. This improvement is more significant on RW with most (58%) of its words are OOV for the PloyGlot vectors, suggesting our model's power in generating consistent word vectors for OOV words. Surprisingly MIMICK performs no better than the edit distance baseline when evaluated on RW. Combined with the fact that it does no better for WS which has a near-zero OOV rate, it suggests MIMICK's limited power of generalizing word vectors towards OOV words, or even reproduce consistent word vector for in-vocabulary words. As a sanity check, we see that all of the embedder models scores obviously better than EditDist when evaluated over common words (WS), showing that all of them are able to at least remember or mimic the word vectors for in-vocabulary words.

Also note that our model is fast to train. With a naive single-thread CPU-only Python implementation, it can finish 100 epochs of training over English PolyGlot vectors within 352 seconds on a machine with an Intel Core i7-6700 (3.4 GHz) CPU, 32GB memory and 1TB SSD. Compared to fastText which, with a fast multithread C++ implementation, takes hours to be trained over giga bytes of text corpus, our method provides a cheap way to generalize reasonably good word vectors for OOV words.

4 Joint Prediction of Part-of-Speech Tags and Morphosyntactic Attributes

Besides word similarity, we try to access our embedders' ability of capturing words' syntactic and semantic features by evaluating with the task of predicting part-of-speech (POS) tags and morphosyntactic attributes for words in a sentence. For each word in a given sentence, the task asks for a POS tag and a label for each applicable morphosyntactic category, such as gender, case or tense.

Dataset We use Universal Dependencies (UD) dataset (Petrov et al., 2012) for this task. UD is an open-community effort to build consistent annotated treebank cross many languages. We pick the specific version 1.4 to enable a direct comparison with Pinter et al. (2017). Since we use PolyGlot vectors to train our word embedders, we conduct experiments on the 23 languages that appear in both Polyglot and UD 1.4.

Model We adopt the same sentence-level bidirectional LSTM model from Pinter et al. (2017) for the joint prediction of both labels. Given a sentence as a sequence of words, we first embed each word using the word embedder we choose and then fed the embeddings into the LSTM. The output of LSTM is then used to predict POS and morphosyntactic tags.

We emphasize the difference in the setting that we *fix* the word embeddings during the training, as to better evaluate the ability and consistency of the embeddings in capturing words' semantics and syntactics, rather than LSTM's ability to memorize words and infer the role of words from their context.

We use the same set of hyperparameters for the LSTM model as Sec. 5.3 in Pinter et al. (2017) and train the model for 20 epochs for each language. The BoS and MIMICK word embedders

Table 3: POS tagging accuracy and morphosyntactic attributes micro F1 over 23 languages (UD 1.4). In parentheses are the gains to MIMICK.

are trained beforehand with PolyGlot dataset using the same way described earlier.

Results The POS tagging accuracies and micro F1 scores for morphosyntactic attributes are reported in Table 3 with word vectors generated by different models. The BoS and MIMICK model here are trained against Polyglot vectors. As a comparison, we include the results using random word vectors of the same dimension (64).

Our BoS model shows steady and significant gain compared to MIMICK embeddings for both tasks in *all* languages. We especially observe the greatest margins for agglutinative languages such as Turkish and Indonesian, and in Germanic languages English, Swedish and Danish, suggesting that our model learns stable representations for morphemes to consistent word type signal.

5 Conclusion

We proposed a subword-level word embedding model and a word vector generalization method that enables extending pre-trained word embeddings with fixed size vocabularies to estimate word embeddings for out-of-vocabulary words. Intrinsic evaluation on word similarity tasks and extrinsic evaluation on POS tagging task demonstrate that our model captures morphological knowledge and generates good estimates of word vectors for OOV words.

Abstract

We present end-to-end neural models for detecting metaphorical word use in context. We show that relatively standard BiLSTM models which operate on complete sentences work well in this setting, in comparison to previous work that used more restricted forms of linguistic context. These models establish a new state-of-the-art on existing verb metaphor detection benchmarks, and show strong performance on jointly predicting the metaphoricity of all words in a running text.

1 Introduction

Metaphors are pervasive in natural language, and detecting them requires challenging contextual reasoning about whether specific situations can actually happen. (Lakoff and Johnson, 1980). For example, in Table 1, “examining” is metaphorical because it is impossible to literally use a “microscope” to examine an entire country. In this paper, we present end-to-end neural models for metaphor detection, which can learn rich contextual word representations that are crucial for accurate interpretation of figurative language.

In contrast, most previous approaches focused on limited forms of linguistic context, for example by only providing SVO triples such as (car, **drink**, gasoline) to the model (Shutova et al., 2016; Tsvetkov et al., 2013; Rei et al., 2017; Bulat et al., 2017). While the verbal arguments provide strong cues, providing the full sentential context supports more accurate prediction, as seen in Table 1. Even in the few cases when the full sentence is used (Köper and im Walde, 2017; Turney et al., 2011; Jang et al., 2016) existing models have used unigram-based features with limited expressivity.

We investigate two common task formulations: (1) given a target verb in a sentence, classifying whether it is metaphorical or not, and (2) given a sentence, detecting all of the metaphorical words (independent of their POS tags). We find that relatively standard architectures based on bi-directional LSTMs (Hochreiter and Schmidhuber, 1997) augmented with contextualized word embeddings (Peters et al., 2018) perform surprisingly well on both tasks, even with modest amount of training data. We improve the previous state-of-the-art by 7.5 F1 on the VU Amsterdam Metaphor Corpus (VUA) for the sequence labeling task (Steen et al., 2010), by 2.5 F1 on the VUA verb clasificiation dataset, and by 4.9 F1 on the MOH-X dataset (Mohammad et al., 2016). Our code is publicly available at `https://github.com/gao-g/metaphor-in-context`.

Rockford teachers are honored for saving a *drowning* student.
You’re **drowning** in student loan debt.

Table 1: Metaphorical usages of the target word are bold faced, and literal usages are italicized. Full sentence context is crucial for metaphor detection.

2 Task

We study two task formulations.

Sequence Labeling: Given a sentence $x_1,\ldots,x_n$, predict a sequence of binary labels $l_1,\ldots,l_n$ to indicate the metaphoricity of each word.

Classification: Given a sentence $x_1,\ldots,x_n$ and a target verb index i, predict a binary label l to indicate the metaphoricity of the target x_i.

While both formulations have been studied in previous work, it is worth noting that the sequence labeling task generalizes the classification task in

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 607–613
Brussels, Belgium, October 31 - November 4, 2018.

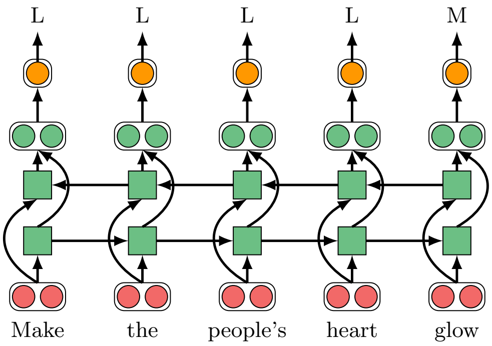

Figure 1: A sequence labeling model for metaphor detection. Every word in a sentence is classified.

that the prediction for the target verb can be extracted from the full sentence predictions. In addition, as will be shown in Section 5, we find that given accurate annotations for all words in a sentence, the sequence labeling model outperforms the classification model even when the evaluation is set up as a classification task.

3 Model

Our models use a bidirectional LSTM to encode a sentence, and a feedforward neural network for classification, optimized for the log-likelihood of gold labels.

Sentence encoding For both sequence labeling and classification, we represent each token x_i in the input sentence with a pre-trained word embedding w_i. To further encode contextual information, we also concatenate ELMo (Embeddings from Language Models) vectors e_i from Peters et al. (2018). These vectors have been shown to be useful for word sense disambiguation, a task closely related to metaphor detection (Birke and Sarkar, 2006).

3.1 Sequence Labeling Model

Figure 1 shows the model architecture. We input the word representation $[w_i; e_i]$ to a bidirectional LSTM, producing a contextualized representation h_i for each token. Then we use a feedforward neural network that takes h_i to predict a label l_i for each word x_i.

When the dataset does not contain annotations for every word, we make the simplifying assumption that every unannotated word is used literally.

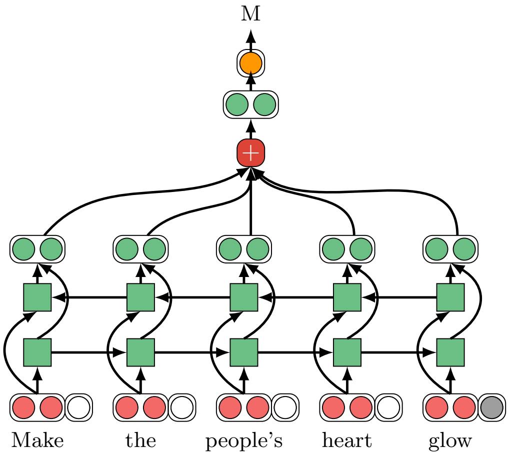

Figure 2: A classification model for metaphor detection. Only a single word per sentence is labeled as metaphorical or literal.

3.2 Classification Model

Figure 2 shows the model architecture. We concatenate an index embedding n_i, which indicates whether x_i is the target verb. We use $[w_i; e_i; n_i]$ as an input to a bidirectional LSTM, producing a contextualized representation h_i.

We add an attention layer by computing the attention weight a_i for token x_i, and compute the representation c as a weighted sum of LSTM output states where W_a and b_a are learned parameters.

$$a_i = \text{SoftMax}_i(W_a h_i + b_a)$$

$$c = \sum_{i=1}^{n} a_i h_i$$

Finally, we feed c to a feedforward network to compute the label scores for target verb.

4 Dataset

We evaluate performance on a number of benchmark datasets, including two for classification (TroFi and MOH\MOH-X) and one for tagging (VUA).[1] Table 2 shows statistics for the verb classification datasets. Despite being two times larger than the MOH dataset, the TroFi dataset contains only 50 unique verbs, and the larger VUA dataset contains over 2K unique verbs. The MOH dataset contains shorter and simpler sentences (example sentences in WordNet), compared to sentences in other datasets which come from resources such as

---

[1] For detailed information about each dataset, please refer to original papers: TroFi (Birke and Sarkar, 2006), MOH (Mohammad et al., 2016), VUA (Steen et al., 2010). MOH-X refers to a subset of MOH dataset used in previous work (Shutova et al., 2016) where verb and its argument are extracted from each sentence.

	# Expl.	% Metaphor	# Uniq. Verb	Avg # Sent. Len
MOH-X	647	49%	214	8.0
MOH	1,639	25%	440	7.4
TroFi	3,737	43%	50	28.3
VUA	23,113	28%	2047	24.5

Table 5: The breakdown of performance on the VUA sequence labeling test set by POS tags. We show data statistics (count, % metaphor) on the training set. We only show POS tags whose % metaphor >10.

news articles. The TroFi and MOH-X datasets are constructed to have higher percentages of metaphor, compared to the natural likelihood of metaphor in a running text, as seen in the VUA dataset.

Classification Experiment Setup We perform 10 fold cross-validation on the MOH-X and TroFi datasets, following prior work. For the VUA dataset, we use the original training and test split (Klebanov et al., 2016), and set aside 10% of the training set as a development set.

Sequence Labeling Experiment Setup The VUA dataset contains annotations for all words in each sentence. We divide the data into training, development, and test set following the same split for the VUA verb classification task. While the label classes are less balanced (only 11% metaphors at the token level), this dataset is much bigger. Table 3 shows the data statistics.

5 Experiments

Evaluation Metric We report precision, recall and F1 measure for the metaphor class as well as the overall accuracy. For the VUA dataset, we also report macro-averaged F1 score across four genres (conversation, academic writing, fiction and news).

Comparison Systems We propose a simple yet effective lexical baseline. It assigns the metaphor label if the word is annotated metaphorically more frequently than as literally in the training set, and the literal label otherwise. We also compare our models to previously published work, including: (1) a logistic regression classifier with features that indicate verb lemmas and the verbs' semantic class from WordNet (Klebanov et al., 2016), (2) a neural similarity network with skip-gram word embeddings (Rei et al., 2017), (3) a balanced logistic regression classifier on target verb lemma that uses a set of features based on multi-sense abstractness rating (Köper and im Walde, 2017), and (4) a CNN-LSTM ensemble model with weighted-softmax classifier which incorporates pre-trained word2vec, POS tags, and word cluster features (Wu et al., 2018).[2]

We experiment with both sequence labeling model (SEQ) and classification model (CLS) for the verb classification task, and the sequence labeling model (SEQ) for the sequence labeling task.

Implementation Details We used 300d GloVe vectors (Pennington et al., 2014) and 1024d ELMo vectors. We used additional 50d index embedding for the classification task. The LSTM module has a 300d hidden state. We applied dropout on the input to LSTM and on the input to the feedforward layer. We fine-tuned learning rate and dropout rate for each model on each dataset. We used SGD to optimize the CLS model and Adam (Kingma and Ba, 2013) for the SEQ model. We used spaCy (Honnibal and Montani, 2017) for lemmatization, tokenization, and part-of-speech tagging.

-ELMo	52.0	48.7	50.8	74.1

Table 7: Ablation study on VUA development set for the verb classification task.

Sequence Labeling Results Performance on the sequence labeling task is reported in Table 4. While prior work (Klebanov et al., 2014; Özbal et al., 2016) reported on the same dataset, the experiment setting is not comparable (they did cross validation on a smaller training set).[3] Our lexical baseline performs strongly in terms of precision, as some words and POS tags are almost exclusively annotated as literal. Our sequence labeling model mainly improves recall.

Table 5 reports the breakdown of performance by POS tags. Not surprisingly, tags with more data are easier to classify. Adposition is the easiest to identify as metaphorical and is also the most frequently metaphorical class (28%). On the other hand, particles are challenging to identify, since they are often associated with multi-word expressions, such as "put **down** the disturbances".

Verb Classification Results Table 6 shows performance on the verb classification task for three datasets (MOH-X , TroFi and VUA).[4]

Our models achieve strong performance on all datasets, outperforming existing models on the MOH-X and VUA datasets. On the MOH-X dataset, the CLS model outperforms the SEQ model, likely due to the simpler overall sentence structure and the fact that the target verbs are the only words annotated for metaphoricity. For the VUA dataset, where we have annotations for all words in a sentence, the SEQ model significantly outperforms the CLS model. This result shows that predicting metaphor labels of context words helps to predict the target verb. We hypothesize that Köper et al. (2017) outperforms our models on the TroFi dataset for a similar reason: their work uses concreteness labels, which highly correlate to metaphor labels of neighboring words in the sentence. Also, their best model uses the verb lemma as a feature, which itself provides a strong clue in the dataset of 50 verbs (see lexical baseline).

Table 7 shows an ablation study on input representations (with or without ELMo vectors). Contextualized word vectors improve the performance of both models by a large margin.

Error Analysis We sampled 100 errors of our best model from the VUA verb classification development set for analysis. Table 8 shows examples. Following the original annotation guideline,[5] we classify metaphors into five categories: direct metaphor, indirect metaphor, implicit metaphor, personification, and borderline case. Indirect metaphor, the most common type for verbs, means that the basic meaning of a word is different from its contextual meaning. Implicit metaphor occurs due to an underlying link which points to a recoverable metaphorical concept.

About half of the errors were false positives, and the other half were false negatives. Among the false negatives, 33% are indirect metaphors, 18% are personifications, and 2% are direct metaphors. Among 55 false positives, 31% of verbs have im-

---

[3] As a point of reference, their macro-averaged F1 scores were 33.25 / 50.6 respectively.

[4] We did not compare to Shutova et al. (2016) as their experiment setting is not comparable.

[5] http://www.vismet.org/metcor/documentation/home.html

CLS	SEQ	Sentence	Metaphor Type
✗	✗	To *throw* up an impenetrable Berlin Wall between you and them could be tactless.	-
✗	✗	In reality you just invent a tale, as if you were **sitting** round a fire in a cave.	direct metaphor
✗	✗	So they **bought** immunity.	indirect metaphor
✗	✗	During the early states of the phased evacuation the logistical problem **facing** the police was the street-by-street warning of the population to make ready for evacuation.	indirect metaphor
✗	✔	There are few things worse than being **bludgeoned** into reading a book you hate.	indirect metaphor
✗	✔	He thought of thick, fat, hot motorways **carving** up that land.	personification
✗	✔	One might *ask* whether motorists are ever justified in knowingly taking risks with other people's lives.	-
✗	✔	The abstract talk of *commuting* by rail or road being replaced by information technology finds a concrete expression in the idea of telecottages.	-
✗	✔	A fly landed on the empty, staring vizor, and *crawled* across it.	-

Table 8: Some examples from the VUA verb classification development set. Metaphorical usages of the target word are bold faced, and literal usages are italicized. Leftmost columns show the correctness of prediction.

plicit arguments that are not explicitly mentioned in the context, 15% have long range dependencies (at least five words away) from core arguments, 10% have arguments with rare word senses, and 5% have anthropomorphic arguments. Finally, we found about half of false negatives and 20% of false positives to be borderline cases, showing the subjective nature of the task.

We sampled 257 dev examples that the CLS model gets wrong but the SEQ model gets correct. We found that the SEQ model outperforms the CLS model on detecting personifications, indirect metaphors, and direct metaphors involving uncommon verbs.

6 Related Work

There has been significant work on studying different features for metaphor detection, including concretenesss and abstractness (Turney et al., 2011; Tsvetkov et al., 2014; Köper and im Walde, 2017), imaginability (Broadwell et al., 2013; Strzalkowski et al., 2013), feature norms (Bulat et al., 2017), sensory features (Tekiroglu et al., 2015; Shutova et al., 2016), bag-of-words features (Köper and im Walde, 2016), and semantic class using WordNet (Hovy et al., 2013; Tsvetkov et al., 2014). More recently, embedding-based approaches (Köper and im Walde, 2017; Rei et al., 2017) showed gains on various benchmarks.

Many neural models with various features and architectures were introduced in the 2018 VUA Metaphor Detection Shared Task. They include LSTM-based models and CRFs augmented by linguistic features, such as WordNet, POS tags, concreteness score, unigrams, lemmas, verb clusters, and sentence-length manipulation (Swarnkar and Singh, 2018; Pramanick et al., 2018; Mosolova et al., 2018; Bizzoni and Ghanimifard, 2018; Wu et al., 2018). Researchers also studied different word embeddings, such as embeddings trained from corpora representing different levels of language mastery (Stemle and Onysko, 2018) and binarized vectors that reflect the General Inquirer dictionary category of a word (Mykowiecka et al., 2018). We show that contextualized word embedding significantly improves metaphor detection. We also study both sequence labeling and classification approaches, suggesting that sequence labeling approach enhances performance when used to jointly predict the metaphoricity of all words in a sentence.

7 Conclusion

In this paper, we present simple biLSTM models augmented with contextualized word representation for metaphor detection. Our models establish new state-of-the-arts across multiple existing benchmarks, and our error analysis shows remaining challenges for metaphor detection.

Distant Supervision from Disparate Sources for Low-Resource Part-of-Speech Tagging

Abstract

We introduce DsDs: a cross-lingual neural part-of-speech tagger that learns from disparate sources of distant supervision, and realistically scales to hundreds of low-resource languages. The model exploits annotation projection, instance selection, tag dictionaries, morphological lexicons, and distributed representations, all in a uniform framework. The approach is simple, yet surprisingly effective, resulting in a new state of the art *without* access to any gold annotated data.

1 Introduction

Low-resource languages lack manually annotated data to learn even the most basic models such as part-of-speech (POS) taggers. To compensate for the absence of direct supervision, work in cross-lingual learning and distant supervision has discovered creative use for a number of alternative data sources to learn feasible models:

- aligned *parallel corpora* to project POS annotations to target languages (Yarowsky et al., 2001; Agić et al., 2015; Fang and Cohn, 2016),
- noisy *tag dictionaries* for type-level approximation of full supervision (Li et al., 2012),
- combination of projection and *type constraints* (Das and Petrov, 2011; Täckström et al., 2013),
- rapid annotation of *seed training data* (Garrette and Baldridge, 2013; Garrette et al., 2013).

However, only one or two compatible sources of distant supervision are typically employed. In reality severely under-resourced languages may require a more pragmatic "take what you can get" viewpoint. Our results suggest that combining supervision sources is the way to go about creating viable low-resource taggers.

We propose a method to strike a balance between model simplicity and the capacity to easily integrate heterogeneous learning signals. Our system is a uniform neural model for POS tagging that learns from *disparate sources of distant supervision* (DsDs). We use it to combine: i) multi-source annotation projection, ii) instance selection, iii) noisy tag dictionaries, and iv) distributed word and sub-word representations. We examine how far we can get by exploiting only the wide-coverage resources that are currently readily available for more than 300 languages, which is the breadth of the parallel corpus we employ.

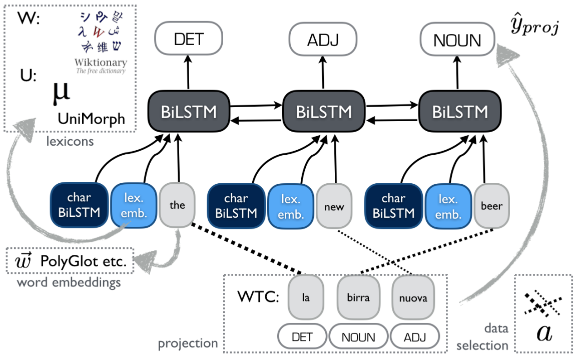

Figure 1: Illustration of DsDs (Distant Supervision from Disparate Sources).

DsDs yields a new state of the art by jointly leveraging disparate sources of distant supervision in an experiment with 25 languages. We demonstrate: i) substantial gains in carefully selecting high-quality instances in annotation projection, ii) the usefulness of lexicon features for neural tagging, and iii) the importance of word embeddings initialization for faster convergence.

2 Method

DsDs is illustrated in Figure 1. The base model is a bidirectional long short-term memory network (bi-LSTM) (Graves and Schmidhuber, 2005; Hochreiter and Schmidhuber, 1997; Plank et al., 2016; Kiperwasser and Goldberg, 2016). Let $x_{1:n}$

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 614–620
Brussels, Belgium, October 31 - November 4, 2018.

be a given sequence of input vectors. In our base model, the input sequence consists of word embeddings $\vec{w}$ and the two output states of a character-level bi-LSTM $\vec{c}$. Given $x_{1:n}$ and a desired index i, the function $BiRNN_\theta(x_{1:n}, i)$ (here instantiated as LSTM) reads the input sequence in forward and reverse order, respectively, and uses the concatenated ($\circ$) output states as input for tag prediction at position i.[1] Our model differs from prior work on the type of input vectors $x_{1:n}$ and distant data sources, in particular, we extend the input with lexicon embeddings, all described next.

Annotation projection. Ever since the seminal work of Yarowsky et al. (2001), projecting sequential labels from source to target languages has been one of the most prevalent approaches to cross-lingual learning. Its only requirement is that parallel texts are available between the languages, and that the source side is annotated for POS.

We apply the approach by Agić et al. (2016), where labels are projected from multiple sources and then decoded through weighted majority voting with word alignment probabilities and source POS tagger confidences. We exploit their wide-coverage Watchtower corpus (WTC), in contrast to the typically used Europarl data. Europarl covers 21 languages of the EU with 400k-2M sentence pairs, while WTC spans 300+ widely diverse languages with only 10-100k pairs, in effect sacrificing depth for breadth, and introducing a more radical domain shift. However, as our results show little projected data turns out to be the most beneficial, reinforcing breadth for depth.

While Agić et al. (2016) selected 20k projected sentences at random to train taggers, we propose a novel alternative: selection by *coverage*. We rank the target sentences by percentage of words covered by word alignment from 21 sources of Agić et al. (2016), and select the top k covered instances for training. In specific, we employ the mean coverage ranking of target sentences, whereby each target sentence is coupled with the arithmetic mean of the 21 individual word alignment coverages for each of the 21 source-language sentences. We show that this simple approach to instance selection offers substantial improvements: across all languages, we learn better taggers with significantly fewer training instances.

Dictionaries. Dictionaries are a useful source for distant supervision (Li et al., 2012; Täckström et al., 2013). There are several ways to exploit such information: i) as type constraints during encoding (Täckström et al., 2013), ii) to guide unsupervised learning (Li et al., 2012), or iii) as additional signal at training. We focus on the latter and evaluate two ways to integrate lexical knowledge into neural models, while comparing to the former two: a) by representing lexicon properties as n-hot vector (e.g., if a word has two properties according to lexicon src, it results in a 2-hot vector, if the word is not present in src, a zero vector), with m the number of lexicon properties; b) by *embedding* the lexical features, i.e., $\vec{e}_{src}$ is a lexicon src embedded into an l-dimensional space. We represent $\vec{e}_{src}$ as concatenation of all embedded m properties of length l, and a zero vector otherwise. Tuning on the dev set, we found the second embedding approach to perform best, and simple concatenation outperformed mean vector representations.

We evaluate two dictionary sources, motivated by ease of accessibility to many languages: WIKTIONARY, a word type dictionary that maps tokens to one of the 12 Universal POS tags (Li et al., 2012; Petrov et al., 2012); and UNIMORPH, a morphological dictionary that provides inflectional paradigms across 350 languages (Kirov et al., 2016). For Wiktionary, we use the freely available dictionaries from Li et al. (2012) and Agić et al. (2017). The size of the dictionaries ranges from a few thousands (e.g., Hindi and Bulgarian) to 2M (Finnish UniMorph). Sizes are provided in Table 1, first columns. UniMorph covers between 8-38 morphological properties (for English and Finnish, respectively).

Word embeddings. Embeddings are available for many languages. Pre-initialization of $\vec{w}$ offers consistent and considerable performance improvements in our distant supervision setup (Section 4). We use off-the-shelf Polyglot embeddings (Al-Rfou et al., 2013), which performed consistently better than FastText (Bojanowski et al., 2016).

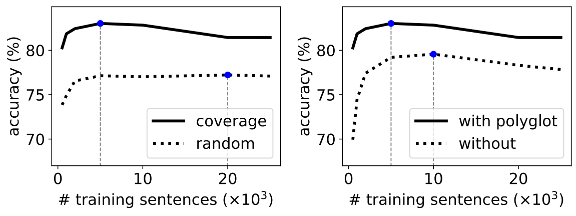
3 Experiments

Baselines. We compare to the following weakly-supervised POS taggers:

- **AGIC:** Multi-source annotation projection with Bible parallel data by Agić et al. (2015).
- **DAS:** The label propagation approach by Das and Petrov (2011) over Europarl data.

---

[1] CRF decoding did not consistently improve POS accuracy, as recently also independently found (Yang et al., 2018).



(a) sentence selection (b) pre-trained embeddings

Figure 2: Learning curves for: a) random vs. coverage-based sentence selection in annotation projection, both with Polyglot embeddings, and b) pre-trained embeddings on top of coverage-based selection. Means over 21 languages.

- **Garrette:** The approach by Garrette and Baldridge (2013) that works with projections, dictionaries, and unlabeled target text.
- **Li:** Wiktionary supervision (Li et al., 2012).

Data. Our set of 25 languages is motivated by accessibility to embeddings and dictionaries. In all experiments we work with the 12 Universal POS tags (Petrov et al., 2012). For development, we use 21 dev sets of the Universal Dependencies 2.1 (Nivre et al., 2017). We employ UD test sets on additional languages as well as the test sets of Agić et al. (2015) to facilitate comparisons. Their test sets are a mixture of CoNLL (Buchholz and Marsi, 2006; Nivre et al., 2007) and HamleDT test data (Zeman et al., 2014), and are more distant from the training and development data.

Model and parameters. We extend an off-the-shelf state-of-the-art bi-LSTM tagger with lexicon information. The code is available at: `https://github.com/bplank/bilstm-aux`. The parameter l=40 was set on dev data across all languages. Besides using 10 epochs, word dropout rate (p=.25) and 40-dimensional lexicon embeddings, we use the parameters from Plank et al. (2016). For all experiments, we average over 3 randomly seeded runs, and provide mean accuracy. For the learning curve, we average over 5 random samples with 3 runs each.

4 Results

Table 1 shows the tagging accuracy for individual languages, while the means over all languages are given in Figure 2. There are several take-aways.

Data selection. The first take-away is that coverage-based instance selection yields substantially better training data. Most prior work on annotation projection resorts to arbitrary selection; informed selection clearly helps in this noisy data setup, as shown in Figure 2 (a). Training on 5k instances results in a sweet spot; more data (10k) starts to decrease performance, at a cost of runtime. Training on all WTC data (around 120k) is worse for most languages. From now on we consider the 5k model trained with Polyglot as our baseline (Table 1, column "5k"), obtaining a mean accuracy of 83.0 over 21 languages.

Embeddings initialization. Polyglot initialization offers a large boost; on average +3.8% absolute improvement in accuracy for our 5k training scheme, as shown in Figure 2 (b). The big gap in low-resource setups further shows their effectiveness, with up to 10% absolute increase in accuracy when training on only 500 instances.

Lexical information. The main take-away is that lexical information helps neural tagging, and *embedding* it proves the most helpful. Embedding Wiktionary tags reaches 83.7 accuracy on average, versus 83.4 for n-hot encoding, and 83.2 for type constraints. Only on 4 out of 21 languages are type constraints better. This is the case for only one language for n-hot encoding (French). The best approach is to embed both Wiktionary and Unimorph, boosting performance further to 84.0, and resulting in our final model. It helps the most on morphological rich languages such as Uralic.

On the test sets (Table 4, right) DsDs reaches 87.2 over 8 test languages intersecting Li et al. (2012) and Agić et al. (2016). It reaches 86.2 over the more commonly used 8 languages of Das and Petrov (2011), compared to their 83.4. This shows that our novel "soft" inclusion of noisy dictionaries is superior to a hard decoding restriction, and including lexicons in neural taggers helps. We did not assume any gold data to further enrich the lexicons, nor fix possible tagset divergences.

5 Discussion

Analysis. The inclusion of lexicons results in higher coverage and is part of the explanation for the improvement of DsDs; see correlation in Figure 3 (a). What is more interesting is that our model benefits from the lexicon beyond its content: OOV accuracy for words *not* present in the lexicon overall improves, besides the expected improvement on known OOV, see Figure 3 (b).

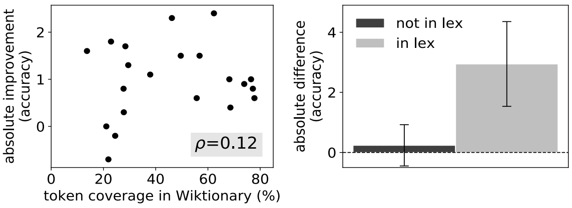
Table 1: Results on the development sets and comparison of our best model to prior work. Lex: Size (word types) of dictionaries (W: Wiktionary, U: UniMorph). TC$_W$: type-constraints using Wiktionary; $\vec{e}_W$ (embedded Wiktionary tags), DsDs: our model with $\vec{e}_{W\cup U}$. Results indicated by † use W only. Best result in boldface; in case of equal means, the one with lower std is boldfaced. Averages over language families (with two or more languages in the sample, number of languages in parenthesis).

More languages. All data sources employed in our experiment are very high-coverage. However, for true low-resource languages, we cannot safely assume the availability of all disparate information sources. Table 2 presents results for four additional languages where some supervision sources are missing. We observe that adding lexicon information always helps, even in cases where only 1k entries are available, and embedding it is usually the most beneficial way. For closely-related languages such as Serbian and Croatian, using resources for one aids tagging the other, and modern resources are a better fit. For example, using the Croatian WTC projections to train a model for Serbian is preferable over in-language Serbian Bible data where the OOV rate is much higher.



(a) coverage vs. accuracy

(b) OOV accuracy

Figure 3: Analysis of DsDs accuracy improvements over the baseline on all development languages with respect to a) token coverage by the lexicon, including Pearson's ρ; b) OOV accuracy for tokens in/not in the lexicon, with 95% confidence intervals of the mean. Here, a token is covered if we can find it in at least one lexicon.

How much gold data? We assume not having access to *any* gold annotated data. It is thus interesting to ask how much gold data is needed to reach our performance. This is a tricky question, as training within the same corpus naturally favors the same corpus data. We test both in-corpus (UD) and out-of-corpus data (our test sets) and notice an important gap: while in-corpus only 50 sentences are sufficient, outside the corpus one would need over 200 sentences. This experiment was done for a subset of 18 languages with both in- and out-of-corpus test data.

Language	Test	Proj	Emb	Lex (10^3) W	U	TnT	5k	TC$_W$	n-hot$_W$	$\vec{e}_W$	DsDs

Table 2: Results for languages with missing data sources: WTC projections, Wiktionary (W), or UniMorph (U). Test sets (Test), projection sources (Proj), and embeddings languages (Emb) are indicated. Comparison to TnT (Brants, 2000) trained on Proj. Results indicated by † use W only.

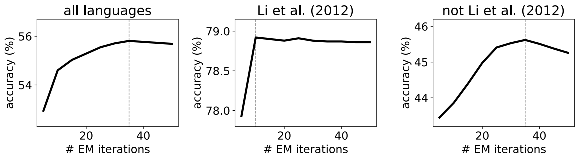

Figure 4: The performance of Li with our dictionary data over EM iterations, separate for the languages from Li et al. (2012) and all the remaining languages in Table 1.

Further comparison. In Table 1 we directly report the accuracies from the original contributions by Das, Li, Garrette, and Agic over the same test data. We additionally attempted to reach the scores of Li by running their tagger over the Table 1 data setup. The results are depicted in Figure 4 as mean accuracies over EM iterations until convergence. We show: i) Li peaks at 10 iterations for their test languages, and at 35 iterations for all the rest. This is in slight contrast to 50 iterations that Li et al. (2012) recommend, although selecting 50 does not dramatically hurt the scores; ii) Our replication falls $\sim$5 points short of their 84.9 accuracy. There is a large 33-point accuracy gap between the scores of Li et al. (2012), where the dictionaries are large, and the other languages in Figure 4, with smaller dictionaries.

Compared to Das, our tagger clearly benefits from pre-trained word embeddings, while theirs relies on label propagation through Europarl, a much cleaner corpus that lacks the coverage of the noisier WTC. Similar applies to Täckström et al. (2013), as they use 1-5M near-perfect parallel sentences. Even if we use much smaller and noisier data sources, DsDs is almost on par: 86.2 vs. 87.3 for the 8 languages from Das and Petrov (2011), and we even outperform theirs on four languages: Czech, French, Italian, and Spanish.

6 Related Work

Most successful work on low-resource POS tagging is based on projection (Yarowsky et al., 2001), tag dictionaries (Li et al., 2012), annotation of seed training data (Garrette and Baldridge, 2013) or even more recently some combination of these, e.g., via multi-task learning (Fang and Cohn, 2016; Kann et al., 2018). Our paper contributes to this literature by leveraging a range of prior directions in a unified, neural test bed.

Most prior work on neural sequence prediction follows the commonly perceived wisdom that hand-crafted features are unnecessary for deep learning methods. They rely on end-to-end training without resorting to additional linguistic resources. Our study shows that this is not the case. Only few prior studies investigate such sources, e.g., for MT (Sennrich and Haddow, 2016; Chen et al., 2017; Li et al., 2017; Passban et al., 2018) and Sagot and Martínez Alonso (2017) for POS tagging use lexicons, but only as n-hot features and without examining the cross-lingual aspect.

7 Conclusions

We show that our approach of distant supervision from disparate sources (DsDs) is simple yet surprisingly effective for low-resource POS tagging. Only 5k instances of projected data paired with off-the-shelf embeddings and lexical information integrated into a neural tagger are sufficient to reach a new state of the art, and both data selection and embeddings are essential components to boost neural tagging performance.

Unsupervised Bilingual Lexicon Induction via Latent Variable Models

Zi-Yi Dou **Zhi-Hao Zhou** **Shujian Huang**
State Key Laboratory for Novel Software Technology, Nanjing University, China
{douzy@smail, zhouzh@nlp, huangsj@nlp}.nju.edu.cn

Abstract

Bilingual lexicon extraction has been studied for decades and most previous methods have relied on parallel corpora or bilingual dictionaries. Recent studies have shown that it is possible to build a bilingual dictionary by aligning monolingual word embedding spaces in an unsupervised way. With the recent advances in generative models, we propose a novel approach which builds cross-lingual dictionaries via latent variable models and adversarial training with no parallel corpora. To demonstrate the effectiveness of our approach, we evaluate our approach on several language pairs and the experimental results show that our model could achieve competitive and even superior performance compared with several state-of-the-art models.

1 Introduction

Learning the representations of languages is a fundamental problem in natural language processing and most existing methods exploit the hypothesis that words occurring in similar contexts tend to have similar meanings (Pennington et al., 2014; Bojanowski et al., 2017), which could lead word vectors to capture semantic information. Mikolov et al. (2013) first point out that word embeddings learned on separate monolingual corpora exhibit similar structures. Based on this finding, they suggest it is possible to learn a linear mapping from a source to a target embedding space and then generate bilingual dictionaries. This simple yet effective approach has led researchers to investigate on improving cross-lingual word embeddings with the help of bilingual word lexicons (Faruqui and Dyer, 2014; Xing et al., 2015).

For low-resource languages and domains, cross-lingual signal would be hard and expensive to obtain, and thus it is necessary to reduce the need for bilingual supervision. Artetxe et al. (2017) successfully learn bilingual word embeddings with only a parallel vocabulary of aligned digits. Zhang et al. (2017) utilize adversarial training to obtain cross-lingual word embeddings without any parallel data. However, their performance is still significantly worse than supervised methods. By combining the merits of several previous works, Conneau et al. (2018) introduce a model that reaches and even outperforms supervised state-of-the-art methods with no parallel data.

In recent years, generative models have become more and more powerful. Both Generative Adversarial Networks (GANs) (Goodfellow et al., 2014) and Variational Autoencoders (VAEs) (Kingma and Welling, 2014) are prominent ones. In this work, we borrow the ideas from both GANs and VAEs to tackle the problem of bilingual lexicon induction. The basic idea is to learn latent variables that could capture semantic meaning of words, which would be helpful for bilingual lexicon induction. We also utilize adversarial training for our model and require no form of supervision. We evaluate our approach on several language pairs and experimental results demonstrate that our model could achieve promising performance. We further combine our model with several helpful techniques and show our model could perform competitively and even superiorly compared with several state-of-the-art methods.

2 Related Work

2.1 Bilingual Lexicon Induction

Extracting bilingual lexica has been studied by researchers for a long time. Mikolov et al. (2013) first observe there is isomorphic structure among word embeddings trained separately on monolingual corpora and they learn the linear transformation between languages. Zhang et al. (2016b) improve the method by constraining the transformation matrix to be orthogonal. Xing et al. (2015) incorporate length normalization during training and

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 621–626
Brussels, Belgium, October 31 - November 4, 2018.

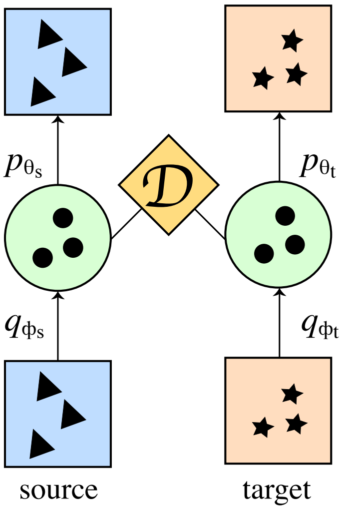

Figure 1: Illustration of our model. ϕ_s and ϕ_t map the source and target word embeddings into latent variables. Discriminator D guides the two latent distributions to be the same.

maximize the cosine similarity instead. They point out that adding an orthogonality constraint can improve performance and has a closed-form solution, which was referred to as Procrustes approach in Smith et al. (2017). Canonical correlation analysis has also been used to map both languages to a shared vector space (Faruqui and Dyer, 2014; Lu et al., 2015).

To reduce the need for supervision signals, Artetxe et al. (2017) use identical digits and numbers to form an initial seed dictionary and then iteratively refine their results until convergence. Zhang et al. (2017) apply adversarial training to align monolingual word vector spaces with no supervision. Conneau et al. (2018) improve the model by combining adversarial training and Procrustes approach, and their unsupervised approach could reach and even outperform state-of-the-art supervised approaches. In this work, we make further improvements and enhance the model proposed in (Conneau et al., 2018) with latent variable model and iterative training procedure.

2.2 Generative Models

VAEs (Kingma and Welling, 2014) represent one of the most successful deep generative models. Standard VAEs assume observed variables are generated from latent variables and the latent variables are sampled from a simple Gaussian distribution. Typically, VAEs utilize an neural inference model to approximate the intractable posterior, and optimize model parameters jointly with a reparameterized variational lower bound. VAEs have been successfully applied in several natural language processing tasks before (Zhang et al., 2016a; Bowman et al., 2016).

GANs (Goodfellow et al., 2014) are another framework for estimating generative models via an adversarial process and have attracted huge attention. The basic strategy is to train a generative model and a discriminative model simultaneously via an adversarial process. Adversarial training technique for matching distribution has proven to be powerful in a variety of tasks (Bowman et al., 2016). Adversarial Autoencoder (Makhzani et al., 2015) is a probabilistic autoencoder that uses the GANs to perform variational inference. By combining a VAE with a GAN, Larsen et al. (2016) use learned feature representations in the GAN discriminator as the basis for the VAE reconstruction objective. GANs have been applied in machine translation before (Yang et al., 2018; Lample et al., 2018).

3 Proposed Approach

In this section, we first briefly introduce VAEs, and then we illustrate the details and training techniques of our proposed model.

3.1 Variational Autoencoder

Variational Autoencoders (VAEs) are deep generative model which are capable of learning complex density models for data via latent variables. Given a nonlinear generative model $p_\theta(x|z)$ with input $x \in \mathbb{R}^D$ and associated latent variable $z \in \mathbb{R}^L$ drawn from a prior distribution $p_0(z)$, the goal of VAEs is to use a recognition model, $q_\phi(z|x)$ to approximate the posterior distribution of the latent variables by maximizing the following variational lower bound

$$\mathcal{L}_{\theta,\phi} = \mathbb{E}_{q_\phi(z|x)}[\log p_\theta(x|z)] - \mathrm{KL}(q_\phi(z|x)||p_0(z)), \tag{1}$$

where KL refers to Kullback-Leibler divergence.

3.2 Our Model

Basically, our model assumes that the source word embedding $\{x_n\}$ and the target word embedding $\{y_n\}$ could be drawn from a same latent variable space $\{z_n\}$, where $\{z_n\}$ is capable of capturing semantic meaning of words.

In contrast to the standard VAE prior that assumes each latent embedding z_n to be drawn from the same latent Gaussian, our model just requires the distribution of latent variables for source and target word embeddings to be equal. To achieve such a goal, we utilize adversarial training to guide the two latent distributions to match with each other.

As in adversarial training, we have networks ϕ_s and ϕ_t for both source and target space, striving to map words into the same latent space, while the discriminator D is a binary classifier which tries to distinguish between the two languages. We also have reconstruction networks θ_s and θ_t as in VAEs.

The objective function for the discriminator D could be formulated as

$$\begin{aligned}\mathcal{L}_D = {} & \mathbb{E}_{z_y \sim q_{\phi_t}(z|y)}[\log D(z_y)] \\ & + \mathbb{E}_{z_x \sim q_{\phi_s}(z|x)}[\log(1 - D(z_x))].\end{aligned} \tag{2}$$

For the source side, the objective is to minimize

$$\begin{aligned}\mathcal{L}_{\phi_s,\theta_s} = {} & \mathbb{E}_{z_x \sim q_{\phi_s}(z|x)}[\log p_{\theta_s}(x|z_x)] \\ & - \mathbb{E}_{z_x \sim q_{\phi_s}(z|x)}[\log D(z_x)].\end{aligned} \tag{3}$$

Here we define $q_{\phi_s}(z|x) = \mathcal{N}(\mu_s(x), \Sigma_s(x))$, where $\mu_s(x) = W_{\mu_s} x$ and $\Sigma_s(x) = \exp(W_{\sigma_s} x)$; W_{μ_s} and W_{σ_s} are learned parameters. We also define the mean of $p_{\theta_s}(x|z)$ to be $W_{\mu_s}^{\mathrm{T}} z$. The objective function and structure for ϕ_t are similar.

The basic framework of our model is shown in Figure 1. As we could see from the figure, our model tries to map the source and target word embedding into the same latent space which could capture the semantic meaning of words.

Theoretical analysis has revealed that adversarial training tries to minimize the Jensen-Shannon (JS) divergence between the real and fake distribution. Therefore, one can view our model as replace KL divergence in Equation 1 with JS divergence and change the Gaussian prior to the target distribution.

3.3 Training Strategy

Our model has two generators ϕ_s and ϕ_t, and we have found that training them jointly would be extremely unstable. In this paper, we propose an iterative method to train our models. Basically, we first initialize W_{μ_t} to be identity matrix and train ϕ_s and θ_s on the source side. After convergence, we freeze W_{μ_s}, and then train ϕ_t and θ_t in the target side. The pseudo-code for this process is shown in Algorithm 1. It should be noted that there is no variance once completing training.

Algorithm 1 Training Strategy

```
$W_{\mu_t} = I$
for $i = 1, \cdots, n_{iter}$ do
    while $\phi_s$ and $\theta_s$ have not converged do
        Update discriminator $D$
        Update $\phi_s$ and $\theta_s$
    end while
    while $\phi_t$ and $\theta_t$ have not converged do
        Update discriminator $D$
        Update $\phi_t$ and $\theta_t$
    end while
end for
```

4 Experiment

Our experiments could be divided into two parts. In the first part, we conduct experiments on small-scale datasets and our main baseline is Zhang et al. (2017). In the second part, we combine our model with several advanced techniques and we compare our model with Conneau et al. (2018) on large-scale datasets.

		#tokens	vocab. size
zh-en	zh	21m	3,349
	en	53m	5,154
es-en	es	61m	4,774
	en	95m	6,637
it-en	it	73m	8,490
	en	93m	6,597

Table 1: Statistics of the non-parallel corpora. Language codes: zh = Chinese, en = English, es = Spanish, it = Italian.

4.1 Small-scale Datasets

In this section, our experiments focus on small-scale datasets and our main baseline model is adversarial autoencoder (Zhang et al., 2017). For justice, we use the same model selection strategy with Zhang et al. (2017), i.e. we choose the model whose sum of reconstruction loss and classification accuracy is the least. The source and target word embeddings would be first mapped into the latent space. For each source word embedding x, it would be first transformed into z_x. The the its k nearest target embeddings would be retrieved and be compared against the entry in a ground truth bilingual lexicon. Performance is measured by top-1 accuracy.

4.1.1 Experiments on Chinese-English Dataset

For this set of experiments, we use the same data as Zhang et al. (2017). The statistics of the final training data is given in Table 1. We use Chinese-English Translation Lexicon Version 3.0 (LDC2002L27) as our ground truth bilingual lexicon for evaluation.

The baseline models are MonoGiza system (Dou et al., 2015), translation matrix (TM) (Mikolov et al., 2013), isometric alignment (IA) (Zhang et al., 2016b) and adversarial training approach (Zhang et al., 2017).

Table 2 summarizes the performance of baseline models and our approach. The results of baseline models are cited from Zhang et al. (2017). As we can see from the table, our model could achieve superior performance compared with other baseline models. Table 3 lists some word translation examples given by our model.

Model	#seeds	Accuracy (%)
MonoGiza w/o emb.	0	0.05
MonoGiza w/ emb.	0	0.09
TM	50	0.29
IA	100	21.79
Zhang et al. (2017)	0	43.31
Ours	0	**51.37**

Table 2: Experimental results on Chinese-English dataset. The results of baseline models are cited from Zhang et al. (2017).

airliner	**railroad**	century	college
service	freight	medieval	student
flight	metro	historian	teacher

Table 3: Word translation examples for Chinese-English dataset. Ground truths are marked in bold.

4.1.2 Experiments on Other Language Pairs Datasets

We also conduct experiments on Spanish-English and Italian-English language pairs. Again, we use the same dataset with Zhang et al. (2017). and the statistics are shown in Table 1. The ground truth bilingual lexica for Spanish-English and Italian-English are obtained from Multilingual Unsupervised and Supervised Embeddings (MUSE) [1].

	Model	Accuracy (%)
es-en	Zhang et al. (2017)	69.22
	Ours	**75.21**
it-en	Zhang et al. (2017)	55.31
	Ours	**61.08**

Table 4: Experimental results on Spanish-English and Italian-English datasets.

The experimental results are shown in Table 4. Because Spanish, Italian and English are closely related languages, the accuracy would be higher than the Chinese-English dataset. Our model is able to outperform baseline model in this setting.

Model	Accuracy (%)		
	en-es	en-ru	en-zh
Methods without refinement

Ours-Refine-CSLS	**82.1**	**48.7**	**33.3**

Table 5: Experimental results on large-scale datasets. Language codes: en=English, es = Spanish, ru = Russian, zh = Chinese.

4.2 Large-scale Datasets

In this section, we integrate our method with Conneau et al. (2018), whose method improves Zhang et al. (2017) by more sophiscated refinement procedure and validation criterion. We replace their first step, namely the adversarial training step, with our model. Basically, we first map the source and target embeddings into the latent space using our algorithm, and then fine-tune the identity mapping in the latent space with the closed-form Procrustes solution. We use their similarity measure, namely cross-domain similarity local scaling (CSLS), to produce reliable matching pairs and validation criterion for unsupervised model selection.

---

[1] https://github.com/facebookresearch/MUSE

We conduct experiments on English-Spanish, English-Russian and English-Chinese datasets, which are the same as Conneau et al. (2018). The results are shown in Table 5. As seen, our model could consistently achieve better performance compared with adversarial training. After refinement, our model could further achieve competitive and even superior results compared with state-of-the-art unsupervised methods. This further demonstrates the capacity of our model.

5 Conclusion

Based on the assumption that word vectors in different languages could be drawn from a same latent variable space, we propose a novel approach which builds cross-lingual dictionaries via latent variable models and adversarial training with no parallel corpora. Experimental results on several language pairs have demonstrated the effectiveness and universality of our model. We hope our method could be beneficial to other areas such as unsupervised machine translation (Lample et al., 2018).

Future directions include validate our model on more realistic scenarios (Dinu et al., 2015) as well as combine our algorithms with more sophiscated adversarial networks (Arjovsky et al., 2017; Gulrajani et al., 2017).

Abstract

Word translation, or bilingual dictionary induction, is an important capability that impacts many multilingual language processing tasks. Recent research has shown that word translation can be achieved in an unsupervised manner, without parallel seed dictionaries or aligned corpora. However, state of the art methods for unsupervised bilingual dictionary induction are based on generative adversarial models, and as such suffer from their well known problems of instability and hyper-parameter sensitivity. We present a statistical dependency-based approach to bilingual dictionary induction that is unsupervised – no seed dictionary or parallel corpora required; and introduces no adversary – therefore being much easier to train. Our method performs comparably to adversarial alternatives and outperforms prior non-adversarial methods.

1 Introduction

Translating words between languages, or more generally inferring bilingual dictionaries, is a long-studied research direction with applications including machine translation (Lample et al., 2017), multilingual word embeddings (Klementiev et al., 2012), and knowledge transfer to low resource languages (Guo et al., 2016). Research here has a long history under the guise of decipherment (Knight et al., 2006). Current contemporary methods have achieve effective word translation through theme-aligned corpora (Gouws et al., 2015), or seed dictionaries (Mikolov et al., 2013).

Mikolov et al. (2013) showed that monolingual word embeddings exhibit isomorphism across languages, and can be aligned with a simple linear transformation. Given two sets word vectors learned independently from monolingual corpora, and a dictionary of seed pairs to learn a linear transformation for alignment; they were able to estimate a complete bilingual lexicon. Many studies have since followed this approach, proposing various improvements such as orthogonal mappings (Artetxe et al., 2016) and improved objectives (Lazaridou et al., 2015).

Obtaining aligned corpora or bilingual seed dictionaries is nevertheless not straightforward for all language pairs. This has motivated a wave of very recent research into *unsupervised* word translation: inducing bilingual dictionaries given only monolingual word embeddings (Conneau et al., 2018; Zhang et al., 2017b,a; Artetxe et al., 2017). The most successful have leveraged ideas from Generative Adversarial Networks (GANs) (Goodfellow et al., 2014). In this approach the generator provides the cross-modal mapping, taking embeddings of dictionary words in one language and 'generating' their translation in another. The discriminator tries to distinguish between this 'fake' set of translations and the true dictionary of embeddings in the target language. The two play a competitive game, and if the generator learns to fool the discriminator, then its cross-modal mapping should be capable of inducing a complete dictionary, as per Mikolov et al. (2013).

Despite these successes, such adversarial methods have a number of well-known drawbacks (Arjovsky et al., 2017): Due to the nature of their min-max game, adversarial training is very unstable, and they are prone to divergence. It is extremely hyper-parameter sensitive, requiring problem-specific tuning. Convergence is also hard to diagnose and does not correspond well to efficacy of the generator in downstream tasks (Hoshen and Wolf, 2018).

In this paper, we propose an alternative statistical dependency-based approach to unsupervised word translation. Specifically, we propose to search for the cross-lingual word pairing that maximizes statistical dependency in terms of squared

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 627–632
Brussels, Belgium, October 31 - November 4, 2018.

loss mutual information (SMI) (Yamada et al., 2015; Suzuki and Sugiyama, 2010). Compared to prior statistical dependency-based approaches such as Kernelized Sorting (KS) (Quadrianto et al., 2009) we advance: (i) through use of SMI rather than their Hilbert Schmidt Independence Criterion (HSIC) and (ii) through jointly optimising cross-modal pairing with representation learning within each view. In contrast to prior work that uses a fixed representation, by non-linearly projecting monolingual world vectors before matching, we learn a new embedding where statistical dependency is easier to establish. Our method: (i) achieves similar unsupervised translation performance to recent adversarial methods, while being significantly easier to train and (ii) clearly outperforms prior non-adversarial methods.

2 Proposed model

2.1 Deep Distribution Matching

Let dataset $\mathcal{D}$ contain two sets of unpaired monolingual word embeddings from two languages $\mathcal{D} = (\{\boldsymbol{x}_i\}_{i=1}^n, \{\boldsymbol{y}_j\}_{j=1}^n)$ where $\boldsymbol{x}, \boldsymbol{y} \in \mathbb{R}^d$. Let π be a permutation function over $\{1, 2, \ldots, n\}$, and $\boldsymbol{\Pi}$ the corresponding permutation indicator matrix: $\boldsymbol{\Pi} \in \{0,1\}^{n\times n}, \boldsymbol{\Pi}\boldsymbol{1}_n = \boldsymbol{1}_n$, and $\boldsymbol{\Pi}^\top\boldsymbol{1}_n = \boldsymbol{1}_n$. Where $\boldsymbol{1}_n$ is the n-dimensional vector with all ones. We aim to optimize for both the permutation $\boldsymbol{\Pi}$ (bilingual dictionary), and non-linear transformations $\boldsymbol{g}_{\boldsymbol{x}}(\cdot)$ and $\boldsymbol{g}_{\boldsymbol{y}}(\cdot)$ of the respective wordvectors, that maximize statistical dependency between the views. While regularising by requiring the original word embedding information is preserved through reconstruction using decoders $\boldsymbol{f}_{\boldsymbol{x}}(\cdot)$ and $\boldsymbol{f}_{\boldsymbol{y}}(\cdot)$. Our overall loss function is:

$$\begin{aligned}
&\underset{\boldsymbol{\Theta}_x,\boldsymbol{\Theta}_y,\boldsymbol{\Pi}}{min} \underbrace{\Omega(\mathcal{D};\boldsymbol{\Theta}_{\boldsymbol{x}},\boldsymbol{\Theta}_{\boldsymbol{y}})}_{Regularizer} - \underbrace{\lambda D_{\boldsymbol{\Pi}}(\mathcal{D};\boldsymbol{\Theta}_{\boldsymbol{x}},\boldsymbol{\Theta}_{\boldsymbol{y}})}_{Dependency},\\
&D_{\boldsymbol{\Pi}}(\mathcal{D};\boldsymbol{\Theta}_{\boldsymbol{x}},\boldsymbol{\Theta}_{\boldsymbol{y}}) = D_{\boldsymbol{\Pi}}(\{\boldsymbol{g}_{\boldsymbol{x}}(\boldsymbol{x}_i), \boldsymbol{g}_{\boldsymbol{y}}(\boldsymbol{y}_{\pi(i)})\}_{i=1}^n),\\
&\Omega(\mathcal{D};\boldsymbol{\Theta}_{\boldsymbol{x}},\boldsymbol{\Theta}_{\boldsymbol{y}}) = \sum_{i=1}^n \|\boldsymbol{x}_i - \boldsymbol{f}_{\boldsymbol{x}}(\boldsymbol{g}_{\boldsymbol{x}}(\boldsymbol{x}_i))\|_2^2\\
&\qquad + \|\boldsymbol{y}_i - \boldsymbol{f}_{\boldsymbol{y}}(\boldsymbol{g}_{\boldsymbol{y}}(\boldsymbol{y}_i))\|_2^2\\
&\qquad + R(\boldsymbol{\Theta}_{\boldsymbol{x}}) + R(\boldsymbol{\Theta}_{\boldsymbol{y}}).
\end{aligned} \tag{1}$$

where $\boldsymbol{\Theta}$s parameterize the encoding and reconstruction transformations, $R(\cdot)$ is a regularizer (e.g., ℓ_2-norm and ℓ_1-norm), and $D_{\boldsymbol{\Pi}}(\cdot,\cdot)$ is a statistical dependency measure. Crucially compared to prior methods such as matching CCA (Haghighi et al., 2008), dependency measures such as SMI do not need comparable representations to get started, making the bootstrapping problem less severe.

2.2 Dependence Estimation

Squared-Loss Mutual Information (SMI) The squared loss mutual information between two random variables $\boldsymbol{x}$ and $\boldsymbol{y}$ is defined as (Suzuki and Sugiyama, 2010):

$$\mathrm{SMI} = \iint \left(\frac{p(\boldsymbol{x},\boldsymbol{y})}{p(\boldsymbol{x})p(\boldsymbol{y})} - 1\right)^2 p(\boldsymbol{x})p(\boldsymbol{y})\mathrm{d}\boldsymbol{x}\mathrm{d}\boldsymbol{y},$$

which is the Pearson divergence (Pearson, 1900) from $p(\boldsymbol{x},\boldsymbol{y})$ to $p(\boldsymbol{x})p(\boldsymbol{y})$. The SMI is an f-divergence (Ali and Silvey, 1966). That is, it is a non-negative measure and is zero only if the random variables are independent.

To measure SMI from a set of samples we take a direct density ratio estimation approach (Suzuki and Sugiyama, 2010), which leads (Yamada et al., 2015) to the estimator:

$$\widehat{\mathrm{SMI}}(\{(\boldsymbol{x}_i,\boldsymbol{y}_i)\}_{i=1}^n) = \frac{1}{2n}\mathrm{tr}\left(\mathrm{diag}\left(\widehat{\boldsymbol{\alpha}}\right)\boldsymbol{K}\boldsymbol{L}\right) - \frac{1}{2},$$

where $\boldsymbol{K} \in \mathbb{R}^{n\times n}$ and $\boldsymbol{L} \in \mathbb{R}^{n\times n}$ are the gram matricies for $\boldsymbol{x}$ and $\boldsymbol{y}$ respectively, and

$$\begin{aligned}
&\widehat{\boldsymbol{H}} = \frac{1}{n^2}(\boldsymbol{K}\boldsymbol{K}^\top) \circ (\boldsymbol{L}\boldsymbol{L}^\top),\\
&\widehat{\boldsymbol{h}} = \frac{1}{n}(\boldsymbol{K}\circ\boldsymbol{L})\boldsymbol{1}_n,\ \ \widehat{\boldsymbol{\alpha}} = \left(\widehat{\boldsymbol{H}} + \lambda\boldsymbol{I}_n\right)^{-1}\widehat{\boldsymbol{h}},
\end{aligned}$$

$\lambda > 0$ is a regularizer and $\boldsymbol{I}_n \in \mathbb{R}^{n\times n}$ is the identity matrix.

SMI for Matching SMI computes the dependency between two sets of variables, under an assumption of known correspondence. In our application this corresponds to a measure of dependency between two *aligned* sets of monolingual wordvectors. To exploit SMI for matching, we introduce a permutation variable $\boldsymbol{\Pi}$ by replacing $\boldsymbol{L} \to \boldsymbol{\Pi}^\top\boldsymbol{L}\boldsymbol{\Pi}$ in the estimator:

$$\widehat{\mathrm{SMI}}(\{(\boldsymbol{x}_i,\boldsymbol{y}_{\pi(i)})\}_1^n) = \frac{1}{2n}\mathrm{tr}\left(\mathrm{diag}\left(\widehat{\boldsymbol{\alpha}}_{\boldsymbol{\Pi}}\right)\boldsymbol{K}\boldsymbol{\Pi}^\top\boldsymbol{L}\boldsymbol{\Pi}\right) - \frac{1}{2},$$

that will enable optimizing $\boldsymbol{\Pi}$ to maximize SMI.

2.3 Optimization of parameters

To initialize $\boldsymbol{\Theta}_{\boldsymbol{x}}$ and $\boldsymbol{\Theta}_{\boldsymbol{y}}$, we first independently estimate them using autoencoders. Then we employ an alternative optimization on Eq. (1) for

$(\boldsymbol{\Theta}_{\boldsymbol{x}}, \boldsymbol{\Theta}_{\boldsymbol{y}})$ and $\boldsymbol{\Pi}$ until convergence. We use 3 layer MLP neural networks for both $\boldsymbol{f}$ and $\boldsymbol{g}$. Algorithm 1 summarises the steps.

Optimization for $\boldsymbol{\Theta}_{\boldsymbol{x}}$ and $\boldsymbol{\Theta}_{\boldsymbol{y}}$ With fixed permutation matrix $\boldsymbol{\Pi}$ (or π), the objective function

$$\min_{\boldsymbol{\Theta}_{\boldsymbol{x}}, \boldsymbol{\Theta}_{\boldsymbol{y}}} \Omega(\mathcal{D}; \boldsymbol{\Theta}_{\boldsymbol{x}}, \boldsymbol{\Theta}_{\boldsymbol{y}}) - \lambda D_{\boldsymbol{\Pi}}(\mathcal{D}; \boldsymbol{\Theta}_{\boldsymbol{x}}, \boldsymbol{\Theta}_{\boldsymbol{y}}) \quad (2)$$

is an autoencoder optimization with regularizer $D_{\boldsymbol{\Pi}}(\cdot)$, and can be solved with backpropagation.

Optimization for $\boldsymbol{\Pi}$ To find the permutation (word matching) $\boldsymbol{\Pi}$ that maximizes SMI given fixed encoding parameters $\boldsymbol{\Theta}_{\boldsymbol{x}}, \boldsymbol{\Theta}_{\boldsymbol{y}}$, we only need to optimize the dependency term $D_{\boldsymbol{\Pi}}$ in Eq. (1). We employ the LSOM algorithm (Yamada et al., 2015). The estimator of SMI for samples $\{\boldsymbol{g}_{\boldsymbol{x}}(\boldsymbol{x}_i), \boldsymbol{g}_{\boldsymbol{y}}(\boldsymbol{y}_{\pi(i)})\}_{i=1}^{n}$ encoded with $\boldsymbol{g}_x, \boldsymbol{g}_y$ is:

$$\widehat{\mathrm{SMI}} = \frac{1}{2n}\mathrm{tr}\left(\mathrm{diag}\left(\widehat{\boldsymbol{\alpha}}_{\boldsymbol{\Theta},\boldsymbol{\Pi}}\right) \boldsymbol{K}_{\boldsymbol{\Theta}_{\boldsymbol{x}}}\boldsymbol{\Pi}^\top \boldsymbol{L}_{\boldsymbol{\Theta}_{\boldsymbol{y}}}\boldsymbol{\Pi}\right) - \frac{1}{2}.$$

Which leads to the optimization problem:

$$\max_{\boldsymbol{\Pi}\in\{0,1\}^{n\times n}} \mathrm{tr}\left(\mathrm{diag}\left(\widehat{\boldsymbol{\alpha}}_{\boldsymbol{\Theta},\boldsymbol{\Pi}}\right) \boldsymbol{K}_{\boldsymbol{\Theta}_{\boldsymbol{x}}}\boldsymbol{\Pi}^\top \boldsymbol{L}_{\boldsymbol{\Theta}_{\boldsymbol{y}}}\boldsymbol{\Pi}\right)$$
$$\text{s.t.} \quad \boldsymbol{\Pi}\mathbf{1}_n = \mathbf{1}_n, \boldsymbol{\Pi}^\top\mathbf{1}_n = \mathbf{1}_n. \quad (3)$$

Since the optimization problem is NP-hard, we iteratively solve the relaxed problem (Yamada et al., 2015):

$$\boldsymbol{\Pi}^{\mathrm{new}} = (1-\eta)\boldsymbol{\Pi}^{\mathrm{old}} +$$
$$\eta \operatorname*{argmax}_{\boldsymbol{\Pi}} \mathrm{tr}\left(\mathrm{diag}\left(\widehat{\boldsymbol{\alpha}}_{\boldsymbol{\Theta},\boldsymbol{\Pi}^{\mathrm{old}}}\right) \boldsymbol{K}_{\boldsymbol{\Theta}_{\boldsymbol{x}}}\boldsymbol{\Pi}^\top \boldsymbol{L}_{\boldsymbol{\Theta}_{\boldsymbol{y}}}\boldsymbol{\Pi}^{\mathrm{old}}\right),$$

where $0 < \eta \leq 1$ is a step size. The optimization problem is a *linear assignment problem* (LAP). Thus, we can efficiently solve the algorithm by using the *Hungarian method* (Kuhn, 1955). To get discrete $\boldsymbol{\Pi}$, we solve the last step by setting $\eta = 1$.

Intuitively, this can be seen as searching for the permutation $\boldsymbol{\Pi}$ for which the data in the two (initially unsorted views) have a matching within-view affinity (gram) matrix, where matching is defined by maximum SMI.

3 Experiments

In this section, we evaluate the efficacy of our proposed method against various state of the art methods for word translation.

Implementation Details Our autoencoder consists of two layers with dropout and a *tanh* nonlinearity. We use polynomial kernel to compute the gram matrices $\boldsymbol{K}$ and $\boldsymbol{L}$. For all pairs of languages, we fix the number of training epochs to 20. All the word vectors are ℓ_2 unit normalized. For CSLS we set the number of neighbors to 10. For optimizing $\boldsymbol{\Pi}$ at each epoch, we set the step size $\eta = 0.75$ and use 20 iterations. For the regularization $R(\boldsymbol{\Theta})$, we use the sum of the Frobenius norms of weight matrices. We train $\boldsymbol{\Theta}$ using full batch gradient-descent, with learning rate 0.05.

Algorithm 1 SMI-based unsupervised word translation

```
Input: Unpaired word embeddings $\mathcal{D} = (\{\boldsymbol{x}_i\}_{i=1}^{n}, \{\boldsymbol{y}_j\}_{j=1}^{n})$.
Init: weights $\boldsymbol{\Theta}_{\boldsymbol{x}}, \boldsymbol{\Theta}_{\boldsymbol{y}}$, permutation matrix $\boldsymbol{\Pi}$.
while not converged do
    Update $\boldsymbol{\Theta}_{\boldsymbol{x}}, \boldsymbol{\Theta}_{\boldsymbol{y}}$ given $\boldsymbol{\Pi}$: Backprop (2).
    Update $\boldsymbol{\Pi}$ given $\boldsymbol{\Theta}_{\boldsymbol{x}}, \boldsymbol{\Theta}_{\boldsymbol{y}}$: LSOM (3).
end while
Output: Permutation Matrix $\boldsymbol{\Pi}$. Params $\boldsymbol{\Theta}_{\boldsymbol{x}}, \boldsymbol{\Theta}_{\boldsymbol{y}}$.
```

Datasets We performed experiments on the publicly available English-Italian, English-Spanish and English-Chinese datasets released by (Dinu and Baroni, 2015; Zhang et al., 2017b; Vulic and Moens, 2013). We name this collective set of benchmarks BLI. We also conduct further experiments on a much larger recent public benchmark, MUSE (Conneau et al., 2018)[1].

Setting and Metrics We evaluate all methods in terms of Precision@1, following standard practice. We note that while various methods in the literature were initially presented as fully supervised (Mikolov et al., 2013), semi-supervised (using a seed dictionary) (Haghighi et al., 2008), or unsupervised (Zhang et al., 2017b), most of them can be straightforwardly adapted to run in any of these settings. Therefore we evaluate all methods both in the unsupervised setting in which we are primarily interested, and also the commonly evaluated semi-supervised setting with 500 seed pairs.

Competitors: Non-Adversarial In terms of competitors that, like us, do not make use of GANs, we evaluate: **Translation Matrix** (Mikolov et al., 2013), which alternates between estimating a linear transformation by least squares and matching by nearest neighbour (NN). **Multilingual Correlation** (Faruqui and Dyer, 2014), and **Matching CCA** (Haghighi et al., 2008), which alternates between matching and estimat-

ing a joint linear subspace. **Kernelized Sorting** (Quadrianto et al., 2009), which directly uses HSIC-based statistical dependency to match heterogeneous data points. **Self Training** (Artetxe et al., 2017) A recent state of the art method that alternate between estimating an orthonormal transformation, and NN matching.

Competitors: Adversarial In terms of competitors that do make use of adversarial training, we compare: **W-GAN** and **EMDOT** (Zhang et al., 2017b) make use of adversarial learning using Wasserstein GAN and Earth Movers Distance respectively. **GAN-NN** (Conneau et al., 2018) uses adversarial learning to train an orthogonal transformation, along with some refinement steps and an improvement to the conventional NN matching procedure called ‘cross-domain similarity local scaling’ (CSLS). Since this is a distinct step, we also evaluate our method with CSLS.

We use the provided code for GAN-NN and Self-Train, while re-implementing EDOT/W-GAN to avoid dependency on theano.

3.1 Results

Fully Unsupervised Table 1 presents comparative results for unsupervised word translation on BLI and MUSE. From these we observe: (i) Our method (bottom) is consistently and significantly better than non-adversarial alternatives (top). (ii) Compared to adversarial alternatives Deep-SMI performs comparably.

All methods generally perform better on the MUSE dataset than BLI. These differences are due to a few factors: MUSE is a significantly

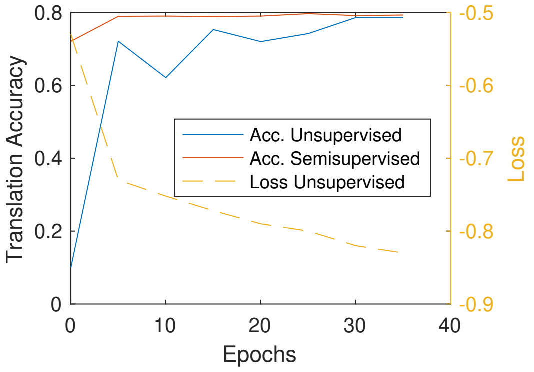

Figure 1: Training process of Deep-SMI

larger dataset than BLI, benefitting methods that can exploit a large amount of training data. In the ground-truth annotation, BLI contains 1-1 translations while MUSE contains more realistic 1-many translations (if any correct translation is picked, a success is counted), making it easier to reach a higher score.

Semi-supervised Results using a 500-word bilingual seed dictionary are presented in Table 2. From these we observe: (i) The conventional methods' performances (top) jump up, showing that they are more competitive if at least some sparse data is available. (ii) Deep-SMI performance also improves, and still outperforms the classic methods significantly overall. (iii) Again, we perform comparably to the GAN methods.

3.2 Discussion

Figure 1 shows the convergence process of Deep-SMI. From this we see that: (i) Unlike the adversarial methods, our objective (Eq. (1)) improves smoothly over time, making convergence much easier to assess. (ii) Unlike the adversarial methods, our accuracy generally mirrors the model's loss. In contrast, the various losses of the adversarial approaches do not well reflect translation accuracy, making model selection or early stopping a challenge in itself. Please compare our Figure 1 with Fig 3 in Zhang et al. (2017b), and Fig 2 in Conneau et al. (2018).

There are two steps in our optimization: matching permutation $\mathbf{\Pi}$ and representation weights $\mathbf{\Theta}$. Although this is an alternating optimization, it is analogous to an EM-type algorithm optimizing latent variables ($\mathbf{\Pi}$) and parameters ($\mathbf{\Theta}$). While local minima are a risk, every optimisation step for either variable reduces our objective Eq. (1). There is no min-max game, so no risk of divergence as in the case of adversarial GAN-type methods.

Our method can also be understood as providing an unsupervised *Deep*-CCA type model for relating heterogeneous data across two views. This is in contrast to the recently proposed unsupervised shallow CCA (Hoshen and Wolf, 2018), and conventional supervised Deep-CCA (Chang et al., 2018) that requires paired data for training; and using SMI rather than correlation as the optimisation objective.

4 Conclusion

We have presented an effective approach to unsupervised word translation that performs comparably to adversarial approaches while being significantly easier to train and diagnose; as well as outperforming prior non-adversarial approaches.

Abstract

This paper proposes an adversarial training method for the multi-task and multi-lingual joint modeling needed for utterance intent classification. In joint modeling, common knowledge can be efficiently utilized among multiple tasks or multiple languages. This is achieved by introducing both language-specific networks shared among different tasks and task-specific networks shared among different languages. However, the shared networks are often specialized in majority tasks or languages, so performance degradation must be expected for some minor data sets. In order to improve the invariance of shared networks, the proposed method introduces both language-specific task adversarial networks and task-specific language adversarial networks; both are leveraged for purging the task or language dependencies of the shared networks. The effectiveness of the adversarial training proposal is demonstrated using Japanese and English data sets for three different utterance intent classification tasks.

1 Introduction

In natural language processing fields, full neural network based methods are suitable for joint modeling as they can simultaneously utilize multiple task data sets or multiple language data sets to improve the performance achieved for individual tasks or languages (Collobert and Weston, 2008). It is known that joint modeling can address the data scarcity problem.

Key natural language processing technologies for spoken dialogue systems include utterance intent classification, which is needed to detect intent labels such as dialogue act (Stolcke et al., 2000; Khanpour et al., 2016), domain (Xu and Sarikaya, 2014), and question type (Wu et al., 2005) from input utterances (Ravuri and Stolcke, 2015a,b, 2016). One problem is that the training data are often limited or unbalanced among different tasks or different languages. Therefore, our motivation is to leverage both multi-task joint modeling and multi-lingual joint modeling to enhance utterance intent classification.

The multi-task and multi-lingual joint modeling can be composed by introducing both task-specific networks, which are shared among different languages, and language-specific networks, which are shared among different tasks (Masumura et al., 2018; Lin et al., 2018). Although joint modeling is mainly intended to improve classification performance in resource-poor tasks or languages, its classification performance is degraded in some minor data sets. This is because the language-specific networks often depend on majority tasks, while the task-specific networks often depend on majority languages. What are needed are task-specific networks that are invariant to languages, and language-specific networks that are invariant to tasks.

In order to explicitly improve the invariance of language and task-specific networks, this paper introduces adversarial training (Goodfellow et al., 2014). Our idea is to train language-specific networks so as to be insensitive to the target task, while training task-specific networks to be insensitive to language. To this end, we introduce multiple domain adversarial networks (Ganin et al., 2016), language-specific task adversarial networks, and task-specific language adversarial networks, into a state-of-the-art fully neural network based joint modeling; we adopt the bidirectional long short-term memory recurrent neural networks (BLSTM-RNNs) with attention mechanism (Yang et al., 2016; Zhou et al., 2016). To the best of our knowledge, this paper is the first study to employ adversarial training for multi-input and multi-output joint modeling.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 633–639
Brussels, Belgium, October 31 - November 4, 2018.

Experiments on Japanese and English data sets demonstrate the effectiveness of the adversarial training proposal. To support spoken dialogue systems, three different utterance intent classification tasks are examined: dialogue act, topic type, and question type classification.

2 Related Work

Joint Modeling: In natural language processing research, joint modeling is usually split into multi-task joint modeling and multi-lingual joint modeling. Multi-task joint modeling has been shown to effectively improve individual tasks (Collobert and Weston, 2008; Liu et al., 2016a,b; Zhang and Weng, 2016; Liu et al., 2016c). In addition, multi-lingual joint modeling is achieved by learning common semantic representations among different languages (Guo et al., 2016; Duong et al., 2016; Zhang et al., 2016, 2017b). In addition, a few work have examined multi-task and multi-lingual joint modeling (Masumura et al., 2018; Lin et al., 2018). Different from the previous work, our novelty is to introduce adversarial training for multi-task and multi-lingual joint modeling.

Adversarial Training: The concept of adversarial training was first proposed by Goodfellow et al. (2014), and many studies in the machine learning field have focused on adversarial training. Adversarial training has been well utilized in text classification (Ganin et al., 2016; Chen et al., 2016; Liu et al., 2017; Miyato et al., 2017; Chen and Cardie, 2018). Most natural language processing papers adopted either the language invariant approach (Chen et al., 2016; Zhang et al., 2017a) or the task invariant approach (Ganin et al., 2016; Liu et al., 2017; Chen and Cardie, 2018). This paper aims to fully utilize both task adversarial training and language adversarial training. To this end, we simultaneously introduce language-specific task adversarial networks and task-specific language adversarial networks.

3 Proposed Method

This section details our adversarial training method for multi-task and multi-lingual joint modeling of utterance intent classification.

In the j-th task utterance intent classification for the i-th language input utterance, intent label $l^{(j)} \in \{1, \cdots, K^{(j)}\}$ is estimated from input utterance $\mathcal{W}^{(i)} = \{w_1^{(i)}, \cdots, w_T^{(i)}\}$ where $i \in \{1, \cdots, I\}$ and $j \in \{1, \cdots, J\}$. Utterance intent classification is followed by estimation of the probabilities of each intent label given input utterance, $P(l^{(j)}|\mathcal{W}^{(i)}, \boldsymbol{\Theta}^{(i,j)})$ where $\boldsymbol{\Theta}^{(i,j)}$ is the trainable model parameter for the combination of the i-th language and the j-th task. In multi-task and multi-lingual joint modeling, $\{\boldsymbol{\Theta}^{(1,1)}, \cdots, \boldsymbol{\Theta}^{(I,J)}\}$ are jointly trained from I language and J task data sets.

3.1 Main Joint Network

The proposed method is founded on a fully neural network that employs I language-specific networks, J task-specific networks, and J classification networks as well as Masumura et al. (2018).

The language-specific network can be shared between multiple tasks, where words in the input utterance are converted into language-specific hidden representations. Each word in the i-th language input utterance $\mathcal{W}^{(i)}$ is first converted into a continuous representation. Next, each word representation is converted into a hidden representation that uses BLSTM-RNNs to take neighboring word context information into account. The t-th language-specific hidden representation for the i-th language is given by:

$$\boldsymbol{w}_t^{(i)} = \texttt{EMBED}(w_t^{(i)}; \boldsymbol{\theta}_{\mathrm{h}}^{(i)}), \tag{1}$$

$$\boldsymbol{h}_t^{(i)} = \texttt{BLSTM}(\{\boldsymbol{w}_1^{(i)}, \cdots, \boldsymbol{w}_T^{(i)}\}, t; \boldsymbol{\theta}_{\mathrm{h}}^{(i)}), \tag{2}$$

where $\texttt{EMBED}()$ is a linear transformational function for word embedding, $\texttt{BLSTM}()$ is a function of the BLSTM-RNN layer, and $\boldsymbol{\theta}_{\mathrm{h}}^{(i)}$ is the trainable parameter for the i-th language-specific network.

In addition, task-specific networks can be shared between multiple languages, where the language-specific hidden representations are converted into task-specific hidden representations. The t-th language-specific hidden representation for the j-th task is given by:

$$\boldsymbol{u}_t^{(j)} = \texttt{BLSTM}(\{\boldsymbol{h}_1^{(i)}, \cdots, \boldsymbol{h}_T^{(i)}\}, t; \boldsymbol{\theta}_{\mathrm{u}}^{(j)}), \tag{3}$$

where $\boldsymbol{\theta}_{\mathrm{u}}^{(j)}$ is the trainable parameter for the j-th task-specific network.

In classification networks for each task, the task-specific hidden representations are summarized as sentence representation $\boldsymbol{s}^{(j)}$ by using a self-attention mechanism that can consider the importance of individual hidden representations (Yang et al., 2016; Zhou et al., 2016; Sawada et al., 2017). Next, predicted probabilities of the j-th task intent labels, $\boldsymbol{o}^{(j)} \in \mathbb{R}^{K^{(j)}}$, are given by:

$$\boldsymbol{s}^{(j)} = \mathtt{ATTENSUM}(\{\boldsymbol{h}_1^{(i)}, \cdots, \boldsymbol{h}_T^{(i)}\}; \boldsymbol{\theta}_{\rm o}^{(j)}), \quad (4)$$

$$\boldsymbol{o}^{(j)} = \mathtt{SOFTMAX}(\boldsymbol{s}^{(j)}; \boldsymbol{\theta}_{\rm o}^{(j)}), \quad (5)$$

where $\mathtt{ATTENSUM}()$ is a weighted sum function with self-attention, $\mathtt{SOFTMAX}()$ is a transformational function with softmax activation, and $\boldsymbol{\theta}_{\rm o}^{(j)}$ is the trainable parameter for the j-th classification network. In the main joint networks of the proposal, $\boldsymbol{\Theta}^{(i,j)}$ corresponds to $\{\boldsymbol{\theta}_{\rm h}^{(i)}, \boldsymbol{\theta}_{\rm u}^{(j)}, \boldsymbol{\theta}_{\rm o}^{(j)}\}$.

3.2 Adversarial Networks

The proposed method combines a language-specific task adversarial network with a task-specific language adversarial network. The task adversarial network is used for training the language-specific networks to be insensitive to target task labels, and the language adversarial network is used for training the task-specific networks to be insensitive to target language labels. In order to efficiently use stochastic gradient descent based training for optimizing the adversarial networks, we use gradient reversal layers, which allow the input vectors during forward propagation, and sign inversion of the gradients during back propagation, to be utilized (Ganin et al., 2016).

The i-th language-specific task adversarial network estimates task labels from the i-th language-specific hidden representations. The predicted probabilities of task labels, $\boldsymbol{x}^{(i)} \in \mathbb{R}^J$, are given by:

$$\tilde{\boldsymbol{h}}_t^{(i)} = \mathtt{GRL}(\boldsymbol{h}_t^{(i)}), \quad (6)$$

$$\tilde{\boldsymbol{h}}^{(i)} = \mathtt{ATTENSUM}(\{\tilde{\boldsymbol{h}}_1^{(i)}, \cdots, \tilde{\boldsymbol{h}}_T^{(i)}\}; \boldsymbol{\theta}_{\rm x}^{(i)}), \quad (7)$$

$$\boldsymbol{x}^{(i)} = \mathtt{SOFTMAX}(\tilde{\boldsymbol{h}}^{(i)}, \boldsymbol{\theta}_{\rm x}^{(i)}), \quad (8)$$

where $\mathtt{GRL}()$ represents the gradient reversal layer, and $\boldsymbol{\theta}_{\rm x}^{(i)}$ is the trainable parameter. The j-th task-specific language adversarial network estimates language labels from the j-th task-specific hidden representations. The predicted probabilities of language labels, $\boldsymbol{y}^{(j)} \in \mathbb{R}^I$, are given by:

$$\tilde{\boldsymbol{u}}_t^{(j)} = \mathtt{GRL}(\boldsymbol{u}_t^{(j)}), \quad (9)$$

$$\tilde{\boldsymbol{u}}^{(j)} = \mathtt{ATTENSUM}(\{\tilde{\boldsymbol{u}}_1^{(j)}, \cdots, \tilde{\boldsymbol{u}}_T^{(j)}\}; \boldsymbol{\theta}_{\rm y}^{(j)}), \quad (10)$$

$$\boldsymbol{y}^{(j)} = \mathtt{SOFTMAX}(\tilde{\boldsymbol{u}}^{(j)}, \boldsymbol{\theta}_{\rm y}^{(j)}), \quad (11)$$

where $\boldsymbol{\theta}_{\rm y}$ is the trainable parameter.

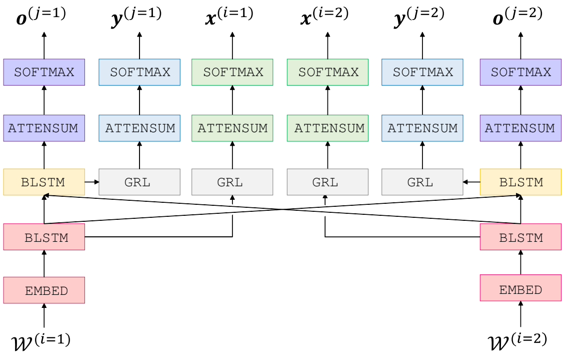

Figure 1: Proposed network structure for two tasks and two languages.

The proposed network structure shown in Figure 1 includes both joint networks and adversarial networks for two tasks and two languages. The red components are language-specific networks, the orange components are task-specific networks, and the purple components are classification networks. In addition, green components are language-specific task adversarial networks, and blue components are task-specific language adversarial networks.

3.3 Training

Our adversarial training proposal jointly optimizes all parameters in both the main joint networks and the adversarial networks by using all training data sets $\{\mathcal{D}^{(1,1)}, \cdots, \mathcal{D}^{(I,J)}\}$ where $\mathcal{D}^{(i,j)}$ represents the sets of the input utterances and the reference. The cross-entropy loss functions of each network are defined as:

$$L_{\boldsymbol{o}} = -\sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{n=1}^{|\mathcal{D}^{(i,j)}|}\sum_{k=1}^{K^{(j)}} \hat{\boldsymbol{o}}_{n,k}^{(j)} \log \boldsymbol{o}_{n,k}^{(j)}, \quad (12)$$

$$L_{\boldsymbol{x}} = -\sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{n=1}^{|\mathcal{D}^{(i,j)}|}\sum_{j'=1}^{J} \hat{\boldsymbol{x}}_{n,j'}^{(i)} \log \boldsymbol{x}_{n,j'}^{(i)}, \quad (13)$$

$$L_{\boldsymbol{y}} = -\sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{n=1}^{|\mathcal{D}^{(i,j)}|}\sum_{i'=1}^{I} \hat{\boldsymbol{y}}_{n,i'}^{(j)} \log \boldsymbol{y}_{n,i'}^{(j)}, \quad (14)$$

where $L_{\boldsymbol{o}}$, $L_{\boldsymbol{x}}$, and $L_{\boldsymbol{y}}$ are the cross entropy loss terms for the classification networks, the task adversarial networks, and the language adversarial networks. $\hat{\boldsymbol{o}}_{n,k}^{(j)}$, $\hat{\boldsymbol{x}}_{n,j'}^{(i)}$, and $\hat{\boldsymbol{y}}_{n,i'}^{(j)}$ are the reference probabilities, and $\boldsymbol{o}_{n,k}$, $\boldsymbol{x}_{n,j'}$, and $\boldsymbol{y}_{n,i'}$ are the estimated probabilities of the k-th label in the j-th task classification network, the j'-th task in the i-th language-specific task adversarial network, and

Task	Utterance	Label
DA	Hello, how are you today?	GREETING
	I am so sorry to hear of your son's accident.	SYMPATHY/AGREE
	Lets go to school an hour early today.	PROPOSAL
TT	What is the highest mountain in the world?	MOUNTAIN
	Who is president of the united states?	PERSON
	What is the name of the most recent Star Wars movie?	MOVIE
QT	Do you like egg salad?	TRUE/FALSE
	How do you correct a hook in a golf swing?	EXPLANATION:METHOD
	Why is blood red?	EXPLANATION:CAUSE

Table 2: Examples of English data sets.

the i'-th language in the j-th task-specific language adversarial network for $\mathcal{W}_n$, respectively.

Due to use of gradient reversal layers, individual parameters are gradually updated as follows:

$$\boldsymbol{\theta}_{\mathtt{o}}^{(j)} \leftarrow \boldsymbol{\theta}_{\mathtt{o}}^{(j)} - \epsilon \frac{\partial L_{\boldsymbol{o}}}{\partial \boldsymbol{\theta}_{\mathtt{o}}^{(j)}}, \tag{15}$$

$$\boldsymbol{\theta}_{\mathtt{y}}^{(j)} \leftarrow \boldsymbol{\theta}_{\mathtt{y}}^{(j)} - \epsilon \beta \frac{\partial L_{\boldsymbol{y}}}{\partial \boldsymbol{\theta}_{\mathtt{y}}^{(j)}}, \tag{16}$$

$$\boldsymbol{\theta}_{\mathtt{u}}^{(j)} \leftarrow \boldsymbol{\theta}_{\mathtt{u}}^{(j)} - \epsilon \Big(\frac{\partial L_{\boldsymbol{o}}}{\partial \boldsymbol{\theta}_{\mathtt{u}}^{(j)}} - \beta \frac{\partial L_{\boldsymbol{y}}}{\partial \boldsymbol{\theta}_{\mathtt{u}}^{(j)}} \Big), \tag{17}$$

$$\boldsymbol{\theta}_{\mathtt{x}}^{(i)} \leftarrow \boldsymbol{\theta}_{\mathtt{x}}^{(i)} - \epsilon \alpha \frac{\partial L_{\boldsymbol{x}}}{\partial \boldsymbol{\theta}_{\mathtt{x}}^{(i)}}, \tag{18}$$

$$\boldsymbol{\theta}_{\mathtt{h}}^{(i)} \leftarrow \boldsymbol{\theta}_{\mathtt{h}}^{(i)} - \epsilon \Big(\frac{\partial L_{\boldsymbol{o}}}{\partial \boldsymbol{\theta}_{\mathtt{h}}^{(i)}} - \alpha \frac{\partial L_{\boldsymbol{x}}}{\partial \boldsymbol{\theta}_{\mathtt{h}}^{(i)}} - \beta \frac{\partial L_{\boldsymbol{y}}}{\partial \boldsymbol{\theta}_{\mathtt{h}}^{(i)}} \Big), \tag{19}$$

where α and β are hyper parameters of the parameter update, and ϵ is the learning rate. Note that adversarial training is suppressed by setting α and β to 0.0. In training, we prepared optimizers for individual data sets. The individual learning rates fall when the validation loss of the target classification network increases.

4 Experiments

Our experiments employed Japanese and English data sets created for three different utterance intent classification tasks. The tasks, dialogue act (DA) classification, topic type (TT) classification, and question type (QT) classification, are intended to support spoken dialogue systems. For example, the task of English DA classification is to obtain a DA label from an input utterance. We used natural language texts as the input utterances and individual label sets were unified between Japanese and English. Data sets employed in experiments were corpora that were made for constructing spoken dialogue systems (Masumura et al., 2018). Each of the data sets were divided into training (Train), validation (Valid), and test (Test) sets. Table 1 shows the number of utterances in individual data sets where #labels represents the number of labels. Table 2 shows English utterances and label examples for individual tasks.

Language	Task	#labels	Train	Valid	Test
Japanese	DA	28	201 K	4 K	4 K
	TT	168	40 K	4 K	4 K
	QT	15	55 K	4 K	4 K
English	DA	28	25 K	3 K	3 K
	TT	168	25 K	3 K	3 K
	QT	15	22 K	2 K	2 K

Table 1: Number of utterances in individual data sets.

4.1 Setups

We examined single-task and mono-lingual modeling, multi-task joint modeling, multi-lingual join modeling, and multi-task and multi-lingual joint modeling with or without adversarial training.

We unified network configurations as follows. Word representation size was set to 128, BLSTM-RNN unit size was set to 400, and sentence representation was set to 400. Dropout was used for `EMBED()` and `BLSTM()`, and the dropout rate was set to 0.5. Words that appeared only once in the training data sets were treated as unknown words. We used mini-batch stochastic gradient descent, in which initial learning rate was set to 0.1. We optimized hyper-parameters of adversarial training (α and β) for the validation sets by varying them from 0.001 to 1.0. Other hyper parameters were also optimized for the validation sets.

4.2 Results

Table 3 shows the results in terms of utterance classification accuracy. For each setup, we constructed five models by varying the initial parameters and evaluated the average accuracy. Line (1) shows baseline results: single-task and mono-lingual modeling. Lines (2) and (3) show results

	Joint modeling		Adversarial Training		Japanese			English		
	Multi-task	Multi-lingual	Task-invariant	Language-invariant	DA	TT	QT	DA	TT	QT
(1).	-	-	-	-	66.6	79.1	87.7	61.8	64.5	83.4
(2)	√	-	-	-	66.5	79.6	89.3	60.6	64.4	**83.7**
(3)	√	-	√	-	66.5	80.6	89.5	61.6	65.7	**83.7**
(4)	-	√	-	-	66.7	78.7	87.2	61.4	64.3	83.0
(5)	-	√	-	√	66.9	79.8	88.2	61.8	64.8	83.3
(6).	√	√	-	-	66.6	79.7	89.3	60.5	65.4	82.6
(7).	√	√	√	-	67.3	81.1	89.6	61.5	66.1	83.5
(8).	√	√	-	√	66.7	80.7	89.5	60.9	**66.7**	83.0
(9).	√	√	√	√	**67.6**	**81.3**	**90.0**	**61.9**	**66.7**	**83.7**

Table 3: Experimental results: utterance classification accuracy (%) for individual test sets.

with only performing multi-task joint modeling, and lines (4) and (5) show results with only performing multi-lingual joint modeling. Note that lines (3) and (5) show the results achieved with adversarial training. Line (6) shows multi-task and multi-lingual joint modeling results: adversarial training was suppressed by setting both α and β to 0.0. Lines (7)–(9) shows the results achieved with adversarial training. Note that setting with bold values achieved the highest performance in our evaluation.

First, in lines (2) and (4), the classification performance deteriorated in some cases, while performance improvements were achieved in other cases. On the other hand, in lines (3) and (5), classification performance in each data sets was improved by introducing adversarial training. This indicates that adversarial training was effective in improving the performance of joint modeling.

Next, line (6) shows that, relative to line 1, multi-task and multi-lingual joint modeling can improve the classification performance for Japanese TT, Japanese QT, and English TT, but classification performance was degraded for English DA and English QT. This indicates that it is difficult to simultaneously improve the classification performance for all data sets because joint modeling often depends on majority tasks or majority languages. In addition, lines (7) and (8) show the introduction of either task adversarial networks or language adversarial networks yielded better performance than line (6) for all data sets. This indicates that adversarial training was effective in improving the performance of multi-task and multi-lingual joint modeling. The best results were achieved by using both language-specific task adversarial networks and task-specific language adversarial networks, line (9). These results confirm that task adversarial networks and language adversarial networks well complement each other. Of particular benefit, the proposed method demonstrated greater classification performance improvements when the number of training utterances per label was small.

5 Conclusions

We have proposed an adversarial training method for the multi-task and multi-lingual joint modeling needed to enhance utterance intent classification. Our adversarial training proposal utilizes both task adversarial networks and language adversarial networks for improving task-invariance in language-specific networks and language-invariance in task-specific networks. Experiments showed that the adversarial training proposal could well realize the benefits of joint modeling in all data sets.

Abstract

In this paper we show that a simple beam approximation of the joint distribution between attention and output is an easy, accurate, and efficient attention mechanism for sequence to sequence learning. The method combines the advantage of sharp focus in hard attention and the implementation ease of soft attention. On five translation and two morphological inflection tasks we show effortless and consistent gains in BLEU compared to existing attention mechanisms.

1 Introduction

In structured input-output models as used in tasks like translation and image captioning, the attention variable decides which part of the input aligns to the current output. Many attention mechanisms have been proposed (Xu et al., 2015; Bahdanau et al., 2014; Luong et al., 2015; Martins and Astudillo, 2016) but the de facto standard is a soft attention mechanism that first assigns attention weights to input encoder states, then computes an attention weighted 'soft' aligned input state, which finally derives the output distribution. This method is end to end differentiable and easy to implement.

Another less popular variant is hard attention that aligns each output to exactly one input state but requires intricate training to teach the network to choose that state. When successfully trained, hard attention is often found to be more accurate (Xu et al., 2015; Zaremba and Sutskever, 2015). In NLP, a recent success has been in a monotonic hard attention setting in morphological inflection tasks (Yu et al., 2016; Aharoni and Goldberg, 2017). For general seq2seq learning, methods like SparseMax (Martins and Astudillo, 2016) and local attention (Luong et al., 2015) were proposed to bridge the gap between soft and hard attention.

In this paper we propose a surprisingly simpler alternative based on the original joint distribution between output and attention, of which existing soft and hard attention mechanisms are approximations. The joint model couples input states individually to the output like in hard attention, but it combines the advantage of end-to-end trainability of soft attention. When the number of input states is large, we propose to use a simple approximation of the full joint distribution called Beam-joint. This approximation is also easily trainable and does not suffer from the high variance of Monte-Carlo sampling gradients of hard attention.

We evaluated our model on five translation tasks and increased BLEU by 0.8 to 1.7 over soft attention, which in turn was better than hard and the recent Sparsemax (Martins and Astudillo, 2016) attention. More importantly, the training process was as easy as soft attention. For further support, we also evaluate on two morphological inflection tasks and got gains over soft and hard attention.

2 Background and Related Work

For sequence to sequence (seq2seq) learning the encoder-decoder model is the standard and we review it here. We then review related work on attention mechanisms on these models.

2.1 Attention-based Encoder Decoder Model

Let $x_1, \ldots, x_m$ denote the tokens in the input sequence that have been transformed by an encoder network to state vectors $\mathbf{x}_1, \ldots, \mathbf{x}_m$, which we jointly denote as $\mathbf{x}_{1\ldots m}$. Let $y_1, \ldots, y_n$ denote the output tokens in the target sequence. The Encoder-Decoder (ED) network factorizes $\Pr(y_1, \ldots, y_n|\mathbf{x}_{1\ldots m})$ as $\prod_{t=1}^{n} \Pr(y_t|\mathbf{x}_{1\ldots m}, \mathbf{s}_t)$ where $\mathbf{s}_t$ is a decoder state summarizing $y_1, \ldots y_{t-1}$. For each t, a hidden attention variable a_t is used to denote which part of $\mathbf{x}_{1\ldots m}$ aligns with y_t. Let $P(a_t = j|\mathbf{x}_{1\ldots m}, \mathbf{s}_t)$ denote the

---

[*] Both authors contributed equally to this work

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 640–645
Brussels, Belgium, October 31 - November 4, 2018.

probability that encoder state $\mathbf{x}_j$ is relevant for output y_t. Typically this is estimated using a softmax function over attention scores computed from $\mathbf{x}_j$ and decoder state $\mathbf{s}_t$ as follows.

$$P(a_t = j|\mathbf{x}_{1\ldots m}, \mathbf{s}_t) = \frac{e^{A_\theta(\mathbf{x}_j,\mathbf{s}_t)}}{\sum_{r=1}^{m} e^{A_\theta(\mathbf{x}_r,\mathbf{s}_t)}} \quad (1)$$

where $A_\theta(.,.)$ is the attention unit that scores each input state $\mathbf{x}_j$ as per the decoder state $\mathbf{s}_t$. Thereafter, in the popular soft-attention mechanism, the attention weighted sum of the input states is used to model log likelihood for each y_t as

$$\log \Pr(y_t|\mathbf{x}_{1\ldots m}) = \log \Pr(y_t|\sum_a P_t(a)\mathbf{x}_a) \quad (2)$$

where $P_t(a_t = j)$ is the short form for $P(a_t = j|\mathbf{x}_{1\ldots m}, \mathbf{s}_t)$. Also, here and in the rest of the paper we drop $\mathbf{s}_t$ from $P(y_t)$ and $P_t(a)$ for ease of notation. The weighted sum $\sum_a P_t(a)\mathbf{x}_a$ is called an input context $\mathbf{c}_t$ which is fed to the decoder RNN along with y_t for computing the next state $\mathbf{s}_{t+1}$.

2.2 Related Work

We next review existing attention types.

Soft Attention is the attention method described in the previous section and is the current standard for seq2seq learning (Xu Chen, 2018; Koehn, 2017). It was proposed for translation in (Bahdanau et al., 2014) and refined further in (Luong et al., 2015). As shown in Eq 2, here each output is derived from an attention averaged input. This diffuses the coupling between the input and output. The advantage of soft attention is end to end differentiability, and fast training and inference.

Hard Attention was proposed in its current form in (Xu et al., 2015) and attends to exactly one input state for an output[1]. During training, log-likelihood is an expectation over sampled attentions:

$$\log P_t(y_t|\mathbf{x}_{1\ldots m}) = \sum_{l=1}^{M} \log P_t(y_t|\mathbf{x}_{\tilde{a_l}}) \quad (3)$$

where $\tilde{a_1}, \ldots, \tilde{a_M}$ are sampled from the multinomial $P_t(a)$. Because of the sampling, the gradient has to be computed by Monte Carlo gradient/REINFORCE (Williams, 1992) and is subject to high variance. Many tricks are required to train hard attention and there is little standardization across implementations. Xu et al (2015) use a combination of REINFORCE and soft attention. Zaremba et al(2015) uses curriculum learning that starts as soft-attention and gradually becomes discrete. Ling& Rush (2017) aggregates multiple samples during training, and a single sampled attention while testing. However, once trained well the sharp focus on memory provided by hard-attention has been found to yield superior performance (Xu et al., 2015; Shankar and Sarawagi, 2018).

Sparse/Local Attention Many attempts have been made to bridge the gap between soft and hard attention. Luong et al (2015) proposes local attention that averages a window of input. This has been refined later to include syntax (Chen et al., 2017; Sennrich and Haddow, 2016; Chen et al., 2018). Another idea is to replace the softmax in soft attention with sparsity inducing operators (Martins and Astudillo, 2016; Niculae and Blondel, 2017). However, all sparse/local attention methods continue to compute $P(y)$ from an attention weighted sum of inputs (Eq: 2) unlike hard attention.

3 Joint Attention-Output Models

We start from an explicit joint representation of the uncertainty of the attention and output variables.

$$\log P_t(y_t|\mathbf{x}_{1\ldots m}) = \log \sum_a P_t(a)P_t(y_t|\mathbf{x}_a) \quad (4)$$

The joint model directly couples individual input states to the output, and thus is a type of hard attention. Also, by taking an expectation, instead of a single hard attention, it enjoys differentiability as in soft-attention. We call this the **full-joint** method.

Unfortunately, either when the vocabulary or the number of encoder states (m) is large, full-joint is not practical. Existing hard and soft attentions can be viewed as its approximations that either marginalize early or hard select attention. We show a surprisingly simple alternative approximation that provides hard attention without its training complexity. Our method called **Beam-joint** deterministically selects the top-k highest attention values and approximates the full joint log probability as

$$\log P_t(y_t|\mathbf{x}_{1\ldots m}) \approx \log \sum_{a \in \text{TopK}(P_t(a))} P_t(a)P_t(y_t|\mathbf{x}_a) \quad (5)$$

Thus, in beam-joint, we first compute the multinomial attention distribution in $O(m)$ time using

---

[1] Note, attention on a single input encoder state does not imply attention on a single input token because RNNs or self-attention capture the context around the token.

Eq 1, select the Top-K input positions from the multinomial, next with hard attention on each position compute K output softmax, and finally compute the attention weighted output mixture distribution. The number of output softmax is K times in normal soft-attention but the actual running time overhead is only 20–30% for translation tasks. We used the default pass-through TopK operator (which is not differentiable) and optimize the beam-approximation directly. We also experimented with a version which smoothly shifts from soft-attention to beam-attention, but found that training the beam-approximation directly leads to best results.

We show empirically that this very simple scheme is surprisingly effective compared to existing hard and soft attention over several translation tasks. Unlike sampling and variational methods that require careful tuning and exotic tricks during training, this simple scheme trains as easily as soft-attention, without significant increase in training time because even $K = 6$ works well enough.

Another reason why our 'sum of probabilities' form performs better could be the softmax barrier effect highlighted in (Yang et al., 2018). The authors argue that the richness of natural language cannot be captured in normal softmax due to the low rank constraint it imposes on input-to-output matrix. They improve performance using a Mixture of Softmax model. Our beam-joint also is a mixture of softmax and possibly achieves higher rank than a single softmax. However their mixture requires learning multiple softmax matrices, whereas ours are due to varying attention and we do not learn any extra parameters than soft attention.

4 Experiments

We compare attention models on two NLP tasks: machine translation and morphological inflection.

4.1 Machine translation

We experiment on five language pairs from three datasets: **IWSLT15 English↔Vietnamese** (Cettolo et al., 2015) which contains 133k train, 1.5k validation(tst2012) and 1.2k test(tst2013) sentence pairs respectively; **IWSLT14 German↔English** (Cettolo et al., 2014) which contains 160k train, 7.2k validation and 6.7k test sentence pairs respectively ; **Workshop on Asian Translation 2017 Japanese→English** (Nakazawa et al., 2016) which contains 2M train, 1.8k validation and 1.8k test sentence pairs respectively. We use a 2 layer bidirectional encoder and a 2 layer unidirectional decoder with 512 hidden LSTM units and 0.2 dropout rate with vanilla SGD optimizer. We base our implementation[2] on the NMT code[3] in Tensorflow. We did no special hyper-parameter tuning and used standard-softmax tuned parameters on a batch size of 64.

Comparing attention models We compare beam-joint (default $K = 6$) with standard soft and hard attention. To further dissect the reasons behind beam-joint's gains, we compare beam-joint with a sampling based approximation of full-joint called Sample-Joint that replaces the TopK in Eq 5 with K attention weighted samples. We train sample-joint as well as hard-attention with REINFORCE with 6-samples. Also to ascertain that our gains are not explained by sparsity alone, we compare with Sparsemax (Martins and Astudillo, 2016).

In Table 1 we show perplexity and BLEU with three beam sizes (B). Beam-joint significantly outperforms all other variants, including the standard soft attention by 0.8 to 1.7 BLEU points. The perplexity shows even a more impressive drop in all five datasets. Also we observe training times for beam-joint to be only 20–30% higher than soft-attention, establishing that beam-joint is both practical and more accurate.

Sample-joint is much worse than beam-joint. Apart from the problem of high variance of gradients in the reinforce step, another problem is that sampling repeats states whereas TopK in beam-joint gets distinct states. Hard attention too faces training issues and performs worse than soft attention, explaining why it is not commonly used in NMT. Sample-joint is better than Hard attention, further highlighting the merits of the joint distribution. Sparsemax is competitive but marginally worse than soft attention. This is concordant with the recent experiments of (Niculae and Blondel, 2017).

Comparison with Full Joint Next we evaluate the impact of our beam-joint approximation against full-joint and soft attention. Full-joint cannot scale to large vocabularies, therefore we only compare on En-Vi with a batch size of 32. Figure 1a shows final BLEU of these methods as well as BLEU against increasing training steps. Beam-joint both converges faster and to a higher score than soft-

(b) BLEU Vs Training steps (Beam=1)

Figure 1: Test BLEU in various settings (Beam=1). Best viewed in color

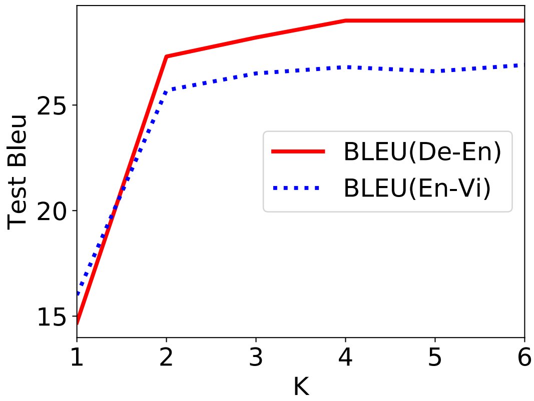

Figure 2: BLEU for Beam-Joint with increasing K. BLEU increases with K and saturates at K=5

attention. For example by 10000 steps (5 epochs), beam-joint has surpassed soft-attention by almost 2 BLEU points (20 vs 22). Moreover beam-joint tracks full-joint well, and both converge finally to similar BLEUs near 27 against 26 for soft attention. This shows that an attention-beam of size 6 suffices to approximate full joint almost perfectly.

Next, in Figure 1b, we compare beam-joint (solid lines) and soft attention (dotted lines) for convergence rates on three other datasets. For each dataset beam-joint trains faster with a consistent improvement of more than 1 BLEU.

Effect of K in Beam-joint We show the effect of K used in TopK of beam-joint in Figure 2 on the En-Vi and De-En tasks. On En-Vi BLEU increases from 16.0 to 25.7 to 26.5 as K increases from 1 to 2 to 3; and then saturates quickly. Similar behavior is observed in the other dataset. This shows that small K values like 6 suffice for translation.

We further evaluate whether the performance gain of beam-joint is due to the softmax barrier alone in Table 2. We used our models trained with K=6, and deployed them for test-time greedy decoding with K set to 1. Since the output now has only a single softmax component, this model faces the same bottleneck as soft-attention. One can observe that as expected these results are worse than beam-joint with K=6, however they still exceed soft-attention by a significant margin, demonstrating that the performance gain is not solely due to the effect of ensembling or softmax-barrier.

4.2 Morphological Inflection

To demonstrate the use of this approach beyond translation, we next consider two morphological inflection tasks. We use (Durrett and DeNero, 2013)'s dataset containing 8 inflection forms for German Nouns (de-N) and 27 forms for German Verbs (de-V). The number of training words is 2364 and 1627 respectively while the validation and test words are 200 each. We train a one layer encoder and decoder with 128 hidden LSTM units each with a dropout rate of 0.2 using Adam(Kingma and Ba, 2014) and measure 0/1 accuracy for soft, hard and full-joint attention models. Due to limited input length and vocabulary, we were able to run directly the full-joint model. We also ran the 100 units wide two layer LSTM with hard-monotonic attention provided by (Aharoni and Goldberg, 2017) labeled Hard-Mono[4]. The table below shows that even for this task full-joint scores over existing attention models[5]. The generic full-joint attention provides slight gains even over the task specific hard-monotonic attention.

Dataset	Soft	Beam-Joint (K=1)	Beam-Joint (K=6)
En-De	23.1	24.5	**24.7**
De-En	27.7	28.4	**29.0**
En-Vi	26.0	26.5	**27.0**

Table 2: Comparing soft attention with Beam-Joint using different values of K during inference. During training $K = 6$ for both Beam-Joint models.

Dataset	Soft	Hard	Hard-Mono	Full-Joint
de-N	85.50	85.13	85.65	**85.81**
de-V	94.91	95.04	95.31	**95.52**

Conclusion

In this paper we showed a simple yet effective approximation of the joint attention-output distribution in sequence to sequence learning. Our joint model consistently provides higher accuracy without significant running time overheads in five translation and two morphological inflection tasks. An interesting direction for future work is to extend beam-joint to multi-head attention architectures as in (Vaswani et al., 2017; Xu Chen, 2018).

Joint Learning for Emotion Classification and Emotion Cause Detection

Ying Chen[1], Wenjun Hou[1], Xiyao Cheng[1], Shoushan Li[2]

Abstract

We present a neural network-based joint approach for emotion classification and emotion cause detection, which attempts to capture mutual benefits across the two sub-tasks of emotion analysis. Considering that emotion classification and emotion cause detection need different kinds of features (affective and event-based separately), we propose a joint encoder which uses a unified framework to extract features for both sub-tasks and a joint model trainer which simultaneously learns two models for the two sub-tasks separately. Our experiments on Chinese microblogs show that the joint approach is very promising.

1 Introduction

The analysis of emotions in texts is an important task in NLP. Traditional studies treat this task as a pipeline of two separated sub-tasks: emotion classification and emotion cause detection. The former identifies the category of an emotion and the latter detects the cause of an emotion. This separated framework makes each sub-task more flexible to deal with, but it neglects the relevance between the two sub-tasks. In this paper, we explore joint approaches which can capture mutual benefits across the relevant two sub-tasks. To the best of our knowledge, this work is the first attempt to incorporate both emotion classification and emotion cause detection into a unified framework.

Although emotion classification relies on affective features and emotion cause detection needs event-based features, we propose a joint encoder which uses a unified framework to extract features for both emotion classification instances and emotion cause detection instances. Then, we propose a joint model trainer which simultaneously learns two models for the two sub-tasks separately. The experiments on Chinese microblogs show that our joint approach can effectively learn models for both sub-tasks.

2 Our Approach

2.1 Corpus

In this paper, we use the human-labeled emotion corpus provided by Cheng *et al.* (2017) as our experimental data (namely Cheng emotion corpus). To better explain our work, we adopt twitter's terminology used in Cheng *et al.* (2017). Cheng emotion corpus can be considered as a collection of subtweets. For each emotion in a subtweet, all emotion keywords expressing the emotion are selected, and then the class and the cause of the emotion are annotated. The emotion categorization used in Huang et al. (2016) is adopted, which includes four basic emotions (i.e., joy, angry, sad and fearful) and three complex emotions (i.e., positive, neutral and negative). E.g. in the following example, the class of the emotion keyword ("😭") is *sad*, and the cause of the emotion is "only I was at home again".

Chinese : 兴冲冲勒跑回家~~发现又是我一个人再家。。😭 早知道就去蹭饭了

English Translation: I was very excited to run back home. I found that only I was at home again.😭 If I knew it earlier, I would have a meal for free.

Figure 1: An example of a subtweet

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 646–651
Brussels, Belgium, October 31 - November 4, 2018.

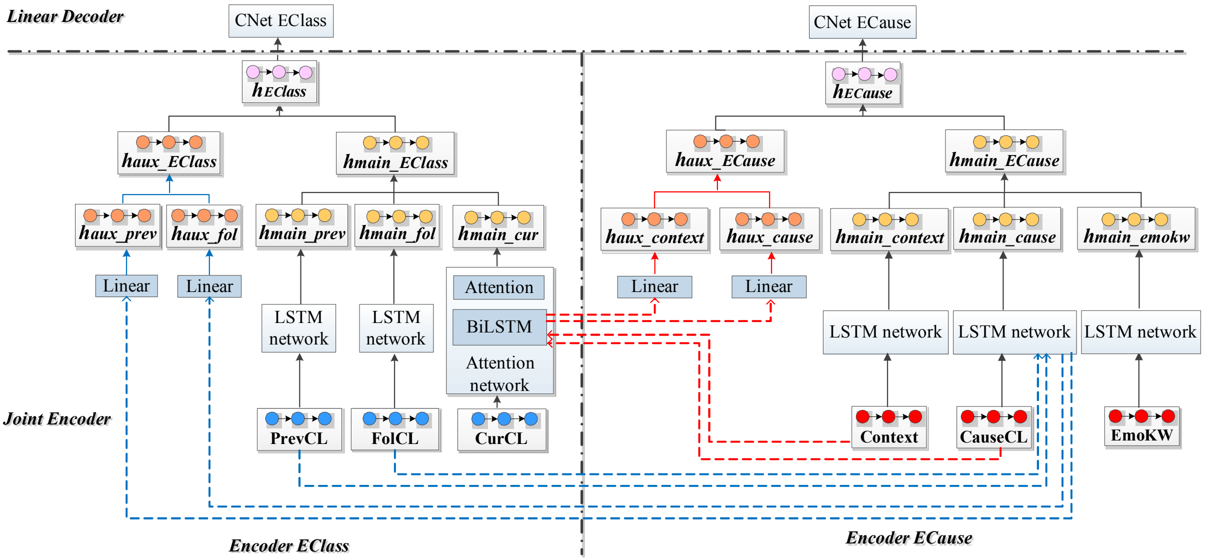

Figure 2: The framework of our joint approach

2.2 Problem Formulation

In this paper, both the emotion classification sub-task (namely *EClass*) and the emotion cause detection sub-task (namely *ECause*) are clause-level. Given an instance which is a clause in a subtweet, *EClass* assigns one of seven labels (i.e. six emotion classes and label ‘*non-emotion*’ which indicates the absence of an emotion) to the instance. Notice, because of the extremely low percentage of emotion ‘*fearful*’ (~0.6% in §3.1 Table 1), we ignore this emotion class in *EClass*. Given an instance which is a pair of <an emotion keyword, a clause in the subtweet>, *ECause* assigns a binary label to the instance to indicates the presence of a causal relation. Moreover, the clause-level *EClass* can effectively avoid the problem of multiple emotions (Li et al., 2015) because clauses are a kind of fine-grained texts.

Furthermore, the input text of an *EClass* instance contains three sequences of words: the previous clause (i.e. *PrevCL*), the current clause (i.e. *CurCL*), and the following clause (i.e. *FolCL*). The previous clause and the following clause provide contextual information for the current clause. The input text of an *ECause* instance also has three sequences of words: the emotion keyword (i.e. *EmoKW*), the current clause (i.e. *CauseCL*) and the context between *EmoKW* and *CauseCL*. The emotion keyword serves as an anchor, the current clause gives the description of an event which may cause the emotion, and the context provides complemental information for the event. Moreover, each word is represented with a vector from our word embedding model which is trained with word2vec[1] and the tweet corpus of Cheng *et al*. (2017).

2.3 The Joint Approach

As shown in Fig. 2, there are two parts in our joint approach which is based on neural networks: a joint encoder (the lower part) which extracts feature representations for both *EClass* instances and *ECause* instances, and a linear decoder (the upper part) which assigns labels to instances according to their representations.

Neural Networks

In the joint encoder, there are two neural networks (the attention network and the LSTM network), and each neural network is composed of several layers: bidirectional LSTM (i.e. BiLSTM) and attention. The BiLSTM layer focuses on the extraction of sequence features, and the attention layer focuses on the learning of word importance (weights). Because of the feature sparse problem in our small-scaled experimental data, the attention network often cannot effectively extract features to represent an event (see §3.2). Thus, in our joint encoder, we use the attention network to extract affective features (e.g. “😱” in Fig. 1) and the LSTM network to extract event-based features (e.g. “I found that only I was at home again” in Fig. 1).

---

[1] https://code.google.com/p/word2vec/

The attention network: we implement the attention network used in Felbo *et al.* (2017), which includes two layers: a BiLSTM layer which extracts a sequence feature for each input word, and an attention layer which represents the input sequence using weighted words.

The LSTM network: the network uses a BiLSTM layer to capture a sequence feature for each input word, and then uses the average of those features as the representation of the input sequence.

In the linear decoder, there are two classification networks (CNet *EClass* and CNet *ECause*) for *EClass* and *ECause* separately. Each classification network uses a linear layer to build a probabilistic classification model.

The Joint Encoder

As shown in Fig. 2, there are two sub-encoders in our joint encoder: Encoder *EClass* (the left part) which provides a representation for an *EClass* instance, and Encoder *ECause* (the right part) which extracts a representation for an *ECause* instance. Given an instance, one sub-encoder extracts a main representation (through the black lines in Fig.2) and the other sub-encoder provides an auxiliary representation (through the blue or red lines in Fig.2). Then, the concatenation of the two representations serves as the final representation for the instance (i.e. h_{EClass} or h_{ECause} in Fig.2). In order to deal with the case that a main representation may be overwhelmed by its corresponding auxiliary representation, linear layers are used to reduce the dimensions of auxiliary representations. Moreover, there are three sequences of words either in the input text of an *EClass* instance or in the input text of an *ECause* instance. In order to effectively use these input sequences, a multi-channel structure is chosen, which encodes the input sequences one by one.

Encoder *EClass*: given the three sequences of words in an *EClass* instance (*PrevCL*, *CurCL* and *FolCL*), the attention network is applied to *CurCL* to extract an affective representation, and the LSTM network is applied to *PrevCL* and *FolCL* separately to extract two event-based representations. Then, the concatenation of the three representations is used as the main representation (i.e. $h_{\text{main\_EClass}}$). Furthermore, in order to extract more contextual information, the LSTM network of Encoder *ECause* is applied to *PrevCL* and *FolCL* (through the blue lines in Fig. 2) to extract the auxiliary representation (i.e. $h_{\text{aux\_EClass}}$), which provides another event-based view for our emotion classification.

Encoder *ECause*: in order to separately deal with the three sequences of words (*EmoKW*, *CauseCL* and *Context*) in an *ECause* instance, the LSTM network is applied to each input sequence and then the concatenation of the three representations is used as the main representation (i.e. $h_{\text{main\_ECause}}$). Furthermore, for each input sequence (*CauseCL* or *Context*), the BiLSTM layer in the attention network is used to extract more event-based features (through the red lines in Fig. 2), and those features serve as an auxiliary representation (i.e. h_{aux_ECause}) which provides another event-based view for our emotion cause detection.

The Joint Model Trainer

During training, two models (*JMEClass* and *JMECause*) are learned simultaneously for the two sub-tasks (*EClass* and *ECause*) separately. Model *JMEClass* contains Encoder *EClass* and CNet *EClass*, and Model *JMECause* contains Encoder *ECause* and CNet *ECause*. Although each model uses auxiliary representations from the other model, but the learning of the model focuses on its own parameters. In other words, gradient calculation is disabled along the dashed lines in Fig. 2.

In each episode, the batch of input data is composed of two sets of instances: *EClass* sub-batch containing only *EClass* instances and *ECause* sub-batch containing only *ECause* instances. Given the batch of data, the parameters of each model are updated according its corresponding loss function. E.g., Model *JMEClass* uses only the *EClass* sub-batch, and its loss function is the mean squared errors of the instances in the sub-batch. In our joint model trainer, the two models are optimized using their own loss functions as pipeline model training does, but they use up-to-date auxiliary representations from each other to help optimization.

3 Experiments

3.1 Experimental Setup

In Cheng emotion corpus, there are ~3,000 subtweets, ~11,000 instances for *EClass*, and ~13,000 instances for *ECause*. Moreover, Table 1 lists the class distribution in Cheng emotion corpus for *EClass*. All experiments in this paper are trained and tested by 5-fold cross-validation on Cheng emotion corpus, and all the results reported are the average ones of 5-fold cross-validation performances. We use the precision, recall and F-score as our evaluation metrics. However, because of the high percentage of label '*non-emotion*' in *EClass* (see Table 1) and label '*0*' in *ECause*, similar to previous work (Li et al. 2015; Felbo et al., 2017; Cheng *et al*., 2017; Gui *et al*., 2017), we report only the evaluation metrics of the six emotion classes for *EClass* and the evaluation metrics of label '*1*' for *ECause*.

Class	%	Class	%
Joy	11.3	Angry	3.5
Sad	2.6	Fearful*	0.6
Positive	8.2	Neutral	4.4
Negative	9.9	Non-emotion	59.5

Table 1: The class distribution in Cheng emotion corpus for *EClass*. (*: ignored)

During our joint training process, the dimension of the word embeddings is 20; the output dimension of the BiLSTM layer used in both the LSTM network and the attention network is 128; the output dimension of the linear network is 8; the batch size is 32.

The two models (*JMEClass* and *JMECause*) which are learned by our joint approach are compared with several pipeline models which are learned in a pipeline manner (i.e. either for *EClass* or for *ECause*) using one of the following state-of-the-art encoders.

- **ATT:** the attention network in Fig.2 .
- **LSTM:** the LSTM network in Fig.2.
- **ATT+LSTM:** an hybrid encoder for emotion classification, which applies *ATT* to *CurCL* and *LSTM* to *PrevCL* and *FolCL*.
- **ConvMSMemnet:** the encoder proposed by Gui et al. (2017) for emotion cause detection, which applies a convolutional multiple-slot deep memory network to *CauseCL*.

3.2 Method Analysis

Table 2 shows the performances of different emotion classification models, where "Sequence" lists the sequences of input words used by each model and each metric is the average performances of six emotion classes. Moreover, Table 3 lists the detailed performances of each emotion class in Model *JMEClass*.

Encoder	Sequence	Prec	Rec	F1
LSTM	*CurCL*	65.5	53.0	58.2
ATT	*CurCL*	67.6	56.5	61.0
	all	67.5	56.7	61.2
ATT+LSTM	all	67.0	57.8	61.7
JMEClass	all	***67.7***	***58.5***	***62.4***

Table 2: The performances of emotion classification models. (all: *PrevCL*, *CurCL* plus *FolCL*)

Class	Prec	Rec	F1
Joy	85.5	83.6	84.5
Angry	62.8	45.0	52.4
Sad	72.6	72.9	72.8
Positive	63.0	54.7	58.6
Neutral	62.5	41.2	49.7
Negative	59.9	53.9	56.7

Table 3: The performances of the six emotions in JMEClass

In Table 2, Model *ATT* + *CurCL* out-performs *LSTM* + *CurCL* by 2.8% in F-scores, where *ATT* is a state-of-the-art encoder for emotion classification (Felbo et al., 2017). The significant performance improvement means that *ATT* can effectively extract affective features in *CurCL*. In fact, the emotion classification on Chinese microblogs can rely much on emotion keywords occurring in *CurCL*. E.g. ~50% emotional instances in our experimental data contains emoticons (e.g. "😭" in Fig. 1) in *CurCL* and those emoticons themselves are strong emotion indicators. Secondly, when different kinds of contextual information are incorporated to Model *ATT* + *CurCL*, different performance improvements obtain (0.2% for *ATT* + *all* and 0.7% for *ATT+LSTM* in F-scores). This indicates that for the emotion classification, the event-based features extracted by *LSTM* are more helpful than the affective features extracted by *ATT*, because contexts often provide the cause event of an emotion. E.g. in Fig. 1, the previous clause of "😭" contains its cause "only I was at home again". Finally, taking the advantage of the event-based features extracted by *JMECause*, *JMEClass* out-performs the best pipeline model (*ATT+LSTM*) by 0.7% in F-scores. This shows that it is important for the emotion classification to have an encoder which can effectively extract event-based features from contexts.

In Table 3, the performance of a basic emotion (i.e., joy, angry or sad) is often better than the one of a complex emotion (i.e., positive, neutral or negative). However, in Table 1, the data size of a basic emotion is often smaller than the one of a complex emotion. This indicates that difference in performance is likely linked to differences in the emotional contents of labels rather than differences in data sizes. E.g. the complex emotion 'negative' (i.e. a collection of complex emotions with negativity, such as 'hate', 'anxious', and so on) is more diverse than the basic emotion 'sad', and this diversity in emotional contents brings more challenges to the detection of this complex emotion. Furthermore, even if both 'sad' and 'angry' are basic emotions and have similar data sizes in our experimental data, it seems much easier to detect 'sad' instances than to detect 'angry' instances. This is maybe because 'angry' is caused by more various events and it is more difficult to capture and utilize those cause events. Thus, it is necessary for the emotion classification to have an encoder which can extract the event-based information of emotion cause from texts.

Encoder	Sequence	Prec	Rec	F1
ConvMS-Memnet	*CauseCL*	34.3	***77.5***	47.5
ATT	all	55.4	60.9	58.0
LSTM	all	***55.6***	61.3	58.3
JMECause	all	53.1	66.7	***59.1***

Table 4: The performances of emotion cause detection models. (all: *EmoKW*, *CauseCL* plus *Context*)

Table 4 shows the performances of different emotion cause detection models, where "Sequence" lists the sequences of input words used by each model. In Table 4, *JMECause* outperforms the best pipeline model (*LSTM*) by 0.8% in F-scores. The *LSTM* encoder is a state-of-the-art approach used for emotion cause detection (Cheng et al., 2017). Furthermore, the performance improvement of *JMECause* is from the significant increasing in recalls (5.4%). This indicates that more emotion causes are correctly detected when the event-based features extracted by Model *JMEClass* are incorporated. Moreover, among all models, the two models (*ATT* and *LSTM*) achieve relatively high precision and relatively low recall, and ConvMS-Memnet obtains the lowest precision and highest recall. This means that both *ATT* and *LSTM* suffer from the feature coverage problem because some useful features cannot be extracted through their encoders, and ConvMS-Memn suffers from the feature quality problem maybe because its encoder cannot handle the informal writing style used in Chinese microblogs.

4 Related Work

In recent years, intensive studies have explored supervised machine learning approaches using various types of features for different-level emotion classification, such as document level (Alm et al. 2005; Li et al. 2014; Huang et al. 2016), sentence level or short text level (Tokushisa et al. 2008; Bhowmick et al. 2009; Xu et al. 2012; Wen and Wan, 2014; Li et al. 2015; Felbo et al., 2017), and so on. Moreover, since both emotion and sentiment belong to affective feeling, some studies have explored the join learning of sentiment classification and emotion classification (Gao et al., 2013; Wang et al., 2015).

In the other hand, most of previous emotion cause detection studies is clause-based, which examine whether a clause around a given emotion keyword is a cause or not. Moreover, these studies (Chen *et al*., 2010; Xu *et al*., 2017; Ghazi *et al*., 2015; Gui *et al*., 2017; Cheng *et al*., 2017) focus on how to extract two kinds of features for supervised model learning: explicit expression patterns (e.g. "to cause", "for"), and implicit features which can reflect the causal relation.

5 Conclusion

In this paper, we focus on a joint learning approach to emotion classification and emotion cause detection on Chinese microblogs, and the experiments show such a joint approach is very promising.

Abstract

Identifying optimistic and pessimistic viewpoints and users from Twitter is useful for providing better social support to those who need such support, and for minimizing the negative influence among users and maximizing the spread of positive attitudes and ideas. In this paper, we explore a range of deep learning models to predict optimism and pessimism in Twitter at both tweet and user level and show that these models substantially outperform traditional machine learning classifiers used in prior work. In addition, we show evidence that a sentiment classifier would not be sufficient for accurately predicting optimism and pessimism in Twitter. Last, we study the verb tense usage as well as the presence of polarity words in optimistic and pessimistic tweets.

1 Introduction

"You know, ever since we were little, I would get this feeling like... Like I'm floating outside of my body, looking down at myself... And I hate what I see... How I'm acting, the way I sound. And I don't know how to change it. And I'm so scared... That the feeling is never gonna go away."

The Edge of Seventeen[1]

Much has been written about optimism and pessimism in psychological studies for decades (Scheier and Carver, 1992). These feelings are affected by one's personality from an early age (as pinpointed above) and can strongly impact one's psychological and physical health. For example, pessimism and negative attitudes impact negatively one's mental health, can induce suicidal thoughts, and affect negatively not only the person in question, but also their family and friends (Peterson and Bossio, 2001; Achat et al., 2000; Scheier et al., 2001). On the other hand, optimism reduces stress and promotes better physical health and overall well-being (Carver et al., 2010).

Despite that optimism and pessimism are under the scrutiny of many researchers (Rasmussen et al., 2009; Kumar et al., 2017), large scale analyses that explore optimism and pessimism in social media have just started to emerge (Ruan et al., 2016). However, Ruan et al. (2016) focused on identifying optimism and pessimism in Twitter using a simple "bag of words" representation with no emphasis on incorporating semantic information hidden in text. Often, a deeper understanding of the text that accounts for textual semantic similarities and the writer's intention are required in order to correctly detect the characteristics of optimistic and pessimistic feelings in tweets. Towards this end, our contributions in this paper are as follows. First, we focus on the question: "Would a deep learning approach help to discover these characteristics better than traditional machine learning classifiers used in prior work?" To our knowledge, we take the first step towards exploring the performance of deep learning models for optimism/pessimism prediction in Twitter and identify the most promising deep learning models for this task. Identifying optimism and pessimism in Twitter has many applications including identifying suicidal/depressive people and providing better social support (e.g., emotional/empathetic support) that can improve people's moods and attitudes (Yan and Tan, 2014; Biyani et al., 2014; Khanpour et al., 2018, 2017; Qiu et al., 2011).

Second, since it may seem intuitive that a positive sentiment is associated with optimism and a negative sentiment with pessimism, we address the question: "Would a sentiment classifier be sufficient to correctly identify optimism and pessimism in social media?" Figure 1 shows evidence that a sentiment tool would not suffice on accurately

Figure 1: Sentiment prediction on tweets with pessimist (left) and optimist (right) connotations.

predicting tweets with pessimistic and optimistic connotations (left and right side of the figure, respectively). We answer the above question by investigating a spectrum of sentiment analysis tools and datasets for optimism/pessimism prediction.

Third, we perform a linguistic analysis, first of its kind, and study the usage of verb tenses (past, present, future) in optimistic and pessimistic tweets, as well as the presence of polarity words associated with both types of tweets.

2 Datasets

In this section, we first describe the optimism/pessimism Twitter dataset and then present two datasets used for sentiment analysis.

The Optimism/Pessimism Twitter dataset (**OPT**) was made available to us by Ruan et al. (2016). The total number of tweets in the dataset is 7,475. These tweets were sampled from data corresponding to 500 optimist and 500 pessimist users, and were manually annotated using Amazon Mechanical Turk. Precisely, each tweet was manually annotated by five independent annotators using a score between -3 (very pessimistic) and 3 (very optimistic). For our evaluation, we consider two different thresholds (0 and 1/-1) on the above score and create two settings as follows. In the first evaluation setting, a tweet is labeled as pessimistic if its score is smaller than or equal to 0, and optimistic, otherwise. In the second evaluation setting, a tweet is labeled as pessimistic if its score is smaller than or equal to -1, and optimistic if its score is greater than or equal to 1. A summary of this dataset is given in Table 1.

	Threshold 0	Threshold 1/-1
Number of tweets	7,475 (O: 4,679)	3,847 (O: 2,507)
Number of users	1,000	1,000

Table 1: Dataset statistics. 'O' stands for optimistic tweets.

The Stanford Sentiment Treebank (**SST**) (Socher et al., 2013) is a corpus for sentiment analysis that capture complex linguistic patterns. This dataset[2] is based on a dataset originally introduced by Pang and Lee (2005) and consists of 10,662 sentences from movie reviews downloaded from rottentomatoes.com. From these sentences, 215,154 phrases were extracted using the Stanford Parser (Klein and Manning, 2003) and labeled using Amazon Mechanical Turk such that each phrase was annotated by 3 human judges.

The Twitter Sentiment Analysis (**TSA**) dataset,[3] available online for download, contains 1,578,627 tweets that are classified as 1 for positive sentiment and 0 for negative sentiment.

3 Experiments and Results

In experiments, we explore several deep learning models for optimism/pessimism prediction. The general training strategy is as follows: sentence embeddings are fed into a sentence encoder to obtain the sentence representation. The classifier consists of three fully connected layers topped by a softmax layer. Dropout was applied to the first layer only. We used several encoders as follows, based on: (1) Bidirectional Long Short Term Memory networks (BiLSTMs), which are a special type of Recurrent Neural Networks (RNNs) (Hochreiter and Schmidhuber, 1997); (2) Convolutional Neural Networks (CNNs), which consist of convolution and max pooling (Kim, 2014); and (3) Stacked Gated RNNs (Chung et al., 2015).

We used SGD optimizer (Goodfellow et al., 2016) with a learning rate of 0.1 and no weight decay. At every tenth epoch we decreased the learn-

Threshold	Tweet Level		User Level	
	0	$1/-1$	0	$1/-1$
BiLSTM	79.65	87.24	**76.65**	90.52
GRUStack	**80.19**	87.76	76.38	**92.24**
CNN	77.78	**90.32**	73.55	91.68
NB	74.20	84.10	71.30	80.10
SVM	67.80	83.30	64.70	81.80

Table 2: Accuracy of deep learning vs. traditional classifiers on the **OPT** dataset (shown as percentage).

ing rate by half. We used mini-batches of 40 samples. Dropout rate was set to 0.5 and the classifier's last three layers have 300, 200, and 100 neurons. We used GloVe vectors (Pennington et al., 2014) trained on Common Crawl 840B[4] with 300 dimensions as fixed word embeddings.

For sentence embedding, after a cleanup process, sentences were transformed into a list of words, then words were replaced with word embeddings (GloVe) and padding was used to align batch sentences to the same size.

3.1 Optimism/Pessimism Prediction

In our first experiment, we explore the above deep learning models on the **OPT** dataset and compare their performance with that of two traditional machine learning classifiers, Naïve Bayes (NB) and Support Vector Machines (SVM), which were used in the previous work for this task by Ruan et al. (2016). In this experiment, the **OPT** dataset is split in train-dev-test as 80-10-10(%), respectively. We repeated each experiment 5 times and averaged the results. Our deep learning implementation is built on top of TensorFlow (Abadi et al., 2015). For NB and SVM, we used their implementation available in scikit-learn (Pedregosa et al., 2011). Table 2 shows the accuracy of all these models at tweet and user level for the two thresholds 0 and 1/-1 (as discussed in Section 2).

We can see that overall, the deep learning models achieve a much higher performance compared with the work by Ruan et al. (2016), i.e., the NB and SVM classifiers on "bag of words," for both tweet and user level with both thresholds, yielding an improvement in performance between 5%-10%. For example, at tweet level and 1/-1 threshold, CNN yields an accuracy of 90.32% as compared with NB, which achieves an accuracy of 84.10%. At user level and 1/-1 threshold, GRUStack yields an accuracy of 92.24%, as compared with 81.80% achieved by SVM. Not surprising, for both tweet and user level, when we use a threshold of 0, the performance of all models is smaller compared with that of models obtained when we use a 1/-1 threshold. Intuitively, this is true since most of the tweets with a human-annotated score between -1 and 1 are in the "gray" area that is harder to classify. Note that Ruan et al. (2016) considered the tweets with a score between -1 and 1 as being neutral.

3.2 Sentiment vs. Optimism/Pessimism

In our second experiment, we investigate the correlation between sentiment and optimism / pessimism, and argue that sentiment analyzers, that are trained to predict sentiment (Liu, 2012; Pang and Lee, 2008), fail to detect optimism and pessimism. Specifically, we train several sentiment classifiers on the large **SST** and **TSA** sentiment datasets (described in Section 2) and evaluate the performance of these classifiers on the optimism/pessimism categories from the **OPT** dataset.

Model	Train	Dev	Test	Acc%
LSTM	SST	SST	OPT	63.20
BiLSTM	SST	SST	OPT	63.60
CNN	SST	SST	OPT	59.60
CNN	TSA	TSA	OPT	67.60
RNN(char)	TSA	OPT	OPT	55.20
GRUStack	OPT	OPT	OPT	**80.19**

Table 3: Performance of sentiment classifiers on **OPT**.

Table 3 shows the performance of several deep learning models trained on either **SST** or **TSA** datasets and evaluated on the **OPT** dataset. Note that the Dev set was used for model selection. As can be seen from the table, the models trained on the sentiment datasets perform poorly on the optimism/pessimism dataset. For example, there is a drop in performance from 80.19% to 67.60% when training on **TSA** (with an even larger decrease when we train on **SST**).

The **SST/TSA** sentiment classifiers are trained to predict the sentiment as negative, neutral, or positive. To calculate the accuracy in Table 3, an optimistic tweet predicted as positive by the sentiment classifier counts as a correct prediction, whereas an optimistic tweet predicted as either neutral or negative by the sentiment classifier counts as an incorrect prediction (similarly for pessimistic tweets). This analysis is done at tweet level for the threshold of 0.

---

[4] https://nlp.stanford.edu/projects/glove/

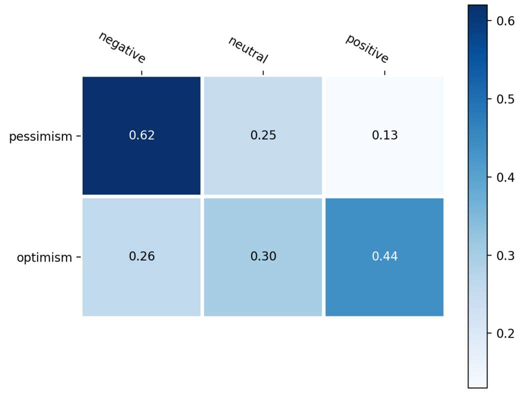

Figure 2: Optimism and pessimism classified as positive, negative, and neutral sentiment.

Figure 2 shows the normalized number of examples from optimism and pessimism categories classified as positive, negative and neutral, using the CNN model trained on **TSA**. Precisely, we show how many tweets from the set of optimistic (or pessimistic) tweets in the **OPT** dataset are predicted as negative, neutral or positive by the **TSA** sentiment classifier. The numbers on each row sum up to 1. As we can see from the figure, although pessimism is more correlated with a negative sentiment, 13% of the pessimistic tweets are classified as positive (with similar results on the optimism category).

3.3 Linguistic Analysis

In this section, we perform a linguistic analysis and study the usage of verb tenses in optimistic and pessimistic tweets, as well as the presence of polarity words associated with both types of tweets. This analysis is done at tweet level with 1/-1 threshold. The reason for using the 1/-1 threshold is that we wanted to study the usage of verb tenses and polarity words in tweets that are clear optimistic or clear pessimistic (far from the decision boundary).

3.3.1 Verb Tenses in Optimism/Pessimism

For this analysis, we used the part of speech tagger spaCy[5] and assigned the verbs to their corresponding tenses according to the Penn Treebank Project; that is, the tags VBD and VBN correspond to past tense, VBG, VBZ , VBP correspond to present tense, whereas an MD tag followed by VB (possibly with a negation between them) corresponds to the future tense.

As mentioned, a tweet was considered optimist if its manually annotated score was above 1 and pessimist if the score was below -1. The numbers of tweets with past, present, and future tenses in the optimistic category are: 1,474, 7,444, and 561, respectively, whereas these numbers in the pessimistic category are: 1,276, 5,311, and 325, respectively.

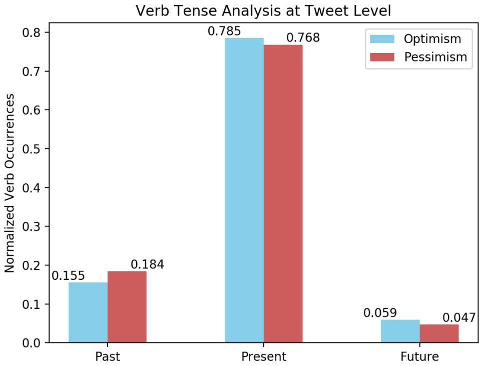

Figure 3: Verb tenses in optimist/pessimist tweets.

Figure 3 shows the normalized verb occurrences at past, present and future tenses in optimistic and pessimistic tweets. As can be seen from the figure, the present tense is the most prevalent for both categories, although there are more present tense verbs in the optimistic category compared with the pessimistic one. We can also observe that more past tense verbs occur in the pessimistic category and less future tense verbs in the pessimistic one.

While there are some common verbs such as "be," "have," and "do," that appear most frequently in both optimistic and pessimistic categories at all three tenses, there are some verbs that are more specific to one category than the other. Examples of such verbs and their frequencies from both categories at the present tense are shown in Table 4. As we can see, optimism is characterized more by verbs with a positive connotation.

[optimism]	*[pessimism]*
('be', 1662) ('have', 738) ('do', 316)	('be', 1198) ('have', 549) ('do', 342)
('love', 266) ('thank', 105) ('look', 98) ('want', 94) ('hope', 70)	('hate', 122) ('f–k', 88) ('kill', 35) ('try', 34) ('cry', 33)

Table 4: Verbs in tweets occurring at present tense.

3.3.2 Polarity Words in Optimism/Pessimism

Next, we analyze the association of polarity words from the positive and negative lexicons constructed by Hu and Liu (2004), in both tweet categories: optimism and pessimism. Instead of using the presence or absence of the words from the two lexicons in tweets, we calculated the cosine similarity between the word embeddings of the words in the two lexicons with the words in the tweets. If the similarity is above 0.8, then we consider the word from the corresponding lexicon to be present in the tweet (or synonym with a word in tweet). Using the cosine similarity between the word embeddings of words in lexicons with words in tweets captures not only the exact match between the words (a cosine similarity of 1 for exact match), but also incorporates the semantic information that exists in the text.

Although this word similarity computation relaxes the exact match/presence of a word in a tweet and aims at incorporating semantic similarity, a high similarity between antonyms may occur since word embeddings are known to not differentiate well between synonyms and antonyms, which tend to appear in similar contexts.

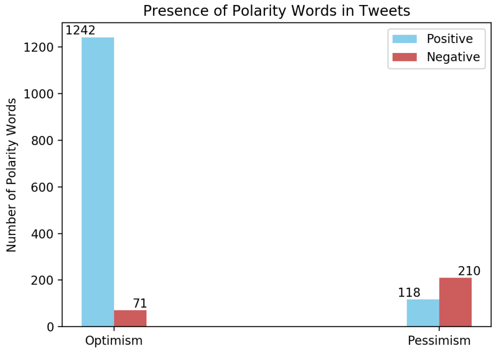

Figure 4: Polarity words in optimist/pessimist tweets.

Figure 4 shows the number of polarity words in optimistic and pessimistic tweets. As shown in the figure, more positive words appear in optimistic tweets compared with negative words (1,242 vs. 71), while there is not a substantial difference between the numbers of positive and negative words in pessimistic tweets (118 vs. 210).

Table 5 shows the top most frequent polarity words associated with optimism and pessimism. As we can see, words with a negative polarity (e.g., bad) although not very frequent, still appear in optimistic tweets. This supports our intuition that a sentiment model is not enough to accurately predict pessimism and optimism in Twitter.

Optimism	
[positive]	*[negative]*
('great', 289)	('bad', 13)
('loved', 279)	('worried', 11)
('wonderful', 155)	('lost', 6)
('glad', 76)	('scared', 5)
('kind', 45)	('terrible', 4)
('thrilled', 29)	('disappointed', 3)
Pessimism	
[positive]	*[negative]*
('great', 29)	('bad', 36)
('kind', 27)	('lost', 18)
('loved', 13)	('scared', 16)
('wonderful', 9)	('alone', 13)
('surprised', 8)	('terrible', 12)
('glad', 6)	('terrified', 12)

Table 5: Top frequent polarity words.

4 Concluding Remarks

In this paper, we explored deep learning models for optimism and pessimism prediction in Twitter and showed that these models substantially outperform traditional classifiers such as Naïve Bayes and Support Vector Machines. To our knowledge, this work is the first computational study that explores optimism and pessimism using deep learning. We also showed that a sentiment classifier would not be sufficient for accurately predicting optimism and pessimism. This topic is less explored despite its importance in many applications such as identifying suicidal/depressive people.

Interesting future directions are: understanding how one's age is correlated with optimism / pessimism; if one user is characterized by a mixture of topics, is that user optimist (pessimist) across all these topics? Thus, decomposing a user's textual data into topic and correlating this with optimism and pessimism may be interesting to explore; last, studying how optimism and pessimism are affected by sarcasm.

As we started our study with a pessimistic quote from the movie "The Edge of Seventeen," we end our study with a quote from the same movie, with a positive sentiment and full of optimism:

"Life's about taking risks. Don't be afraid to put yourself out there."

Abstract

Newspapers need to attract readers with headlines, anticipating their readers' preferences. These preferences rely on topical, structural, and lexical factors. We model each of these factors in a multi-task GRU network to predict headline popularity. We find that pre-trained word embeddings provide significant improvements over untrained embeddings, as do the combination of two auxiliary tasks, news-section prediction and part-of-speech tagging. However, we also find that performance is very similar to that of a simple Logistic Regression model over character n-grams. Feature analysis reveals structural patterns of headline popularity, including the use of forward-looking deictic expressions and second person pronouns.

1 Introduction

The data generated from online news consumption constitutes a rich resource, which allows us to explore the relation between news content and user opinions and behaviors. In order to stay in business, newspapers need to pay attention to this information. For example, what headlines do users click on, and why? With the volume of news being consumed online today, there is great interest in addressing this problem algorithmically. We collaborate with a large Danish newspaper, who gave us access to several years' worth of headlines, and the number of clicks generated by readers.

We aggregate the viewing logs to classify headlines as popular or unpopular, and build models to predict those classifications. We use an expanded version of the dataset investigated by Hardt and Rambow (2017). That work found that bag-of-word models based on headlines did indeed have predictive value concerning viewing behavior, although models based on the article body were more accurate. As Hardt and Rambow noted, this is somewhat paradoxical: how can a model based on the article text be better at predicting clicks? After all, the choice to click on an article must be based on the headline alone – the article is only seen *after* the clicking decision is made. Hardt and Rambow speculate that "it is possible that the headline on its own gives readers a lot of semantic information which we are not capturing with our features, but which the whole article does provide. So human readers can "imagine" the article before they read it and implicitly base their behavior on their expectation." (Hardt and Rambow, 2017)

In other words, readers are able to *anticipate* the contents of an article in advance from a headline, because of the linguistic and world knowledge that they bring to bear when assessing the headline. If we can incorporate this "future" knowledge into a prediction model, we are likely to improve performance.

We test this hypothesis by defining ways to model aspects of the lexical, structural, and topical knowledge of human news readers:

- **Lexical – Word Embeddings:** we provide our models with pretrained word embeddings from large datasets. This models aspects of the rich lexical information and association that human readers bring to bear in reading a headline.
- **Structural – POS Tagging:** part of speech information is a basic component of structural linguistic knowledge, reflected in the structure of common headline templates such as "Can X do Y?" or "You will not believe what happened when X".
- **Topical – Section Prediction:** Each article is labeled with a section (sports, politics, etc). We include a task which predicts the section of a headline. This models the ability of a news reader to understand the most salient

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 659–664
Brussels, Belgium, October 31 - November 4, 2018.

and interesting topical material in a headline text.

We use a multi-task learning (MTL) setup (Caruana, 1993), which provides a natural framework to test the above hypotheses: one of the first uses of MTL was to include the outcome of future diagnostic tests into a prediction task (Caruana et al., 1996).

We explore the effect of pretrained word embeddings, and the effects of auxiliary tasks involving POS tagging and section prediction. We find that the combination of all of these factors results in substantial improvements over the baseline and the previous work, which used a single-task system. We also build logistic regression models, both for word and character n-grams. The word-based models have the advantage that the predictiveness of individual words can be examined.

While the word n-gram models have performance comparable to the baseline neural net, the character n-gram model has higher performance, competing with the best MTL result. This finding is in line with the results from Zhang et al. (2015).

Our results indicate that MTL can indeed provide the tools to implement prediction processes that involve expectations about the future. Given the successful integration of two auxiliary tasks, we see this as a promising starting point for future research. However, the performance parity with the character model underscores the fact that simple model architectures still have a place. Our findings, in line with other current work (Benton et al., 2017), shine light on the question of auxiliary task selection and their interaction, and highlight that MTL results should be rigorously tested.

A good predictive model is a powerful diagnostic tool for editors, allowing them to select proposed headlines. However, journalism is a creative production process, so detection is only part of the application. We also want to be able to give strategic advice to headline *writers*. To this end, we report an analysis of common n-gram features in the word-based logistic regression model, that provide some insights into successful headline patterns.

Contributions We explore an MTL architecture with two auxiliary tasks for headline popularity prediction. We show how aspects of lexical, structural, and topical knowledge are all relevant for headline popularity. The positive results reported here provide a fruitful basis for further development of MTL models for news data. We also analyze lexical features that are predictive of headline popularity.

Figure 1: Example of Jyllands-Posten headline as seen by audience

2 Data

News Data The present work is based on a significantly expanded and cleaned version of the dataset used by Hardt and Rambow (2017). This dataset includes Jyllands-Posten articles and logs. Jyllands-Posten is a major Danish newspaper (and became known to an international audience over the cartoon controversy). The data covers a period from July 2015 through July 2017. We removed any articles from before July 2015, when the viewing logs began, since these older articles have unreliable numbers of clicks. The resulting dataset consists of 82,532 articles and a total of 281,005,390 user views. We furthermore extracted the news section each article belongs to (sports, politics, etc.) from the URL.

We bin the articles by numbers of clicks into 2 bins, thus defining a classification task: is the article in the top 50% of clicks or not? The data is divided into 80% training, and 10% each development and test data.

Figure 1 shows the top headline on the Jyllands-Posten web site for August 27, 2018. Our data does not include information such as the position of a headline on the page, and possible associated graphical material.

Additional Data In addition to the news data from JP, we obtained a corpus of 100 million words of Danish text from the Society for Danish Language and Literature, or DSL (Jørg Asmussen, 2018). This corpus was collected from diverse sources over a period from 1990 to 2010. The corpus has been automatically annotated for part of speech and lemmatization, and we use this for our POS tagging task. We also downloaded the Danish Wikipedia, which consists of approximately 49 million words of Danish text. We use these corpora in conjunction with the JP article texts to induce pre-trained Danish word-embeddings.

Data Statement A. CURATION RATIONALE The dataset is collected by Jyllands-Posten as part of a general strategy to understand user behavior and preferences with respect to the news content on the site.

B. LANGUAGE VARIETY The data is Danish (da-DK).

C. SPEAKER DEMOGRAPHIC The text is produced by professional journalists.

D. ANNOTATOR DEMOGRAPHIC There is no manual annotation of the text.

E. SPEECH SITUATION The texts were produced from July 2015 until July 2017; the intended audience is Danish news consumers.

F. TEXT CHARACTERISTICS The text is standard, mainstream Danish journalism.

3 Models

Our task is to predict which articles get the most user clicks, based on the headline alone. We report results using logistic regression and a neural network, using MTL.

Logistic Regression We define the following features for logistic regression models:

1. *n-chars*: sequences of n characters, with n ranging from 2 to 6 in all experiments.

2. *word unigrams*: *tfidf* scores for all word unigrams

3. *word bigrams*: *tfidf* scores for all word bigrams

GRU Neural Network While the task is classification, which could be done with a feed-forward model, we want a sequential architecture, so that we can incorporate POS tagging as an auxiliary task, adding POS output at each time step.

Based on good results in recent work (Lee and Dernoncourt, 2016), (Liu et al., 2016), we choose a Recurrent Neural Network architecture and after a series of experiments on the training and validation set, we obtained the best results using GRU (Gated Recurrent Unit) units.

Each layer k consists of two sets of units, labeled fw and bw that process the sequence forwards and backwards respectively, so that information from the whole sequence is available on every timestep t. The two directions' activations are concatenated and fed to a fully-connected softmax (for multi-class classification) or sigmoid layer (for binary classification) to get the output probability y_t^k of the task associated with layer k. So that higher level tasks can benefit, we embed the output probabilities using the fully connected label embedding LE layer, a technique used on similar scenarios (Rønning et al., 2018). The embedded label gets concatenated with the GRU output to get the activation a_t^k that gets fed in the next layer, or the final fully connected prediction layer, as presented in figure 2.

In the sequential auxiliary task, i.e. POS tagging, this is done for every timestep, while for the classification tasks the prediction is made on the final timestep.

For regularization, we apply dropout on every layer of our network.

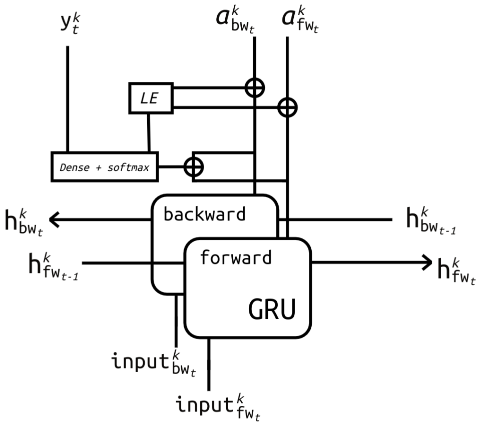

Figure 2: Representation of a single timestep t for a pair of forward-backward units on layer k where h_{t-1}^k is the previous hidden state.

Auxiliary Tasks In our setup, we use two auxiliary tasks:

1. *POS tagging*: we include POS tagging using the DSL dataset on the first recurrent layer of the GRU.

2. *Section prediction*: we include classification into one of the 227 sections of the Jyllands-

Posten website. The output for this task is based on the penultimate recurrent layer.

Hyper-parameters and Training We perform a grid search to find the best hyper-parameters for a single-task model (i.e., without any auxiliary tasks) and then keep those settings for all our experiments. We settle on a model with hidden size $H = 112$ and $N_k = 3$ layers, respectively. The dropout probability $p = 0.3$ gave best results for both models.

We train the model for 10 epochs using Adam optimizer with the default parameters, clipping the gradient updates so that their norm is not higher than 5. We train the different tasks sequentially for each epoch, with the lower level (POS tagging) first and the popularity prediction last. Additionally, we decay the learning rate by a factor of 0.9 after each epoch. While this is not common with adaptive methods such as Adam, it performed better. We stop training if the accuracy on the development set stops improving.

4 Results

Tables 1 and 2 report accuracy for logistic regression and neural classifiers. We also give the best score from Hardt and Rambow (2017) for comparison purposes (note, though, that the data sets are not identical and can therefore not be directly compared). We observe a substantial improvement over the baseline GRU when incorporating the pre-trained embeddings and both auxiliary tasks. It seems that pretrained embeddings and MTL act at least partly as regularizers, as these models trained for more epochs without overfitting. Interestingly, we observe a similar improvement over the word-based logistic regression models with a character n-gram model.

5 Analysis and Discussion

Our main focus in this paper is on MTL as a framework to explore the lexical, structural and topical knowledge involved in users' selection of headlines. However, recognizing a popular headline and giving advice on how to write one are not the same: we want to provide editors and journalists with insights as to what constructions are likely to attract more eyeballs.

One way to explore this is to examine individual words and their contribution to predictiveness. Table 3 displays the top 20 unigrams based on their coefficients in the logistic regression model. For each unigram we provide a translation (if needed) and a comment. We classify several unigrams as Deictic-reference. This follows Blom and Hansen (2015), who suggest that headline ”clickbait” often relies on forward-looking expressions, such as ”This”, as in, e.g., ”This is how you should eat an avocado”. Here, ”this” is a referring expression, but the reader understands that the antecedent will be found in the article body. Several of these top unigrams are names that are of specific topical interest in areas such as sports and politics. Others mention topics of more general interest (Researchers, dead, found). The second person pronoun is also on the list – in general, it was found that second person pronouns are far more predictive of popularity than first or third person pronouns. Finally, several unigrams identify sections of the newspaper of particular interest (car, weather, analysis, and satire).

6 Related Work

Prediction of news headline popularity is an increasingly important problem, as news consumption has moved online. The insights and models described here might well be applicable to related problems of interest: for example, Balakrishnan and Parekh (2014) and Jaidka et al. (2018) study the problem of predicting clicks on email subject lines.

Subramanian et al. (2018) show that a regression-based multitask approach can increase performance for the classification prediction of popularity. Their work looks at the popularity of online petitions, but the methodology applies to our subject as well, and ties in with the approaches taken in this project.

Benton et al. (2017) caution that in order to evaluate MTL results properly, we need to take the number of parameters into account. Our results to some extent support this finding, by showing that a simpler linear model can fare equally well on the task.

The choice of auxiliary tasks greatly influences the performance of MTL architectures, prompting several recent investigations into the selection process (Alonso and Plank, 2017; Bingel and Søgaard, 2017). However, it is still unclear whether these tasks serve as mere regularizers, or whether they can also impart some additional information.

7 Conclusion

We presented an exploratory approach to predicting newspaper article popularity from headlines alone. Using pre-trained embeddings and a MTL setup, we are able to incorporate rich structural and semantic knowledge into the task and substantially improve performance. While the results are encouraging and allow the exploration of further auxiliary tasks (for example article word prediction), we find that a simple character-based n-gram model performs competitively. These findings highlight two aspects: 1) For any application of MTL, this is a strong case for comparing the results to non-deep models. While it is comparatively easy to show an improvement over the basic STL model, there might be other simple models that are competitive. 2) The selection of auxiliary tasks greatly influences the performance, even beyond simple regularization, and in a non-linear way. It does, however, provide us with a tool to test human intuitions about task interactions and the importance of certain problem aspects.

Acknowledgments

Thanks to A. Michele Colombo for help with the data and experiments. We also thank Jyllands-Posten for giving us access to the data, and to DSL for data for embeddings and POS annotations.

Abstract

Inferring the agreement/disagreement relation in debates, especially in online debates, is one of the fundamental tasks in argumentation mining. The expressions of agreement/disagreement usually rely on argumentative expressions in text as well as interactions between participants in debates. Previous works usually lack the capability of jointly modeling these two factors. To alleviate this problem, this paper proposes a hybrid neural attention model which combines self and cross attention mechanism to locate salient part from textual context and interaction between users. Experimental results on three (dis)agreement inference datasets show that our model outperforms the state-of-the-art models.

1 Introduction

The rise of various discussion forums and online debate platforms, has given users a lot of opportunities to express themselves and argue with each other. The online argumentation and discussion are always initiated and evolved by expressions of agreement or disagreement of participants. Inferring the agreement/disagreement in online debates is crucial for many other tasks in broader analysis of social media and argumentation mining, such as stance identification (Somasundaran and Wiebe, 2010), claim/argument extraction (Hidey et al., 2017) and persuasion analysis (Tan et al., 2016).

It is observed that the expression of agreement/disagreement in debates can be decomposed into two factors: 1) the self-expression of claims and 2) argumentative expressions to interact with other participants. To illustrate this observation, we show some examples in Figure 1, which is one of quote-response pair (Q-R pair) in 4forum online debate website. The response expressed disagreement with the claim in quote text. The mark *?* at the end of sentence carries strong emotion of authors, while the phrase *why doesn't He answer* refers to the claims of *God IS GOOD* and express the refutation to it.

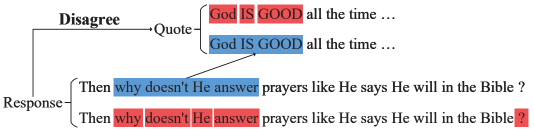

Figure 1: Sampled Q-R Pair with topic of evolution where the words colored red deliver crucial meaning of the text itself, while the words colored blue clarify the interactive relation between users.

Previous works on agreement/disagreement inference mainly focus on exploiting features to model the semantic information which only reveals author's self-expression. (Rosenthal and McKeown, 2015; Menini and Tonelli, 2016). These existing models treat agreement/disagreement inference as a ordinary sentiment classification problem and ignore the interactions between participants in the discussion. In order to jointly leverage the semantic information of the text and interactions between Q-R pairs, we regard the (dis)agreement inference as a special case of Natural Language Inference (NLI) (Rocktäschel et al., 2016), and propose a hybrid neural attention model to this problem. The proposed model consists of two kinds of attention: 1) **self attention** locates salient parts in text of quote and response, and 2) **cross attention** captures the interactive argumentations between Q-R pairs. The fusion of self and cross attention model is capable of jointly modeling the two important factors of inferring (dis)agreement in debates.

The main contributions of this paper are: (1) We propose a neural attention model for (dis)agreement inference which converts this

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 665–670
Brussels, Belgium, October 31 - November 4, 2018.

problem to a natural language inference task. The proposed model incorporates self and cross attention mechanism, jointly capturing significant part for current context and extracting interactive relations between Q-R pairs. (2) Experimental results on three datasets show that the proposed model significantly improves performance (measured by $F1$ score and accuracy) of state-of-the-art models by 1% on average. The visualization of extracted attention demonstrates different attention mechanism works effectively in different aspect for (dis)agreement inference.

2 Related Work

With the development of social forums, works on (dis)agreement inference have shifted to online debate. Abbott et al. (2011) utilize word-based and dependencies-based features to recognize disagreement in Internet Argument Corpus (IAC) (Walker et al., 2012). Rosenthal and McKeown (2015) present a new corpus derived from participant information, Agreement by Create Debaters (ABCD), and investigate new features for conversational structure. Further, Menini and Tonelli (2016) develop a SVM classifier to detect disagreement, relying on three aspects including sentiment-based, semantic and surface features extracted from both whole text and topic-related part. However, the performances of all these models highly depend on the quality of hand-crafted features. And these representations cannot reflect the interaction between quote and response.

In other NLP tasks, the end-to-end deep learning approaches with attention mechanism have shown impressive results. The attention mechanism is proposed by Bahdanau et al. (2014) in machine translation for selecting alignment between original words and foreign words before translation. For Document Classification, Yang et al. (2016) apply a hierarchical attention from word-level to sentence-level with learnable context vector. In Natural Language Inference (NLI), Liu et al. (2016) construct an inner-attention with mean pooling vector to seize important part from text itself. Hao et al. (2017) propose an cross attention modeling mutual influence between question and answer for Question Answering (QA). But there is no neural attention model incorporating both contextual and interactive information in the scenario of (dis)agreement inference.

3 Model

The overall architecture of our model is shown in Figure 2, comprising two parallel bi-directional LSTM (Hochreiter and Schmidhuber, 1997) networks as quote and response encoder and two attention components that respectively extract self and cross attention.

3.1 Quote and Response Encoder

A quote of length T is denoted as $[q_1, q_2, \cdots, q_T]$, where $q_t \in \mathbb{R}^{d_e}$ is the d_e-dimensional representation of the t-th word in the text sequence. Similarly, the corresponding response can be represented as $[r_1, r_2, \cdots, r_T]$, which shares the same vector space with quote. To model the dependence relation of text sequence, we leverage bi-directional LSTM (BiLSTM) to encode quote and response. The BiLSTM consists of a forward $\overrightarrow{LSTM}$ which reads the text from x_1 to x_T and a backward $\overleftarrow{LSTM}$ which reads from x_T to x_1:

$$\overrightarrow{h_t} = \overrightarrow{LSTM}(x_t), t \in [1, T] \quad (1)$$

$$\overleftarrow{h_t} = \overleftarrow{LSTM}(x_t), t \in [T, 1] \quad (2)$$

Through concatenation, we obtain the representation of each time step $h_t = [\overrightarrow{h_t}; \overleftarrow{h_t}] \in \mathbb{R}^{2d}$ which integrates the information around x_t. The quote and response are encoded as $h_Q = [\overrightarrow{h_Q}; \overleftarrow{h_Q}] \in \mathbb{R}^{T\times 2d}$ and $h_R = [\overrightarrow{h_R}; \overleftarrow{h_R}] \in \mathbb{R}^{T\times 2d}$ respectively.

3.2 Attention Component

After encoding the implicit word semantics, we acquire the representation of both quote and response.

Self Attention

The first source taken into consideration should be the text sequence itself, i.e. the attention from quote to quote itself and that from response to response itself. When issuing an opinion, people tend to center on several keywords which convey the main idea. Thus in some sense, self attention is a kind of dependency parsing that drives the model to focus on salient parts of the context. Here, for quote $h_Q = [h_Q^1, h_Q^2, \cdots, h_Q^T]$, self attention generates signal s_Q^t by:

$$s_Q^t = \frac{\exp[\delta(h_Q^t)]}{\sum_{i=1}^{T} \exp[\delta(h_Q^i)]} \quad (3)$$

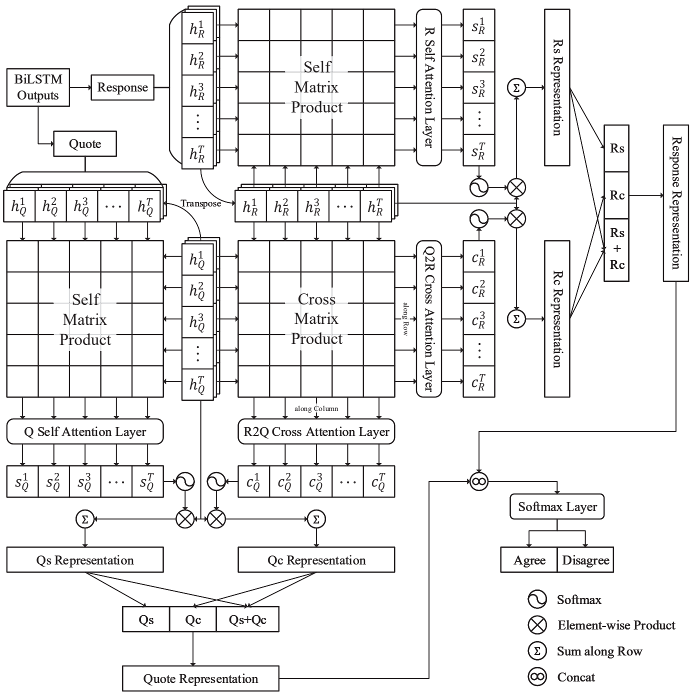

Figure 2: Model Architecture.

where δ is a transformation mapping $2d$-dimensional vector into scalar value, with learnable weight $W_S \in \mathbb{R}^T$ and bias $b_S \in \mathbb{R}$ defined as:

$$\delta(h_Q^t) = \tanh[W_S(h_Q \cdot (h_Q^t)^{\mathrm{T}}) + b_S] \qquad (4)$$

Similarly, with another parallel transformation, the self attention signal of response can be calculated as above. Then, we can obtain a more compact representation of quote and response respectively derived from the weighted sum, where $Q_S, R_S \in \mathbb{R}^{2d}$.

$$Q_S = \textstyle\sum_{t=1}^{T} s_Q^t h_Q^t \qquad (5)$$

$$R_S = \textstyle\sum_{t=1}^{T} s_R^t h_R^t \qquad (6)$$

Cross Attention

Another prominent facet comes from the relation between each Q-R pair, i.e the attention from quote to response and that from response to quote. In whether disagreement or agreement cases, both quote and response provides a precise context for each other. The cross attention integrates interactive influence which produces more specific features for (dis)agreement inference.

As discussed above, cross attention c_Q^t, c_R^t for quote and response can be computed by:

$$c_Q^t = \frac{\exp[\gamma(h_R^t)]}{\sum_{i=1}^{T}\exp[\gamma(h_R^i)]} \qquad (7)$$

$$c_R^t = \frac{\exp[\gamma'(h_Q^t)]}{\sum_{i=1}^{T}\exp[\gamma'(h_Q^i)]} \qquad (8)$$

where γ and γ' are two parallel transformation with learnable weight matrix $W_C, W_C' \in \mathbb{R}^T$ and bias $b_C, b_C' \in \mathbb{R}$ defined as:

$$\gamma(h_R^t) = \tanh[W_C(h_Q \cdot (h_R^t)^{\mathrm{T}}) + b_C] \qquad (9)$$

$$\gamma'(h_Q^t) = \tanh[W_C'(h_R \cdot (h_Q^t)^{\mathrm{T}}) + b_C'] \qquad (10)$$

The representation of whole sequence $Q_C, R_C \in \mathbb{R}^{2d}$ embracing cross attention signal are:

$$Q_C = \textstyle\sum_{t=1}^{T} c_Q^t h_Q^t \qquad (11)$$

$$R_C = \textstyle\sum_{t=1}^{T} c_R^t h_R^t \qquad (12)$$

Hybrid Attention

In order to cooperate the advantage of self attention and cross attention, we design hybrid attention to get a more specific representation for quote and response:

$$Q = Q_S \oplus Q_C \oplus (Q_S + Q_C) \qquad (13)$$

$$R = R_S \oplus R_C \oplus (Q_S + Q_C) \qquad (14)$$

where $Q, R \in \mathbb{R}^{6d}$ and $\oplus$ is the vector concatenation operation.

3.3 (Dis)agreement Inference

Finally, the quote representation Q and response representation R are concatenated as a vector v. We use a fully-connected network to project $12d$-dimensional representation into n-dimensional vector space, i.e.

$$y = softmax(W_l v + b_l) \tag{15}$$

where $y \in \mathbb{R}^n$ is predicted probability distribution for (dis)agreement inference, W_l and b_l are parameters of softmax layer.

In a supervised learning framework, we train our model in an end-to-end way. Given a set of training data $\{(Q_i, R_i), y_i\}$, let $\widehat{y_i}$ denote the predicted probability distribution, the goal of training is to minimize the cross-entropy loss:

$$loss = -\sum_i \sum_j y_i^j \log \widehat{y}_i^j \tag{16}$$

where i is the index of quote-response pair, j is the index of class and y_i is the ground truth of corresponding pair.

4 Experiment and Results

As prior work, we concentrate on direct disagreement and agreement between quote-response (Q-R) pairs. Specifically, in the proposed model, the size of hidden units is 128 and all word embeddings are initialized by GloVe (Pennington et al., 2014) of 300d. Both length of quote and response are set to 64, padded where necessary. Adam is the optimizer of model whose learning rate is $1e-3$, β is $(0.9, 0.999)$, ϵ is $1e-8$ and weight decay is $1e-5$. All models are trained by mini-batch of 32 instances, with 5-fold cross validation.

4.1 Datasets

We conduct experiments on three most commonly-used (dis)agreement inference datasets. Table 1 shows the detail of these datasets.

Table 1: Detail of Datasets

Dataset	# Disagree	# Agree	# Neutral
IAC	6,157	1,113	-
DP	12,899	11,875	-
ABCD	25,200	13,519	72,683

- *Internet Argument Corpus (IAC)* (Walker et al., 2012) is a corpus crawled from online political debate `4forums.com`. Following prior work, we compute average score for each pair and convert the score into binary labels, with $[-5, -1]$ as disagreement and $[+1, +5]$ as agreement.
- *Debatepedia (DP)* (Menini and Tonelli, 2016). DP corpus is crawled from `debatepedia.org`, which is an online encyclopedia of debates.
- *Agreement by Create Debaters (ABCD)* (Rosenthal and McKeown, 2015) is developed from `createdebate.com` with labels of agreement, disagreement and neutral. As the original settings, the comparison experiments are conducted on a balanced training set by downsampling and the full test set.

4.2 Comparison with Baseline Methods

As shown in Table 2, by accuracy and average $F1$-score in percentage, we compare our model with the best performing model of corresponding dataset to our knowledge. These models are reported in (Abbott et al., 2011; Menini and Tonelli, 2016; Rosenthal and McKeown, 2015) as Naive Bayes (NB), JRipχ^2 (ruled based classifier using χ^2 for feature selection), SVM, Maximum Entropy (ME), exploiting a rich suite of features including n-grams, sentiment lexicon and syntax.

We also analyze the contribution of each component in ablation experiment. BiLSTM-sum and BiLSTM-concat refer only sum or concat operation is applied to both self and cross attention respectively. Results show that BiLSTM-hybrid gives the best performance across all datasets regardless of data sizes. For smaller dataset such as IAC, our model outperforms the previous best methods by 8.8%. This outcome is consistent across other larger datasets with a significant improvement of 19.6% on DP. What' s more important, on DP, the length of text is longer than other datasets, so ordinary BiLSTM suffering from gradient vanishing results in the poor performance. It is the hybrid attention that effects. As for ABCD, compared with ME based on textual features, Our BiLSTM-hybrid also gives superior performance of average $F1$ in 3-way inference. Since ABCD is a corpus annotated by meta-thread rules, the ME attaching conversational structure attains the best

Table 2: Experimental results on three datasets.

2-way Inference				3-way Inference	
IAC		DP		ABCD	
Approaches	Accuracy	Approaches	Accuracy	Approaches	Average $F1$
NB	60.3	SVM	74.0	ME	50.8
JRipχ^2	68.2	-	-	ME+structure*	**77.6**
Liu et al., 2016	74.9	Liu et al., 2016	92.4	Liu et al., 2016	76.5
BiLSTM	72.9	BiLSTM	55.2	BiLSTM	71.1
BiLSTM-self	76.1	BiLSTM-self	93.5	BiLSTM-self	75.8
BiLSTM-cross	76.4	BiLSTM-cross	93.3	BiLSTM-cross	75.9
BiLSTM-sum	76.4	BiLSTM-sum	93.3	BiLSTM-sum	76.4
BiLSTM-concat	76.8	BiLSTM-concat	93.5	BiLSTM-concat	76.4
BiLSTM-hybrid	**77.0**	BiLSTM-hybrid	**93.6**	BiLSTM-hybrid	76.9

(*) Conversational structure is a corpus-specific feature.

performance. We think it a corpus-specific feature with weak generalization ability.

In addition, we adapt a NLI-oriented model proposed by Liu et al. (2016) as a stronger baseline, which comprises inner-attention with mean pooling. The mean pooling of text encoder is set as the summary representation for inner-attention to seize important part from text itself. It is similar to our self attention but with coarse-grained level from text to word. The results imply that our BiLSTM-hybrid modeling additional interaction with fine-grained attention from word to word performs better.

4.3 Qualitative Analysis

To validate that different attention focuses on different part of text sequence, we visualize the outputs of self attention layer and cross attention layer, with a Q-R pair of disagreement from IAC. As show in Figure 3, darker color indicates larger weight in the corresponding attention vector.

In quote, the self attention selects *good* which is exactly the point that quote wants to argue. Similarly, the self attention selects *?* in response, which indicates a rhetorical mood to show disagreement. On the other hand, even though *why doesn't he answer* in response is endowed less weight from the self attention, the cross attention highlights it and *god* in quote. When inspecting the cross matrix product of this pair, Figure 4 demonstrates that our method is able to model the reference between *god is good* and *why doesn't he answer* in the whole interactive context.

5 Conclusion

In this paper, we propose a hybrid attention based neural network for (dis)agreement inference in debate. The main motivation is to jointly leverage self attention for textual context and cross attention for interactions between users to improve the capability of inference on agreement/disagreement relations. Experimental results show that our model outperforms several strong baselines. Visualization of extracted attention of our model illustrates that our models is effective in capturing the main point from different aspects.

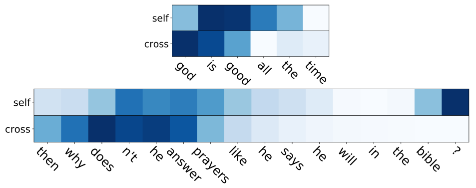

Figure 3: Attention Visualization. The topic is about evolution and the attitude of response is *disagreement*.

Increasing In-Class Similarity by Retrofitting Embeddings with Demographic Information

Abstract

Most text-classification approaches represent the input based on textual features, either feature-based or continuous. However, this ignores strong non-linguistic similarities like homophily: people within a demographic group use language more similar to each other than to non-group members. We use homophily cues to retrofit text-based author representations with non-linguistic information, and introduce a trade-off parameter. This approach increases in-class similarity between authors, and improves classification performance by making classes more linearly separable. We evaluate the effect of our method on two author-attribute prediction tasks with various training-set sizes and parameter settings. We find that our method can significantly improve classification performance, especially when the number of labels is large and limited labeled data is available. It is potentially applicable as preprocessing step to any text-classification task.

1 Introduction

Predicting socio-demographic author characteristics is becoming ever more relevant with the pervasive use of user-generated content. Classifying user attributes such as age and gender is useful for a number of applications both in the public sector, where it can support the investigation of crime (in forensic linguistics) or the determination of social policies, and in the private sector, where companies want to profile a potential consumer market, targeting communication strategies and advertising to specific communities. Furthermore, recent work in NLP has shown that incorporating author attributes in various NLP tasks can also improve performance (Volkova et al., 2013; Hovy, 2015; Hovy and Søgaard, 2015; Lynn et al., 2017; Preotiuc-Pietro et al., 2016).

In these tasks, authors are typically represented via their linguistic profiles, i.e., information available in the text. This includes both word-based features as well as continuous representations (embeddings). Generally, linguistic features are divided into content-related and strictly stylistic features. While the first can be effectively represented by (n-grams of) words which capture the topic and meaning of a text, the second ones focus on the use of function words, expressions, pronouns, syntactic structures, etc. There is evidence in the literature that content-related text characteristics are more effective than stylistic features for gender and age prediction (Fatima et al., 2017; Rosenthal and McKeown, 2011). This effect is the consequence of a non-linguistic auto-selection process known as *homophily*: people within in a demographic group tend to be more similar to each other than to other groups, and subjects belonging to different groups are therefore naturally more prone to discuss different topics.

Despite the large amount of available social media data (in April 2018, Facebook had more than two billion active users, YouTube and WhatsApp each one-and-a-half billion, and Twitter 330 million, see statista.com), we often encounter scenarios with limited availability of ground-truth user attributes, leading to remarkable performance differences to, say, blogs. This difference is due to the shortness of social media texts and the wider range of topics (Rangel et al., 2016), which weaken linguistic profile features. In such cases, improving author representations beyond the linguistic profiles can be especially useful.

We implement this intuition of leveraging demographic homophily by using retrofitting (Faruqui et al., 2015), a method introduced to refine word vectors to reflect semantic similarity information from lexicons. In our case, we increase the similarity between the (linguistically-based) continuous authors representations within each class (here: age or gender). Authors who

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 671–677
Brussels, Belgium, October 31 - November 4, 2018.

share the same gender or age therefore get more similar vector representations (see section 3.2). This effectively increases class-separability and can thereby improve classification performance.

We also experiment with a trade-off parameter α, which controls the relative influence of the retrofitting process vs. the original embedding vector on the retrofit representation, allowing us to explore the effect of both factors on the final prediction outcome.

In order to extend the in-class homophily information to unlabeled data, we induce a transformation matrix to translate between the original and retrofitted embedding space. This matrix can be applied to unlabeled data to transform the author representations in the test set.

We use a set of almost 100K authors to predict age and gender. In order to explore limited-resource scenarios, we experiment with a range of training set sizes. Our results indicate that demographic retrofitting of linguistic representations substantially increases classification performance for age and gender prediction, especially in low-resource scenarios.

It is an easy, fast, and efficient preprocessing step that can substantially improve classification performance. We show our method for author-attribute prediction, but believe it can potentially be applied to *any* text-classification task.

Contributions In this paper, we introduce demographic retrofitting based on in-class homophily, and make the following contributions:

1. we present a substantial expansion of the original retrofitting algorithm (Faruqui et al., 2015). In contrast to prior work, which relies on external ontologies, our method relies solely on the information contained within the training data.

2. We show how to generalize the transformation from training data to unlabeled data, using a translation matrix.

3. We publicly release all our data and models on our GitHub page, https://github.com/Bocconi-NLPLab/retrofit_attributes.

2 Data

We use data from Hovy et al. (2015), a collection of reviews of online companies from various countries, including author information. We select all reviews written in English from American and British sources, if they include both age and gender of the author, and if the review is at least 10 tokens long (shorter reviews tend to be mistokenized URLs or replies). We aggregate the reviews by users, so that each instance is a collection of texts' from a unique user. This leaves us with 98,608 individual users, and about 8M words (roughly 80 words per instance). For each user, we use the age (discretized by decade) and gender (self-stated as binary, and augmented by Hovy et al. (2015) based on the users' first name) as target variables. We minimally preprocess the text data, collapsing all numbers into 0s, and tokenizing via spacy (Honnibal and Johnson, 2015).

3 Methodology

In our experiments, we are interested in the effect of homophily-inducing retrofitting on author-attribute prediction. In order to evaluate the effect, we compare the performance of author representations based on linguistic input to the performance of the same representation retrofitted to the author attribute class in question. In this section, we outline the details for the different steps.

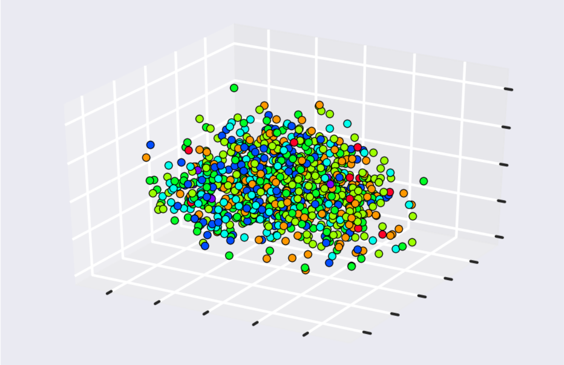
3.1 Linguistic author representations

We train Doc2Vec, a paragraph2vec (Le and Mikolov, 2014) implementation, on the corpus, inducing a 98K-by-300 matrix D, where each row represents an author. We follow the parametrization suggested in Lau and Baldwin (2016), setting the window size to 15, minimum word-frequency to 10, negative samples to 5, downsampling rate to 0.00001, and run for 1000 iterations. We use the resulting author embeddings as input to the author-attribute classifier (see 3.4). We induce the author embeddings over the entire corpus of 98K authors, without recurrence to age or gender information.

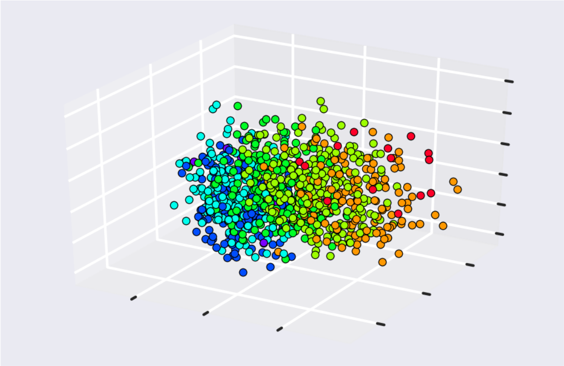
As comparison, we also create a bag-of-words (BOW) representation with the same dimensionality. We use χ^2 as selection criterion to find the top 300 words in the training data, separately for both age and gender classification.

3.2 Retrofitting

Our goal is to enhance the author representations, which are based on linguistic similarity, with demographic information about the target variable (say, age). In order to introduce this information into the vector space, we rely on *retrofitting*, by in-



(a) Non-retrofitted



(b) Retrofitted

Figure 1: Schematic representation of 500 authors colored by age group, without (top) and with (bottom) retrofitting

creasing the similarity of authors within the same target group (say, people in their 20s). We thereby separate the target classes in embedding space, making them easier to differentiate by a classifier.

Faruqui et al. (2015) introduced retrofitting of word vectors based on external ontologies, such as WordNet (Miller, 1995) or PPDB (Ganitkevitch et al., 2013). Instead of these resources, we map each labeled author to the list of all other authors with the same label in the training data. Formally, we create a set Ω containing tuples of authors $(d_i, d_j | y_i = y_j)$. We do this separately for each demographic dimension - age and gender.

During retrofitting, we iteratively update the author representation in the training data (initially linguistically-based) to increase the cosine similarity between authors within the same class (as defined in Ω). This creates a retrofitted matrix $\hat{D}_{train}$ of the original author matrix D_{train}. The update for an author representation d_i is a weighted combination of the original embedding and the average over all its current neighbors:

$$\hat{d}_i = \alpha d_i + \beta \frac{\sum_{j:(i,j)\in\Omega} \hat{d}_j}{N}$$

where d_i is the original linguistic representation vector, $N = |\{\forall j : (i,j) \in \Omega\}|$ is the set of all embeddings in the same label group, and α and β are hyper-parameters that control the trade-off between the original representation and the updates from the neighboring embeddings during retrofitting. In Faruqui et al. (2015), $\alpha = \beta$. In contrast, we define

$$\beta = 1 - \alpha$$

By varying α from 0 to 1, we can control the strength of the retrofitting process. $\alpha = 1$ simply reproduces the original matrix, i.e., $\hat{D} = D$, whereas $\alpha = 0$ only relies on the neighborhood updates after the initialization. Figure 1 shows a sample of 500 users in a non-retrofitted (1a) and retrofitted (1b) 3D embedding space, colored by class. The color distribution shows how people belonging to the same group get drawn closer to each other in embeddings space when using retrofitting.

3.3 Translation

We can only retrofit the embeddings of authors in the training set D_{train}, since we need information about the class label in order to construct Ω. However, the retrofitting process changes the configuration of the embedding space (into $\hat{D}_{train}$), so a separating hyperplane learned on $\hat{D}_{train}$ will not be applicable to a test set D_{test} in the original embedding space.

In order to extend the homophily information to authors in the test set, we use a *translation matrix* T (a 300×300 matrix), which approximates the transformation from the original training data matrix D_{train} into the retrofitted matrix $\hat{D}_{train}$. We obtain T by minimizing the least-square difference in $D_{train} \cdot T = \hat{D}_{train}$.

T captures the retrofitting operation, and allows us to modify the test subjects' representations *as if* age and gender were known, despite the absence of class information. In particular, by applying T to the matrix of the author embeddings in the unlabeled test set D_{test}, we obtain a retrofitted version $\hat{D}_{test}$ that preserves the transformation learned on the training data. Since the least-square approximation is not perfect, we find that in practice fitting a classifier on the approximation $D_{train} \cdot T$

works better than using $\hat{D}_{train}$, acting as a regularizer.

3.4 Classification

We retrofit the author embeddings in the training set (see 3.2) and learn a translation matrix to transform the representations of the remaining authors in the test set. We train three separate Logistic Regression classifiers: one on author embeddings, one on the retrofit embeddings, and one on BOW features. It is technically possible to retrofit BOW representations as well, but in practice, the classifier does not converge, as word count-based vectors do not represent a continuous space that captures latent similarities.

We then use the three classifiers to predict the author attributes of the remaining authors in the test data set. We evaluate the results via micro-F1 score (averaged over 100 runs), since our tasks include imbalanced multi-class scenarios: micro-F1 weights the contribution of each class according to their relative size and is therefore more informative than accuracy.

Since we are interested in the effect of the training set size on performance, we vary the number of available training examples from 1000 to 10,000, using the remaining authors as test set. For each training set size, we collect 100 random subsamples and average over them.

4 Results

The learning curves in Figure 2 show that retrofitting outperforms both the original author embeddings and BOW representations for age (top) and gender (bottom) prediction in terms of F1. The effect is stronger when little training data is available. We evaluate the statistical significance of the difference between results with retrofitting and original embeddings via a bootstrap sampling test. We do not test against BOW, since this is consistently lower than embeddings. The resulting p-value are given in the respective figures. For gender classification, there are small, but not significant improvements with retrofitting. By contrast, for age classification, small values of α (0.01, 0.1, and 0.25) result in significantly better classification than when using any other method.

The performance differences between the methods are generally more pronounced for age-prediction, which has 10 possible labels, than for gender prediction (two labels). The difference in optimal α value suggests a relation between α and label space.

In both tasks, the best result is achieved by choosing a low α, i.e., by giving more weight to the demographic association of the users than to their linguistic feature representations. In practice, this value should be determined via cross-validation: here we show different levels of α in order to give some intuition of its on performance. Note that the curves for the original embeddings and BOW are unaffected by α and do not change. We repeat them at each figure for comparison. Increasing α eventually converges with the original embeddings, but we see that even intermediate values can be close to the original embeddings.

5 Related Work

The first studies to apply statistical NLP techniques to author attribute prediction are Koppel et al. (2002); Argamon et al. (2003), using the British National Corpus (BNC). The same authors also introduced the use of blogs as data source (Koppel et al., 2006).

In recent years, predicting socio-demographic variables from text has seen increased interest, with several corpora for the classification of age and gender, covering various languages, such as English (Schler et al., 2006; Rosenthal and McKeown, 2011), Spanish, French, German, Dutch (Company and Wanner, 2015), Greek (Mikros, 2012), Chinese (Zhang et al., 2016), and Vietnamese (Pham et al., 2009).

A big contribution in this field, however, was the shared tasks of the PAN workshops (Rangel et al., 2013, 2014, 2015, 2016).

Research has identified a variety of linguistic features, ranging from "stylistic features with n-grams models, parts-of-speech, collocations, LDA, different readability indexes, vocabulary richness, correctness or verbosity" (Rangel et al., 2016). However, none of these papers used demographic information directly in the author representations.

Closest to our method are Lopez-Monroy et al. (2013), who propose the use of second-order representations. They created specific profiles for the target classes, and exploited them for the creation of the profile of each document. In both cases, the linguistic representation of the documents passes through a class-related profile.

The methods applied in the PAN workshops also reflect the recent research trend towards word embeddings, which we explore in this pa-

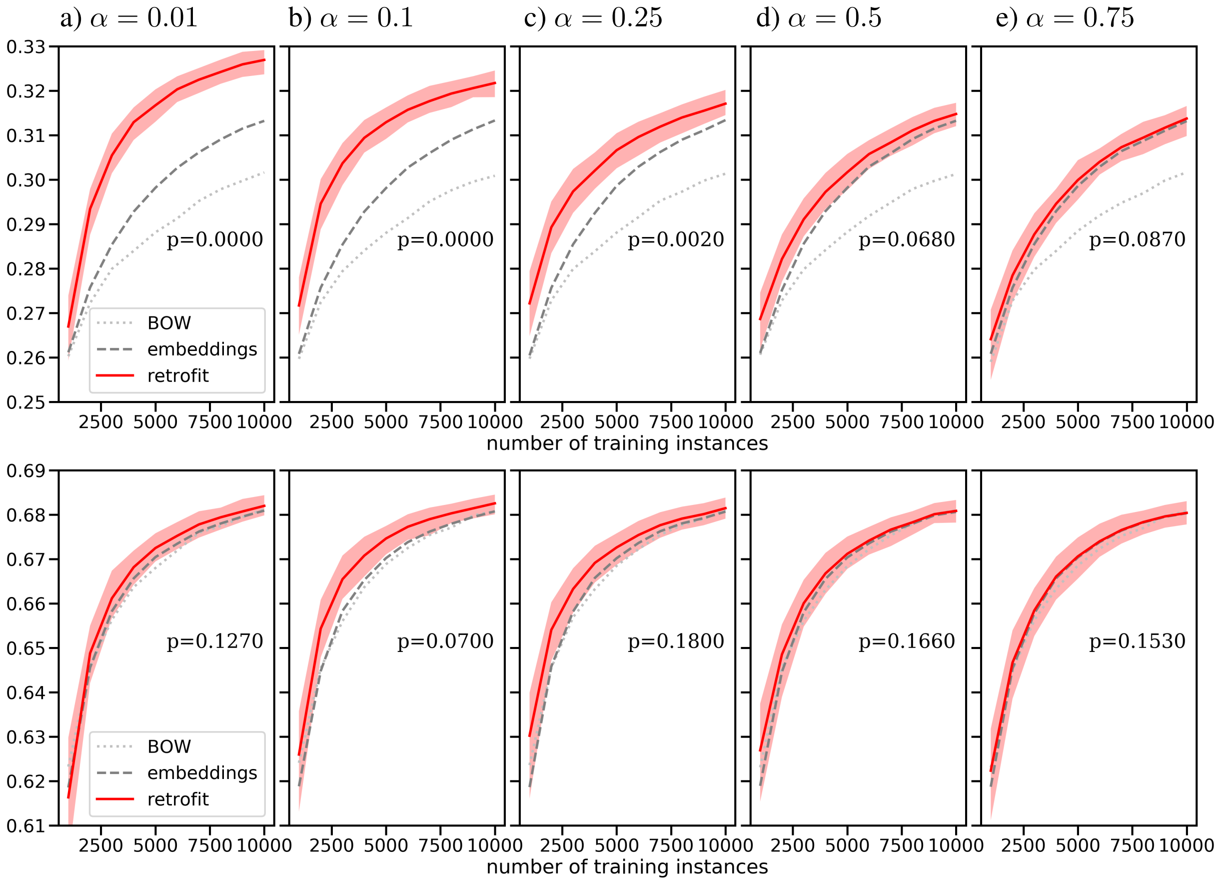


Figure 2: Learning curves (micro-F1) for 3 classifiers on age (top) and gender prediction (bottom) for different values of α. Retrofitting influence decreases from left to right. All data points averaged over 100 runs. Shaded area is 95%-confidence interval for retrofitting. p-values denote statistical difference between original and retrofit embeddings according to bootstrap test.

per. Bayot and Gonçalves (2016) first used `word2vec` embeddings as input features to a SVM classifier, followed by the use of convolutional (CNN) and recurrent neural networks (RNN) by Miura et al. (2017). Markov et al. (2016) also created document representations through word2vec, using a Logistic Regression classifier.

6 Conclusion

We explore retrofitting text-based author embeddings with non-linguistic demographic information to increase in-class similarity. This method increases class-separability to improve classification performance. We use a corpus of almost 100K users, and evaluate the effect of our method on age and gender prediction for various levels of available training data. We find that aggressive retrofitting (prioritizing homophily over linguistic embeddings) is beneficial for prediction performance, especially when the available amount of training data is limited. While the effect diminishes with increased training data size, our approach provides a simple method to incorporate non-linguistic knowledge into author representations. For another application (introducing geographic information into city representations), see Hovy and Purschke (2018). Our method is fast, simple, and applicable to any problem represented in embedding space. It is therefore a viable preprocessing step to any text-classification task.

A Syntactically Constrained Bidirectional-Asynchronous Approach for Emotional Conversation Generation

Abstract

Traditional neural language models tend to generate generic replies with poor logic and no emotion. In this paper, a syntactically constrained bidirectional-asynchronous approach for emotional conversation generation (E-SCBA) is proposed to address this issue. In our model, pre-generated emotion keywords and topic keywords are asynchronously introduced into the process of decoding. It is much different from most existing methods which generate replies from the first word to the last. Through experiments, the results indicate that our approach not only improves the diversity of replies, but gains a boost on both logic and emotion compared with baselines.

1 Introduction

In recent years, as artificial intelligence has developed rapidly, researchers are pursuing technologies with greater similarities to human intelligence. As a subjective factor, emotion performs an elemental difference between humans and machines. In other words, machines that could understand emotion would be more responsive to human needs. For example, in education, positive emotions improve students' learning efficiency (Kort et al., 2002). In healthcare, mood prediction can be used in mental health counseling to help anticipate and prevent suicide or depression (Taylor et al., 2017; Jaques et al., 2017). To make machine more intelligent, we must resolve the conundrum of emotional interactions.

There are tons of researches about conversation, an important channel for communication between humans. And lots of work has recently been carried out in open-domain conversation devoted to generating meaningful replies (Vinyals and Le, 2015; Li et al., 2016; Serban et al., 2016). Unfortunately, the factors considered in these methods only concerns topic, like (Xing et al., 2017), where they failed to take emotion into account. Unlike the former, the work in (Zhou et al., 2017) first addressed the emotional factor in large-scale conversation generation, and it showed that emotional replies obtain superior performances compared to the baselines that did not consider emotion. However, two defects still manifest themselves in the aforementioned models. **First**, all methods above only adopted a single factor (i.e., topic or emotion), because of which the bias of information can not comprehensively summarize the human conversations to achieve favorable results. **Second**, the way that generates replies from the first word to the last can lead to a decline in diversity, limited by the high-frequency generic words in the beginning (e.g., I and you), as argued in (Mou et al., 2016).

The deficiencies above inspire us to introduce a new approach called E-SCBA, studying both emotion and topic. Three main contributions are presented in this paper: (1) It conducts a study of compound information, which constitutes the syntactic constraint in the conversation generation. (2) Different from the work in (Mou et al., 2016), a bidirectional-asynchronous decoder with multi-stage strategy is proposed to utilize the syntactic constraint. It ensures the unobstructed communication between different information and allows a fine-grained control of the reply to address the problem of fluency and grammaticality as argued in (Ghosh et al., 2017; Zhou et al., 2017). (3) Our experiments show that E-SCBA work better on emotion, logic and diversity than the general seq2seq and other models that consider only a single factor during the generation.

2 Model

2.1 Overview

The whole process of emotional conversation generation consists of the following three steps:

---

[*] The corresponding author of this paper.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 678–683
Brussels, Belgium, October 31 - November 4, 2018.

***Step I*:** Given a post, we first use two networks combined with category embeddings to respectively predict emotion keyword and topic keyword that should appear in the final reply (see Section 2.2).

***Step II*:** After the prediction, a newly designed decoder is used to introduce both keywords into the content[1], as shown in Figure 1. It first produces a sequence of hidden states based on the emotion keyword (Step I), and then uses an emotional attention mechanism to affect the generation of middle sequence, which is based on the topic keyword (Step II). The remaining two sides are ultimately generated by the combination of middle part and keywords (Step III). A detailed description is given in Section 2.3.

***Step III*:** Finally, a direction selector is used to arrange the generated reply in a logically correct order by selecting the better one from forward and backward forms of the reply generated in the last step (see Section 2.4).

In this work, we default that the replies contain at least one emotion keyword and one topic keyword, which are expected to appear in the dictionaries we used.

2.2 Keyword Predictor

The keywords to be selected are pre-stored in the prepared dictionaries. The adopted emotion dictionary was proposed by (Xu et al., 2008), which contains 27,466 emotion words divided into 7 categories: *Happy*, *Like*, *Surprise*, *Sad*, *Fear*, *Angry* and *Disgust*. The adopted topic dictionary was obtained by the LDA model (Blei et al., 2003), including 10 categories with 100 words for each category. And to avoid situations in which emotion and topic keywords are predicted to be the same word, all the overlapping words in these two dictionaries default to emotion keywords.

The prediction of emotion and topic keywords follows the similar path. We first derive topic category and emotion category from the post with two classifiers separately. To be more specific, the pretrained LDA model is used for the topic category inference. And the work in (Sun et al., 2018) is applied for emotion. The concrete model is an emotion transfer network. Given a specific external stimuli (e.g., a sentence), the network produce an emotional response, which is specifically an emotion category in this work. After this, combining the sum of hidden states $\tilde{h} = \sum_{i=1}^{T} h_i$ from encoder and the category embeddings $\boldsymbol{k} = \{k^{et}, k^{tp}\}$, keywords are predicted as follows:

$$p(w_{et}^{k}|\boldsymbol{x}, k^{et}) = softmax(\mathbf{W}_{et}^{w}[\tilde{h}; k^{et}]) \quad (1)$$

$$p(w_{tp}^{k}|\boldsymbol{x}, k^{tp}) = softmax(\mathbf{W}_{tp}^{w}[\tilde{h}; k^{tp}]) \quad (2)$$

where w_{et}^{k} and w_{tp}^{k} separately represent the emotion keyword and topic keyword that are expected to appear in the reply.

2.3 Bidirectional-Asynchronous Decoder

Due to the decoder architecture shown in Figure 1, we suppose the reply in this section is $\boldsymbol{y} = (\boldsymbol{y}^{ct}, w_{tp}^{k}, \boldsymbol{y}^{md}, w_{et}^{k}, \boldsymbol{y}^{ce})$[2] where $\boldsymbol{y}^{md}$ is the middle part between two keywords and $\boldsymbol{y}^{ct}$, $\boldsymbol{y}^{ce}$ represent the remaining sides connected to the topic keyword and emotion keyword. The generation of middle part $\boldsymbol{y}^{md} = (y_1^{md}, ..., y_K^{md})$ can be described as follows:

$$c_j^{et} = f_{att}^{et}(s_{j-1}^{tp}, \{s_i^{et}\}_{i=1}^{K'}) \quad (3)$$

$$p(\boldsymbol{y}^{md}|\boldsymbol{x}, \boldsymbol{w}^{k}) = \prod_{j=1}^{K} p(y_j^{md}|y_{j-1}^{md}, s_j^{tp}, c_j^{et}) \quad (4)$$

where $\boldsymbol{w}^{k} = < w_{et}^{k}, w_{tp}^{k} >$ represents the set of keywords, s_i^{et} and s_j^{tp} separately represent the decoding state of the steps that introduce emotion keyword and topic keyword. c_j^{et} is the emotional constrain unit at time j, computing by the emotion control function f_{att}^{et} as follows:

$$c_j^{et} = \sum_{i=1}^{K'} \alpha_{j,i}^{et} s_i^{et} \quad (5)$$

$$\alpha_{j,i}^{et} = \frac{\exp(e_{j,i}^{et})}{\sum_{t=1}^{K'} \exp(e_{j,t}^{et})} \quad (6)$$

$$e_{j,i}^{et} = (\mathbf{v}_{\alpha}^{md})^{T} tanh(\mathbf{W}_{\alpha}^{md} s_{j-1}^{tp} + \mathbf{U}_{\alpha}^{md} s_i^{et}) \quad (7)$$

where $e_{j,i}^{et}$ represents the impact scores of the emotion state s_i^{et} on the topic state s_{j-1}^{tp}.

After generating the middle part, we connect it with the keywords to form a new sequence. Two seq2seq models are used to encode the connected

---

[1] Syntactic constraint starts to work here, and can be intuitively interpreted as relative positions of emotion words and topic words, as well as different combinations between them.

[2] For the training data in opposite direction, we reversed the target replies to meet the requirement.

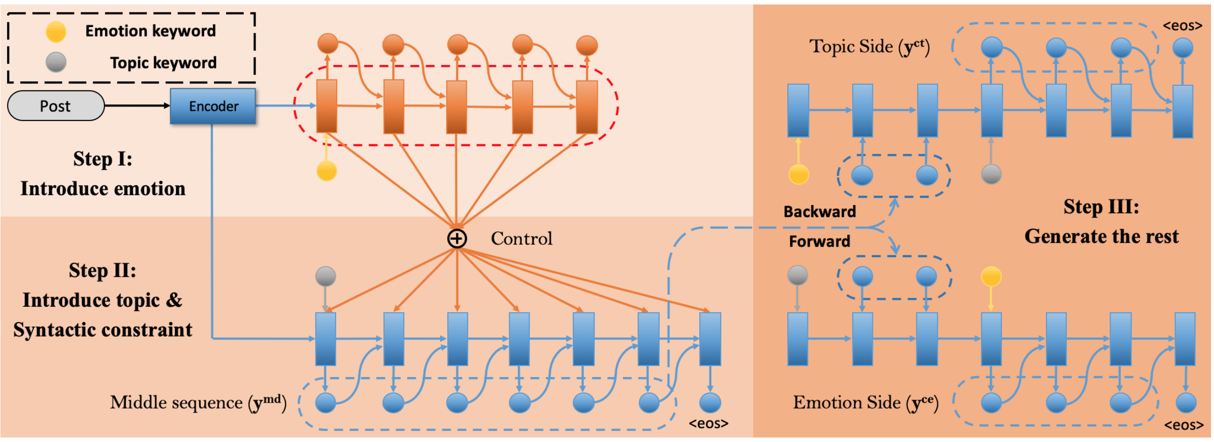

Figure 1: The process of generating replies in the test. The middle part of the reply is generated in Steps I and II, and the remaining two sides are generated in Step III. The RNN networks used in the decoder do not share the parameters with each other.

sequences and decode $\boldsymbol{y}^{ce} = (y^{ce}_1, ..., y^{ce}_M)$ and $\boldsymbol{y}^{ct} = (y^{ct}_1, ..., y^{ct}_N)$, as below:

$$p(\boldsymbol{y}^{ce}|\boldsymbol{w}^k, \boldsymbol{y}^{md}) = p(\boldsymbol{y}^{ce}|[w^k_{tp}, \boldsymbol{y}^{md,f}, w^k_{et}]) \quad (8)$$

$$p(\boldsymbol{y}^{ct}|\boldsymbol{w}^k, \boldsymbol{y}^{md}) = p(\boldsymbol{y}^{ct}|[w^k_{et}, \boldsymbol{y}^{md,b}, w^k_{tp}]) \quad (9)$$

where $\boldsymbol{y}^{md,f}$ and $\boldsymbol{y}^{md,b}$ are the forward and backward situations of the middle part, respectively.

2.4 Direction Selector

To make the samples meet the requirements of decoder, by default we place the topic keyword as the first keyword on the left and the emotion keyword on the right in training. However, in real situations, the topic keyword does not always appear before the emotion keyword, where we must determine correct direction by the machine.

By connecting the results in the preceding section, we get $\boldsymbol{y}^f = (\boldsymbol{y}^{ct,b}, w^k_{tp}, \boldsymbol{y}^{md,f}, w^k_{et}, \boldsymbol{y}^{ce,f})$ as the forward situation and $\boldsymbol{y}^b$ means the backward situation. GRU networks are used as encoders to process sequences in different situations, which do not share parameters. And the direction is predicted by:

$$p(d|\boldsymbol{y}^f, \boldsymbol{y}^b) = sigmoid(\mathbf{W}^d[\tilde{h}^{d,f}, \tilde{h}^{d,b}]) \quad (10)$$

$$\tilde{h}^{d,*} = \sum_{i=1}^{T'} \mathbf{GRU}(y^*_i) \quad (11)$$

where $* \in \{f, b\}$ means forward or backward. After the operation completes, one of the sequences $\boldsymbol{y}^f$ and $\boldsymbol{y}^b$ should conform to our expectations.

3 Experiment

3.1 Data

We evaluated and trained E-SCBA on the emotional conversation dataset NLPCC2017. There are a total of 1,119,201 Chinese post-reply pairs in the set. The dictionaries mentioned in Section 2.2 were used to mark the conversation. The cases whose replies contain both emotion keywords and topic keywords account for 42.6% (476,121) of the total[3], which are suitable data for the bidirectional-asynchronous decoder. We randomly sampled 8,000 for validation, 3,000 for testing and the rest for training. We also sampled another 60,000 pairs from the training set to train the LDA model[4] mentioned in Section 2.2. Besides, an error analysis is presented based on a Chinese movie subtitle dataset which is collected from the Internet.

3.2 Metrics

To evaluate our approach, we use the metrics as below:

Embedding-based Metrics: We measure the similarity computed by cosine distance between a candidate reply and the target reply using sentence-level embedding, following the work in (Liu et al., 2016; Serban et al., 2017).

---

[3] Please note that we did not use the original labels of the dataset, but the emotion categories of the keywords as labels to avoid unnecessary bias. For cases that contain multiple topic keywords or emotion keywords, we chose the keywords that appear less frequently to reduce imbalances.

[4] High frequency words and stop words, which have no benefit to the topics, were removed in advance.

Table 2: The results of automatic evaluation (G–E = Greedy Matching, E–A = Embedding Average, V–E = Vector Extrema).

Distinct Metrics: By computing the number of different unigrams (Distinct-1) and bigrams (Distinct-2), we measure information and diversity in the candidate replies, following the work in (Li et al., 2016; Xing et al., 2017).

Human Annotations: We asked four annotators to evaluate the replies[5] generated from our approach and baselines from *Consistency*, *Logic* and *Emotion*. *Consistency* measures fluency and grammaticality of the reply on a three-point scale: 0, 1, 2; *Logic* measures the degree to which the post and the reply logically match on a three-point scale[6] as above; *Emotion* judges whether the reply includes the right emotion. A score of 0 means the emotion is wrong or there is no emotion, and a score of 1 is the opposite.

3.3 Baselines

In the experiments, E-SCBA is compared with the following baselines:

S2S: the general seq2seq model with attention method (Bahdanau et al., 2014).

S2S-STW: the model uses a synchronous method that starts generating its reply solely and directly from the topic keyword.

S2S-SEW: the model uses a synchronous method that starts generating its reply solely and directly from the emotion keyword.

S2S-AW: the model uses an asynchronous method the same as (Mou et al., 2016).

The synchronous method in S2S-STW and S2S-SEW was mentioned in (Mou et al., 2015), acting as the contrast to the asynchronous models.

3.4 Results and Discussion

The results of automatic evaluation are shown in Table 2. Compared with the best model (S2S-AW) that considers only a single factor, E-SCBA makes significant improvement on the distinct metrics (+0.056 and +0.165), which verifies the effectiveness of taking both emotion and topic information into account to improve the diversity. Likewise, our approach also respectively achieves 0.042, 0.068 and 0.043 gains on G-M, E-A and V-E, benefiting from the compound information that captures the thrust of human conversation so that E-SCBA has a better ability to learn the goal distribution. Furthermore, the grades of the asynchronous models are higher than the synchronous models on both kinds of metrics, showing that the asynchronous method is a more suitable way for content-introducing conversation generation.

Table 1 depicts the human annotations (*t-test*: $p < 0.05$ for C and L, $p < 0.01$ for E). Overall, E-SCBA outperforms S2S-AW on all three metrics, where the compound information plays a positive role in the comprehensive promotion. However, in *Surprise* and *Angry*, the grades of *Consistency* and *Logic* are not satisfactory, since the data for them are much less than others (*Surprise* (1.2%)

---

[5] 700 conservations in total, 100 for each emotion category, were sampled randomly from the test set.

[6] If a reply is too short or turns up frequently, it would be annotated as either 0 or 1 (if the annotator thought the reply related to the post), like ”Me too” and ”I think so”.

Post	Emotion	Chinese	English(translated)
受当局追捕，我们只能秘密活动。 Hunted by the authorities, we work in secret.	Disgust	有一种被**嘲讽**的**感觉**。	There is a **sense** of being **mocked**.
我一直在观察你们的制作过程。 I have been observing your production process.	Happy	我**希望**你继续**努力**	I **hope** you keep **working hard**
假如你那天阻止了他，事情就不会这样了。 If you had stopped him that day, things would have been different.	Sad	不要**回忆**过去的**日子**了！	Don’t **look back** on the **past**!
普通民众中也可以拥有某些权利的概念。 The general public can also have some concepts of rights.	Like	可以**作为**他们**生活**的一部分	This can **be** a part of their **life**
我们现在也可以离开这里了。 We can also leave here now.	Sad	**挺遗憾**的。	What a **pity**.
那个人最期待的是像你这样的美女送这个箱子。 The man is looking forward to having a beautiful girl like you to send this box.	Disgust	我**期待**的是像你这样的**流氓**	I am **looking forward to** a **hooligan** like you

Table 3: Sampled conversations with a corresponding emotion from the Chinese movie subtitle data.

and *Angry* (0.7%)). Besides, the score of *Emotion* in *Surprise* has a big difference from others. We think the reason is that the characteristic of *Surprise* overlaps with other categories that have much more data, such as *Happy*, which interferes with the learning efficiency of the approach in *Surprise*. Meanwhile, it is harder for annotators to determine which one is the right emotion.

3.5 Case Study and Error Analysis

In this section, we sampled some typical cases from a Chinese movie subtitle dataset to do a further error analysis. The cases are shown in Table 3. The post of weibo and movie subtitle are applied in different scenes to obey different distributions. The weaker correlation between training sets and test sets can present a more reliable study.

The first three conversations are positive samples and others are negative samples that have content with flaws. For the reply in the antepenultimate line, its problem is the faint emotion. Since the emotion keyword in this sentence is a polysemic word, and it expresses a meaning with no emotion here. Under diverse circumstances, a polysemic word probably have different meanings, emotional or neutral. For example, the word ”like” can be a generic word when it denotes *similar*, but it can also be an emotion word when it denotes *enjoy*. Same situation also occurs in Chinese. Besides, we notice that if the LDA model pick a meaningless topic keyword from the dictionary, our approach may have a difficulty in generating a diverse and long reply, as the reply in the penultimate line. The lack of information causes generic replies which are consisted of few words generated from the networks. The last line presents another limitation. The emotion keyword *hooligan* corresponds to the post and the topic keyword *looking forward to* is meaningful, but the combination of them, *looking forward to* a *hooligan*, does not conform to the normal logic. This situation is caused by the fact that two kinds of keywords are generated independently before decoding, and it may cause a mismatch. In the future, we will try to explore different network architectures to make keywords interact with each other during the generation.

4 Conclusion

In this paper, we proposed a novel conversation generation approach (E-SCBA) to make a more comprehensive optimization for the quality of reply, which introduces both emotion and topic knowledge into the generation. The newly designed decoder makes use of syntactic knowledge to constrain generation and ensures fluency and grammaticality of reply. Experiments show that our approach can generate replies that have rich diversity and feature both emotion and logic.

Abstract

The lack of labeled data is one of the main challenges when building a task-oriented dialogue system. Existing dialogue datasets usually rely on human labeling, which is expensive, limited in size, and in low coverage. In this paper, we instead propose our framework *auto-dialabel* to automatically cluster the dialogue intents and slots. In this framework, we collect a set of context features, leverage an autoencoder for feature assembly, and adapt a dynamic hierarchical clustering method for intent and slot labeling. Experimental results show that our framework can promote human labeling cost to a great extent, achieve good intent clustering accuracy (84.1%), and provide reasonable and instructive slot labeling results.

1 Introduction

Building a task-oriented dialogue system is challenging. In real world, unlabeled dialogue data is usually available for companies who has interactive platform with users. Based on these unlabeled data, the well-known sequence-to-sequence framework (Sutskever et al., 2014; Cho et al., 2014) is widely used in dialogue response generation (Vinyals and Le, 2015; Sordoni et al., 2015; Shang et al., 2015), but it can not handle task-oriented scenario well since it needs accuracy instead of fluency. Generally, a task-oriented dialogue system needs to realize user's *intent*, which means *user's current goal in a dialogue session*. To fulfill this intent, the system usually needs several key information (*slot*). As shown in Figure 1, a dialogue utterance is labeled with *intent* flight, and several *slots* such as its from_location, arrive_time. Training a task-oriented dialogue system usually needs abundant such labeled data.

Existing well-known dialogue datasets are mostly human-labeled, such as ATIS (Hemphill et al., 1990), DSTC (Williams et al., 2013), Frames (El Asri et al., 2017), and the Stanford dataset (Eric et al., 2017). Human-labeled datasets are expensive to produce, limited in size, and restricted to a specific domain, which make them difficult to extend. Moreover, the intent and slot label sets are usually decided by human experience. Since we usually do not know the exact intents or slots of a new unlabeled data, the assigned label names may be subjective in some extent. To better assist the human labeling process, Wen et al. (2017) proposed an improved version of *Wizard-of-Oz* (Kelley, 1984) data collection methods, which incorporate crowdsourcing to collect domain specific data. Instead of human-labeling, Cohn et al. (1995) proposed a semisupervised framework *active learning*, which can minimize the need for human annotation in a certain extent. However, these approaches are still mostly or selectively human-labeled, and may be distracted by the disadvantages raised above.

Thus, in this paper, we propose an unsupervised labeling method to automatically cluster dialogue intents and corresponding slots. Since the intent of a dialogue utterance may depend on its topic or some frequent key words, utterances in the same intent may share similar context features. Hence, we cluster these utterances into different intents. Given a new dialogue dataset whose number and type of intents are uncharted, the clustering process does not need any prior information and can derive a new set of intents. We modify dynamic clustering methods to automatically decide the number of clustering classes. The clustered intents are labeled as integer indices. Before clustering, for better utilization of extracted features, we leverage an autoencoder to map all features into the same space. For the slot labeling, since the phrases of same slots such as location and time may share same type of features, we leverage a similar way to cluster slots within each intent.

Depart_time	8 am
Arrive_time	11 pm
Round_trip	one way

Figure 1: An example of the dialogue labeling task.

Experimental results on the ATIS dataset (Hemphill et al., 1990) show that our proposed methods can achieve 84.1% intent clustering accuracy, and provide reasonable and instructive slot labeling results. Moreover, since the whole process is unsupervised, it can be much faster and more consistent and objective than human labeling, and extended to other domains. We think the proposed methods can be a good attempt for the automatic dialogue labeling task.

2 Auto-Dialabel Framework

Formally, we treat a multi-turn dialogue session $\mathcal{D} = \{\mathcal{Q}_1, \mathcal{R}_1, \cdots, \mathcal{Q}_\mathcal{N}, \mathcal{R}_\mathcal{N}\}$ as a sequence of $\mathcal{N}$ query-response pairs between two interlocutors, in which *query* $\mathcal{Q}_*$ represents user's utterance and *response* $\mathcal{R}_*$ represents assistance's utterance. Each query utterance $\mathcal{Q}_t$ should be labeled with an intent $\mathcal{I}_t \in [0, \mathcal{K}]$, which represents the interlocutor's purpose in current utterance. $\mathcal{K}$ is the number of intent classes, and should be dynamically decided during the labeling procedure.

Since each intent has its corresponding slots, for intent $\mathcal{I}_t$, we set its slot as $\mathcal{S}_t = \{\mathcal{S}_{t,1}, \cdots, \mathcal{S}_{t,L_t}\}$, where $\mathcal{L}_t$ is number of slots in $\mathcal{I}_t$. $\mathcal{S}_t$ is also learned automatically and dynamically.

In detail, given a set of query utterances, the unsupervised dialogue auto-labeling system labels the intents and slots based on the following steps:

feature extraction and assembly, which extracts a set of context features $\mathcal{F}$ from query utterance, and leverages an autoencoder to compress each extracted feature into same size, then concatenate them as the assembled feature embedding $\mathcal{E}$.

intent clustering, which adopt dynamic hierarchical clustering to get intents based on $\mathcal{E}$.

slot clustering, which leverages the same clustering methods to get slots based on word-level features and labeled intents.

The process of intent labeling is shown in Figure 2. Slot labeling has a similar process to intent labeling. Features are a key to both intent labeling and slot labeling. We first introduce the feature extraction and assembly, which involves all the features used in our model. It is noted that we leverage all the features for intent clustering while we only use word-level features for slot labeling.

2.1 Feature Extraction and Assembly

We design a set of context features $\mathcal{F}_*$ at different levels of granularity to model the query utterance, including *word embedding*, *POS tag*, *frequent key words*, and *topic features*.

Word Embedding Given an n-words $\mathcal{Q} = \{w_1, \cdots, w_n\}$, intuitively, the feature of $\mathcal{Q}$ relied on each words within it. One frequently-used way to model a sentence by words is to use a mean pooling for all word embeddings: $\mathcal{F}_\mathcal{W} = \frac{1}{n}\sum_i^n \textit{embedding of } w_i$

POS Tag Since the distribution of the POS tag may effect the sentence's structure in syntactic level, we use *bag-of-POS* as the POS tag feature $\mathcal{F}_\mathcal{P}$. Given n_p types of POS tags, $\mathcal{F}_\mathcal{P} = \{p_1, \cdots, p_{n_p}\}$ is a discrete vector in which each dimension p_i represents the existence of a POS tag POS_i.

Frequent Key Words In several occasions, the intent of a sentence is decided by some *key words*. So we specially emphasize it by introducing the frequent key words feature $\mathcal{F}_\mathcal{X}$. $\mathcal{F}_\mathcal{X} = \{x_1, \cdots, x_c\}$ represents the information of key words in query utterance. To centralize the word information, we cluster all the noun words into c different classes by its word embedding, then count the occurrence frequency of each class as a discrete vector $\mathcal{F}_\mathcal{X}$.

Topic The topic-level feature denotes the topic information of query utterance. We leverage an unsupervised topic model to get the topic distribution $\mathcal{F}_\mathcal{T} \in \mathbb{R}^t$ as the topic-level feature, t is the number of topics. Since query utterance are short

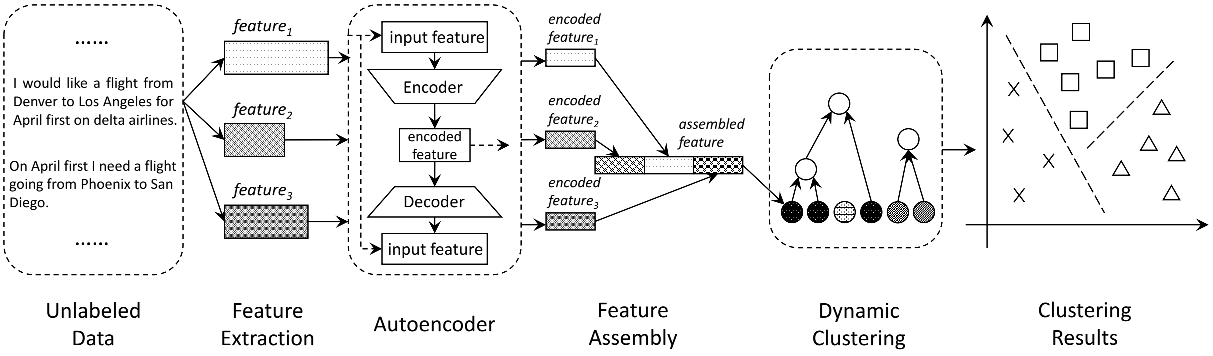

Figure 2: An illustration of our proposed auto-dialabel framework for intent labeling.

texts, while conventional topic models such as LDA and PLSA depends on document-level word co-occurrence patterns to detect topics, which may suffer from data sparsity, thus directly applying those models may not work well. In this paper, we leverage the biterm topic model (BTM) proposed by Yan et al. (2013) for better performance.

The assembled feature embedding $\mathcal{E}$ is the combination of each $\mathcal{F}_i$. Since each $\mathcal{F}_i$ has different dimensions, which may unequally affect the clustering results, we use an autoencoder to encode all $\mathcal{F}_i$ into same dimensions as $\mathcal{E}_i$, then we concatenate all the $\mathcal{E}_i$ as $\mathcal{E}$, which will be used in the clustering procedure, as shown in Figure 2.

2.2 Intent Clustering

Since given a new set of dialogue data, we do not know the number of intents it contains, thus we adapt the hierarchical clustering method to a *dynamic* version which can automatically decide the end of the clustering process by the cohesion of different classes. At the beginning of clustering, each query utterance is considered as a different class. At each steps, the cluster model chooses two classes which are the closest in distance, and cluster them into the same class. We use radial basis function (rbf) as the clustering distance. This process ends when all the distances exceed the threshold value, which is tuned on a labeled dataset, and fixed for future use.

2.3 Slot Clustering

Since slots usually correspond to intents, we do slot labeling based on both the query utterance and the labeled intents. Considering that most slots are composed of noun words, we extract all the noun words in a dialogue, and leverage the same clustering methods as in the intent clustering part to cluster them into different slot classes. Note that the slot clustering are word-level. So in *feature extraction*, it did not extract the topic-level features.

3 Experiments

3.1 Dataset and Baseline Systems

We conduct experiments on the widely used ATIS dataset (Hemphill et al., 1990). The clustering parameters are tuned on the training set of the ATIS dataset (Hemphill et al., 1990), while the experiments are conducted on its test set. During clustering, we tune the clustering distance limit since it may be more general than the number of classes, and can be transferred to other datasets. The radial basis function (rbf) is used with sklearn default settings.

Since there is no existing systems specially designed for unsupervised dialogue labeling, we choose three well-known and widely used sentence representation methods, and leverage the results vector for clustering as our baseline systems. The first one is the BTM topic model (Yan et al., 2013). We use the topic distribution for clustering. The second one is the CDSSM model proposed by Shen et al. (2014). We use the clickthrough data for pre-training and get encoded sentence vector for clustering. The third one is the sentence embedding calculated by the average of word embedding in query utterance. For each baseline, we leverage the k-means for clustering and use the gold intent number as the cluster number of these models.

3.2 Intent Labeling

We leverage glove.6B.300d (Pennington et al., 2014) as the pre-trained word embedding in all the baseline and proposed systems. The POS tag is labeled through NLTK toolkit (Bird et al., 2009).

Models	Intent Labeling Acc (%)
topic model	25.4
CDSSM vector	20.7
glove embedding	25.6
auto-dialabel	**84.1**

Table 1: Intent labeling accuracy.

The topic number of BTM is set to 20 as default. Each encoded feature dimension is set to 30, then concatenated to a 120 dimension assembled vector. We have 17 kinds of gold intents, and our system predicted 18 kinds of intents. Since the clustering results have no label information, we sort the predicted intent classes and gold intent classes by size, and manually map them. We leverage intent labeling accuracy as the evaluation metrics.

3.2.1 Overall Performance

Our auto-dialabel can reduce the tedious work of understanding the intent of each dialogue utterance and finding slot words in it. It clusters all utterances into several intent classes, and words into slot classes, which leaves human labelers only small labors to set label names for each class. Experimental results show that with auto-dialabel, we can label the whole ATIS dataset in less than 1 hour from end to end, compared to days we spend by human labeling. Table 1 shows the performance comparison of our model with other baseline systems. From Table 1, we find that our proposed auto-dialabel achieves high intent labeling accuracy (84.1%) and outperforms other baseline systems by a large margin. This may be because that the baseline systems are not specifically designed for intent scenario so that they can not handle the intent and slot clustering well, or are not capable of capturing complex intent relevant information.

3.2.2 Ablation Tests

Feature Extraction The feature extraction part extracts 4 kinds of features. We conduct ablation tests including and excluding each kind of features to see the performance. The results are shown in Table 2. From Table 2, we find the frequent key information as the most important feature. Since the intent is usually influenced by key words occurring in utterance, these kind of features can better capture key information which contributes most to the intent detection. On the contrary, the topic feature is less useful. Since it is not designed for this task, the information it represents may not directly assist the detection of intents.

Model	Acc	Model	Acc	Model	Acc
$\mathcal{F}_{\mathcal{T}}$	50.8	$-\mathcal{F}_{\mathcal{T}}$	78.9	*no_encode*	32.5
$\mathcal{F}_{\mathcal{X}}$	78.0	$-\mathcal{F}_{\mathcal{X}}$	77.5	*K-means*	28.5
$\mathcal{F}_{\mathcal{W}}$	75.9	$-\mathcal{F}_{\mathcal{W}}$	80.7	*Spectral*	40.7
$\mathcal{F}_{\mathcal{P}}$	70.2	$-\mathcal{F}_{\mathcal{P}}$	78.3	***auto-dialabel***	**84.1**

Table 2: Intent labeling ablation tests. $\mathcal{F}_*$ shows the performance of the system with only feature $\mathcal{F}_*$. $-\mathcal{F}_*$ shows the performance of the system excluded feature $\mathcal{F}_*$. *no_encode* shows the performance of the system excluded the autoencoder parts.

Intent	Slot
flight	*period_of_day* : noon, evening *month_name* : november, april *day_name* : monday, sunday *city_name* : cleveland, houston
ground_service	*period_of_day* : night, morning; *day_name* : monday; *city_name* : denver, washington

Table 3: Slot clustering cases

Feature Assembly We concatenate the originally extracted features for clustering. The results are shown in Table 2 as *no_encode*, which suggests that the encoding part is essential in feature assembly. Since each feature has a different dimension, if we alternatively concatenate them directly, the ”longer” feature may get more ”attention”, which may distract the clustering results. Generally, encoding all the features into the same dimension is an efficient way to balance the information.

Dynamic Clustering To test the performance of our modified dynamic clustering method, we leverage two most common used clustering methods for ablation test, which are k-means and spectral clustering. Both clustering numbers are set to gold intent number. The results are shown in Table 2, and we can find both methods perform worse than our methods, which shows that our methods can handle this task well. Besides, both baseline methods need prior intent number which is unavailable in advance in most cases. Compared with these baseline clustering methods, our method can dynamically determine the intent number and is more practical.

3.3 Slot Labeling

Due to the limitation of space, we just show some slot clustering result cases in Table 3. After manually assigning names, we find that auto-dialabel can extract about 70% of the slots with accuracy, including *city_name*, *period_of_day*, *month_name*, and *day_name*. The labeled slots above are the main slots for this scenario and could cover a large portion of airline ticket reservation demands. Generally, the slots clustered by auto-dialabel are reasonable and constructive.

4 Conclusion

In this paper, we formalize the auto-labeling task for dialogue data, and propose an unsupervised framework *auto-dialabel*. We design a set of linguistics and neural-network based features, leverage an autoencoder for feature assembly, and modify a hierarchical clustering method for dialogue intents and slots labeling. Experimental results show that our framework can achieve 84.1% intent clustering accuracy, and provide reasonable and instructive slot labeling results.

Abstract

The use of connectionist approaches in conversational agents has been progressing rapidly due to the availability of large corpora. However current generative dialogue models often lack coherence and are content poor. This work proposes an architecture to incorporate unstructured knowledge sources to enhance the next utterance prediction in chit-chat type of generative dialogue models. We focus on Sequence-to-Sequence (Seq2Seq) conversational agents trained with the Reddit News dataset, and consider incorporating external knowledge from Wikipedia summaries as well as from the NELL knowledge base. Our experiments show faster training time and improved perplexity when leveraging external knowledge.

1 Introduction

Much of the research in dialogue systems from the last few years has focused on replacing all (or some) of its components with Deep Neural Network (DNN) architectures (Levin and Pieraccini, 1997; Dahl et al., 2012; Li et al., 2017; Serban et al., 2016a,b; Vinyals and Le, 2015). These DNN models are trained end-to-end with large corpora of human-to-human dialogues, and essentially learn to mimic human conversations.

Although these models can represent the input context, the need for a dedicated external memory to remember information in context was pointed out and mechanisms were introduced in models like Memory Networks (Sukhbaatar et al., 2015; Bordes et al., 2016; Gulcehre et al., 2018), and the Neural Turing Machine (Graves et al., 2014). Although these models, in theory, are better at maintaining the *state* using their memory component, they require longer training time and excessive search for hyperparameters.

In this paper we explore the possibility of incorporating external information in dialogue systems as a mechanism to supplement the standard context encoding and facilitate the generation to be more specific with faster learning time. Furthermore, especially in the case of chit-chat systems, knowledge can be leveraged from different topics (education, sports, news, travel, etc.). Current memory-based architectures cannot efficiently handle access to large unstructured external knowledge sources.

In this work, we build on the popular Encoder-Decoder model, and incorporate external knowledge as an additional continuous vector. The proposed Extended Encoder-Decoder (Ext-ED) architecture learns to predict the embedding of the relevant external context during training and, during testing, uses an augmented *state* of external context and encoder final state to generate the next utterance. We evaluate our model with experiments on Reddit News dataset, and consider using either the Wikipedia summary (Scheepers, 2017) or the NELL KB (Carlson et al., 2010) as a source of external context.

2 Related Work

Incorporating supplemental knowledge in neural conversational agents has been addressed in a few recent works on dialogue systems. Previous research however was mostly in the context of goal-driven dialogue systems, where the knowledge-base is highly structured, and queried to obtain very specific information (e.g. bus schedules, restaurant information, more broad tourist information).

Few goal-oriented dialogues research use external information directly from the web or relevant data sources. An exception is (Long et al., 2017), which searches the web for relevant infor-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 690–695
Brussels, Belgium, October 31 - November 4, 2018.

mation that pertains to the input context and provides them as suggestions (like advising on places to visit while the user intends to visit a city). Similarly, instead of dynamically querying the web, (Ghazvininejad et al., 2017) pre-trains the model from facts in Foursquare (Yang et al., 2013) to select relevant facts as suggestions.

Moving closer to unstructured domains, but still within task-driven conversations, (Lowe et al., 2015) proposes a way of retrieving relevant responses based on external knowledge sources. The model selects relevant knowledge from Ubuntu man pages and uses it to retrieve a relevant context-response pair that is inline with the knowledge extracted. Similarly, (Young et al., 2017) extracts relations within the context and parses over it to score the message response pairs. The relational knowledge provides a way of incorporating useful knowledge or *common sense* as termed by the authors.

Though (Guu et al., 2017) did not directly make use of an external knowledge source, they used an *edit vector* that aids in editing a sampled prototype sentence. This is relevant to our proposed model as the generated response is conditioned on a supplementary vector similar to the external context vector discussed later in this paper.

3 Technical Background

3.1 Recurrent Neural Networks

The Recurrent Neural Network (RNN) is a variant of neural network used for learning representations of inputs, $\boldsymbol{x_{1:T}}$, that have an inherent sequential structure (speech, video, dialogue etc.). In natural language processing, RNNs are used to learn language models that generalize over n-gram models (Katz, 1987). The RNN maintains a hidden state, h_t, that is an abstraction of inputs observed until time-step t of the input sequence, and uses x_t to operate on them. RNN uses two projection functions, U and W, for computing operations on input and hidden states respectively. A third function, V, to map h_t to the output, y_t, the output of the RNN at every time step t. y_t, is a distribution over the next token given the previous tokens, and is computed as a function of h_t. The functions of the RNN can be explained as shown in Equations 1 and 2,

$$h_t = g\left(U \cdot x_t + W \cdot h_{t-1} + b\right), \tag{1}$$

$$y_t = V \cdot h_t + d, \tag{2}$$

where y_t is the output, x_t is the vector representation of input token, h_t is the internal state of the RNN at time t and g is a non-linear function (like *tanh* or *sigmoid*). RNNs are trained with Back Propagation Through Time (BPTT) (Rumelhart et al., 1988) to compute weight updates using the derivative of a loss function with respect to the parameters over all previous time-steps.

3.2 Seq2Seq Dialogue Architecture

Generative dialogue models (Sutskever et al., 2014; Serban et al., 2015) extends the language model learned by RNNs to generate natural language that are conditioned not only on the previous words generated in the response but also on a representation of the input context. The ability of such a learning module to *understand* an input sequence of words (that we call context ($\boldsymbol{c^i_{1:T}}$)) and *generate* a response $\boldsymbol{r^i_{1:T}}$ tantamount to solving the *dialogue task*.

(Vinyals and Le, 2015) first proposed a vanilla LSTM (Hochreiter and Schmidhuber, 1997) dialogue model that encodes a given context with an LSTM (*Encoder*) and feeds it to another LSTM (*Decoder*) that generates a response token-by-token. Here the choice of encoder and decoder modules can be any recurrent architectures like GRU (Cho et al., 2014), RNN, Bi-directional LSTM (Schuster and Paliwal, 1997), etc. The model is then trained to learn a conditional distribution over the vocabulary for generating the next token in response to the i^{th} context as shown in Equation 3:

$$P\left(\boldsymbol{r^i_{1:T}} \mid \boldsymbol{c^i_{1:T}}\right) = \Pi_{k=1}^{T} P\left(r^i_k \mid \boldsymbol{r^i_{1:k-1}}, \boldsymbol{c^i_{1:T}}\right). \tag{3}$$

With neural language models, this form can aid in maintaining long term dependencies and the next word distribution can be made to conditionally depend on an arbitrarily long context. Sophisticated models have made significant architectural improvements to aid better modelling of the contexts (Serban et al., 2016b).

4 Extended Encoder Decoder Architecture

The primary objective of the proposed architecture is to supplement response generation with external knowledge relevant to the context. Most of the knowledge sources that are available are free-form and lack suitable structure for easy querying of relevant information. In this work, we attempt to incorporate such unstructured knowledge corpora for dialogue generation in Seq2Seq models.

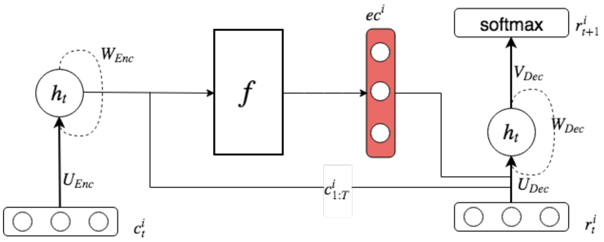

Figure 1: Architecture Diagram of Extended Encoder Decoder Model.

4.1 The Model

The Extended Encoder Decoder (Ext-ED) model, shown in Figure 1, uses an encoder LSTM (parameterized as $\boldsymbol{\Theta}_{Enc}$) to encode the i^{th} context, $\boldsymbol{c^i_{1:T}}$, and a fully connected layer (f) to predict an external context vector ($\boldsymbol{ec^i}$) conditioned on the encoded context. The predicted external context vector, $\boldsymbol{ec^i}$, is provided to the decoder LSTM ($\boldsymbol{\Theta}_{Dec}$) at every step, augmented with the encoder final state and previous predicted token, to generate the next token in the response:

$$P\left(\boldsymbol{ec^i} \mid \boldsymbol{c^i_{1:T}}\right) = f\left(\boldsymbol{\Theta_{Enc}}\left(\boldsymbol{c^i_{1:T}}\right)\right) \quad (4)$$

$$P\left(\boldsymbol{r^i_{1:T}} \mid \boldsymbol{c^i_{1:T}}\right) = \Pi_{k=1}^{T} P\left(r^i_k \mid \boldsymbol{r^i_{1:k-1}}, \boldsymbol{c^i_{1:T}}, \boldsymbol{ec^i}\right). \quad (5)$$

The decoder is provided with an encoding of the context along with the external knowledge encoding, as $\boldsymbol{ec^i}$ acts as information supplement to the knowledge available in the context as shown in Equations 4 and 5.

During training, the gradients for Ext-ED parameters ($f, \Theta_{Enc}, \Theta_{Dec}$) are computed by backpropagating the gradients for parameters with respect to losses in Equations 6, 7 and 8:

$$\mathcal{L}_1 = \sum_{k=1}^{T} Q\left(r^i \mid \hat{ec}^i, c^i\right) \log P\left(r^i \mid c^i\right), \quad (6)$$

$$\mathcal{L}_2 = \|\hat{\boldsymbol{ec}}^i - \boldsymbol{ec^i}\|_2, \quad (7)$$

$$\mathcal{L}_3 = -\sum_{k=1}^{T} Q\left(r^i \mid c^i, \mathbf{0}\right) \log P\left(r^i \mid c^i\right). \quad (8)$$

Here $\mathcal{L}_1$ is the log-likelihood that is used to make the model distribution mimic the data distribution. $\mathcal{L}_2$ trains f to correctly predict ec^i, and $\mathcal{L}_3$ trains Θ_{Dec} to make use of the external context by forcing it the model distribution to diverge when not provided with the external context (ec^i is set to $\mathbf{0}$ vector). In the loss equations, P and Q represent the data and the model learned distributions respectively, and $\boldsymbol{ec^i}$ and $\hat{\boldsymbol{ec}}^{\boldsymbol{i}}$ represent true and model(f) predicted external knowledge encoding.

4.2 External Context Vector

We use Wikipedia summary (Scheepers, 2017) and NELL knowledge base (KB) (Carlson et al., 2010) to compute the external knowledge encoding for every context in the context-response pairs. Algorithm 1 oultines the pseudocode for computing the external context vector ($\boldsymbol{ec^i}$). For i^{th} input context, the methods *Return_All_Values_for_Entity* or *Wiki_Summary_Query* is used to extract the external knowledge vector, ec^i, from NELL KB or Wikipedia summary sources.

Algorithm 1: Get_External_Context _Vector ($\boldsymbol{c^i_{1:T}}$)

```
$\boldsymbol{ec^i} \leftarrow$ zero_vector
$\#\_Ext\_Tokens \leftarrow 0$
for t in range (1,T) do
    if $c^i_t$ is not a stop word then
        External_Tokens$_{List}$ ←
          Wiki_Summary_Query($c^i_t$)
        % Return_All_Values_for_Entity($c^i_t$)
        for token in External_Tokens$_{List}$ do
            $\boldsymbol{ec^i} \leftarrow \boldsymbol{ec^i}$ +
              GloVe_Embedding(token)
            $\#\_Ext\_Tokens \leftarrow \#\_Ext\_Tokens + 1$
return $\frac{\boldsymbol{ec^i}}{\#\_Ext\_Tokens}$
```

The external context encoding, $\boldsymbol{ec^i}$, is a fixed length continuous embedding of the knowledge from external sources, as having all the words sampled (represented as a Bag of Words) proved to be a severe computational overhead because of sparsity.

The continuous embedding of external context provides an additional conditioning with relevant external knowledge that is used to generate the next utterance. Although this is the intended hypothesis, there are certain expected characteristics that are desirable of external knowledge sources for them to be useful:

- The knowledge vectors being away from the

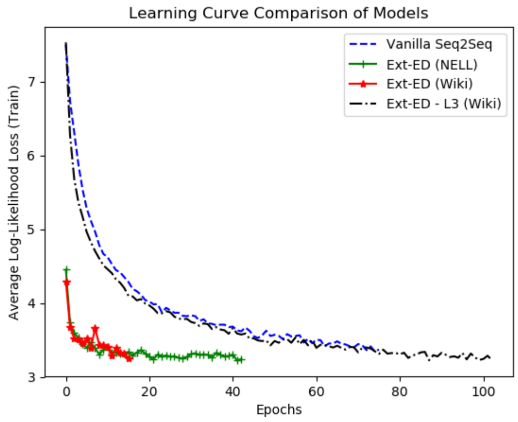

Figure 2: Convergence of Sequence loss (cross-entropy loss in sequential outputs) over different models during training.(-L3 in legend denote exclusion of $\mathcal{L}_3$ loss from gradient computation.)

mean of their distribution.

- The knowledge vectors having high variance.

We analyzed the knowledge vectors constructed using the two knowledge sources and the distribution of distances of $\boldsymbol{ec^i}$ from their mean. The variance of this distribution in NELL KB was *1.44* and from that of Wikipedia summary was *0.73*. Mean distance was very low (*0.77*) in the case of Wikipedia compared to that of NELL (*2.16*). We observed that the vectors not being spread out made them less useful than the encoded context itself in the initial experiments.

5 Experiments and Discussion

We evaluated Ext-ED by training with Reddit News dataset, and incorporated Wikipedia Summary and NELL KB as sources of external knowledge. The objective of the experiments are threefold: (1) to evaluate the ability of the model to make use of the external context to condition the response; (2) to analyze the training time with the additional knowledge provided; and (3) to observe any tangible differences in training with the two knowledge sources.

For the first analysis, we trained Ext-ED with external context ($\mathbb{R}^{100}$) and validated it without providing it (see Ext-ED - $\mathcal{L}_3$ Ablation in Table 1). Without the inclusion of $\mathcal{L}_3$, Ext-ED did not find the external context useful and the performance was not very different from a Vanilla Seq2Seq dialogue model (Figure 2). The encoder context had enough variance to be a viable information source and hence the external context was ignored. This can be observed from similar learning curves of *Vanilla Seq2Seq, Ext-ED - L3 (Wiki)* models in Figure 2.

With propagating back gradients with respect to $\mathcal{L}_3$, we observed that the model learns to use the external context, but, as discussed in Section 4.2, the variance in the external context vectors constructed using the two knowledge sources was too low. To fix this, we scaled the external context vectors with $\mathcal{N}(4, 1)$. This improved the variance in the knowledge that subsequently improved the usefulness of these vectors which was also observed in Figure 2.

Model	PPL	BLEU-4
Vanilla Seq2Seq	38.09	0.437
Ext-ED - $\mathcal{L}_3$ (Wiki)	38.37	0.435
Ext-ED - $\mathcal{L}_3$ Ablation	37.06	0.425
Ext-ED (Wiki)	**30.26**	**0.53**
Ext-ED (NELL KB)	**29.07**	**0.525**
Ext-ED Ablation	601.8	0.274

Table 1: Comparison of BLEU (sentence_bleu) and Perplexity scores on validation set across different models.

The provision of external knowledge improved the Perplexity and BLEU-4 scores as shown in Table 1. Though the improvements are reasonable, the metrics used are not strong indicators for evaluating the influence of external contexts in dialogue. But, they do indicate that the prediction accuracy is improved with the inclusion of external knowledge sources. The poor perplexity for Ext-ED Ablation is because the model is conditioned to predict the next utterance using $\boldsymbol{ec^i}$ and when not provided the context alone is not sufficiently informative. Another way to interpret this would be to see that the external context and and the dialogue context provide complementary information for better predicting the next utterance. Further, the experiments illustrated that the model, when provided with an *informative* source of knowledge (the one that has higher variance), will let the model converge faster. One possible hypothesis is that $\boldsymbol{ec^i}$, which has high variance and is provided as input in every step of decoding, is learned before the RNN parameters converge. The information in $\boldsymbol{ec^i}$ is relevant to the context and subsequently helps in training the decoder faster.

6 Conclusion

The proposed model, Extended Encoder Decoder, offers a framework to incorporate unstructured external knowledge to generate dialogue utterances. The experiments helped in understanding the need for external knowledge sources for improving learning time, and helped characterize the value of external knowledge sources. The experiments showed that external knowledge improved the learning time of the models. In future work, we aim to add more experiments with dialogue tasks that require understanding a supplementary source of knowledge to solve the task. Also, we plan to look at specialized tasks that naturally evaluate the influence of external knowledge, to help the model to generate diverse responses.

Abstract

Categorizing a patient's intentions during clinical interactions in general and within motivational interviewing specifically may improve decision making in clinical treatments. Within this paper, we propose a method that models the temporal flow of a conversation and the transition between topics by using domain adaptation on a clinical dialogue corpus comprising Motivational Interviewing (MI) sessions. We deploy Bi-LSTM and topic models jointly to learn theme shifts across different time stages within these hour-long MI sessions to assess the patient's intent to change their habits or to sustain them respectively. Our experiments show promising results and improvements after considering temporality in the classification task over our baseline. This result confirms and extends related literature that has manually identified that certain phases within MI sessions are more predictive of patient outcomes than others.

1 Introduction

Motivational Interviewing (MI) (Miller and Rollnick, 2012) is a collaborative communication style used to address a variety of health problems such as alcohol and drug use. Accurately understanding the patient's intentions to change from his/her speech during the session could greatly enhance the efficacy of MI. Motivational Interviewing Skill Code (MISC) is a coding system that captures client language, specifically change talk (CT) and sustain talk (ST) (Miller et al., 2008). However, reliable MISC coding is labor-intensive and requires domain expertise. Recent computational annotation methods have been proposed to automatically classify patients' behaviors within MI (Xiao et al., 2016; Pérez-Rosas et al., 2017; Gibson et al., 2017). To this end, Recurrent Neural Networks (RNN) that capture sequential information are applied for the classification of patient behavior.

Recent research shows that themes and words within a conversation change across time (Dufour et al., 2016). Similarly within MI, topics and the patient's attitude towards their willingness to change might shift. Within this work, we investigate how shifts in themes across time affects performance of the intention classifications for the dialogue.

Specifically, we focus on the patient intent classification task and propose a method that adopts the temporal factor by domain adaptation to improve performance of the classifiers. We evaluate our approach on a dataset of college alcoholism (Carey et al., 2009; Borsari et al., 2012), containing transcripts of MI conducted with U.S. college students. Specifically, we first explore the theme shift and give a brief analysis by topic modeling (Blei et al., 2003). We then utilize Bi-directional Long Short-Term Memory (Bi-LSTM) (Graves and Schmidhuber, 2005) to encode utterances from both word and topic embeddings. Next, we concatenate both contextual information with the encoded utterance representations. Finally, we jointly train a unified representation of utterance by domain adversarial training and patient intent classification. We show that this approach can lead to improvements in classification performance.

2 Dataset

We conduct our experiments on a clinical dataset of college student alcoholism (Carey et al., 2009; Borsari et al., 2012), where we obtain 193 MI transcripts with a total of 83677 utterances. Each of the MI session ranged between 60 and 90 minutes. Each client utterance was coded using the MISC. In this paper, we focus on classifying patient behavior on the utterance-level. Specifically, we classify patient behavior on collapsed MISC

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 696–701
Brussels, Belgium, October 31 - November 4, 2018.

Table 1: Examples of utterances in Alcoholism Treatment. "I" stands for interventionist and "P" for patient. MISC codes are provided in the third column. P and I codes are coded following MISC. Change talk (CT), sustain talk (ST), and follow neutral (FN) codes are also provided.

Role	Conversation	MISC
I	Maybe you could tell me a little bit about what you do on the weekends, what your weekends have been like.	quo
P	Well we go out, but before we go out we just drink in the dorm room.	FN
I	Has this sort of changed your thinking, are things different than they were when you came in?	quc
P	I mean, I feel guilty about drinking,	CT (o+3)
I	Yeah. So it feels like, or it sounds like social social drinking is a big part of how you meet other people.	res
P	It's just, like ... and I don't mean to sound mean, but about the kids who don't drink, and people think that, "Oh, the kids who dont drink are losers".	ST (o-3)

annotation codes into with three categories: "CT": *Change talk* indicates utterances that reflect motivating factors related to change; "ST": *Sustain talk* indicate the patient has no intentions to change; "FN": *Follow neutral* means there is no indication of patient inclination. An example conversation snippet, highlighting all three sources of information is provided in Table 1. The intention labels (o+3, o-3) are only available for patients, whose '+' and '-' refer to change vs sustain talk (CT vs ST) and the number measures the "strength of client language," which represents a subjective assessment by human annotators, and the 'quo' and 'quc' refer to "open question" and "closed questions", which are only for interventionist (see (Borsari et al., 2015) for details regarding the coding strategy). While the MISC codes of client utterances within MISC are more complex and comprise other types of annotations, we focus on human intention modeling (i.e., CT vs. ST vs. FN) only.

How the theme of dialogue shift overtime?

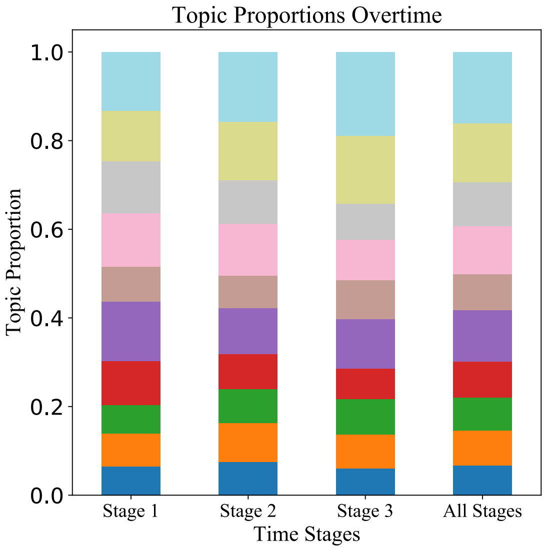

Figure 1: 10 topic proportions of patient's utterance across time stages.

We qualitatively examined how the distribution of content changes across different time stages. To measure the distribution of content, we trained a topic model with 10 topics using Gensim (Řehůřek and Sojka, 2010) with default parameters. The data doesn't have associated timestamps, thus we empirically split each MI transcript by the number of patient utterances equally into three time stages, stage 1, stage 2 and stage 3. We calculated the proportion of each topic within the same time period by take the average of all transcripts. We then normalized the topic distributions and finally visualize the extent to which distributions of the 10 topics varies by time.

We can observe the varied topic distributions across different stages of conversations, where the topic distributions are plotted from the bottom to the top. There are some topics have more variations, such as topic 4, and some topics are very stable such as topic 1 [1]. Recent research shows the performance of classification tasks might be impacted by the temporal character of language (Huang and Paul, 2018). Thus, it might be desirable to model the temporality in the computational classifiers.

---

[1] The 5 top words of topic 4 and 1: yeah, go, friends, know, people; beer, alcohol, games, meeting, playing.

3 Model

The architecture of the proposed model is shown in Figure 2. We feed four types of information to the model: topic- and word-level data of the utterance (*content*), preceding interventionist verbal behavior (*context*) and prior MISC annotations of utterances (*MISC*). Particularly, we empirically extracted previous 5 utterances as context and 10 previous codes as MISC[2], where we set “unk” as the default.

Embeddings. We built two types of embeddings, word embedding and topic embedding. We created word embeddings from Googles pretrained Word2Vec (Mikolov et al., 2013) and created topic embeddings from a trained LDA (Blei et al., 2003) specific to the corpus. We treated each MISC as one document and trained an embedding model.

Unified Representation. We apply Bidirectional LSTM (Bi-LSTM) (Graves and Schmidhuber, 2005) on the inputs. Dropouts (Srivastava et al., 2014) are applied on the outputs of Bi-LSTM. We merge the outputs by concatenation and feed the outputs to the dense layer to learn a unified representation of the utterance.

Joint Learning. We apply domain adversarial training (Ganin et al., 2016) only on the topic inputs from learned topic representations. Our intuition is that the topic distributions across different stages of the MI session could track the variations of patients’ intents. We empirically split the conversation into three time stages: Stage 1-3 (i.e, beginning, middle, and end). The goal of domain adversarial training is converted to a time stage prediction task, which aims to differentiate topic themes both locally and globally. We used one-hot encoding to represent labels of the prediction tasks. We deploy softmax functions for both time stage and intention predictions. We use categorical cross entropy to jointly optimize the training process of the two classification tasks: domain classification and patient intent classification.

4 Experiments

Each utterance is lowercased and tokenized by NLTK (Bird et al., 2009). We filter out the utterances that are shorter than 5 tokens and then remove punctuations. Finally, we obtain 22432 patient utterances. The dataset is stratified and split into training set (80%), validation set (10%) and testing set (10%), as shown in Table 2. We train our models on the training set and run grid search to find the optimal parameters on the validation set by the weighted F1 score.

Table 2: Statistics of the processed dataset.

Datasets	Train	Valid	Test	Total
CT	6246	779	768	7794
ST	3099	406	401	3906
FN	8600	1058	1074	10732
All				22432

The details of optimized parameters are listed as follows. The models were trained for 15 epochs with a batch size of 64. Each utterance and its context are padded to 50 words. The utterance’s previous MISC codes are padded to 10. We pad the sequences with an “unknown”-token. The size of LSTMs was tuned in the range of $[100, 150, 200]$ and the size of dense layer tuned within $[100, 150, 200]$. We select the activation function of the Dense layer within $\{$relu (Hahnloser et al., 2000), tanh, softplus$\}$ (Hahnloser et al., 2000). We tried different flip gradient value within $[0.05, 0.01, 0.005]$ for the domain adversarial training. We tuned the dropout rate between $[0.1, 0.2]$. The optimizer was selected either RMSprop (Hinton et al., 2012) or Adam (Kingma and Ba, 2014) with a fixed learning rate of 0.001. Finally, we empirically set the loss weight of the domain adversarial training to 0.05.

We trained the topic model on the MI corpus using Gensim (Řehůřek and Sojka, 2010). The number of topics was selected by coherence scores among 5, 10, 20 topics. We used Google pre-trained word embedding with 300 dimensions (Mikolov et al., 2013). We obtained 50-dimension code embedding by Word2vec (Mikolov et al., 2013) for the MISC codes, where each sequence of MISC were treated as a document.

We select three different approaches as our baselines with the inputs: content, context, MISC, and topic.

- (Pérez-Rosas et al., 2017) with rich linguistic features (denote as Perez2017_lin): We reproduced their method. We used scikit-learn (Buitinck et al., 2013) to ex-

---

[2] We encode 10 MISC codes prior to the current one as a sequence of 10 “words”, then we treat the sequence as an additional input document.

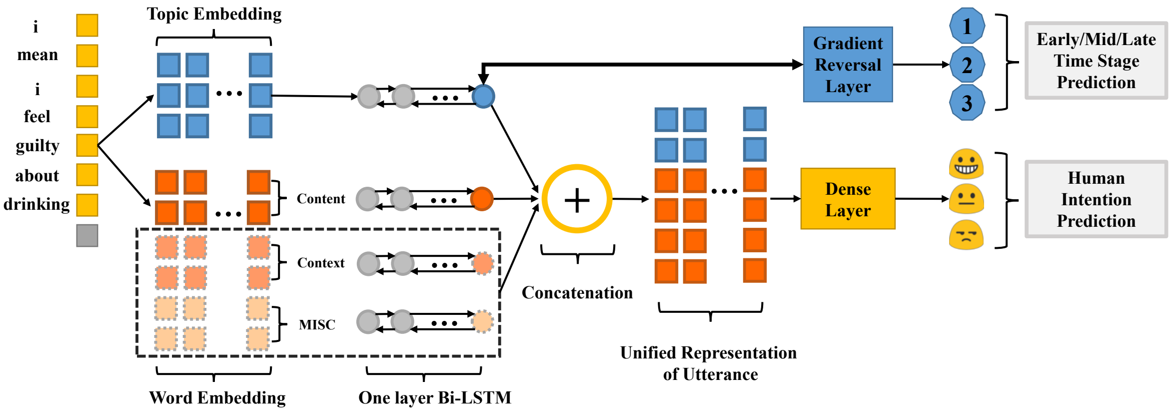

Figure 2: The proposed model learns from tow different channels: word and topic channels. The topic channel captures the theme shifts across stages while the word channel aims to capture the behavior indicators within each utterance.

tract n-gram features, and applied Stanford Parser (Manning et al., 2014) to extract Part-of-Speech (POS). We replaced LIWC (Pennebaker et al., 2001) by a free and open source lexicon (Mohammad and Turney, 2013) to extract semantic features. We use Ngram+ to denote the rich linguistic features.

- (Pérez-Rosas et al., 2017) with embeddings (denote as Perez2017_vec): Word embedding shows superior results over the n-gram features in the classification tasks (Mikolov et al., 2013) in the recent past. We experiment feeding the classifier with word vectors while we keep the same parameter settings as the Perez2017_lin baseline. We deploy the strategy of concatenating word embeddings to build representations of utterances, which is denoted as "Vec-con".
- (Xiao et al., 2016) (denoted as Xiao2016): Their approach applies Bi-directional RNN to encode each utterance by both the utterance itself and its preceding one. There are two major differences between their method and ours: first, they did not consider temporality in their model, second, they did not use the previous MISC sequences as inputs. They used Gated Recurrent Unit (GRU) (Chung et al., 2014) as the RNN cell.

We use the "Co", "Ct", "MISC" to denote the utterance (*content*), preceding interventionist verbal behavior (*context*) and prior MISC annotations of utterances (*MISC*) respectively. And we use "All" to denote all of the inputs[3]. We use the "T" to denote temporal shifts proposed in our paper. We balance training weights for the classification labels. We use metrics from scikit-learn (Buitinck et al., 2013) to evaluate the classification performance by precision, recall and weighted F1 on the intention labels.

4.1 Results and Discussion

Table 3: Results of classification evaluations.

Features	Method	Precision	Recall	F1
	Perez2017_lin			
Ngram+	Co	0.62	0.62	0.62
	Co+Ct	0.60	0.61	0.61
	All	0.61	0.61	0.62
	Perez2017_vec			
Vec-con	Co	0.60	0.58	0.59
	Co+Ct	0.61	0.59	0.60
	All	0.61	0.57	0.58
	Xiao2016			
Vec	Co	0.65	0.63	0.64
	Co+Ct	0.68	0.64	0.65
	All	0.67	0.67	0.67
	Proposed model			
Vec	Co+T	0.65	0.64	0.65
	Co+Ct+T	0.70	0.66	0.68
	All+T	0.74	0.67	0.70

The results of our experiments are summarized in the Table 3. Findings indicate that our proposed approach leads to a small performance boost after using the topic embeddings. Thus, our sim-

---

[3] The baselines did not use one or more inputs (the context and MISC) in the original publications. We used different combinations for fair comparison.

ple feature augmentation approach has the potential to make classifiers more robust. In addition, the contextual information (“Ct”) is quite useful to identify the patients’ current intentions, and the sequential information through time stages has strong indications of human intentions.

Significance Analysis

We conducted significance analysis to compare Xiao2016 and our proposed method. Because Xiao2016 only used content and context inputs, in this analysis, we train our method with the same inputs (Co+Ct). We followed the method of bootstrap samples (Berg-Kirkpatrick et al., 2012) to create 50 pairs of training and test datasets with replacement, where we keep the sizes the same in the Table 2. We keep the same experimental steps and use the parameters that achieved the best performances in the Table 3 to train the models.

To compare the two approaches, we conduct a paired t-test comparing the achieved F1 scores of both models. We used a two-tail test instead of one tail test used in the paper due to its increased rigor and lack of prior assumptions (Dror et al., 2018). The test reveals a significant result with $t(85) = 3.084$ and $p = 0.00275$. The result shows that we can reject the null hypothesis that our proposed method is not better than Xiao2016.

5 Conclusion

In this paper, we focus on the temporal characteristics of the MI corpus and propose a simple method that models the temporal factor within a single MI session. We jointly learn the utterance representation via time stage and intention predictions and the proposed model improves the performance of the classification task. The identified intent of clients could help therapists adjust their treatment strategy. In future work, we will investigate other external sources of knowledge, such as acoustic cues and videos to further improve the performance of the model.

An Auto-Encoder Matching Model for Learning Utterance-Level Semantic Dependency in Dialogue Generation

Abstract

Generating semantically coherent responses is still a major challenge in dialogue generation. Different from conventional text generation tasks, the mapping between inputs and responses in conversations is more complicated, which highly demands the understanding of utterance-level semantic dependency, a relation between the whole meanings of inputs and outputs. To address this problem, we propose an Auto-Encoder Matching (AEM) model to learn such dependency. The model contains two auto-encoders and one mapping module. The auto-encoders learn the semantic representations of inputs and responses, and the mapping module learns to connect the utterance-level representations. Experimental results from automatic and human evaluations demonstrate that our model is capable of generating responses of high coherence and fluency compared to baseline models.[1]

1 Introduction

Automatic dialogue generation task is of great importance to many applications, ranging from open-domain chatbots (Higashinaka et al., 2014; Vinyals and Le, 2015; Li et al., 2016, 2017a; Su et al., 2018) to goal-oriented technical support agents (Bordes and Weston, 2016; Zhou et al., 2017; Asri et al., 2017). Recently there is an increasing amount of studies about purely data-driven dialogue models, which learn from large corpora of human conversations without hand-crafted rules or templates. Most of them are based on the sequence-to-sequence (Seq2Seq) framework (Sutskever et al., 2014) that maximizes the probability of gold responses given the previous dialogue turn. Although such methods offer great promise for generating fluent responses, they still suffer from the poor semantic relevance between inputs and responses (Xu et al., 2018). For example, given "What's your name" as the input, the models generate "I like it" as the output.

Recently, the neural attention mechanism (Luong et al., 2015; Vaswani et al., 2017) has been proved successful in many tasks including neural machine translation (Ma et al., 2018b) and abstractive summarization (Lin et al., 2018), for its ability of capturing word-level dependency by associating a generated word with relevant words in the source-side context. Recent studies (Mei et al., 2017; Serban et al., 2017) have applied the attention mechanism to dialogue generation to improve the dialogue coherence. However, conversation generation is a much more complex and flexible task as there are less "word-to-words" relations between inputs and responses. For example, given *"Try not to take on more than you can handle"* as the input and *"You are right"* as the response, each response word can not find any aligned words from the input. In fact, this task requires the model to understand the utterance-level dependency, a relation between the whole meanings of inputs and outputs. Due to the lack of utterance-level semantic dependency, the conventional attention-based methods that simply capture the word-level dependency achieve less satisfying performance in generating high-quality responses.

To address this problem, we propose a novel **Auto-Encoder Matching** model to learn utterance-level dependency. First, motivated by Ma et al. (2018a), we use two auto-encoders to learn the semantic representations of inputs and responses in an unsupervised style. Second, given the utterance-level representations, the mapping module is taught to learn the utterance-level dependency. The advantage is that by explicitly separating representation learning and dependency

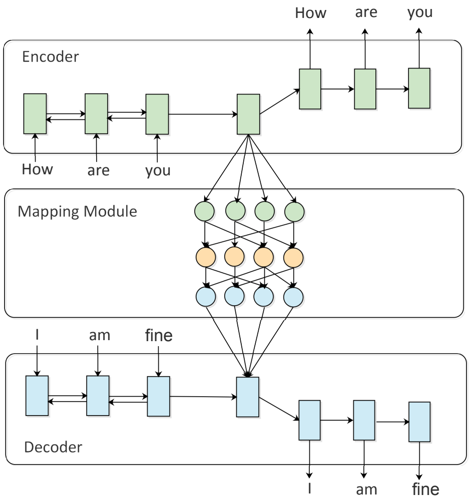

Figure 1: An illustration of the Auto-Encoder Matching model. The encoder and decoder are two auto-encoders that are responsible for learning the semantic representations. The mapping module is responsible for learning the utterance-level dependency.

learning, the model has a stronger modeling ability compared to traditional Seq2Seq models. Experimental results show that our model substantially outperforms baseline methods in generating high-quality responses.

Our contributions are listed as follows:

- To promote coherence in dialogue generation, we propose a novel Auto-Encoder Matching model to learn the utterance-level dependency.
- In our proposed model, we explicitly separate utterance representation learning and dependency learning for a better expressive ability.
- Experimental results on automatic evaluation and human evaluation show that our model can generate much more coherent text compared to baseline models.

2 Approach

In this section, we introduce our proposed model. An overview is presented in Section 2.1. The details of the modules are shown in Sections 2.2, 2.3 and 2.4. The training method is introduced in Section 2.5.

2.1 Overview

The proposed model contains three modules: an encoder, a decoder, and a mapping module, as shown in Figure 1.

In general, our model is different from the conventional sequence-to-sequence models. The encoder and decoder are both implemented as auto-encoders (Baldi, 2012). They learn the internal representations of inputs and target responses, respectively. In addition, a mapping module is built to map the internal representations of the input and the response.

2.2 Encoder

The encoder E_θ is an unsupervised auto-encoder based on Long Short Term Memory Networks (LSTM) (Hochreiter and Schmidhuber, 1996). As it is essentially a LSTM-based Seq2Seq model, we name the encoder and decoder of the auto-encoder "source-encoder" and "source-decoder". To be specific, the encoder E_θ receives the source text $x = \{x_1, x_2, ..., x_n\}$, and encodes it to an internal representation h, and then decodes h to a new sequence $\tilde{x} = \{\tilde{x}_1, \tilde{x}_2, ..., \tilde{x}_n\}$ for the reconstruction of the input. We extract the hidden state h as the semantic representation. The encoder E_θ is trained to reduce the reconstruction loss, whose loss function is defined as follows:

$$J_1(\theta) = -\log P(\tilde{x}|x;\theta) \qquad (1)$$

where θ refers to the parameters of the encoder E_θ.

2.3 Decoder

Similar to the encoder, our decoder D_ϕ is also a LSTM-based auto-encoder. However, as there is no target text provided in the testing stage, we propose the customized implementation, which is illustrated in Section 2.5. Here in the introduction of the decoder, we do not provide the testing details. Similarly, we name the encoder and decoder of the auto-encoder "target-encoder" and "target-decoder". The target-encoder receives the target $y = \{y_1, y_2, ..., y_n\}$ and encodes it to a utterance-level semantic representation s, and then decodes s to a new sequence to approximate the target text. The loss function is identical to that of the encoder:

$$J_2(\phi) = -\log P(\tilde{y}|y;\phi) \qquad (2)$$

2.4 Mapping Module

As our model is constructed for dialogue generation, we design the mapping module to ensure that the generated response is semantically consistent with the source. There are many matching models that can be used to learn such dependency relations (Hu et al., 2014; Guo et al., 2016; Pang et al., 2016; Chen et al., 2018). For simplicity, we only use a simple feedforward network for implementation. The mapping module M_γ transforms the source semantic representation h to a new representation t. To be specific, we implement a multi-layer perceptron (MLP) $g(\cdot)$ for M_γ and train it by minimizing the L2-norm loss $J_3(\gamma)$ of the transformed representation t and the semantic representation of target response s:

$$\begin{aligned} t &= g(h) \\ J_3(\gamma) &= \frac{1}{2}\|t - s\|_2^2 \end{aligned} \tag{3}$$

2.5 Training and Testing

In the testing stage, given an input utterance, the encoder E_θ, the decoder D_ϕ, and the matching module M_γ work together to produce a dialogue response. The source-encoder first receives the input x and encodes it to a semantic representation h of the source utterance. Then, the mapping module transforms h to t, a target response representation. Finally, t is sent to the target-decoder for response generation.

In the training stage, besides the auto-encoder loss and the mapping loss, we also use an end-to-end loss $J_4(\theta, \phi, \gamma)$:

$$J_4(\theta, \phi, \gamma) = -\log P(y|x; \theta, \phi, \gamma) \tag{4}$$

$$= -\sum_{t=1}^{T} \log P(y_t|x, y_{1..t-1}; \theta, \phi, \gamma) \tag{5}$$

where x is the source input, y is the target response, and T is the length of response sequence. The model learns to generate $\tilde{y}$ to approximate y by minimizing the reconstruction losses $J_1(\theta)$ and $J_2(\phi)$, the mapping loss $J_3(\gamma)$, and the end-to-end loss $J_4(\theta, \phi, \gamma)$. The details are illustrated below:

$$\begin{aligned} J = \lambda_1 \left[J_1(\theta) + J_2(\phi)\right] + \lambda_2 J_3(\gamma) \\ + \lambda_3 J_4(\theta, \phi, \gamma) \end{aligned} \tag{6}$$

where J refers to the total loss, and λ_1, λ_2, and λ_3 are hyperparameters.

3 Experiment

We conduct experiments on a high-quality dialogue dataset called **DailyDialog** built by Li et al. (2017b). The dialogues in the dataset reflect our daily communication and cover various topics about our daily life. We split the dataset into three parts with 36.3K pairs for training, 11.1K pairs for validation, and 11.1K pairs for testing.

3.1 Experimental Details

For dialogue generation, we set the maximum length to 15 words for each generated sentence. Based on the performance on the validation set, we set the hidden size to 512, embedding size to 64 and vocabulary size to 40K for baseline models and the proposed model. The parameters are updated by the Adam algorithm (Kingma and Ba, 2014) and initialized by sampling from the uniform distribution ($[-0.1, 0.1]$). The initial learning rate is 0.002 and the model is trained in minibatches with a batch size of 256. λ_1 and λ_3 are set to 1 and λ_2 is set to 0.01 in Equation (6). It is important to note that for a fair comparison, we re-implement the baseline models with the best settings on the validation set. After fixing the hyperparameters, we combine the training and validation sets together as a larger training set to produce the final model.

3.2 Results

We use BLEU (Papineni et al., 2002), to compare the performance of different models, and use the widely-used BLEU-4 as our main BLEU score. The results are shown in Table 1. The proposed AEM model significantly outperforms the Seq2Seq model. It demonstrates the effectiveness of utterance-level dependency on improving the quality of generated text. Furthermore, we find that the utterance-level dependency also benefits the learning of word-level dependency. The improvement from the AEM model to the AEM+Attention model[2] is 0.68 BLEU-4 point. It is much more obvious than the improvement from the Seq2Seq model to the Seq2Seq+Attention, which is 0.29 BLEU-4 point.

We also report the diversity of the generated responses by calculating the number of distinct unigrams, bigrams, and trigrams. The results are shown in Table 2. We find that the AEM model achieves significant improvement on the diversity of generated text. The number of unique trigram of the AEM model is almost six times more

---

[2] With the additional attention mechanism, the outputs of attention-based decoder and our decoder are combined together to predict the probability of response words.

Models	BLEU-1	BLEU-2	BLEU-3	BLEU-4
Seq2Seq	12.43	4.57	2.69	1.84
AEM	13.55	4.89	3.04	2.16
Seq2Seq+Attention	13.63	4.99	3.05	2.13
AEM+Attention	**14.17**	**5.69**	**3.78**	**2.84**

Table 1: BLEU scores for the AEM model and the Seq2Seq model.

Models	Dist-1	Dist-2	Dist-3
Seq2Seq	0.8K	2.7K	5.5K
AEM	3.1K	14.8K	31.2K
Seq2Seq+Attention	2.5K	13.6K	34.6K
AEM+Attention	**3.3K**	**23.2K**	**53.9K**

Table 2: Diversity scores for the AEM model and the Seq2Seq model. Dist-1, Dist-2, and Dist-3 are respectively the number of distinct unigrams, bigrams, and trigrams in the generated text.

Models	Fluency	Coherence	G-Score
Seq2Seq	6.97	3.51	4.95
AEM	**8.11**	4.18	5.82
Seq2Seq+Attention	5.11	3.30	4.10
AEM+Attention	7.92	**4.97**	**6.27**

Table 3: Human evaluation results of the AEM model and the Seq2Seq model.

Input 1: *My name is David. What is my name?*
Seq2Seq: *Ours, maria.*
AEM: *Pardon me? It is unreasonable!*

Input 2: *I'm going to kill you!*
Seq2Seq: *I know. I'm a good man.*
AEM: *What?!?!!!! No!!*

Input 3: *I hate you.*
Seq2Seq: *I'm not.*
AEM: *You do? you're a sweet girl.*

Input 4: *How are you?*
Seq2Seq: *Fine.*
AEM: *Fine. I'm good.*

Input 5: *Can you say 'Hello'?*
Seq2Seq: *Yeah, I guess.*
AEM: *Sure, I guess.*

Table 4: Examples generated by the AEM model and the Seq2Seq model.

than that of the Seq2Seq model. Also, it should be noticed that the attention mechanism performs almost the same compared to the AEM model (31.2K vs. 34.6K in terms of Dist-3), which indicates that the utterance-level dependency and the word-level dependency are both indispensable for dialogue generation. Therefore, by combining the two dependencies together, the AEM+Attention model achieves the best results. Such improvements are expected. With the increase of the relevance of the generated text, it gets harder for the model to generate repeated responses. In our experimental results, the number of repetitive "I don't know" in the AEM+Attention model is reduced by 50% compared to the Seq2Seq model.

For dialogue generation, human evaluation is more convincing, so we also report human evaluation results on the test set. We randomly choose 100 utterances in daily communication style for the human evaluation, each of which is sent to different models to generate responses. The results are distributed to the annotators who have no knowledge about which model the sentence is from. All annotators have linguistic background. They are asked to score the generated responses in terms of fluency and coherence. Fluency represents whether each sentence is in correct grammar. Coherence evaluates whether the generated response is relevant to the input. The score ranges from 1 to 10 (1 is very bad and 10 is very good). To evaluate the overall performance, we use the geometric mean of fluency and coherence as the final evaluation metric.

Table 3 shows the results of human evaluation. The inter-annotator agreement is satisfactory considering the difficulty of human evaluation. The Pearson's correlation coefficient is 0.69 on coherence and 0.57 on fluency, with $p < 0.0001$. First, it is clear that the AEM model outperforms the Seq2Seq model with a large margin, which proves the effectiveness of the AEM model on generating high quality responses. Second, it is interesting to note that with the attention mechanism, the coherence is decreased slightly in the Seq2Seq model but increased significantly in the AEM model. It suggests that the utterance-level dependency greatly benefits the learning of word-level dependency. Therefore, it is expected that the AEM+Attention model achieves the best G-score.

Table 4 shows the examples generated by the AEM model and the Seq2Seq model. For easy questions (ex. 4 and ex. 5), they both perform well. For hard questions (ex. 1 and ex. 2), the proposed model obviously outperforms the Seq2Seq model. It shows that the utterance-level dependency learned by the proposed model is useful for handling complex inputs.

3.3 Error Analysis

Although our model achieves the best performance, there are still several failure cases. We find that the model performs badly for the inputs with unseen words. For instance, given "Bonjour" as the input, it generates "Stay out of here" as the output. It shows that the proposed model is sensitive to the unseen utterance representations. Therefore, we would like to explore more approaches to address this problem in the future work. For example, the auto-encoders can be replaced by variational auto-encoders to ensure that the distribution of utterance representations is normal, which has a better generalization ability.

4 Conclusion

In this work, we propose an Auto-Encoder Matching model to learn the utterance-level semantic dependency, a critical dependency relation for generating coherent and fluent responses. The model contains two auto-encoders that learn the utterance representations in an unsupervised way, and a mapping module that builds the mapping between the input representation and response representation. Experimental results show that the proposed model significantly improves the quality of generated responses according to automatic evaluation and human evaluation, especially in coherence.

A Dataset for Document Grounded Conversations

Kangyan Zhou, Shrimai Prabhumoye, Alan W Black
Carnegie Mellon University, Pittsburgh, PA, USA
`{kangyanz, sprabhum, awb}@cs.cmu.edu`

Abstract

This paper introduces a document grounded dataset for conversations. We define "Document Grounded Conversations" as conversations that are about the contents of a specified document. In this dataset the specified documents were Wikipedia articles about popular movies. The dataset contains 4112 conversations with an average of 21.43 turns per conversation. This positions this dataset to not only provide a relevant chat history while generating responses but also provide a source of information that the models could use. We describe two neural architectures that provide benchmark performance on the task of generating the next response. We also evaluate our models for engagement and fluency, and find that the information from the document helps in generating more engaging and fluent responses.

1 Introduction

At present, dialog systems are considered to be either task-oriented, where a specific task is the goal of the conversation (e.g. getting bus information or weather for a particular location); or non-task oriented where conversations are more for the sake of themselves, be it entertainment or passing the time. Ultimately, we want our agents to smoothly interleave between task-related information flow and casual chat for the given situation. There is a dire need of a dataset which caters to both these objectives.

Serban et al. (2015) provide a comprehensive list of available datasets for building end-to-end conversational agents. Datasets based on movie scripts (Lison and Tiedemann, 2016; Danescu-Niculescu-Mizil and Lee, 2011a) contain artificial conversations. The Ubuntu Dialogue Corpus (Lowe et al., 2015) is based on technical support logs from the Ubuntu forum. The Frames dataset (Asri et al., 2017) was collected to solve the problem of frame tracking. These datasets do not provide grounding of the information presented in the conversations. Zhang et al. (2018) focuses on personas in dialogues: each worker has a set of predefined facts about the persona that they can talk about. Most of these datasets lack conversations with large number of on-topic turns.

We introduce a new dataset which addresses the concerns of grounding in conversation responses, context and coherence in responses. We present a dataset which has real human conversations with grounding in a document. Although our examples use Wikipedia articles about movies, we see the same techniques being valid for other external documents such as manuals, instruction booklets, and other informational documents. We build a generative model with and without the document information and find that the responses generated by the model with the document information is more engaging (+7.5% preference) and more fluent (+0.96 MOS). The perplexity also shows a 11.69 point improvement.

2 The Document Grounded Dataset

To create a dataset for document grounded conversations, we seek the following things: (1) A set of documents (2) Two humans chatting about the content of the document for more than 12 turns. We collected conversations about the documents through Amazon Mechanical Turk (AMT). We restrict the topic of the documents to be movie-related articles to facilitate the conversations. We initially experimented with different potential domains. Since movies are engaging and widely known, people actually stay on task when discussing them. In fact in order to make the task interesting, we offered a choice of movies to the participants so that they are invested in the task.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 708–713
Brussels, Belgium, October 31 - November 4, 2018.

2.1 Document Set Creation

We choose Wikipedia (Wiki) [1] articles to create a set of documents $\boldsymbol{D} = \{d_1, \ldots, d_{30}\}$ for grounding of conversations. We randomly select 30 movies, covering various genres like thriller, super-hero, animation, romantic, biopic etc. We extract the key information provided in the Wiki article and divide it into four separate sections. This was done to reduce the load of the users to read, absorb and discuss the information in the document. Hence, each movie document d_i consists of four sections $\{s_1, s_2, s_3, s_4\}$ corresponding to basic information and three key scenes of the movie. The basic information section s_1 contains data from the Wikipedia article in a standard form such as year, genre, director. It also includes a short introduction about the movie, ratings from major review websites, and some critical responses. Each of the key scene sections $\{s_2, s_3, s_4\}$ contains one short paragraph from the plot of the movie. Each paragraph contains on an average 7 sentences and 143 words. These paragraphs were extracted automatically from the original articles, and were then lightly edited by hand to make them of consistent size and detail. An example of the document is attached in Appendix.

2.2 Dataset Creation

To create a dataset of conversations which uses the information from the document, involves the participation of two workers. Hence, we explore two scenarios: (1) Only one worker has access to the document and the other worker does not and (2) Both the workers have access to the document. In both settings, they are given the common instructions of chatting for at least 12 turns.

Scenario 1: One worker has document. In this scenario, only one worker has access to the document. The other worker cannot see the document. The instruction to the worker with the document is: *Tell the other user what the movie is, and try to persuade the other user to watch/not to watch the movie using the information in the document*; and the instruction to the worker without the document is: *After you are told the name of the movie, pretend you are interested in watching the movie, and try to gather all the information you need to make a decision whether to watch the movie in the end*. An example of part of the dialogue for this scenario is shown in Table 1.

user2:	Hey have you seen the inception?
user1:	No, I have not but have heard of it. What is it about
user2:	It's about extractors that perform experiments using military technology on people to retrieve info about their targets.

Table 1: An example conversation for scenario 1. User 1 does not have access to the document, while User 2 does. The full dialogue is attached in the Appendix.

User 2:	I thought The Shape of Water was one of Del Toro's best works. What about you?
User 1:	Did you like the movie?
User 1:	Yes, his style really extended the story.
User 2:	I agree. He has a way with fantasy elements that really helped this story be truly beautiful.

Table 2: An example conversation for scenario 2. Both User 1 and User 2 have access to the Wiki document. The full dialogue is attached in the Appendix.

Scenario 2: Both workers have document. In this scenario, both the workers have access to the same Wiki document. The instruction given to the workers are: *Discuss the content in the document with the other user, and show whether you like/dislike the movie*. An example of the dialogue for this scenario is shown in Table 2.

Workflow: When the two workers enter the chat-room, they are initially given only the first section on basic information s_1 of the document d_i. After the two workers complete 3 turns (for the first section 6 turns is needed due to initial greetings), the users will be shown the next section. The users are encouraged to discuss information in the new section, but are not constrained to do so.

2.3 Dataset Statistics

The dataset consists of total 4112 conversations with an average of 21.43 turns. The number of conversations for scenario 1 is 2128 and for scenario 2 it is 1984. We consider a turn to be an exchange between two workers (say $w1$ and w_2). Hence an exchange of w_1, w_2, w_1 has 2 turns (w_1, w_2) and (w_2, w_1). We show the comparison of our dataset as **CMU Do**cument **G**rounded Conversations (CMU_DoG) with other datasets in Table 3.

---

[1] https://en.wikipedia.org

Dataset	# Utterances	Avg. # of Turns
CMU_DoG	130000	31
Persona-chat (Zhang et al., 2018)	164,356	14
Cornell Movie (Danescu-Niculescu-Mizil and Lee, 2011b)	304,713	1.38
Frames dataset (Asri et al., 2017)	19,986	15

Table 3: Comparison with other datasets. The average number of turns are calculated as the number of utterances divided by the number of conversations for each of the datasets.

	Rating 1	Rating 2	Rating 3	Rating 2& 3
Total # of conversations	1443	2142	527	2669
Total # of utterances	28536	80104	21360	101464
Average # utterances/conversation	19.77(13.68)	35.39(8.48)	40.53(12.92)	38.01(9.607)
Average length of utterance	7.51(50.19)	10.56(8.51)	16.57(15.23)	11.83(10.58)

Table 4: The statistics of the dataset. Standard deviation in parenthesis.

One of the salient features of CMUDoG dataset is that it has mapping of the conversation turns to each section of the document, which can then be used to model conversation responses. Another useful aspect is that we report the quality of the conversations in terms of how much the conversation adheres to the information in the document.

Split Criteria: We automatically measure the quality of the conversations using BLEU (Papineni et al., 2002) score. We use BLEU because we want to measure the overlap of the turns of the conversation with the sections of the document. Hence, a good quality conversation should use more information from the document than a low quality conversation. We divide our dataset into three ratings based on this measure. The BLEU score is calculated between all the utterances $\{x_1, \ldots, x_n\}$ of a conversation C_i and the document d_i corresponding to C_i. We eliminate incomplete conversations that have less than 10 turns. The percentiles for the remaining conversations are shown in Table 5. We split the dataset into three ratings based on BLEU score.

Percentile	20	40	60	80	99
BLEU	0.09	0.20	0.34	0.53	0.82

Table 5: The distribution of BLEU score for conversations with more than 10 turns.

Rating 1: Conversations are given a rating of 1 if their BLEU score is less than or equal to 0.1. We consider these conversations to be of low-quality.

Rating 2: All the conversations that do not fit in rating 1 and 3 are marked with a rating of 2.

Rating 3: Conversations are labeled with a rating of 3, only if the conversation has more than 12 turns and has a BLEU score larger than 0.587. This threshold was calculated by summing the mean (0.385) and the standard deviation (0.202) of BLEU scores of the conversations that do not belong rating 1.

The average BLEU score for workers who have access to the document is 0.22 whereas the average BLEU score for the workers without access to the document is 0.03. This suggests that even if the workers had external knowledge about the movie, they have not extensively used it in the conversation. It also suggests that the workers with the document have not used the information from the document verbatim in the conversation. Table 4 shows the statistics on the total number of conversations, utterances, and average number of utterances per conversation and average length of utterances for all the three ratings.

3 Models

In this section we discuss models which can leverage the information from the document for generating responses. We explore generative models for this purpose. Given a dataset $\boldsymbol{X} = \{x_0, \ldots, x_n\}$ of utterances in a conversation C_i, we consider two settings: (1) to generate a response x_{i+1} when given only the current utterance x_i and (2) to generate a response x_{i+1} when given the corresponding section s_i and the previous utterance x_i.

Without section: We use the sequence-to-sequence model (Sutskever et al., 2014) to build our baseline model. Formally, let $\boldsymbol{\theta}_E$ represent the parameters of the encoder. Then the representation $\boldsymbol{h}_{x_i}$ of the current utterance x_i is given by:

$$\boldsymbol{h}_{x_i} = \text{Encoder}(\boldsymbol{x}_i; \boldsymbol{\theta}_E) \tag{1}$$

Samples of x_{i+1} are generated as follows:

$$p(\hat{\boldsymbol{x}}|\boldsymbol{h}_{x_i}) = \prod_t p(\hat{x}_t|\hat{\boldsymbol{x}}^{<t}, \boldsymbol{h}_{x_i}) \tag{2}$$

where, $\hat{\boldsymbol{x}}^{<t}$ are the tokens generated before $\hat{x}_t$. We also use global attention (Luong et al., 2015) with copy mechanism (See et al., 2017) to guide our generators to replace the unknown (UNK) tokens. We call this model **SEQ**.

With section: We extend the sequence-to-sequence framework to include the section s_i corresponding the current turn. We use the same encoder to encode both the utterance and the section. We get the representation $\boldsymbol{h}_{x_i}$ of the current utterance x_i using Eq. 1. The representation of the section is given by:

$$\boldsymbol{h}_{s_i} = \text{Encoder}(\boldsymbol{s}_i; \boldsymbol{\theta}_E) \tag{3}$$

The input at each time step t to the generative model is given by $h_t = [x_{t-1}; h_s]$, where x_{t-1} is the embedding of the word at the previous time step. We call this model **SEQS**.

Experimental Setup: For both SEQ and SEQS model, we use a two-layer bidirectional LSTM as the encoder and a LSTM as the decoder. The dropout rate of the LSTM output is set to be 0.3. The size of hidden units for both LSTMs is 300. We set the word embedding size to be 100, since the size of vocabulary is relatively small[2]. The models are trained with adam (Kingma and Ba, 2014) optimizer with learning rate 0.001 until they converge on the validation set for the perplexity criteria. We use beam search with size 5 for response generation. We use all the data (i.e all the conversations regardless of the rating and scenario) for training and testing. The proportion of train/validation/test split is 0.8/0.05/0.15.

4 Evaluation

In what follows, we first present an analysis of the dataset, then provide an automatic metric for evaluation of our models–perplexity and finally present the results of human evaluation of the generated responses for engagement and fluency.

scenario	NW	LT
1	0.78	12.85
2	5.84	117.12

Table 6: The results of data analysis. LT refers to the average length of x_i in scenario 1 and $x_i, \ldots, x_{i+k}$ in scenario 2.

Dataset analysis: We perform two kinds of automated evaluation to investigate the usefulness of the document in the conversation. The first one is to investigate if the workers use the information from the document in the conversation. The second analysis is to show that the document adds value to the conversation. Let the set of tokens in the current utterance x_i be N, the set of tokens in the current section s_i be M, the set of tokens in the previous three utterances be H, and the set of stop words be S. In scenario 1, we calculate the set operation (NW) as $|((N \cap M) \setminus H) \setminus S|$. Let the tokens that appear in all the utterances $(x_i, \ldots, x_{i+k})$ corresponding to the current section s_i be K and the tokens that appear in all the utterances $(x_i, \ldots, x_{i+p})$ corresponding to the previous section s_{i-1} be P. In scenario 2, we calculate the set operation (NW) as $|((K \cap M) \setminus P) \setminus S|$. The results in Table 6 show that people use the information in the new sections and are not fixated on old sections. It also shows that they use the information to construct the responses.

Perplexity: To automatically evaluate the fluency of the models, we use perplexity measure. We build a language model on the train set of responses using ngrams up to an order of 3[3]. The generated test responses achieve a perplexity of 21.8 for the SEQ model and **10.11** for the SEQS model. This indicates that including the sections of document helps in the generation process.

4.1 Human Evaluation

We also perform two kinds of human evaluations to evaluate the quality of predicted utterances – engagement and fluency. These experiments are performed on Amazon Mechanical Turk.

Engagement: We set up a pairwise comparison following Bennett (2005) to evaluate the engagement of the generated responses. The test presents the chat history (1 utterance) and then, in random

---

[2] The total number of tokens is 46000, and we limit the vocabulary to be 10000 tokens.

[3] We use the SRILM toolkit (Stolcke, 2002)

order, its corresponding response produced by the SEQ and SEQS models. A third option "No Preference" was given to participants to mark no preference for either of the generated responses. The instruction given to the participants is "Given the above chat history as context, you have to pick the one which can be best used as the response based on the engagingness." We randomly sample 90 responses from each model. Each response was annotated by 3 unique workers and we take majority vote as the final label. The result of the test is that SEQ generated responses were chosen only 36.4% times as opposed to SEQS generated responses which were chosen **43.9%** and the "No Preference" option was chosen 19.6% of times. This result shows the information from the sections improves the engagement of the generated responses.

Fluency: The workers were asked to evaluate the fluency of the generated response on a scale of 1 to 4, where 1 is unreadable and 4 is perfectly readable. We randomly select 120 generated responses from each model and each response was annotated by 3 unique workers. The SEQ model got a low score of 2.88, contrast to the SEQS score of **3.84**. This outcome demonstrates that the information in the section also helps in guiding the generator to produce fluent responses.

5 Conclusion

In this paper we introduce a crowd-sourced conversations dataset that is grounded in a predefined set of documents which is available for download [4]. We perform multiple automatic and human judgment based analysis to understand the value the information from the document provides to the generation of responses. The SEQS model which uses the information from the section to generate responses outperforms the SEQ model in the evaluation tasks of engagement, fluency and perplexity.

Out-of-domain Detection based on Generative Adversarial Network

Abstract

The main goal of this paper is to develop *out–of–domain* (OOD) detection for dialog systems. We propose to use only in–domain (IND) sentences to build a generative adversarial network (GAN) of which the discriminator generates low scores for OOD sentences. To improve basic GANs, we apply feature matching loss in the discriminator, use domain–category analysis as an additional task in the discriminator, and remove the biases in the generator. Thereby, we reduce the huge effort of collecting OOD sentences for training OOD detection. For evaluation, we experimented OOD detection on a multi–domain dialog system. The experimental results showed the proposed method was most accurate compared to the existing methods.

1 Introduction

Multi–domain dialog systems (Hakkani-Tur et al., 2016; Jiang et al., 2014; Lee et al., 2013; Ryu et al., 2015; Seon et al., 2014) should detect whether an input request is *out–of–domain* (OOD) because users do not know the exact coverages of those systems. One important problem of building OOD detection is the huge effort required to collect OOD sentences. This paper focuses on developing an accurate OOD detection method that requires only in–domain (IND) sentences for training, so this paper can reduce the effort of collecting OOD sentences.

For OOD detection, sentences would be represented in a continuous vector space in which IND cases are distinguished from OOD cases. Therefore, we use the existing *sentence embedding* method for OOD detection (Ryu et al., 2017). The authors train a recurrent neural network (RNN) for *domain–category analysis* task, in which one domain–category is assigned to an input sentence. Due to the similarity between OOD detection and domain–category analysis, the extracted features (i.e., representation) of the RNN contain information about domain–category. In addition, the word representations are pre–trained from a large unlabelled corpus, so the sentence embedding method has the advantage in understanding rare or unknown words that are likely to appear in OOD sentences.

Afterwards, we use the learned representations of IND sentences to train *one–class classifiers* that distinguish IND sentences from OOD sentences. We propose to use a *generative adversarial network* (GAN) (Goodfellow et al., 2014) that consists of a generator G and a discriminator D. We train D that distinguishes the IND sentences from the fake sentences generated by G, so we expect D to reject OOD sentences. We apply three modifications to improve basic GANs. To the best of our knowledge, this is the first study that uses GANs to solve OOD detection.

2 Related Work

Lane et al. (2007) proposed an *in–domain verification* method. The authors first build a basic binary classifier for each domain, and then build a meta classifier that takes the scores by the basic binary classifiers as input. However, in our experiment, many OOD sentences were misclassified into IND because OOD sentences were not in the negative examples of the classifiers. Therefore, the confidence scores of the basic binary classifiers are not sufficiently reliable evidences of OOD. Also, understanding rare or unknown words remains a problem because bag–of–words model is used.

Ryu et al. (2017) proposed an *autoencoder*–based method. The authors use neural sentence embedding that has the advantage in representing rare or unknown words. Based on those distributed sentence representations, an autoencoder

is trained on IND sentences. The autencoder will have low reconstruction errors for IND sentences, so an input sentence can be classified into either IND or OOD. However, the autoencoder–based method has a limitation in expandability. When the weights are initialized carefully and regularization techniques are applied, the trained autoencoder reconstructs any input accurately. This result means that the reconstruction errors by the *ideal* autoencoder are not reliable evidence of OOD, so in OOD detection, autoencoders have little room for improvement.

3 Methods

As we discussed in Section 1, we use the sentence embedding to represent sentences in an 300–dimensional continuous vector space. We propose to use a GAN to OOD detection; a GAN consists of two adversarial components: generator G and discriminator D. G generates artificial data to deceive D. D distinguishes real data from the artificial data generated by G. GAN is an unsupervised algorithm because learning G and D does not require labels. Standard GANs are trained based on the objective function $V(D,G)$ as

$$\begin{aligned}\min_G \max_D V(D,G) = {} & \mathbb{E}_{\boldsymbol{x}\sim p_{\text{data}}}[\log D(\boldsymbol{x})] \\ & + \mathbb{E}_{\boldsymbol{z}\sim p_{\boldsymbol{z}}(\boldsymbol{z})}[\log 1 - D(G(\boldsymbol{z}))].\end{aligned} \quad (1)$$

So GAN is a minimax two–player game because G minimizes $V(D,G)$, and D maximizes $V(D,G)$.

We propose to use GANs to obtain a one–class classifier for OOD detection. When we train G to generate sentences similar to IND sentences and D to classify real IND sentences and fake sentences generated by G, we expect D to reject OOD sentences. Therefore, we use the low confidence score by D about an input sentence as the evidence that the sentence is OOD.

Let $p_{\mathbf{z}}(z)$ be a continuous uniform distribution $(-1,1)$. We define G that generates fake data $G(\mathbf{z}) \in \mathrm{R}^m$ from input noise $\mathbf{z} \sim p_{\mathbf{z}}(z)$, $\mathbf{f}$ that extracts features from either real data $\mathbf{x}$ of $(\mathbf{x},\mathbf{y}) \sim p_{\text{data}}(\mathbf{x},\mathbf{y})$ or $G(\mathbf{z})$, and D that measures the probability of either $\mathbf{f}(\mathbf{x})$ or $\mathbf{f}(G(\mathbf{z}))$ from the real data as

$$\begin{aligned} G(\mathbf{z}) &= \sigma_h(\mathbf{W}_g\mathbf{z}), && (2)\\ \mathbf{f}(\mathbf{x}) &= \sigma_h(\mathbf{W}_h\mathbf{x} + \mathbf{b}_f), && (3)\\ \mathbf{f}(G(\mathbf{z})) &= \sigma_h(\mathbf{W}_h G(\mathbf{z}) + \mathbf{b}_f), && (4)\\ D(\mathbf{f}(\mathbf{x})) &= \sigma_g(\mathbf{W}_d\mathbf{f}(\mathbf{x}) + \mathbf{b}_d), && (5)\\ D(\mathbf{f}(G(\mathbf{z}))) &= \sigma_g(\mathbf{W}_d\mathbf{f}(G(\mathbf{z})) + \mathbf{b}_d), && (6)\end{aligned}$$

where $\mathbf{W}_g$, $\mathbf{W}_f$, and $\mathbf{W}_d$ are weight matrices, $\mathbf{b}_f$ and $\mathbf{b}_d$ are bias vectors. So we define two objective functions

$$\begin{aligned} L_{\text{D}} = {} & -\mathbb{E}_{(\mathbf{x},\mathbf{y})\sim p_{\text{data}}(\mathbf{x},\mathbf{y})}[\log D(\mathbf{f}(\mathbf{x}))] && (7)\\ & - \mathbb{E}_{\mathbf{z}\sim p_{\mathbf{z}}(\mathbf{z})}[\log(1 - D(\mathbf{f}(G(\mathbf{z}))))], \\ L_{\text{G}} = {} & -\mathbb{E}_{\mathbf{z}\sim p_{\mathbf{z}}(\mathbf{z})}[\log D(\mathbf{f}(G(\mathbf{z})))]. && (8)\end{aligned}$$

Because $G(\mathbf{z})$ continuously changes during the training, f of traditional GAN also changes. Thus we define $C \in \mathbb{R}^{|D|}$ that computes domain–category of $\mathbf{f}(\mathbf{x})$ as

$$C(\mathbf{f}(\mathbf{x})) = \text{softmax}(\mathbf{W}_c\mathbf{f}(\mathbf{x}) + \mathbf{b}_c), \quad (9)$$

where $\mathbf{W}_c$ is a weight matrix and $\mathbf{b}_c$ is a bias vector. We expect f trained by the losses of both D

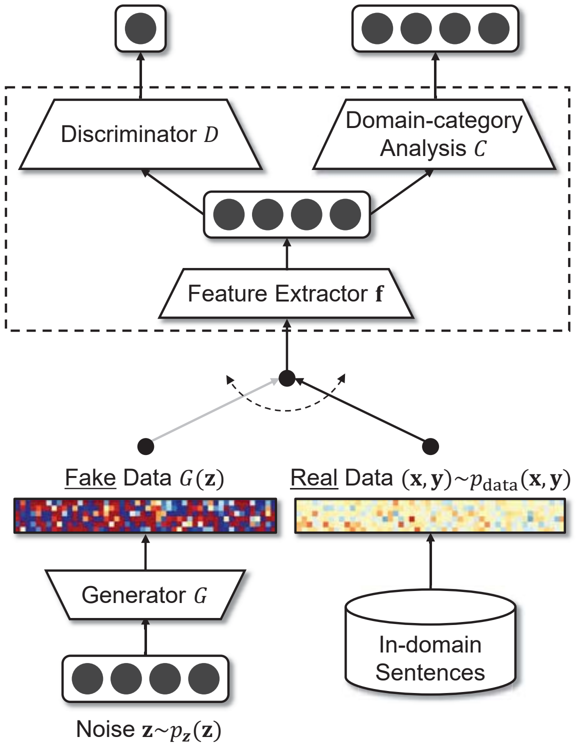

Figure 3: Generative adversarial network for out–of–domain sentence detection.

and C to be more stable than f trained by the loss of only D, so we define an objective function

$$L_{\text{C}} = \mathbb{E}_{(\mathbf{x},\mathbf{y})\sim p_{\text{data}}(\mathbf{x},\mathbf{y})}[H(C(\mathbf{f}(\mathbf{x})),\mathbf{y})], \qquad (10)$$

where $H(p,q)$ is the categorical cross entropy and $\mathbf{y}$ is the true domain–category.

In addition, GAN suffers from a *mode collapse* problem in which G generates samples with a low variance. To solve the problem, we remove the biases in the generator because the G was trained to use the biases mainly instead of the weights to generate data.

Second, we apply feature matching (Salimans et al., 2016). The authors say "Instead of directly maximizing the output of the discriminator, the new objective requires the generator to generate data that matches [sic] the statistics of the real data, where we use the discriminator only to specify the statistics that we think are worth matching". So G is trained to generate high variance sentence $G(\mathbf{z})$ by additional objective function

$$L_{\text{f}} = ||\mathbb{E}_{(\mathbf{x},\mathbf{y})\sim p_{\text{data}}(\mathbf{x},\mathbf{y})}\mathbf{f}(\mathbf{x}) - \mathbb{E}_{\mathbf{z}\sim p_{\mathbf{z}}(\mathbf{z})}\mathbf{f}(G(\mathbf{z}))||_2^2. \qquad (11)$$

Based on our design of GAN, we train D, C, $\mathbf{f}$, and G as Algorithm 1. To implement our GAN for one–class classification, we use the Tensorflow library (Abadi et al., 2015). We train our models by using Adam (Kingma and Ba, 2015) optimizer with a mini–batch size of 256 and an initial learning rate of 0.01 that is decreased linearly during 500 epochs. All weights are initialized from a zero–centered Normal distribution with standard deviation 1.0.

```

4 Experiments

4.1 Data Set

We experimented on a data set of 6,268 Korean sentences. We collected 706 OOD sentences about three domains: hotel, message, and smalltalk; and 5,562 IND sentences about fourteen domains: airplane, alarm, bus, call, car navigation, diet talk, exchange, general, schedule, songfinder, time, train, and TV control. We used eighty percent of the IND sentences to train the models; we used the remaining IND sentences and all OOD sentences for testing.

4.2 Evaluation Metrics

We use *equal error rate* (EER) to represent the accuracy of OOD detection (Lane et al., 2007). EER is the error rate at which false acceptance rate

$$\text{FAR} = \frac{\text{Number of } \textit{accepted} \text{ OOD sentences}}{\text{Number of OOD sentences}} \qquad (12)$$

and false rejection rate

$$\text{FRR} = \frac{\text{Number of } \textit{rejected} \text{ ID sentences}}{\text{Number of ID sentences}} \qquad (13)$$

are equal.

We performed each experiment 20 times, and recorded the average EER of OOD detection.

4.3 Compared Methods

We have three variations of vanilla GAN: to remove the biases, to add domain–category analy-

Table 1: EERs [%] ± s.d. (n = 20) of OOD detection.

Method	EER
Local outlier factor	13.33
One–class SVM	13.76
Autoencoder	9.24 ± 0.43
GAN with biases	15.93 ± 5.82
GAN	9.18 ± 0.30
GAN with DCA task	9.17 ± 0.40
GAN with FM loss	9.04 ± 0.30
GAN with DCA task and FM loss	8.96 ± 0.34

sis (DCA) task, and to add feature matching (FM) loss. So we assessed five settings about GAN.

We compare our method to three one–class classifiers. (1) *Local outlier factor* (Breunig et al., 2000) compares the local density of a point to the local densities of its neighbors, and considers the point that has lower density than their neighbors as an outlier. The local density of a point is defined by the distance to its nearest neighbors. (2) *One–class support vector machines* (One–class SVMs) (Schölkopf et al., 2001) that treats the origin as a negative example to learn a decision function. (3) *Autoencoder* is explained in Section 2.

4.4 Results

In the experiments (Table 1), the best EER (8.96%) was obtained by the GAN in which all three of our variations are applied ($p < 0.05$). This result means that (1) removing the biases and using the feature matching prevented the generator from mode collapse problem and (2) using domain–category analysis as an auxiliary task stabilized the training of feature extractor. Compared to the other one–class classification methods including the autoencoder, the proposed GAN was most accurate ($p < 0.05$), so we can say that the discriminator scores of the GAN are reliable evidence for OOD detection (Table 2).

5 Conclusion

In this paper, we aimed at building OOD detection without OOD sentences for training. We proposed to use the discriminator of a GAN, which is trained on only IND sentences. The proposed method outperformed the existing methods in our data set.

Table 2: Average score [%] by the discriminator of the GAN.

Data	Score
IND training sentences	98.69 (± 3.36)
Fake sentences $G(\mathbf{z})$	0.20 (± 1.70)
IND test sentences	88.59 (± 28.09)
OOD test sentences	8.04 (± 23.10)

To train the GAN, we used the distributed sentence representations computed from the pre–trained sentence embeddings instead of symbolic sentences. However, we think the limitation of the pre–trained sentence embeddings can be overcome by building a GAN that generates symbolic sentences and discriminates them.

Abstract

This paper presents a task for machine listening comprehension in the argumentation domain and a corresponding dataset in English. We recorded 200 spontaneous speeches arguing for or against 50 controversial topics. For each speech, we formulated a question, aimed at confirming or rejecting the occurrence of potential arguments in the speech. Labels were collected by listening to the speech and marking which arguments were mentioned by the speaker. We applied baseline methods addressing the task, to be used as a benchmark for future work over this dataset. All data used in this work is freely available for research.

1 Introduction

Machine reading comprehension (MRC) is the NLP task equivalent to reading comprehension tests that assess the understanding of written texts by humans. MRC is usually realized as a question answering (QA) task through multiple-choice questions or as a cloze test (Richardson et al., 2013; Hermann et al., 2015; Hill et al., 2015). With the abundance of multimedia content nowadays, this line of work has been extended to speech, by applying QA methods to speech transcripts, i.e. the output of automatic speech recognition (ASR). In such works, the task is consequently referred to as 'spoken question answering' (Li et al., 2018), 'question answering over speech transcripts' (Turmo et al., 2007; Lamel et al., 2008) or *machine listening comprehension* (MLC) (Chung and Glass, 2018).

We continue this line of work, and present a listening comprehension task and associated benchmark data over argumentative content. In the argumentation domain, such as political debates, people are often exposed directly to the audio (or the video), without access to a written version. Human comprehension is then done in real-time through listening. We simulate this scenario in our dataset. Namely, annotation is carried out by *listening* to debate speeches rather than by reading transcripts as done in prior work. The auditory modality is richer than written text in terms of the signal available to listeners, e.g., prosody. Similarly, machine comprehension can make use of the extra-lexical signal. The dataset we construct and release enables utilizing such signals, as done for instance in (Lippi and Torroni, 2016) for detecting claims in debates.

Most often, in both reading and listening comprehension tasks, the answer is explicitly mentioned in the text; frequently, the answer is even an actual segment of the text, as in SQuAD (Rajpurkar et al., 2016), one of the most popular MRC datasets. Conversely, in argumentation, presuppositions are fundamental (Habernal et al., 2018), inferences are more subtle and the answer may rely on common knowledge. Going beyond the factoid level, Tseng et al. (2016) presented a listening comprehension task over TOEFL listening tests.[1] In comparison, our data consists of spontaneous speech and is not adapted for non-native speakers.

We use data from iDebate[2], a high-quality, curated database of controversial topics – referred to as "motions", as in formal parliamentary proposals – with a list of arguments for and against each motion. We selected 50 motions, and recorded experienced debaters making four speeches for each of them (two for and two against the motion). We then asked annotators to listen to a speech and presented them with a list of arguments that were proposed independently in iDebate for the motion. The annotators had to mark which of these argu-

ments were mentioned in the speech (see Section 2 for further details). Example 1 shows one such argument alongside a speech snippet, demonstrating the unique nature of this domain and data. Specifically, the argument against the motion is implied from the speech, but is not explicitly mentioned in it.

Example 1 **(Positively labeled argument)**
Motion: *We should introduce goal line technology [in sports]*
Argument: *Controversy and debate are a part of the game*
Speech stance: *opposing ("con")*
... people also like it to some extent when officials make mistakes, because it adds to some of the like drama, the, oh, what if this happened? ... And I think that one of the biggest things that fans enjoy bonding over is when refs make mistakes that are blatantly wrong.

---

iDebate was chosen since its arguments are good candidates to construct comprehension questions: more than half of the assessed arguments are mentioned in our recorded speeches, and the large majority of the speeches contain at least one of the arguments suggested by iDebate. Furthermore, each argument in iDebate is coupled with a counter-argument. Those, in turn, may be used to rebut each argument that was detected through MLC, suggesting intriguing future directions to explore the released data. In a task related to ours, Boltužić and Šnajder (2014) have searched iDebate arguments in user argumentative comments. Their work, though, consisted of only two motions and included written, rather than audio data.

We release our annotated data and the results of baseline methods applied to it as a benchmark dataset for the MLC task. The dataset includes 200 speeches for 50 motions, in English. For each speech we include the following: (i) the audio version of the speech; (ii) manual and automatic transcripts; (iii) a labeled listening comprehension question, consisting of a set of arguments from iDebate that potentially appear in the speech.

The main contributions of this work are: (i) proposal of the new task of listening comprehension over argumentative content, a domain very different from those previously used for reading or listening comprehension tasks; (ii) a comprehensive and rich labeled dataset of 200 speeches covering 50 topics, transcribed both automatically and manually, and labeled for the listening comprehension task; (iii) establishment of baselines over the dataset.

All the recordings, their transcripts and labels are available for research at `https://www.research.ibm.com/haifa/dept/vst/debating_data.shtml`.

2 Data

iDebate iDebate contains a list of controversial topics, phrased as parliamentary motions. Each motion is associated with arguments (referred to as "points") supporting or contesting it. Each argument may be comprised of several sentences and is briefly summarized in a *title*.

Selecting iDebate motions At the time of this research, iDebate contained 684 motions.[3] We selected 50 clearly-defined motions, and simplified their phrasing when necessary. For example, we rephrased "This House believes that cannabis should be legalised" to "We should legalize cannabis".

Producing debate speeches We recorded argumentative speeches for each motion. First, two speeches supporting each motion were recorded by two experienced debaters. In doing so, we followed the process described in (Mirkin et al., 2018), where a speaker is presented with a motion and its description and is instructed to record a few minutes speech that supports it, with 10 minutes to prepare, but without checking any online materials. Given a speech supporting the motion, we asked another debater to listen to it and then record a speech rebutting it, and in consequence – opposing the motion. These response speeches are of different nature than the initial speeches beyond the opposite stance, as they often contain references and rebuttal to arguments mentioned in this initial speech.

Through this process, we produced in total 200 speeches recorded by 14 different speakers, equally distributed between the motions, and between the "pro" and "con" stances. Each speech was transcribed automatically using Watson ASR.[4] The transcripts were split automatically into sentences using a bi-directional LSTM that was trained on spoken language corpora (Pahuja et al., 2017). For completeness of the dataset,

---

[3] We accessed iDebate on Jan. 28, 2018.

[4] https://www.ibm.com/watson/services/speech-to-text

for each ASR transcript we include a manually-corrected "reference" human transcript, including manually added punctuation. Based on the human transcripts, we computed the word error rate (WER) of the ASR transcripts: 8.03% on average. For comparison, the WER of the ASR transcripts in (Li et al., 2018) is 22.73%.

Labeling Given the recorded speeches, we carried out a labeling task employing experienced annotators, all of whom are highly proficient English-speakers. Given a motion and a speech, the annotators were instructed to listen to it once, preferably without pausing, and select which ones of iDebate argument titles were mentioned in it, or *None* if none of them was. Specifically, they were instructed to answer positively if it would be correct to say that "the speaker argued that arg ..." where arg is the argument's title. A single question contained all the iDebate titles for the motion, which have the suitable stance for the given speech. Each of the 200 questions was answered by five annotators.

On average, the labeled data contains 4.4 argument titles per speech, where a title contains 10.5 words and an argument text includes 6 sentences and 156 words.

Labeling results In 173 (86.5%) of the speeches, at least one iDebate argument was found, and 248 (∼56%) of the iDebate arguments were labeled as positive at least once.

In order to analyze agreement between annotators, we transformed each multiple-choice question to a set of binary questions containing a speech and a single argument title. This amounted to 878 annotated speech–argument pairs, of which 354 (40.3%) are labeled as positive (i.e. an average of ∼1.8 positive arguments per speech). The average pairwise Cohen's Kappa (Cohen, 1960) score over the labels is 0.52 (0.55 for supporting and 0.50 for opposing speeches). The Fleiss' Kappa (Fleiss, 1971) is 0.52. Noteworthy, 78.5% of the labels were of high confidence: four or five annotators agreed on the label. Figure 1 shows the distribution of positive answers over the binary questions.

We analyzed a sample of arguments–speech pairs that had low agreement between annotators, i.e., those that have two or three positive labels. One reason for disagreement that we identified concerns argument titles that contain two claims, of which only one is argued by the speaker. An example is the title "Gambling is associated with other forms of addiction and harmful behaviour" concerning the motion "We should ban gambling". In a speech about this motion, only "addiction" was mentioned but not "harmful behaviour", resulting with two annotators accepting it and three rejecting it. Another possible source of disagreement is argument titles that are semantically similar, but not identical to the arguments presented in the speech. For instance, two of five annotators accepted the argument "on-line gambling affects families" when the speaker argued on the effects of gambling on families, but did not mention on-line gambling specifically.

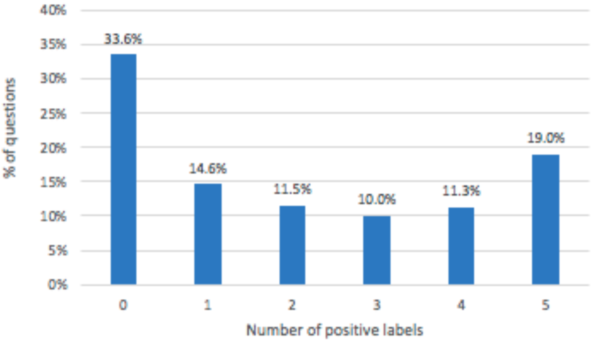

Figure 1: The percentage of binary questions labeled as positive by 0 to 5 annotators.

Listening vs. reading To corroborate the reliability of our labeling through listening, we repeated the task for 40 randomly sampled speeches, replacing only the audio with manual human transcripts of the speeches.[5] The average pairwise Cohen's Kappa score over the labels is 0.59 and the Fleiss' Kappa is 0.60. While these may indicate that the reading task is somewhat easier (e.g. because the annotator can read the text multiple times), it was encouraging to discover that audio-based labeling achieves similar results to text-based labeling: we compared the labels obtained via reading and via listening and found that 87% of them were identical. Labeling by listening is closer to the task of listening comprehension than labeling via reading. Another advantage is that it removes the need to manually transcribe the speeches (in our experience, ASR transcripts are not ideal for labeling). As mentioned, in our

---

[5] We use manual and not ASR transcripts for this analysis, under the assumption that when listening, the annotators are also receiving error-free content.

released dataset we do provide human transcripts for all speeches.

Analysis of potential bias Recent works showed undesired artifacts in natural language inference datasets, namely that in some datasets for inferring relations between two texts, inference can in fact be done by only considering one of them (Schwartz et al., 2017; Gururangan et al., 2018; Tsuchiya, 2018; Poliak et al., 2018). To explore this issue in our dataset, we assessed the correlation between several features of the argument title and the label. Specifically, we computed the Spearman's correlation (Spearman, 1904) between the label and the title's length, occurrences of named entities or negation words in the title, and the correlation between the labels and the titles' 100 most frequent words, stopwords excluded. This resulted in low correlation coefficients, summarized in Table 1. This preliminary analysis suggests that naive features extracted from the title are not sufficient for predicting its label.[6]

Feature	**Spearman ρ**
Title length	-0.07
Named entity	-0.08
Negation	-0.03
Frequent words	0.14

Table 1: Spearman correlation between labels and features of argument titles. For the frequent words, the figure shown is the maximum (absolute) correlation found between positive labels and words from the titles. The words which yielded this correlation were "women" and "environment".

3 Evaluation

Next, we establish baselines for our annotated dataset. All baselines are based on simple unsupervised text similarity methods for selecting which arguments were mentioned in a debate speech. Strictly, this is an entailment task rather than a similarity task, and similarity serves here as an approximation. Below we describe the establishment of the baselines.

Evaluation configurations We considered two ways of representing a speech and two ways of representing an argument, to a total of four different experimental configurations. A speech can be represented as a single text or as the set of its sentences. When a speech is represented by a set of sentences, we considered the maximum similarity score obtained by a sentence in the speech. For the speech text we used the ASR transcripts of the audio speeches, with the automatic split into sentences, as described in Section 2. The sentence-based configurations, therefore, depend on the specific automatic splitting of the texts into sentences. An argument can be represented using only its title or by its extended text. The validity of matching an argument's text against the speech while labels refer to titles stems from entailment transitivity: under the observation that in our data an argument text typically entails its title, if an argument text is mentioned in the speech (i.e. is entailed by it), its title is also entailed by the speech (that is, given that typically $arg \Rightarrow title$, if $speech \Rightarrow arg$ then $speech \Rightarrow title$.)

Evaluation metric The performance of each method is calculated as the average accuracy over speeches in the test set, where the accuracy of a speech is the ratio of correct answers out of the number of choices presented for it. This ensures that each speech contributes equally to the overall accuracy regardless of the number of potential arguments associated with it. Since there is an equal number of speeches per motion, this is also the average accuracy over motions.[7]

Development and test sets We randomly split the data into development and test sets (*dev* and *test* below), such that 60% of the motions (30 motions, 120 speeches, 60 of each of supporting and opposing speeches) are in *dev* and 40% (80 speeches) are in *test*. For each method, we select a threshold that maximizes accuracy over *dev*, and apply it to *test*. In other words, an argument is considered to be mentioned in the speech if its similarity score is above the threshold.

---

[6] We thank the anonymous reviewers for helping us improve this analysis.

[7] We chose accuracy over precision and recall since we wished to give an equal weight to each question; therefore, a micro-average score – where we consider each argument-speech pair as an item in the calculation – was unsuitable. With a small number of pairs per question, one often encounters anomalies: when there are no positive labels, recall is undefined, and when no positive prediction is given for a question, precision is undefined.

3.1 Assessed methods

***All-yes* baseline** As a reference point, we compute the accuracy obtained when all arguments are predicted to be mentioned in the speech, resulting in 39.8% accuracy.

word2vec (*w2v*) We create a w2v (Mikolov et al., 2013) vector representation for each text, removing stopwords; each word is represented by a 200-dimensional word embedding learned over Wikipedia. A *tfidf*-weighted average of the word embeddings represents each text, where *idf* values are counted when considering each Wikipedia sentence as a document. Given a pair of texts, their score is the cosine similarity between their vector representations.

skip-thought (ST) Kiros et al. (2015) presented a general sentence encoder, that has been applied successfully to a variety of tasks such as semantic relatedness and paraphrase detection, often obtaining state of the art results. We use its available implementation to encode the texts as vectors, and compute the cosine similarity between them.

3.2 Results

Table 2 shows the accuracy of all *w2v* configurations. Representing an argument using its more verbose several-sentences-long content outperforms using its short single-sentence title. On the speech side, considering each sentence separately is preferable to using the entire speech. We compared the results of the best *w2v*-based configuration (*arg-sentence*), to the performance of the *skip-thought* auto-encoder. In this setting, encoding individual speech sentences and an argument, the accuracy of *skip-thought* was 60.2%.

Method	Accuracy (%)
all-yes	39.8
w2v title-speech	49.8
w2v arg-speech	57.6
w2v title-sentence	55.8
w2v arg-sentence	64.6
ST arg-sentence	60.2

Table 2: Accuracy results over the test set ASR transcripts, for *w2v* and *skip-thought* (ST).

The highest scoring method, *w2v arg-sentence*, reaches, then, a rather modest accuracy of 64.6%. One weakness of this method, revealed through analysis of its false positive predictions, is its tendency to prefer longer sentences. It is nevertheless substantially superior to the trivial *all-yes* baseline, as well as its *all-no* counterpart.

As explained, we chose accuracy as the main metric for this benchmark as it enables computing macro-average scores over speeches with a variable number of arguments. For reference, the micro-average precision and recall scores of the *w2v arg-sentence* are 57.1% and 43% respectively, with an F_1 score of 49.1%. Optimizing for this metric enables controlling the trade-off between precision and recall with a threshold, depending on the end-application needs.

In sum, we have set a baseline for this task by computing similarity between averaged word embeddings vectors. This simple method can be used as a starting point for future works on this dataset.

4 Conclusions

Machine listening comprehension is a challenging task, whose complexity stems, among other things, from the difficulty to handle spoken language and from errors due to automatic transcription. The argumentation domain, often with complex and elaborate reasoning, relying on presuppositions and world knowledge, adds another dimension to this complexity. In this work, we suggest a task and a corresponding benchmark dataset to assess comprehension in this domain. We focused on the task of confirming the occurrence of arguments in a speech, which – as shown in this work – can be handled to some degree with standard textual inference methods. Other types of questions can be formulated over this data in following work. We release a rich dataset, accompanied with benchmarks, that can drive various studies in listening comprehension and argumentation mining.

5 Acknowledgments

We are thankful to the debaters and annotators who took part in the creation of this dataset.

Abstract

We tackle discourse-level relation recognition, a problem of determining semantic relations between text spans. Implicit relation recognition is challenging due to the lack of explicit relational clues. The increasingly popular neural network techniques have been proven effective for semantic encoding, whereby widely employed to boost semantic relation discrimination. However, learning to predict semantic relations at a deep level heavily relies on a great deal of training data, but the scale of the publicly available data in this field is limited. In this paper, we follow Rutherford and Xue (2015) to expand the training data set using the corpus of explicitly-related arguments, by arbitrarily dropping the overtly presented discourse connectives. On the basis, we carry out an experiment of sampling, in which a simple active learning approach is used, so as to take the informative instances for data expansion. The goal is to verify whether the selective use of external data not only reduces the time consumption of retraining but also ensures a better system performance. Using the expanded training data, we retrain a convolutional neural network (CNN) based classifer which is a simplified version of Qin et al. (2016)'s stacking gated relation recognizer. Experimental results show that expanding the training set with small-scale carefully-selected external data yields substantial performance gain, with the improvements of about 4% for accuracy and 3.6% for F-score. This allows a weak classifier to achieve a comparable performance against the state-of-the-art systems.

1 Introduction

Since the Penn Discourse Treebank of version 2.0 (PDTB) was released in 2008 (Prasad et al., 2008), there is a significant amount of research has been carried out on discourse-level relation recognition between a variety of text spans (namely, argument-argument relations). From a perspective of inclusion or omission of conjunctions, the study in this field has been directed toward two issues: recognizing explicit relations or implicit. Listed below are two pairs of arguments, where the arguments in 1) hold an explicit causal relation while those in 2) are implicitly related with a causal relation.

> 1) [She left the company]$_{Arg1}$ **because** [she would move to California]$_{Arg2}$.
>
> 2) [We have never seen the kitty since then]$_{Arg1}$. [John told us the kitty has been adopted]$_{Arg2}$.

In general, the explicit relations can be directly signaled by the conjunctions (also called connectives) which inherently exist, such as the conjunction "*because*" in 1). This allows a predictor to speculate relations by the word senses of conjunctions. Using conjunctions as relational predicates, the earlier study has achieved a prediction performance of no less than 93% for accuracy (Pitler and Nenkova, 2009). By contrast, the implicit relations like that in 2) are difficult to automatically recognize due to the lack of conjunctions.

We focus on the implicit relation recognition in this paper, and follow Rutherford and Xue (2015) to strengthen the current neural discourse-level relation classification by expanding the training data set. The explicit-to-implicit (Exp2Imp for short) relation transformation is used. In particular, we propose to introduce active learning into the data expansion process, with the aim to reduce redundancy and reinforce the use of informative instances. In our experiments, we cooperate active learning with a simple version of Exp2Imp transformation. Experimental results show that such a cooperation allows substantial improvements to be achieved for 4 main relation types in PDTB.

2 Related Work

Multi-class implicit relation recognition can be boiled down to a classification problem. This encourages the study of supervised classification at the earlier time (Pitler and Nenkova, 2009; Lin et al., 2009; Louis et al., 2010; Park and Cardie, 2012; Rutherford and Xue, 2014). Recently, the neural network based approaches become increasingly popular due to the capacity of deep semantic learning and understanding (Zhang et al., 2015; Qin et al., 2016; Chen et al., 2016; Qin et al., 2017; Liu and Li, 2016). However, a large amount of labeled data is urgently needed to train the models. (Rutherford and Xue, 2015; Braud and Denis, 2016; Liu et al., 2016; Wu et al., 2017).

The explicitly-related arguments in the corpus of PDTB has been sufficiently proven to be usable for creating implicitly-related arguments (Rutherford and Xue, 2015; Braud and Denis, 2016; Liu et al., 2016; Wu et al., 2017), only if the omission of inherent conjunctions will not distort the original semantic relations (Rutherford and Xue, 2015). Benefiting from the high-accuracy explicit relation recognition, a simple pattern, such as `Argument1`+*because*+`Argument2`, may enable the acquisition of countless explicitly-related arguments from texts. It makes it possible to cooperate with Rutherford and Xue (2015)'s Exp2Imp relation transformation for creating a tremendous number of labeled implicit relation instances.

However, it is inevitable to bring in the redundant information when using such a scale of unrefined artificial instances to directly expand the existing training data. This causes a time-consuming retraining process. By contrast, random sampling for retrenchment may leave informative instances out of the expanded data set.

Active learning (AL) is especially applicable to redundancy reduction. It is able to automatically select the most informative samples for use in a cycle of training. Nowadays, there have been a variety of AL models successfully used in different language processing tasks (Li and Guo, 2013; Guo and Wang, 2015; Yang et al., 2015; Zhang et al., 2017; Ramirez-Loaiza et al., 2017). This allows us to draw lessons from the experiences.

3 Informative Instances

In general, in the field of machine learning, an informative instance is defined as the one which has been classified with less confidence (i.e., higher uncertainty). Assume that $I_{r_j}(x_i, M)$ refers to the the level of uncertainty at which a classifier *M* determines an instance x_i as the member of the class r_j, thus x_i is informative only if it significantly increases the level of uncertainty:

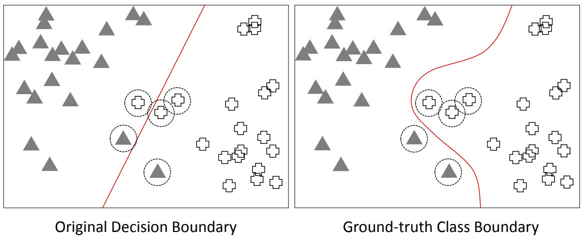

Figure 1: Examples of informative instances

$$x^* = \arg\max \sum_{r_j \in R} I_{r_j}(x_i; M) \qquad (1)$$

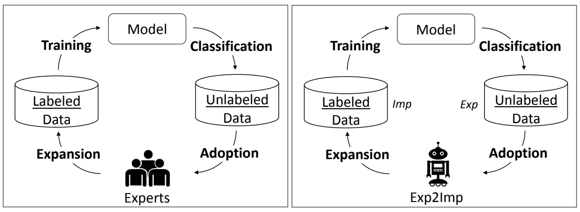
The utilization of informative instances in data expansion for training has been proven effective in improving the fully-supervised classification models. For example, the instances marked with a dot-dashed circle in Figure 1 can be regarded to be informative. It is because a classifier may fail to deterministically distinguish between them. If using such instances as additional training data, we may retrain the classifier to revise the original decision boundary, and pursue the ground-truth.

4 Active Learning (AL)

AL is a kind of retraining mechanism by data expansion. Figure 2 shows the workflow, which primarily includes 4 steps:

- **Step 1**: in which a learning model is required to be trained on the previously labeled data.
- **Step 2**: where the well-trained model is used to classify the unlabeled external data.
- **Step 3**: relies on the classification results to evaluate informativeness over the unlabeled data. The informative instances will be eventually adopted for manual annotation.
- **Step 4**: adds the newly annotated data to the existing, and retrains the learning model.

It is noteworthy that AL is not an "once-for-all" deal. On the contrary, it needs to be carried out repeatedly and iteratively, until a predefined condition is met, such as the time at which the classification performance remains almost the same within



General AL workflow   Cooperating AL with Exp2Imp

Figure 2: Workflows of ALs

a series of successive iterations, or termination after a fixed number of iterations.

5 Cooperating AL with Exp2Imp

We cooperate AL with Exp2Imp transformation. The workflow is also shown in Figure 2, where the labeled data set contains a certain number of implicitly-related argument pairs, while the unlabeled the explicitly-related.

In each iteration of AL, a classifier is trained on the labeled implicitly-related argument pairs, but it is driven to forcibly classify the explicitly-related argument pairs. On the basis, informativeness measurement is performed to sample the informative explicitly-related argument pairs. And then, instead of experts, the Exp2Imp transformation module serves as an annotator to mark the relations of the sampled argument pairs. Along with the automatically-annotated relations, such argument pairs are used as the counterfeit implicit relation instances. They are eventually added to the original labeled data set for expansion.

5.1 Informativeness Measurement

We employ an uncertainty sampling function (Zhu et al., 2008; Settles, 2010; Yang et al., 2015; Ramirez-Loaiza et al., 2017) to measure the informativeness:

$$Inf(x_i) = \sum_{r_j \in R} I_{r_j}(x_i; M) \qquad (2)$$

$$= \sum_{r_j \in R} P(r_j|x_i) \log P(r_j|x_i) \qquad (3)$$

where, for an instance x_i, the entropy of the predicted probabilities over all kinds of PDTB relation classes is used as the score of informativeness.

In order to reduce the computational complexity in practice, we sample informative instances in an iteration-independent batch-by-batch manner. In each iteration, a batch of instances in the unlabeled data set will be taken, only if their informativeness scores are higher than a constant threshold θ:

$$U' = \{x_i \mid Inf(x_i) > \theta, \forall x_i \in U\} \qquad (4)$$

where, U is the unlabeled data set while U' consists of the potentially informative instances.

Learning rate	0.001	Filter size	$(2, 3, 5)$
Number of filter	512	Optimizer	Adam
Batch size	128	threshold θ	0.95

Table 1: Hyperparameter settings of CNN

5.2 Statistical Information based Exp2Imp

We implement a much simpler Exp2Imp transformation model than Rutherford and Xue (2015)'s work. Statistical information is used.

For an explicitly-related argument pair in U, we rely on the conjunction to determine the relation. For example, if the arguments are syntactically connected by the conjunction "*because*", their relation will be identified as `Contingency` (`Causality` plus `Condition`). We previously look up conjunctions in a small subset of U and analysis the ground-truth explicit relations they signal. If a conjunction invariably signals a single type of relation (e.g., because→ `Contingency`), we preserve the one-to-one correspondence between the conjunction and the relation type. Else if a conjunction used to signal multiple-type relations, we align it solely with the relation it most frequently signals ever.

The Exp2Imp module first determines explicit relations based on conjunction-relation alignment, and then omits the conjunctions to create the counterfeit implicitly-related argument pairs.

5.3 CNN based Classification

We follow Qin et al. (2016) to use Siamese CNN for argument modeling and relation classification. The 300-dimensional word embeddings and 50-dimensional POS embeddings are used to represent the arguments. We also follow Mikolov et al. (2013) to pretrain the word embeddings and initialize the POS by random sampling in [-1,1]. Table 1 shows the hyperparameter settings.

The source codes of AL, Exp2Imp and Siamese CNN[1] to fully reproduce the experiments has been made publicly available, to which we attached the set of informative training data.

Table 2: The four-way classification performance

6 Experimentation

We experiment on the PDTB v2.0 (Prasad et al., 2008). Sections 2-20 are used as the benchmark training set. They are also used as the labeled set in the AL process. Sections 21-22 are taken as the test set and sections 0-1 the development set.

The ground-truth explicitly-related argument pairs in the PDTB corpus are divided into two subsets: one consists of 450 instances which are used for aligning conjunctions and relation types, the other is consisted of 17,000 instances and used as the unlabeled data set U in the AL process.

6.1 Main Results

For the purpose of comparison, we expand the benchmark training data set (**Baseline**) in two different ways: **Blender** and **AL**. Blender combines the benchmark with U. Exp2Imp transformation is performed for the instances in U. Thus Blender mixes the true implicitly-related argument pairs and all the counterfeits in U. By contrast, AL samples informative counterfeits for expansion.

We train CNN on the benchmark and the expanded versions, and test the best-developed models for four-way classification among the relation types of `Expansion` (**Exp**), `Contingency` (**Con**), `Comparison` (**Com**) and `Temporality` (**Tem**). Table 2 shows the performance. It can be observed that simply adding all the counterfeits to the training data set negatively influences the learning process, causing a performance loss of about 1.73% for macro F_1 and 2.08% for accuracy. This may result from the fact that the relations of some counterfeits change to be uncertain due to the omission of inherent conjunctions. Such counterfeits probably mislead CNN during the learning process.

Systems	Accuracy	Macro F_1
IO (2015)	57.10	40.50
MNN (2016)	57.27	44.98
MTN (2016)	-	42.50
DSWE (2017)	58.85	44.84
MANN (2017)	57.39	**47.80**
Ours	**60.63**	44.48

Table 3: Comparison with the state of the art

On the contrary, AL obtains a substantial performance gain. Using about 15 percent of instances in U for expansion, AL improves CNN with 3.85% for accuracy and 3.63% for macro F_1. This may imply that the carefully-selected counterfeits by AL most probably have positive effects on the retraining. The uncertainty caused by arbitrary conjunction omission plays a counter-productive role, prompting CNN to pursue more precise classification boundaries in the AL process.

6.2 Discussion

6.2.1 Comparison to Expansion Methods

We compare the proposed method to the recently popular, all of which more or less expand the training data, so as to introduce comprehensive linguistic knowledge into the learning process:

- Intelligent Omission (**IO**) (Rutherford and Xue, 2015) consciously omits conjunctions in explicitly related argument pairs to create counterfeits. Herein, a model is developed to identify the counterfeits whose semantic relations keep unchanged after conjunction omission. Such samples are used for expansion.

- Multi-task Neural Network (**MNN**) (Liu et al., 2016). The training set is expanded with RST-DT (Carlson et al., 2003) and NYT (Sandhaus, 2008). The other two MNN based models include Wu et al. (2016)'s **MTN** and Lan et al. (2017)'s **MANN**. MANN is more sophisticated due to the use of attention mechanism, while MTN acts as a bilingual discourse analysis system. Both of them introduce external datasets in the training processes, NANT and BiSynData, respectively .

- **DSWE** based CNN model (Wu et al., 2017), where Discourse-Specific Word Embeddings (DSWE) are used. DSWE are pre-trained on the large English Gigaword corpus.

It can be found that our method achieves competitive performance, showing the best accuracy and almost comparable F score to those of most competitors. It is noteworthy that the neural network we use is much weaker than the sophisticated MNN, MTN and MANN. Besides, there are fewer instances used for expansion than that for training DSWE. This may imply that AL is cost-effective.

6.2.2 Informative Instances

We randomly sample a couple of informative instances by tracking the AL process, along with some less informative cases. They helps illustrate the intuition that informativeness verification benefits data cleaning, in the process of using counterfeits for distant supervision.

> 3) [He further said that it would study other alternatives]$_{Arg1}$ **omitted conjunction** [it hasn't yet made any proposals to shareholders]$_{Arg2}$.
>
> Conjunction: **however**
> Relation: `Comparison.Contrast`
>
> 4) [all of a sudden you are relegated to a paltry sum]$_{Arg1}$ **omitted conjunction** [you become a federal judge]$_{Arg2}$.
>
> Conjunction: **when**
> Relation:`Temporality.Synchrony`

The instances listed above are to some extent informative. When the conjunctions inherently connecting the arguments were pruned off, the semantic relations changed to be uncertain. For example, assume the conjunctions "*however*" and "*when*" are respectively replaced by "*therefore*" and "*although*", the arguments in 3) will appear to have a `Contingency.Causality` relation as well, and those in 4) seems to hold a `Contingency.Compromise` relation with a very reasonable possibility. It means that the relations the argument pair hold are ambiguous if there isn't any manually-edited explicit relational signal (e.g., conjunction). Nevertheless, from the other perspective, such instances are frankly useful for training a classifier. It is because:

- Learning to distinguish the relations of such arguments is challenging beyond other cases.
- A challenging task enables the training process to be more strict but effective.
- This makes it possible to learn the subtle differences among argument pairs which belong to different relation classes.

On the contrary, the instances listed below are far from informative. There are less alternative relations can be imaged to replace the original, even if the conjunctions "*although*" and "*because*" have been pruned off. Note that such instances are undoubtedly useful at the very beginning of the training process. At that time, they facilitate the initialization of fuzzy classification boundaries. However, they are most probably useless for calibrating the boundaries at the level of subtle difference.

> 5) [She was dreadful to her war-damaged husband]$_{Arg1}$ **omitted conjunction** [she was kind and playful to her children]$_{Arg2}$.
>
> Conjunction: **although**
> Relation: `Comparison.Contrast`
>
> 6) [The ad was devastating]$_{Arg1}$. **omitted conjunction** [it raised questions about Mr. Courter's credibility]$_{Arg2}$.
>
> Conjunction: **because**
> Relation: `Contingency.Cause`

7 Conclusion

This paper demonstrates the contributions of AL to the enhancement of implicit relation classification. Using an AL model, we successfully sample a batch of informative explicitly-related argument pairs. Following Exp2Imp strategy, we convert the arguments into implicitly-related cases. This helps expand training data for fully-supervised relation modeling. By retraining, we enable a weak CNN model to achieve competitive performance.

Active learning can be systematically cooperated with Rutherford and Xue (2015)'s intelligent omission. This will enable the sampling of both informative and reliable instances for data expansion. Besides, using the carefully expanded training data set, the sophisticated learning model like MNN may be further enhanced significantly.

Abstract

Split and rephrase is the task of breaking down a sentence into shorter ones that together convey the same meaning. We extract a rich new dataset for this task by mining Wikipedia's edit history: WikiSplit contains one million naturally occurring sentence rewrites, providing sixty times more distinct split examples and a ninety times larger vocabulary than the WebSplit corpus introduced by Narayan et al. (2017) as a benchmark for this task. Incorporating WikiSplit as training data produces a model with qualitatively better predictions that score 32 BLEU points above the prior best result on the WebSplit benchmark.

A classic leaf symptom is water-soaked lesions between the veins which appear as angular leaf-spots where the lesion edge and vein meet.

A classic leaf symptom is the appearance of angular, water-soaked lesions between the veins. The angular appearance results where the lesion edge and vein meet.

Figure 1: A split-and-rephrase example extracted from a Wikipedia edit, where the top sentence had been edited into two new sentences by removing some words (yellow) and adding others (blue).

1 Introduction

A complex sentence can typically be rewritten into multiple simpler ones that together retain the same meaning. Performing this *split-and-rephrase* task is one of the main operations in text simplification, alongside paraphrasing and dropping less salient content (Siddharthan, 2006; Zhu et al., 2010; Woodsend and Lapata, 2011, i.a.). The area of automatic text simplification has received a lot of attention (Siddharthan, 2014; Shardlow, 2014), yet still holds many open challenges (Xu et al., 2015). Splitting sentences in this way could also benefit systems where predictive quality degrades with sentence length, as observed in, e.g., relation extraction (Zhang et al., 2017) and translation (Koehn and Knowles, 2017). And the schema-free nature of the task may allow for future supervision in the form of crowd-sourced rather than expensive expert annotation (He et al., 2015).

Narayan et al. (2017) introduce the WebSplit corpus for the split-and-rephrase task and report results for several models on it. Aharoni and Goldberg (2018) improve WebSplit by reducing overlap in the data splits, and demonstrate that neural encoder-decoder models (Bahdanau et al., 2014) perform poorly, even when enhanced with a copy mechanism (Gu et al., 2016; See et al., 2017).

One limitation of the WebSplit examples themselves is that they contain fairly unnatural linguistic expression using a small vocabulary. We introduce new training data mined from Wikipedia edit histories that have some noise, but which have a rich and varied vocabulary over naturally expressed sentences and their extracted splits. Figure 1 gives an example of how a Wikipedia editor rewrote a single sentence into two simpler ones. We create WikiSplit, a set of one million such examples mined from English Wikipedia, and show that models trained with this resource produce dramatically better output for split and rephrase.

Our primary contributions are:

- A scalable, language agnostic method for extracting split-and-rephrase rewrites from Wikipedia edits.
- Public release of the English WikiSplit dataset, containing one million rewrites: http://goo.gl/language/wiki-split
- By incorporating WikiSplit into training, we more than double (30.5 to 62.4) the BLEU score obtained on WebSplit by Aharoni and Goldberg (2018).

---

Table 1: Examples of correct and noisy sentence splits extracted from Wikipedia edits. Noise from unsupported or missing statements is visualized with the same coloring as in Figure 1.

2 The WikiSplit Corpus

WebSplit provides a basis for measuring progress on splitting and rephrasing sentences. However, its small size, inherent repetitiveness, and synthetic nature limit its broader applicability. In particular, we see it as a viable benchmark for evaluating models, but not for training them. To that end, we introduce the WikiSplit corpus and detail its construction next.

2.1 Mining Wikipedia Edits

Wikipedia maintains snapshots of entire documents at different timestamps, which makes it possible to reconstruct edit histories for documents. This has been exploited for many NLP tasks, including sentence compression (Yamangil and Nelken, 2008), text simplification (Yatskar et al., 2010; Woodsend and Lapata, 2011; Tonelli et al., 2016) and modeling semantic edit intentions (Yang et al., 2017).

To construct the WikiSplit corpus, we identify edits that involve sentences being split. A list of sentences for each snapshot is obtained by stripping HTML tags and Wikipedia markup and running a sentence break detector (Gillick, 2009). Temporally adjacent snapshots of a Wikipedia page are then compared to check for sentences that have undergone a split like that shown in Figure 1. We search for splits in both temporal directions.

Given all candidate examples extracted this way, we use a high-precision heuristic to retain only high quality splits. To extract a full sentence C and its candidate split into $S = (S_1, S_2)$, we require that C and S_1 have the same trigram prefix, C and S_2 have the same trigram suffix, and S_1 and S_2 have different trigram suffixes. To filter out misaligned pairs, we use BLEU scores (Papineni et al., 2002) to ensure similarity between the original and the split versions.

Thresh. δ	Correct	Unsupp.	Miss.	Size
0.1	161	35	6	1.4m
0.2	168	35	4	1.0m
0.3	169	31	4	0.5m

Table 2: Quality vs corpus size trade-off when setting the similarity threshold. The counts are for a random sample of 100 split-and-rephrase examples extracted using our method (i.e., 200 simple sentences). Keys: **Unsupp**orted; **Miss**ing

Specifically, we discard pairs where BLEU(C, S_1) or BLEU(C, S_2) is less than δ (an empirically chosen threshold). If multiple candidates remain for a given sentence C, we retain $\arg\max_S (\text{BLEU}(C, S_1) + \text{BLEU}(C, S_2))$.[1]

2.2 Corpus Statistics and Quality

Our extraction heuristic is imperfect, so we manually assess corpus quality using the same categorization schema proposed by Aharoni and Goldberg (2018); see Table 1 for examples of *correct*, *unsupported* and *missing* sentences in splits extracted from Wikipedia. We do this for 100 randomly selected examples using three different

---

[1] We attempted to mitigate other noise inherent in Wikipedia by removing items that 1) repeated a token more than three times in a row; 2) contained a token longer than 25 characters; 3) were suggestive of profane vandalism.

	WebSplit		WikiSplit	
	Count	Unique	Count	Unique
C	1.3m	17k	1.0m	1.0m
S'	6.1m	28k	2.0m	1.9m
t	344k	7k	33.1m	633k

Table 3: Training corpus statistics in terms of complex sentences (C), simple sentences ($S' = \cup_i S_i$) and tokens (t, appearing across unique complex sentences). WikiSplit provides much greater diversity and scale.

thresholds of δ. As shown in Table 2, δ=0.2 provides the best trade-off between quality and size.

Out of the 100 complex sentences in the sample, only 4 contained information that was not completely covered by the simple sentences. In our corpus, every complex sentence is split into two simpler sentences, so the sample contains 200 simple sentences. Out of these we found 168 (84%) to be correct, while 35 (18%) contained unsupported facts. Thus, for the overall sample of 100 split-and-rephrase examples, 68% are perfect while 32% contain some noise (either unsupported facts or missing information). We stress that our main goal is to use data extracted this way as training data and accept that its use for evaluation is an imperfect signal with some inherent noise and bias (by construction).

After extraction and filtering, we obtain over one million examples of sentence splits from around 18 million English documents. We randomly reserved 5000 examples each for tuning, validation and testing, producing 989,944 unique complex training sentences, compared to the 16,938 of WebSplit (cf. Table 3).

2.3 Comparison to WebSplit

Narayan et al. (2017) derived the WebSplit corpus by matching up sentences in the WebNLG corpus (Gardent et al., 2017) according to partitions of their underlying meaning representations (RDF triples). The WebNLG corpus itself was created by having crowd workers write sentential realizations of one or more RDF triples. The resulting language is often unnatural, for example, *"Akeem Dent once played for the Houston Texans team which is based in Houston in Texas."*[2]

Repetition arises because the same sentence fragment may appear in many different examples. This is to be expected given that WebSplit's small vocabulary of 7k words must account for the 344k tokens that make up the distinct complex sentences themselves.[3]

This is compounded in that each sentence contains a named entity by construction. In contrast, our large new WikiSplit dataset offers more natural and diverse text (see examples in Table 1), having a vocabulary of 633k items covering the 33m tokens in its distinct complex sentences.

The task represented by our WikiSplit dataset is *a priori* both harder and easier than that of the WebSplit dataset – harder because of the greater diversity and sparsity, but potentially easier due to the uniform use of a single split.

Of the two datasets, WebSplit is better suited for evaluation: its construction method guarantees cleaner data than is achieved by our extraction heuristic, and it provides multiple reference decompositions for each complex sentence, which tends to improve the correlation of automatic metrics with human judgment in related text generation tasks (Toutanova et al., 2016).

3 Experiments

In order to understand how WikiSplit can inform the split-and-rephrase task, we vary the composition of the training set when training a fixed model architecture. We compare three training configurations: WEBSPLIT only, WIKISPLIT only, and BOTH, which is simply their concatenation.

Text-to-text training instances are defined as all the unique pairs of (C, S), where C is a complex sentence and S is its simplification into multiple simple sentences (Narayan et al., 2017; Aharoni and Goldberg, 2018). For training, we delimit the simple sentences with a special symbol. We depart from the prior work by only using a subset of the WebSplit training set: we take a fixed sub-sample such that each distinct C is paired with a single S, randomly selected from the multiple possibilities in the dataset. This scheme produced superior performance in preliminary experiments.

As a quality measure, we report multi-reference *corpus-level* BLEU[4] (Papineni et al., 2002), but

WEBSPLIT	34.2	30.5	2.0	8.8
WIKISPLIT	60.4	58.0	2.0	11.2
BOTH	**62.4**	**60.1**	2.0	11.0

Table 5: Results on the WebSplit v1.0 test set when varying the training data while holding model architecture fixed: corpus-level BLEU, sentence-level BLEU (to match past work), simple sentences per complex sentence, and tokens per simple sentence (micro-average). AG18 is the previous best model by Aharoni and Goldberg (2018), which used the full WebSplit training set, whereas we downsampled it.

include sentence-level BLEU (sBLEU) for direct comparison to past work.[5] We also report length-based statistics to quantify splitting.

We use the same sequence-to-sequence architecture that produced the top result for Aharoni and Goldberg (2018), "Copy512", which is a one-layer, bi-directional LSTM (cell size 512) with attention (Bahdanau et al., 2014) and a copying mechanism (See et al., 2017) that dynamically interpolates the standard word distribution with a distribution over the words in the input sentence. Training details are as described in the Appendix of Aharoni and Goldberg (2018) using the OpenNMT-py framework (Klein et al., 2017).[6]

3.1 Results

We compare to the SOURCE baseline, which is the previously reported method of taking the unmodified input sentence as prediction, and we add SPLITHALF, the natural baseline of deterministically splitting a complex sentence into two equal-length token sequences and appending a period to the first one.

Table 4 compares our three training configurations on the validation sets of both WebSplit and WikiSplit. The WEBSPLIT model scores 35.3 BLEU on the WebSplit validation set but fails to generalize beyond its narrow domain, as evidenced by reaching only 4.2 BLEU on the WikiSplit validation set.

The example predictions in Table 7 illustrate how this model tends to drop content ("Alfred Warden", "mouth", "Hamburg"), hallucinate common elements from its training set ("food", "ingredient", "publisher") and generally fails to produce coherent sentences.

In contrast, the WIKISPLIT model achieves 59.4 BLEU on the WebSplit validation set, *without observing any in-domain data.* It also outperforms the two deterministic baselines on both validation sets by a non-trivial BLEU margin. This indicates that the WikiSplit training data enable better generalization than when using WebSplit by itself. Reintroducing the downsampled, in-domain training data (BOTH) further improves performance on the WebSplit evaluation.

These gains in BLEU from using WikiSplit carry over to the blind manual evaluation we performed on a random sample of model predictions on the WebSplit validation set. As shown in Table 6, the BOTH model produced the most accurate output (95% correct simple sentences), with the lowest incidence of missed or unsupported statements. Our manual evaluation includes the corresponding outputs from Aharoni and Goldberg (2018) (AG18), which were 22% accurate.

The examples in Table 7 demonstrate that the WIKISPLIT and BOTH models produce much more coherent output which faithfully rephrases the input. In Example 1, the combined model (BOTH) produces three fluent sentences, overcoming the strong bias toward two-sentence output inherent in the majority of its training examples.

We relate our approach to prior work on WebSplit v1.0 by reporting scores on its test set in Table 5. Our best performance in BLEU is again obtained by combining the proposed WikiSplit dataset with the downsampled WebSplit, yielding a 32 point improvement over the prior best result.

---

[5] Past work on WebSplit (Narayan et al., 2017; Aharoni and Goldberg, 2018) reported macro-averaged *sentence-level* BLEU, calculated without smoothing precision values of zero. We found this ill-defined case occurred often for low-quality output.

Input	*Der beglückte Florindo is an opera composed by Handel in Hamburg in 1708 as part of a double opera , the other part being Die verwandelte Daphne .*
WebSplit	Handel opera is the publisher of the opera opera . Handel is the capital of 1708 .
WikiSplit	Der beglückte Florindo is an opera composed by Handel in Hamburg in 1708 . It was part of a double opera , the other part being Die verwandelte Daphne .
Both	Der beglückte Florindo is an opera composed by Handel in Hamburg in 1708 as part of a double opera . The other part being Die verwandelte Daphne .

Table 7: Example model predictions for items from each validation set. AG18 gives the output of the Copy512-model of Aharoni and Goldberg (2018), while the other outputs are from our models trained on the corresponding data.

4 Conclusion and Outlook

Our results demonstrate a large, positive impact on the split-and-rephrase task when training on large, diverse data that contains some noise. This suggests that future improvements may come from finding other such sources of data as much as from modeling. The new WikiSplit dataset is intended as training data, but for further progress on the split-and-rephrase task, we ideally need evaluation data also derived from naturally occurring sentences, and an evaluation metric that is more sensitive to the particularities of the task.

5 Acknowledgments

BLEU is Not Suitable for the Evaluation of Text Simplification

Elior Sulem, Omri Abend, Ari Rappoport
Department of Computer Science, The Hebrew University of Jerusalem
`{eliors|oabend|arir}@cs.huji.ac.il`

Abstract

BLEU is widely considered to be an informative metric for text-to-text generation, including Text Simplification (TS). TS includes both lexical and structural aspects. In this paper we show that BLEU is not suitable for the evaluation of sentence splitting, the major structural simplification operation. We manually compiled a sentence splitting gold standard corpus containing multiple structural paraphrases, and performed a correlation analysis with human judgments.[1] We find low or no correlation between BLEU and the grammaticality and meaning preservation parameters where sentence splitting is involved. Moreover, BLEU often negatively correlates with simplicity, essentially penalizing simpler sentences.

1 Introduction

BLEU (Papineni et al., 2002) is an n-gram-based evaluation metric, widely used for Machine Translation (MT) evaluation. BLEU has also been applied to monolingual translation tasks, such as grammatical error correction (Park and Levy, 2011), summarization (Graham, 2015) and text simplification (Narayan and Gardent, 2014; Štajner et al., 2015; Xu et al., 2016), i.e. the rewriting of a sentence as one or more simpler sentences.

Along with the application of parallel corpora and MT techniques for TS (e.g., Zhu et al., 2010; Wubben et al., 2012; Narayan and Gardent, 2014), BLEU became the main automatic metric for TS, despite its deficiencies (see §2). Indeed, focusing on lexical simplification, Xu et al. (2016) argued that BLEU gives high scores to sentences that are close or even identical to the input, especially when multiple references are used. In their experiments, BLEU failed to predict simplicity, but obtained a higher correlation with grammaticality and meaning preservation, relative to the SARI metric they proposed.

In this paper, we further explore the applicability of BLEU for TS evaluation, examining BLEU's informativeness where sentence splitting is involved. Sentence splitting, namely the rewriting of a single sentence as multiple sentences while preserving its meaning, is the main structural simplification operation. It has been shown useful for MT preprocessing (Chandrasekar et al., 1996; Mishra et al., 2014; Li and Nenkova, 2015) and human comprehension (Mason and Kendall, 1979; Williams et al., 2003), independently from other lexical and structural simplification operations. Sentence splitting is performed by many TS systems (Zhu et al., 2010; Woodsend and Lapata, 2011; Siddharthan and Angrosh, 2014; Narayan and Gardent, 2014, 2016). For example, 63% and 80% of the test sentences are split by the systems of Woodsend and Lapata (2011) and Zhu et al. (2010), respectively (Narayan and Gardent, 2016). Sentence splitting is also the focus of the recently proposed Split-and Rephrase sub-task (Narayan et al., 2017; Aharoni and Goldberg, 2018), in which the automatic metric used is BLEU.

For exploring the effect of sentence splitting on BLEU scores, we compile a human-generated gold standard sentence splitting corpus – HSplit, which will also be useful for future studies of splitting in TS, and perform correlation analyses with human judgments. We consider two reference sets. First, we experiment with the most common set, proposed by Xu et al. (2016), evaluating a variety of system outputs, as well as HSplit. The references in this setting explicitly emphasize lexical operations, and do not contain splitting or content deletion.[2] Second, we experiment with HSplit as

---

[2] Nevertheless, they are also used in contexts where struc-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 738–744
Brussels, Belgium, October 31 - November 4, 2018.

the reference set, evaluating systems that focus on sentence splitting. The first setting allows assessing whether BLEU with the standard reference set is a reliable metric on systems that perform splitting. The second allows assessing whether BLEU can be adapted to evaluate splitting, given a reference set so oriented.

We find that BLEU is often negatively correlated with simplicity, even when evaluating outputs without splitting, and that when evaluating outputs with splitting, it is less reliable than a simple measure of similarity to the source (§4.2). Moreover, we show that BLEU cannot be adapted to assess sentence splitting, even where the reference set focuses on this operation (§4.3). We conclude that BLEU is not informative and is often misleading for TS evaluation and for the related Split and Rephrase task.

2 Related Work

The BLEU Metric. BLEU (Papineni et al., 2002) is reference-based, where the use of multiple references is used to address cross-reference variation. To address changes in word order, BLEU uses n-gram precision, modified to eliminate repetitions across the references. A brevity term penalizes overly short sentences. Formally:

$$\mathrm{BLEU} = \mathrm{BP} \times \exp(\sum_{n=1}^{N} w_n \log(p_n))$$

where BP is the brevity penalty term, p_n are the modified precisions, and w_n are the corresponding weights, which are usually uniform in practice.

The experiments of Papineni et al. (2002) showed that BLEU correlates with human judgments in the ranking of five English-to-Chinese MT systems and that it can distinguish human and machine translations. Although BLEU is widely used in MT, several works have pointed out its shortcomings (e.g., Koehn and Monz, 2006). In particular, Callison-Burch et al. (2006) showed that BLEU may not correlate in some cases with human judgments since a huge number of potential translations have the same BLEU score, and that correlation decreases when translation quality is low. Some of the reported shortcomings are relevant to monolingual translation, such as the impossibility to capture synonyms and paraphrases that are not in the reference set, or the uniform weighting of words.

BLEU in TS. While BLEU is standardly used for TS evaluation (e.g., Xu et al., 2016; Nisioi et al., 2017; Zhang and Lapata, 2017; Ma and Sun, 2017), only few works tested its correlation with human judgments. Using 20 source sentences from the PWKP test corpus (Zhu et al., 2010) with 5 simplified sentences for each of them, Wubben et al. (2012) reported positive correlation of BLEU with simplicity ratings, but no correlation with adequacy. T-BLEU (Štajner et al., 2014), a variant of BLEU which uses lower n-grams when no overlapping 4-grams are found, was tested on outputs that applied only structural modifications to the source. It was found to have moderate positive correlation for meaning preservation, and positive but low correlation for grammaticality. Correlation with simplicity was not considered in this experiment. Xu et al. (2016) focused on lexical simplification, finding that BLEU obtains reasonable correlation for grammaticality and meaning preservation but fails to capture simplicity, even when multiple references are used. To our knowledge, no previous work has examined the behavior of BLEU on sentence splitting, which we investigate here using a manually compiled gold standard.

3 Gold-Standard Splitting Corpus

In order to investigate the effect of correctly splitting sentences on the automatic metric scores, we build a parallel corpus, where each sentence is modified by 4 annotators, according to specific sentence splitting guidelines. We use the complex side of the test corpus of Xu et al. (2016).[3]

While Narayan et al. (2017) recently proposed the semi-automatically compiled WEB-SPLIT dataset for training automatic sentence splitting systems, here we generate a completely manual corpus, without a-priori splitting points nor do we pre-suppose that all sentences should be split. This corpus enriches the set of references focused on lexical operations that were collected by Xu et al. (2016) for the same source sentences and can also be used as an out-of-domain test set for Split-and-Rephrase (Narayan et al., 2017).

We use two sets of guidelines. In Set 1, annotators are required to split the original as much as possible, while preserving the sentence's gram-

---

tural operations are involved (Nisioi et al., 2017; Sulem et al., 2018b).

[3] `https://github.com/cocoxu/simplification` includes the corpus, the SARI metric and the SBMT-SARI system. The corpus comprises 359 sentences.

maticality, fluency and meaning. The guidelines include two sentence splitting examples.[4] In Set 2, annotators are encouraged to split only in cases where it simplifies the original sentence. That is, simplicity is implicit in Set 1 and explicit in Set 2. In both sets, the annotators are instructed to leave the source unchanged if splitting violates grammaticality, fluency or meaning preservation.[5]

Each set of guidelines is used by two annotators, with native or native-like proficiency in English. The obtained corpora are denoted by HSplit1, HSplit2 (for Set 1), and HSplit3 and HSplit4 (for Set 2), each containing 359 sentences. Table 1 presents statistics for the corpora. Both in terms of the number of splits per sentence (# Sents) and in terms of the proportion of input sentences that have been split (SplitSents), we observe that the average difference within each set is significantly greater than the average difference between the sets.[6] This suggests that the number of splits is less affected by the explicit mention of simplicity than by the inter-annotator variability.

	# Sents	SplitSents (%)
HSplit1	1.93	68
HSplit2	2.28	86
HSplit3	1.87	63
HSplit4	1.99	71
HSplitAverage	2.02	72

Table 1: Statistics for the sentence splitting benchmark. #Sents denotes the average number of sentences in the output. SplitSents denotes the proportion of input sentences that have been split. The last row presents the average scores of the 4 HSplit corpora.

4 Experiments

4.1 Experimental Setup

Metrics. In addition to BLEU,[7] we also experiment with (1) iBLEU (Sun and Zhou, 2012) which was recently used for TS (Xu et al., 2016; Zhang et al., 2017) and which takes into account the BLEU scores of the output against the input and against the references; (2) the Flesch-Kincaid Grade Level (FK; Kincaid et al., 1975), computed at the system level, which estimates the readability of the text with a lower value indicating higher readability;[8] (3) SARI (Xu et al., 2016), which compares the n-grams of the system output with those of the input and the human references, separately evaluating the quality of words that are added, deleted and kept by the systems. For completeness, we also experiment with the negative Levenshtein distance to the source (-LD$_{SC}$), which serves as a measure of conservatism.[9]

We explore two settings. In one ("Standard Reference Setting", §4.2), we use two sets of references: the Simple Wikipedia reference (yielding BLEU-1ref and iBLEU-1ref), and 8 references obtained by crowdsourcing by Xu et al. (2016) (yielding BLEU-8ref, iBLEU-8ref and SARI-8ref). In the other ("HSplit as Reference Setting", §4.3), we use HSplit as the reference set.

Systems. For "Standard Reference Setting", we consider both a case where evaluated systems do not perform any splittings on the test set ("Systems/Corpora without Splits"), and one where we evaluate these systems, along with the HSplit corpus, used in the role of system outputs ("All Systems/Corpora"). Systems include six MT-based simplification systems, including outputs of the state-of-the-art neural TS system of Nisioi et al. (2017), in four variants: either default settings or initialization by word2vec, for each both the highest and the fourth ranked hypotheses in the beam are considered.[10] We further include Moses (Koehn et al., 2007) and SBMT-SARI (Xu et al., 2016), a syntax-based MT system tuned against SARI, and the identity function (outputs are same as inputs). The case which evaluates outputs with sentence splitting additionally includes the four HSplit corpora and the HSplit average scores.

For "HSplit as Reference Setting", we consider the outputs of six simplification systems whose main simplification operation is sentence splitting: DSS, DSS^m, SEMoses, SEMoses^m, SEMoses$_{LM}$ and SEMoses$^m_{LM}$, taken from (Sulem et al., 2018b).

Human Evaluation. We use the evaluation benchmark provided by Sulem et al. (2018b),[11] including system outputs and human evaluation scores corresponding to the first 70 sentences of

---

[4] Examples are taken from Siddharthan (2006).

[5] Examples are not provided in the case of Set 2 so as not to give an a-priori notion of simplicity. The complete guidelines are found in the supplementary material.

[6] Wilicoxon's signed rank test, $p = 1.6 \cdot 10^{-5}$ for #Sents and $p = 0.002$ for SplitSents.

[7] System-level BLEU scores are computed using the multi-bleu Moses support tool. Sentence-level BLEU scores are computed using NLTK (Loper and Bird, 2002).

[8] We thus computed the correlation in §4.2 for -FK.

[9] LD$_{SC}$ is computed using NLTK.

[10] Taking the fourth hypothesis rather than the first has been found to yield considerably less conservative TS systems.

Table 2: Spearman correlation (and p-values) at the system level between the rankings of automatic metrics and of human judgments for "Standard Reference Setting". Automatic metrics (rows) include BLEU and iBLEU (each used either with a single reference or with 8 references), the negative Flesh-Kincaid Grade Level (-FK), and SARI, computed with 8 references. We also include the negative Levenshtein distance between the output and the source (-LD$_{SC}$). Human judgments are of the Grammaticality (G), Meaning Preservation (M), Simplicity (S) and Structural Simplicity (StS) of the output. The left-hand side reports correlations where only simplifications that do not include sentence splitting are considered. The right-hand side reports correlations where the HSplit corpora are evaluated as well (see text). BLEU negatively correlates with S and StS in both cases, and shows little to no correlation with G and M where sentence splitting is involved.

the test corpus of Xu et al. (2016), and extend it to apply to HSplit as well.

The evaluation of HSplit is carried out by 3 in-house native English annotators, who rated the different input-output pairs for the different systems according to 4 parameters: Grammaticality (G), Meaning preservation (M), Simplicity (S) and Structural Simplicity (StS). G and M are measured using a 1 to 5 scale. A -2 to +2 scale is used for measuring simplicity and structural simplicity. For computing the inter-annotator agreement of the whole benchmark (including the system outputs and the HSplit corpora), we follow Pavlick and Tetreault (2016) and randomly select, for each sentence, one annotator's rating to be the rating of Annotator 1 and the rounded average rating of the two other annotators to be the rating of Annotator 2. We then compute weighted quadratic κ (Cohen, 1968) between Annotator 1 and 2. Repeating this process 1000 times, the obtained medians and 95% confidence intervals are 0.42 ± 0.002 for G, 0.77 ± 0.001 for M and 0.59 ± 0.002 for S and StS.

4.2 Results with Standard Reference Setting

Description of the Human Evaluation Scores. The human evaluation scores for each parameter are obtained by averaging over the 3 annotators. The scores at the system level are obtained by averaging over the 70 sentences. In the "All systems/corpora" case of the "Standard Reference Setting", where 12 systems/corpora are considered, the range of the average G scores at the system level is from 3.71 to 4.80 (σ = 0.29). For M, this max-min difference between the systems is 1.23 (σ=0.40). For S and StS, the differences are 0.53 (σ = 0.17) and 0.65 (σ = 0.20). At the sentence level, considering 840 sentences (70 for each of the system/corpora), the G and M scores vary from 1 to 5 (σ equals 0.69 and 0.85 respectively), and the S and StS scores from -1 to 2 (σ equals 0.53 and 0.50).

In the "Systems/corpora without Splits" case of the "Standard Reference Setting", where 7 systems/corpora are considered, the max-min difference at the system level are again 1.09 (σ = 0.36) and 1.23 (σ = 0.47) for G and M respectively. For S and StS, the differences are 0.45 and 0.49 (σ = 0.18). At the sentence level, considering 490 sentences (70 for each of the system/corpora), the G and M scores vary from 1 to 5 (σ equals 0.78 and 1.01 respectively), and the S and StS scores from -1 to 2 (σ equals 0.51 and 0.46).

Comparing HSplit to Identity. Comparing the BLEU score on the input (the identity function) and on the HSplit corpora, we observe that the former yields much higher BLEU scores. Indeed, BLEU-1ref obtains 59.85 for the input and 43.90 for the HSplit corpora (averaged over the 4 HSplit corpora). BLEU-8ref obtains 94.63 for the input and 73.03 for HSplit.[12] The high scores obtained for Identity, also observed by Xu et al. (2016), indicate that BLEU is a not a good predictor for relative simplicity to the input. The drop in the BLEU scores for HSplit is not reflected by the human evaluation scores for grammaticality (4.43 for AvgHSplit vs. 4.80 for Identity) and meaning preservation (4.70 vs. 5.00), where the decrease between Identity and HSplit is much more limited. For examining these tendencies in more detail, we compute the correlations between the au-

---

[12] These scores concern the first 70 sentences of the corpus. A similar phenomenon is observed on the whole corpus (359 sentences). BLEU-1ref obtains 59.23 for the input and 45.68 for HSplit. BLEU-8ref obtains 94.93 for the input and 75.68 for HSplit.

tomatic metrics and the human evaluation scores. They are described in the following paragraph.

Correlation with Human Evaluation. The system-level Spearman correlations between the rankings of the automatic metrics and the human judgments (see §4.1) are presented in Table 2. We find that in all cases BLEU and iBLEU negatively correlate with S and StS, indicating that they fail to capture simplicity and structural simplicity. Where gold standard splits are evaluated as well, BLEU's and iBLEU's failure to capture StS is even more pronounced. Moreover, BLEU's correlation with G and M in this case disappears. In fact, BLEU's correlation with M in this case is considerably lower than that of -LD$_{SC}$ and its correlation with G is comparable, suggesting BLEU is inadequate even as a measure of G and M if splitting is involved.

We examine the possibility that BLEU mostly acts as a measure of conservatism, and compute the Spearman correlation between -LD$_{SC}$ and BLEU. The high correlations we obtain between the metrics indicate that this may be the case. Specifically, BLEU-1ref obtains correlations of 0.86 ($p = 7 \times 10^{-3}$) without splits and of 0.52 ($p = 0.04$) where splitting is involved. BLEU-8ref obtains 0.82 ($p = 0.01$) and 0.55 ($p = 0.03$).

SARI obtains positive correlations with S, of 0.52 (without splits) and 0.26 (all systems/corpora), but correlates with StS in neither setting. This may stem from SARI's focus on lexical, rather than structural TS.

Similar trends are observed in the sentence-level correlation for S, StS and M, whereas G sometimes benefits in the sentence level from including HSplit in the evaluation. For G and M, the correlation with BLEU is lower than its correlation with -LD$_{SC}$ in both cases.

	G	**M**	**S**	**StS**
BLEU	0.36^*	0.43^*	$0.17\ (3 \cdot 10^{-4})$	$0.17\ (3 \cdot 10^{-4})$
iBLEU	0.32^*	0.40^*	$0.15\ (8 \cdot 10^{-4})$	$0.15\ (8 \cdot 10^{-4})$
SARI	-0.05 (0.2)	-0.11 (0.02)	$0.18\ (10^{-4})$	$0.19\ (6 \cdot 10^{-5})$
-LD$_{SC}$	0.65^*	0.66^*	0.21^*	$0.20\ (10^{-5})$

Table 3: Sentence-level Spearman correlation (and p-values) between the automatic metrics and the human ratings for "HSplit as Reference Setting". $^*p < 10^{-5}$.

4.3 Results with HSplit as Reference Setting

We turn to examining whether BLEU may be adapted to address sentence splitting, if provided with references that include splittings.

Description of the Human Evaluation Scores. In the "HSplit as Reference Reference Setting", where 6 systems are considered, the max-min difference at the system level is 0.16 (σ = 0.06) for G, 0.37 for M (σ = 0.15), and 0.41 for S and StS (σ equals 0.20 and 0.19 respectively). At the sentence level, considering 420 sentences (70 for each of the systems), the G and M scores vary from 1 to 5 (σ equals 0.99 and 0.88 respectively), and the S and StS scores from -2 to 2 (σ equals 0.63).

Correlation with Human Evaluation. On the system-level Spearman correlation between BLEU and human judgments, we find that while correlation with G is high (0.57, $p = 0.1$), it is low for M (0.11, $p = 0.4$), and negative for S (-0.70, $p = 0.06$) and StS (-0.60, $p = 0.1$). Sentence-level correlations of BLEU and iBLEU are positive, but they are lower than those obtained by LD$_{SC}$. See Table 3.

To recap, results in this section demonstrate that even when evaluated against references that focus on sentence splitting, BLEU fails to capture the simplicity and structural simplicity of the output.

5 Conclusion

In this paper we argued that BLEU is not suitable for TS evaluation, showing that (1) BLEU negatively correlates with simplicity, and that (2) even as a measure of grammaticality or meaning preservation it is comparable to, or worse than -LD$_{SC}$, which requires no references. Our findings suggest that BLEU should not be used for the evaluation of TS in general and sentence splitting in particular, and motivate the development of alternative methods for structural TS evaluation, such as (Sulem et al., 2018a).

Acknowledgments

We would like to thank the annotators for participating in our generation and evaluation experiments. We also thank the anonymous reviewers for their helpful advices. Abstract

How to generate relevant and informative responses is one of the core topics in response generation area. Following the task formulation of machine translation, previous works mainly consider response generation task as a mapping from a source sentence to a target sentence. To realize this mapping, existing works tend to design intuitive but complex models. However, the relevant information existed in large dialogue corpus is mainly overlooked. In this paper, we propose Sequence to Sequence with Prototype Memory Network (S2SPMN) to exploit the relevant information provided by the large dialogue corpus to enhance response generation. Specifically, we devise two simple approaches in S2SPMN to select the relevant information (named prototypes) from the dialogue corpus. These prototypes are then saved into prototype memory network (PMN). Furthermore, a hierarchical attention mechanism is devised to extract the semantic information from the PMN to assist the response generation process. Empirical studies indicate the advantage of our model over several classical and strong baselines.

1 Introduction

Dialogue systems, or say, chatbots are usually considered as the future of human-computer interaction and extensive works have been done in this area (Wen et al., 2016; Qiu et al., 2017; Wen et al., 2017; Kreyssig et al., 2018).

As one of the main approaches for dialogue system design, response generation has attracted more and more attention from research community. Neural networks based models like Seq2Seq architecture (Vinyals and Le, 2015; Shang et al., 2015) are proven to be effective to generate valid responses for a dialogue system. However, as revealed in many previous works (Li et al., 2016a; Wu et al., 2018), ”safe reply” is still an open problem and lots of efforts are made to generate more informative responses (Li et al., 2016a; Mou et al., 2016; Li et al., 2016b; Qiu et al., 2017; Li et al., 2017; Zhao et al.; He et al., 2017; Zhou et al., 2017; Liu et al., 2018; Chen et al., 2018).

Note that in this paper when we say response generation, we focus on single turn chit-chat for that other tasks like multi-turn (Zhang et al., 2018) or goal-oriented (Kan et al., 2018)generation could be partly considered as the extensions of single-turn generation.

Though existing works mentioned above are helpful in some ways, they all follow the task formulation proposed by (Ritter et al., 2011), which considers response generation (RG) task as a mapping from a source sentence to a target sentence like machine translation (MT). This task formulation ignores the natural difference between MT and RG: MT deals with sentence pairs of the same meanings while RG needs to realize the meaning transformation from a source post to the target response. In this sense, the meaning transformation is more difficult than machine translation. Hence, many researchers have designed more and more complex models. However, given a target post, the relevant information covered by the dialogue corpus is usually overlooked. It is intuitive that the responses for a similar post would provide more contextual information to guide the response generation. To this end, we are interested in exploiting the relevant responses in the training set as soft prototypes to assist the response generation.

Specifically, in this paper, we propose Sequence to Sequence with Prototype Memory Network (named S2SPMN). We introduce two Prototype Memory Networks (PMNs) to store the relevant responses extracted from the dialogue corpus: static PMN and dynamic PMN. Tested on a widely used benchmark dataset, the proposed

Brussels, Belgium, October 31 - November 4, 2018.

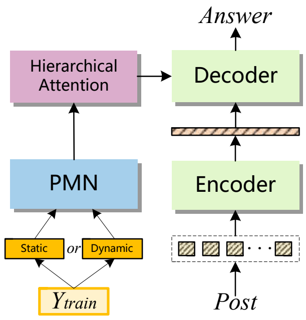

Figure 1: S2SPMN Framework

S2SPMN produces more informative responses than the standard and strong baselines. To the best of our knowledge, it is the first work leveraging prototype information in dialogue corpus in response generation area.

The contributions of this paper could be summarized as follows:

(1) We propose S2SPMN, a simple yet effective response generation model which could leverage relevant information in dialogue corpus to assist response generation.

(2) Empirical studies indicate the superiority of proposed S2SPMN over other methods.

2 Architecture

2.1 Problem Definition

Given a dialogue dataset $\Gamma = \{X_i, Y_i\}_{i=1}^{N}$, where Y_i is the response for a post X_i, we aim to train a model with Γ such that the model can generate an accurate and informative response for a new post X'. Here, we propose to exploit the relevant information provided by Γ. Let $T' = (r_1, r_2, ..., r_m)$ refers to the prototype memory network constructed for post X', where r_i is the i-th relevant response (named prototype) extracted from dialogue dataset Γ. The goal is to derive the model to generate the response Y': $p(Y'|X') = p(Y'|T', X')$.

In following sections, we firstly introduce the generation framework with hierarchical attention mechanism assuming PMN is constructed. Then we will introduce two kinds of PMNs: static PMN and dynamic PMN.

2.2 Sequence-to-Sequence with Prototype Memory Network

S2SPMN is built with a Seq2Seq encoder-decoder framework (Sutskever et al., 2014) with the attention mechanism (Bahdanau et al., 2014). We use LSTM (Hochreiter and Schmidhuber, 1997) to materialize both encoder and decoder. The hidden state at t-th encoding step is generated from previous hidden state h_{t-1} and current input x_t as follows:

$$h_t = lstm(x_t, h_{t-1}) \tag{1}$$

For decoder, at i-th timestep, s_i is the decoder's hidden state and p_i is the probability distribution of candidate words .

$$s_i = lstm(y_{i-1}, s_{i-1}, c_i, o_i) \tag{2}$$

$$p_i = softmax(MLP(s_i, y_{t-1}, o_i, c_i)) \tag{3}$$

where $MLP()$ is a one-layer perception, o_i is the hierarchical attention over entire prototype memory network which will be formalized in following sections. c_i is the summarization for the post regarding to the hidden state s_{i-1}:

$$c_i = \sum_{j=1}^{T} \alpha_{ij} h_j, \quad \alpha_{ij} = \frac{exp(e_{ij})}{\sum_{k=1}^{T} exp(e_{ik})} \tag{4}$$

$$e_{ij} = v_1^T MLP(s_{i-1}, h_j) \tag{5}$$

where v_1 is the attention parameter.

2.3 Prototype Memory Network

Given a post X', a set of responses are selected from training set as prototypes and are then saved into the Prototype Memory Network(PMN). We propose two kinds of Prototype Memory Networks.

Static PMN: For static PMN(SPMN), we randomly select m responses before training starts and the entire PMN remains unchanged during the training process. That is, we use the same prototypes for all the post-response pairs.

Dynamic PMN: In dynamic PMN(DPMN), prototypes are selected by retrieving the most relevant posts. We calculate the cosine similarity with TF-IDF weighting scheme between the given post and all the posts in training set. We consider top-m posts and put the associated responses into DPMN. This means that the prototypes are characteristic for each post-response pair.

In both SPMN and DPMN, m is a predefined hyper-parameter controlling the size of the PMN. Each prototype is represented with the concatenation of word embeddings. We perform zero padding for both SPMN and DPMN with a pseudo word[1], making the length for the representation of each prototype be the same. Here we denote the prototype memory network as PMN = $\{r_1, r_2, ..., r_m\}$, in which r_m is the representation of m-th prototype and m is the size of the PMN. And $r_m = \{w_{m,1}, w_{m,2}, ..., w_{m,l}\}$ where $w_{m,i}$ is the embedding of i-th word, and l is the maximum allowable length for a prototype.

For both SPMN and DPMN, we select responses rather than posts although sometimes they have similar vocabularies and syntactic structure. We believe that using responses as prototypes could help with the meaning transformation from post to response. In DPMN, all the retrieved prototypes could be considered as responses to the target post. It is intuitive that the generated response would have similar representation to these prototypes.

2.4 Hierarchical Attention Mechanism

We use a two-stage hierarchical attention mechanism to extract useful information in PMN and integrate it into the decoding process. The first stage is a sentence level attention over entire PMN to generate the abstractive prototype $\hat{r}_i$ at each timestep:

$$\hat{r}_i = \sum_{j=1}^{M} \beta_{ij} r_j, \quad \beta_{ij} = \frac{exp(f_{ij})}{\sum_{k=1}^{M} exp(f_{ik})} \quad (6)$$

$$f_{ij} = v_2^T MLP(s_{i-1}, r_j) \quad (7)$$

where v_2 is the attention parameter.

The second stage is a word level attention o_i over the generated $\hat{r}_i = \{\hat{w}_1, \hat{w}_2, ..., \hat{w}_l\}$ and is calculated as follows:

$$o_i = \sum_{j=1}^{l} \gamma_{ij} \hat{w}_j, \quad \gamma_{ij} = \frac{exp(g_{ij})}{\sum_{k=1}^{l} exp(g_{ik})} \quad (8)$$

$$g_{ij} = v_3^T MLP(s_{i-1}, \hat{w}_j) \quad (9)$$

where v_3 is the attention parameter.

3 Experiment

3.1 Experiment Setup

We use a subset of STC dataset (Shang et al., 2015) crawled from Weibo, the largest social media in China. The vocabulary size is set to be $8,000$ for computational efficiency and words out of vocabulary are replaced by the symbol ”unk”. We remove sentences longer than 25 words or containing more than 2 unk symbols. After preprocessing step, we have $315,980$ post-response pairs in training set, $3,510$ pairs in validation set and 300 in test set.

In our model, we use one-layer LSTM and the hidden size is set to be 600 in both encoder and decoder. For all the words used in our model, the embedding size is 300. Mini-batch learning is used and batch size is set as 64. We use simple SGD for optimization and the initial learning rate is set to be 0.2.

3.2 Evaluation Metrics

We use two automatic evaluation metrics including Perplexity and Distinct. Human evaluation is also conducted as the only gold standard for response generation is human judgement.

Perplexity: Following (Vinyals and Le, 2015) and (Xing et al., 2017), we use perplexity as one of our automatic evaluation metrics. Perplexity could measure the holistic condition of model learning. A lower perplexity score indicates better generalization performance. Perplexity on both validation set (PPL-V) and test set (PPL-T) are presented in table 2.

Distinct-1, Distinct-2: Distinct-1 and distinct-2 calculate the ratios of distinct unigrams and bigrams in the generated responses respectively (Li et al., 2016a; Xing et al., 2017; Wu et al., 2018). The higher score suggests that the generated response is more diverse and informative. Here, we report the distinct-1 and distinct-2 scores on entire test set.

Human Annatation: We further recruit human annotators to judge the quality of the generated answers for all the qa-pairs in test set. Responses generated by all the methods are pooled and randomly shuffled for each annotator. A score between 0 and 2 is assigned to each generated answer based on the following criteria:

+2: the answer is natural and relevant to the question.

+1: the answer can be used as a reply, but is not informative enough (e.g. “我也是” (me too), “不知道” (I don’t know)).

+0: the answer is irrelevant and unclear in meaning (e.g. too many grammatical errors to understand).

---

SPMN500	21.67%	55.00%	23.33%	0.6534
SPMN1000	19.17%	52.50%	28.33%	0.7330
DPMN100	12.08%	**56.67**%	**31.25**%	0.6280

Table 2: Human Annotation

3.3 Results Comparation

We use a standard baseline and a strong baseline for comparison.

S2SA: The standard Seq2Seq model with an attention mechanism (Vinyals and Le, 2015).

TAS2S: One of the existing state-of-the-art neural models based on Seq2Seq architecture. The topical words relevant to the post are considered via an attention mechanism when decoding (Xing et al., 2017).

As for our models, we use SPMN to denote the generating method with static prototype memory networks and DPMN with dynamic prototype memory networks. The numbers following model names are the size of PMN.

Automatic Evaluation: Table 1 shows the automatic evaluation results. We see that both SPMN and DPMN obtain huge improvements over the two baselines in terms of PPL-V and PPL-T. Also, we observe that SPMN1000 outperforms SPMN500 in all the four automatic metrics. Note that each post has the same prototypes provided by SPMN. This is reasonable that the relevant response is more likely to be covered by storing more prototypes in SPMN. As for the DPMN, we can see that DPMN achieves the best performance with only 100 prototypes in terms of PPL-T, compared with the other 4 methods. This suggests that using a retrieval mechanism to incorporate the relevant responses brings more useful information for better response generation. Note that S2SA outperforms the others in terms of distinct-1 and distinct-2. Further human evaluation indicates that many responses generated by S2SA are irrelevant and meaningless, which could inevitably increase the distinct scores.

Human Annotation: Table 2 shows human annotation results. It is clear that our models (SPMN500, SPMN1000, DPMN100) generate much more informative and valid responses and much less meaningless or "safe" responses than baseline models (S2SA, TAS2S). Specifically, SPMN500, SPMN1000 and DPMN100 all outperform S2SA and TAS2S by producing more informative and valid responses. Also, we can find that DPMN still outperforms SPMN500 and SPMN1000 with only 100 relevant responses, which is consistent with the observation made in automatic evaluation (in terms of PPL-V and PPL-T).

Case Study Table 3 shows several cases generated by different models. Note that the size of training set and vocabulary used in our experiments are relatively small compared to millions of qa-pairs used in other works (Xing et al., 2017; Wu et al., 2018), so it's reasonable that bad cases sometimes occur in results of baselines. However, our models, no matter the static one or the dynamic one, could generate amazing responses which are not only grammatical and informative, but also have some emotional expressions like the use of punctuation and repetition.

4 Related Work

4.1 Natural language generation

How to generate grammatical and interesting sentences in different situations is one of the core topics in natural language processing area. Extensive works are proposed to generate poems (Zhang et al., 2017), abstracts (Wang and Ling, 2016), arguments (Hua and Wang, 2018), stories (Peng et al., 2018) and so on. Although existing approaches are useful in some ways, it's still difficult to generate natural sentences from scratch and integrating retrieved results has recently become a new fashion in this area. Hua and Wang (2018) proposed an encoder-decoder style neural network-based argument generation model enriched with externally retrieved evidence from Wikipedia. Li et al. (2018) devised a Retrieve-Rerank-Rewrite model for abstractive summarization which uses retrieved results as soft template to assist the decoding process.

Table 3: The answers generated by different models for the sampled questions.

4.2 Response generation

Hand-craft rules, retrieval and generation are three main solutions for conversational AI and generation is the most interesting one in current research community. Li et al. (2016a; 2016b; 2017) proposed a series of works in solving the ”safe reply” problem using different approaches like redefining the objective function or leveraging GAN. Xing et al. (2017) considered topic coherence issue by incorporating topical words. Dynamically restricting the target vocabulary is also an interesting idea and Wu et al. (2018) proposed to filter irrelevant words while achieving better computational efficiency . He et al. (2017) introduced copy mechanism to simulate people’s behaviors in real conversations and the proposed model could copy useful words from source sentences. Zhou et al. (2017) indicated that emotion is quite important in real dialogues thus an emotional chatting machine was devised to generate emotional responses. Liu et al. (2018) proposed a neural knowledge diffusion (NKD) model to introduce knowledge into dialogue generation.

5 Conclusion and Future Work

In this paper, we propose S2SPMN, a simple yet effective response generation model by exploiting relevant information contained in large dialogue dataset. Empirical studies indicate that simply selecting responses from training set as prototypes and integrating them into the generation process could dramatically improve the quality of generated responses. Moreover, our model is very flexible and could be adapted to any other Seq2Seq based generation methods. Most importantly, we claim the intrinsic difference between RG and MT and propose a new way to define response generation.

As the first work trying to help with the meaning transformation between source and target, we have obtained the encouraging progress. However, we know that there are still many directions to enrich the proposed framework. In future work, we would like to devise more sophisticated solutions to bridge the semantic gap in RG and explore linguistic patterns in conversations like what has been done in discourse analysis (Lei et al., 2018) .

Abstract

Recently, Reinforcement Learning (RL) approaches have demonstrated advanced performance in image captioning by directly optimizing the metric used for testing. However, this shaped reward introduces learning biases, which reduces the readability of generated text. In addition, the large sample space makes training unstable and slow. To alleviate these issues, we propose a simple coherent solution that constrains the action space using an n-gram language prior. Quantitative and qualitative evaluations on benchmarks show that RL with the simple add-on module performs favorably against its counterpart in terms of both readability and speed of convergence. Human evaluation results show that our model is more human readable and graceful. The implementation will become publicly available upon the acceptance of the paper[1].

1 Introduction

Image captioning (Farhadi et al., 2010; Kulkarni et al., 2011; Yao et al., 2017; Lu et al., 2016; Dai et al., 2017; Li et al., 2017) aims at generating natural language descriptions of images. Advanced by recent developments of deep learning, many captioning models rely on an encoder-decoder based paradigm (Vinyals et al., 2015), where the input image is encoded into hidden representations using a Convolutional Neural Network (CNN) followed by a Recurrent Neural Network (RNN) decoder to generate a word sequence as the caption. Further, the decoder RNN can be equipped with spatial attention mechanisms (Xu et al., 2015) to incorporate precise visual contexts, which often yields performance improvements empirically.

Although the encoder-decoder framework can be effectively trained with maximum likelihood estimation (MLE) (Salakhutdinov, 2010), recent research (Ranzato et al., 2015) have pointed out that the MLE based approaches suffer from the so-called exposure bias problem. To address this problem, (Ranzato et al., 2015) proposed a Reinforcement Learning (RL) based training framework. The method, developed on top of the REINFORCE algorithm (Williams, 1992), directly optimizes the non-differentiable test metric (*e.g.* BLEU (Papineni et al., 2002), CIDEr (Vedantam et al., 2015), METEOR (Banerjee and Lavie, 2005) *etc.*), and achieves promising improvements. However, learning with RL is a notoriously difficult task due to the high-variance of gradient estimation. Actor-critic (Sutton and Barto, 1998) methods are often adopted, which involves training an additional value network to predict the expected reward. On the other hand, (Rennie et al., 2017) designed a self-critical method that utilizes the output of its own test-time inference algorithm as the baseline to normalize the rewards, which leads to further performance gains.

Beside to the high-variance problem, we notice that there are two other drawbacks of RL-based captioning methods that are often overlooked in the literature. First, while these methods can directly optimize the non-differentiable rewards and achieve high test scores, the generated captions contain many repeated trivial patterns, especially at the end of the sequence. Table 1 shows examples of bad-endings generated by a self-critical based RL algorithm (model details refer to Section 4). Specifically, 46.44% generated captions end with phrases as “with a”, “on a”, “of a”, *etc.* (for detailed statistics see Appendix A), on the MSCOCO (Chen et al., 2015) validation set with the standard data splitting by (Karpathy and Li, 2015). The reason is that the shaped reward function biases the learning. In Figure 1, we see these additive patterns at the end of captions, although make no sense to humans, yield to a higher re-

BLEU4=50
CIDEr=101.0

Figure 1: A demonstration of the sequence with bad ending has higher BLEU and CIDEr scores compared to the one without.

ward. Empirically, removing these endings results in a huge performance drop of around 6%. (Paulus et al., 2017) has also reported that in abstractive summarization, using RL only achieves high ROUGE (Lin, 2004) score, yet the human-readability is very poor. The second drawback is that RL-based text generation is sample-inefficient due to the large action space. Specifically, the search space is of size $O(|\mathcal{V}|^T)$, where $\mathcal{V}$ is a set of words, T is the sentence length, and $|\cdot|$ denotes the cardinality of a set. This often makes training unstable and converge slowly.

In this work, to tackle these two issues, we propose a simple yet effective solution by introducing coherent language constraints on local action selections in RL. Specifically, we first obtain word-level n-gram (Kneser and Ney, 1995) model from the training set and then use it as an effective prior. During the action sampling step in RL, we reduce the search space of actions based on the constitution of the previous word contexts as well as our n-gram model. To further promote samples with high rewards, we sample multiple sentences during the training and update the policy based on the best-rewarded one. Such simple treatments prevent the appearance of bad endings and expedite the convergence while maintaining comparable performance to the pure RL counterpart. In addition, the proposed framework is generic, which can be applied to many different kinds of neural structures and applications.

2 Model Architecture

Encoder-Decoder Model: We adopt a similar structure as GNIC (Vinyals et al., 2015), which first encodes an image I to a dense vector h_I by CNN. The vector h_I is then fed as the input to an LSTM-based (Hochreiter and Schmidhuber, 1997) language model decoder. At each step t, the LSTM receives the previous output w_{t-1} as the input; computes the hidden state h_t; and predicts the next word w_t as below:

$$\begin{aligned} & h_t = \text{LSTM}(h_{t-1}, w_{t-1}), \quad l_t = W_l h_t \\ & w_t \sim \text{softmax}(l_t), \end{aligned} \tag{1}$$

where $w_0 = h_I$ and h_0 and c_0 are initialized to zero. The generation ends if a special token *end* is predicted.

Attention Model: Instead of utilizing a static representation of the image, attention mechanism dynamically reweights the spatial features from CNN to focus on the different region of the image at each word generation. We specifically consider the standard architecture used in (Xu et al., 2015), where $\mathcal{A} = \{a_1, a_2, ..., a_L\}$ is the spatial feature set and each $a_i \in R^D$ corresponds to features extracted at different image locations. Then the hidden states of the LSTM is computed as

$$\begin{aligned} & e_{ti} = f_{\text{att}}(a_i, h_{t-1}), \quad \beta_{ti} = \frac{\exp(e_{ti})}{\sum_{k=1}^{L} \exp(e_{tk})}, \\ & z_t = \sum_{k=1}^{L} \beta_{tk} a_k, \quad h_t = \text{LSTM}([h_{t-1}, z_t], w_{t-1}), \end{aligned} \tag{2}$$

where f_{att} is an attention model, which we use a single fully connected layer conditioned on the previous hidden state. Once h_t is obtained, the word generation is same as equation (1).

Sequence Generation with RL: We follow the training procedure of (Rennie et al., 2017). The decoder LSTM can be viewed as a "policy" denoted by p_θ, where θ is the set of parameters of the network. At each time step t, the policy chooses an action by generating a word w_t and obtains a new “state” (*i.e.* hidden states of LSTM, attention weights, *etc.*). Once the end token is generated, a “reward” r is given based on the score (*e.g.* CIDEr or BLEU) of the predicted sentence. The goal is to maximize the expected reward as

$$L(\theta) = \mathbb{E}_{w^s \sim p_\theta}[r(w^s)], \tag{3}$$

where $w^s = \{w_1^s, w_2^s, ..., w_T^s\}$ are sampled words at every time step. The REINFORCE algorithm (Williams, 1992) provides unbiased gradient estimation of θ as

$$\nabla_\theta L(\theta) \approx r(w^s) \nabla_\theta \log p_\theta(w^s), \tag{4}$$

using a single sequence.

Variance Reduction with Self-Critical: We reduce the variance of the gradient estimator by using the self-critical approach as

$$\nabla_\theta L(\theta) \approx (r(w^s) - r(\bar{w})) \nabla_\theta \log p_\theta(w^s), \tag{5}$$

where $\bar{w}_t$ is the baseline reward calculated by the current model under the inference algorithm used at test time defined as

$$\bar{w}_t = \arg\max_{w_t} p_\theta(w_t | h_t). \tag{6}$$

Then, sequences have rewards higher than $\bar{w}$ will be increased in probability, while samples result in lower reward will be suppressed.

3 Prior Language Constraint with N-Gram Model

Method: We collect all n-grams (n=3 or 4 in our experiments) from a corpus of captions. We use the training set from MSCOCO to avoid the usage of the additional resource. Thus, a fair comparison to previous methods is guaranteed. Then, we filter the n-grams with frequencies lower than five. The set of remaining ones is denoted as $\mathcal{F}$. During training, given the previous tokens predicted by the decoder, we constraint the sample space the current prediction by

$$w_t \sim \text{softmax}(p_\theta(w_t^s) \cdot \boldsymbol{\alpha_t}), \tag{7}$$

where $\boldsymbol{\alpha_i}$ is an indicator vector whose length is the vocabulary size $|\mathcal{V}|$ and its elements are non-zero only if the corresponding word and the previous $(n-1)$-gram constitute a valid n-gram in $\mathcal{F}$ as

$$\boldsymbol{\alpha_t}[k] = \begin{cases} 1 & \text{if } \{w_{t-n+1}^s, \cdots, w_{t-1}^s, k\} \in \mathcal{F} \\ 0 & \text{otherwise} \end{cases}. \tag{8}$$

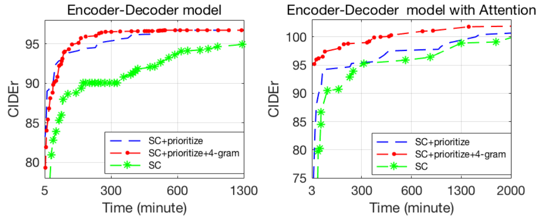

Figure 2: Training time of models with (right) and without (left) spatial attention.

Discussion: The key motivation for applying the above constraint is two-fold: (1) this ensures generated captions always formed by valid n-grams, which provides us a direct way of eliminating the repeated common phrases and bad-endings like the ones in Table 1; and (2) this shrinks the size of action space, which makes the training converges much faster. For MSCOCO, action space is changed from more than 9,000 to 56 on average.

4 Experiments

Dataset: We perform both quantitative and qualitative evaluations on MSCOCO dataset. The dataset contains 123,287 images and each image has at least five human captions. To seek fair comparison to others, we use the publicly available splits, which contains 82,783 training, 5,000 validation and 5,000 testing images.

Implementation Details: Our implementations are based on the publicly project.[2] We use an ImageNet pre-trained 101-layered ResNet[3] (He et al., 2016) to extract visual features. We consider two types (see Section 2) of architectural training with RL: (1) the plain encoder-decoder, and (2) the encoder-decoder with attention. For the former one, we represent each image by a 2,048-dimension vector by extracting the features from the last convolutional layer with average pooling. For the attention model, we apply spatial adaptive max pooling and the output feature map has the size of $14 \times 14 \times 2,048$. At each time step, the attention model produces weights over 196 spatial locations. The size of word embeddings and the hidden dimension of the LSTM are set to 512 for all experiments. More details are in Appendix B.

Compared Methods: We report our results in four different settings, which include the combinations of with/without attention and using tri-/four-

gram. We directly compare with our counterparts that have the same structures but no n-gram modules. Specifically, they are encoder-decoder based self-critical (ED-SC), and the one with attention (Att-SC). In addition, since our experimental setup is almost identical to many existing works, we also include their reported results, which include (Karpathy and Li, 2015; Xu et al., 2015; Ranzato et al., 2015; Ren et al., 2017). At last, we also include the performance of our warm-start models - the models trained by MLE (Vinyals et al., 2015) using cross entropy (ED-XE and Att-XE) - as a reference.

Evaluation Metric and Performance Adjustment: We report performance on FIVE metrics: BLEU4, METEOR, ROUGE-L,CIDEr and Bad Ending Rate. For the self-critical baselines, we report two sets of performances: 1) the captions directly generated by the model; and 2) the sequences of removing bad endings of the generated captions, based on the distribution in Appendix A.

Results: Table 2 summarizes the performances of our models compared with other baselines. We see that without performance adjustments, the self-critical RL with attention performs the best. However, since it contains many bad endings, our method achieves supreme results after these repeated patterns are removed. We also provide some qualitative comparison between our attention model and self-critical in Appendix C.

Efficient Training: We show that constraining the action space leads to a more efficient RL training in Figure 2. CIDEr score is calculated after removing bad endings. We plot three curves using architectures with/without attentions. The Green curve is the self-critical, the blue one is with prioritized sampling, and the red one is our final model with 4-gram constraint. We observe that we can speed up almost twice than its counterpart.

Online Evaluation: We also evaluate our attention model on COCO online server[4] and results are reported in Table 3. Att-SC gets a higher score than ours in the online test, however, with a lot of bad endings where the bad ending ratio is 72.7%.

Human Evaluation: We also implement human evaluation on the results generated by our Att-4-gram compared with Att-SC. We randomly select 200 images from the test set. Each time, one image with two captions generated by two different models are shown to the volunteer and three choices are provided: (1) the first one is better; (2) both are the same level; (3) the second one is better. See more details in Appendix D. In Table 5, our model wins 400 times and performs more closely to human than Att-SC.

Evaluating Captions Diversity: To further evaluate the quality of the caption model, we follow (Shetty et al., 2017) to measure the diversity of the generated captions. We compute the novelty score of our 4-gram model, which is defined as whether a particular caption has been observed in the training set. When two models have the same level predictive performances (*e.g.* CIDEr), a higher novelty score usually indicates more diverse generations. We conduct the experiment five times and report the averaged novelty score of our 4-gram model and the Att-SC, which are 77.83% and 59.28% respectively. As the reference, the METEOR and novelty scores reported in (Shetty et al., 2017) are 23.6, and 79.84%, respectively.

5 Neural Language Models Extension

Inspired by the paper reviews, we extend our model by adopting another language prior to evaluating the effectiveness of constraining action space during REINFORCE training. We train our neural language model based on the MSCOCO caption corpus with an LSTM unit.

LSTM Language Model: Given a word series $\{w_0, w_1, ..., w_T\}$, the target of a neural language model is to maximize the log-likelihood as:

$$\max_{\theta} \log p_\theta(w_0, w_1, ..., w_T). \tag{9}$$

We model $p_\theta(w_0, w_1, ..., w_T)$ by an LSTM unit:

$$\begin{aligned} \log p_\theta(w_0, ..., w_T) &= \sum_{t=1}^{T} \log p_{\theta_{LM}}(w_t|h_{t-1}) \\ h_t &= \text{LSTM}_{LM}(h_{t-1}, w_{t-1}), \end{aligned} \tag{10}$$

where w_0 is set to a *start* token for all sentences. h_0 and c_0 are initialized to zero. After obtaining the optimized θ^*_{LM}, we can use it to constrain the action space similar to the N-gram language model. Specifically, given previous $t-1$ sampled words from current caption model, we compute $p_{\theta^*_{LM}}(w_t|w_0, w_1, ..., w_{t-1})$, which is the probability of the next word over the entire vocabulary. We then apply a simple thresholding rule to form a subset of valid words for the captioning model.

$$\begin{aligned} \boldsymbol{\alpha_t}[k] &= \begin{cases} 1 & \text{if } \{k\} \in \mathcal{F} \\ 0 & \text{otherwise} \end{cases}, \text{where} \\ \mathcal{F} &= \{w_t | p_{\theta^*_{LM}}(w_t|w_0, w_1, ..., w_{t-1}) \geq \eta\}. \end{aligned} \tag{11}$$

η is a hyperparameter.

Additional Experiments The word embedding size and hidden dimension of θ_{LM} are set to 256 for this experiment. We use Adam optimizer for training language model and the learning rate is set to 0.001. The batch size of language model training and REINFORCE training are both set to 20 in the experiments. η is set to 0.00005 for the first word and increases by a factor of two for every timestep. We report our results in two settings, which include the combination of with/without attention for the caption model (termed ED-LSTM-LM and Att-LSTM-LM). We use the same warm-start models as in the N-gram experiments. The performances are summarized in Table 4 and Table 3. We see that the neural language model provides further performance gains compared to the N-gram model without introducing any bad-endings. This is because that the LSTM language model covers a larger context than N-gram, which helps to generate more accurate captions.

6 Conclusion

In this paper, we present a simple but efficient approach to RL-based image caption by considering n-gram language prior to constrain the action space. Our method converges faster and achieves better results than self-critical setting after removing bad endings in the generated captions. In addition, captions generated by our models are more human readable and graceful. We further extend our ideas using neural language model. The results demonstrate that the captioning models are more beneficial from the neural language model than the N-gram model.

Abstract

Image paragraph captioning models aim to produce detailed descriptions of a source image. These models use similar techniques as standard image captioning models, but they have encountered issues in text generation, notably a lack of diversity between sentences, that have limited their effectiveness. In this work, we consider applying sequence-level training for this task. We find that standard self-critical training produces poor results, but when combined with an integrated penalty on trigram repetition produces much more diverse paragraphs. This simple training approach improves on the best result on the Visual Genome paragraph captioning dataset from 16.9 to 30.6 CIDEr, with gains on METEOR and BLEU as well, without requiring any architectural changes.

1 Introduction

Image captioning aims to describe the objects, actions, and details present in an image using natural language. Most image captioning research has focused on single-sentence captions, but the descriptive capacity of this form is limited; a single sentence can only describe in detail a small aspect of an image. Recent work has argued instead for image paragraph captioning with the aim of generating a (usually 5-8 sentence) paragraph describing an image.

Compared with single-sentence captioning, paragraph captioning is a relatively new task. The main paragraph captioning dataset is the Visual Genome corpus, introduced by Krause et al. (2016). When strong single-sentence captioning models are trained on this dataset, they produce repetitive paragraphs that are unable to describe diverse aspects of images. The generated paragraphs repeat a slight variant of the same sentence multiple times, even when beam search is used. Prior work, discussed in the following section, tried to address this repetition with architectural changes, such as hierarchical LSTMs, which separate the generation of sentence topics and words.

In this work, we consider an approach for training paragraph captioning models that focuses on increasing the diversity of the output paragraph. In particular, we note that self-critical sequence training (SCST) (Ranzato et al., 2015; Rennie et al., 2016), a technique which uses policy gradient methods to directly optimize a target metric, has been successfully employed in standard captioning, but not in paragraph captioning. We observe that during SCST training the intermediate results of the system lack diversity, which makes it difficult for the model to improve. We address this issue with a simple repetition penalty which downweights trigram overlap.

Experiments show that this technique greatly improves the baseline model. A simple baseline, non-hierarchical model trained with repetition-penalized SCST outperforms complex hierarchical models trained with both cross-entropy and customized adversarial losses. We demonstrate that this strong performance gain comes from the combination of repetition-penalized search and SCST, rather than from either individually, and discuss how this impacts the output paragraphs.

2 Background and Related Work

Nearly all modern image captioning models employ variants of an encoder-decoder architecture. As introduced by Vinyals et al. (2014), the encoder is a CNN pre-trained for classification and the decoder is a LSTM or GRU. Following work in machine translation, Xu et al. (2015) added an attention mechanism over the encoder features. Recently, Anderson et al. (2017) further improved single-sentence captioning performance by incorporating object detection in the encoder (bottom-up attention) and adding an LSTM layer before attending to spatial features in the decoder (top-

Brussels, Belgium, October 31 - November 4, 2018.

down attention).

Single-sentence and paragraph captioning models are evaluated with a number of metrics, including some designed specifically for captioning (CIDEr) and some adopted from machine translation (BLEU, METEOR). CIDEr and BLEU measure accuracy with n-gram overlaps, with CIDEr weighting n-grams by TF-IDF (term-frequency inverse-document-frequency), and METEOR uses unigram overlap, incorporating synonym and paraphrase matches. We discuss these metrics in greater detail when analyzing our experiments.

Related Models Krause et al. (2016) introduced the first large-scale paragraph captioning dataset, a subset of the Visual Genome dataset, along with a number of models for paragraph captioning. Empirically, they showed that paragraphs contain significantly more pronouns, verbs, coreferences, and greater overall "diversity" than single-sentence captions. Whereas most single-sentence captions in the MSCOCO dataset describe only the most important object or action in an image, paragraph captions usually touch on multiple objects and actions.

The paragraph captioning models proposed by Krause et al. (2016) included template-based (non-neural) approaches and two encoder-decoder models. In both neural models, the encoder is an object detector pre-trained for dense captioning. In the first model, called the flat model, the decoder is a single LSTM which outputs an entire paragraph word-by-word. In the second model, called the hierarchical model, the decoder is composed of two LSTMs, where the output of one sentence-level LSTM is used as input to the other word-level LSTM.

Recently, Liang et al. (2017) extended this model with a third (paragraph-level) LSTM and added adversarial training. In total, their model (RTT-GAN) incorporates three LSTMs, two attention mechanisms, a phrase copy mechanism, and two adversarial discriminators. To the best of our knowledge, this model achieves state-of-the-art performance of 16.9 CIDEr on the Visual Genome dataset (without external data).

For our experiments, we use the top-down single-sentence captioning model in Anderson et al. (2017). This model is similar to the "flat" model in Krause et al. (2016), except that it incorporates attention with a top-down mechanism.

3 Approach

The primary issue in current paragraph captioning models, especially non-hierarchical ones, is lack of diversity of topic in the output paragraph. For example, for the image of a skateboarder in Figure 1, the flat model outputs "The man is wearing a black shirt and black pants" seven times. This example is not anomalous: it is a typical failure case of the model. Empirically, in validation, ground truth paragraphs contain 0.62 repeated trigrams on average, whereas paragraphs produced by the flat cross-entropy model contain 25.9 repeated trigrams on average.

3.1 Self-Critical Sequence Training

Self-critical sequence training (SCST) is a sequence-level optimization procedure proposed by Rennie et al. (2016), which has been widely adopted in single-sentence captioning but has not yet been applied to paragraph captioning. This method provides an alternative approach to word-level cross-entropy which can incorporate a task specific metric.

Sequence-level training employs a policy gradient method to optimize directly for a non-differentiable metric, such as CIDEr or BLEU. This idea was first applied to machine translation by Ranzato et al. (2015) in a procedure called MIXER, which incrementally transitions from cross-entropy to policy gradient training. To normalize the policy gradient reward and reduce variance during training, MIXER subtracts a baseline estimate of the reward as calculated by a linear regressor.

SCST replaces this baseline reward estimate with the reward obtained by the test-time inference algorithm, namely the CIDEr score of greedy search. This weights the gradient by the difference in reward given to a sampled paragraph compared to the current greedy output (see Eq. 3-9 in (Rennie et al., 2016)). Additionally, SCST uses a hard transition from cross-entropy to policy gradient training. The final gradient is:

$$-\mathbb{E}_{w^s \sim p_\theta}[(r(w^s) - r(w^g))\nabla_\theta \log p_\theta(w^s \mid x)]$$

Where w^s is a sampled paragraph, w^g is a greedy decoded paragraph, r is the reward (e.g CIDEr), p_θ is the captioning model.

Figure 1: Example paragraph outputs of our model. The final example is a failure case of both our model and the non-penalized model. Our model does not suffer from the repetition problem of the non-penalized, but it does not produce a great caption because it does not understand that the image is black-and-white.

3.2 Repetition Penalty

In preliminary experiments, we find that directly applying SCST is not effective for paragraph captioning models. Table 1 shows that when training with SCST, the model performs only marginally better than cross-entropy. In further analysis, we see that the greedy baseline in SCST training has very non-diverse output, which leads to poor policy gradients. Unlike in standard image captioning, the cross-entropy model is too weak for SCST to be effective.

To address this problem, we take inspiration from recent work in abstractive text summarization, which encounters the same challenge when producing paragraph-length summaries of documents (Paulus et al., 2017). These models target the repetition problem by simply preventing the model from producing the same trigram more than once during inference. We therefore introduce an inference constraint that penalizes the log-probabilities of words that would result in repeated trigrams. The penalty is proportional to the number of times the trigram has already been generated.

Formally, denote the (pre-softmax) output of the LSTM by o, where the length of o is the size of the target vocabulary and o_w is the log-probability of word w. We modify o_w by $o_w \to o_w - k_w \cdot \alpha$, where k_w is the number of times the trigram completed by word w has previously been generated in the paragraph, and α is a hyperparameter which controls the degree of blocking. When $\alpha = 0$, there is no penalty, so we have standard greedy search. When $\alpha \to \infty$, or in practice when α exceeds about 5, we have full trigram blocking.

We incorporate this penalty into the greedy baseline used to compute policy gradients in SCST. During inference, we employ the same repetition-penalized greedy search.

4 Methods and Results

For our paragraph captioning model we use the top-down model from Anderson et al. (2017). Our encoder is a convolutional network pretrained for object detection (as opposed to dense captioning, as in Krause et al. (2016) and Liang et al. (2017)).

	METEOR	CIDEr	BLEU-1	BLEU-2	BLEU-3	BLEU-4
Krause et al. (Template)	14.31	12.15	37.47	21.02	12.30	7.38
Krause et al. (Flat w/o object detector)	12.82	11.06	34.04	19.95	12.20	7.71
Krause et al. (Flat)	13.54	11.14	37.30	21.70	13.07	8.07
Krause et al. (Hierarchical)	15.95	13.52	41.90	24.11	14.23	8.69
Liang et al. (w/o discriminator)	16.57	15.07	41.86	24.33	14.56	8.99
Liang et al.	17.12	16.87	41.99	24.86	14.89	9.03
Ours (XE training, w/o rep. penalty)	13.66	12.89	32.78	19.00	11.40	6.89
Ours (XE training, w/ rep. penalty)	15.17	22.68	35.68	22.40	14.04	8.70
Ours (SCST training, w/o rep. penalty)	13.63	13.77	29.67	16.45	9.74	5.88
Ours (SCST training, w/ rep. penalty)	**17.86**	**30.63**	**43.54**	**27.44**	**17.33**	**10.58**

Table 1: Results of our model compared with prior published results. Note that Liang et al. (2017) also trains a model on additional data, but here we only compare models trained on Visual Genome. Also note that our models employ greedy search, whereas other models employ beam search.

The encoder extracts between 10 and 100 objects per image and applies spatial max-pooling to yield a single feature vector of dimension 2048 per object. The decoder is a 1-layer LSTM with hidden dimension 512 and top-down attention.

Evaluation is done on the Visual Genome dataset with the splits provided by Krause et al. (2016). We first train for 25 epochs with cross-entropy (XE) loss, using Adam with learning rate $5 \cdot 10^{-4}$. We then train an additional 25 epochs with repetition-penalized SCST targeting a CIDEr-based reward, using Adam with learning rate $5 \cdot 10^{-5}$.

Our PyTorch-based implementation is available at `https://github.com/lukemelas/image-paragraph-captioning`.

Results Table 1 shows the main experimental results. Our baseline cross-entropy captioning model gets similar scores to the original flat model. When the repetition penalty is applied to a model trained with cross-entropy, we see a large improvement on CIDEr and a minor improvement on other metrics.[1] When combining the repetition penalty with SCST, we see a dramatic improvement across all metrics, and particularly on CIDEr. Interestingly, SCST only works when its baseline reward model is strong; for this reason the combination of the repetition penalty and SCST is particularly effective.

Table 2 compares the effect of training with different values of the penalty hyperparameter α, demonstrating that intermediate values of α ($\approx$ 2.0) perform slightly better than large values. An intermediate value of α discourages the model from producing repeat trigrams, but still permits the model to output them when there are no likely alternative phrases.

α	METEOR	CIDEr	BLEU-4
0.0	13.8	13.6	5.9
1.0	17.4	28.9	10.2
2.0	**17.7**	**31.4**	**10.8**
4.0	17.6	30.1	10.4
10.0	17.5	30.6	9.9

Table 2: Varying the repetition penalty α (on the validation set). $\alpha = 10$ is equivalent to trigram blocking.

	XE w/o penalty	XE w/ penalty	SCST w/ penalty
Avg. # of trigram repeats in output	25.9	0.67	3.70
Avg. # unique trigram overlaps btw. output and ground truth	2.23	2.97	3.49

Table 3: Analysis of different model outputs ($\alpha = 2.0$ for models w/ penalty)

Finally, Table 3 shows quantitative changes in trigram repetition and ground truth matches. The cross-entropy model fails to generate enough unique phrases. Blocking these entirely gives some benefit, but the SCST model is able to raise the total number of matched trigrams while reintroducing few repeats.

---

[1] We believe the improvement may be largest on CIDEr because, in the calculation of CIDEr, n-gram counts are clipped to the number of times each n-gram appears in the reference sentence. However, a similar procedure is applied in calculating BLEU, on which we show lesser improvements.

5 Conclusion

This work targets increased diversity in image paragraph captioning. We show that training with SCST combined with a repetition penalty leads to a substantial improvement in the state-of-the-art for this task, without requiring architectural changes or adversarial training. In future work, we hope to further address the language issues of paragraph generation as well as extend this simple approach to other tasks requiring long-form text or paragraph generation.

A Graph-theoretic Summary Evaluation for ROUGE

Elaheh ShafieiBavani, Mohammad Ebrahimi, Raymond Wong, Fang Chen
University of New South Wales, Sydney, Australia
Data61 CSIRO, Sydney, Australia
{elahehs,mohammade,wong,fang}@cse.unsw.edu.au

Abstract

ROUGE is one of the first and most widely used evaluation metrics for text summarization. However, its assessment merely relies on surface similarities between peer and model summaries. Consequently, ROUGE is unable to fairly evaluate summaries including lexical variations and paraphrasing. We propose a graph-based approach adopted into ROUGE to evaluate summaries based on both lexical and semantic similarities. Experiment results over TAC AESOP datasets show that exploiting the lexico-semantic similarity of the words used in summaries would significantly help ROUGE correlate better with human judgments.

1 Introduction

Quantifying the quality of summaries is an important and necessary task in the field of automatic text summarization. Among the metrics proposed for this task (Hovy et al., 2006; Tratz and Hovy, 2008; Giannakopoulos et al., 2008), ROUGE (Lin, 2004) is the first and still most widely used one (Graham et al., 2015). This metric measures the concordance of system-generated (peer) summaries and human-generated reference (model) summaries by determining n-grams, word sequences, and word pair matches. ROUGE assumes that a peer summary is of high quality if it shares many words or phrases with a model summary. However, different terminology may be used to refer to the same concepts and hence relying only on lexical overlaps may underrate content quality scores. For clarity, consider the following two sentences:

(i) *They strolled around the city.*
(ii) *They took a walk to explore the town.*

These sentences are semantically similar, but lexically different. If one of them is included in a model summary, while a peer summary contains another one, ROUGE or other surface based evaluation metrics cannot capture their similarity due to the minimal lexical overlap. We aim to help ROUGE with identifying the semantic similarities of linguistic items, and consequently tackling the main problem of its bias towards lexical similarities.

Considering senses instead of words, we use the Personalized PageRank (PPR) algorithm (Haveliwala, 2002) to leverage repetitive random walks on WordNet 3.0 (Fellbaum, 1998) as a semantic network. We disambiguate each word into its intended sense, and obtain the probability distribution of each sense over all senses in the network. Weights in this distribution denote the relevance of the corresponding senses. At each iteration, we measure the semantic similarity by looking at the path taken by the random walker, and weighting the overlaps between a pair of ranked PPR vectors. Our graph-based approach (ROUGE-G) computes semantic similarity scores between n-grams, along with their match counts, to perform both semantic and lexical comparisons of peer and model summaries. The experiment results indicate that ROUGE-G variants significantly outperform their corresponding variants of ROUGE. Beyond enhancing the evaluation prowess of ROUGE, due to its lexico-semantic analysis of summaries, we believe that ROUGE-G has the potential to expand the applicability of ROUGE to abstractive summarization.

2 Background

In the summarization literature, a couple of ROUGE variants (i.e., ROUGE-1, ROUGE-2, ROUGE-SU4) are reported to have a strong correlation with human assessments, and are frequently used to evaluate summaries (Lin and Och, 2004; Owczarzak and Dang, 2011; Over and Yen, 2004). Although ROUGE is a popular evaluation metric, improving the current evaluation metrics is

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 762–767
Brussels, Belgium, October 31 - November 4, 2018. ©2018 Association for Computational Linguistics

still an open research area. Many of these efforts are analyzed and gathered in the surveys provided by Steinberger and Ježek (2012). Herein, we try to briefly review the most significant ones. Since DUC 2005, the Pyramid metric (Passonneau et al., 2005) was introduced as one of the principal metrics for evaluating summaries in the TAC conference. However, this metric is semi-automated and requires manual identification of summary content units (SCUs). Soon after, Hovy et al. (2006) proposed a metric based on comparison of basic syntactic units (Basic Elements) between peer and model summaries. This metric, BE-HM, was specified as one of the baselines in the TAC AESOP task. Among systems participated in this task from 2009 to 2011, AutoSummENG (DEMOKRITOSGR) (Giannakopoulos et al., 2008) is one of the top systems which compares the graph representations of peer and model summaries. Recently, some evaluation metrics have studied the effectiveness of word semantic similarity to evaluate summaries including terminology variations and paraphrasing (Baroni et al., 2014; ShafieiBavani et al., 2017, 2018). For instance, an automated variant of the Pyramid metric has used distributional semantics to map text content within peer summaries to SCUs (Passonneau et al., 2013). A more recent metric, ROUGE-WE, (Ng and Abrecht, 2015) has also enhanced ROUGE by incorporating the use of a variant of word embeddings, called word2vec (Mikolov et al., 2013).

3 Graph-Theoretic Summary Evaluation

Given a pair of peer and model summaries, we compute PPR vectors at the following levels: (i) *sense level*, to disambiguate each word (having a set of senses); and (ii) *n-gram level*, to measure the semantic similarity. We compare the PPR vectors of each pair of n-grams using the following measures: (i) *Path-based:* considering the path that the random walker takes at each iteration to get to a particular node; (ii) *Rank and Weight:* weighting the overlaps between a pair of ranked PPR vectors.

3.1 Vector Representation

The WordNet graph has edges of various types, with the main types being hypernymy and meronymy to connect nodes containing senses. However, we do not use these types, and consider an edge as an undirected semantic or lexical relation between two synsets. We have utilized the WordNet graph enriched by connecting a sense - irrespective of its part-of-speech (POS) - with all the other senses that appear in its disambiguated gloss (Pilehvar and Navigli, 2015). Dimension of the vector representation is the number of connected nodes in the graph. For better clarity, we consider the adjacency matrix A for our semantic graph, and perform iterative random walks beginning at a set of senses S on WordNet with the probability mass of $p^{(0)}(S)$, which is uniformly distributed across the senses $s_i \in S$, and the mass for all $s_i \notin S$ set to zero. This provides a frequency or multinomial distribution over all senses in WordNet, with a higher probability assigned to senses that are frequently visited. The PPR vector of S is given by:

$$p^{(k)}(S) = dAp^{(k-1)}(S) + (1-d)p^{(0)}(S) \qquad (1)$$

At each iteration, the random walker may follow one of the edges with probability d or jump back to any node $s_i \in S$ with probability $(1-d)/|S|$. Following the standard convention, the value of damping factor d is set to 0.85. The number of iterations k is also set to 20, which is sufficient for the distribution to converge.

3.2 Comparing Vectors

Conventional measures for comparing PPR vectors calculate the probability that a random walker meets a particular node after a specific number of iterations, which is potentially problematic (Rothe and Schütze, 2014). For example, consider the following connected nodes:

The PPR vectors of *suit* and *dress* have some weight on *tailor*, which is desirable. However, the PPR vector of *law* will also have a non-zero weight for *tailor*. Consequently, *law* and *dress* are spuriously similar because of the node *tailor*. To prevent this type of false similarity, the random walker needs to take into account the walking path to reach a particular node (Rothe and Schütze, 2014). We formalize this by defining the semantic similarity of two sets of nodes I and J as:

$$Sim_{sem}(I,J) = \sum_{x=0}^{k} c^x \times RW(p^{(x)}(I), p^{(x)}(J)) \qquad (2)$$

where damping factor c was optimized on the TAC 2010 (Owczarzak and Dang, 2010) AESOP dataset, and set to 0.7 to ensure that early meetings are more valuable than later meetings. At each iteration x, we compare PPR vectors by ranking their dimensions (senses) based on their values, and weighting the overlaps between them (Equation 3). Hence, we weight the similarity such that differences in the highest ranks (most important senses in a vector) are penalized more than differences in lower ranks. This measure has proven to be superior to cosine similarity, Jensen-Shannon divergence, and Rank-Biased Overlap for comparing vectors (Pilehvar et al., 2013).

$$RW(Y,Z) = \begin{cases} \frac{\sum_{h \in H} (r_h(Y) + r_h(Z))^{-1}}{\sum_{i=1}^{|H|} (2i)^{-1}}, & \text{if } |H| > 0 \\ 0, & \text{otherwise} \end{cases} \tag{3}$$

where H is the intersection of all senses with non-zero probability in both vectors Y and Z. $r_h(Y)$ denotes the rank of sense h in vector Y, where rank 1 is the highest rank. The denominator is used as a normalization factor that guarantees a maximum value of one. The minimum value is zero and occurs when there is no overlap, i.e., $|H| = 0$.

3.3 Calculating ROUGE-G

We combine lexical and semantic similarities to compute ROUGE-G-N:

$$\text{ROUGE-G-N} = \frac{\sum_{M \in \{ModelSums\}} \sum_{\substack{n\text{-}gram_m \in M, \\ n\text{-}gram_p \in PeerSum}} Sim_{LS}(n\text{-}gram_m, n\text{-}gram_p)}{\sum_{M \in \{ModelSums\}} \sum_{n\text{-}gram_m \in M} Count(n\text{-}gram_m)} \tag{4}$$

where Sim_{LS} is the score of lexico-semantic similarity between a pair of n-grams in model summary ($n\text{-}gram_m$) and peer summary ($n\text{-}gram_p$):

$$\begin{aligned} Sim_{LS}(n\text{-}gram_m, n\text{-}gram_p) = \\ \beta \times Count_{match}(n\text{-}gram_m, n\text{-}gram_p) \\ + (1-\beta) \times Sim_{sem}(n\text{-}gram_m, n\text{-}gram_p) \end{aligned} \tag{5}$$

Scaling factor β was optimized on the TAC 2010 AESOP dataset, and set to 0.5 to reach the best correlation with the manual metrics. $Count_{match}(n\text{-}gram_m, n\text{-}gram_p)$ is the maximum number of the $n\text{-}gram$ co-occurring in a peer summary and a set of model summaries.

3.4 Disambiguation of n-grams

Prior to measuring semantic similarities, each word in n-grams has to be analyzed and disambiguated into its intended sense. However, conventional word sense disambiguations are not applicable due to the lack of contextual information. Hence, we seek the semantic alignment that maximizes the similarity of the senses of the compared words. As an example (Pilehvar et al., 2013), consider two sentences of *"a1. Officers fired."* and *"a2. Several policemen terminated in corruption probe."*, the semantic alignment procedure has been performed as $"P_{a1}.\ officer^3_n, fire^4_v"$, *and* $"P_{a2}.\ policeman^1_n, terminate^4_v, corruption^6_n, probe^1_n"$. t^i_p denotes the i-th sense of a word t in WordNet with POS p. After alignment, among all possible pairings of all senses of $fire_v$ to all senses of all words in *a2*, the sense $fire^4_v$ (employment termination) obtains the maximal similarity value of $Sim_{sem}(fire^4_v, terminate^4_v) = 1$.

3.5 OOV Handling

Out-of-vocabulary (OOV) words are the words that are not defined in the corresponding lexical resource, hence, they will be ignored while generating PPR vectors. The reason is that they do not have an associated node in the WordNet graph for the random walk to be initialized from. To take them into consideration, we add an extra dimension for each OOV term in the resulting PPR vector. Following Pilehvar and Navigli (2015), we set the associated weights of the new dimensions to 0.5 so as to guarantee their placement among the top dimensions in their vectors.

4 Experiments

4.1 Data and Metrics

The only available datasets for the task of Summarization Evaluation are three AESOP datasets[1] provided by TAC 2009, 2010, and 2011. Among them, we optimize scaling factors using the TAC 2010 AESOP dataset, and evaluate ROUGE-G on the TAC 2011 (Owczarzak and Dang, 2011) AESOP dataset for two main reasons: (i) it is the only dataset on which evaluation metrics can be assessed for their ability to measure summary Readability; (ii) To be in line with the most recent work (ROUGE-WE) that has also been evaluated

---

[1] https://tac.nist.gov/data/

only on this dataset for measuring the Readability scores. This dataset consists of 44 topics, and a set of 10 documents for each topic. There are four human-crafted model summaries for each document set. A summary for each topic is generated by each of the 51 summarizers which participated in the main TAC summarization task. The output of participating automatic metrics is tasked to be compared against human judgments using three manual metrics of *Pyramid*, *Readability*, and *Responsiveness*. Hence, the outputs are scored based on their summary content, linguistic quality, and a combination of both, respectively.

Prior to computing correlation of ROUGE-G variants with manual metrics, ROUGE-G scores have reliably been computed (95% confidence intervals) under ROUGE bootstrap resampling with the default number of sampling point (1000). Correlation of ROUGE-G evaluation scores with the human judgments is then assessed with three metrics of correlation: Pearson r; Spearman ρ; and Kendall τ. We compute scores using the default NIST settings for baselines in the TAC 2011 AESOP task (with stemming and keeping stopwords).

4.2 Results

We evaluate ROUGE-G, against the top metrics (C_S_IIITH3, DemokritosGR1, Catolicasc1) among the 23 metrics participated in TAC AESOP 2011, ROUGE, and the most recent related work (ROUGE-WE) (Table 1). Overall results support our proposal to consider semantics besides surface with ROUGE. Since the large/small differences in competing correlations with human assessment are not an acceptable proof of superiority/inferiority in performance of one metric over another, significance tests should be applied. To better clarify the effectiveness of ROUGE-G, we have used pairwise Williams significance test recommended by Graham et al. (2015) for summarization evaluation. Accordingly, evaluation of a given summarization metric, M_{new}, takes the form of quantifying three correlations: $r(M_{new}, H)$, that exists between the evaluation metric scores for summarization systems and corresponding human assessment scores; $r(M_{base}, H)$, that stands for the correlation of baseline metrics with human judges; and the third correlation, between evaluation metric scores themselves, $r(M_{base}, M_{new})$. It can happen for a pair of competing metrics for which the correlation between metric scores is strong, that a small difference in competing correlations with human assessment is significant, while, for a different pair of metrics with a larger difference in correlation, the difference is not significant (Graham et al., 2015). Using this significance test, the results show that all increases in correlations of ROUGE-G compared to ROUGE and ROUGE-WE variants are statistically significant ($p < 0.05$). We analyze the correlation results reported in Table 1 in the following.

ROUGE-G-2 achieves the best correlation with Pyramid, regarding all correlation metrics. Moreover, every ROUGE-G variant outperforms its corresponding ROUGE and ROUGE-WE variants, regardless of the correlation metric used. However, the only exception is ROUGE-SU4, which correlates slightly better with Pyramid when measuring with Pearson correlation. One possible reason is that Pyramid measures content similarity between peer and model summaries, while the variants of ROUGE-G favor semantics behind the content for measuring similarities. Since some of the semantics attached to the skipped words are lost in the construction of skip-bigrams, ROUGE-SU4 shows a better correlation comparing to ROUGE-G-SU4.

For Responsiveness, ROUGE-G-SU4 achieves the best correlation when measuring with Pearson. We also observe that ROUGE-G-2 obtains the best correlation with Responsiveness while measuring with the Spearman and Kendall rank correlations. The reason is that semantic interpretation of bigrams is easier, and that of contiguous bigrams is much more precise. We also see that every variant of ROUGE-G outperforms its corresponding ROUGE and ROUGE-WE variants.

The readability score is based on grammaticality, structure, and coherence. Although our main goal is not to improve the readability, ROUGE-G-SU4 and ROUGE-G-2 are observed to correlate very well with this metric when measured with the Pearson and Spearman/Kendall rank correlations, respectively. Besides, every variant of ROUGE-G represents the best correlation results comparing to its corresponding variants of ROUGE and ROUGE-WE for all correlation metrics. This is likely due to considering word types and POS tagging while aligning and disambiguating n-grams. POS features are shown by Feng et al. (2010) to be helpful in predicting linguistic quality.

We optimize scaling factor β (Equation 5) on the TAC 2010 AESOP dataset. Figure 1 shows

	Pyramid			Responsiveness			Readability		
Metric	Pearson	Spearman	Kendall	Pearson	Spearman	Kendall	Pearson	Spearman	Kendall
C_S_IIITH3	0.965	0.903	0.758	0.933	0.781	0.596	0.731	0.358	0.242
DemokritosGR1	0.974	0.897	0.747	0.947	0.845	0.675	0.794	0.497	0.359

ROUGE-G-SU4	0.979	0.898	0.741	**0.957**	0.814	0.616	**0.823**	0.445	0.334

Table 1: Correlation results with the manual metrics of Pyramid, Responsiveness, and Readability using the correlation metrics of Pearson r, Spearman ρ, and Kendall τ. The best correlations are specified in bold, and the underlined scores show the top correlations in the TAC AESOP 2011.

the correlation results by the variants of ROUGE-G with Pyramid (Pyr) and Responsiveness (Rsp) metrics measured by Pearson. The best results are observed when $\beta = 0.5$. Performance deteriorates when β approaches 1.0 which indicates the ROUGE scores without any touch of semantic similarity. Decreasing β to zero causes the exclusion of lexical match counts, and consequently inappropriateness of the outcomes. This shows the importance of using both lexical and semantic similarities to fairly judge the quality of summaries.

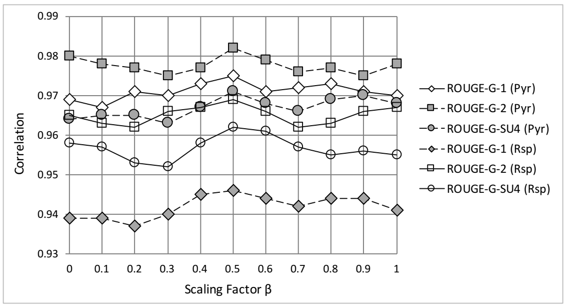

Figure 1: Exploring scaling factor β

It is noteworthy that we have evaluated our approach with the following settings for computing and comparing PPR vectors: (i) *Path-based* with *Rank and Weight* measure (current setting); (ii) *Path-based* with *cosine similarity*; (iii) Excluding *path-based* measure and using *Rank and Weight* measure solely. The results showed that the current setting performs better than the other two.

5 Conclusion

This paper presents ROUGE-G to overcome the limitation of high lexical dependency in ROUGE. Our approach leverages a sense-based representation to calculate PPR vectors for n-grams. The semantic similarity of n-grams are then computed using a formalization of *Path-based* and *Rank and Weight* measures. We finally improve on ROUGE by performing both semantic and lexical analysis of summaries. Experiments over the TAC AESOP datasets demonstrate that ROUGE-G achieves higher correlations with manual judgments in comparison with ROUGE.

In order to demonstrate the effectiveness of ROUGE-G to fairly evaluate abstractive summaries, we need to conduct experiments on a dataset composed of abstractive summaries. However, we evaluated our approach on the TAC 2011 AESOP dataset, which is made of summaries that were generated mostly by extractive systems. Since there is not such dataset at the time of writing this paper, we can continue building on this work by using model summaries, which are abstractive in nature, as a proxy. Thereupon, it is possible to incorporate *jackknifing* procedure in the scoring process in order to see whether our metric can differentiate between peer summaries (naturally extractive) vs. model summaries (naturally abstractive).

Abstract

Recent work on abstractive summarization has made progress with neural encoder-decoder architectures. However, such models are often challenged due to their lack of explicit semantic modeling of the source document and its summary. In this paper, we extend previous work on abstractive summarization using Abstract Meaning Representation (AMR) with a neural language generation stage which we guide using the source document. We demonstrate that this guidance improves summarization results by 7.4 and 10.5 points in ROUGE-2 using gold standard AMR parses and parses obtained from an off-the-shelf parser respectively. We also find that the summarization performance using the latter is 2 ROUGE-2 points higher than that of a well-established neural encoder-decoder approach trained on a larger dataset. Code is available at `https://github.com/sheffieldnlp/AMR2Text-summ`

1 Introduction

Abstractive summarization is the task of automatically producing the summary of a source document through the process of paraphrasing, aggregating and/or compressing information. Recent work in abstractive summarization has made progress with neural encoder-decoder architectures (See et al., 2017; Chopra et al., 2016; Rush et al., 2015). However, these models are often challenged when they are required to combine semantic information in order to generate a longer summary (Wiseman et al., 2017). To address this shortcoming, several works have explored the use of Abstract Meaning Representation (Banarescu et al., 2013, AMR). These were motivated by AMR's capability to capture the predicate-argument structure which can be utilized in information aggregation during summarization.

However, the use of AMR also has its own shortcomings. While AMR is suitable for information aggregation, it ignores aspects of language such as tense, grammatical number, etc., which are important for the natural language generation (NLG) stage that normally occurs in the end of the summarization process. Due to the lack of such information, approaches for NLG from AMR typically infer it from regularities in the training data (Pourdamghani et al., 2016; Konstas et al., 2017; Song et al., 2016; Flanigan et al., 2016), which however is not suitable in the context of summarization. Consequently, the main previous work on AMR-based abstractive summarization (Liu et al., 2015) only generated bag-of-words from the summary AMR graph.

In this paper, we propose an approach to guide the NLG stage in AMR-based abstractive summarization using information from the source document. Our objective is twofold: (1) to retrieve the information missing from AMR but needed for NLG and (2) improve the quality of the summary. We achieve this in a two-stages process: (1) estimating the probability distribution of the side information, and (2) using it to guide a Luong et al. (2015)'s seq2seq model for NLG.

Our approach is evaluated using the Proxy Report section from the AMR dataset (Knight et al., 2017, LDC2017T10) which contains manually annotated document and summary AMR graphs. Using our proposed guided AMR-to-text NLG, we improve summarization results using both gold standard AMR parses and parses obtained using the RIGA (Barzdins and Gosko, 2016) parser by 7.4 and 10.5 ROUGE-2 points respectively. Our model also outperforms a strong baseline seq2seq model (See et al., 2017) for summarization by 2 ROUGE-2 points.

2 Related Work

Abstractive Summarization using AMR: In Liu et al. (2015) work, the source document's sentences were parsed into AMR graphs, which were then combined through merging, collapsing and graph expansion into a single AMR graph representing the source document. Following this, a summary AMR graph was extracted, from which a bag of concept words was obtained without attempting to form fluent text. Vilca and Cabezudo (2017) performed a summary AMR graph extraction augmented with discourse-level information and the PageRank (Page et al., 1998) algorithm. For text generation, Vilca and Cabezudo (2017) used a rule-based syntactic realizer (Gatt and Reiter, 2009) which requires substantial human input to perform adequately.

Seq2seq using Side Information: In Neural Machine Translation (NMT) field, recent work (Zhang et al., 2018) explored modifications to the decoder of seq2seq models to improve translation results. They used a search engine to retrieve sentences and their translation (referred to as translation pieces) that have high similarity with the source sentence. When similar n-grams from a source document were found in the translation pieces, they rewarded the presence of those n-grams during the decoding process through a scoring mechanism calculating the similarity between source sentence and the source side of the translation pieces. Zhang et al. (2018) reported improvements in translation results up to 6 BLEU points over their seq2seq NMT baseline. In this paper we use the same principle and reward n-grams that are found in the source document during the AMR-to-Text generation process. However we use a simpler approach using a probabilistic language model in the scoring mechanism.

3 Guiding NLG for AMR-based summarization

We first briefly describe the AMR-based summarization method of Liu et al. (2015) and then our guided NLG approach.

3.1 AMR-based summarization

In Liu et al. (2015)'s work, each of the sentence of the source document was parsed into an AMR graph, and combined into a source graph, $G = (V, E)$ where $v \in V$ and $e \in E$ are the unique concepts and the relations between pairs of concepts. They then extracted a summary graph, G' using the following sub-graph prediction:

$$G' = \underset{\hat{G}=(\hat{V},\hat{E})}{\arg\max} \sum_{v \in \hat{V}} \boldsymbol{\theta}^{\intercal}\mathbf{f}(v) + \sum_{e \in \hat{E}} \boldsymbol{\psi}^{\intercal}\mathbf{f}(e) \qquad (1)$$

where $\mathbf{f}(v)$ and $\mathbf{f}(e)$ are the feature representations of node v and edge e respectively. The final summary produced was a bag of concept words extracted from G'. This output we will be replacing with our proposed guided NLG.

3.2 Unguided NLG from AMR

Our baseline is a standard (unguided) seq2seq model with attention (Luong et al., 2015) which consists of an encoder and a decoder. The encoder computes the hidden representation of the input, $\{z_1, z_2, \ldots, z_k\}$, which is the linearized summary AMR graph, G' from Liu et al. (2015), following Van Noord and Bos (2017)'s preprocessing steps. Following this, the decoder generates the target words, $\{y_1, y_2, \ldots, y_m\}$, using the conditional probability $P_{s2s}(y_j|y_{<j}, z)$, which is calculated using the equation

$$P_{s2s}(y_j|y_{<j}, z) = \text{softmax}(\mathbf{W}_s\tilde{\mathbf{h}}_t) \qquad (2)$$

, where the attentional hidden state, $\tilde{\mathbf{h}}_t$ is calculated using the equation

$$\tilde{\mathbf{h}}_t = \tanh(\mathbf{W}_c[\mathbf{c}_t; \mathbf{h}_t]) \qquad (3)$$

, where $\mathbf{c}_t$ is the source context vector, and $\mathbf{h}_t$ is the target RNN hidden state. The source context vector is defined as the weighted average over all the source RNN hidden states, $\bar{\mathbf{h}}_s$, given the alignment vector, $\mathbf{a}_t$ where $\mathbf{a}_t$ is defined as

$$\mathbf{a}_t(s) = \frac{\exp(\text{score}(\mathbf{h}_t, \bar{\mathbf{h}}_s))}{\sum_{s'} \exp(\text{score}(\mathbf{h}_t, \bar{\mathbf{h}}_{s'}))} \qquad (4)$$

3.3 Guided NLG from AMR

Our goal is to improve the text generated from the summary AMR graph by the probability distribution of the seq2seq model, P_{s2s} using the source document. Since not all sentences in the source document will be used in generating the summary, we prune the source document to a set of k sentences which have the highest similarity with the summary AMR graph. For graph-to-graph similarity comparison, we use the source document AMR parses and calculate the Longest Common

Subsequence (LCS) between the linearized AMR parses and the summary AMR graph. We keep the top-k sentences sorted by LCS length. To distinguish this pruned document from the source document, we refer to the former as side information.

Our aim is is to combine P_{s2s} with the probability distribution estimated using words in the side information, P_{side}, in order to score each word given its context during decoding. We estimate P_{side} as the linear interpolation of 2-gram to 4-gram probabilities in the form of

$$\begin{aligned} P_{side}(x_j|x_{j-3}^{j-1}) &= \lambda_3 P_{LM}(x_j|x_{j-3}^{j-1}) \\ &+ \lambda_2 P_{LM}(x_j|x_{j-2}^{j-1}) \\ &+ \lambda_1 P_{LM}(x_j|x_{j-1}) \end{aligned} \tag{5}$$

, where x_j is a word occurring in side information document, P_{LM} is an N-gram LM estimated using Maximum Likelihood:

$$P_{LM}(x_j|x_{j-N-1}^{j-1}) = \frac{\text{count}(x_{j-N-1} \ldots x_j)}{\text{count}(x_{j-N-1} \ldots x_{j-1})} \tag{6}$$

and λ_i is defined as

$$\lambda_i = \theta\lambda_{i-1} \text{ where } \theta \in \mathbb{R},\ \lambda_i > 0 \text{ and } \sum_i \lambda_i = 1 \tag{7}$$

where θ is a hyper-parameter that we tune using the dev dataset during the experiments.

Lastly, we combine the probability distribution of the decoder, P_{s2s} with that provided by the side information, P_{side}, as follows:

$$s(y_j|y_{<j}, z) = log\, a + \psi * log(\frac{b}{a} + 1) \tag{8}$$

where ψ is a hyper-parameter determining the influence of the side information on the decoding process, a is $P_{s2s}(y_j|y_{<j}, z)$ and b is $P_{side}(y_j|y_{j-3}^{j-1})$. $s(y_j|y_{<j}, z)$ is used during beam search replacing $P_{s2s}(y_j|y_{<j}, z)$ for all words that occur in the side information. The intuition behind Eq. 8 is that we are rewarding word y_j when it appears in similar context in the side information, i.e. the source document being summarized.

4 Experiments

We conduct experiments in order to answer the following questions about our proposed approach: (1) Is our baseline model comparable with the state-of-the-art AMR-to-text approaches? (2) Does the guidance from the source document improve the result of AMR-to-Text in the context of summarization? (3) Does the improvement in AMR-to-Text hold when we use the generator for abstractive summarization using AMR? We answer each of these in the following paragraphs.

Model	BLEU
Our model (unguided NLG)	21.1
NeuralAMR (Konstas et al., 2017)	22.0
TSP (Song et al., 2016)	22.4
TreeToStr (Flanigan et al., 2016)	23.0

Table 1: Results for AMR-to-text

AMR-to-Text baseline comparison We compare our baseline model (described in §3.2) against previous works in AMR-to-text using the data from the recent SemEval-2016 Task 8 (May, 2016, LDC2015E86). Table 1 reports BLEU scores comparing our model against previous works. Here, we see that our model achieves a BLEU score comparable with the state-of-the-art, and thus we argue that it is sufficient to be used in our subsequent experiments with guidance.

Guided NLG for AMR-to-Text In this experiment we apply our guided NLG mechanism described in §3.3 to our baseline seq2seq model. To isolate the effects of guidance we skip the actual summarization process and proceed to directly generating the summary text from the gold standard summary AMR graphs from the Proxy Report section. To determine the hyper-parameters, we perform a grid search using the dev dataset, where we found the best combination of ψ, θ and k are 0.95, 2.5 and 15 respectively. We have two different settings for this experiment: the oracle and non-oracle settings. In the oracle setting, we directly use the gold standard summary text as the guidance for our model. The intuition is that in this setting, our model knows precisely which words should appear in the summary text, thus providing an upper bound for the performance of our guided NLG approach. In the non-oracle setting, we use the mechanism described in §3.3. We also compare them against the baseline (unguided) model from §3.2. Table 2 reports performance for all models. The difference between the guided and the unguided model is 16.2 points in BLEU and 9.9 points in ROUGE-2, while there is room for improvement as evidenced by the difference between the oracle and non-oracle result.

Guided NLG for full summarization In this experiment we combine our guided NLG model

Model	BLEU	F_1 ROUGE		
		R-1	R-2	R-L
Guided NLG (Oracle)	61.3	79.4	63.7	76.4
Guided NLG	45.8	70.7	49.5	64.9
Unguided NLG	29.6	68.6	39.6	61.3

Table 2: BLEU and ROUGE results for guided and unguided models using test dataset.

with Liu et al. (2015)'s work in order to generate fluent texts from their summary AMR graphs using the hyper-parameters tuned in the previous paragraph. Liu et al. (2015) used parses from both the manual annotation of the Proxy dataset as well as those obtained using the JAMR parser (Flanigan et al., 2014). Instead of JAMR we use the RIGA parser (Barzdins and Gosko, 2016) which had the highest accuracy in the SemEval 2016 Task 8 (May, 2016). We compare our result against Liu et al. (2015)'s bag of words[1], the unguided AMR-to-text model from §3.2, and a seq2seq summarization model (OpenNMT BRNN)[2,3] which summarizes directly from the source document to summary sentence without using AMR as an interlingua and is trained on CNN/DM corpus (Hermann et al., 2015) using the same settings as See et al. (2017).

AMR parses	NLG Model	F_1 ROUGE		
		R-1	R-2	R-L
Gold	Guided	40.4	20.3	31.4
	Unguided	38.9	12.9	27.0
	Liu et al. (2015)	39.6	6.2	22.1
RIGA	Guided	42.3	21.2	33.6
	Unguided	37.8	10.7	26.9
	Liu et al. (2015)	40.9	5.5	21.4
Directly from Text	OpenNMT BRNN 2 layer, emb 256, hidden 1024	36.1	19.2	31.1

Table 3: The F_1 ROUGE scores for guided, unguided, Liu et al. (2015) (BoW) results in Gold and RIGA parses, and seq2seq summarization. All models are run using test dataset.

In Table 3, we can see that our approach results in improvements over both the unguided AMR-to-text and the standard seq2seq summarization. One interesting note is that using the RIGA parses result in higher ROUGE scores than the gold parses for the guided model in our experiment. This phenomenon was also observed in Liu et al. (2015)'s experiment where the summary graphs extracted from automatic parses had higher accuracy than those extracted from manual parses. We hypothesize this can be attributed to how the AMR dataset is annotated as there might be discrepancies in different annotator's choices of AMR concepts and relations for sentences with similar wording. In contrast, the AMR parsers introduce errors, but they are consistent in their choices of AMR concepts and relations. The discrepancies in the manual annotation could have impacted the performance of the AMR summarizer that we use more negatively than the noise introduced due to the AMR parsing errors.

NLG Model	Generated Summary

5 Conclusion and Future Works

In this paper we proposed a guided NLG approach that substantially improves the output of AMR-based summarization. Our approach uses a simple guiding process based on a probabilistic language model. In future work we aim to improve summarization performance by jointly training the guiding process with the AMR-based summarization process.

Abstract

Practical summarization systems are expected to produce summaries of varying lengths, per user needs. While a couple of early summarization benchmarks tested systems across multiple summary lengths, this practice was mostly abandoned due to the assumed cost of producing reference summaries of multiple lengths. In this paper, we raise the research question of whether *reference summaries of a single length* can be used to reliably evaluate *system summaries of multiple lengths*. For that, we have analyzed a couple of datasets as a case study, using several variants of the ROUGE metric that are standard in summarization evaluation. Our findings indicate that the evaluation protocol in question is *indeed competitive*. This result paves the way to practically evaluating varying-length summaries with simple, possibly existing, summarization benchmarks.

1 Introduction

Automated summarization systems typically produce a text that mimics a manual summary. In these systems, an important aspect is the output summary length, which may vary according to user needs. Consequently, output length has been a common tunable parameter in pre-neural summarization systems and has been incorporated recently in few neural models as well (Kikuchi et al., 2016; Fan et al., 2017; Ficler and Goldberg, 2017).

It was originally assumed that summarization systems should be assessed across multiple summary lengths. For that, the earliest Document Understand Conference (DUC) (NIST, 2011) benchmarks, in 2001 and 2002, defined several target summary lengths and evaluated each summary against (manually written) reference summaries of the same length.

However, due to the high cost incurred, subsequent DUC and TAC (NIST, 2018) benchmarks (2003-2014), as well as the more recently popular datasets CNN/Daily Mail (Nallapati et al., 2016) and Gigaword (Graff et al., 2003), included references and evaluation for just one summary length per input text. Accordingly, systems were asked to produce a *single* summary, of corresponding length. This decision was partly supported by an observation that system rankings tended to correlate across different summary lengths (Over et al., 2007), even though, as we show in Section 2, this correlation is limited.

In this paper, we propose that the summarization community should consider resuming evaluating summarization systems over *multiple* length outputs, as it would allow better assessment of length-related performance within and across systems (illustrated in Section 3). To avoid the need in multiple-length reference summaries we raise the following research question: *can reference summaries of a single length be used to evaluate system summaries of multiple lengths, as reliably as when using references of multiple lengths, with respect to different standard evaluation metrics?* Recently, Kikuchi et al. (2016) evaluated system summaries of three different lengths against reference summaries of a single length. Yet, their evaluation methodology was not assessed through correlation to human judgment, as has been commonly done for other automatic evaluation protocols. Here, we provide a closer look into this methodology, given its potential value.

As a first accessible case study, we test our research question over the DUC 2001 and 2002 data (Section 2). To the best of our knowledge, these are the only two datasets that include multiple length reference and submitted system summaries, as well as manual assessment of the latter. Our analysis reveals that, for this data and with respect to various highly utilized automatic ROUGE metrics, the answer to our question is affirmative, in

terms of correlation with human judgment.

Our promising results suggest repeating the assessment methodology presented here in future work, to test our question over more recent and broader summarization datasets and human evaluation schemes. This, in turn, would allow the community to feasibly resume proper evaluation and deliberate development of systems that target effective summaries across a range of lengths.

2 Case Study Analysis

Here, we first examine the relevance of our proposal to reinstitute summarization evaluation over multiple summary lengths. Then, we investigate our research question of whether using reference summaries of a single length suffices for evaluating system summaries of multiple lengths. We turn to the DUC 2001 and 2002 multi-document summarization datasets, which, to the best of our knowledge, are the only available datasets that provide the necessary requirements for this analysis (see Table 1).

The importance of evaluating and comparing systems at several lengths is demonstrated with the observation that system rankings can change quite significantly at different summary lengths. In 2001, the Spearman correlation between the available human rankings of systems at the 50-word and 400-word lengths is 0.61. For example, the system ranked first at length 50 ranks sixth at lengths 200 and 400. Even for the human system ranking at the 100-word length, which deviates the least from human rankings at the other lengths, the correlation with system ranking at the 400 length is only 0.73. Generally, the larger the difference between a pair of summary lengths, the greater the fluctuation in system rankings. Similar trends were observed for DUC 2002, and when comparing system rankings by automatic ROUGE scoring (both rankings are elaborated below). Obviously, such performance differences are overlooked when evaluating systems over summaries of a single length.

Next, we turn to investigate our research question. In this paper, we examine it with respect to automatic summary evaluation, which has become most common for system development and evaluation, thanks to its speed and low cost. Specifically, we use several variants of the ROUGE metric (Lin, 2004), which is almost exclusively utilized as an automatic evaluation metric class for summarization. ROUGE variants are based on word sequence overlap between a system summary and a reference summary, where each variant measures a different aspect of text comparison. Despite its pitfalls, ROUGE has shown reasonable correlation of its system scores to those obtained by manual evaluation methods (Lin, 2004; Over and James, 2004; Over et al., 2007; Nenkova et al., 2007; Louis and Nenkova, 2013; Peyrard et al., 2017), such as SEE (Lin, 2001), responsiveness (NIST, 2006) and Pyramid (Nenkova et al., 2007).

We follow the same methodology of assessing the reliability of automatic evaluation scores by measuring their correlation to human evaluation scores. In our case, DUC 2001 and 2002 applied the SEE manual evaluation method. NIST assessors compared systems' summaries to reference summaries, which were all decomposed into a list of elementary discourse units (EDUs). Each reference EDU was marked throughout the system EDUs and was scored for how well it was expressed. The final manually evaluated scores, called the *human mean content coverage scores*, are provided in the DUC datasets. We can then correlate the human-based system ranking, attained from these provided scores, to the system ranking attained from the automatic scores that we calculate using our proposed methodology.

As a baseline, we consider the ROUGE Recall scores obtained by the standard reference summary configuration (Standard, first row in Table 2), that is, when system summaries of each length (table columns) are evaluated against reference summaries of the same length. This is the same configuration used by Lin (2004) when introducing and assessing ROUGE. Then, looking into our research question, we consider reference summary configurations in which system summaries of all lengths are evaluated against reference summaries of a single chosen length (OnlyNNN, subsequent rows of Table 2). In each configuration (each row), we repeat the evaluation twice: once using the complete set of available reference sum-

Table 3: Averaged correlations (across system summary lengths, equivalent to the rightmost columns in Table 2) for different ROUGE variants (column pairs) and reference summary configurations (rows), when using 1 reference or multiple. The first row presents absolute correlations, with relative differences in subsequent rows.

maries of the utilized reference length, and once with just one randomly chosen reference summary from that set (the 3refs and 1ref sub-columns).

For each reference summary configuration, we compute ROUGE Recall system scores[1] for the three common ROUGE variants R-1, R-2 and R-L, which compare unigrams, bigrams and the longest common subsequence, respectively. System scores, per summary length, are obtained by averaging across all summarized texts. We then calculate their Pearson correlation[2] with the available human mean content coverage scores for the systems. The first row of Table 2 shows these correlations, considering the R-1 scores for the DUC 2001 systems, per summary length. The subsequent rows show the corresponding figures for the single-reference-length configurations. For readability, we present in these rows the relative *differences* to the Standard baseline row. Hence, positive values indicate a configuration that is at least as good as the standard configuration.

Table 3 presents correlations averaged over all summary lengths, for the three ROUGE variants over both datasets. We see in the tables that evaluating system summaries of all lengths against references of a single length often performs on par with the standard configuration. In particular, the single fixed set of 50-word reference summaries performs overall as well as the standard approach, and, although not substantially, is the most effective configuration within the data analyzed. In other words, in this dataset, the 50-word reference summaries provide a "test sample" for evaluating the longer system summaries, which is as effective as the same length references used by the standard method.

We note that even when a single reference summary is available, reasonable correlations with human scores are obtained for the 50 word reference. This suggests that it may be possible to compare system summaries of multiple lengths even against a single reference summary, of a relatively short length. This observation seems to deserve further assessment over recent large scale datasets, such as CNN/DailyMail, which provide a single relatively short reference for each summarized text.

In addition to correlation to human assessment, we computed the correlations between system rankings calculated by Standard and those calcu-

---

[1] Omitting stop words.

[2] Following Lin (2004). Spearman ranking correlations provide similar results.

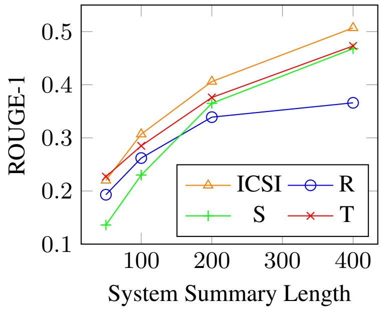

Figure 1: R-1 scores of a few systems, evaluated against the 50-word reference set of DUC 01. Systems R, S and T are from DUC 01; ICSISumm is a later competitive system (Gillick et al., 2008).

lated by Only50, at each system summary length. We find very high correlations (above 0.95 for all system summary lengths, in both datasets) when using multiple references and slightly lower (0.85 to 0.9) with one reference summary. These figures show that the Only50 configuration ranks systems very similarly to Standard.

To further verify our results, we computed correlations in two additional settings. First, we conducted the same analysis, excluding 2-3 of the worst systems, which might artificially boost the correlation (Rankel et al., 2013). Second, we computed score differences between all pairs of systems, for both human and ROUGE scores, and computed the correlation between these two sets of differences (Rankel et al., 2011). In both cases we observed rather consistent results, assessing that a single set of short reference summaries evaluates system summaries of different lengths just as well as the standard configuration.

3 Cross-length Summary Evaluation

This section illustrates how system performances can be measured and compared when evaluating them on outputs of varying lengths against a single reference point. Figure 1 presents the ROUGE scores of the Only50 configuration for three DUC-01 submitted systems, and for ICSISumm (Gillick et al., 2008), a later competitive system.

As expected when measuring ROUGE Recall against a fixed reference length, longer system summaries typically cover more of the reference summaries content than shorter ones, yielding higher scores. Yet, it can be noted, for example, that the value of the 400-word summary of system R in the figure is lower than that of the 200-word summaries of the other systems. Such a comparison is impossible in the standard setup, as each system length is evaluated against different reference summaries. We note that similar comparisons are embedded in the evaluations of Steinberger and Jezek (2004) and Kikuchi et al. (2016), who also evaluated multiple summary lengths.

Further, one can define the marginal value of longer summaries of a given system as the ROUGE score increase per number of additional words, namely the graph slope. This denotation allows measuring the effectiveness of producing longer summaries. For example, deploying system R, we might decide to output only summaries no longer than 200 words, since the marginal value of longer summaries becomes too small. The other systems, on the other hand, seem marginally effective also in 400 word summaries.

4 Discussion

We proposed the potential value of evaluating summarization systems at different summary lengths. Such evaluations would allow proper evaluation of systems' "length knob", tracking how their ranking changes across summary lengths as well as tracking the cross-length behavior of individual systems. Given that reference summaries of a single length are usually available in practice, we analyzed the potential use of *reference summaries of a single length* for evaluating *system summaries of multiple lengths*. We found, on the only two datasets readily available for such analysis, that this configuration is as reliable as the standard configuration, which evaluates each system summary against a reference of a matching length.

To broadly substantiate our findings, we propose future work that would follow our assessment methodology over test samples from current datasets (e.g. CNN/DailyMail), judging performance of current systems and utilizing current manual evaluation protocols. This would require preparing, for limited samples, additional manually crafted summaries of several lengths and manually evaluating system summaries of corresponding lengths. Using such data, it will be possible to repeat our analysis and test the broader validity of the single-reference-length configuration. If broadly assessed, it will be possible to start evaluating system summaries of multiple lengths over most currently available datasets, leveraging the available single-length reference summaries. Future benchmarks could require systems to produce different length outputs, while feasibly evaluating them using the existing, single length, reference summaries. This, in turn, is likely to drive research to better address the need for producing high quality summaries flexibly across a range of summary lengths, a dimension that has been disregarded for long.

Acknowledgments

We would like to thank the anonymous reviewers for their constructive comments. We thank Yinfei Yang for his assistance in producing the ICSISumm summaries that we utilized in our analysis. Abstract

Extractive summarization models require sentence-level labels, which are usually created heuristically (e.g., with rule-based methods) given that most summarization datasets only have document-summary pairs. Since these labels might be suboptimal, we propose a latent variable extractive model where sentences are viewed as latent variables and sentences with activated variables are used to infer gold summaries. During training the loss comes *directly* from gold summaries. Experiments on the CNN/Dailymail dataset show that our model improves over a strong extractive baseline trained on heuristically approximated labels and also performs competitively to several recent models.

1 Introduction

Document summarization aims to automatically rewrite a document into a shorter version while retaining its most important content. Of the many summarization paradigms that have been identified over the years (see Mani 2001 and Nenkova and McKeown 2011 for comprehensive overviews), two have consistently attracted attention: *extractive* approaches generate summaries by copying parts of the source document (usually whole sentences), while *abstractive* methods may generate new words or phrases which are not in the document.

A great deal of previous work has focused on extractive summarization which is usually modeled as a sentence ranking or binary classification problem (i.e., sentences which are top ranked or predicted as `True` are selected as summaries). Early attempts mostly leverage human-engineered features (Filatova and Hatzivassiloglou, 2004) coupled with binary classifiers (Kupiec et al., 1995), hidden Markov models (Conroy and O'leary, 2001), graph based methods (Mihalcea, 2005), and integer linear programming (Woodsend and Lapata, 2010).

The successful application of neural network models to a variety of NLP tasks and the availability of large scale summarization datasets (Hermann et al., 2015; Nallapati et al., 2016) has provided strong impetus to develop data-driven approaches which take advantage of continuous-space representations. Cheng and Lapata (2016) propose a hierarchical long short-term memory network (LSTM; Hochreiter and Schmidhuber 1997) to learn context dependent sentence representations for a document and then use yet another LSTM decoder to predict a binary label for each sentence. Nallapati et al. (2017) adopt a similar approach, they differ in their neural architecture for sentence encoding and the features used during label prediction, while Narayan et al. (2018) equip the same architecture with a training algorithm based on reinforcement learning. Abstractive models (Nallapati et al., 2016; See et al., 2017; Paulus et al., 2017) are based on sequence-to-sequence learning (Sutskever et al., 2014; Bahdanau et al., 2015), however, most of them underperform or are on par with the baseline of simply selecting the leading sentences in the document as summaries (but see Paulus et al. 2017 and Celikyilmaz et al. 2018 for exceptions).

Although seemingly more successful than their abstractive counterparts, extractive models require sentence-level labels, which are not included in most summarization datasets (only document and gold summary pairs are available). Sentence labels are usually obtained by rule-based methods (Cheng and Lapata, 2016) or by maximizing the ROUGE score (Lin, 2004) between a subset of sentences and the human written summaries (Nallapati et al., 2017). These methods do not fully exploit the human summaries, they only create `True`/`False` labels which might be suboptimal.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 779–784
Brussels, Belgium, October 31 - November 4, 2018.

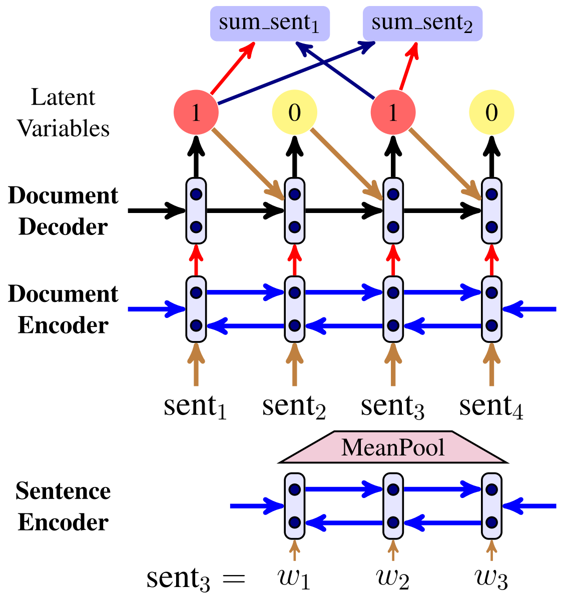

Figure 1: Latent variable extractive summarization model. sent$_i$ is a sentence in a document and sum_sent$_i$ is a sentence in a gold summary of the document.

In this paper we propose a latent variable extractive model and view labels of sentences in a document as binary latent variables (i.e., zeros and ones). Instead of maximizing the likelihood of "gold" standard labels, the latent model directly maximizes the likelihood of human summaries given selected sentences. Experiments on the CNN/Dailymail dataset (Hermann et al., 2015) show that our latent extractive model improves upon a strong extractive baseline trained on rule-based labels and also performs competitively to several recent models.

2 Model

We first introduce the neural extractive summarization model upon which our latent model is based on. We then describe a sentence compression model which is used in our latent model and finally move on to present the latent model itself.

2.1 Neural Extractive Summarization

In extractive summarization, a subset of sentences in a document is selected as its summary. We model this problem as an instance of sequence labeling. Specifically, a document is viewed as a sequence of sentences and the model is expected to predict a `True` or `False` label for each sentence, where `True` indicates that the sentence should be included in the summary. It is assumed that during training sentences and their labels in each document are given (methods for obtaining these labels are discussed in Section 3).

As shown in the lower part of Figure 1, our extractive model has three parts: a *sentence encoder* to convert each sentence into a vector, a *document encoder* to learn sentence representations given surrounding sentences as context, and a *document decoder* to predict sentence labels based on representations learned by the document encoder. Let $\mathcal{D} = (S_1, S_2, \dots, S_{|\mathcal{D}|})$ denote a document and $S_i = (w_1^i, w_2^i, \dots, w_{|S_i|}^i)$ a sentence in $\mathcal{D}$ (where w_j^i is a word in S_i). Let $Y = (y_1, \dots, y_{|\mathcal{D}|})$ denote sentence labels. The sentence encoder first transforms S_i into a list of hidden states $(\mathbf{h}_1^i, \mathbf{h}_2^i, \dots, \mathbf{h}_{|S_i|}^i)$ using a Bidirectional Long Short-Term Memory Network (Bi-LSTM; Hochreiter and Schmidhuber 1997; Schuster and Paliwal 1997). Then, the sentence encoder yields $\mathbf{v}_i$, the representation of S_i, by averaging these hidden states (also see Figure 1):

$$\mathbf{v}_i = \frac{1}{|S_i|} \sum_j \mathbf{h}_j^i \tag{1}$$

In analogy to the sentence encoder, the document encoder is another Bi-LSTM but applies on the sentence level. After running the Bi-LSTM on a sequence of sentence representations $(\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_{|\mathcal{D}|})$, we obtain context dependent sentence representations $(\mathbf{h}_1^E, \mathbf{h}_2^E, \dots, \mathbf{h}_{|\mathcal{D}|}^E)$.

The document decoder is also an LSTM which predicts sentence labels. At each time step, it takes the context dependent sentence representation of S_i produced by the document encoder as well as the prediction in the previous time step:

$$\mathbf{h}_i^D = \text{LSTM}(\mathbf{h}_{i-1}^D, \begin{bmatrix} \mathbf{W}_e \; e(y_{i-1}) \\ \mathbf{h}_i^E \end{bmatrix}) \tag{2}$$

where $\mathbf{W}_e \in \mathbb{R}^{d \times 2}$ is the label embedding matrix (d is the hidden dimension for the document decoder LSTM) and y_{i-1} is the prediction at time step $i-1$; the predicted label distribution for y_i is:

$$p(y_i | y_{1:i-1}, \mathbf{h}_{i-1}^D) = \text{softmax}(\mathbf{W}_o \, \mathbf{h}_i^D) \tag{3}$$

where $\mathbf{W}_o \in \mathbb{R}^{2 \times d}$.

The model described above is usually trained by minimizing the negative log-likelihood of sentence labels in training documents; it is almost identical to Cheng and Lapata (2016) except that we use a word-level long short-term memory network coupled with mean pooling to learn sentence representations, while they use convolutional neural network coupled with max pooling (Kim et al., 2016).

2.2 Sentence Compression

We train a sentence compression model to map a sentence selected by the extractive model to a sentence in the summary. The model can be used to evaluate the quality of a selected sentence with respect to the summary (i.e., the degree to which it is similar) or rewrite an extracted sentence according to the style of the summary.

For our compression model we adopt a standard attention-based sequence-to-sequence architecture (Bahdanau et al., 2015; Rush et al., 2015). The training set for this model is generated from the same summarization dataset used to train the exractive model. Let $\mathcal{D} = (S_1, S_2, \dots, S_{|\mathcal{D}|})$ denote a document and $\mathcal{H} = (H_1, H_2, \dots, H_{|\mathcal{H}|})$ its summary. We view each sentence H_i in the summary as a target sentence and assume that its corresponding source is a sentence in $\mathcal{D}$ most similar to it. We measure the similarity between source sentences and candidate targets using ROUGE, i.e., $S_j = \text{argmax}_{S_j} \text{ROUGE}(S_j, H_i)$ and $\langle S_j, H_i \rangle$ is a training instance for the compression model. The probability of a sentence $\hat{H}_i$ being the compression of $\hat{S}_j$ (i.e., $p_{s2s}(\hat{H}_i|\hat{S}_j)$) can be estimated with a trained compression model.

2.3 Latent Extractive Summarization

Training the extractive model described in Section 2.1 requires sentence-level labels which are obtained heuristically (Cheng and Lapata, 2016; Nallapati et al., 2017). Our latent variable model views sentences in a document as binary variables (i.e., zeros and ones) and uses sentences with activated latent variables (i.e., ones) to infer gold summaries. The latent variables are predicted with an extractive model and the loss during training comes from gold summaries *directly*.

Let $\mathcal{D} = (S_1, S_2, \dots, S_{|\mathcal{D}|})$ denote a document and $\mathcal{H} = (H_1, H_2, \dots, H_{|\mathcal{H}|})$ its human summary (H_k is a sentence in $\mathcal{H}$). We assume that there is a latent variable $z_i \in \{0, 1\}$ for each sentence S_i indicating whether S_i should be selected, and $z_i = 1$ entails it should. We use the extractive model from Section 2.1 to produce probability distributions for latent variables (see Equation (3)) and obtain them by sampling $z_i \sim p(z_i|z_{1:i-1}, \mathbf{h}^D_{i-1})$ (see Figure 1). $\mathcal{C} = \{S_i|z_i = 1\}$, the set of sentences whose latent variables equal to one, are our current extractive summaries. Without loss of generality, we denote $\mathcal{C} = (C_1, \dots, C_{|\mathcal{C}|})$. Then, we estimate how likely it is to infer the human summary $\mathcal{H}$ from $\mathcal{C}$. We estimate the likelihood of summary sentence H_l given document sentence C_k with the compression model introduced in Section 2.2 and calculate the normalized[1] probability s_{kl}:

$$s_{kl} = \exp\left(\frac{1}{|H_l|} \log p_{s2s}(H_l|C_k)\right) \quad (4)$$

The score R_p measures the extent to which $\mathcal{H}$ can be inferred from $\mathcal{C}$:

$$R_p(\mathcal{C}, \mathcal{H}) = \frac{1}{|\mathcal{C}|} \sum_{k=1}^{|\mathcal{C}|} \max_{l=1}^{|\mathcal{H}|} s_{kl} \quad (5)$$

For simplicity, we assume one document sentence can only find one summary sentence to explain it. Therefore, for all H_l, we only retain the most evident s_{kl}. $R_p(\mathcal{C}, \mathcal{H})$ can be viewed as the "precision" of document sentences with regard to summary sentences. Analogously, we also define R_r, which indicates the extent to which $\mathcal{H}$ can be covered by $\mathcal{C}$:

$$R_r(\mathcal{C}, \mathcal{H}) = \frac{1}{|\mathcal{H}|} \sum_{l=1}^{|\mathcal{H}|} \max_{k=1}^{|\mathcal{C}|} s_{kl} \quad (6)$$

$R_r(\mathcal{C}, \mathcal{H})$ can be viewed as the "recall" of document sentences with regard to summary sentences. The final score $R(\mathcal{C}, \mathcal{H})$ is the weighted sum of the two:

$$R(\mathcal{C}, \mathcal{H}) = \alpha\, R_p(\mathcal{C}, \mathcal{H}) + (1 - \alpha)\, R_r(\mathcal{C}, \mathcal{H}) \quad (7)$$

Our use of the terms "precision" and "recall" is reminiscent of relevance and coverage in other summarization work (Carbonell and Goldstein, 1998; Lin and Bilmes, 2010; See et al., 2017).

We train the model by minimizing the negative expected $R(\mathcal{C}, \mathcal{H})$:

$$\mathcal{L}(\theta) = -\mathbb{E}_{(z_1,\dots,z_{|\mathcal{D}|}) \sim p(\cdot|\mathcal{D})}[R(\mathcal{C}, \mathcal{H})] \quad (8)$$

where $p(\cdot|\mathcal{D})$ is the distribution produced by the neural extractive model (see Equation (3)). Unfortunately, computing the expectation term is prohibitive, since the possible latent variable combinations are exponential. In practice, we approximate this expectation with a single sample from

---

[1] We also experimented with unnormalized probabilities (i.e., excluding the exp in Equation (4)), however we obtained inferior results.

the distribution of $p(\cdot|\mathcal{D})$. We use the REINFORCE algorithm (Williams, 1992) to approximate the gradient of $\mathcal{L}(\theta)$:

$$\nabla\mathcal{L}(\theta) \approx \sum_{i=1}^{|\mathcal{D}|} \nabla \log p(z_i|z_{1:i-1}, \mathbf{h}_{i-1}^{D})[R(\mathcal{C},\mathcal{H}) - b_i]$$

Note that the model described above can be viewed as a reinforcement learning model, where $R(\mathcal{C},\mathcal{H})$ is the reward. To reduce the variance of gradients, we also introduce a baseline linear regression[2] model b_i (Ranzato et al., 2016) to estimate the expected value of $R(\mathcal{C},\mathcal{H})$. To avoid random label sequences during sampling, we use a pre-trained extractive model to initialize our latent model.

3 Experiments

Dataset and Evaluation We conducted experiments on the CNN/Dailymail dataset (Hermann et al., 2015; See et al., 2017). We followed the same pre-processing steps as in See et al. (2017). The resulting dataset contains 287,226 document-summary pairs for training, 13,368 for validation and 11,490 for test. To create sentence level labels, we used a strategy similar to Nallapati et al. (2017). We label the subset of sentences in a document that maximizes ROUGE (against the human summary) as `True` and all other sentences as `False`. Using the method described in Section 2.2, we created a compression dataset with 1,045,492 sentence pairs for training, 53,434 for validation and 43,382 for testing. We evaluated our models using full length F1 ROUGE (Lin, 2004) and the official `ROUGE-1.5.5.pl` script. We report ROUGE-1, ROUGE-2, and ROUGE-L.

Implementation We trained our extractive model on an Nvidia K80 GPU card with a batch size of 32. Model parameters were uniformly initialized to $[-\frac{1}{\sqrt{c}}, \frac{1}{\sqrt{c}}]$ (c is the number of columns in a weight matrix). We used Adam (Kingma and Ba, 2014) to optimize our models with a learning rate of 0.001, $\beta_1 = 0.9$, and $\beta_2 = 0.999$. We trained our extractive model for 10 epochs and selected the model with the highest ROUGE on the validation set. We rescaled the gradient when its norm exceeded 5 (Pascanu et al., 2013) and regularized all LSTMs with a dropout rate of 0.3 (Srivastava et al., 2014; Zaremba et al., 2014). We also applied word dropout (Iyyer et al., 2015) at rate 0.2. We set the hidden unit size $d = 300$ for both word-level and sentence-level LSTMs and all LSTMs had one layer. We used 300 dimensional pre-trained FastText vectors (Joulin et al., 2017) to initialize our word embeddings. The latent model was initialized from the extractive model (thus both models have the same size) and we set the weight in Equation (7) to $\alpha = 0.5$. The latent model was trained with SGD, with learning rate 0.01 for 5 epochs. During inference, for both extractive and latent models, we rank sentences with $p(y_i = \texttt{True}|y_{1:i-1}, \mathcal{D})$ and select the top three as summary (see also Equation (3)).

Model	R-1	R-2	R-L
LEAD3	40.34	17.70	36.57
LEAD3 (Nallapati et al., 2017)	39.20	15.70	35.50
abstract	35.46	13.30	32.65
pointer+coverage	39.53	17.28	36.38
abstract-RL	**41.16**	15.75	**39.08**
abstract-ML+RL	39.87	15.82	36.90
SummaRuNNer	39.60	16.20	35.30
EXTRACT-CNN	40.11	17.52	36.39
REFRESH (Narayan et al., 2018)	40.00	18.20	36.60
EXTRACT	40.62	18.45	37.14
LATENT	41.05	**18.77**	37.54
LATENT+COMPRESS	36.69	15.43	34.33

Table 1: Results of different models on the CNN/Dailymail test set using full-length F1 ROUGE-1 (R-1), ROUGE-2 (R-2), and ROUGE-L (R-L).

Comparison Systems We compared our model against LEAD3, which selects the first three leading sentences in a document as the summary and a variety of abstractive and extractive models. Abstractive models include a sequence-to-sequence architecture (Nallapati et al., 2016); *abstract*), its pointer generator variant (See et al. 2017; *pointer+coverage*), and two reinforcement learning-based models (Paulus et al. 2017; *abstract-RL* and *abstract-ML+RL*). We also compared our approach against an extractive model based on hierarchical recurrent neural networks (Nallapati et al. 2017; *SummaRuNNer*), the model described in Section 2.1 (EXTRACT) which encodes sentences using LSTMs, a variant which employs CNNs instead (Cheng and Lapata 2016; EXTRACT-CNN), as well as a similar system based on reinforcement learning (Narayan et al. 2018; REFRESH).

---

[2] The linear regression model b_t is trained by minimizing the mean squared error between the prediction of b_t and $R(\mathcal{C},\mathcal{H})$.

Results As shown in Table 1, EXTRACT, our extractive model outperforms LEAD3 by a wide margin. EXTRACT also outperforms previously published extractive models (i.e., *SummaRuNNer*, EXTRACT-CNN, and REFRESH). However, note that *SummaRuNNer* generates anonymized summaries (Nallapati et al., 2017) while our models generate non-anonymized ones, and therefore the results of EXTRACT and *SummaRuNNer* are not strictly comparable (also note that LEAD3 results are different in Table 1). Nevertheless, EXTRACT exceeds LEAD3 by +0.75 ROUGE-2 points and +0.57 in terms of ROUGE-L, while *SummaRuNNer* exceeds LEAD3 by +0.50 ROUGE-2 points and is worse by −0.20 points in terms of ROUGE-L. We thus conclude that EXTRACT is better when evaluated with ROUGE-2 and ROUGE-L. EXTRACT outperforms all abstractive models except for *abstract-RL*. ROUGE-2 is lower for *abstract-RL* which is more competitive when evaluated against ROUGE-1 and ROUGE-L.

Our latent variable model (LATENT; Section 2.3) outperforms EXTRACT, despite being a strong baseline, which indicates that training with a loss directly based on gold summaries is useful. Differences among LEAD3, EXTRACT, and LATENT are all significant with a 0.95 confidence interval (estimated with the ROUGE script). Interestingly, when applying the compression model from Section 2.2 to the output of our latent model (LATENT+COMPRESS), performance drops considerably. This may be because the compression model is a sentence level model and it removes phrases that are important for creating the document-level summaries.

4 Conclusions

We proposed a latent variable extractive summarization model which leverages human summaries directly with the help of a sentence compression model. Experimental results show that the proposed model can indeed improve over a strong extractive model while application of the compression model to the output of our extractive system leads to inferior output. In the future, we plan to explore ways to train compression models tailored to our summarization task.

On the Abstractiveness of Neural Document Summarization

Abstract

Many modern neural document summarization systems based on encoder-decoder networks are designed to produce abstractive summaries. We attempted to verify the degree of abstractiveness of modern neural abstractive summarization systems by calculating overlaps in terms of various types of units. Upon the observation that many abstractive systems tend to be near-extractive in practice, we also implemented a pure copy system, which achieved comparable results as abstractive summarizers while being far more computationally efficient. These findings suggest the possibility for future efforts towards more efficient systems that could better utilize the vocabulary in the original document.

1 Introduction

Document summarization has been a hot research topic in natural language processing for long. When human writers summarize a document, they often edit its constituent sentences in order to succinctly capture the meaning of the document. For instance, Jing and McKeown (2000) observed that summary authors trimmed extraneous content, combined sentences, replaced phrases or clauses with more general or specific variants. The abstractive summaries thus involve sentences which deviate from those of the source document in structure or content.

On the contrary, automated summarization generally produces extractive summaries by selecting complete sentences from the source document (Nenkova et al., 2011) to ensure that the output is grammatical.

Recently, many modern neural summarization systems based on encoder-decoder networks have been proposed, aiming at producing abstractive summaries. These systems highly rely on the attention mechanism (Bahdanau et al., 2015) that focus on different parts of input during the decoding stage. Some also suggested to use a copying mechanism (Gulcehre et al., 2016; Gu et al., 2016) to directly copy words from input. This naturally brings us to a question: in how much degree are current neural document summarizers abstractive? In this work, we conduct such a study on the popularly-used CNN / DailyMail news corpora. By calculating various types of overlaps between summaries generated by neural abstractive summarizers and the original document, we verified that many systems are in fact heavily extracting text spans from input.

Recent studies found that automated methods can generate a wider range of summaries by extracting over sub-sentential units of meaning, such as elementary discourse units (EDUs), from the source documents rather than whole sentences (Li et al., 2016; Durrett et al., 2016). We built on a rather standard pointer-generator system to produce a summarizer that purely copies from input. Limited vocabulary size makes the new summarizer more computationally efficient, without loss of performance. The findings in this paper may hint future studies towards more efficient and more effective near-extractive systems, instead of a less important target of improving abstraction.

To summarize, in this paper we provide:

- A quantitative analysis on how abstractive current neural document summarizers are by calculating various types of content overlap with the input documents.
- A simple modification on the standard pointer-generator document summarizer to produce equally good near-extractive summaries while being more computationally efficient due to largely reduced vocabulary size.

2 Neural Abstractive Summarization

Recently end-to-end training with encoder-decoder neural networks (Sutskever et al., 2014) have achieved huge success in data sufficient sequence transduction tasks such as machine translation, which brings potential applications for summarization tasks, especially for abstractive settings. Earlier practice is mostly achieved on abstractive sentence summarization (Rush et al., 2015), which is essentially sentence simplification working on short text inputs. These neural sentence abstraction models are able to achieve good ROUGE (Lin and Hovy, 2003) scores on headline generation benchmarks, [1] but have not been proved to be useful for generating summaries with multiple sentences for full documents with longer contexts, which is the main focus of this study on document summarization.

One possible way for document-level neural summarization is to design hierarchical encoding to represent sentences and words at different levels. Related studies treat a document as a sequence of sentences and take sentence embeddings as input for a document-level RNN, while using a convolutional network or recurrent network to generate sentence vectors from original tokens (Cheng and Lapata, 2016). Meanwhile, the attention mechanism will become hierarchical as well (Nallapati et al., 2016). When decoding, sentence-level attention weights will be used as input for calculating word-level attention weights. Experimental results in previous work suggest that such schemes could be useful for extractive summarization when calculating sentence weights, but could only generate rather disappointing results for abstractive summaries.

It has been shown to be useful to incorporate the copying mechanism (Gulcehre et al., 2016; Gu et al., 2016; See et al., 2017) that allows a word to be generated by directly copying an input word rather than producing all words from the hidden state from scratch. Meanwhile, directly optimizing ROUGE via reinforcement learning has been shown to be more effective than optimizing reference likelihood (Paulus et al., 2018).

Recent work has achieved improvements by modeling attention based on more structured inter-sentence relationships such as graphs (Tan et al., 2017; Yasunaga et al., 2017). In practice, a severe issue of repetitive generation has been reported in other related work. It has been shown helpful to encourage diversity and novelty in calculating attention weights (Chen et al., 2016; Nema et al., 2017), or incorporating different modules with mutual communications to encode different paragraphs in the input document (Celikyilmaz et al., 2018). Another perspective is to promote better information coverage, such as pre-estimating term frequencies in the target summary (Suzuki and Nagata, 2017) or directly introducing a coverage loss between encoder states and decoder states (See et al., 2017).

Among the aforementioned related studies, a few proposed systems explicitly targeted at generating *abstractive* summaries for documents. However, these systems highly rely on the attention mechanism and/or copying mechanism that heavily depends on different part of input during the decoding stage. This naturally brings to a question on whether neural summarizers are indeed generating abstractive summaries after reading and digesting the input document, or they are just extracting subparts of the original document to perform near-extractive summaries.

3 Quantitative Analysis

3.1 Approaches

To verify whether current abstractive neural summarizers are just lazy generators that tend to copy original words and text spans, we computed the overlaps between the output summaries and the original article using the overlapping ratio measured by the following units: longest common subsequences (LCS), n-grams, and full sentences.

We studied a few representative systems that explicitly claim to have the ability to output *abstractive* summaries. The systems we compared in this work include:

- A basic sequence-to-sequence model with the attention mechanism.
- The pointer-generator system plus coverage mechanism presented by See et al. (2017).
- The graph-based attention system by Tan et al. (2017), aiming at better capturing salient information.
- The Distraction system by Chen et al. (2016), which attempt to distract attention.

---

[1] One caveat is that achieving high ROUGE scores on datasets with single references only is not an indication that the system is indeed generating good results.

- The deep reinforced model (Paulus et al., 2018) which combines intra-attention mechanism and reinforcement learning to target for better ROUGE scores and summary quality. to traverse between different content of a document so as to better grasp the overall meaning for summarization.

We also attempted to include some other popular abstractive document summarizers such as the SummaRuNNer system (Nallapati et al., 2017), but we failed to reach the authors to get their system outputs.

We collected experimental results from these systems on two large-scale corpora of CNN and DailyMail, which have been almost exclusively used in recent work on neural document summarization. The corpora were originally constructed in (Hermann et al., 2015) by collecting human generated abstractive highlights from the news stories. Just like almost all recent studies on neural summarization, the main conclusions might vary on other domains or even other news datasets.

3.2 Results

Table 1 displays the results of overlaps calculated for various system outputs over the original documents. Note that the authors of the Distraction system (Chen et al., 2016) did not conduct experiments on the Daily Mail subset of data, therefore only the results on CNN dataset are shown. We also include overlap results of manually-written reference summary highlights for comparison.

We can observe that the outputs from the pointer-generator systems (See et al., 2017) have the most amount of overlaps in terms of whole sentences, and most of the words or n-grams are in fact taken from the original document without further modifications or paraphrases. This observation is predictable since the system relies heavily on the pointer network module that directly copy from the input. The deep Reinforced model (Paulus et al., 2018), which relies on an intra-attention mechanism, also have rather high overlaps with the original document, suggesting that it is also an near-extractive system by some degree.

Other abstractive neural summarizers do not tend to directly copy full sentences, but do not generate words beyond the lexical choices used in the input document either, with considerably large overlaps of n-grams in general. A notable exception is the graph-based attention system where the overlap statistics are close to manually-written reference summaries. However, we manually checked a few samples and observed that the produced summaries tend to generate contents that do not conform to the information conveyed in the original documents. This is also verified in manual rating scores described later.

We conclude that currently many neural news summarizers which claimed to be abstractive tend to directly copy large spans of contents from the original documents, at least on the CNN / Daily Mail dataset which is the almost exclusively used benchmark in recent studies.

4 Near-Extractive Summarization

Now that we have observed large long-span overlaps between generated summaries and the original documents, it is natural to think about the following question: Do we really need to generate tokens from decoder states in a neural summarizer rather than just simply copying spans from input?

As previously mentioned, near-extractive summaries containing smaller text units from the input document have been shown sufficient for producing good summaries. On the other hand, generating words from a decoder state is based on time-consuming calculations of a softmax distribution, given that the vocabulary size is relatively large. Therefore, we would like to try abandoning decoder word generation, while just directly copying words from the input document instead.

4.1 Approach

We built a summarizer that only copy input words for outputs with trivial modifications upon the pointer-generator model (See et al., 2017). Specifically, it implements a sequence-to-sequence model that uses the soft attention distribution to produce an output sequence whose elements are all from the input sequence, similar to what a pointer network (Vinyals et al., 2015) does. We simply use the attention distribution as the final copy distribution, while the model does not generate words from the whole vocabulary using a softmax layer as in original recurrent networks. The training objective is to maximize the likelihood of words contained in reference summaries, similar to what has been used in the SummaRuNNer system for abstractive training (Nallapati et al., 2017). We keep using the same hyperparameters as in the original pointer-generator model.

	LCS	unigram	bigram	4-gram	sentence
Reference	75.0%	87.6%	49.0%	34.0%	3.5%
Seq2seq	87.4%	93.2%	76.0%	66.0%	10.8%
Pointer-generator	98.2%	99.8%	92.5%	93.0%	60.1%
Pointer-generator+coverage	98.8%	99.9%	96.1%	94.0%	70.0%
Reinforced (Paulus et al., 2018)	90.6%	95.8%	85.3%	80.2%	19.3%
Graph attention (Tan et al., 2017)	74.3%	82.3%	59.9%	42.1%	3.3%
Reference(CNN)	63.0%	75.2%	39.2%	25.9%	0.8%
Distraction (Chen et al., 2016) (CNN)	74.7%	94.0%	65.4%	38.7%	0.8%

Table 1: The overlap proportions between summaries and the original document

4.2 Experiments

We conducted experiments on the CNN / Daily Mail datasets and adopt the widely used ROUGE metrics (Lin and Hovy, 2003) for evaluation as previous work did.

Table 2 shows the ROUGE scores for the produced summaries. We can see that a pure copy system could produce equally or slightly better results in terms of word-matching metrics. The coverage mechanism introduced by See et al. (2017) is also effective for a pure copy system. As a side note, we verified the observation from See et al. (2017) that current neural summarizers cannot genuinely outperform a properly implemented LEAD baseline that simply takes the first three sentences from the original document, at least for the datasets used here that mainly consist of news describing events or activities.

	R-1	R-2	R-L
PtrGen	36.44	15.66	33.42
PtrGen + cov	39.53	17.28	36.38
Ptr	37.44	16.08	34.25

Lead3	**39.98**	17.25	36.20

Table 2: ROUGE scores on CNN/Daily Mail

We also conducted human evaluation on outputs for a sample of 30 documents in the common subpart of the system inputs. We asked three raters to evaluate on the following metrics in a summary using 1-5 scoring scheme (5 is the best, and rational numbers were allowed if raters felt uncertain over some cases): *informativeness* (INF), *relevance* (REL), *fluency* (FLU) and *coherence* (COH), as used by Grusky et al. (2018). The results are listed in Table 3. We find the pure copy system performs similarly to the pointer-generator. However, we can also observe a rough trend that: the more abstractive a system is, the higher the chance of generating irrelevant or grammatically worse content. Such observation is consistent with manual evaluation results conducted by another study towards more abstraction (Kryściński et al., 2018), in parallel to our work. This is a signal that other than pursuing for heavily abstractiveness, we could also spend more efforts on directly identifying and extracting useful pieces from the input, in order to get more controlled and more useful summaries with better quality beyond the heavily biased ROUGE metrics (Chaganty et al., 2018).

	INF	REL	FLU	COH
Lead3	2.97	3.20	4.10	3.33

GraphAtt	2.75	2.87	2.47	2.14
Reference	3.71	4.32	4.54	4.12

Table 3: Human ratings

A larger merit for implementing a pure copy system is that it is more computationally effective than abstractive summarizers that generate words in a large vocabulary from decoder states. Table 4 lists the speed for decoding as well as the memory costs in training for the pure copy system, compared with the original pointer-generator system. The numbers are averaged results from multiple runs on the same computing environment of Tesla M40 GPU. We can see that the speed doubles from a pure copy summarizer, while the GPU memory cost is reduced to around a quarter.

We visualize the copying probabilities (attention weights) for an example summary along with the original document in Figure 1. We can observe that the pure copy system tends to attend on con-

	Pure copy	PtrGen
Decoding Speed	0.87 step/s	0.44 step/s
GPU Usage	2216MB	8368MB
Memory Cost	2.67GB	3.30GB

5 Conclusion

In this work we attempted to quantify the abstractiveness of modern neural abstractive summarization systems by calculating overlaps of various units. Inspired by the observation that many systems tend to be near-extractive, we also implemented a pure copy system and achieved comparable performance while being far more efficient. Giving the observations that the abstractive summaries produced by current systems have lower quality than extractive summaries, our study should give hints for focusing on better extractions from the input, rather than deliberately pursuing for more abstraction but losing real quality beyond automatic metrics.

Acknowledgments

Abstract

Automatic essay scoring (AES) is the task of assigning grades to essays without human interference. Existing systems for AES are typically trained to predict the score of each single essay at a time without considering the rating schema. In order to address this issue, we propose a reinforcement learning framework for essay scoring that incorporates quadratic weighted kappa as guidance to optimize the scoring system. Experiment results on benchmark datasets show the effectiveness of our framework.

1 Introduction

In recent years, neural networks have been widely used to grade student essays automatically and achieve state-of-the-art performance. In particular, a distributed representation is learned for an essay with variant neural networks and a linear layer is then used to produce the final score. Existing researches focus on learning better essay representation using different neural networks, including long short-term memory (LSTM) network (Taghipour and Ng, 2016), hierarchical convolutional neural networks (CNN) (Dong and Zhang, 2016), hierarchical CNN-LSTM structure with attention mechanism (Dong et al., 2017), and SkipFlow LSTM (Tay et al., 2017).

The major evaluation metric for AES is quadratic weighted kappa (QWK), which is also the official metric of Automated Student Assessment Prize[1] (ASAP). It evaluates the scoring results by taking rating schema into consideration. Because QWK is not differentiable, it is hard to train systems via optimizing this metric directly. Alternatively, existing AES systems are typically trained to predict the score for a single essay and optimized using mean square error (MSE). The gap between training and testing also limits the performance of state-of-the-art AES systems.

Recently, reinforcement learning (RL) has been introduced to optimize models in terms of non-differentiable quality metrics and studies have shown its effectiveness for various tasks including language generation (Ranzato et al., 2015; Rennie et al., 2016; Zhang et al., 2017), machine translation (Bahdanau et al., 2016) and relation classification (Feng et al., 2018).

Inspired by these researches, we propose a novel reinforcement learning framework that incorporates QWK as the guidance to optimize the essay scoring system. In our framework, we score a pack of essays at a time and the scoring of each single essay is treated as an action. The QWK value computed for the pack of essays is then delivered as a reward to update the scoring system. Because the existing regression-based essay scorer is unable to generate a probability distribution in nature, it is non-trivial to be used within the reinforcement learning framework. We therefore propose to use a classification-based scoring system instead. The proposed framework is evaluated in the benchmark datasets from ASAP and experiment results confirm its effectiveness on two different settings of essay representation structures.

2 Model

Typically, an essay scorer contains two components, namely, essay representation and essay scoring. The component of essay representation transforms an input essay into a distributed vector and the component of essay scoring assigns a score to the essay based on the vector. Both components are usually trained jointly. In order to incorporate QWK to guide the process of essay scoring, we introduce a novel essay scoring strategy named *packed evaluation*. At each time, essay scorer grades a pack of essays together with the target essay, and QWK is calculated for the pack.

Brussels, Belgium, October 31 - November 4, 2018.

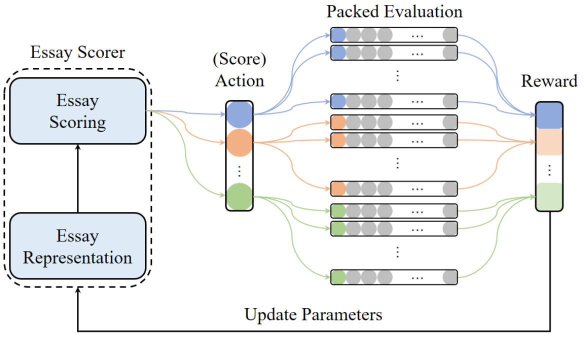

Figure 1: The reinforcement learning framework for automatic essay scoring. Node in color stands for a target essay and nodes in grey are essays randomly chose to form a pack for QWK calculation.

To avoid contingency, for each target essay, we repeat the packed evaluation multiple times by randomly choosing other essays in a pack. And the average QWK it achieves is set to be the reward. The reward is then delivered to the essay scorer as a weak signal to supervise the scorer. Figure 1 illustrates the training process of our model. We will introduce the different parts in detail in the rest of this section.

2.1 Essay Representation

This component converts an input essay into a dense vector as its representation. Recurrent neural networks (Williams and Zipser, 1989) are widely used to learn a representation for a sequence of words for essay scoring. Following existing researches, we also use recurrent neural networks (RNN) and test two different structures.

Bidirectional LSTM We first use a double-layer bi-directional LSTM network (Hochreiter and Schmidhuber, 1997) to process the essay. LSTM is a variant of recurrent neural network which uses gates to control the information flow. Our LSTM processes one word at a timestamp. Given the word embedding sequence $\{x_1, x_2, ..., x_n\}$ for the essay, the hidden states of the LSTM are calculated as follows:

$$f_t = \sigma(W_f x_t + U_f h_{t-1} + b_f)$$

$$i_t = \sigma(W_i x_t + U_i h_{t-1} + b_i)$$

$$o_t = \sigma(W_o x_t + U_o h_{t-1} + b_o)$$

$$\tilde{c}_t = tanh(W_c x_t + U_c h_{t-1} + b_c)$$

$$c_t = f_t \circ c_{t-1} + i_t \circ \tilde{c}_t$$

$$h_t = o_t \circ tanh(c_t)$$

where $W_f, W_i, W_o, W_c, U_f, U_i, U_o$ and U_c are weight matrices, b_f, b_i, b_o and b_c are bias vectors. σ denotes sigmoid function and $\circ$ denotes element-wise multiplication.

In particular, the average value over all hidden states of each LSTM layer are computed, and we concatenate the mean states of the two layers together as the embedding vector of the essay. Given $h_{i,j}$ as the *j-th* hidden state of the *i-th* layer, the layer outputs and the essay embedding vector E are defined as follows:

$$output_i = \frac{1}{n}\sum_{j=1}^{n} h_{i,j}$$

$$E = \begin{bmatrix} output_0 \\ output_1 \end{bmatrix}$$

Dilated LSTM Dilated recurrent neural networks (Chang et al., 2017) are proved to be more effective than traditional RNNs in long sequence processing, by capturing multi-timescale information along the sequence, with the mechanism of dilated skip connections.

Denoting $s^i_t = f(x^i_t, s^i_{t-1})$ as the iteration of cell states in traditional RNNs, states in dilated RNNs are iterated as $s^i_t = f(x^i_t, s^i_{t-k^i})$, where k^i is the skip length in the *i-th* layer. In order to keep the most information active, we simply concatenate the average hidden states of every layer to form the essay embedding.

$$E = concat(output_i), for\ i\ in\ 1, 2, ..., L$$

where L is the number of layers.

2.2 Essay Scoring

Traditionally, a linear layer with sigmoid function is used to score an essay. Given an essay embedding vector E, the essay score is calculated as follows:

$$y = sigmoid(W_l^T E + b_l)$$

where W_l and b_l are weight vector and bias for scoring. By running n examples together, mean square error is used to evaluate the predicted score.

$$loss_{MSE} = \frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2$$

where y and $\hat{y}$ are score vectors representing predicted scores and ground truth scores, respectively. As we can see, such objective function is unable to take rating schema into consideration.

The regression-based scorer only outputs a single value without probability distribution. It is thus non-trivial to use it for policy learning in RL framework directly. Therefore, we propose to use a classification-based scorer, in which different score categories and their probabilities constitute an action space.

Classification-based Scoring We first feed the essay vector into a fully connected layer, then softmax function is used to transform the output into a probability distribution. Given an essay embedding vector E, the probability distribution vector c is calculated as follows:

$$c = softmax(W_c E + b_c)$$

where W_c and b_c are weight matrix and bias vector, respectively.

Given the ground truth category, cross entropy loss is applied to evaluate the agreement of the probabilities as follows:

$$loss_{CE} = -\sum_{i=1}^{N} Y_i log(c_i)$$

where N is the number of categories, which is equal to the number of possible ratings. Y is a one-hot vector with the element representing the ground truth category set as one.

Inter-class Penalty Cross entropy loss used in classification-based scorer does not imply the difference between categories, i.e. the rank information that is deemed to be important for essay scoring. Thus we enforce a penalty in addition to the cross entropy loss. Inspired by the definition of QWK, the penalty vector p is defined as follows:

$$p_i = \frac{(i - score)^2}{(N-1)^2}$$

where $score$ is the ground truth score of the essay.

The penalty loss function is defined as:

$$loss_P = \sum_{i=1}^{N} c_i p_i$$

Mixed Scoring In practice, we jointly train both a regression-based scoring layer and a classification-based scoring layer over the same document representation to help the classification-based scorer converge. By combining the two scorers together, the overall loss function can be written as:

$$loss_{pre} = \alpha_0 loss_{MSE} + \beta_0 loss_{CE} + \gamma_0 loss_P$$

where α_0, β_0 and γ_0 are hyper parameters. Mixed scoring is used as a pre-train model for our essay scorer in the phase of reinforcement learning.

2.3 Reinforcement Learning

We define our loss function as the negative expected reward:

$$loss_{RL} = -\mathrm{E}_{\tau \sim p(\tau)} r(\tau)$$

where τ is the set of actions, r denotes the reward, which is the average QWK an essay achieves in the packed evaluation.

By running n examples at a time, according to the REINFORCE algorithm (Williams, 1992), an approximated gradient can be calculated by:

$$\frac{\partial loss_{RL}}{\partial \theta} = \sum_{i=1}^{n} [\partial log(p_{i,y}|E_i;\theta) R_i]$$

where θ denotes all parameters relevant to score calculation, and $\partial log(p_{i,y}|E_i;\theta)$ can be computed by standard back propagation.

Note that only the classification-based scorer is involved in the process of reinforcement learning for essay scoring. The overall loss function for this phase can be written as:

$$loss_{overall} = \alpha_1 loss_{RL} + \beta_1 loss_{CE} + \gamma_1 loss_P$$

where α_1, β_1 and γ_1 are hyper parameters.

2.4 Quadratic Weighted Kappa(QWK)

QWK calculation emphasizes on the overall rating schema. By setting QWK as the reward, our model is trained at a macro aspect taking the grading specialty of different sets of essays into consideration.

An *N-by-N* quadratic weight matrix *W* is first computed to encode the rating information.

$$W_{i,j} = \frac{(i-j)^2}{(N-1)^2}$$

where N is the number of possible ratings. An *N-by-N* matrix *A* is calculated such that $A_{i,j}$ corresponds to the number of essays that receive a score *i* by the human rater, and a score *j* by the scoring system. Another *N-by-N* matrix *B* is constructed as the outer product of the histogram vectors of the two ratings. *A* and *B* are then normalized such that they have the same sum. Finally, from the three matrices, the quadratic weighted kappa is calculated as follows:

$$\kappa = 1 - \frac{\Sigma_{i,j} W_{i,j} A_{i,j}}{\Sigma_{i,j} W_{i,j} B_{i,j}}$$

set	# of essays	avg. of len.	rating range
1	1783	350	2-12
2	1800	350	1-6
3	1726	150	0-3
4	1772	150	0-3
5	1805	150	0-4
6	1800	150	0-4
7	1569	250	0-30
8	723	650	0-60

Table 1: Details of the ASAP dataset.

3 Experiment

3.1 Experiment Setup

The ASAP dataset is used for evaluation. It consists of essays written by middle-school English-speaking students ranging among eight different topics. More details are listed in Table 1. As there are no released labels for the test data, we separate the validation set and test set from the original training data. Following Taghipour and Ng (2016) and Dong et al. (2017), we use 5-fold cross-validation. In each fold, the split is 60%, 20%, 20% for training, validation and testing respectively.

All essays are parsed with the NLTK[2] tokenizer. We pre-train the word embedding via word2vec (Mikolov et al., 2013) on the whole dataset. The number of hidden states in LSTMs is 200. We use a four-layer double-directional dilated LSTM with skip lengths 1,2,4,8 in each layer respectively. During the training and the scoring, scores are scaled to range [0,1] for regression-based scorer. They are restored to integers when calculating QWK values. In the RL phase, the pack size is 64 essays, and packed evaluation is repeated 7 times per essay. The essay scorer for RL is pre-trained by mixed scoring.

We compare the performance of different approaches:

- **B0**: This model uses a double-layer bi-directional LSTM to encode an essay and mean square error as objective function to train the essay scorer;
- **B1**: This is a classification-based scorer and it is trained jointly with a regression-based scorer;
- **P0**: Based on B1, this model incorporates penalty loss function;
- **P1**: This model shares the same settings with *P0*, but uses dilated LSTM instead of a double-layer bi-directional LSTM for essay representation;
- **RL0**: This model uses *P0* as the scorer under our reinforcement learning framework;
- **RL1**: This model uses *P1* as the scorer under our reinforcement learning framework.

set	B0	B1	P0	RL0	P1	RL1
1	.711	.666	.666	.680	.759	**.766**
2	.582	.579	.579	.589	.630	**.659**
3	.627	.653	.662	.670	.673	**.688**
4	.758	.758	.761	.771	.768	**.778**
5	.768	.781	.786	.796	.795	**.805**
6	.776	.786	.787	**.798**	.790	.791
7	**.766**	.711	.726	.737	.748	.760
8	**.604**	.491	.525	.545	.536	.545
Avg	.699	.678	.687	.698	.712	**.724**

Table 2: Experiment results for different models in terms of QWK. **Bolded** number is the best performance in each row.

3.2 Results

The overall results of our models in terms of QWK are shown in Table 2. We have the following findings:

- By incorporating a penalty loss to the classification scorer, the performance of *P0* is equal to or better than *B1* on all the eight sets. This indicates the effectiveness of combining rank information with cross-entropy loss for essay scoring.
- By replacing double-layer bi-directional LSTM with dilated LSTM, *P1* improves the QWK values by a large margin compared with *P0* on all the eight sets. This indicates the effectiveness of using dilated LSTM for document representation for the task of automatic essay scoring. The performance improvement brought by *P1* compared to *P0* is even greater when the length of essays are higher (set 1,2,7,8, see Table 1), indicating that dilated networks are specifically better at long sequence processing.
- By incorporating QWK to guide the optimization of essay scorer, approaches (*RL0* and *RL1*) with reinforcement learning strategy can improve the performance consistently on all the eight sets compared to their counterparts (*P0* and *P1*). We also performed

---

[2] http://www.nltk.org

one-tailed *t*-test, showing that the improvements brought by reinforcement learning are significant with $p < 0.05$ compared to their base scorer models (*RL1* vs. *P1* and *RL2* vs. *P2*).

- The performance of classification-based scorer *B1* can equate or improve the performance on four datasets (set 3,4,5,6) compared with regression-based scorer *B0*. The rating ranges for set 1,2,7,8 are much greater than set 3,4,5,6 (see Table 1). The performance difference between *B1* and *B0* decreases (from positive to negative) when the number of rating categories increases. This is because when the number of categories get larger, it requires much more parameters for the classification-based scorer to be well trained. Given N categories, the classification layer should output N probabilities for each category per essay, costing N times more parameters than regression-based scoring.

4 Related Work

There are two lines of research related to our work including text quality evaluation and reinforcement learning for natural language processing.

4.1 Text Quality Evaluation

Traditionally, AES models are usually divided into three categories: classification, regression and ranking. Naive Bayes models are mostly used in classification tasks. Larkey (1998) use bag-of-word features. Following that, Rudner and Liang (2002) develop a system based on multinomial Bernoulli Naive Bayes, using content and style features. E-rater (Attali and Burstein, 2004) is one of the earliest systems to adopt regression methods. Phandi et al. (2015) use correlated Bayesian Linear Ridge Regression (cBLRR) focusing on domain-adaptation tasks. Ranking models use linguistic features. Yannakoudakis et al. (2011) formulate AES as a pair-wise ranking problem by ranking the order of pair essays. Chen and He (2013) formulate AES into a list-wise ranking problem by considering the order relation among the whole essays.

Argument quality evaluation is a task closely related to AES, which involves evaluation of argumentative texts with various grains (argument-level, post-level, etc.). Tan et al. (2016); Wei et al. (2016a); Wang et al. (2017) make use of linguistic features to evaluate the persuasiveness of arguments in online forums. Wei et al. (2016b); Ji et al. (2018) consider features from the perspectives of argumentation interaction between participants. Persing and Ng (2017) construct their model based on error types for argumentation.

4.2 Reinforcement Learning for Natural Language Processing

Being able to optimize non-differentiable quality metrics, reinforcement learning has been widely used in natural language processing tasks such as machine translation (Bahdanau et al., 2016), image captioning (Rennie et al., 2016; Zhang et al., 2017) and text summarization (Ranzato et al., 2015). To the best of our knowledge, this paper is the first attempt to optimize the scorer by QWK that considers rating schema.

Skip connections in RNNs are capable of capturing long-term dependencies in sequences. Vezhnevets et al. (2017) introduces dilated LSTM to allow its manager to operate at a low temporal resolution. Yu et al. (2017) propose a reinforcement learning method to let the network learn how long to skip.

5 Conclusion and Future Work

In this paper, we propose a reinforcement learning framework incorporating QWK metric as the reward to train the essay scoring system directly. A packed evaluation strategy is used for QWK computation and the scoring of each essay is treated as a single action. In particular, dilated LSTM is used to encode an essay, and a softmax layer is utilized for essay grading. Experiment results on benchmark datasets prove that training the grading system toward QWK is effective.

Further analysis on experiment results indicates the disadvantage of using a classification-based scorer for essays with complex grading schema. One of the future directions can be exploring other kinds of scoring actions than classification under the reinforcement learning framework.

Identifying Well-formed Natural Language Questions

Manaal Faruqui **Dipanjan Das**
Google AI Language

Abstract

Understanding search queries is a hard problem as it involves dealing with "word salad" text ubiquitously issued by users. However, if a query resembles a well-formed question, a natural language processing pipeline is able to perform more accurate interpretation, thus reducing downstream compounding errors. Hence, identifying whether or not a query is well formed can enhance query understanding. Here, we introduce a new task of identifying a well-formed natural language question. We construct and release a dataset of 25,100 publicly available questions classified into well-formed and non-wellformed categories and report an accuracy of 70.7% on the test set. We also show that our classifier can be used to improve the performance of neural sequence-to-sequence models for generating questions for reading comprehension.

1 Introduction

User issued search queries often do not follow formal grammatical structure, and require specialized language processing (Bergsma and Wang, 2007; Barr et al., 2008; Manshadi and Li, 2009; Mishra et al., 2011). Traditional natural language processing (NLP) tools trained on formal text (e.g. treebanks) often have difficulty analyzing search queries; the lack of regularity in the structure of queries makes it difficult to train models that can optimally process the query to extract information that can help understand the user intent behind the query (Baeza-Yates et al., 2006).

One clear direction to improve query processing is to annotate a large number of queries with the desired annotation scheme. However, such an annotation can be prohibitively expensive and models trained on such queries might suffer from freshness issues, as the domain and nature of queries evolve frequently (Markatos, 2001; Bawa et al., 2003; Roy et al., 2012). Another direction is to obtain a paraphrase of the given query that is a grammatical natural language question, and then analyze that paraphrase to extract the required information (Nogueira and Cho, 2017; Buck et al., 2018). There are available tools and datasets, such as Quora question paraphrases and the Paralex dataset (Fader et al., 2013) – for identifying query paraphrases (Wang et al., 2017; Tomar et al., 2017), but these datasets do not contain information about whether a query is a natural language question or not. Identifying well-formed natural language questions can also facilitate a more natural interaction between a user and a machine in personal assistants or chatbots (Yang et al., 2014; Mostafazadeh et al., 2016) or while recommending related queries in search-engines.

Identifying a well-formed question should be easy by parsing with a grammar, such as the English resource grammar (Copestake and Flickinger, 2000), but such grammars are highly precise and fail to parse more than half of web queries. Thus, in this paper we present a model to predict whether a given query is a well-formed natural language question. We construct and publicly release a dataset of 25,100 queries annotated with the probability of being a well-formed natural language question (§2.1). We then train a feed-forward neural network classifier that uses the lexical and syntactic features extracted from the query on this data (§2.2). On a test set of 3,850 queries, we report an accuracy of 70.1% on the binary classification task. We also demonstrate that such a query well-formedness classifier can be used to improve the quality of a sequence-to-sequence question generation model (Du et al., 2017) by showing an improvement of 0.2 BLEU score in its performance (§3). Our dataset ise available for download at `http://goo.gl/language/query-wellformedness`.

Brussels, Belgium, October 31 - November 4, 2018.

Query	Well-formed?	Reasoning
what is the breed of scooby doo?	1	Grammatical and an explicit question
tell me whats the breed of scooby doo?	0	A command but not a question
headache evenings?	0	Ungrammatical and not a question
what causes headaches during evenings	1	Grammatical and an explicit question
what 12.5 as a fraction?	0	An explicit question but ungrammatical

Table 1: Examples of well-formed and non-wellformed queries according to the annotation guideline.

2 Well-formed Natural Language Question Classifier

In this section we describe the data annotation, and the models used for question well-formedness classification.

2.1 Dataset Construction

We use the Paralex corpus (Fader et al., 2013) that contains pairs of noisy paraphrase questions. These questions were issued by users in WikiAnswers (a Question-Answer forum) and consist of both web-search query like constructs (*"5 parts of chloroplast?"*) and well-formed questions (*"What is the punishment for grand theft?"*), and thus is a good resource for constructing the question well-formedness dataset. We select 25,100 queries from the unique list of queries extracted from the corpus such that no two queries in the selected set are paraphrases. The queries are then annotated into well-formed or non-wellformed questions. We define a query to be a well-formed natural language question if it satisfies the following:

1. Query is grammatical.
2. Query is an explicit question.
3. Query does not contain spelling errors.

Query (q)	$p_{wf}(q)$
population of owls just in north america?	0.0
who disscoverd rihanna?	0.2
what countries have genocide happened in?	0.6
what is released when an ion is formed?	1.0

Table 2: Examples of human annotations on query well-formedness.

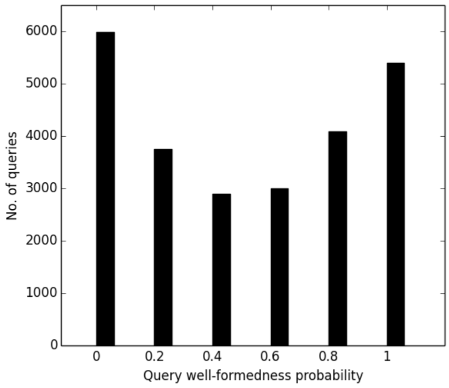

Figure 1: The distribution of the annotated questions according to well-formedness probability.

Table 1 shows some examples that were shown to the annotators to illustrate each of the above conditions. Every query was labeled by five different crowdworkers with a binary label indicating whether a query is well-formed or not. We average the ratings of the five annotators to get the probability of a query being well-formed. Table 2.1 shows some queries with obtained human annotation. Humans are pretty good at identifying an implicit query (*"Population of owls..."*) or a simple well-formed question (*"What is released..."*), but may miss out on subtle spelling mistakes like "disscovered" or disagree on whether the determiner "the" is needed before the word "genocide" (*"What countries have genocide happened in?"*). Similar to other NLP tasks like entailment (Dagan et al., 2006; Bowman et al., 2015), paraphrasing (Wieting et al., 2015) etc. we rely on the wisdom of the crowd to get such annotations in order to make the data collection scalable and language-independent.

Figure 1 is the histogram of query well-formedness probability across the dataset. Interestingly, the number of queries where at least 4 or more annotators agree[1] on well-formedness is large: $|\{q \mid 0.8 \le p_{wf}(q) \le 0.2\}| = 19206$ queries. These constitute 76.5% of all queries in the dataset. The Fleiss' kappa (Fleiss, 1971) for measuring agreement among multiple annotators is computed to be $\kappa = 0.52$ which shows moderate agreement (Landis and Koch, 1977). We

---

[1] At least 4 annotators label the query with 0 or 1.

then randomly divided the dataset in approx. 70%, 15%, 15% ratio into training, development and test sets containing 17500, 3750, and 3850 queries respectively. While testing, we consider every query well-formed where at least 4 out of 5 annotators ($p_{wf} \geq 0.8$) marked it as well-formed.[2]

2.2 Model

We use a feed-forward neural network with 2 hidden layers with ReLU activations (Glorot et al., 2011) on each layer and a softmax at the output layer predicting 0 or 1. We extract a variety of features from the query which can be helpful in the classification. We extract character-3, 4-grams and word-1, 2-grams as they can be helpful in capturing spelling errors. In addition to lexical features, we also extract syntactic features that can inform the model on any anomaly in the structure of the query. Specifically, we annotate the query with POS-tags using SyntaxNet POS tagger (Alberti et al., 2015) and extract POS-1, 2, 3-grams.[3] Every feature in the network is represented as a real-valued embedding. All the n-grams embeddings of every feature type are summed together and concatenated to form the input layer as shown in Figure 2. The model is trained using cross-entropy loss against the gold labels for each query. The hyperparameters are tuned to maximize accuracy on the dev set and results are reported on the test set.

Hyperparameters. We fix the size of the first and second hidden layers to be 128 and 64 respectively. The character n-gram embeddings were of length 16 and all other feature embeddings were of length 25. We use stochastic gradient descent with momentum for optimization with learning rate tuned over $[0.001 - 0.3]$, a batch size of 32 and 50000 training steps.

2.3 Experiments

Baselines. The majority class baseline is 61.5% which corresponds to all queries being classified non-wellformed. The question word baseline that classifies any query starting with a question word as a well-formed question gets 54.9%.[4] Also, we used a single-layer word-level biLSTM encoder with hidden layer of length 50 to encode the question and then use this representation in the softmax layer to predict the label (Lee and Dernoncourt, 2016). This classifier achieved 65.8%.

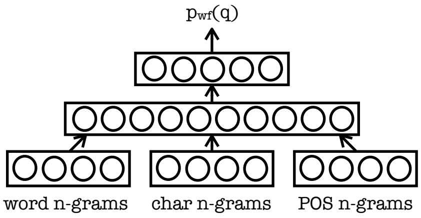

Figure 2: A feed-forward neural network for query well-formedness classification.

Model	Accuracy (%)
majority class baseline	61.5
word bi-LSTM baseline	65.8
question word baseline	54.9
word-1	65.4
word-1, 2	65.5
word-1, 2 char-3, 4	66.9
word-1, 2 POS-1, 2, 3	**70.7**
word-1, 2 char-3, 4 POS-1, 2, 3	70.2
Approx. human upper bound	88.4

Table 3: Performance of well-formedness query classifier on the test set.

Results. The best performance obtained is 70.7% while using word-1, 2-grams and POS-1, 2, 3-grams as features. Using POS n-grams gave a strong boost of 5.2 points over word unigrams and bigrams. Although character-3, 4-grams gave improvement over word unigrams and bigrams, the performance did not sustain when combined with POS tags.[5] A random sample of 1000 queries from the test set were annotated by one of the authors of the paper with proficiency in English, which matched the gold label with 88.4% accuracy providing an approximate upper-bound for model performance.

A major source of error is our model's inability to understand deep semantics and syntax. For example, *"What is the history of dirk bikes?"* is labeled as a non-wellformed question with $p_{wf} =$

---

[2] We randomly selected 100 queries and manually determined if each of those queries were well-formed. We found $p_{wf}(q) = 0.8$ to be the value above which all queries were well-formed.

[3] The use of dependency labels as features and use of pre-trained Glove embeddings did not show improvement and hence omitted here for space constraints.

[4] List of question words: `https://en.wikipedia.org/wiki/Interrogative_word`

[5] We assumed character n-grams to help identify spelling mistakes, but our dataset has relatively few misspelled words–only 6 in 100 random queries.

0 by annotators because of the misspelled word “dirk” (the correct word is “dirt”). However, the POS tagger identifies “dirk” as a noun and as “NN NNS” is a frequent POS-bigram, our model tags it as a well-formed question with $p_{wf} = 0.8$, unable to identify that the word does not fit in the context of the question. Another source of error is the inability to capture long term grammatical dependencies. For example, in *“What sort of work did Edvard Munch made ?”* the verb “made” is incorrectly in the past tense instead of present tense. Our model is unable to capture the relationship between “did” and “made” and thus marks this as a well-formed question.

3 Improving Question Generation

Automatic question generation is the task of generating questions that ask about the information or facts present in either a given sentence or paragraph (Vanderwende, 2008; Heilman and Smith, 2010). Du et al. (2017) present a state-of-the-art neural sequence-to-sequence model to generate questions from a given sentence/paragraph. The model used is an attention-based encoder-decoder network (Bahdanau et al., 2015), where the encoder reads in a given text and the decoder is an LSTM RNN that produces the question by predicting one word at a time.

Du et al. (2017) use the SQuAD question-answering dataset (Rajpurkar et al., 2016) to develop a question generation dataset by pairing sentences from the text with the corresponding questions. The question generation dataset contains approx 70k, 10k, and 12k training, development and test examples. Their current best model selects the top ranked question from the n-best list produced by the decoder as the output. We augment their system by training a discriminative reranker (Collins and Koo, 2005) with the model score of the question generation model and the well-formedness probability of our classifier as features to optimize BLEU score (Papineni et al., 2002) between the selected question from the 10-best list and the reference question on the development set. We then use this reranker to select the best question from the 10-best list of the test set.

We use the evaluation package released by Chen et al. (2015) to compute BLEU-1 and BLEU-4 scores.[6] Table 4 shows that the reranked question selected using our query well-formedness classifier improves the BLEU-4 score of a seq-to-seq question generation model from 12.0 to 12.2. The oracle improvement, by selecting the sentence from the list that maximizes the BLEU-4 score is 15.2. However, its worth noting that an increase in well-formedness doesn’t guarantee an improved BLEU score, as the oracle sentence maximizing the BLEU score might be fairly non-wellformed (Callison-Burch et al., 2006). For example, *“who was elected the president of notre dame in?”* has a higher BLEU score to the reference *“who was the president of notre dame in 1934?”* than our well-formed question *“who was elected the president of notre dame?”*. Figure 3 shows a question generation example with the output of Du et al. (2017) as the baseline result and the reranked question using the wellformed probability.

Model	BLEU-1	BLEU-4
Baseline	41.3	12.0
Reranked	**41.6**	**12.2**

Table 4: Reranking the n-best output of a neural seq2seq question generation model using well-formedness probability.

Sentence: montana is home to the rocky mountain elk foundation and has a historic big game hunting tradition.
Gold question: what is the name of the big game hunting foundation in montana?

seq2seq: what is a historic big game hunting tradition? ($p_{wf} = 0.7$)
Reranked: what is the name of the historic big game tradition? ($p_{wf} = 0.8$)

Figure 3: Example showing question selection from the n-best list using our reranking model.

4 Related Work

We have referenced much of the related work throughout the paper. We now review another orthogonally related field of work. Grammatical error correction (GEC) is the task of correcting the grammatical errors (if any) in a piece of text (Ng et al., 2014). As GEC includes not just identification of ungrammatical text but also correcting the text to produce grammatical text, its a more complex task. However, grammatical error prediction (Schmaltz et al., 2016; Daudaravicius et al., 2016) is the task of classifying whether or not a sentence is grammatical, which is more closely related to

---

[6] BLEU-x uses precision computed over $[1, x]$-grams.

our task as classifying a question as well-formed requires making judgement on both the style and grammar of the text.

5 Conclusion

We proposed a new task of well-formed natural language question identification and established a strong baseline on a new dataset that can be downloaded at: `http://goo.gl/language/query-wellformedness`. We also showed that question well-formedness information can be a helpful signal in improving state-of-the-art question generation systems.

Abstract

Deep neural networks reach state-of-the-art performance for wide range of natural language processing, computer vision and speech applications. Yet, one of the biggest challenges is running these complex networks on devices such as mobile phones or smart watches with tiny memory footprint and low computational capacity. We propose on-device Self-Governing Neural Networks (SGNNs), which learn compact projection vectors with local sensitive hashing. The key advantage of SGNNs over existing work is that they surmount the need for pre-trained word embeddings and complex networks with huge parameters. We conduct extensive evaluation on dialog act classification and show significant improvement over state-of-the-art results. Our findings show that SGNNs are effective at capturing low-dimensional semantic text representations, while maintaining high accuracy.

1 Introduction

Deep neural networks are one of the most successful machine learning methods outperforming many state-of-the-art machine learning methods in natural language processing (Sutskever et al., 2014), speech (Hinton et al., 2012) and visual recognition tasks (Krizhevsky et al., 2012). The availability of high performance computing has enabled research in deep learning to focus largely on the development of deeper and more complex network architectures for improved accuracy. However, the increased complexity of the deep neural networks has become one of the biggest obstacles to deploy deep neural networks on-device such as mobile phones, smart watches and IoT (Iandola et al., 2016). The main challenges with developing and deploying deep neural network models on-device are (1) the tiny memory footprint, (2) inference latency and (3) significantly low computational capacity compared to high performance computing systems such as CPUs, GPUs and TPUs on the cloud.

There are multiple strategies to build lightweight text classification models for on-device. One can create a small dictionary of common *input* → *category* mapping on the device and use a naive look-up at inference time. However, such an approach does not scale to complex natural language tasks involving rich vocabularies and wide language variability. Another strategy is to employ fast sampling techniques (Ahmed et al., 2012; Ravi, 2013) or incorporate deep learning models with graph learning like (Bui et al., 2017, 2018), which result in large models but have proven to be extremely powerful for complex language understanding tasks like response completion (Pang and Ravi, 2012) and Smart Reply (Kannan et al., 2016).

In this paper, we propose Self-Governing Neural Networks (SGNNs) inspired by projection networks (Ravi, 2017). SGNNs are on-device deep learning models learned via embedding-free projection operations. We employ a modified version of the locality sensitive hashing (LSH) to reduce input dimension from millions of unique words/features to a short, fixed-length sequence of bits. This allows us to compute a projection for an incoming text very fast, on-the-fly, with a small memory footprint on the device since we do not need to store the incoming text and word embeddings. We evaluate the performance of our SGNNs on Dialogue Act classification, because (1) it is an important step towards dialog interpretation and conversational analysis aiming to understand the intent of the speaker at every utterance of the conversation and (2) deep learning methods reached state-of-the-art (Lee and Dernoncourt, 2016; Khanpour et al., 2016; Tran et al., 2017; Ortega and Vu, 2017).

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 804–810
Brussels, Belgium, October 31 - November 4, 2018.

The main contributions of the paper are:

- Novel Self-Governing Neural Networks (SGNNs) for on-device deep learning for short text classification.

- Compression technique that effectively captures low-dimensional semantic text representation and produces compact models that save on storage and computational cost.

- On the fly computation of projection vectors that eliminate the need for large pre-trained word embeddings or vocabulary pruning.

- Exhaustive experimental evaluation on dialog act datasets, outperforming state-of-the-art deep CNN (Lee and Dernoncourt, 2016) and RNN variants (Khanpour et al., 2016; Ortega and Vu, 2017).

2 Self-Governing Neural Networks

We model the Self-Governing network using a *projection* model architecture (Ravi, 2017). The *projection* model is a simple network with dynamically-computed layers that encodes a set of efficient-to-compute operations which can be performed directly on device for inference. The model defines a set of efficient "projection" functions $\mathbb{P}(\vec{x}_i)$ that project each input instance $\vec{x}_i$ to a different space $\Omega_{\mathbb{P}}$ and then performs learning in this space to map it to corresponding outputs y_i^p. A very simple projection model comprises just few operations where the inputs $\vec{x}_i$ are transformed using a series of T projection functions $\mathbb{P}^1, ..., \mathbb{P}^T$ followed by a single layer of activations.

2.1 Model Architecture

In this work, we design a Self-Governing Neural Network (SGNN) using multi-layered locality-sensitive projection model. Figure 1 shows the model architecture of the on-device SGNN network. The *self-governing* property of this network stems from its ability to learn a model (e.g., a classifier) without having to initialize, load or store any feature or vocabulary weight matrices. In this sense, our method is a truly **embedding-free** approach unlike majority of the widely-used state-of-the-art deep learning techniques in NLP whose performance depends on embeddings pre-trained on large corpora. Instead, we use the projection functions to dynamically transform each input to a low-dimensional representation. Furthermore, we stack this with additional layers and non-linear activations to achieve deep, non-linear combinations of projections that permit the network to learn complex mappings from inputs x_i to outputs y_i. An SGNN network is shown below:

$$\begin{aligned} i_p &= [\mathbb{P}^1(x_i), ..., \mathbb{P}^T(x_i)] && (1) \\ h_p &= \sigma(W_p \cdot i_p + b_p) && (2) \\ h_t &= \sigma(W_t \cdot h_{t-1} + b_t) && (3) \\ y_i &= \texttt{softmax}(W_o \cdot h_k + b_o) && (4) \end{aligned}$$

where, i_p refers to the output of projection operation applied to input x_i, h_p is applied to projection output, h_t is applied at intermediate layers of the network with depth k followed by a final `softmax` activation layer at the top. In a k-layer SGNN, h_t, where $t = p, p+1, ..., p+k-1$ refers to the k subsequent layers after the projection layer. W_p, W_t, W_o and b_p, b_t, b_o represent trainable weights and biases respectively.

The projection transformations use pre-computed parameterized functions, i.e., they are not trained during the learning process, and their outputs are concatenated to form the hidden units for subsequent operations. Each input text x_i is converted to an intermediate feature vector (via raw text features such as skip-grams) followed by projections.

$$x_i \xrightarrow{\mathbb{F}} \vec{x}_i \xrightarrow{\mathbb{P}} [\mathbb{P}^1(x_i), ..., \mathbb{P}^T(x_i)] \quad (5)$$

On-the-fly Computation. The transformation step $\mathbb{F}$ dynamically extracts features from the raw input. Text features (e.g., skip-grams) are converted into feature-ids f_j (via hashing) to generate a sparse feature representation $\vec{x}_i$ of feature-id, weight pairs (f_j, w_j) . This intermediate feature representation is passed through projection functions $\mathbb{P}$ to construct projection layer i_p in SGNN. For this last step, a projection vector $\mathbb{P}^k$ is first constructed on-the-fly using a hash function with feature ids f_j in $\vec{x}_i$ and fixed seed as input, then dot product of the two vectors $< \vec{x}_i, \mathbb{P}^k >$ is computed and transformed into binary representation $\mathbb{P}^k(\vec{x}_i)$ using $sgn(.)$ of the dot product.

As shown in Figure 1, both $\mathbb{F}$ and $\mathbb{P}$ steps are computed on-the-fly, i.e., no word-embedding or vocabulary/feature matrices need to be stored and looked up during training or inference. Instead feature-ids and projection vectors are dynamically computed via hash functions. For intermediate feature weights w_j, we use observed counts in

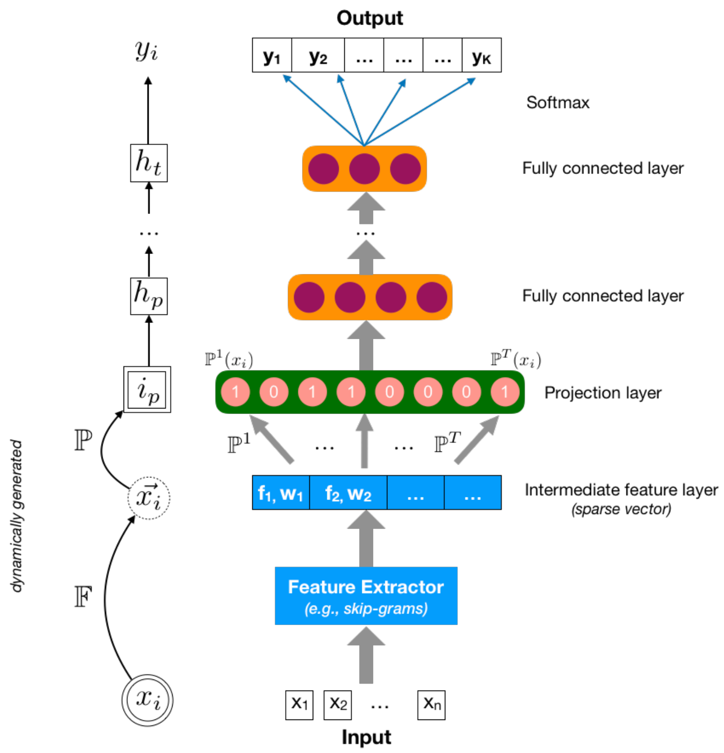

Figure 1: Self-Governing Neural Network (SGNN) architecture.

each input text and do not use pre-computed statistics like idf. Hence the method is embedding-free.

Model Optimization. The SGNN network is trained from scratch on the task data using a supervised loss defined wrt ground truth $\hat{y}_i$:

$$\mathcal{L}(.) = \sum_{i \in N} \texttt{cross} - \texttt{entropy}(y_i, \hat{y}_i) \quad (6)$$

During training, the network learns to choose and apply specific projection operations $\mathbb{P}^j$ (via activations) that are more predictive for a given task. The choice of the type of projection matrix $\mathbb{P}$ as well as representation of the projected space $\Omega_{\mathbb{P}}$ has a direct effect on computation cost and model size. We leverage an efficient randomized projection method and use a binary representation $\{0,1\}^d$ for $\Omega_{\mathbb{P}}$. This yields a drastically lower memory footprint both in terms of number and size of parameters.

Computing Projections. We employ an efficient randomized projection method for the projection step. We use locality sensitive hashing (LSH) (Charikar, 2002) to model the underlying projection operations in SGNN. LSH is typically used as a dimensionality reduction technique for clustering (Manning et al., 2008). LSH allows us to project similar inputs $\vec{x}_i$ or intermediate network layers into hidden unit vectors that are nearby in metric space. We use repeated binary hashing for $\mathbb{P}$ and apply the projection vectors to transform the input $\vec{x}_i$ to a binary hash representation denoted by $\mathbb{P}_k(\vec{x}_i) \in \{0,1\}$, where $[\mathbb{P}_k(\vec{x}_i)] := sgn[\langle \vec{x}_i, \mathbb{P}_k \rangle]$. This results in a d-bit vector representation, one bit corresponding to each projection row $\mathbb{P}_{k=1...d}$.

The same projection matrix $\mathbb{P}$ is used for training and inference. We never need to explicitly store the random projection vector $\mathbb{P}_k$ since we can compute them on the fly using hash functions over feature indices with a fixed row seed rather than invoking a random number generator. This also permits us to perform projection operations that are linear in the *observed* feature size rather than the *overall* feature or vocabulary size which can be prohibitively large for high-dimensional data, thereby saving both memory and computation cost. Thus, SGNN can efficiently model high-dimensional sparse inputs and large vocabulary sizes common for text applications instead of relying on feature pruning or other pre-processing heuristics employed to restrict input sizes in standard neural networks for feasible training. The binary representation is significant since this results in a significantly compact representation for the *projection* network parameters that in turn considerably reduces the model size.

SGNN Parameters. In practice, we employ T different projection functions $\mathbb{P}^{j=1...T}$, each resulting in d-bit vector that is concatenated to form the projected vector i_p in Equation 5. T and d vary depending on the *projection* network parameter configuration specified for $\mathbb{P}$ and can be tuned to trade-off between prediction quality and model size. Note that the choice of whether to use a single projection matrix of size $T \cdot d$ or T separate matrices of d columns depends on the type of projection employed (dense or sparse). For the intermediate feature step $\mathbb{F}$ in Equation 5, we use skip-gram features (3-grams with skip-size=2) extracted from raw text.

2.2 Training and Inference

We use the compact bit units to represent the *projection* in SGNN. During training, the network learns to move the gradients for points that are nearby to each other in the projected bit space $\Omega_{\mathbb{P}}$ in the same direction. SGNN network is trained end-to-end using backpropagation. Training can progress efficiently with stochastic gradient descent with distributed computing on high-performance CPUs or GPUs.

Complexity. The overall complexity for SGNN inference, governed by the projection layer, is $O(n \cdot T \cdot d)$, where n is the observed feature size (*not* overall vocabulary size) which is linear in input size, d is the number of LSH bits specified for each projection vector $\mathbb{P}_k$, and T is the number of projection functions used in $\mathbb{P}$. The model size (in terms of number of parameters) and memory storage required for the *projection* inference step is $O(T \cdot d \cdot C)$, where C is the number of hidden units in h_p in the multi-layer projection network and typically smaller than $T \cdot d$.

3 Datasets and Experimental Setup

3.1 Data Description

We conduct our experimental evaluation on two dialog act benchmark datasets.

- **SWDA:** Switchboard Dialog Act Corpus (Godfrey et al., 1992; Jurafsky et al., 1997) is a popular open domain dialogs corpus between two speakers with 42 dialogs acts.
- **MRDA:** ICSI Meeting Recorder Dialog Act Corpus (Adam et al., 2003; Shriberg et al., 2004) is a dialog corpus of multiparty meetings with 5 tags of dialog acts.

Datasets	Class	Vocab.	Train	Validation	Test
SwDA	42	20K	193K	23K	5K
MRDA	5	12K	78K	16K	15K

Table 1: Dialog Act Datasets Statistics

Table 1 summarizes dataset statistics. We use the train, validation and test splits as defined in (Lee and Dernoncourt, 2016; Ortega and Vu, 2017).

3.2 Experimental Setup

We setup our experimental evaluation, as follows: given a classification task and a dataset, we generate an on-device model. The size of the model can be configured (by adjusting the projection matrix $\mathbb{P}$) to fit in the memory footprint of the device, i.e. a phone has more memory compared to a smart watch. For each classification task, we report $Accuracy$ on the test set.

3.3 Hyperparameter and Training

For both datasets we used the following: 2-layer SGNN ($\mathbb{P}_{T=80,d=14} \times \text{FullyConnected}_{256} \times \text{FullyConnected}_{256}$), mini-batch size of 100, dropout rate of 0.25, learning rate was initialized to 0.025 with cosine annealing decay (Loshchilov and Hutter, 2016). Unlike prior approaches (Lee and Dernoncourt, 2016; Ortega and Vu, 2017) that rely on pre-trained word embeddings, we learn the projection weights on the fly during training, i.e word embeddings (or vocabularies) do not need to be stored. Instead, features are computed on the fly and are dynamically compressed via the projection matrices into projection vectors. These values were chosen via a grid search on development sets, we do not perform any other dataset-specific tuning. Training is performed through stochastic gradient descent over shuffled mini-batches with Nesterov momentum optimizer (Sutskever et al., 2013), run for 1M steps.

4 Results

Tables 2 and 3 show results on the SwDA and MRDA dialog act datasets. Overall, our SGNN model consistently outperforms the baselines and prior state-of-the-art deep learning models.

4.1 Baselines

We compare our model against a majority class baseline and Naive Bayes classifier (Lee and Dernoncourt, 2016). Our model significantly outperforms both baselines by 12 to 35% absolute.

4.2 Comparison against State-of-art Methods

We also compare our performance against prior work using HMMs (Stolcke et al., 2000) and recent deep learning methods like CNN (Lee and Dernoncourt, 2016), RNN (Khanpour et al., 2016) and RNN with gated attention (Tran et al., 2017).

To the best of our knowledge, (Lee and Dernoncourt, 2016; Ortega and Vu, 2017; Tran et al., 2017) are the latest approaches in dialog act classification, which also reported on the same data splits. Therefore, we compare our research against these works. According to (Ortega and Vu, 2017), prior work by (Ji and Bilmes, 2006) achieved promising results on the MRDA dataset, but since the evaluation was conducted on a different data split, it is hard to compare them directly.

For both SwDA and MRDA datasets, our SGNNs obtains the best result of 83.1 and 86.7 accuracy outperforming prior state-of-the-art work. This is very impressive given that we work with very small memory footprint and we do not rely on pre-trained word embeddings. Our study also shows that the proposed method is very effective for such natural language tasks compared to more complex neural network architectures such as deep CNN (Lee and Dernoncourt, 2016) and RNN variants (Khanpour et al., 2016; Ortega and Vu, 2017). We believe that the compression techniques like locality sensitive projections jointly coupled with non-linear functions are effective at capturing low-dimensional semantic text representations that are useful for text classification applications.

4.3 Discussion on Model Size and Inference

LSTMs have millions of parameters, while our on-device architecture has just 300K parameters (order of magnitude lower). Most deep learning methods also use large vocabulary size of 10K or higher. Each word embedding is represented as 100-dimensional vector leading to a storage requirement of $10,000 \times 100$ parameter weights just in the first layer of the deep network. In contrast, SGNNs in all our experiments use a fixed 1120-dimensional vector regardless of the vocabulary or feature size, dynamic computation results in further speed up for high-dimensional feature spaces. This amounts to a huge savings in storage and computation cost wrt FLOPs (floating point operations per second).

Method	Acc.
Majority Class (baseline) (Ortega and Vu, 2017)	33.7
Naive Bayes (baseline) (Khanpour et al., 2016)	47.3

5 Conclusion

We proposed Self-Governing Neural Networks for on-device short text classification. Experiments on multiple dialog act datasets showed that our model outperforms state-of-the-art deep leaning methods (Lee and Dernoncourt, 2016; Khanpour et al., 2016; Ortega and Vu, 2017). We introduced a compression technique that effectively captures low-dimensional semantic representation and produces compact models that significantly save on storage and computational cost. Our approach does not rely on pre-trained embeddings and efficiently computes the projection vectors on the fly. In the future, we are interested in extending this approach to more natural language tasks. For instance, we built a multilingual SGNN model for customer feedback classification (Liu et al., 2017) and obtained 73% on Japanese, close to best performing system on the challenge (Plank, 2017). Unlike their method, we did not use any pre-processing, tagging, parsing, pre-trained embeddings or other resources.

Acknowledgments

We would like to thank the anonymous reviewers for their valuable feedback and suggestions.

Abstract

We focus on the multi-label categorization task for short texts and explore the use of a hierarchical structure (HS) of categories. In contrast to the existing work using non-hierarchical flat model, the method leverages the hierarchical relations between the categories to tackle the data sparsity problem. The lower the HS level, the worse the categorization performance. Because lower categories are fine-grained and the amount of training data per category is much smaller than that in an upper level. We propose an approach which can effectively utilize the data in the upper levels to contribute categorization in the lower levels by applying a Convolutional Neural Network (CNN) with a fine-tuning technique. The results using two benchmark datasets show that the proposed method, Hierarchical Fine-Tuning based CNN (HFT-CNN) is competitive with the state-of-the-art CNN based methods.

1 Introduction

Short text categorization is widely studied since the recent explosive growth of online social networking applications (Song et al., 2014). In contrast with documents, short texts are less topic-focused in texts. Major attempts to tackle the problem is to expand short texts with knowledge extracted from the textual corpus, machine-readable dictionaries, and thesauri (Phan et al., 2008; Wang et al., 2008; Chen et al., 2011; Wu et al., 2012). However, because of domain-independent nature of dictionaries and thesauri, it is often the case that the data distribution of the external knowledge is different from the test data collected from some specific domain, which deteriorates the overall performance of categorization. A methodology which maximizes the impact of pre-defined domains/categories is needed to improve categorization performance.

More recently, many authors have attempted to apply deep learning techniques including CNN (Wang et al., 2015; Zhang and Wallace, 2015; Zhang et al., 2017; Wang et al., 2017), the attention based CNN (Yang et al., 2016), bag-of-words based CNN (Johnson and Zhang, 2015a), and the combination of CNN and recurrent neural network (Lee and Dernoncourt, 2016; Zhang et al., 2016) to text categorization. Most of them demonstrated that neural network models are powerful for learning features from texts, while they focused on single-label or a few labels problem. Several efforts have been made to multi-labels (Johnson and Zhang, 2015b; Liu et al., 2017). Liu *et al.* explored a family of new CNN models which are tailored for extreme multi-label classification (Liu et al., 2017). They used a dynamic max pooling scheme, a binary cross-entropy loss, and a hidden bottleneck layer to improve the overall performance. The results by using six benchmark datasets where the label-set sizes are up to 670K showed that their method attained at the best or second best in comparison with seven state-of-the-art methods including FastText (Joulin et al., 2017) and bag-of-words based CNN (Johnson and Zhang, 2015a). However, all of these attempts aimed at utilizing a large volume of data.

We address the problem of multi-label short text categorization and explore the use of a HS of categories. The lower level of categories are fine-grained compared to the upper level of categories. Moreover, it is often the case that the amount of training data in a lower level is much smaller than that in an upper level which deteriorates the overall performance of categorization. We propose an approach which can effectively utilize the data in the upper levels to contribute categorization in lower levels by applying fine-tuning to the CNN which can learn a HS of categories and incorporate

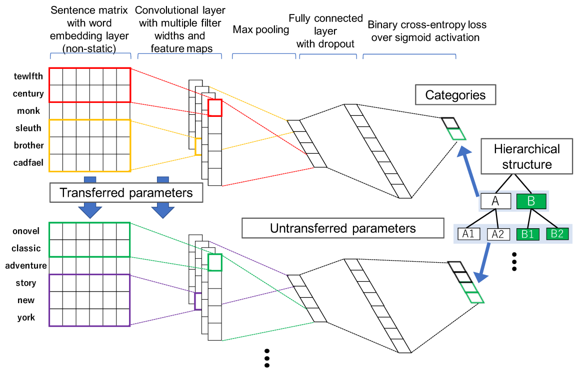

Figure 1: HFT-CNN model

granularity of categories into categorization. We transferred the parameters of CNN trained from upper to lower levels according to the HS, and finely tuned parameters. The main contributions of our work can be summarized: (1) We propose a method that maximizes the impact of pre-defined categories to alleviate data sparsity in multi-label short texts. (2) We empirically examined a fine-tuning with CNN that fits to learn a HS of categories defined by lexicographers, and (3) The results show that our method is competitive to the state-of-the-art CNN based methods by using two benchmark datasets, especially it is effective for categorization of short texts consisting of a few words with a large number of labels.

2 Hierarchical Fine-Tuning based CNN

2.1 CNN architecture

Similar to other CNN (Johnson and Zhang, 2015a; Liu et al., 2017), our HFT-CNN model shown in Figure 1 is based on (Kim, 2014). Let $\mathbf{x}_i \in \mathbb{R}^k$ be the k-dimensional word vector with the i-th word in a sentence obtained by applying skip-gram model provided in fastText[1]. A sentence with length n is represented as $\mathbf{x}_{1:n} = [\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_n] \in \mathbb{R}^{nk}$. A convolution filter $\mathbf{w} \in \mathbb{R}^{hk}$ is applied to a window size of h words to produce a new feature, $c_i = f(\mathbf{w} \cdot \mathbf{x}_{i:i+h-1} + b)$ where $b \in \mathbb{R}$ indicates a bias term and f refers to a non-linear activation function. We applied this convolution filter to each possible window size in the sentence and obtained a feature map, $m \in \mathbb{R}^{n-h+1}$. As shown in Figure 1, we then apply a max pooling operation over the feature map and obtain the maximum value $\hat{m}$ as a feature of this filter. We obtained multiple filters by varying window sizes and multiple features. These features form a pooling layer and are passed to a fully connected layer. In the fully connected layer, we applied dropout (Hinton et al., 2012). The dropout randomly sets values in the layer to 0. Finally, we obtained the probability distribution over categories. The network is trained with the objective that minimizes the binary cross-entropy (BCE) of the predicted distributions and the actual distributions by performing stochastic gradient descent.

2.2 Hierarchical structure learning

Our key idea is to use a fine-tuning technique in CNN to tackle the data sparsity problem, especially a lower level of a HS. Following a HS, we transferred the parameters of CNN trained in the upper levels to the lower levels which are worse trained because of the lack of data, and then finely tuned parameters of CNN for lower levels (Figure 1). This approach can effectively utilize the data in the upper levels to contribute categorization in the lower levels.

Fine-tuning is motivated by the observation that the earlier features of CNN contain more generic features that should be effective for many tasks, but later layers of the CNN becomes progressively more specific to the details of the classes contained in the original dataset. The motivation is identical to a HS of categories as we first learn to distinguish among generic categories at the upper level of a hierarchy, then learns lower level distinctions by using only within the appropriate top level of the HS. We note that fine-tuning the last few layers are usually sufficient for transfer learning as the last few layers become more specific features. However, the HS consisting of deep level needs to fine-tune the early layers as well because the distance between the upper and lower level of categories is significant. For this reason, we transferred two layers shown in Figure 1, i.e., a layer obtained by word embedding and the convolutional layer. We used them as an initial parameter to learn the second level of a hierarchy. We repeated this procedure from the top level to the bottom level of a hierarchy. We note that a HS consists of many levels. We fine-tune between adjacent layers only because they are more correlated with each other compared to distant layers.

2.3 Multi-label categorization

Each test instance is classified into categories with probabilities/scores by applying HFT-CNN. We

Dataset	#L	Tr	Te	C
RCV1	4	23,149	781,265	103
Amazon670K	9	490,449	153,025	670,091

Table 1: Data Statistics: #L shows the depth of a hierarchy. Tr and Te refer to the # of training and test data, respectively. C indicates the total # of categories.

then utilize a constraint of a HS to obtain final results which differs from the existing work on non-hierarchical flat model (Johnson and Zhang, 2015a; Liu et al., 2017). This is done by using two scoring functions: One is a Boolean Scoring Function (BSF). Another is a Multiplicative Scoring Function (MSF). Both functions set a threshold value and categories whose scores exceed the threshold value are considered for selection. The difference is that BSF has a constraint that a category can only be selected if its ancestor categories are selected. MSF does not have such a constraint, i.e., we extracted all the categories whose scores exceeded the threshold value and sorted them in descending order as the system's assignments.

3 Experiments

3.1 Data and HFT-CNN model setting

We selected two benchmark datasets having a HS from the extreme classification repository[2]: RCV1 (Lewis et al., 2004) and Amazon670K (Leskovec and Krevl, 2015). All the documents in RCV1 and item descriptions in Amazon670K are tagged by using Tree Tagger (Schmid, 1995). We used nouns, verbs, and adjectives. We then applied fastText. Each dataset has an official training and test sets. We used each fold in the experiments. We choose titles from the training and test set on RCV1. The maximum number of words in the title was 13 words. Each text of Amazon670K consists of a product name and its item description. We extracted the first 13 words from each item description and used them in the experiments. Table 1 presents the statistics on the datasets. We divided the training data into two folds; we used 5% to tuning the parameters, and the remains to train the models. Our model setting is shown in Table 2[3]. In the experiments, we run three times for each model and obtained the averaged performance.

3.2 Evaluation Metrics

We used the standard F1 measure. Furthermore, we evaluated our method by two rank-based evaluation metrics: the precision at top k, P@k and the Normalized Discounted Cumulated Gains, NDCG@k which are commonly used for comparing extreme multi-label classification methods (Liu et al., 2017). We calculated P@k and NDCG@k for each test data and then obtained an average over all the test data.

3.3 Basic results

We compared HFT-CNN with a method which has hierarchical-based categorization but without fine-tuning (WoFT-CNN) and Flat model to examine the effect of the fine-tuning. WoFT-CNN shows that we independently trained parameters of CNN for each level and trained parameters are not transferred. Flat means that we simply applied our CNN model. The results are shown in Table 3. The HFT-CNN is better than WoFT-CNN and Flat model except for Micro-F1 obtained by WoFT-CNN(M) in Amazon670K. We also found that the overall results obtained by MSF were better to those obtained by BSF.

3.4 Comparison with state-of-the-art method

We chose XML-CNN as a comparative method because their method attained at the best or second best compared to the seven existing methods in six benchmark datasets (Liu et al., 2017). Original XML-CNN is implemented by using Theano[4], while we implemented HFT-CNN by Chainer[5]. In order to avoid the influence of differences in libraries, we implemented XML-CNN by Chainer and compared it with HFT-CNN. We used the author-provided implementation in Chainer's version of XML-CNN. We recall that we set convolutional filters with the window sizes to (2,3,4) and the stride size to 1 because of short text. To make a fair comparison, we also evaluated XML-CNN with the same window sizes and stride size as HFT-CNN.

Liu et al. evaluated their method by using P@k and NDCG@k. We used their metrics as well as F1 measure. We did not set a threshold value on BSF and MSF when we evaluated by using these metrics, but instead, we used a ranked list of cate-

P@5	**51.09**	∗50.84	49.93	49.75
G@1	**86.54**	85.39	84.62	84.12
G@3	**76.26**	75.05	74.50	74.13
G@5	**72.84**	71.46	70.99	70.74

Table 4: Comparative results: "1" and "2" of XML show the stride size=1 and 2 by XML-CNN, respectively. "G" stands for NDCG.

gories assigned to the test instance. The results are shown in Table 4. HFT-CNN with BSF/MSF has the best scores with statistical significance compared to both of the XML-CNNs. On RCV1, HFT-CNN(B) in P@1 and NDCG@1 were worse than XML-CNN(1), while HFT-CNN(M) with the same metrics were statistically significant compared to XML-CNN(1). This is not surprising because hierarchical fine-tuning does not contribute to the accuracy at the top level as the trained parameters on the top level have not changed in the level.

We also examined the affection on each system performance by the depth of a hierarchical structure. Figure 2 shows Micro-F1 at each hierarchical level. The deeper the hierarchical level, the worse the system's performance. However, HFT-CNN is still better than XML-CNNs. The improvement by MSF was 1.00 $\sim$ 1.34% by Micro-F1 and 3.77 $\sim$ 10.07% by Macro-F1 on RCV1. On Amazon670K, the improvement was 1.10 $\sim$ 9.26% by Micro-F1 and 1.10 $\sim$ 3.60% by Macro-F1. This shows that hierarchical fine-tuning fits to learn the hierarchical category structure.

We recall that we focused on the multi-label problem. Figures 3 illustrates Micro-F1 and Macro-F1 against the number of categories per short text. We can see from RCV1 in Figure 3 that Micro-F1 obtained by HFT-CNN and XML-CNNs were not statistically significant difference in the number of categories, while Macro-F1 by HFT-CNN except for the number of 13 categories was constantly better to XML-CNNs. On Amazon670K data, when the number of categories assigned to the short text is less than 38, HFT-CNN was better than XML-CNNs or HFT-CNN was not statistically significant compared to XML-CNNs by both F1-scores. However, when it exceeds 39, HFT-CNN was worse than XML-CNNs. One possible reason is the use of BSF: a category can only be selected if its ancestor categories are selected. Therefore, once the test data could not be classified into categories correctly, their child categories also cannot be correctly assigned to the test data. In contrast, as shown in Figure 5, HFT-CNN by MSF was better than XML-CNNs in both Micro and Macro F1 even in the deep level of a hierarchy. From the observations, a robust scoring function is needed for further improvement.

It is important to note that how the ratio of training data affects the overall performance as we focused on the data sparsity problem. Figure

(a) Micro-F1 (RCV1) (b) Macro-F1 (RCV1) (c) Micro-F1 (Amazon670K) (d) Macro-F1 (Amazon670K)

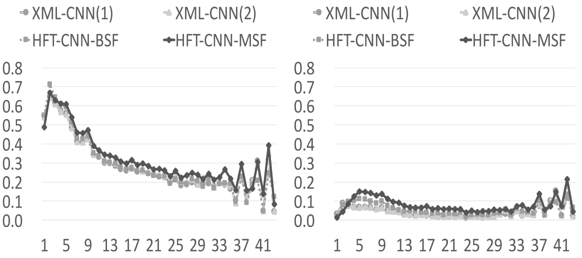
Figure 4: Performance against a ratio of the training data



(a) Micro-F1 (Amazon670K) (b) Macro-F1 (Amazon670K)

Figure 5: Performance against the # of categories per short text: Comparison with HFT-CNN by MSF and other methods

4 shows Micro and Macro-F1 against a ratio of the training data. Overall, the curves show that more training helps the performance, while the curves obtained by HFT-CNN drop slowly compared to other methods in both datasets and evaluation metrics. From the observations mentioned in the above, we can conclude that fine-tuning works well, especially in the cases that the number of the training data per category is small.

4 Conclusion

We have presented an approach to multi-label categorization for short text. The comparative results with XML-CNN showed that HFT-CNN is competitive, especially for the cases that there exists only a small amount of training data. Future work will include: (i) incorporating lexical semantics such as named entities and domain-specific senses for further improvement, (ii) extending the method to utilize label dependency constraints (Bi and Kwok, 2011), and (iii) improving the accuracy of the top ranking categories to deal with P@1 and NDCG@1 metrics.

Abstract

Deep neural networks have been displaying superior performance over traditional supervised classifiers in text classification. They learn to extract useful features automatically when sufficient amount of data is presented. However, along with the growth in the number of documents comes the increase in the number of categories, which often results in poor performance of the multiclass classifiers. In this work, we use external knowledge in the form of topic category taxonomies to aide the classification by introducing a deep hierarchical neural attention-based classifier. Our model performs better than or comparable to state-of-the-art hierarchical models at significantly lower computational cost while maintaining high interpretability.

1 Introduction

A large number of documents are being generated all over the world everyday, and as a result automatic text classification has become an essential tool for searching, retrieving, and managing the text (Allahyari et al., 2017). There has been an increasing trend in developing data-driven neural text classifiers (Collobert et al., 2011; Lai et al., 2015; Zhang et al., 2015; Yogatama et al., 2017; Conneau et al., 2017), due to their ability to handle large-scale corpora and their robustness in automatic feature extraction.

However, text classification has become increasingly challenging as the number of categories grows with continually expanding corpus. To alleviate this problem, one form of the external knowledge – class taxonomy – has been introduced to aid the classification in a hierarchical fashion (Koller and Sahami, 1997). In general, hierarchical classifiers can be categorized into two broad approaches: *local* (*top-down* and *bottom-up*) and *global* (or *big-bang*) (Silla and Freitas, 2011). The local approaches create a unique classifier for each parent node in the taxonomy (Liu et al., 2001; Quinn and Laier, 2006; Vens et al., 2008; Kowsari et al., 2017), while global approaches create a single classifier for the entire taxonomy (Silla Jr and Freitas, 2009).

Kowsari et al. (2017) recently proposed a hierarchical neural-based model called HDLTex, which displayed superior performance over traditional non-neural-based models with a top-down structure. However, HDLTex suffers the inherited disadvantage of the *top-down* approach: the number of sub-models grows exponentially with respect to the number of sub-trees. This is especially problematic in HDLTex, as it uses deep networks with a large number of parameters for the sub-models, and the combined model itself grows exponentially with the depth of taxonomy.

In contrast, we propose a unified *global* deep neural-based classifier that overcomes the problem of exploding models. The backbone of our approach is one encoder-decoder structure that sequentially predicts the class label of the next level, conditioned on a dynamic document representation obtained based on a variant of an attention mechanism (Bahdanau et al., 2015). The contribution of our paper is as follows:

1. We propose an end-to-end *global* neural attention-based model for hierarchical classification, which performs better than the state-of-the-art hierarchical classifier at lower computation cost.

2. We empirically show that the use of hierarchical taxonomy provides a robust classifier, by comparing with state-of-the-art flat classifiers.

Brussels, Belgium, October 31 - November 4, 2018.

2 Literature Review

Traditional text classification methods focus on selecting a good set of features (for example,TF-IDF (Salton and Buckley, 1987)) to represent the documents and employing non-linear classifiers such as SVM (Dumais et al., 1998; Joachims, 1999; Tong and Koller, 2001), decision trees (Apté et al., 1994), or Naive Bayes (McCallum et al., 1998; Kim et al., 2006) methods for text classification. More recent work has employed deep neural networks to merge feature extraction and classification into one joint process, where the model parameters can be learned through back-propagation (Xue et al., 2008; Lai et al., 2015; Zhang et al., 2015). A common theme in these convolutional neural networks (CNN)-based or recurrent neural network (RNN)-based approaches is to create a document representation from either the last hidden state of the RNN or via some pooling operations on all hidden states.

Furthermore, the attention mechanism (Bahdanau et al., 2015; Sutskever et al., 2014) has been adapted for these CNN/RNN structures for text classification (Lin et al., 2017), providing high interpretability and allowing us to inspect which parts of the text are discriminative for a particular sample.

In addition, external knowledge has been examined as a way to boost the performance of text classifiers (Collobert and Weston, 2008a; Ngiam et al., 2011; Howard and Ruder, 2018). One form of external knowledge is built on top of the hierarchical relations of the classes (Koller and Sahami, 1997), where a class taxonomy is used to improve the performance of the end-level classification[1]. Most of the hierarchical classifiers[2] perform classification by navigating through the hierarchy in *top-down* approaches (Liu et al., 2001; Quinn and Laier, 2006; Vens et al., 2008), where a local classifier is constructed at each parent node. The state-of-the-art hierarchical classifier HDLTex is proposed by Kowsari et al. (2017). It combines deep neural networks in the *top-down* fashion where a separate neural network (either CNN or RNN) is built at each parent node to classify its children.

3 Model

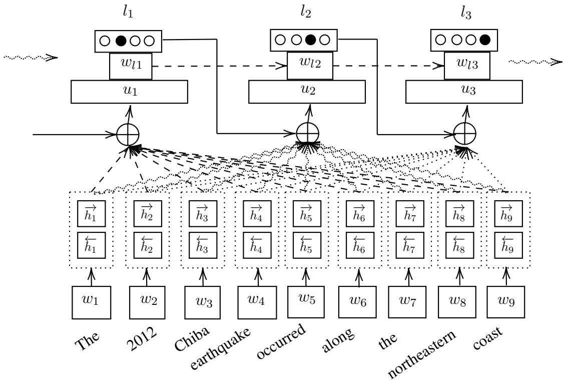

Figure 1: Proposed model architecture

Our proposed model (Figure 1) consists of three parts: 1) a bidirectional LSTM encoder (Hochreiter and Schmidhuber, 1997) that transforms each word into vector representations based on their context. 2) an attention module that helps to generate dynamic document representations across different level of classification, 3) multi-layer perceptron (MLP) classifiers at each level that makes the prediction of classes at that level based on the dynamically generated document representation and the level masking.

Our hierarchical classification model can be viewed as a sequence-to-sequence model, where a sequence of word embeddings is used to generate a sequence of hierarchical class labels. In addition, we employ a modified attention module from the traditional attention mechanism used in sequential generation tasks (Bahdanau et al., 2015; Sutskever et al., 2014). Instead of computing attention weights conditioned on the hidden state of the decoder at time step i, we condition on the parent category embedding c_{k-1}. This is intuitive in our setting as the document representation should depend on the parent class predicted by the model.

Formally, suppose we are given a document with n tokens $D = (w_1, w_2, ..., w_n)$ and its category labels of m levels $C = (c_1, \ldots, c_m), c_k \in \{c_1^{l_k}, \ldots, c_{s_k}^{l_k}\}$ where l_k indicates the k-th level of the class taxonomy and s_k represents the number of classes in level k [3]. A bidirectional LSTM is

---

[1] Classifiers that do not take into account the hierarchy and are only concerned with predicting the leaf nodes are termed *flat* classifiers in this work.

[2] We use the term "hierarchical classifiers" to refer the models that follow the external taxonomy of class labels, which is substantially different from hierarchical attention networks (Yang et al., 2016). In Yang et al. (2016), hierarchical attention networks refer to the hierarchical nature of their attention mechanism; the model attends to the sentences first and then attends to the words.

[3] We suppose w_i and c_i are word embeddings and class embedding respectively.

first used to extract features of the document:

$$\overrightarrow{h_t} = \overrightarrow{LSTM}(w_t, \overrightarrow{h_{t-1}}), \\ \overleftarrow{h_t} = \overleftarrow{LSTM}(w_t, \overleftarrow{h_{t+1}}). \tag{1}$$

The encoder's hidden states $H = (h_1, \ldots, h_n)$ are constructed by the concatenation of $(\overrightarrow{h_t})$ and $(\overleftarrow{h_t})$ as $h_i = [\overrightarrow{h_t}, \overleftarrow{h_t}]$.

When classifying the class label at level k, we first form contextual word features $\bar{H}_k$ by concatenating the previously predicted category embedding c_{k-1} (parent) with each of the encoder's outputs $H = (h_1, \ldots, h_n)$:

$$\bar{H}_k = H \oplus c_{k-1}. \tag{2}$$

Then, we transform these n vectors in $\bar{H}_k$ into n attention scores (scalars) through a series of linear and non-linear transformations:

$$a_k = \text{softmax}(w_{s2}\text{tanh}(W_{s_1}\bar{H}_k^T)). \tag{3}$$

As one single attention distribution might only focus on a specific component of the semantics in the document, we follow Lin et al. (2017)'s work to perform m hops of attention and form the multi-head attention matrix A_k $(m \times n)$. To encourage diversity over the multiple hops of the attention distributions, we employ the Frobenius norm penalty (Lin et al., 2017) $P = \left\| A_k A_k^\top - I \right\|_F^2$ to force the attention hops to focus on different aspects of the semantics.

The document representation for level k is obtained by multiplying the multi-head attention matrix and the contextual word features:

$$D_k = W_{s_3} A_k \bar{H}_k. \tag{4}$$

Finally, a two layered multi-layer perceptron (MLP) is employed to classify the category at level k:

$$d_k = \text{RELU}(W_D[D_k, d_k - 1]), \\ y_k = \text{softmax}(W_k d_k) \tag{5}$$

Normally, the softmax in Equation 5 is computed over all class labels across the entire taxonomy levels. This is not desirable when the taxonomy is deep and the number of classes is large. We solve this by employing a *level masking* technique where we mask out all the classes that are not in the current classification level k. The loss is then calculated as the joint cross entropy loss among all levels of the taxonomy: $l = \sum_{i=1}^{m} l_i$.

	DBpedia	WOS

Mean document length	106.9	200.7

Table 1: Dataset Comparison

4 Experimental Setup

Dataset Two datasets are used for our experiments: Web of Science (WOS) and DBpedia. Web of Science (WOS) is a hierarchical two-level taxonomy dataset that contains 46,985 documents collected from *Web of Science* (Reuters, 2012) by Kowsari et al. (2017). Despite its small size, WOS is used as a benchmark dataset for hierarchical classification as it provides the raw text for deep neural models to train on[4].

As deep learning models usually contain a large number of parameters that need to be learned, to prevent over-fitting (Lawrence et al., 1997; Srivastava et al., 2014) we usually need a large dataset to train upon. Thus, we curated a bigger dataset with hierarchical labels from Wikipedia meta information provider DBpedia[5]. Compared to WOS, our DBpedia dataset is larger in two aspects: the number of data instances and the number of hierarchical levels (Table 1). The DBpedia ontology was first used in Zhang et al. (2015) for flat text classification. We instead use the DBpedia ontology to construct a dataset with a three-level taxonomy of classes. In order to ensure enough documents per-class, we only extract leaf-classes with more than 200 documents. We also randomly subsample 3,000 documents per category to balance the number of leaf-level categories. This results in 381,025 documents in total, which we split into 90% for training (from which 10% were kept aside for validation) and 10% on testing, on which we report our classification metrics[6].

Baselines State-of-the-art *flat* classifiers such as FastText (Joulin et al., 2017), Bi-directional

---

[4] The LSHTC dataset (Partalas et al., 2015) has been widely used as a benchmark for hierarchical text classification. However, the raw texts are not available which makes it difficult to extract features for modern neural approaches. Instead, only the tf-idf vectors are provided as inputs with no option to retrieve the original text (even after consulting with the original authors we were unable to procure it).

Our model (34M params)	99.21	96.03	95.32	**93.72**	89.32	82.42	**77.46**

Table 2: Test accuracy on the WOS and DBpedia datasets. The flat baseline models are trained without the hierarchical taxonomy of classes and therefore only have results on the leaf-node classification.

LSTM with max/mean pooling (Collobert and Weston, 2008b; Lee and Dernoncourt, 2016) and the Structured Self-attentive classifier (Lin et al., 2017) are used for the comparison. We noticed that using the default hyperparameters of the Structured Self-attentive classifier with high attention hops ($m >= 8$) performed poorly compared to use just one attention hop ($m = 1$). Therefore, we reported the results of using one attention hop ($m = 1$) as our baselines for fair comparison. We also compare our classifier to the state-of-the-art hierarchical classifier HDLTex (Kowsari et al., 2017).

Hyperparameters We use 300-dimensional word embeddings which are randomly initialized and fine-tuned during training. Two-layer Bidirectional LSTM with 300 hidden units in each layer are employed. In the multi-head attention mechanism, we use 4 heads (hops) with 0.1 Frobenius norm penalty because it gives the best validation performance. The final fully-connected MLP layer W_D has 1200 hidden units. In addition, we add 0.4 dropout on BiLSTM layers and MLP layers to prevent over-fitting.

For optimization, we use the standard Adam optimizer (Kingma and Ba, 2014) with the learning rate of 0.001, weight decay of 10^{-4} and 10^{-6} for WOS and DBpedia, respectively. The gradients are clipped to 0.5 in order to prevent exploding gradients. All the results are obtained after 25 epochs of training. After every 10 epochs, we reduce the learning rate by half if the validation accuracy is not improving. We employ early-stopping to select the best model. In addition, a weighted loss function is utilized to balance the performance on under-represented classes.

Hierarchical Evaluation For evaluating hierarchical models, we present the *teacher-forcing* result on each level, such as l_1, l_2 and l_3. This indicates the per-level classification performance when we provide the true parent class to the classifier while predicting the next class. However, this is not desirable as during inference we should not have access to the correct parent class. Hence we also present the *Overall* score in Table 2, where the classifier uses its own prediction as the parent class.

5 Results

Our model is significantly better than the existing state-of-the-art hierarchical baseline (Table 2). Although, we also see that both hierarchical classifiers (ours and HDLTex) perform comparably with or slightly worse than the state-of-the-art flat classifiers in terms of accuracy. However, the robustness analysis we performed in Table 3 indicates that hierarchical models are more robust in their errors since most of the errors generated by hierarchical classifiers remain within the correct tree of the parent class, while flat classifiers do worse. For example, on WOS, 88.57% of all classified data by our hierarchical model is within the correct subtree compared to 85.56% for the flat classifier.

Classifier	Correct parent	Predicted parent
Flat classifier - BiLSTM Max Pooling	90.74	85.56
Hierarchical approach - Our model	93.03	88.57

Table 3: Robustness analysis of taxonomy on the WOS dataset. We compare the success rate of our model and the BiLSTM flat classifier. The success rate is defined as the number of times the predicted class is within the same subtree as the correct parent. We calculate this in two scenarios: 1. when the true parent class is manually provided, or *teacher-forced* (Correct parent), and 2. when the true parent class is predicted by our model (Predicted parent)

Interestingly, the class taxonomy seems to be more beneficial in boosting the performance of hierarchical classifiers on WOS than DBpedia. The hierarchical classifiers perform better on the

Figure 2: WOS dataset attention rereading per level. Highlighted words indicate the attented words. Stronger color denote higher focus of attention. We note that the attention spread becomes much more focused in Level 2 compared to its parent Level 1.

leaf-node level classification of WOS than that on DBpedia. We observe this behaviour due to the dataset of DBpedia being shorter in average length making it easier to classify for *flat* classifiers, hence hierarchical classifiers overfit on the training data.

In addition to the performance improvement on both datasets over HDLTex, our model takes significantly less time and resources to train, especially when the dataset is large in terms of the intermediate non-leaf nodes in the output taxonomy. As HDLTex needs to build one sub-classifier for each parent nodes, the number of sub-classifiers grows quickly. For example, there are 80 parent nodes in the taxonomy of the DBpedia dataset and HDLTex needs to build 80 RNNs, where each sub-classifier contains around 67 million parameters. As a consequence, we can barely fit the whole model of HDLTex on our CPU [7] because it requires 60 GB RAM to build these 80 deep neural networks.

6 Discussion

Analysis of Attention The intuition behind building dynamic document representations, using multiple attentions across different hierarchical levels, is to have a re-reading effect over the taxonomy. When we first encounter an article as humans, we tend to read it carefully, but on subsequent reads we can easily identify the key aspects of the article. We find in our exploratory experiments the attention vectors behave exactly the same. For the first level, the attention values are more spread out to help our classifier pick various important aspects of the article, but on the subsequent levels, the attention is more focused towards specific keywords for that subclass, as the example shown in Figure 2 [8]. We perform additional qualitative analysis of attention spread which is provided in Appendix.

7 Conclusion

In this work, we propose a light-weight neural-based hierarchical classifier that performs better than or comparable to the state-of-the-art hierarchical model at lower computation cost. Our model employs an adapted version of attention to represent documents dynamically through the hierarchy, which provides additional interpretability of the dynamic document representations. In addition, we demonstrate that the robustness of flat text classification can be improved by using external knowledge such as a hierarchical taxonomy. As a future direction, we will advance our model to automatically construct the hierarchical taxonomy in order to improve text classification with a large number of classes.

Acknowledgements

We thank Compute Canada and Calcul Quebec for providing the GPU compute resources. We would also express our appreciation to our sponsors, Pierre Arbour Foundation and FRQNT for supporting Koustuv Sinha and NSERC for supporting Yue Dong for this research.

---

[7] It is not possible to fit the entire model in one GPU as our best GPU has the RAM capacity of 12GB, one needs to have multiple GPU's and parallel execution for this task.

[8] We use the same visualization script as of Lin et al. (2017).

Labeled Anchors and a Scalable, Transparent, and Interactive Classifier

Jeffrey Lund, Stephen Cowley, Wilson Fearn, Emily Hales, Kevin Seppi

Abstract

We propose Labeled Anchors, an interactive and supervised topic model based on the anchor words algorithm (Arora et al., 2013). Labeled Anchors is similar to Supervised Anchors (Nguyen et al., 2014) in that it extends the vector-space representation of words to include document labels. However, our formulation also admits a classifier which requires no training beyond inferring topics, which means our approach is also fast enough to be interactive. We run a small user study that demonstrates that untrained users can interactively update topics in order to improve classification accuracy.

In this paper, we concern ourselves with the problem of interactive and transparent text classification. The value of such a classifier can be seen in the events shortly before the 2016 US presidential election when FBI Director James Comey notified Congress that the FBI had obtained emails from candidate Hillary Clinton's private email server which potentially contained state secrets. Nearly a week later, just two days before the election, Comey announced that nothing had been found in the emails that warranted prosecution. Many speculate that the timing of these announcements may have influenced the election.

There are times when the ability to quickly analyze large quantities of text is of critical importance. In the case of the Clinton emails, manual inspection appears to have been possible in one week's time, but there could have been less controversy if the emails had been categorized in a shorter period of time. Furthermore, in future cases the data may be too large for manual analysis.

While there are many text classification algorithms, none are both interactive and transparent at scale. We require interactivity because we would like to leverage human intuition to improve classification accuracy for a specific task. Transparency not only enables interactivity, but also allows users to inspect the classifier and gain confidence in the results.

Topic models such as Latent Dirichlet Allocation (or LDA) (Blei et al., 2003) aim to automatically distill large collections of documents into topics. These topics can be used to perform document classification (Rubin et al., 2012). Furthermore, work has been done to increase the human interpretability of topics (Mimno et al., 2011). Traditionally, topic models are graphical models which typically scale poorly to large data. A faster alternative is the Anchor Words algorithm, which relies on non-negative matrix factorization to infer topics (Arora et al., 2013). Ordinarily, this factorization is NP-Hard (Arora et al., 2012), but with certain separability assumptions related to "anchor" words which uniquely identify topics, the factorization is scalable.

The Interactive Topic Model (Hu et al., 2011) allows human knowledge to be injected into the model in order to shape the topics in some meaningful way. While this model does incorporate user feedback, it is not fast enough to be truly interactive. A more scalable alternative is Tandem Anchors, which allows users to specify anchor words in order to influence the resulting topics (Lund et al., 2017).

A separate line of topic modeling research deals with supervised topic modeling, which allows document labels to influence topic inference (Mcauliffe and Blei, 2008). The most recent work on supervised topic modeling is Supervised Anchors (Nguyen et al., 2014). This approach uses document labels to influence the selection of anchor words, which in turn affects the resulting topics. However, Supervised Anchors requires a

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 824–829
Brussels, Belgium, October 31 - November 4, 2018.

downstream classifier to be trained using topics as features.

Our main contribution combines the idea of Tandem Anchors with Supervised Anchors to produce text classification which is both interactive and transparent. Additionally, the mathematical approach we take to build this classification requires no training beyond inferring topics, unlike Supervised Anchors which requires both topic inference and significant additional time for training a downstream classifier. While Supervised Anchors requires the construction of an external classifier, our approach generates the classifier as part of topic inference. Consequently, our model is extremely fast and scalable compared to Supervised Anchors. We demonstrate that users are able to use our model to interactively improve document classification accuracy by manipulating topics.

1 Labeled Anchors

In this section we describe our approach, combining interactive and supervised topic modeling, which we call Labeled Anchors. We extend the Anchor Words algorithm (Arora et al., 2013) which takes as input a $V \times D$ matrix M of document-word counts and recovers a $V \times K$ matrix A of word probabilities conditioned by topic, where there are V word types, D documents, and K topics. Our approach extends this algorithm to incorporate L possible document labels.

1.1 Vanilla Anchor Words

In order to compute the topic-word matrix A, the Anchor Words algorithm uses a $V \times V$ cooccurrence matrix $\bar{Q}$. Each entry $\bar{Q}_{i,j}$ gives the conditional probability of word j occurring after observing word i in a document. Following Appendix D.1 of Arora et al. (2013), $\bar{Q}$ is obtained by row-normalizing Q, which in turn is constructed using

$$Q = \bar{M}\bar{M}^T - \hat{M} \qquad (1)$$

where $\bar{M}$ is a normalized version of the document-word matrix M giving equal weight to each document regardless of document length, and $\hat{M}$ accounts for words not cooccurring with themselves.

$\bar{Q}$ is a V-dimensional vector-space representation of each word and is used to compute a set of anchor words S. Each anchor word uniquely identifies a topic by having non-zero probability in one topic only. These anchors are computed using an adaptation of the Gram-Schmidt process from Arora et al. (2013). Once the set of anchor words S has been computed, we reconstruct the non-anchor words as a convex combination of the anchor word vectors. The coefficients of these combinations C are computed using exponentiated gradient descent to optimize

$$C_i = \underset{C_i}{argmin}\, D_{KL}(\bar{Q}_i || \sum_{k \in S} C_{i,k}\bar{Q}_k) \qquad (2)$$

where i is the ith word of the vocabulary, $\bar{Q}_i$ is the vector-space representation of word i, and $D_{KL}(\cdot||\cdot)$ is Kullback-Leibler divergence.[1]

Because the occurrence pattern of each anchor word throughout the documents must mirror that of the topic it anchors, each coefficient $C_{i,j}$ gives the conditional probability of topic j occurring given word i. This is the inverse conditioning we desire in the topic-word matrix A. We can therefore compute A using Bayes' Rule by multiplying the coefficient matrix C with the empirical probability of each word to get the probability of a word given a particular topic.

1.2 Vector-Space Representations

Supervised Anchors (Nguyen et al., 2014) augments $\bar{Q}$ by appending L additional columns to $\bar{Q}$ corresponding to the probability of words cooccurring with the L possible document labels. Because this augmented vector-space representation includes dimensions corresponding to document labels, both the anchor words and the resulting topics will reflect the document labels.

Our algorithm, called Labeled Anchors, also augments the vector-space representation to include the L document labels. However, we do not directly modify $\bar{Q}$. Instead, we treat the L possible document labels as words and pretend that we observe these label pseudowords directly in each labeled document; a graphical representation of this is shown below in Figure 1.[2]

Consequently, our document-word matrix M is a $(V + L) \times D$ matrix. The first V entries of each column of M give the word counts for a particular document. The last L entries are zero, except for the entry corresponding to the label of that document.

We then construct $\bar{Q}$ using Equation 1, obtaining an order $V + L$ square matrix. As with Su-

---

[1] Alternatively, we can use l^2-norm in place of KL-divergence.

[2] We could add multiple such words per label, but our preliminary experiments indicate that one per label is sufficient.

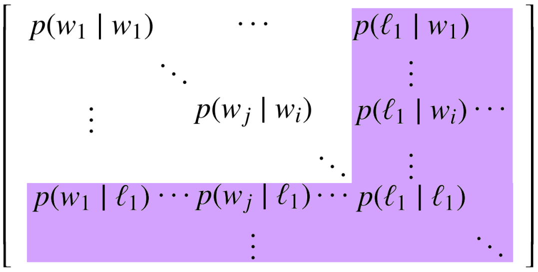

Figure 1: Labeled Anchors treats labels as observed words in each labeled documents and updates $\bar{Q}$ under this assumption, creating the additional rows and columns highlighted here.

pervised Anchors, these additional L dimensions guide anchor selection to include anchors which reflect the underlying document labels. When we use Equation 2 to compute C, we also obtain an additional L rows of coefficients which each correspond to the conditional probability of a topic given a label. Finally, the first V rows of A are computed using Bayes' Rule to give us the probability of words given topics.

Labeled Anchors inherits the run time characteristics of the original Anchor Words algorithm. As shown in Arora et al. (2013), topic recovery requires $O(KV^2 + K^2VT)$, where V is the size of the vocabulary, K is the number of anchors/topics, and T is the average number of iterations (typically around 100 in our experiments). Since $V \gg K$, adding any modest number of topics (less than 200) does not noticeably increase the runtime. Furthermore, since vocabulary size tends to grow logarithmically with respect to the size of the data (Heaps, 1978), this approach is scalable even for very large datasets.

1.3 Free Classifier

Note that once the cooccurrence matrix $\bar{Q}$ has been computed, the recovery of the topic-word matrix A scales with the size of the vocabulary, not the size of the data. However, Supervised Anchors requires topic assignments for each training document[3] for use as features for some downstream classifier. Therefore, the process of building a classifier scales linearly with the number of documents and can be time consuming compared to topic recovery.

In contrast, the formulation of Labeled Anchors allows us to construct a classifier with no additional training. To do so, rather than using LDA with fixed topics, we employ a simple model similar to Labeled LDA (Ramage et al., 2009) with the following generative story for an individual document containing N words:

1. Draw label $\ell \sim Cat(\lambda)$
2. For each $i \in [1, ..., N]$:
   (a) Draw topic assignment $z_i|\ell \sim Cat(\psi_l)$
   (b) Draw word $w_i|z_i \sim Cat(\phi_{z_i})$

The prior over document labels λ is simply the proportion of each label in the training data. We can estimate topic-label probabilities ψ using the last L rows of the coefficient matrix C, while the word-topic probabilities ϕ are the first V rows of A. Using these hyperparameters, we make predictions using the following:

$$\ell^* = \underset{\ell}{argmax}\ p(\ell|\mathbf{w}) = \underset{\ell}{argmax}\ p(\ell, \mathbf{w}) \quad (3)$$

$$= \underset{\ell}{argmax} \sum_{z_1=1}^{K} ... \sum_{z_N=1}^{K} p(\ell, \mathbf{z}, \mathbf{w}) \quad (4)$$

$$= \underset{\ell}{argmax}\ p(\ell) \prod_{i=1}^{N} \sum_{z_i=1}^{K} p(z_i|\ell) p(w_i|z_i) \quad (5)$$

$$= \underset{\ell}{argmax}\ \lambda_\ell \prod_{i=1}^{N} \sum_{z_i=1}^{K} \psi_{\ell,z_i} \phi_{z_i,w_i} \quad (6)$$

$$= \underset{\ell}{argmax}\ log\lambda_\ell + \sum_{i=1}^{N} log \left(\sum_{z_i=1}^{K} C_{\ell,z_i} A_{z_i,w_i} \right) \quad (7)$$

where Equation 4 unmarginalizes the probabilities across the word-topic assignments, Equation 5 uses the model's conditional independencies to expand and simplify the probabilities, Equation 6 explicitly uses the parameters from the generative model, and Equation 7 transitions to the matrix representations for these probabilities as found in Section 1.2. In Equation 7 we also switch to log space to mitigate numeric precision issues.

1.4 User Interaction

Assuming that $\bar{Q}$ is precomputed and fixed, Labeled Anchors is fast enough to allow interactive modification of the topics as well as interactive display of classification accuracy, even on large datasets. The final step to solving the problem of creating an interactive and transparent classifier is to allow users to inject domain specific knowledge

---

[3] This is typically done using LDA with fixed topics.

Table 1: Runtime for Labeled Anchors and Supervised Anchors on various subsets of Amazon product reviews. Labeled Anchors is dramatically faster than Supervised Anchors and scales to much larger datasets.

into the topic model. To do so, we use the idea of Tandem Anchors (Lund et al., 2017), which allows users to manually select sets of words to form anchors.

Ordinarily, anchor words can be somewhat inscrutable to human users. Because anchor words must uniquely identify topics, good anchors are typically esoteric low-to-mid frequency words. Intuitive, high frequency words usually appear in multiple topics. However, if we examine Equation 2, we can see that the anchor words are just points in V-dimension space; they do not actually have to correspond to any particular word so long as that point in space uniquely identifies a topic.

Tandem Anchors allows multiple words to form a single anchor pseudoword by computing the element-wise harmonic mean of a set of words. Since the harmonic mean tends towards the lowest values, the resulting pseudoword anchor largely ignores superfluous cooccurrence patterns in the constituent words. Consequently, while individual words forming the anchor may be ambiguous, users can combine multiple ambiguous words to intuitively express a single coherent idea.

2 Experimental Results

Before running a user study to validate that Labeled Anchors works as an interactive and transparent classifier, we first run a synthetic experiment to determine the runtime characteristics of our algorithm. We take subsets of a large collection of Amazon reviews[4] to produce datasets of various sizes. Using this data, we compare the runtime of Labeled Anchors with that of Supervised Anchors. All results are obtained using a single core of an Intel Core i7-4770K.[5]

As shown in Table 1, Labeled Anchors is orders of magnitude faster than Supervised Anchors, even for moderately sized datasets. Both Labeled Anchors and Supervised Anchors require us to recover topic-word distributions, an operation which scales with the size of the vocabulary. However, Supervised Anchors also requires us to infer document-topic distributions in order to train an external classifier, an operation which scales linearly with the number of documents. Since vocabulary size typically grows logarithmically with respect to the number of documents (Heaps, 1978), Labeled Anchors scales much better than Supervised Anchors.

When a user updates the anchors, the system must reinfer the topics, create the classifier, and evaluate the development dataset, all within a few seconds. If the update is too slow, the interaction will suffer due to increased cognitive load on users (Cook and Thomas, 2005). Results from an exploratory user study confirm this: when participants are faced with update times around 10 seconds, they are not successful in their topic-based tasks.[6]

Having established that Labeled Anchors is fast enough to be interactive, we now demonstrate that participants can use our system to improve topics for classification. In order demonstrate the role of human knowledge in interactive topic modeling, we ask the users to identify sentiment (i.e. product rating) rather than product category, since the natural topics which arise from the Anchor Words algorithm tend to reflect product category instead of rating. We preprocess a set of Amazon product reviews with standard tokenization, stopword removal, and by removing words which appear in fewer than 100 documents. After preprocessing, empty documents are discarded, resulting in 39,388 documents. We use an 80/20 train/test split, with 1,500 training documents reserved as development data. We recruit five participants drawn from a university student body. The median age is 21. Three are male and two are female. None of the students have any prior familiarity with topic modeling.

We present the participants with a user interface similar to that of Lund et al. (2017). Users can view and edit a list of anchor words (or rather, sets of words which form each anchor), and they can view the top ten most probable words for each topic. We display the classification accuracy on the development data to give users an indication of

---

[4] http://jmcauley.ucsd.edu/data/amazon

[5] Our Python implementation is available at `https://github.com/byu-aml-lab/ankura`.

[6] For this reason, we do not report interactive results with Supervised Anchors.

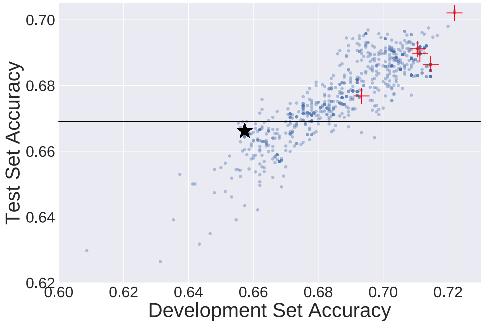

Figure 2: User study accuracy results comparing accuracy on the development set to the accuracy on the test set. The black horizontal line indicates the baseline accuracy from Supervised Anchors. The black star indicates the initial accuracy using Gram-Schmidt anchors with Labeled Anchors. The blue dots indicate various intermediate steps while editing the anchors. The red pluses are the final states after each user completes the task.

how they are doing. After a brief training on the interface, users are asked to modify the anchors to produce topics which reflect the underlying product ratings and improve the classification accuracy on the development dataset as much as possible. Participants are given forty minutes to perform this task.

Figure 2 summarizes the results of our user study. With just baseline anchors from Gram-Schmidt, the classification accuracy of Labeled Anchors is on par with that of Supervised Anchors using logistic regression as the downstream classifier. However, because Labeled Anchors is fast enough to allow interaction, participants are able to improve classification accuracy on the development set by an average of 5.31%. This corresponds to a 2.31% increase in accuracy on the test set.

We record each step of the user interactions and find a Pearson correlation coefficient of .88 between development accuracy and test accuracy. Thus, Labeled Anchors allows participants to interactively see updated classification accuracy and have confidence that held-out test accuracy will also improve.

With regard to the interaction that users had with the dataset, we observe several common strategies. Firstly, we notice that users who made more edits tend to have more success in terms of accuracy; this validates our assertion that slower update times hurt performance. Secondly, users end with a median of 21 topics, which is close to the 20 topics they start with, suggesting that either the users felt like this was an appropriate number of topics, or that they felt uneasy drastically changing the total number of topics from what they started with. Lastly, we find that users chose more single word anchors than we expected, with about 88% of anchors being single word anchors. Most of the multiword anchors users used were short 2-3 word phrases which did not have an obvious single word counterpart.

3 Conclusion

Our results demonstrate that Labeled Anchors yields a classifier that is both human-interpretable and fast. Our approach not only combines the strengths of Supervised Anchors and Tandem Anchors, but introduces a mathematical construct for producing a classifier as a by-product of topic inference. Compared to Supervised Anchors, which requires costly training of a downstream classifier in addition to topic inference, our approach is much more scalable. Using Labeled Anchors, our participants are able to adjust the classifier so as to obtain superior classification results than those produced by Supervised Anchors alone.

Returning to our original motivating problem of quickly annotating a large collection of unlabeled emails, we assert that our approach could aid in quickly labeling the entire collection. With a modest investment of manual annotation, the initial training set could be labeled, and then with the help of our system the remaining documents could be automatically labeled in a transparent and explainable fashion.

Coherence-Aware Neural Topic Modeling

Abstract

Topic models are evaluated based on their ability to describe documents well (i.e. low perplexity) and to produce topics that carry coherent semantic meaning. In topic modeling so far, perplexity is a direct optimization target. However, topic coherence, owing to its challenging computation, is not optimized for and is only evaluated after training. In this work, under a neural variational inference framework, we propose methods to incorporate a topic coherence objective into the training process. We demonstrate that such a coherence-aware topic model exhibits a similar level of perplexity as baseline models but achieves substantially higher topic coherence.

1 Introduction

In the setting of a topic model (Blei, 2012), perplexity measures the model's capability to describe documents according to a generative process based on the learned set of topics. In addition to describing documents well (i.e. achieving low perplexity), it is desirable to have topics (represented by top-N most probable words) that are human-interpretable. Topic interpretability or coherence can be measured by *normalized point-wise mutual information* (NPMI) (Aletras and Stevenson, 2013; Lau et al., 2014). The calculation of NPMI however is based on look-up operations in a large reference corpus and therefore is non-differentiable and computationally intensive. Likely due to these reasons, topic models so far have been solely optimizing for perplexity, and topic coherence is only evaluated after training. As has been noted in several publications (Chang et al., 2009), optimization for perplexity alone tends to negatively impact topic coherence. Thus, without introducing topic coherence as a training objective, topic modeling likely produces sub-optimal results.

Compared to classical methods, such as mean-field approximation (Hoffman et al., 2010) and collapsed Gibbs sampling (Griffiths and Steyvers, 2004) for the latent Dirichlet allocation (LDA) (Blei et al., 2003) model, neural variational inference (Kingma and Welling, 2013; Rezende et al., 2014) offers a flexible framework to accommodate more expressive topic models. We build upon the line of work on topic modeling using neural variational inference (Miao et al., 2016, 2017; Srivastava and Sutton, 2017) and incorporate topic coherence awareness into topic modeling.

Our approaches of constructing topic coherence training objective leverage pre-trained word embeddings (Mikolov et al., 2013; Pennington et al., 2014; Salle et al., 2016; Joulin et al., 2016). The main motivation is that word embeddings carry contextual similarity information that is highly related to the mutual information terms involved in the calculation of NPMI. In this paper, we explore two methods: (1) we explicitly construct a differentiable surrogate topic coherence regularization term; (2) we use word embedding matrix as a factorization constraint on the topical word distribution matrix that implicitly encourages topic coherence.

2 Models

2.1 Baseline: Neural Topic Model (NTM)

The model architecture shown in Figure 1 is a variant of the Neural Variational Document Model (NVDM) (Miao et al., 2016). Let $x \in \mathbb{R}^{|V|\times 1}$ be the bag-of-words (BOW) representation of a document, where $|V|$ is the size of the vocabulary and let $z \in \mathbb{R}^{K\times 1}$ be the latent topic variable, where K is the number of topics. In the encoder $q_\phi(z|x)$, we have $\pi = f_{MLP}(x)$, $\mu(x) = l_1(\pi)$, $\log \sigma(x) = l_2(\pi)$, $h(x,\epsilon) = \mu + \sigma \odot \epsilon$, where $\epsilon \sim \mathcal{N}(0, I)$, and finally $z = f(h) = \mathrm{ReLU}(h)$. The functions l_1 and l_2 are linear transformations

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 830–836
Brussels, Belgium, October 31 - November 4, 2018.

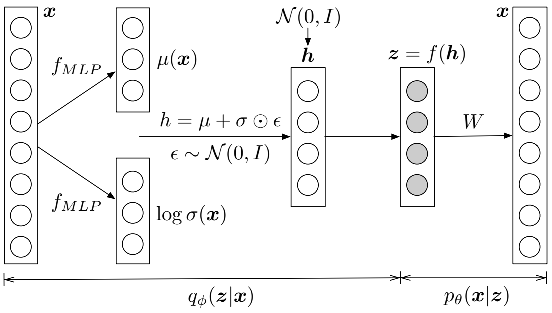

Figure 1: Model architecture

with bias. We choose the multi-layer perceptron (MLP) in the encoder to have two hidden layers with $3 \times K$ and $2 \times K$ hidden units respectively, and we use the sigmoid activation function. The decoder network $p_\theta(x|z)$ first maps z to the predicted probability of each of the word in the vocabulary $y \in \mathbb{R}^{|V|\times 1}$ through $y = \text{softmax}(Wz + b)$, where $W \in \mathbb{R}^{|V|\times K}$. The log-likelihood of the document can be written as $\log p_\theta(x|z) = \sum_{i=1}^{|V|}\{x \odot \log y\}$. We name this model Neural Topic Model (NTM) and use it as our baseline. We use the same encoder MLP configuration for our NVDM implementation and all variants of NTM models used in Section 3. In NTM, the objective function to maximize is the usual *evidence lower bound* (ELBO) which can be expressed as

$$\mathcal{L}_{ELBO}(x^i)$$
$$\approx \frac{1}{L}\sum_{l=1}^{L} \log p_\theta(x^i|z^{i,l}) - D_{KL}(q_\phi(h|x)||p_\theta(h))$$

where $z^{i,l} = \text{ReLU}(h(x^i, \epsilon^l))$, $\epsilon^l \sim \mathcal{N}(0, I)$. We approximate $\mathbb{E}_{z\sim q(z|x)}[\log p_\theta(x|z)]$ with Monte Carlo integration and calculate the Kullback-Liebler (KL) divergence analytically using the fact $D_{KL}(q_\phi(z|x)||p_\theta(z)) = D_{KL}(q_\phi(h|x)||p_\theta(h))$ due to the invariance of KL divergence under deterministic mapping between h and z.

Compared to NTM, NVDM uses different activation functions and has $z = h$. Miao (2017) proposed a modification to NVDM called Gaussian Softmax Model (GSM) corresponding to having $z = \text{softmax}(h)$. Srivastava (2017) proposed a model called ProdLDA, which uses a Dirichlet prior instead of Gaussian prior for the latent variable h. Given a learned W, the practice to extract top-N most probable words for each topic is to take the most positive entries in each column of W (Miao et al., 2016, 2017; Srivastava and Sutton, 2017). This is an intuitive choice, provided that z is non-negative, which is indeed the case for NTM, GSM and ProdLDA. NVDM, GSM, and ProdLDA are state-of-the-art neural topic models which we will use for comparison in Section 3.

2.2 Topic Coherence Regularization: NTM-R

The topic coherence metric NPMI (Aletras and Stevenson, 2013; Lau et al., 2014) is defined as

$$\text{NPMI}(\boldsymbol{w})$$
$$= \frac{1}{N(N-1)} \sum_{j=2}^{N}\sum_{i=1}^{j-1} \frac{\log \frac{P(w_i,w_j)}{P(w_i)P(w_j)}}{-\log P(w_i, w_j)}$$

where $\boldsymbol{w}$ is the list of top-N words for a topic. N is usually set to 10. For a model generating K topics, the overall NPMI score is an average over all topics. The computational overhead and non-differentiability originate from extracting the co-occurrence frequency from a large corpus[1].

From the NPMI formula, it is clear that word-pairs that co-occur often would score high, unless they are rare word-pairs – which would be normalized out by the denominator. The NPMI scoring bears remarkable resemblance to the contextual similarity produced by the inner product of word embedding vectors. Along this line of reasoning, we construct a differentiable, computation-efficient word embedding based topic coherence (WETC).

Let E be the row-normalized word embedding matrix for a list of N words, such that $E \in \mathbb{R}^{N\times D}$ and $\|E_{i,:}\| = 1$, where D is the dimension of the embedding space. We can define *pair-wise* word embedding topic coherence in a similar spirit as NPMI:

$$\text{WETC}_{PW}(E) = \frac{1}{N(N-1)} \sum_{j=2}^{N}\sum_{i=1}^{j-1} \langle E_{i,:}, E_{j,:}\rangle$$
$$= \frac{\sum\{E^T E\} - N}{2N(N-1)}$$

where $\langle \cdot, \cdot \rangle$ denotes inner product. Alternatively, we can define *centroid* word embedding topic coherence

$$\text{WETC}_C(E) = \frac{1}{N}\sum\{Et^T\}$$

where vector $t \in \mathbb{R}^{1\times D}$ is the centroid of E, normalized to have $\|t\| = 1$. Empirically, we found

---

[1] A typical calculation of NPMI over 50 topics based on the Wikipedia corpus takes ∼20 minutes, using code provided by (Lau et al., 2014) at `https://github.com/jhlau/topic_interpretability`.

that the two WETC formulations behave very similarly. In addition, both WETC$_{PW}$ and WETC$_{C}$ correlate to human judgement almost equally well as NPMI when using `GloVe` (Pennington et al., 2014) vectors[2].

With the above observations, we propose the following procedure to construct a WETC-based surrogate topic coherence regularization term: (1) let $E \in \mathbb{R}^{|V| \times D}$ be the pre-trained word embedding matrix for the vocabulary, rows aligned with W; (2) form the W-weighted centroid (topic) vectors $T \in \mathbb{R}^{D \times K}$ by $T = E^T W$; (3) calculate the cosine similarity matrix $S \in \mathbb{R}^{|V| \times K}$ between word vectors and topic vectors by $S = ET$; (4) calculate the W-weighted sum of word-to-topic cosine similarities for each topic $C \in \mathbb{R}^{1 \times K}$ as $C = \sum_i (S \odot W)_{i,:}$. Compared to WETC$_C$, in calculating C we do not perform top-N operation in W, but directly use W for weighted sum. Specifically, we use W-weighted topic vector construction in Step-2 and W-weighted sum of the cosine similarities between word vectors and topic vectors in Step-4. To avoid unbounded optimization, we normalize the rows of E and the columns of W before Step-2, and normalize the columns of T after Step-2. The overall maximization objective function becomes $\mathcal{L}_R(x; \theta, \phi) = \mathcal{L}_{ELBO} + \lambda \sum_i C_i$, where λ is a hyper-parameter with positive values controlling the strength of topic coherence regularization. We name this model NTM-R.

2.3 Word Embedding as a Factorization Constraint: NTM-F and NTM-FR

Instead of allowing all the elements in W to be freely optimized, we can impose a factorization constraint of $W = E\hat{T}$, where E is the pre-trained word embedding matrix that is *fixed*, and only $\hat{T}$ is allowed to be learned through training. Under this configuration, $\hat{T}$ lives in the embedding space, and each entry in W is the dot product similarity between a topic vector $\hat{T}_i$ and a word vector E_j. As one can imagine, similar words would have similar vector representations in E and would have similar weights in each column of W. Therefore the factorization constraint encourages words with similar meaning to be selected or de-selected together thus potentially improving topic coherence.

We name the NTM model with factorization constraint enabled as NTM-F. In addition, we can apply the regularization discussed in the previous section on the resulting matrix W and we name the resulting model NTM-FR.

Metric	Perplexity		NPMI	
Number of topics	50	200	50	200
LDA				
LDA, mean-field	1046	1195	0.11	0.06

Table 1: Comparison to LDA and neural variational models on the *20NewsGroup* dataset. Best numbers are bolded. The blue underlined row highlights the best NPMI and perplexity tradeoff as discussed in text.

3 Experiments and Discussions

3.1 Results on *20NewsGroup*

First, we compare the proposed models to state-of-the-art neural variational inference based topic models in the literature (NVDM, GSM, and ProdLDA) as well as LDA benchmarks, on the *20NewsGroup* dataset[3]. In training NVDM and all NTM models, we used `Adadelta` optimizer (Zeiler, 2012). We set the learning rate to 0.01 and train with a batch size of 256. For NTM-R, NTM-F and NTM-FR, the word embedding we used is `GloVe` (Pennington et al., 2014) vectors pre-trained on Wikipedia and Gigaword with 400,000 vocabulary size and 50 embedding dimensions[4]. The topic coherence regularization coefficient λ is set to 50. The results are presented in Table 1.

Overall we can see that LDA trained with collapsed Gibbs sampling achieves the best perplexity, while NTM-F and NTM-FR models achieve the best topic coherence (in NPMI). Clearly, there is a trade-off between perplexity and NPMI as identified by other papers. So we constructed Figure 2, which shows the two metrics from various models. For the models we implemented, we additionally

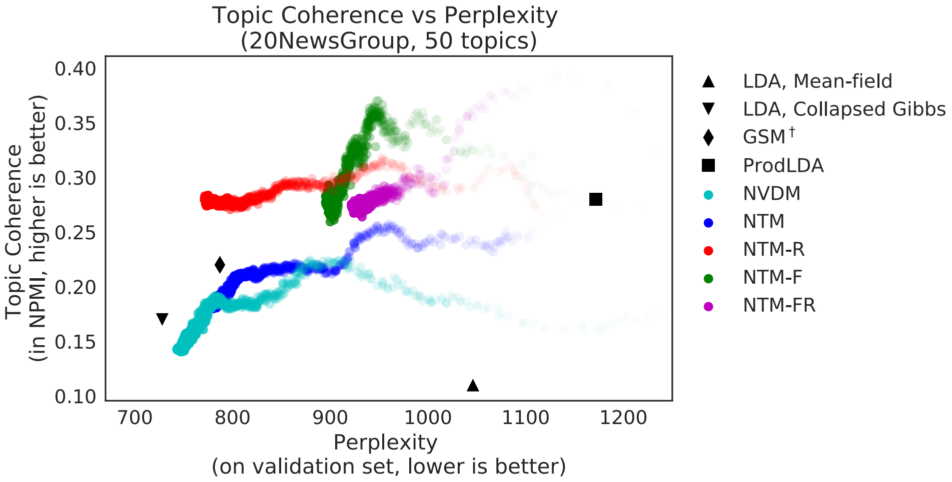

Figure 2: NPMI vs. perplexity for various models at 50 topics. For NVDM and NTM models the traces correspond to the evolution over training epochs. High transparency is the beginning of the training.

show the full evolution of these two metrics over training epochs.

From Figure 2, it becomes clear that although ProdLDA exhibits good performance on NPMI, it is achieved at a steep cost of perplexity, while NTM-R achieves similar or better NPMI at much lower perplexity levels. At the other end of the spectrum, if we look for low perplexity, the best numbers among neural variational models are between 750 and 800. In this neighborhood, NTM-R substantially outperforms the GSM, NVDM and NTM baseline models. Therefore, we consider NTM-R the best model overall. Different downstream applications may require different tradeoff points between NPMI and perplexity. However, the proposed NTM-R model does appear to provide tradeoff points on a Pareto front compared to other models across most of the range of perplexity.

3.2 Comments on NTM-F and NTM-FR

It is worth noting that although NTM-F and NTM-FR exhibit high NPMI early on, they fail to maintain it during the training process. In addition, both models converged to fairly high perplexity levels. Our hypothesis is that this is caused by NTM-F and NTM-FR's substantially reduced parameter space - from $|V| \times K$ to $D \times K$, where $|V|$ ranges from 1,000 to 150,000 in a typical dataset, while D is on the order of 100.

Some form of relaxation could alleviate this problem. For example, we can let $W = E\hat{T} + A$, where A is of size $|V| \times K$ but is heavily regularized, or let $W = EQ\hat{T}$ where Q is allowed as additional free parameters. We leave fully addressing this to future work.

3.3 Validation on other Datasets

To further validate the performance improvement from using WETC-based regularization in NTM-R, we compare NTM-R with the NTM baseline model on a few more datasets: DailyKOS, NIPS, and NYTimes[5] (Asuncion and Newman, 2007). These datasets offer a wide range of document length (ranging from ∼100 to ∼1000 words), vocabulary size (ranging from ∼7,000 to ∼140,000), and type of documents (from news articles to long-form scientific writing). In this set of experiments, we used the same settings and hyperparameter λ as before and did not fine-tune for each dataset. The results are presented in Figure 3. In a similar style as Figure 2, we show the evolution of NPMI and WETC versus perplexity over epochs until convergence.

Among all datasets, we observed improved NPMI at the same perplexity level, validating the effectiveness of the topic coherence regularization. However, on the NYTimes dataset, the improvement is quite marginal even though WETC improvements are very noticeable. One particularity about the NYTimes dataset is that approximately 58,000 words in the 140,000-word vocabulary are named entities. It appears that the large number of named entities resulted in a divergence between NPMI and WETC scoring, which is an issue to address in the future.

4 Conclusions

In this work, we proposed regularization and factorization constraints based approaches to incorporate awareness of topic coherence into the formulation of topic models: NTM-R and NTM-F respectively. We observed that NTM-R substantially improves topic coherence with minimal sacrifice in perplexity. To our best knowledge, NTM-R is the first topic model that is trained with an objective towards topic coherence – a feature directly contributing to its superior performance. We further showed that the proposed WETC-based regularization method is applicable to a wide range of text datasets.

A Word Embedding Topic Coherence

As studied in (Aletras and Stevenson, 2013) and (Lau et al., 2014), the NPMI metric for assessing topic coherence over a list of words $\boldsymbol{w}$ is defined in Eq. 1.

$$\text{NPMI}(\boldsymbol{w}) = \frac{1}{N(N-1)} \sum_{j=2}^{N} \sum_{i=1}^{j-1} \frac{\log \frac{P(w_i, w_j)}{P(w_i)P(w_j)}}{-\log P(w_i, w_j)} \quad (1)$$

where $P(w_i)$ and $P(w_i, w_j)$ are the probability of words and word pairs, calculated based on a reference corpus. N is usually set to 10, by convention, so that NPMI is evaluated over the topic-10 words for each topic. For a model generating K topics, the overall NPMI score is an average over all the topics. The computational overhead comes from extracting the relevant co-occurrence frequency from a large corpus. This problem is exacerbated when the look-up also requires a small sliding window as the authors of (Lau et al., 2014) suggested. A typical calculation of 50 topics based on a few million documents from the Wikipedia corpus takes ∼20 minutes[6].

For a list of words $\boldsymbol{w}$ of length N, we can assemble a corresponding word embedding matrix $E \in \mathbb{R}^{N \times D}$ with each row corresponding to a word in the list. D is the dimension of the embedding space. Averaging across the rows, we can obtain vector $t \in \mathbb{R}^{1 \times D}$ as the centroid of all the word vectors. It may be regarded as a "topic" vector. In addition, we assume that each row of E and t is normalized, i.e. $\|t\| = 1$ and $\|E_{i,:}\| = 1$. With these, we define *pair-wise* and *centroid* word embedding topic coherence WETC_{PW} and WETC_{C} as follows:

$$\begin{aligned}\text{WETC}_{PW}(E) &= \frac{1}{N(N-1)} \sum_{j=2}^{N} \sum_{i=1}^{j-1} \langle E_{i,:}, E_{j,:} \rangle \\ &= \frac{\sum\{E^T E\} - N}{2N(N-1)}\end{aligned} \quad (2)$$

$$\text{WETC}_C(E) = \frac{1}{N} \sum \{E t^T\} \quad (3)$$

where $\langle \cdot, \cdot \rangle$ denotes inner product. The simplification in Eq. 2 is due to the row normalization of E.

In this setting, we have the flexibility to use any pre-trained word embeddings to construct E. To experiment, we compared several recently developed variants [7]. The dataset from (Aletras and Stevenson, 2013) provides human ratings for 300 topics coming from 3 corpora: 20NewsGroup (20NG), New York Times (NYT) and genomics scientific articles (Genomics), which we use as the human gold standard. We use Pearson and Spearman correlations to compare NPMI and WETC scores against human ratings. The results are shown in Table 2.

WETC$_{PW}$	0.37	0.57	0.79	0.80	0.65	0.64
WETC$_{C}$	0.47	0.57	0.81	0.80	0.65	0.64

Table 2: NPMI and WETC correlation with human gold standard (P: Pearson, S: Spearman)

From Table 2 we observed a minimal difference between pair-wise and centroid based WETC in general. Overall, `GloVe` appears to perform the best across different types of corpora and its correlation with human ratings is very comparable to NPMI-based scores. Our NPMI calculation is based on the Wikipedia corpus and should serve as a fair comparison. In addition to the good correlation exhibited by WETC, the evaluation of WETC only involves matrix multiplications and summations and thus is fully differentiable and several orders of magnitude faster than NPMI calculations. WETC opens the door of incorporating topic coherence as a training objective, which is the key idea we will investigate in the subsequent sections. It is worth mentioning that, for `GloVe`, the low dimensional embedding (50d) appears to perform almost equally well as high dimensional embedding (300d). Therefore, we will use Glove-400k-50d in all subsequent experiments.

While the WETC metric on its own might be of interest to the topic modeling research community, we leave the task of formally establishing it as a standard metric in place of NPMI to future work. In this work, we still use the widely accepted NPMI as the objective topic coherence metric for model comparisons.

Utilizing Character and Word Embeddings for Text Normalization with Sequence-to-Sequence Models

Daniel Watson, Nasser Zalmout and Nizar Habash
Computational Approaches to Modeling Language Lab
New York University Abu Dhabi
{daniel.watson,nasser.zalmout,nizar.habash}@nyu.edu

Abstract

Text normalization is an important enabling technology for several NLP tasks. Recently, neural-network-based approaches have outperformed well-established models in this task. However, in languages other than English, there has been little exploration in this direction. Both the scarcity of annotated data and the complexity of the language increase the difficulty of the problem. To address these challenges, we use a sequence-to-sequence model with character-based attention, which in addition to its self-learned character embeddings, uses word embeddings pre-trained with an approach that also models subword information. This provides the neural model with access to more linguistic information especially suitable for text normalization, without large parallel corpora. We show that providing the model with word-level features bridges the gap for the neural network approach to achieve a state-of-the-art F_1 score on a standard Arabic language correction shared task dataset.

1 Introduction

Text normalization systems have many potential applications – from assisting native speakers and language learners with their writing, to supporting NLP applications with sparsity reduction by cleaning large textual corpora. This can help improve benchmarks across many NLP tasks.

In recent years, neural encoder-decoder models have shown promising results in language tasks like translation, part-of-speech tagging, and text normalization, especially with the use of an attention mechanism. In text normalization, however, previous state-of-the-art results rely on developing many other pipelines on top of the neural model. Furthermore, such neural approaches have barely been explored for this task in Arabic, where previous state-of-the-art systems rely on combining various statistical and rule-based approaches.

We experiment with both character embeddings and pre-trained word embeddings, using several embedding models, and we achieve a state-of-the-art F_1 score on an Arabic spelling correction task.

2 Related Work

The encoder-decoder neural architecture (Sutskever et al., 2014; Cho et al., 2014) has shown promising results in text normalization tasks, particularly in character-level models (Xie et al., 2016; Ikeda et al., 2016). More recently, augmenting this neural architecture with the attention mechanism (Bahdanau et al., 2014; Luong et al., 2015) has dramatically increased the quality of results across most NLP tasks. However, in text normalization, state-of-the-art results involving attention (e.g., Xie et al. 2016) also rely on several other models during inference, such as language models and classifiers to filter suggested edits. Neural architectures at the word level inherently rely on multiple models to align and separately handle out-of-vocabulary (OOV) words (Yuan and Briscoe, 2016).

In the context of Arabic, we are only aware of one attempt to use a neural model for end-to-end text normalization (Ahmadi, 2017), but it fails to beat all baselines reported later in this paper. Arabic diacritization, which can be considered forms of text normalization, has received a number of neural efforts (Belinkov and Glass, 2015; Abandah et al., 2015). However, state-of-the-art approaches for end-to-end text normalization rely on several additional models and rule-based approaches as hybrid models (Pasha et al., 2014; Rozovskaya et al., 2014; Nawar, 2015; Zalmout and Habash, 2017), which introduce direct human knowledge into the system, but are limited to correcting specific mistakes and rely on expert knowledge to be developed.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 837–843
Brussels, Belgium, October 31 - November 4, 2018.

3 Approach

Many common mistakes addressed by text normalization occur fundamentally at the character level. Moreover, the input data tends to be too noisy for a word-level neural model to be an end-to-end solution due to the high number of OOV words. In Arabic, particularly, mistakes may range from simple orthographic errors (e.g., positioning of Hamzas) and keyboard errors to dialectal code switching and spelling variations, making the task more challenging than a generic language correction task. We opt for a character-level neural approach to capture these highly diverse mistakes. While this method is less parallelizable due to the long sequence lengths, it is still more efficient due to the small vocabulary size, making inference and beam search computationally feasible.

3.1 Neural Network Architecture

Given an input sentence $\mathbf{x}$ and its corrected version $\mathbf{y}$, the objective is to model $P(\mathbf{y}|\mathbf{x})$. The vocabulary can consist of any number of unique tokens, as long as the following are included: a padding token to make input batches have equal length, the two canonical start-of-sentence and end-of-sentence tokens of the encoder-decoder architecture, and an OOV token to replace any character outside the training data during inference. Each character x_i in the source sentence $\mathbf{x}$ is mapped to the corresponding d_{ce}-dimensional row vector $\mathbf{c_i}$ of a learnable $d_{voc} \times d_{ce}$ embedding matrix, initialized with a random uniform distribution with mean 0 and variance 1. For the encoder, we learn d-dimensional representations for the sentence with two gated recurrent unit (GRU) layers (Cho et al., 2014), making only the first layer bidirectional following Wu et al. (2016). Like long short-term memory (Hochreiter and Schmidhuber, 1997), GRU layers are well-known to improve the performance of recurrent neural networks (RNN), but are slightly more computationally efficient than the former.

For the decoder, we use two GRU layers along with the attention mechanism proposed by Luong et al. (2015) over the encoder outputs h_i. The initial states for the decoder layers are learned with a fully-connected $\tanh$ layer in a similar fashion to Cho et al. (2014), but we do so from the first encoder output. During training, we use scheduled sampling (Bengio et al., 2015) and feed the d_{ce}-dimensional character embeddings at every time step, but using a constant sampling probability. While tuning scheduled sampling, we found that introducing a sampling probability provided better results than relying on the ground truth, i.e., teacher forcing (Williams and Zipser, 1989). However, introducing a schedule did not yield any improvement as opposed to keeping the sampling probability constant and unnecessarily complicates hyperparameter search. For both the encoder and decoder RNNs, we also use dropout (Srivastava et al., 2014) on the non-recurrent connections of both the encoder and decoder layers during training.

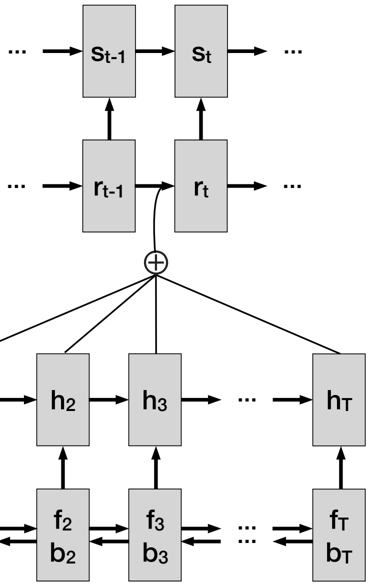

Figure 1: Illustration of the encoder and decoder recurrent layers.

The decoder outputs are fed to a final softmax layer that reshapes the vectors to dimension d_{voc} to yield an output sequence $\mathbf{y}$. The loss function is the canonical cross-entropy loss per time step averaged over the y_i.

3.2 Word Embeddings

To address the challenge posed by the small amount of training data, we propose adding pre-trained word-level information to each character embedding. To learn these word representations, we use FastText (Bojanowski et al., 2016), which extends Word2Vec (Mikolov et al., 2013) by adding subword information to the word vector. This is very suitable for this task, not only because many mistakes occur at the character level,

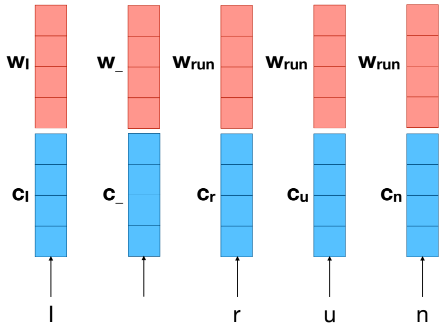

Figure 2: Illustration showing how the character embeddings are enriched with word-level features.

Baseline	P	R	F_1
MLE	77.08	41.56	54.00
MADAMIRA	77.47	32.10	45.39
MLE then MADAMIRA	64.38	38.42	48.12
MADAMIRA then MLE	73.55	44.61	**55.54**

Table 1: Baselines scores on the QALB 2014 shared task development set.

but also because FastText handles almost all OOVs by omitting the Word2Vec representation and simply using the subword-based representation. It is possible, yet extremely rare that FastText cannot handle a word– this can occur if the word contains an OOV n-gram or character that did not appear in the data used to train the embeddings. It should also be noted that these features are only fed to the encoder layer; the decoder layer only receives d_{ce}-dimensional character embeddings as inputs, and the softmax layer has a d_{voc}-dimensional output.

Each character embedding $\mathbf{c_i}$ is replaced by the concatenation $[\mathbf{c_i}; \mathbf{w_j}]$ before being fed to the encoder-decoder model, where $\mathbf{w_j}$ is the d_{we}-dimensional word embedding for the word in which $\mathbf{c_i}$ appears in. This effectively handles almost all cases except white spaces, in which we just always append a d_{we}-dimensional vector $\mathbf{w\_}$ initialized with a random uniform distribution of mean 0 and variance 1. For OOVs, we just append the whitespace embedding $\mathbf{w\_}$ to the word's characters.

3.3 Inference

During inference, the decoder layer uses a beam search, keeping a fixed number (i.e., beam width) of prediction candidates with the highest log-likelihood at each step. Whenever an "end-of-sentence" token is produced in a beam, the decoder stops predicting further tokens for it. We then pick the individual beam with the highest overall log-likelihood as our prediction. As a final step, we reduce text sequences that are repeated six or more times to a threshold of 5 repetitions (e.g., `"abababababab"` → `"ababababab"`). This helps address rare cases where the decoder misbehaves and produces non-stop repetitions of text, and also helps avoid extreme running times for the NUS MaxMatch scorer (Dahlmeier and Ng, 2012), which we use for evaluation and comparison purposes.

4 Evaluation

4.1 Data

We tested the proposed approach on the QALB dataset, a corpus for Arabic language correction and subject of two shared tasks (Zaghouani et al., 2014; Mohit et al., 2014; Rozovskaya et al., 2015). Following the guidelines of both shared tasks, we only used the training data of the QALB 2014 shared task corpus (19,411 sentences). Similarly, the validation dataset used is only that of the QALB 2014 shared task, consisting of 1,017 sentences. We use two blind tests, one from each year. During training, we only kept sentences of up to 400 characters in length, resulting in the loss of 172 sentences.

4.2 Metric

Like in the QALB shared tasks, we use the *MaxMatch* scorer to compute the optimal word-level edits that map each source sentence to its respective corrected sentence. We report the F_1 score of these edits against those provided in the gold data by the same tool. We compare against the best reported system in the QALB 2014 shared task test set (CLMB) (Rozovskaya et al., 2014), as well as the best in the QALB 2014 shared task development and the QALB 2015 shared task test sets (CUFE) (Nawar, 2015).

4.3 Baselines

We consider two different baselines. The first is the output from MADAMIRA (Pasha et al., 2014), a tool for morphological analysis and disambiguation of Arabic. The second is using maximum likelihood estimation (MLE) based on the counts of the MaxMatch gold edits from the training data; that is, each word or phrase gets either replaced

Model	P	R	F_1
Wide embeds	80.80	59.80	68.73
+ preprocessing	79.63	58.81	67.57
Narrow embeds	80.00	62.46	**70.15**
+ preprocessing	80.25	57.80	67.20
Concat embeds	80.74	61.10	69.56
+ preprocessing	79.81	58.28	67.37

or kept as is, depending on the most common action in the training data. We found that, unlike Eskander et al. (2013) suggested, first using MADAMIRA and then MLE yields better results than composing these in the reverse order. The results are presented in Table 1.

4.4 Model Settings

In all experiments, we used batch and character embedding sizes of $b = d_{ce} = 128$, hidden layer size of $d = 256$, dropout probability of 0.1, decoder sampling probability of 0.35, and gradient clipping with a maximum norm of 10. When running all the trained models during inference, we used a beam width of 5. We used the Adam optimizer (Kingma and Ba, 2014) with a learning rate of 0.0005, $\epsilon = 1 \cdot 10^{-8}$, β_1=0.9, and β_2=0.999, and trained the model for 30 epochs. We report three different setups with FastText word embeddings: narrow, wide, and the concatenation of both. For each of these, we report results on two separately trained models: one without preprocessing, and one with MADAMIRA and then MLE preprocessing to the inputs. We also report an ablation study where we choose the best of these six trained models and compare against two separately trained models with identical setups, but using Word2Vec and no word-level features, respectively.

All the word embeddings used are of dimension $d_{we} = 300$, and were trained with a single epoch over the Arabic Gigaword corpus (Parker et al., 2011). In the experiments including preprocessing, the respective word vectors were obtained from Gigaword preprocessed with MADAMIRA. The narrow and wide word embeddings were trained with context windows of sizes 2 and 5, respectively. All other hyperparameters were kept to the default FastText values, except the minimum n-gram size, which was reduced from 3 to 2 to compensate for single-character prefixes and suffixes that appear in Arabic when omitting the short vowels (Erdmann et al., 2018).

Model	P	R	F_1
No word embeds	81.55	56.13	66.49
Word2Vec	**82.16**	51.53	63.33
FastText	80.00	**62.46**	**70.15**

Table 3: Ablation tests on the QALB 2014 shared task development dataset. All settings used no preprocessing and narrow word embeddings.

4.5 Results

Development set results are shown in Tables 2 and 3, test set results in Table 4. In all models, training without preprocessing consistently yielded better results than their analogues with the inputs pre-fed to MADAMIRA and then MLE. All the FastText embeddings setups with no preprocessing outperformed the previous state-of-the-art results in the development dataset. We hypothesize that this is occurs because the model has access to more examples of errors to normalize during training, thereby increasing performance. The best performing model was that with the narrow word embeddings; consistent with the results of Zalmout et al. (2018) showing the superior performance of narrow word embeddings over both wide embeddings and the concatenation of both. This is justified by Goldberg (2015) and Trask et al. (2015), who illustrate that wider word embeddings tend to capture more semantic information, while narrower word embeddings model more syntactic phenomena.

In our ablation study, we compared the performance of the narrow FastText embeddings against narrow Word2Vec embeddings trained over the same Arabic Gigaword corpus with the same hyperparameters, as well as to no word-level embeddings at all. The results, displayed in Table 3, show that using only Word2Vec slightly increases precision but significantly hurts recall. This highlights the effectiveness of using FastText for text normalization, as well as the need to handle OOVs in a noisy context for word-level representations to help in this particular problem. Despite that having OOV cases can help the model by indicating that a word is likely erroneous, this does not provide linguistic information the way FastText does. The narrow FastText embeddings with no prepro-

cessing setup achieved state-of-the-art results in all three datasets, beating all systems in both the 2014 and 2015 QALB shared tasks in F_1 score.

4.6 Error Analysis

We conducted a detailed error analysis of 101 sentences from the development set (6,370 words). The sample contained 1,594 erroneous words (25%). The errors were manually classified in a number of categories, which are presented in Table 5. The Table indicates the percentage of the error type in the whole set of errors as well as the error-specific F_1 and an example. Some common problems, Hamza (glottal stop) and Ta Marbuta (feminine ending), are well handled in our best system. This is due to their commonality in the training data. Other types are less common – dialectal constructions, consonantal switches and Mood/Case. Punctuation is very common, however it is also very idiosyncratic. We also note the presence of a small percentage (0.5%) of gold errors. For more information on Arabic language orthography issues from a computational perspective, see (Buckwalter, 2007; Habash, 2010; Habash et al., 2012).

Gold%	**Error Type**	F_1	**Example**
4.8	Ta Marbuta	95.4	كتابه → كتابة
29.8	Hamza	92.8	تاييد → تأييد
10.5	Space	87.5	ماسبب → ما سبب
0.8	Alif Maqsura	83.3	التى → التي
0.7	Repeated Letter	81.8	الرجاااال → الرجال
0.6	Wa of Plurality	66.7	قالو → قالوا
39.3	Punctuation	56.4	$NIL \rightarrow .$
2.2	Multiple Types	43.1	ألقيامه → القيامة
1.7	Consonant Switch	41.0	شحص → شخص
1.6	Other Types	38.3	التقل → القتل
2.3	Mood & Case	33.3	مصريون → مصريين
2.8	Dialect	32.8	هيكتب → سيكتب
1.3	Deleted Letter	n/a	سيتصر → سينتصر
1.1	Grammar	n/a	يتجاوز → يتجاوزون
0.5	Gold Error	n/a	اللتى → التى

5 Conclusion and Future Work

We propose a novel approach to text normalization by enhancing character embeddings with word-level features that model subword information and model syntactic phenomena. This significantly improves the neural model's recall, allowing the correction of more complex and diverse errors. Our approach achieves state-of-the-art results in the QALB dataset, despite it being small and seemingly unsuited for a neural model. Moroever, our neural model is sophisticated enough to not benefit from preprocessing techniques that reduce the number of errors in the data. Our approach is general enough to be implemented for any other text normalization task and does not rely on domain-specific knowledge to develop.

Future directions include expanding the number of training pairs via synthetic data generation, where generative models can potentially add human-like errors to a large, unannotated corpus. Different sequence-to-sequence architectures, such as the Transformer module (Vaswani et al., 2017), could also be explored and researched more exhaustively. The word-level features provided by FastText could also be replaced by separately trained neural approaches that generate word embeddings from a word's characters (e.g., ELMo embeddings, Peters et al. 2018), and could also be fine-tuned towards specific applications. Another interesting direction includes hybrid word-character architectures, where the encoder receives word-level features, while the decoder operates at the character level. We are also interested in applying our approach to other languages and dialects.

Abstract

Topic coherence is increasingly being used to evaluate topic models and filter topics for end-user applications. Topic coherence measures how well topic words relate to each other, but offers little insight into the utility of the topics in describing the documents. In this paper, we explore the topic intrusion task — the task of guessing an outlier topic given a document and a set of topics — and propose a method to automate it. We improve upon the state-of-the-art substantially, demonstrating its viability as an alternative method for topic model evaluation.

1 Introduction

Topic models have traditionally been evaluated using model perplexity, but there is an increasing trend to use topic coherence as a task-independent evaluation (Newman et al., 2010; Mimno et al., 2011; Aletras and Stevenson, 2013; Lau et al., 2014; Röder et al., 2015). In earlier work (Bhatia et al., 2017), we showed that topic coherence as a standalone evaluation can be misleading, which we illustrated with an adversarial topic model that produces highly coherent topics that collectively tell us little about the content of the document collection.

We went on to explore an alternative approach to assessing topics using topic intrusion, based on the manual task of Chang et al. (2009). In the original topic intrusion setup, users are presented with a document, a set of associated topics (from a topic model) and an intruder topic, and are tasked to find the intruder. Success in the task demonstrates that the topics learnt by the topic model are relevant to the document. We proposed a method to automate this (Bhatia et al., 2017), by training a support vector regression model based on information retrieval (IR) and word co-occurrence features to predict the intruder topic.

Although our earlier method is able to distinguish between good and bad topic models (at the model-level), we provided no evaluation at the document level other than the observation that "there are still slight disparities between human annotators and the automated method in intruder topic selection". Additionally, the method involves a number of dependencies on complex external systems such as Indri, and no implementation of the method was ever released. In this paper, we extend our earlier work (Bhatia et al., 2017) as follows: (1) we improve the results based on a novel neural model and provide additional analysis of document-level evaluation via mean-absolute-error; (2) we propose a new metric to measure the performance of the system; and (3) we release an open source implementation of our system.[1]

2 Related Work

Chang et al. (2009) introduced the word and topic intrusion tasks to assess topic models. Since then, various automatic measures to assess topics have been proposed (Newman et al., 2010; Mimno et al., 2011; Aletras and Stevenson, 2013). Lau et al. (2014) compared and contrasted these approaches, and proposed a variant method based on normalised pointwise mutual information. Röder et al. (2015) conducted a systematic search using a framework that combines various existing measures.

In Bhatia et al. (2017), we revisited the topic intrusion task of Chang et al. (2009), and explored its viability as an alternative task-independent approach for topic model evaluation. We tested a number of topic models and found that there can be large discrepancies between conventional topic coherence measures and topic intrusion results, suggesting that topics can be individually coherent but

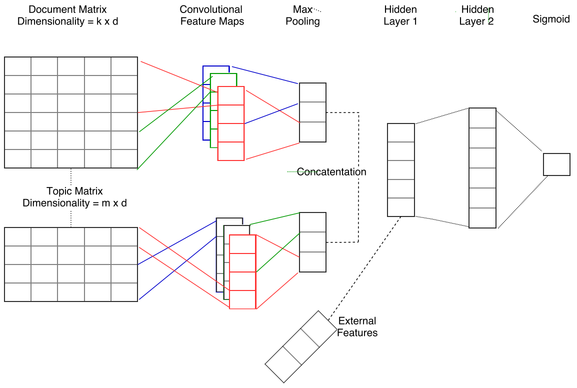

Figure 1: Architecture diagram of our method

poor descriptors of the documents. In addition, we proposed a method to automate the topic intrusion task and reported encouraging correlation levels with human judgements for model-level evaluation.

3 Datasets and Topic Models

We conduct our experiments using the datasets of Bhatia et al. (2017): (1) APNEWS, a collection of Associated Press news articles; and (2) the British National Corpus ("BNC": Burnard (1995)), made up of excerpts from diverse sources such as journals, books, letters, and articles. For the topic models we experiment with the following: standard LDA (`lda`: Blei et al. (2003)), correlated topic model (`ctm`: Blei and Lafferty (2006)), non-parametric topic model (`hca`: Buntine and Mishra (2014)), neural topic model (`ntm`: Cao et al. (2015)), and an adversarial topic model (`cluster`: Bhatia et al. (2017)). `cluster` is adversarial in the sense that it is designed to produce topics that are coherent but poor descriptors of documents.

4 Methodology

In this section, we briefly describe the topic intrusion task and propose an improved methodology to automate it.

4.1 Task

Chang et al. (2009) first proposed the topic intrusion task with the aim of assessing whether topics associated with a document capture its content. In this task, an annotator is presented with a document along with its top-3 highest probability topics and a low probability intruder topic, and are asked to identify the outlier intruder topic. Bhatia et al. (2017) incorporate an additional constraint: the intruder topic has to have high probability for at least one other document. Their rationale is to ensure that the intruder is interpretable. We follow the approach of our earlier work (Bhatia et al., 2017) when generating intruder topics.

4.2 Human Judgements

To assess our methodology, we need human annotations for the topic intrusion task. We collect human judgements using Amazon Mechanical Turk. Each HIT is comprised of 5 documents, and each document is paired with 4 topics (3 real and 1 intruder). To control for annotation quality, an additional document–topics pair is inserted as part of the HIT. The control item's intruder topic is generated by randomly sampling words from the corpus vocabulary. To pass the quality control, an annotator has to select the correct intruder topic; they are filtered out if their pass rate over all controls is < 0.6.[2]

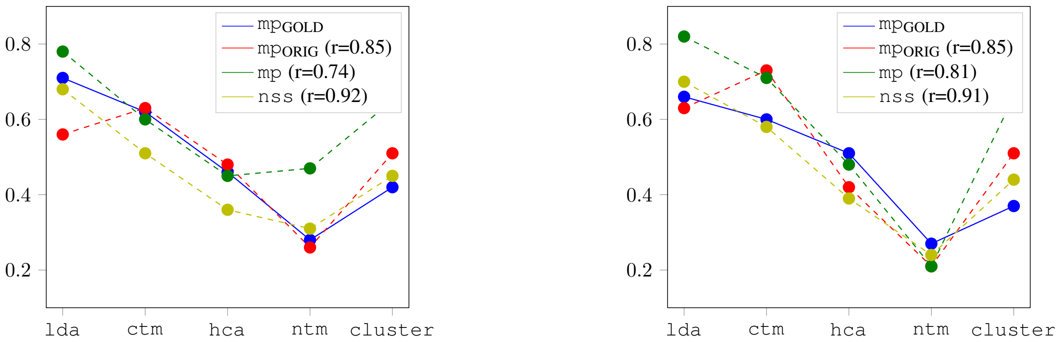
Each HIT is judged by 10 workers. We collect additional annotations by releasing the task internally to a small number of local workers. We needed to carry out some annotations internally to make sure that each HIT had at least 4 annotations. The average number of internal annotations was approximately 1.6. For each topic model, we collected annotations for 100 documents on 2 corpora (5 topic models $\times$ 100 documents $\times$ 2 collections $=$ 1000). After filtering and including internal judgements we have an average of 6.7 and 6.9 annotations for APNEWS and BNC, respectively.

4.3 Intruder Topic Detection

We propose a neural network model to automatically predict intruder topics. Our model is inspired by Severyn and Moschitti (2015), where they combine a learn-to-rank deep learning architecture in an IR setting to rank the documents for a given query. We adapt it to our topic intrusion task by ranking topics for a given document. Our task takes the form of a document d_i with corresponding topics $T_i = \{t_i^1, t_i^2, t_i^3, t_i^4\}$, where 3 topics are real and 1 is the intruder. The topic set T_i has labels $Y_i = \{y_i^1, y_i^2, y_i^3, y_i^4\}$ ("1" denotes the intruder topic, or "0" otherwise). We train using a pointwise ranking approach, where training examples

---

[2] We fixed the threshold to 0.6 based on preliminary experiments. We found that it was a challenging task, and this value provides quality without filtering out most of the workers.



(a) APNEWS

(b) BNC

Figure 2: $\texttt{mp}_{\text{GOLD}}$ vs. System Scores at the model level

are triples of (d_i, t_i^j, y_i^j) — essentially the task is formulated as a binary classification problem.

The architecture of our network is given in Figure 1. The input to our model is a document–topic pair, with each represented as a sequence of words. These words are mapped to embeddings, via embedding matrix $W \in \mathbb{R}^{|V| \times d}$, where V is the vocabulary and d the dimensionality of the embeddings. The document embeddings $E_d \in \mathbb{R}^{k \times d}$ (k = document length) and topic embeddings $E_t \in \mathbb{R}^{m \times d}$ (m = number of topic words) are processed via convolutional layers (Kim, 2014; Severyn and Moschitti, 2015) to produce two hidden representations for the document and topic. The convolution operation is performed using feature maps of varying size followed by a max-pooling operation to produce a constant-length vector. The document and topic hidden representations are concatenated and fed to 2 dense layers and ultimately reduced to a sigmoid-activated score.

4.3.1 External IR Feature

A good topic model learns common themes in the document collection. A limitation of our network is the lack of global- or collection-level information (as the input consists of only a document and topic). To incorporate collection-level information, we include an IR feature where we query document d_i using the topic words of t_i^j. We use Okapi BM25 (Robertson and Walker, 1994) to compute the relevance score of the document with respect to its N topic words independently, thereby constructing an N-dimensional feature vector.[3] This external feature vector is incorporated into the network after the convolutional layers (see Figure 1).

Model	BNC → APNEWS			APNEWS → BNC		
	$\texttt{mp}_{\text{ORIG}}$	mp	nss	$\texttt{mp}_{\text{ORIG}}$	mp	nss

Overall	0.46	0.37	**0.20**	0.42	0.36	**0.21**

Table 1: mae between $\texttt{mp}_{\text{GOLD}}$ and nss/mp. "BNC → APNEWS" means the model is trained on BNC and tested on APNEWS. Boldface indicates optimal performance for each dataset.

4.4 Aggregating Human and System Scores for a Document

For each document we have a number of workers identifying the intruder topic. To aggregate the results, Chang et al. (2009) define model precision ($\texttt{mp}_{\text{GOLD}}$), which is the proportion of workers who correctly identified the intruder, as a proxy for how clearly the intruder topic is inappropriate for the document.

Our system and that of Bhatia et al. (2017) compute several scores for a document (one for each topic). Bhatia et al. (2017) select the topic with the maximum score as the intruder, and compute model precision (mp) based on that. This yields binary precision scores (i.e. the model either predicts the intruder correctly or not) and ignores the relative magnitude of the system score. We additionally propose using the normalised sigmoid score (nss) as a means of scoring the intruder topic for a given document, which is computed by normalising the raw sigmoid scores over all topics.

Table 2: Examples of best topics (top-half) and worst topics (bottom-half) based on `nss`.

4.4.1 Implementation Details

For our experiments, we train the model on outputs from all topics models over one dataset, and test it on the other (cross-domain training). We use a single channel for the convolutional networks, pad the documents as necessary ($k = 200$), and use the top-10 words to represent a topic (i.e. $m = 10$). Word embeddings are initialised using pre-trained GloVe (Pennington et al., 2014) vectors ($d = 100$), and their weights are fixed during training. We use kernel windows of width $= \{3, 5, 7\}$ with 100 feature maps each and two (fully-connected) hidden layers, with dimensionality of 50 and 10. We use a dropout rate of 0.5, 0.5 and 0.25 after the document, topic and first hidden layer, respectively. We set the batch size to 100, and use Adam as the optimizer with a learning rate of 0.001. For activation functions, we use ReLU for the fully-connected layers and sigmoid for the final layer. To reduce variance, we run the models with 8 different seeds for initialisation and take the average for a topic's sigmoid score.

5 Results

By taking the mean of $\texttt{mp}_{\text{GOLD}}$ and `mp` over documents, Bhatia et al. (2017) compute a single human/system score for each topic model. Although this resulted in a strong correlation between $\texttt{mp}_{\text{GOLD}}$ and `mp`, the evaluation is limited to model-level comparison: it separates good topic models from bad topic models, but does not provide any insights into the performance of each top model over individual documents. We aim to improve model-level correlation in this work, in addition to analysing document-level evaluation, i.e. investigating how well the system predicts $\texttt{mp}_{\text{GOLD}}$ for each individual document.

We present plots of human and system scores in Figure 2. There are 3 system scores: `mp` of Bhatia et al. (2017) ($\texttt{mp}_{\text{ORIG}}$), and `mp` and `nss` of our proposed system. In general, we found strong correlation for all systems, but `nss` of our proposed system performs substantially better than $\texttt{mp}_{\text{ORIG}}$, though our `mp` is lower than $\texttt{mp}_{\text{ORIG}}$.

To compare the performance of our system with human judgements at the document level, we compute mean absolute error (`mae`) between $\texttt{mp}_{\text{GOLD}}$ and `nss`/`mp`, as summarised in Table 1. We find for both datasets `nss` consistently outperforms $\texttt{mp}_{\text{ORIG}}$ and `mp` by a substantial margin, and also has a score close to human judgements. We can attribute this to the fact that `nss` provides more nuanced system predictions (over the full range $[0, 1]$), whereas `mp` tends to be binary.[4]

6 Discussion

One motivation we have in this paper is to test whether topic intrusion can be used as an alternative means for assessing topics. Given the encouraging

---

[4] Strictly speaking, it is continuous as it is averaged over the runs for the multiple random seeds, but in general, it tends to be (close to) 0 or 1.

`mae` results, we attempt to use `nss` to rank topics produced by a topic model.

To accomplish this, we first filter out the topics that occur in less than 5 documents as top 1-topic: these topics tend to be noisy, and as such do not appear with significant weight in any documents. For each of the filtered topics we randomly select 5–10 documents for which it is a top topic and calculate its mean `nss` over these documents. We then use the topics' mean `nss` to rank them; in Table 2 we show some selected best and worst topics for different topic models. Overall, the top-ranked topics appear to be more descriptive than the bottom-ranked topics. Having said that, we found instances where coherent topics have low `nss` ranking (e.g. `ctm` topics in the bottom half of Table 2), but stress that ultimately the topic intrusion approach to assessing topics is very different to topic coherence. We include a more comprehensive list of best/worst topics in the supplementary material.

7 Conclusion

We explore an alternative approach to evaluate topic models based on topic allocations in documents, i.e. via topic intrusion. We propose an automated method that improves upon the state-of-the-art substantially at the model- and document-levels, and demonstrate that it can be used to rank/filter topics. As future work we intend to explore ways that combine both the topic coherence and topic intrusion for topic model evaluation.

Abstract

The text in many web documents is organized into a hierarchy of section titles and corresponding prose content, a structure which provides potentially exploitable information on discourse structure and topicality. However, this organization is generally discarded during text collection, and collecting it is not straightforward: the same visual organization can be implemented in a myriad of different ways in the underlying HTML. To remedy this, we present a flexible system for automatically extracting the hierarchical section titles and prose organization of web documents irrespective of differences in HTML representation. This system uses features from syntax, semantics, discourse and markup to build two models which classify HTML text into section titles and prose text. When tested on three different domains of web text, our domain-independent system achieves an overall precision of 0.82 and a recall of 0.98. The domain-dependent variation produces very high precision (0.99) at the expense of recall (0.75). These results exhibit a robust level of accuracy suitable for enhancing question answering, information extraction, and summarization.[1]

1 Introduction

Web text continues to be an immense resource for researchers working in NLP and related areas, but its typographic structure (i.e., its visual organization) remains underutilized. Many texts on the web are organized into sections based on the topics presented, and each section has a title followed by prose text. The title tends to be visually distinct to separate it from the prose that succeeds it. Apart from improving the readability of the page, this explicit organization makes titles act as intuitive indexes for the prose text(s) that follow them. In other words, titles are concise summaries of the following prose text.

Most current methods of web text extraction do not separate titles from prose text, instead treating the entire document as a single unit without internal structure. However, this internal organization has the potential to provide input to a variety of NLP tasks that can make use of information on topicality or discourse structure. In the case of question answering, this information can facilitate identifying maximally relevant sections to search for answers. It can also increase accuracy by filtering out false positives and minor references related to the topic of the question, which might be present in other sections. For information retrieval tasks, semantic matching of the search terms can be performed on the titles first, followed by a search on the prose texts associated with closely matching headers.

However, detecting the titles and prose segments in an HTML document is difficult for two reasons. One of them is the flexibility of HTML, which allows the same typographic layout to be represented in code in multiple ways. Tags are also nested with varying depths. Figure 1 illustrates this problem: similar title and prose text segments from four website privacy policies[2] have altogether different HTML tag structures. The second problem is that it is not straightforward to distinguish the information (encoded in HTML) that is necessary for title-prose detection from the rest of the HTML structure, including unrelated links, multiple tags with little or no content and page headers and footers. Sieving only useful information from these pages requires a flexible approach.

We present ASDUS (Automatic Segment Detection using Unsupervised and Supervised learning), a system that uses a variety of features of text and markup structure to identify the title and prose organization of HTML documents automatically. Our approach effectively strips away all unrelated HTML and produces simplified HTML with a predictable tag structure, thus making the extraction of section titles and prose text straightforward for downstream applications. We present two approaches, a domain-independent approach that requires no prior training and a domain-dependent approach that takes advantage of a labeled corpus. The domain-independent approach (abbreviated *DI*) yields an overall precision of 0.82, recall of 0.98 and coverage of 97.21%. The domain dependent approach (*DD*) produces an overall precision of 0.99, recall of 0.75 and coverage of 93.10%. We are releasing ASDUS and associated datasets to the research community for use and improvement.

2 Related Work

The detection of titles and prose in web documents has received little (if any) prior attention, but we briefly survey literature in some related areas.

Titles can be thought of as metalinguistic descriptions for the prose text they are associated with. Wilson (2013) attempted to identify a core metalinguistic vocabulary for the English language and to automatically identify instances of metalanguage usage. Deixis present in a text can also be considered metadata and detection of deixis helps in structuring the flow of information. Wilson and Oberlander (2014) attempted to capture word senses related to deixis.

Topic classification is the problem of segregating a document into different topics, and argumentative zoning (Teufel et al., 1999) was an early effort that shares some goals with the present work, as it addressed the detection of the main thematic areas in research articles. Teufel and Kan (2011) built a robust argumentative zoning system which used maximum entropy modeling to go with morphological features. Conditional random fields were adopted for categorization of sentences of a scientific abstract into different sections by Hirohata et al. (2008). Using posterior discourse and lexical constraints as features, Guo et al. (2013) improved upon existing information structure analysis of scientific documents through unsupervised and minimal supervised learning.

HTML structure analysis is the process of extracting useful information by utilizing the underlying HTML document structure. Information extraction from HTML using machine learning was introduced in SRV (Freitag, 1998), a top-down relational algorithm for information extraction. This system aimed at filling pre-defined slots for a web page in a particular domain. A set of extraction rules suitable to extract information from a website is called a wrapper (Flesca et al., 2004). Dalvi et al. (2011) worked on enhancing wrapper induction techniques by introducing a generic framework which allows for training on noisy data. Liao et al. (2015) used web block segmentation and machine learning algorithms to retrieve business event data, such as coupons, tickets, and sales campaigns. García-Plaza et al. (2017) worked on using fuzzy logic to leverage HTML markup for web page clustering. Using four essential features viz., text frequency, title, emphasis and position, they define 31 independent rules to arrive at the importance of a text segment. Unlike our approach, which is independent of the tag structures and learns patterns on its own, these methods depend on handcrafted rules and similar tag structures to identify various sections of the document.

3 Approach

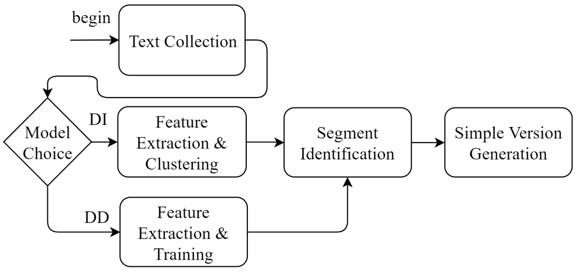

Figure 2: Stages of the DI and DD approaches.

3.1 Domain-Independent Approach (DI)

Figure 2 depicts the stages of this approach, which are explained in detail below.

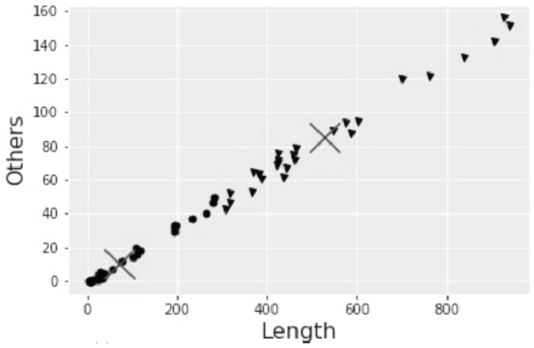

Figure 3: The graph shows two clusters. The one nearer to the origin is the title cluster and the farther one is the prose cluster. Cluster medians are marked with Xs.

Text Collection: Using jsoup (Hedley, 2017), we parse the HTML file and for each non-empty tag encountered we extract a tuple consisting of the text and its XPath.

Feature Extraction and Clustering: For each tuple, we extract a set of features which aids in differentiating titles from prose text. The features are own text length, next text length, number of punctuation symbols, number of sentences, number of stop words (stop words were derived from Weka (Hall et al., 2009)), number of discourse cues, number of named entity slots and number of words with capitalized initial letter. We calculated the number of discourse cues as the sum of explicit discourse markers provided by Denver (2018) and the number of coreference chains. We used Stanford CoreNLP (Manning et al., 2014) for identifying coreference chains and named entities.

Titles tend to contain less text than prose segments, as well as fewer punctuation symbols, stop words, discourse markers, sentences and named entities. Since titles are not followed immediately by titles (in most cases), the next text length feature helps to remove false positives for title identification. All these features are collapsed into two dimensions, one being the text length and the other being the linear combination of remaining features.

K-means clustering (using scikit-learn (Pedregosa et al., 2011)) is performed on the feature set to group it into two mutually exclusive subsets. Figure 3 shows an example plot of the clustering. We obtain two distinct clusters with the title cluster closer to the origin and the prose cluster away from the origin. We leverage this property to obtain the label of the title cluster by identifying the label for the origin ([0,0]). Each text segment (and thus each tuple) is classified into title or prose using the k-means model.

Segment Identification: For each potential title identified in the previous phase, an overlap score is calculated by measuring the overlap between the lemmatized form of words belonging to the title and the lemmatized form of words from the next text segment. Based on experiments on a development set, the overlap threshold was set to 75%. Titles with overlap scores exceeding the threshold and their corresponding XPaths are added to the list of probable title candidates.

Simple Version Generation: Each element in the final title list is marked with a custom attribute in the original HTML. To generate the simple version, a top down parse of the HTML is performed, wherein nodes with custom attribute (titles) are enclosed in <*h2*> tags and the text between two consecutive titles (prose) is enclosed in <*p*> tags. For the last segment, the prose text immediately following the title is added. For subsequent prose sections, a unigram overlap score similar to the one in the previous step is performed to avoid the addition of unrelated text, such as a page footer. Legitimate textual content appearing before the first title is included in the final output under an uncategorized title.

Type of Doc.	# Docs.	# Titles	# Prose
Privacy	152	3611	14506
TOS	100	2299	7818
Misc.	51	685	3676

Table 1: Test set details of the DI approach.

3.2 Domain-Dependent Approach (DD)

The DD approach differs from the DI approach by feature selection: the DD approach trains a neural network classifier on previously labeled examples.

Feature Extraction and Training: To construct labeled data for training, we chose to use web privacy policies due to their lengthy nature, the presence of a reasonable number of segments, the presence of relatively similar content with varying HTML structure across websites and their importance to the general public. We annotated each HTML tag of 100 web privacy policies with one of three labels: title, prose and unrelated. We built two word embedding models (using gensim (Řehůřek and Sojka, 2010)), one using text from the titles and the other using prose texts. Then for each HTML tag, we calculated two semantic relatedness scores: one between the title embedding and the text in the tag (*t-score*), and the other between the prose embedding and the text in the tag (*p-score*). The t-score is the log probability for a text segment with respect to the title embedding. The p-score is the log probability for a text segment with respect to the prose embedding. The intuition behind using these scores is that the t-score will be higher for titles and lower for prose text. Similarly, the p-score will be higher for prose text than titles. The t-score, p-score and length of the text formed the feature set. Using Tensor Flow (Abadi et al., 2015), we trained a feed forward neural network (h1=24, h2=48) to classify text between tags as title, prose or unrelated.

4 Dataset and Results

The problem of automatic detection of titles and prose text in HTML documents has received scant prior attention. Due to this, a corpus containing HTML documents along with their respective annotated versions (titles and prose sections annotated) was unavailable. This lack of data prompted the creation of a new corpus consisting of web documents and their respective annotated versions.

The dataset consisted of three sets of web documents to achieve an exhaustive evaluation of the system. The first set consisted of 152 website privacy policies. We collected 80 of them from Amazon Alexa's top 100 websites list for 2016 and 72 from the top two websites of each top Google Trends entry of 2017. Privacy policies of various companies have different HTML structure. They tend to contain many sections with each section having a title and corresponding prose text. They are also lengthy and include essential information which is often neglected by most users (Wilson et al., 2016). These factors make privacy policies ideal candidates for testing ASDUS. For the second set, we used www.randomlists.com to generate a list of 200 random sites. We selected the websites which had terms of service in English, and this left us with 100 documents. Similar to privacy policies, terms of service documents offer a reliable set of testing opportunities. For the third set, we wanted greater diversity in content and domain, leading us to chose web pages by collecting the top two to four Google search results for the following topics: *news, sports, botany, web design, photography, data science, cookie policies, HTML, history, migraine, dataset, technical documentation, shoes, grammar, kids stories and cricket*. We skipped web pages which did not have sectional demarcations. Table 1 has more details on the size of the dataset. The dataset for the DD approach consisted of the same 152 web privacy policies which were used in the DI approach. Privacy policies of different websites have content related to similar topics which makes them specific and suitable for the DD approach. Out of 152, 122 were used for training and development and the remaining 30 were used for testing. We manually annotated the entire data set and created sanitized versions out of them for evaluation.

We evaluated our models in two ways. One was the ability to detect all title and prose segments, measured via precision, recall and F-1 scores. This metric is evaluated by comparing the simplified output of ASDUS with the sanitized version. The output was deemed correct only when the system detected and produced both the title and its corresponding prose section. The second facet of evaluation was to determine the percentage of legitimate original text reproduced in the output. We name this the *coverage* of the output. A higher coverage indicates lower loss of text, which is desirable.

The results of the DI approach are presented in Table 2. The near-perfect recall is due to the ro-

Type	P	R	F1	S	C
PP	0.75	0.97	0.85	3611	96.92%
TOS	0.92	0.99	0.95	2299	98.85%
Misc	0.89	0.98	0.93	685	95.86%
Avg	0.82	0.98	0.89	6595	97.21%

Table 2: Results of the DI model. Columns represent type of web document, precision, recall, F-1 score, support and coverage respectively. Under *Type*, PP=privacy policies, TOS=terms of service, Misc=miscellaneous and Avg=weighted average.

bust method of learning XPaths of all titles coupled with the clustering method, which ensured the detection of nearly all the segments. Precision is slightly lower because some prose texts with relatively short lengths were wrongly classified as titles. The feature set enables the creation of two distinct clusters, which in turn results in all titles being detected during the clustering phase. To test the effect of each feature on the final results, an ablation study was conducted by removing one different feature from each run. This resulted in a total of seven runs, whose results are depicted in Table 3. The dropped feature is listed in the first column. The biggest drop in performance occurs when the own text length feature is dropped. The drop in F-1 scores in all runs suggests the contribution of every feature towards the result. The removal of discourse markers and named entity slots resulted in the least decrease in performance, and the greatest decrease came from removing text length.

Dropped Feature	P	R	F1
text length	0.69	0.73	0.71
stop words	0.75	0.75	0.75
punctuation symbols	0.76	0.79	0.77
sentences	0.76	0.79	0.77
next text length	0.76	0.81	0.78
capitalized first letter	0.78	0.80	0.79
discourse markers	0.79	0.85	0.81
named entity slots	0.79	0.85	0.81
None	**0.82**	**0.98**	**0.85**

Table 3: Results of the ablation study for the DI approach. The columns indicate dropped feature, precision, recall and F-1 score respectively.

In sharp contrast to the DI approach, the DD approach (Table 4) has high precision owing to the similarity of title texts across documents in the same domain and differences between vocabularies of title and prose text. Training on word embeddings of titles has rendered the system sensitive to variations, resulting in the rejection of many legitimate titles, which in turn led to the slightly lower recall and coverage values. This over-fitting can be mitigated by training on a larger corpus and by increasing the context window while generating word embeddings of prose text.

Precision	Recall	F-1	Supp.	Cover
0.99	0.75	0.86	754	93.10%

Table 4: Results of the DD model.

The complementary nature of the two models is identifiable from the results. The word embeddings of the DD approach contribute towards precision, and the lexical and morphological features of the DI approach contribute towards recall. We can treat the word embeddings as the semantic aspect of the underlying text and the lexical and morphological characteristics of the DI model as the syntactic aspect. Both of these aspects of language thus inform the orthographic structure of documents. However, the domain-independence or the ability of the DI approach to work on different domains without the need for prior labeled data is a substantial advantage over the DD approach, which requires pre-labeled data. Annotation of HTML documents and generation of the sanitized version is a tedious process and requires human effort, lending value to both methods.

5 Future Work and Conclusion

The two methods presented in this paper were effective in identifying the title and prose texts of segments of HTML pages. The DI approach, with its high coverage, is desirable when the penalty for losing text is high. The DD approach can be used in situations where precision is prioritized over recall. In the future, we intend to build upon our methods and enable automatic detection of subheaders. This would lead to the identification of hierarchical organization of the text, which provides a novel approach to generate web ontologies. Further, we have planned to generate titles for prose text essentially creating micro-summaries of text, a relatively unexplored area.

Abstract

In this work, we examine methods for data augmentation for text-based tasks such as neural machine translation (NMT). We formulate the design of a data augmentation policy with desirable properties as an optimization problem, and derive a generic analytic solution. This solution not only subsumes some existing augmentation schemes, but also leads to an extremely simple data augmentation strategy for NMT: randomly replacing words in *both the source sentence and the target sentence* with other random words from their corresponding vocabularies. We name this method SwitchOut. Experiments on three translation datasets of different scales show that SwitchOut yields consistent improvements of about 0.5 BLEU, achieving better or comparable performances to strong alternatives such as word dropout (Sennrich et al., 2016a). Code to implement this method is included in the appendix.

1 Introduction and Related Work

Data augmentation algorithms generate extra data points from the empirically observed training set to train subsequent machine learning algorithms. While these extra data points may be of lower quality than those in the training set, their quantity and diversity have proven to benefit various learning algorithms (DeVries and Taylor, 2017; Amodei et al., 2016). In image processing, simple augmentation techniques such as flipping, cropping, or increasing and decreasing the contrast of the image are both widely utilized and highly effective (Huang et al., 2016; Zagoruyko and Komodakis, 2016).

However, it is nontrivial to find simple equivalences for NLP tasks like machine translation, because even slight modifications of sentences can result in significant changes in their semantics, or require corresponding changes in the translations in order to keep the data consistent. In fact, indiscriminate modifications of data in NMT can introduce noise that makes NMT systems brittle (Belinkov and Bisk, 2018).

Due to such difficulties, the literature in data augmentation for NMT is relatively scarce. To our knowledge, data augmentation techniques for NMT fall into two categories. The first category is based on back-translation (Sennrich et al., 2016b; Poncelas et al., 2018), which utilizes monolingual data to augment a parallel training corpus. While effective, back-translation is often vulnerable to errors in initial models, a common problem of self-training algorithms (Chapelle et al., 2009). The second category is based on word replacements. For instance, Fadaee et al. (2017) propose to replace words in the target sentences with rare words in the target vocabulary according to a language model, and then modify the aligned source words accordingly. While this method generates augmented data with relatively high quality, it requires several complicated preprocessing steps, and is only shown to be effective for low-resource datasets. Other generic word replacement methods include word dropout (Sennrich et al., 2016a; Gal and Ghahramani, 2016), which uniformly set some word embeddings to 0 at random, and Reward Augmented Maximum Likelihood (RAML; Norouzi et al. (2016)), whose implementation essentially replaces some words in the target sentences with other words from the target vocabulary.

In this paper, we derive an extremely simple and efficient data augmentation technique for NMT. **First,** we formulate the design of a data augmentation algorithm as an optimization problem, where we seek the data augmentation policy that maximizes an objective that encourages two desired properties: smoothness and diversity. This optimization problem has a tractable analytic solution,

*: Equal contributions.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 856–861
Brussels, Belgium, October 31 - November 4, 2018.

which describes a generic framework of which both word dropout and RAML are instances. **Second,** we interpret the aforementioned solution and propose a novel method: independently replacing words in *both the source sentence and the target sentence* by other words uniformly sampled from the source and the target vocabularies, respectively. Experiments show that this method, which we name SwitchOut, consistently improves over strong baselines on datasets of different scales, including the large-scale WMT 15 English-German dataset, and two medium-scale datasets: IWSLT 2016 German-English and IWSLT 2015 English-Vietnamese.

2 Method

2.1 Notations

We use uppercase letters, such as X, Y, etc., to denote random variables and lowercase letters such as x, y, etc., to denote the corresponding actual values. Additionally, since we will discuss a data augmentation algorithm, we will use a hat to denote augmented variables and their values, *e.g.* $\widehat{X}$, $\widehat{Y}$, $\widehat{x}$, $\widehat{y}$, etc. We will also use boldfaced characters, such as $\mathbf{p}$, $\mathbf{q}$, etc., to denote probability distributions.

2.2 Data Augmentation

We facilitate our discussion with a probabilistic framework that motivates data augmentation algorithms. With X, Y being the sequences of words in the source and target languages (*e.g.* in machine translation), the canonical MLE framework maximizes the objective

$$J_{\text{MLE}}(\theta) = \mathbb{E}_{x,y \sim \widehat{\mathbf{p}}(X,Y)} \left[\log \mathbf{p}_\theta(y|x)\right].$$

Here $\widehat{\mathbf{p}}(X,Y)$ is the empirical distribution over all training data pairs (x,y) and $\mathbf{p}_\theta(y|x)$ is a parameterized distribution that we aim to learn, *e.g.* a neural network. A potential weakness of MLE is the mismatch between $\widehat{\mathbf{p}}(X,Y)$ and the true data distribution $\mathbf{p}(X,Y)$. Specifically, $\widehat{\mathbf{p}}(X,Y)$ is usually a bootstrap distribution defined only on the observed training pairs, while $\mathbf{p}(X,Y)$ has a much larger support, *i.e.* the entire space of valid pairs. This issue can be dramatic when the empirical observations are insufficient to cover the data space.

In practice, data augmentation is often used to remedy this support discrepancy by supplying additional training pairs. Formally, let $\mathbf{q}(\widehat{X},\widehat{Y})$ be the augmented distribution defined on a larger support than the empirical distribution $\widehat{\mathbf{p}}(X,Y)$. Then, MLE training with data augmentation maximizes

$$J_{\text{AUG}}(\theta) = \mathbb{E}_{\widehat{x},\widehat{y} \sim \mathbf{q}(\widehat{X},\widehat{Y})} \left[\log \mathbf{p}_\theta(\widehat{y}|\widehat{x})\right].$$

In this work, we focus on a specific family of $\mathbf{q}$, which depends on the empirical observations by

$$\mathbf{q}(\widehat{X},\widehat{Y}) = \mathbb{E}_{x,y \sim \widehat{\mathbf{p}}(x,y)} \left[\mathbf{q}(\widehat{X},\widehat{Y}|x,y)\right].$$

This particular choice follows the intuition that an augmented pair $(\widehat{x},\widehat{y})$ that diverges too far from any observed data is more likely to be invalid and thus harmful for training. The reason will be more evident later.

2.3 Diverse and Smooth Augmentation

Certainly, not all $\mathbf{q}$ are equally good, and the more similar $\mathbf{q}$ is to $\mathbf{p}$, the more desirable $\mathbf{q}$ will be. Unfortunately, we only have access to limited observations captured by $\widehat{\mathbf{p}}$. Hence, in order to use $\mathbf{q}$ to bridge the gap between $\widehat{\mathbf{p}}$ and $\mathbf{p}$, it is necessary to utilize some assumptions about $\mathbf{p}$. Here, we exploit two highly generic assumptions, namely:

- **Diversity:** $\mathbf{p}(X,Y)$ has a wider support set, which includes samples that are more diverse than those in the empirical observation set.

- **Smoothness:** $\mathbf{p}(X,Y)$ is smooth, and similar (x,y) pairs will have similar probabilities.

To formalize both assumptions, let $s(\widehat{x},\widehat{y};x,y)$ be a similarity function that measures how similar an augmented pair $(\widehat{x},\widehat{y})$ is to an observed data pair (x,y). Then, an ideal augmentation policy $\mathbf{q}(\widehat{X},\widehat{Y}|x,y)$ should have two properties. First, based on the smoothness assumption, if an augmented pair $(\widehat{x},\widehat{y})$ is more similar to an empirical pair (x,y), it is more likely that $(\widehat{x},\widehat{y})$ is sampled under the true data distribution $\mathbf{p}(X,Y)$, and thus $\mathbf{q}(\widehat{X},\widehat{Y}|x,y)$ should assign a significant amount of probability mass to $(\widehat{x},\widehat{y})$. Second, to quantify the diversity assumption, we propose that the entropy $\mathbb{H}[\mathbf{q}(\widehat{X},\widehat{Y}|x,y)]$ should be large, so that the support of $\mathbf{q}(\widehat{X},\widehat{Y})$ is larger than the support of $\widehat{\mathbf{p}}$ and thus is closer to the support $\mathbf{p}(X,Y)$. Combining these assumptions implies that $\mathbf{q}(\widehat{X},\widehat{Y}|x,y)$ should maximize the objective

$$\begin{aligned} J(\mathbf{q};x,y) = &\ \mathbb{E}_{\widehat{x},\widehat{y} \sim \mathbf{q}(\widehat{X},\widehat{Y}|x,y)} \left[s(\widehat{x},\widehat{y};x,y)\right] \\ &+ \tau \mathbb{H}(\mathbf{q}(\widehat{X},\widehat{Y}|x,y)), \end{aligned} \tag{1}$$

where τ controls the strength of the diversity objective. The first term in (1) instantiates the smoothness assumption, which encourages $\mathbf{q}$ to draw samples that are similar to (x, y). Meanwhile, the second term in (1) encourages more diverse samples from $\mathbf{q}$. Together, the objective $J(\mathbf{q}; x, y)$ extends the information in the "pivotal" empirical sample (x, y) to a diverse set of similar cases. This echoes our particular parameterization of $\mathbf{q}$ in Section 2.2.

The objective $J(\mathbf{q}; x, y)$ in (1) is the canonical maximum entropy problem that one often encounters in deriving a max-ent model (Berger et al., 1996), which has the analytic solution:

$$\mathbf{q}^*(\widehat{x}, \widehat{y}|x, y) = \frac{\exp\left\{s(\widehat{x}, \widehat{y}; x, y)/\tau\right\}}{\sum_{\widehat{x}', \widehat{y}'} \exp\left\{s(\widehat{x}', \widehat{y}'; x, y)/\tau\right\}} \tag{2}$$

Note that (2) is a fairly generic solution which is agnostic to the choice of the similarity measure s. Obviously, not all similarity measures are equally good. Next, we will show that some existing algorithms can be seen as specific instantiations under our framework. Moreover, this leads us to propose a novel and effective data augmentation algorithm.

2.4 Existing and New Algorithms

Word Dropout. In the context of machine translation, Sennrich et al. (2016a) propose to randomly choose some words in the source and/or target sentence, and set their embeddings to 0 vectors. Intuitively, it regards every new data pair generated by this procedure as similar enough and then includes them in the augmented training set. Formally, word dropout can be seen as an instantiation of our framework with a particular similarity function $s(\hat{x}, \hat{y}; x, y)$ (see Appendix A.1).

RAML. From the perspective of reinforcement learning, Norouzi et al. (2016) propose to train the model distribution to match a target distribution proportional to an exponentiated reward. Despite the difference in motivation, it can be shown (*c.f.* Appendix A.2) that RAML can be viewed as an instantiation of our generic framework, where the similarity measure is $s(\widehat{x}, \widehat{y}; x, y) = r(\widehat{y}; y)$ if $\widehat{x} = x$ and $-\infty$ otherwise. Here, r is a task-specific reward function which measures the similarity between $\widehat{y}$ and y. Intuitively, this means that RAML only exploits the smoothness property on the target side while keeping the source side intact.

SwitchOut. After reviewing the two existing augmentation schemes, there are two immediate insights. Firstly, augmentation should not be restricted to only the source side or the target side. Secondly, being able to incorporate prior knowledge, such as the task-specific reward function r in RAML, can lead to a better similarity measure.

Motivated by these observations, we propose to perform augmentation in both source and target domains. For simplicity, we separately measure the similarity between the pair $(\widehat{x}, x)$ and the pair $(\widehat{y}, y)$ and then sum them together, *i.e.*

$$s(\widehat{x}, \widehat{y}; x, y)/\tau \approx r_x(\widehat{x}, x)/\tau_x + r_y(\widehat{y}, y)/\tau_y, \tag{3}$$

where r_x and r_y are domain specific similarity functions and τ_x, τ_y are hyper-parameters that absorb the temperature parameter τ. This allows us to factor $\mathbf{q}^*(\widehat{x}, \widehat{y}|x, y)$ into:

$$\begin{aligned} \mathbf{q}^*(\widehat{x}, \widehat{y}|x, y) = & \frac{\exp\left\{r_x(\widehat{x}, x)/\tau_x\right\}}{\sum_{\widehat{x}'} \exp\left\{r_x(\widehat{x}', x)/\tau_x\right\}} \\ & \times \frac{\exp\left\{r_y(\widehat{y}, y)/\tau_y\right\}}{\sum_{\widehat{y}'} \exp\left\{r_y(\widehat{y}', y)/\tau_y\right\}} \end{aligned} \tag{4}$$

In addition, notice that this factored formulation allows $\widehat{x}$ and $\widehat{y}$ to be sampled independently.

Sampling Procedure. To complete our method, we still need to define r_x and r_y, and then design a practical sampling scheme from each factor in (4). Though non-trivial, both problems have been (partially) encountered in RAML (Norouzi et al., 2016; Ma et al., 2017). For simplicity, we follow previous work to use the *negative* Hamming distance for both r_x and r_y. For a more parallelized implementation, we sample an augmented sentence $\widehat{s}$ from a true sentence s as follows:

1. Sample $\widehat{n} \in \{0, 1, ..., |s|\}$ by $\mathbf{p}(\widehat{n}) \propto e^{-\widehat{n}/\tau}$.
2. For each $i \in \{1, 2, ..., |s|\}$, with probability $\widehat{n}/|s|$, we can replace s_i by a uniform $\widehat{s_i} \neq s_i$.

This procedure guarantees that any two sentences $\widehat{s}_1$ and $\widehat{s}_2$ with the same Hamming distance to s have the same probability, but slightly changes the relative odds of sentences with different Hamming distances to s from the true distribution by negative Hamming distance, and thus is an approximation of the actual distribution. However, this efficient sampling procedure is much easier to implement while achieving good performance.

Algorithm 1 illustrates this sampling procedure, which can be applied independently and in parallel for each batch of source sentences and target sentences. Additionally, we open source our implementation in TensorFlow and in PyTorch (respectively in Appendix A.5 and A.6).

Algorithm 1: Sampling with SwitchOut.

```
Input   : $s$: a sentence represented by vocab integral ids,
          $\tau$: the temperature, $V$: the vocabulary
Output  : $\widehat{s}$: a sentence with words replaced
Function HammingDistanceSample($s$, $\tau$, $|V|$):
    Let $Z(\tau) \leftarrow \sum_{n=0}^{|s|} e^{-n/\tau}$ be the partition function.
    Let $p(n) \leftarrow e^{-n/\tau}/Z(\tau)$ for $n = 0, 1, ..., |s|$.
    Sample $\widehat{n} \sim p(n)$.
    In parallel, do:
        Sample $a_i \sim$ Bernoulli($\widehat{n}/|s|$).
        if $a_i = 1$ then
            $\widehat{s}_i \leftarrow$ Uniform($V \backslash \{s_i\}$).
        else
            $\widehat{s}_i \leftarrow s_i$.
        end
    return $\widehat{s}$
```

3 Experiments

Datasets. We benchmark SwitchOut on three translation tasks of different scales: 1) IWSLT 2015 English-Vietnamese (en-vi); 2) IWSLT 2016 German-English (de-en); and 3) WMT 2015 English-German (en-de). All translations are word-based. These tasks and pre-processing steps are standard, used in several previous works. Detailed statistics and pre-processing schemes are in Appendix A.3.

Models and Experimental Procedures. Our translation model, *i.e.* $\mathbf{p}_\theta(y|x)$, is a Transformer network (Vaswani et al., 2017). For each dataset, we first train a standard Transformer model without SwitchOut and tune the hyper-parameters on the dev set to achieve competitive results. (w.r.t. Luong and Manning (2015); Gu et al. (2018); Vaswani et al. (2017)). Then, fixing all hyper-parameters, and fixing $\tau_y = 0$, we tune the τ_x rate, which controls how far we are willing to let $\widehat{x}$ deviate from x. Our hyper-parameters are listed in Appendix A.4.

Baselines. While the Transformer network without SwitchOut is already a strong baseline, we also compare SwitchOut against two other baselines that further use existing varieties of data augmentation: 1) word dropout on the source side with the dropping probability of $\lambda_{\text{word}} = 0.1$; and 2) RAML on the target side, as in Section 2.4. Additionally, on the en-de task, we compare SwitchOut against back-translation (Sennrich et al., 2016b).

Method	**en-de**	**de-en**	**en-vi**
Transformer	21.73	29.81	27.97
+WordDropout	20.63	**29.97**	28.56
+SwitchOut	**22.78**†	29.94	**28.67**†
+RAML	22.83	30.66	28.88
+RAML +WordDropout	20.69	30.79	28.86
+RAML +SwitchOut	**23.13**†	**30.98**†	**29.09**

Table 1: Test BLEU scores of SwitchOut and other baselines (median of multiple runs). Results marked with † are statistically significant compared to the best result without SwitchOut. For example, for en-de results in the first column, +SwitchOut has significant gain over Transformer; +RAML +SwitchOut has significant gain over +RAML.

SwitchOut vs. Word Dropout and RAML. We report the BLEU scores of SwitchOut, word dropout, and RAML on the test sets of the tasks in Table 1. To account for variance, we run each experiment multiple times and report the median BLEU. Specifically, each experiment without SwitchOut is run for 4 times, while each experiment with SwitchOut is run for 9 times due to its inherently higher variance. We also conduct pairwise statistical significance tests using paired bootstrap (Clark et al., 2011), and record the results in Table 1. For 4 of the 6 settings, SwitchOut delivers significant improvements over the best baseline without SwitchOut. For the remaining two settings, the differences are not statistically significant. The gains in BLEU with SwitchOut over the best baseline on WMT 15 en-de are all significant ($p < 0.0002$). Notably, SwitchOut on the source demonstrates as large gains as these obtained by RAML on the target side, and SwitchOut delivers further improvements when combined with RAML.

SwitchOut vs. Back Translation. Traditionally, data-augmentation is viewed as a method to enlarge the training datasets (Krizhevsky et al., 2012; Szegedy et al., 2014). In the context of neural MT, Sennrich et al. (2016b) propose to use artificial data generated from a weak back-translation model, effectively utilizing monolingual data to enlarge the bilingual training datasets. In connection, we compare SwitchOut against back translation. We only compare SwitchOut against back translation on the en-de task, where the amount of bilingual training data is already sufficiently large[2]. The

---

[2] We add the extra monolingual data from `http://data.statmt.org/rsennrich/wmt16_backtranslations/en-de/`

Method	en-de
Transformer	21.73
+SwitchOut	22.78
+BT	21.82
+BT +RAML	21.53
+BT +SwitchOut	22.93
+BT +RAML +SwitchOut	**23.76**

Table 2: Test BLEU scores of back translation (BT) compared to and combined with SwitchOut (median of 4 runs).

BLEU scores with back-translation are reported in Table 2. These results provide two insights. First, the gain delivered by back translation is less significant than the gain delivered by SwitchOut. Second, SwitchOut and back translation are not mutually exclusive, as one can additionally apply SwitchOut on the additional data obtained from back translation to further improve BLEU scores.

Effects of τ_x and τ_y. We empirically study the effect of these temperature parameters. During the tuning process, we translate the dev set of the tasks and report the BLEU scores in Figure 1. We observe that when fixing τ_y, the best performance is always achieved with a non-zero τ_x.

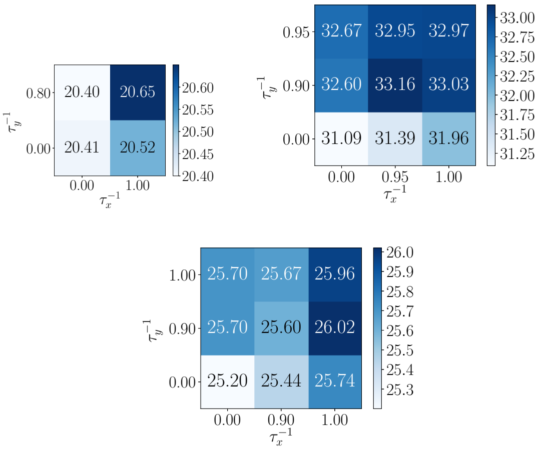

Figure 1: Dev BLEU scores with different τ_x and τ_y. *Top left*: WMT 15 en-de. *Top right*: IWSLT 16 de-en. *Bottom*: IWSLT 15 en-vi.

Where does SwitchOut Help the Most? Intuitively, because SwitchOut is expanding the support of the training distribution, we would expect that it would help the most on test sentences that are *far from those in the training set* and would thus benefit most from this expanded support. To test this hypothesis, for each test sentence we find its most similar training sample (*i.e.* nearest neighbor), then bucket the instances by the distance to their nearest neighbor and measure the gain in BLEU afforded by SwitchOut for each bucket. Specifically, we use (negative) word error rate (WER) as the similarity measure, and plot the bucket-by-bucket performance gain for each group in Figure 2. As we can see, SwitchOut improves increasingly more as the WER increases, indicating that SwitchOut is indeed helping on examples that are far from the sentences that the model sees during training. This is the desirable effect of data augmentation techniques.

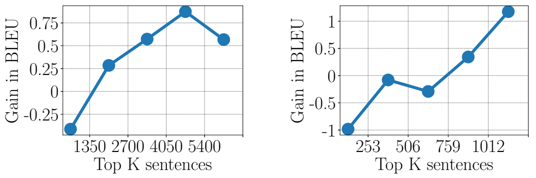

Figure 2: Gains in BLEU of RAML+SwitchOut over RAML. x-axis is ordered by the WER between a test sentence and its nearest neighbor in the training set. *Left*: IWSLT 16 de-en. *Right*: IWSLT 15 en-vi.

4 Conclusion

In this paper, we propose a method to design data augmentation algorithms by solving an optimization problem. These solutions subsume a few existing augmentation schemes and inspire a novel augmentation method, SwitchOut. SwitchOut delivers improvements over translation tasks at different scales. Additionally, SwitchOut is efficient and easy to implement, and thus has the potential for wide application.

Improving Unsupervised Word-by-Word Translation with Language Model and Denoising Autoencoder

Abstract

Unsupervised learning of cross-lingual word embedding offers elegant matching of words across languages, but has fundamental limitations in translating sentences. In this paper, we propose simple yet effective methods to improve word-by-word translation of cross-lingual embeddings, using only monolingual corpora but without any back-translation. We integrate a language model for context-aware search, and use a novel denoising autoencoder to handle reordering. Our system surpasses state-of-the-art unsupervised neural translation systems without costly iterative training. We also analyze the effect of vocabulary size and denoising type on the translation performance, which provides better understanding of learning the cross-lingual word embedding and its usage in translation.

1 Introduction

Building a machine translation (MT) system requires lots of bilingual data. Neural MT models (Bahdanau et al., 2015), which become the current standard, are even more difficult to train without huge bilingual supervision (Koehn and Knowles, 2017). However, bilingual resources are still limited to some of the selected language pairs—mostly from or to English.

A workaround for zero-resource language pairs is translating via an intermediate (pivot) language. To do so, we need to collect parallel data and train MT models for source-to-pivot and pivot-to-target individually; it takes a double effort and the decoding is twice as slow.

Unsupervised learning is another alternative, where we can train an MT system with only monolingual corpora. Decipherment methods (Ravi and Knight, 2011; Nuhn et al., 2013) are the first work in this direction, but they often suffer from a huge latent hypothesis space (Kim et al., 2017).

Recent work by Artetxe et al. (2018) and Lample et al. (2018) train sequence-to-sequence MT models of both translation directions together in an unsupervised way. They do back-translation (Sennrich et al., 2016a) back and forth for every iteration or batch, which needs an immensely long time and careful tuning of hyperparameters for massive monolingual data.

Here we suggest rather simple methods to build an unsupervised MT system quickly, based on word translation using cross-lingual word embeddings. The contributions of this paper are:

- We formulate a straightforward way to combine a language model with cross-lingual word similarities, effectively considering context in lexical choices.
- We develop a postprocessing method for word-by-word translation outputs using a denoising autoencoder, handling local reordering and multi-aligned words.
- We analyze the effect of different artificial noises for the denoising model and propose a novel noise type.
- We verify that cross-lingual embedding on subword units performs poorly in translation.
- We empirically show that cross-lingual mapping can be learned using a small vocabulary without losing the translation performance.

The proposed models can be efficiently trained with off-the-shelf softwares with little or no changes in the implementation, using only monolingual data. The provided analyses help for better learning of cross-lingual word embeddings for translation purpose. Altogether, our unsupervised MT system outperforms the sequence-to-sequence neural models even without training signals from the opposite translation direction, i.e. via back-translation.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 862–868
Brussels, Belgium, October 31 - November 4, 2018.

2 Cross-lingual Word Embedding

As a basic step for unsupervised MT, we learn a word translation model from monolingual corpora of each language. In this work, we exploit cross-lingual word embedding for word-by-word translation, which is state-of-the-art in terms of type translation quality (Artetxe et al., 2017; Conneau et al., 2018).

Cross-lingual word embedding is a continuous representation of words whose vector space is shared across multiple languages. This enables distance calculation between word embeddings across languages, which is actually finding translation candidates.

We train cross-lingual word embedding in a fully unsupervised manner:

1. Learn monolingual source and target embeddings independently. For this, we run skip-gram algorithm augmented with character n-gram (Bojanowski et al., 2017).
2. Find a linear mapping from source embedding space to target embedding space by adversarial training (Conneau et al., 2018). We do not pre-train the discriminator with a seed dictionary, and consider only the top $V_{\text{cross-train}}$ words of each language as input to the discriminator.

Once we have the cross-lingual mapping, we can transform the embedding of a given source word and find a target word with the closest embedding, i.e. nearest neighbor search. Here, we apply cross-domain similarity local scaling (Conneau et al., 2018) to penalize the word similarities in dense areas of the embedding distribution.

We further refine the mapping obtained from Step 2 as follows (Artetxe et al., 2017):

3. Build a synthetic dictionary by finding mutual nearest neighbors for both translation directions in vocabularies of $V_{\text{cross-train}}$ words.
4. Run a Procrustes problem solver with the dictionary from Step 3 to re-train the mapping (Smith et al., 2017).
5. Repeat Step 3 and 4 for a fixed number of iterations to update the mapping further.

3 Sentence Translation

In translating sentences, cross-lingual word embedding has several drawbacks. We describe each of them and our corresponding solutions.

3.1 Context-aware Beam Search

The word translation using nearest neighbor search does not consider context around the current word. In many cases, the correct translation is not the nearest target word but other close words with morphological variations or synonyms, depending on the context.

The reasons are in two-fold: 1) Word embedding is trained to place semantically related words nearby, even though they have opposite meanings. 2) A hubness problem of high-dimensional embedding space hinders a correct search, where lots of different words happen to be close to each other (Radovanović et al., 2010).

In this paper, we integrate context information into word-by-word translation by combining a language model (LM) with cross-lingual word embedding. Let f be a source word in the current position and e a possible target word. Given a history h of target words before e, the score of e to be the translation of f would be:

$$L(e; f, h) = \lambda_{\text{emb}} \log q(f, e) + \lambda_{\text{LM}} \log p(e|h)$$

Here, $q(f, e)$ is a lexical score defined as:

$$q(f, e) = \frac{d(f, e) + 1}{2}$$

where $d(f, e) \in [-1, 1]$ is a cosine similarity between f and e. It is transformed to the range $[0, 1]$ to make it similar in scale with the LM probability. In our experiments, we found that this simple linear scaling is better than sigmoid or softmax functions in the final translation performance.

Accumulating the scores per position, we perform a beam search to allow only reasonable translation hypotheses.

3.2 Denoising

Even when we have correctly translated words for each position, the output is still far from an acceptable translation. We adopt sequence denoising autoencoder (Hill et al., 2016) to improve the translation output of Section 3.1. The main idea is to train a sequence-to-sequence neural network model that takes a noisy sentence as input and produces a (denoised) clean sentence as output, both of which are of the same (target) language. The model was originally proposed to learn sentence embeddings, but here we use it directly to actually remove noise in a sentence.

Training label sequences for the denoising network would be target monolingual sentences, but we do not have their noisy versions at hand. Given a clean target sentence, the noisy input should be ideally word-by-word translation of the corresponding source sentence. However, such bilingual sentence alignment is not available in our unsupervised setup.

Instead, we inject artificial noise into a clean sentence to simulate the noise of word-by-word translation. We design different noise types after the following aspects of word-by-word translation.

3.2.1 Insertion

Word-by-word translation always outputs a target word for every position. However, there are a plenty of cases that multiple source words should be translated to a single target word, or that some source words are rather not translated to any word to make a fluent output. For example, a German sentence "*Ich höre zu.*" would be translated to "*I'm listening to.*" by a word-by-word translator, but "*I'm listening.*" is more natural in English (Figure 1).

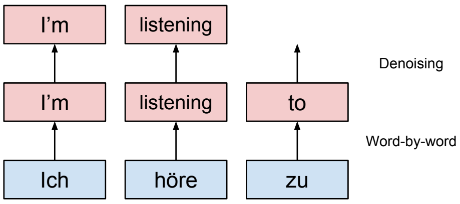

Figure 1: Example of denoising an insertion noise.

We pretend to have extra target words which might be translation of redundant source words, by inserting random target words to a clean sentence:

1. For each position i, sample a probability $p_i \sim \text{Uniform}(0, 1)$.
2. If $p_i < p_{\text{ins}}$, sample a word e from the most frequent V_{ins} target words and insert it before position i.

We limit the inserted words by V_{ins} because target insertion occurs mostly with common words, e.g. prepositions or articles, as the example above. We insert words only before—not after—a position, since an extra word after the ending word (usually a punctuation) is not probable.

3.2.2 Deletion

Similarly, word-by-word translation cannot handle the contrary case: when a source word should be translated into more than one target words, or a target word should be generated from no source words for fluency. For example, a German word "*im*" must be "*in the*" in English, but word translation generates only one of the two English words. Another example is shown in Figure 2.

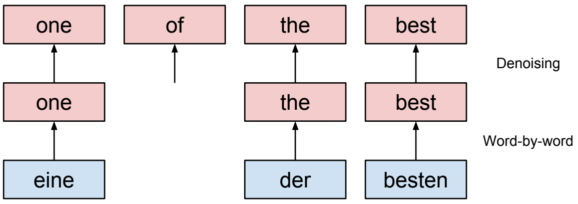

Figure 2: Example of denoising a deletion noise.

To simulate such situations, we drop some words randomly from a clean target sentence (Hill et al., 2016):

1. For each position i, sample a probability $p_i \sim \text{Uniform}(0, 1)$.
2. If $p_i < p_{\text{del}}$, drop the word in the position i.

3.2.3 Reordering

Also, translations generated word-by-word are not in an order of the target language. In our beam search, LM only assists in choosing the right word in context but does not modify the word order. A common reordering problem of German→English is illustrated in Figure 3.

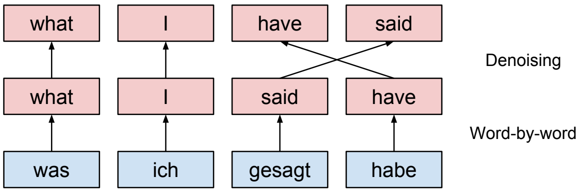

Figure 3: Example of denoising the reordering noise.

From a clean target sentence, we corrupt its word order by random permutations. We limit the maximum distance between an original position and its new position like Lample et al. (2018):

1. For each position i, sample an integer δ_i from $[0, d_{\text{per}}]$.
2. Add δ_i to index i and sort the incremented indices $i + \delta_i$ in an increasing order.
3. Rearrange the words to be in the new positions, to which their original indices have moved by Step 2.

System	de-en BLEU [%]	en-de BLEU [%]	fr-en BLEU [%]	en-fr BLEU [%]
Word-by-Word	11.1	6.7	10.6	7.8
+ LM	14.5	9.9	13.6	10.9
+ Denoising	**17.2**	**11.0**	**16.5**	13.9
(Lample et al., 2018)	13.3	9.6	14.3	15.1
(Artetxe et al., 2018)	-	-	15.6	15.1

Table 1: Translation results on German↔English `newstest2016` and French↔English `newstest2014`. Beam size is 10 and top 100 words are considered in the nearest neighbor search.

This is a generalized version of swapping two neighboring words (Hill et al., 2016). Reordering is highly dependent of each language, but we found that this noise is generally close to word-by-word translation outputs.

Insertion, deletion, and reordering noises were applied to each mini-batch with different random seeds, allowing the model to see various noisy versions of the same clean sentence over the epochs.

Note that the deletion and permutation noises are integrated in the neural MT training of Artetxe et al. (2018) and Lample et al. (2018) as additional training objectives. Whereas we optimize an independent model solely for denoising without architecture change. It allows us to easily train a larger network with a larger data. Insertion noise is of our original design, which we found to be the most effective (Section 4.1).

4 Experiments

We applied the proposed methods on WMT 2016 German↔English task and WMT 2014 French↔English task. For German/English, we trained word embeddings with 100M sentences sampled from News Crawl 2014-2017 monolingual corpora. For French, we used News Crawl 2007-2014 (around 42M sentences). The data was lowercased and filtered to have a maximum sentence length 100. German compound words were splitted beforehand. Numbers were replaced with category labels and recovered back after decoding by looking at the source sentence. Also, frequent casing was applied to the translation output.

fasttext (Bojanowski et al., 2017) was used to learn monolingual embeddings for only the words with minimum count 10. MUSE (Conneau et al., 2018) was used for cross-lingual mappings with $V_{\text{cross-train}}$ = 100k and 10 refinement iterations (Step 3-5 in Section 2). Other parameters follow the values in Conneau et al. (2018). With the same data, we trained 5-gram count-based LMs using KenLM (Heafield, 2011) with its default setting.

Denoising autoencoders were trained using Sockeye (Hieber et al., 2017) on News Crawl 2016 for German/English and News Crawl 2014 for French. We considered only top 50k frequent words for each language and mapped other words to `<unk>`. The unknowns in the denoised output were replaced with missing words from the noisy input by a simple line search.

We used 6-layer Transformer encoder/decoder (Vaswani et al., 2017) for denoisers, with embedding/hidden layer size 512, feedforward sublayer size 2048 and 8 attention heads.

As a validation set for the denoiser training, we used `newstest2015` (German ↔ English) or `newstest2013` (French ↔ English), where the input/output sides both have the same clean target sentences, encouraging a denoiser to keep at least clean part of word-by-word translations. Here, the noisy input showed a slight degradation of performance; the model seemed to overfit to specific noises in the small validation set.

Optimization of the denoising models was done with Adam (Kingma and Ba, 2015): initial learning rate 0.0001, checkpoint frequency 4000, no learning rate warmup, multiplying 0.7 to the learning rate when the perplexity on the validation set did not improve for 3 checkpoints. We stopped the training if it was not improved for 8 checkpoints.

Table 1 shows the results. LM improves word-by-word baselines consistently in all four tasks, giving at least +3% BLEU. When our denoising model is applied on top of it, we have additional gain around +3% BLEU. Note that our methods do not involve any decoding steps to generate pseudo-parallel training data, but still perform better than unsupervised MT systems that rely on repetitive back-translations (Artetxe et al., 2018; Lample et al., 2018) by up to +3.9% BLEU. The total training time of our method is only 1-2 days with a single GPU.

4.1 Ablation Study: Denoising

d_{per}	p_{del}	V_{ins}	BLEU [%]
2			14.7
3			**14.9**
5			14.9
3	0.1		**15.7**
	0.3		15.1
3	0.1	10	16.8
		50	**17.2**
		500	16.8
		5000	16.5

Table 2: Translation results with different values of denoising parameters for German→English.

To examine the effect of each noise type in denoising autoencoder, we tuned each parameter of the noise and combined them incrementally (Table 2). Firstly, for permutations, a significant improvement is achieved from $d_{\text{per}} = 3$, since a local reordering usually involves a sequence of 3 to 4 words. With $d_{\text{per}} > 5$, it shuffles too many consecutive words together, yielding no further improvement. This noise cannot handle long-range reordering, which is usually a swap of words that are far from each other, keeping the words in the middle as they are.

Secondly, we applied the deletion noise with different values of p_{del}. 0.1 gives +0.8% BLEU, but we immediately see a degradation with a larger value; it is hard to observe one-to-many translations more than once in each sentence pair.

Finally, we optimized V_{ins} for the insertion noise, fixing $p_{\text{ins}} = 0.1$. Increasing V_{ins} is generally not beneficial, since it provides too much variations in the inserted word; it might not be related to its neighboring words. Overall, we observe the best result (+1.5% BLEU) with $V_{\text{ins}} = 50$.

4.2 Ablation Study: Vocabulary

We also examined how the translation performance varies with different vocabularies of cross-lingual word embedding in Table 3. The first three rows show that BPE embeddings performs worse than word embeddings, especially with smaller vocabulary size. For small BPE tokens (1-3 characters), the context they meet during the embedding training is much more various than a complete word, and a direct translation of such small token to a BPE token of another language would be very ambiguous.

Vocabulary		BLEU [%]
	Merges	
BPE	20k	10.4
	50k	12.5
	100k	13.0
	$V_{\text{cross-train}}$	
Word	20k	14.4
	50k	14.4
	100k	**14.5**
	200k	14.4

Table 3: Translation results with different vocabularies for German→English.

For word level embeddings, we compared different vocabulary sizes used for training the cross-lingual mapping (the second step in Section 2). Surprisingly, cross-lingual word embedding learned only on top 20k words is comparable to that of 200k words in the translation quality. We also increased the search vocabulary to more than 200k but the performance only degrades. This means that word-by-word translation with cross-lingual embedding depends highly on the frequent word mappings, and learning the mapping between rare words does not have a positive effect.

5 Conclusion

In this paper, we proposed a simple pipeline to greatly improve sentence translation based on cross-lingual word embedding. We achieved context-aware lexical choices using beam search with LM, and solved insertion/deletion/reordering problems using denoising autoencoder. Our novel insertion noise shows a promising performance even combined with other noise types. Our methods do not need back-translation steps but still outperforms costly unsupervised neural MT systems. In addition, we proved that for general translation purpose, an effective cross-lingual mapping can be learned using only a small set of frequent words, not on subword units.

Abstract

Decipherment of homophonic substitution ciphers using language models (LMs) is a well-studied task in NLP. Previous work in this topic scores short local spans of possible plaintext decipherments using n-gram LMs. The most widely used technique is the use of beam search with n-gram LMs proposed by Nuhn et al. (2013). We propose a beam search algorithm that scores the entire candidate plaintext at each step of the decipherment using a neural LM. We augment beam search with a novel rest cost estimation that exploits the prediction power of a neural LM. We compare against the state of the art n-gram based methods on many different decipherment tasks. On challenging ciphers such as the Beale cipher we provide significantly better error rates with much smaller beam sizes.

1 Introduction

Breaking substitution ciphers recovers the *plaintext* from a *ciphertext* that uses a 1:1 or homophonic cipher key. Previous work using pretrained language models (LMs) for decipherment use n-gram LMs (Ravi and Knight, 2011; Nuhn et al., 2013). Some methods use the Expectation-Maximization (EM) algorithm (Knight et al., 2006) while most state-of-the-art approaches for decipherment of 1:1 and homophonic substitution ciphers use beam search and rely on the clever use of n-gram LMs (Nuhn et al., 2014; Hauer et al., 2014). Neural LMs globally score the entire candidate plaintext sequence (Mikolov et al., 2010). However, using a neural LM for decipherment is not trivial because scoring the entire candidate partially deciphered plaintext is computationally challenging. We solve both of these problems in this paper and provide an improved beam search based decipherment algorithm for homophonic ciphers that exploits pre-trained neural LMs for the first time.

2 Decipherment Model

We use the notation from Nuhn et al. (2013). Ciphertext $f_1^N = f_1..f_i..f_N$ and plaintext $e_1^N = e_1..e_i..e_N$ consist of vocabularies $f_i \in V_f$ and $e_i \in V_e$ respectively. The beginning tokens in the ciphertext (f_0) and plaintext (e_0) are set to "\$" denoting the beginning of a sentence. The substitutions are represented by a function $\phi : V_f \rightarrow V_e$ such that 1:1 substitutions are *bijective* while homophonic substitutions are *general*. A cipher function ϕ which does not have every $\phi(f)$ fixed is called a partial cipher function (Corlett and Penn, 2010). The number of fs that are fixed in ϕ is given by its cardinality. ϕ' is called an extension of ϕ, if f is fixed in ϕ' such that $\delta(\phi'(f), \phi(f))$ yields true $\forall f \in V_f$ which are already fixed in ϕ where δ is Kronecker delta. **Decipherment** is then the task of finding the ϕ for which the probability of the deciphered text is maximized.

$$\hat{\phi} = \arg\max_{\phi} p(\phi(f_1)...\phi(f_N)) \tag{1}$$

where $p(.)$ is the language model (**LM**). Finding this argmax is solved using a beam search algorithm (Nuhn et al., 2013) which incrementally finds the most likely substitutions using the language model scores as the ranking.

2.1 Neural Language Model

The advantage of a neural LM is that it can be used to score the entire candidate plaintext for a hypothesized partial decipherment. In this work, we use a state of the art byte (character) level neural LM using a multiplicative LSTM (Radford et al., 2017).

Consider a sequence $S = w_1, w_2, w_3, ..., w_N$. The LM score of S is $\texttt{SCORE}(S)$:

$$\begin{aligned} P(S) &= P(w_1, w_2, w_3, ..., w_N) \\ P(S) &= \prod_{i=1}^{N} P(w_i \mid w_1, w_2, ..., w_{i-1})) \\ \texttt{SCORE}(S) &= -\sum_{i=1}^{N} log(P(w_i \mid w_{<i})) \end{aligned} \tag{2}$$

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 869–874
Brussels, Belgium, October 31 - November 4, 2018.

2.2 Beam Search

Algorithm 1 is the beam search algorithm (Nuhn et al., 2013, 2014) for solving substitution ciphers. It monitors all partial hypotheses in lists H_s and H_t based on their quality. As the search progresses, the partial hypotheses are extended, scored with `SCORE` and appended to H_t. `EXT_LIMITS` determines which extensions should be allowed and `EXT_ORDER` picks the next cipher symbol for extension. The search continues after pruning: $H_s \leftarrow \texttt{HISTOGRAM\_PRUNE}(H_t)$. We augment this algorithm by updating the `SCORE` function with a neural LM.

Algorithm 1 Beam Search for Decipherment

```
function (BEAM_SEARCH (EXT_ORDER, EXT_LIMITS))
    initialize sets $H_s$, $H_t$
    CARDINALITY = 0
    $H_s$.ADD(($\emptyset$,0))
    while CARDINALITY < $|V_f|$ do
        $f$ = EXT_ORDER[CARDINALITY]
        for all $\phi \in H_s$ do
            for all $e \in V_e$ do
                $\phi$' := $\phi \cup \{(e, f)\}$
                if EXT_LIMITS($\phi$') then
                    $H_t$.ADD($\phi$',SCORE($\phi$'))
        HISTOGRAM_PRUNE($H_t$)
        CARDINALITY = CARDINALITY + 1
        $H_s = H_t$
        $H_t$.CLEAR()
    return WINNER($H_s$)
```

3 Score Estimation (`SCORE`)

Score estimation evaluates the quality of the partial hypotheses ϕ. Using the example from Nuhn et al. (2014), consider the vocabularies $V_e = \{a, b, c, d\}$ and $V_f = \{A, B, C, D\}$, extension order (B, A, C, D), and ciphertext `$ ABDDCABCDADCABDC $`. Let $\phi = \{(a, A), (b, B))\}$ be the partial hypothesis. Then $\texttt{SCORE}(\phi)$ scores this hypothesized partial decipherment (only A and B are converted to plaintext) using a pre-trained language model in the hypothesized plaintext language.

3.1 Baseline

The initial rest cost estimator introduced by Nuhn et al. nuhnbeam computes the score of hypotheses only based on partially deciphered text that builds a shard of n adjacent solved symbols. As a heuristic, n-grams which still consist of unsolved cipher-symbols are assigned a trivial estimate of probability 1. An improved version of rest cost estimation (Nuhn et al., 2014) consults lower order n-grams to score each position.

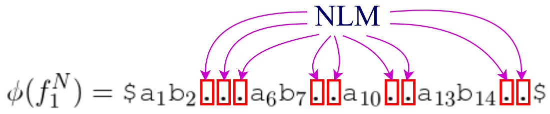
3.2 Global Rest Cost Estimation

The baseline scoring method greatly relies on local context, *i.e.* the estimation is strictly based on partial character sequences. Since this depends solely on the n-gram LM, the true conditional probability under Markov assumption is not modeled and, therefore, context dependency beyond the window of $(n - 1)$ is ignored. Thus, attempting to utilize a higher amount of context can lower the probability of some tokens resulting in poor scores.

We address this issue with a new improved version of the rest cost estimator by supplementing the partial decipherment $\phi(f_1^N)$ with predicted plaintext text symbols using our neural language model (NLM). Applying $\phi = \{(a, A), (b, B))\}$ to the ciphertext above, we get the following partial hypothesis:

$$\phi(f_1^N) = \texttt{\$a}_1\texttt{b}_2\texttt{...a}_6\texttt{b}_7\texttt{..a}_{10}\texttt{..a}_{13}\texttt{b}_{14}\texttt{..\$}$$

We introduce a scoring function that is able to score the entire plaintext including the missing plaintext symbols. First, we sample[1] the plaintext symbols from the NLM at all locations depending on the deciphered tokens from the partial hypothesis ϕ such that these tokens maintain their respective positions in the sequence, and at the same time are sampled from the neural LM to fit (probabilistically) in this context. Next, we determine the probability of the entire sequence including the scores of sampled plaintext as our rest cost estimate.



In our running example, this would yield a score estimation of the partial decipherment, $\phi(f_1^N)$:

$$\phi(f_1^N) = \$\, \mathrm{a}_1\mathrm{b}_2\mathrm{d}_3\mathrm{c}_4\mathrm{c}_5\mathrm{a}_6\mathrm{b}_7\mathrm{c}_8\mathrm{d}_9\mathrm{a}_{10}\mathrm{d}_{11}\mathrm{d}_{12}\mathrm{a}_{13}\mathrm{b}_{14}\mathrm{d}_{15}\mathrm{c}_{16}\ \$$$

Thus, the neural LM is used to predict the score of the full sequence. This method of global scoring evaluates each candidate partial decipherment by scoring the entire message, augmented by the sam-

---

[1] The char-level sampling is done incrementally from left to right to generate a sequence that contains the deciphered tokens from ϕ at the exact locations they occur in the above $\phi(f_1^N)$. If the LM prediction contradicts the hypothesized decipherment we stop sampling and start from the next character.

Cipher	Length	Unique Symbols	Obs/ symbol
Zodiac-408	408	54	7.55
Beale Pt. 2	763	180	4.23

Table 1: Homophonic ciphers used in our experiments.

pled plaintext symbols from the NLM. Since more terms participate in the rest cost estimation with global context, we use the plaintext LM to provide us with a better rest cost in the beam search.

3.3 Frequency Matching Heuristic

Alignment by frequency similarity (Yarowsky and Wicentowski, 2000) assumes that two forms belong to the same lemma when their relative frequency fits the expected distribution. We use this heuristic to augment the score estimation (`SCORE`):

$$\texttt{FMH}(\phi') = \left| log \left(\frac{\nu(f)}{\nu(e)} \right) \right| \qquad f \in V_f, \quad e \in V_e \tag{3}$$

$\nu(f)$ is the percentage relative frequency of the ciphertext symbol f, while $\nu(e)$ is the percentage relative frequency of the plaintext token e in the plaintext language model. The closer this value to 0, the more likely it is that f is mapped to e.

Thus given a ϕ with the $\texttt{SCORE}(\phi)$, the extension ϕ' (Algo. 1) is scored as:

$$\texttt{SCORE}(\phi') = \texttt{SCORE}(\phi) + \texttt{NEW}(\phi') - \texttt{FMH}(\phi') \tag{4}$$

where `NEW` is the score for symbols that have been newly fixed in ϕ' while extending ϕ to ϕ'. Our experimental evaluations show that the global rest cost estimator and the frequency matching heuristic contribute positively towards the accuracy of different ciphertexts.

4 Experimental Evaluation

We carry out 2 sets of experiments: one on letter based 1:1, and another on homophonic substitution ciphers. We report Symbol Error Rate (SER) which is the fraction of characters in the deciphered text that are incorrect.

The character NLM uses a single layer multiplicative LSTM (mLSTM) (Radford et al., 2017) with 4096 units. The model was trained for a single epoch on mini-batches of 128 subsequences of length 256 for a total of 1 million weight updates. States were initialized to zero at the beginning of each data shard and persisted across updates to simulate full-backprop and allow for the forward propagation of information outside of a given subsequence. In all the experiments we use a character NLM trained on English Gigaword corpus augmented with a short corpus of plaintext letters of about 2000 words authored by the Zodiac killer[2].

4.1 1:1 Substitution Ciphers

In this experiment we use a synthetic 1:1 letter substitution cipher dataset following Ravi and Knight (2008), Nuhn et al. (2013) and Hauer et al. (2014). The text is from English Wikipedia articles about history[3], preprocessed by stripping the text of all images, tables, then lower-casing all characters, and removing all non-alphabetic and non-space characters. We create 50 cryptograms for each length 16, 32, 64, 128 and 256 using a random Caesar-cipher 1:1 substitution.

Length	Beam	SER(%) 1	SER(%) 2
64	100	4.14	4.14
	1,000	1.09	1.04
	10,000	0.08	0.12
	100,000	0.07	0.07
128	100	7.31	7.29
	1,000	1.68	1.55
	10,000	0.15	0.09
	100,000	0.01	0.02

Table 2: Symbol Error Rates (SER) based on Neural Language Model and beam size (Beam) for solving 1:1 substitution ciphers of lengths 64 and 128, respectively. SER 1 shows beam search with global scoring, and SER 2 shows beam search with global scoring with frequency matching heuristic.

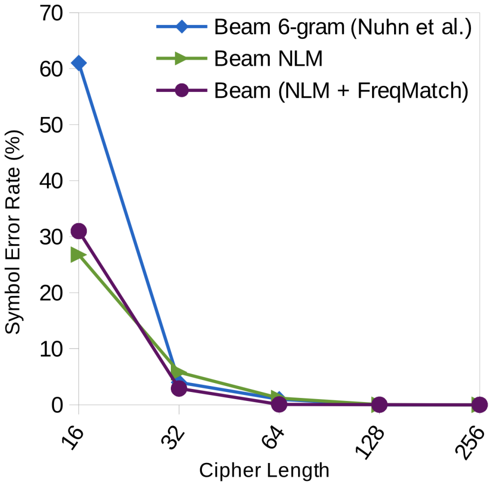


Figure 1: Symbol error rates for decipherment of 1:1 substitution ciphers of different lengths. The beam size is 100k. Beam 6-gram model uses the beam search from Nunh et al. (2013).

Figure 2: First few lines from part two of the Beale cipher. The letters have been capitalized.

Fig 1 plots the results of our method for cipher lengths of 16, 32, 64, 128 and 256 alongside Beam 6-gram (the best performing model) model (Nuhn et al., 2013)

4.2 An Easy Cipher: Zodiac-408

Zodiac-408, a homophonic cipher, is commonly used to evaluate decipherment algorithms.

Beam	SER (%) 1	SER (%) 2
10k	3.92	3.18
100k	2.40	1.91
1M	1.47	**1.22**

Table 3: Symbol Error Rates (SER) based on Neural Language Model and beam size (Beam) for deciphering Zodiac-408, respectively. SER 1 shows beam search with global scoring, and SER 2 shows beam search with global scoring with the frequency matching heuristic.

Our neural LM model with global rest cost estimation and frequency matching heuristic with a beam size of 1M has SER of 1.2% compared to the beam search algorithm (Nuhn et al., 2013) with beam size of 10M with a 6-gram LM which gives an SER of 2%. The improved beam search (Nuhn et al., 2014) with an 8-gram LM, however, gets 52 out of 54 mappings correct on the Zodiac-408 cipher.

4.3 A Hard Cipher: Beale Pt 2

Part 2 of the Beale Cipher is a more challenging homophonic cipher because of a much larger search space of solutions. Nunh et al. (2014) were the first to automatically decipher this Beale Cipher.

With an error of 5% with beam size of 1M vs 5.4% with 8-gram LM and a pruning size of 10M, our system outperforms the state of the art (Nuhn et al., 2014) on this task.

Figure 3: First 119 characters from deciphered Zodiac-408 text. The letters have been capitalized.

Beam	SER (%) 1	SER (%) 2
10k	41.67	48.33
100k	7.20	10.09
1M	**4.98**	5.50

Table 4: Symbol Error Rates (SER) based on Neural Language Model and beam size (Beam) for deciphering Part 2 of the Beale Cipher. SER 1 shows beam search with global scoring, and SER 2 shows beam search with global scoring with the frequency matching heuristic.

5 Related Work

Automatic decipherment for substitution ciphers started with dictionary attacks (Hart, 1994; Jakobsen, 1995; Olson, 2007). Ravi and Knight (2008) frame the decipherment problem as an integer linear programming (ILP) problem. Knight et al. (2006) use an HMM-based EM algorithm for solving a variety of decipherment problems. Ravi and Knight (2011) extend the HMM-based EM approach with a Bayesian approach, and report the first automatic decipherment of the Zodiac-408 cipher.

Berg-Kirkpatrick and Klein (2013) show that a large number of random restarts can help the EM approach.Corlett and Penn (2010) presented an efficient A* search algorithm to solve letter substitution ciphers. Nuhn et al. (2013) produce better results in faster time compared to ILP and EM-based decipherment methods by employing a higher order language model and an iterative beam search algorithm. Nuhn et al. (2014) present various improvements to the beam search algorithm in Nuhn et al. (2013) including improved rest cost estimation and an optimized strategy for ordering decipherment of the cipher symbols. Hauer et al. (2014) propose a novel approach for solving mono-alphabetic substitution ciphers which combines character-level and word-level language model. They formulate decipherment as a tree search problem, and use Monte Carlo Tree Search (MCTS) as an alternative to beam search. Their approach is the best for short ciphers.

Greydanus (2017) frames the decryption process as a sequence-to-sequence translation task and uses a deep LSTM-based model to learn the decryption algorithms for three polyalphabetic ciphers including the Enigma cipher. However, this approach needs supervision compared to our approach which uses a pre-trained neural LM. Gomez et al. (2018) (CipherGAN) use a generative adversarial network to learn the mapping between the learned letter embedding distributions in the ciphertext and plaintext. They apply this approach to shift ciphers (including Vigenère ciphers). Their approach cannot be extended to homophonic ciphers and full message neural LMs as in our work.

6 Conclusion

This paper presents, to our knowledge, the first application of large pre-trained neural LMs to the decipherment problem. We modify the beam search algorithm for decipherment from Nuhn et al. (2013; 2014) and extend it to use global scoring of the plaintext message using neural LMs. To enable full plaintext scoring we use the neural LM to sample plaintext characters which reduces the beam size required. For challenging ciphers such as Beale Pt 2 we obtain lower error rates with smaller beam sizes when compared to the state of the art in decipherment for such ciphers.

Rapid Adaptation of Neural Machine Translation to New Languages

Graham Neubig, Junjie Hu
Language Technologies Institute, Carnegie Mellon University
`{gneubig,junjieh}@cs.cmu.edu`

Abstract

This paper examines the problem of adapting neural machine translation systems to new, low-resourced languages (LRLs) as *effectively* and *rapidly* as possible. We propose methods based on starting with massively multilingual "seed models", which can be trained ahead-of-time, and then continuing training on data related to the LRL. We contrast a number of strategies, leading to a novel, simple, yet effective method of "similar-language regularization", where we jointly train on both a LRL of interest and a similar high-resourced language to prevent over-fitting to small LRL data. Experiments demonstrate that massively multilingual models, even without any explicit adaptation, are surprisingly effective, achieving BLEU scores of up to 15.5 with *no* data from the LRL, and that the proposed similar-language regularization method improves over other adaptation methods by 1.7 BLEU points average over 4 LRL settings.[1]

1 Introduction

When disaster strikes, news and social media are invaluable sources of information, allowing humanitarian organizations to rapidly mitigate crisis situations and save lives (Vieweg et al., 2010; Neubig et al., 2011; Starbird et al., 2012). However, language barriers looms large over these efforts, especially when disasters occur in parts of the world that use less common languages. In these cases, machine translation (MT) technology can be a valuable tool, with one widely-heralded success story being the deployment of Haitian Creole-to-English translation systems during the earthquakes in Haiti (Lewis, 2010; Munro, 2010).

However, data-driven MT systems, particularly neural machine translation (NMT; Kalchbrenner and Blunsom (2013); Bahdanau et al. (2015)), require large amounts of training data, and creating high-quality systems in low-resource languages (LRLs) is a difficult challenge where research efforts have just begun (Gu et al., 2018). Another hurdle, which to our knowledge has not been covered in previous research, is the *time* it takes to create such a system. In a crisis situation, time is of the essence, and systems that require days or weeks of training will not be desirable or even feasible.

In this paper we focus on the question: *how can we create MT systems for new language pairs as accurately as possible, and as quickly as possible?* To examine this question we propose NMT methods at the intersection of cross-lingual transfer learning (Zoph et al., 2016) and multilingual training (Johnson et al., 2016), two paradigms that, to our knowledge, have not been used together in previous work. Our methods, laid out in §2 follow the process of training a seed model on a large number of languages, then fine-tuning the model to improve its performance on the language of interest. We propose a novel method of *similar-language regularization* (SLR) where training data from a second similar languages is used to help prevent over-fitting to the small LRL dataset.

In the experiments in §3, we attempt to answer two questions: (1) Which method of creating multilingual systems and adapting them to an LRL is the most effective way to increase accuracy? (2) How can we create the strongest system possible with a bare minimum of training time? The results are sometimes surprising – we first find that a single monolithic model trained on 57 languages can achieve BLEU scores as high as 15.5 with *no* training data in the new source language whatsoever. In addition, the proposed method starting with a universal model then fine-tuning with the SLR proves most effective, achieving gains of 1.7

Brussels, Belgium, October 31 - November 4, 2018.

BLEU points averaged over several language pairs compared to previous methods adapting to only the LRL.

2 Training Paradigms

In this paper, we consider the setting where we have a *source LRL* of interest, and we want to translate into English.[2] All of our adaptation methods are based on first training on larger data including other languages, then fine-tuning the model to be specifically tailored to the LRL. We first discuss a few multilingual training paradigms from previous literature (§2.1), then discuss our proposed adaptation methods (§2.2).

2.1 Multilingual Modeling Methods

We use three varieties of multilingual training:

Single-source modeling ("Sing.") is the first method, using only parallel data between the LRL of interest and English. This method is straightforward and the resulting model will be most highly tailored to the final test language pair, but the method also has the obvious disadvantage that training data is very sparse.

Bi-source modeling ("Bi") trains an MT system with two source languages: one LRL that we would like to translate from, and a second highly related high-resource language (HRL): the *helper* source language.[3] This method is inspired by Johnson et al. (2016), who examine multilingual translation models to/from English and two highly related languages such as Spanish/Portuguese or Japanese/Korean. The advantage of this method is that it allows the LRL to learn from a highly similar helper, potentially increasing accuracy.

All-source modeling ("All") trains not only on a couple source languages, but instead creates a universal model on all of the languages that we have at our disposal. In our experiments (§3.1) this entails training systems on 58 source languages, to our knowledge the largest reported in NMT experiments.[4] This paradigm allows us to train a single model that has wide coverage of vocabulary and syntax of a large number of languages, but also has the drawback in that a single model must be able to express information about all the languages in the training set within its limited parameter budget. Thus, it is reasonable to expect that this model may achieve worse accuracy than a model created specifically to handle a particular source language.

In the following, we will consider adaptation methods that focus on tailoring a more general model (i.e. bi-source or universal) to a more specific model (i.e. single-source or bi-source).

2.2 Adaptation to New Languages

As noted in the introduction, there are two major requirements: the *accuracy* of the system is important and the *training time required* from when we learn of a need for translation to when we can first start producing adequate results. Throughout the discussion, we will compare various adaptation paradigms with respect to these two aspects.

2.2.1 Adaptation by Fine-tuning

Our first adaptation method, inspired by Zoph et al. (2016) is based on fine-tuning to the source language of interest. Within our experiments, we will test this setting, but also make two distinctions between the types of adaptation:

Seed Model Variety: Zoph et al. (2016) performed experiments taking a bilingual system trained on a different language (e.g. French) and adapting it to a new LRL (e.g. Uzbek). We can also take universal model and adapt it to the new language, a setting that we examine (to our knowledge, for the first time) in this work.

Warm vs. Cold Start: Another contrast is whether we have training data for the LRL of interest while training the original system, or whether we only receive training data *after* the original model has already been trained. We call the former *warm start*, and the latter *cold start*. Intuitively, we expect warm-start training to perform better, as having access to the LRL of interest during the training of the original model will ensure that it can handle the LRL to some extent. However, the cold-start scenario is also of interest: we may want to spend large amounts of time training a strong model, then quickly adapt to a new language that we have never seen before in our training data as data becomes available. For the cold-start models, we start with a model that is only trained on the HRL similar to the LRL (Bi$^-$), or a model trained

---

[2] Translation into LRLs, is a challenging and interesting problem in it's own right, but beyond the scope of the paper.

[3] "Related" could mean different things: typologically related or having high lexical overlap. In our experiments our LRLs are all selected to have an helper that is highly similar in both aspects, but choosing an appropriate helper when this is not the case is an interesting problem for future work.

[4] In contrast to Gu et al. (2018), who train on 10 languages. Malaviya et al. (2017); Tiedemann (2018) train NMT on over 1,000 languages, but only as a feature extractor for downstream tasks; MT accuracy itself is not evaluated.

LRL	train	dev	test	HRL	train

slk	61.5k	2,271	2,445	ces	103k

Table 1: Data sizes in sentences for LRL/HRL pairs

on all languages *but* the LRL (All^{-}).

2.2.2 Similar-Language Regularization

One problem with adapting to a small amount of data in the target language is that it will be very easy for the model to over-fit to the small training set. To alleviate this problem, we propose a method of *similar language regularization*: while training to adapt to the language of interest, we also add some data from another similar HRL that has sufficient resources to help prevent overfitting. We do this in two ways:

Corpus Concatenation: Simply concatenate the data from the two corpora, so that we have a small amount of data in the LRL, and a large amount of data in the similar HRL.

Balanced Sampling: Every time we select a minibatch to do training, we either sample it from the LRL, or from the HRL according to a fixed ratio. We try different sampling strategies, including sampling with a 1-to-1 ratio, 1-to-2 ratio, and 1-to-4 ratio for the LRL and HRL respectively.

3 Experiments

3.1 Experimental Setup

We perform experiments on the 58-language-to-English TED corpus (Qi et al., 2018), which is ideal for our purposes because it has a wide variety of languages over several language families, some high-resourced and some low-resourced. Like Qi et al. (2018), we experiment with Azerbaijani (aze), Belarusian (bel), and Galician (glg) to English, and also additionally add Slovak (slk), a slightly higher resourced language, for contrast. These languages are all paired with a similar HRL: Turkish (tur), Russian (rus), Portuguese (por), and Czech (ces) respectively. Data sizes are shown in Table 1.

Models are implemented using `xnmt` (Neubig et al., 2018), commit `8173b1f`, and start with the recipe for training on IWSLT TED[5]. The model consists of an attentional neural machine translation model (Bahdanau et al., 2015), using bi-directional LSTM encoders, 128-dimensional word embeddings, 512-dimensional hidden states, and a standard LSTM-based decoder.

Following standard practice (Sennrich et al., 2016; Denkowski and Neubig, 2017), we break low-frequency words into subwords using the `sentencepiece` toolkit.[6] There are two alternatives for creating subword units: *jointly* learning subwords over all source language, or *separately* learning subwords for each source language, then taking the union of all the subword vocabularies as the vocabulary for the multilingual model. Previous work on multilingual training has preferred the former (Nguyen and Chiang, 2017), but in this paper we use the latter for two reasons: (1) because data in the LRL will not affect the subword units from the other languages, in the cold-start scenario we can postpone creation of subword units for the LRL until directly before we start training on the LRL itself, and (2) we need not be concerned with the LRL being "overwhelmed" by the higher-resourced languages when calculating statistics used in the creation of subword units, because all languages get an equal share.[7] In the experiments, we use a subword vocabulary of 8,000 for each language.

We also compare with two additional baselines: phrase-based MT implemented in `Moses`,[8] and unsupervised NMT implemented in `undreamt`.[9] `Moses` is trained on the bilingual data only (training multilingually reduced average accuracy), and `undreamt` is trained on all monolingual data available for the LRL and English.

3.2 Experimental Results

Table 2 shows our main translation results, with warm-start scenarios in the upper half and cold-start scenarios in the lower half.

Does Multilingual Training Help? To answer this question, we can compare the warm-start Sing., Bi, and All settings, and find that the answer is a resounding yes, gains of 7-13 BLEU points are obtained by going from single-source to bi-source or all-source training, corroborating previous work (Gu et al., 2018). Bi-source models tend to perform slightly better than all-source models, indicating that given identical parameter

Table 2: BLEU for single-source (Sing.), bi-source (Bi), and all-source universal (All) models, with adapted counterparts. 1-1, 1-2, 1-4 indicate balanced sampling from §2.2. Bold indicates highest score.

capacity, training on a highly resourced language is effective. Comparing with the phrase-based baseline, as noted by Koehn and Knowles (2017) NMT tends to underperform on low-resource settings when trained only on the data available for these languages. However, multilingual training of any variety quickly remedies this issue; all outperform phrase-based handily.

More interestingly, examining the cold-start results, we can see that even systems with *no* data in the target language are able to achieve non-trivial accuracies, up to 15.5 BLEU on glg-eng. Interestingly, in the cold-start scenario, the All$^-$ model bests the Bi$^-$ model, indicating that massively multilingual training is more useful in this setting. In contrast, the unsupervised NMT model struggles, achieving a BLEU score of around 0 for all language pairs – this is because unsupervised NMT requires high-quality monolingual embeddings from the same distribution, which can be trained easily in English, but are not available in the low-resource languages we are considering.

Does Adaptation Help? Regarding adaptation, we can first observe that regardless of the original model and method for adaptation, adaptation is helpful, particularly (and unsurprisingly) in the cold-start case. When adapting directly to only the target language ("→Sing."), adapting from the massively multilingual model performs better, indicating that information about all input languages is better than just a single language. Next, comparing with our proposed method of adding similar language regularization ("→Bi"), we can see that this helps significantly over adapting directly to the LRL, particularly in the cold-start case where we can observe gains of up to 1.7 BLEU points. Finally, in our data setting, corpus concatenation outperforms balanced sampling in both the cold-start and warm-start scenarios.

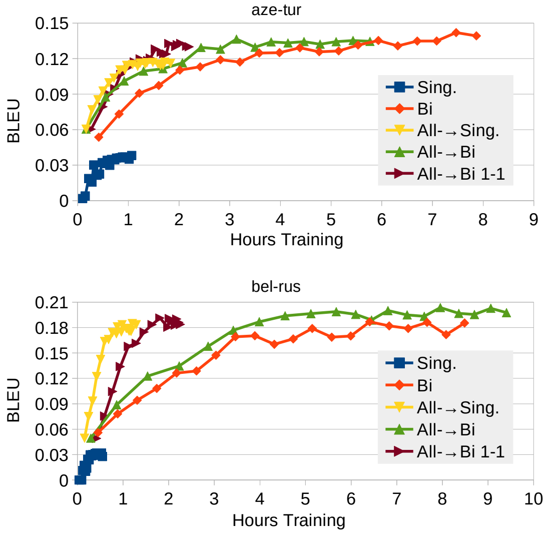

Figure 1: Example of adaptation on the aze-eng and bel-eng development sets

How Can We Adapt Most Efficiently? Finally, we revisit adapting to new languages efficiently, with Figure 1 showing BLEU vs. hours training for the aze/tur and bel/rus source language pairs (others were similar). We can see that in all cases the cold-start models (All$^-$ →) either outperform or are comparable in final accuracy to the from-scratch single-source and bi-source models. In addition, all of the adapted models converge faster than the bi-source from-scratch trained models, indicating that adapting from seed models is a good strategy for rapid construction of MT systems in new languages. Comparing the cold-start adaptation strategies, we can see that in general, the higher the density of target language training data, the faster the training converges to a solution, but the worse the final solution is. This suggests that there is a speed/accuracy tradeoff in the amount of similar language regularization we apply during fine-tuning.

4 Related Work

While adapting MT systems to new languages is a long-standing challenge (Schultz and Black, 2006; Jabaian et al., 2013), multilingual NMT is highly promising in its ability to abstract across language boundaries (Firat et al., 2016; Ha et al., 2016; Johnson et al., 2016). Results on multilingual training for low-resource translation (Gu et al., 2018; Qi et al., 2018) further demonstrates this potential, although these works do not consider adaptation to new languages, the main focus of our work. Notably, we did not examine partial freezing of parameters, another method proven useful for cross-lingual adaptation (Zoph et al., 2016); this is orthogonal to our multi-lingual training approach but the two methods could potentially be combined. Finally, unsupervised NMT approaches (Artetxe et al., 2017; Lample et al., 2018, 2017) require no parallel data, but rest on strong assumptions about high-quality comparable monolingual data. As we show, when this assumption breaks down these methods fail to function, while our cold-start methods achieve non-trivial accuracies even with no monolingual data.

5 Conclusion

This paper examined methods to rapidly adapt MT systems to new languages by fine-tuning. In both warm-start and cold-start scenarios, the best results were obtained by adapting a pre-trained universal model to the low-resource language while regularizing with similar languages.

Compact Personalized Models for Neural Machine Translation

Joern Wuebker, Patrick Simianer, John DeNero
Lilt, Inc.
`first_name@lilt.com`

Abstract

We propose and compare methods for gradient-based domain adaptation of self-attentive neural machine translation models. We demonstrate that a large proportion of model parameters can be frozen during adaptation with minimal or no reduction in translation quality by encouraging structured sparsity in the set of offset tensors during learning via group lasso regularization. We evaluate this technique for both batch and incremental adaptation across multiple data sets and language pairs. Our system architecture—combining a state-of-the-art self-attentive model with compact domain adaptation—provides high quality personalized machine translation that is both space and time efficient.

1 Introduction

Professional translators typically translate a collection of related documents drawn from a domain for which they have a set of previously translated examples. Domain adaptation is critical to providing high quality suggestions for interactive machine translation and post-editing interfaces. When many translators use the same shared service, the system must train and apply a *personalized* adapted model for each user. We describe a system architecture and training method that achieve high space efficiency, time efficiency, and translation performance by encouraging structured sparsity in the set of offset tensors stored for each user.

Effective model personalization requires both *batch* adaptation to an in-domain training set, as well as *incremental* adaptation to the test set. Batch adaptation is applied when a user uploads relevant translated documents before starting to work. Incremental adaptation is applied when a user provides a correct translation of each segment just after receiving machine translation suggestions, and the system is able to train on that correction before generating suggestions for the next segment. This is referred to as *a posteriori* adaptation by Turchi et al. (2017). Our experiments compare both types of adaptation. There are cases for which incremental adaptation achieves better performance using fewer examples, as examples drawn directly from the test set are often highly relevant to subsequent parts of that test set. There are also cases for which the gains from both types of domain adaptation are additive.

The time required to translate and to adapt both must be minimal in a personalized translation service. Interactive translation requires suggestions to be generated at typing speed, and incremental adaptation must occur within a few hundred milliseconds to keep up with a translator's typical workflow. The service can be expected to store models for a large number of users and dynamically load and adapt models for many active users concurrently. Therefore, minimizing the number of parameters stored for each user's personalized model is important both for reducing storage requirements and latency. We achieve space and time efficiency by representing each user's model as an offset from the unadapted baseline parameters and encouraging most offset tensors to be zero during adaptation.

We show that group lasso regularization can be applied to a self-attentive Transformer model to freeze up to 75% of the parameters with minimal or no loss of adapted translation quality across experiments on four English→German data sets. We confirm these findings for six additional language pairs.

2 Related Work

There is extensive work on incremental adaptation from human post edits or simulated post edits, both for statistical machine translation (Green et al., 2013; Denkowski et al., 2014a,b; Wuebker et al., 2015) and neural machine translation (Peris et al.,

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 881–886
Brussels, Belgium, October 31 - November 4, 2018.

2017; Turchi et al., 2017; Karimova et al., 2017). Both Turchi et al. (2017) and Karimova et al. (2017) apply vanilla fine-tuning algorithms. In addition to fine-tuning towards user corrections, the former applies *a priori* adaptation to retrieved data that is similar to the incoming source sentences. Peris et al. (2017) propose a variant of fine-tuning with passive-aggressive learning algorithms. In contrast to these papers, where all model parameters are possibly altered during training, this work focuses on space efficiency of the adapted models.

Regularization methods that promote or enforce sparsity have been previously used in the context of sparse feature models for SMT: Duh et al. (2010) presented an application of multi-task learning via ℓ_1/ℓ_2 regularization for feature selection in an N-best reranking task. A similar approach, employing ℓ_1/ℓ_2 regularization for feature selection and multi-task learning, was developed by Simianer et al. (2012) and Simianer and Riezler (2013) for tuning of SMT systems. Both works report improvements from regularization.

Techniques for enforcing sparse models using ℓ_1 regularization during stochastic gradient descent optimization were previously developed for linear models (Tsuruoka et al., 2009).

An extremely space efficient method for personalized model adaptation is presented by Michel and Neubig (2018). Here, adaptation is performed solely on the output vocabulary bias vector. Another notable approach for creating compact models is student-teacher-training or knowledge distillation (Kim and Rush, 2016). To the best of our knowledge, this has not been applied in a domain adaptation setting.

3 Self-Attentive Translation Model

The neural machine translation systems used in this work are based on the Transformer model introduced by Vaswani et al. (2017), which uses self-attention rather than recurrent or convolutional layers to aggregate information across words. In addition to its superior performance, its main practical advantage over recurrent models is faster training.

The Transformer follows the encoder-decoder paradigm. Source word vectors $x_1, \dots, x_m$ are chosen from an embedding matrix X_e. A series of stacked encoder layers generate intermediate representations $z_1, \dots, z_m$. Each layer of the encoder consists of two sub-layers: a multi-head *self-attention* layer that uses scaled dot-product attention over all source positions, followed by a feed-forward *filter* layer. Layer normalization (Ba et al., 2016), dropout (Srivastava et al., 2014), and residual connections (He et al., 2016) are applied to each sub-layer.

A series of stacked decoder layers produces a sequence of target word vectors $y_1, \dots, y_n$. Each decoder layer has three sub-layers: self-attention, encoder-attention, and a filter. For target position j, the *self-attention* layer can attend to any previous target position $j' \in [1, j]$, with target words offset by one so that representations at j can observe word $j-1$, but not word j. The *encoder-attention* layer can attend to the final encoder state z_i for any source position $i \in [1, m]$. Observed target word vectors are chosen from an embedding matrix Y_e, and target word j is predicted from y_j via a soft-max layer parameterized by an output projection matrix Y_o.

The encoders in this work have six layers that have a *self-attention* sub-layer size of 256 and a *filter* sub-layer size of 512. Each filter performs two linear transformations and a ReLU activation:

$$f(x) = \max(0, xW_1 + b_1)W_2 + b_2.$$

The decoders in this work have three layers, and all sub-layer sizes are 256. The decoder sub-layers are simplified versions of those described in Vaswani et al. (2017): The *filter* sub-layers perform only a single linear transformation, and layer normalization is only applied once per decoder layer after the *filter* sub-layer.

Unlike in Vaswani et al. (2017), none of X_e, Y_e, or Y_o share parameters in our TensorFlow[1] implementation. Baseline models are optimized with Adam (Kingma and Ba, 2015).

4 Compact Adaptation

4.1 Fine Tuning

Personalized machine translation requires batch adaptation to a domain-relevant bitext (such as a user provided translation memory) as well as incremental adaptation to the test set. We apply fine-tuning, which involves continuing to train model parameters with a gradient-based method on domain-relevant data, as a simple and effective method for neural translation domain adaptation (Luong and Manning, 2015). The fine-tuned model without regularization and clipping is denoted as the *Full Model*. Confirming previous work, we found that

---

[1] `https://www.tensorflow.org/`

stochastic gradient descent (SGD) is the most effective optimizer for fine tuning (Turchi et al., 2017). In our experiments, batch adaptation uses a batch size of 7000 words for 10 Epochs and a fixed learning rate of 0.1, dropout of 0.1, and label smoothing with $\epsilon_{ls} = 0.1$ (Szegedy et al., 2016).

Incremental adaptation uses a batch size of one and a learning rate of 0.01. To ensure a strong adaptation effect within a single document, we set dropout and label smoothing to zero and perform up to three SGD updates on each segment. After each update, we measure the model perplexity on the current training example and continue with another update if the perplexity is still above 1.5.

4.2 Offset Tensors

In a personalized translation service, adapted models need to be loaded quickly, so a space-efficient representation is critical for time efficiency as well. Production speed requirements using contemporary cloud hardware limit model sizes to roughly 10M parameters per user, while a high-quality baseline Transformer model typically requires 35M parameters or more. We propose to store the parameters of an adapted model as an offset from the baseline model. Each tensor is a sum $W = W_b + W_u$, where W_b is from the baseline model and is shared across all adapted models, while the offset W_u is specific to an individual user domain. Space efficiency is achieved by only storing W_u for a subset of tensors and setting the rest of the offset tensors to zero.

One approach to achieving model sparsity is to manually partition the network into a small number of regions and systematically evaluate translation performance when storing offsets for only one region. We define five distinct regions, which are evaluated in isolation: Outer layers (the first and last layers of both encoder and decoder), inner layers (all the remaining layers), the two embedding matrices X_e and Y_e, and the output projection matrix Y_o. The latter three are each stored as a single matrix and each contributes 10.3M parameters to the full model size in English→German. During adaptation, the embedding matrices are only updated for vocabulary present in the training examples, and so the offsets can be stored efficiently as a sparse collection of columns. The same principle can be applied to the output projection matrix by only updating parameters corresponding to vocabulary items that appears in the adaptation examples (denoted *Sparse Output Proj.* in Table 1).

A second approach to achieving model sparsity is to use a procedure to select the subset of offset tensors that are stored. For example, we evaluate a simple policy that stores an offset for all tensors whose average change in parameter values is higher than a threshold. This set is selected on a development domain and held fixed for all other domains. We refer to this method as *fixed* adaptation.

4.3 Tensor Selection via Group Lasso

A group sparse regularization penalty such as group lasso can be applied to the offset tensors for simultaneous regularization and tensor selection. This penalty drives entire offset tensors to zero, so that they do not need to be stored or loaded. We add the following regularization term to the loss function (Scardapane et al., 2017):

$$R_{\ell_{1,2}}(\mathcal{T}) = \sum_{T \in \mathcal{T}} \sqrt{|T|} \|\Delta T\|_2 \qquad (1)$$

$$\|\Delta T\|_2 = \sum_{\tau \in T} \Delta\tau^2 \qquad (2)$$

Here, each tensor corresponds to one group. $\mathcal{T}$ denotes the set of all tensors in the model, $\tau \in T$ the set of all weights within a single tensor and $\Delta\tau$ the size of the offset for τ. Note that we are regularizing the *difference* between the parameters of the adapted model and the baseline model, rather than regularizing the full network parameters directly. In this way, we maintain the expressive power of the full network while minimizing the size of the adapted models. Group lasso regularization is equivalent to ℓ_1 regularization when the group size is 1. Sparsity among groups is encouraged because the ℓ_1 norm serves as a convex proxy for the ℓ_0 norm, which would explicitly penalize the number of non-zero elements (Yuan and Lin, 2006). To facilitate tensor selection, we define a threshold ϑ to clip offset tensors ΔT with average weight $\frac{1}{|T|} \sum_{\tau \in T} \Delta\tau < \vartheta$ to zero. Both the threshold ϑ and the regularization weight λ were manually tuned on a development domain and set to $\vartheta = 10^{-4}$ and $\lambda = 10^{-6}$. We apply clipping to all tensors except the embedding and output projection matrices X_e, Y_e and Y_o. As our production constraints allow us to retain only one of the three, we pre-select the sparse output projection as part of the model and exclude the embedding matrices from adaptation. This method will be denoted as *Lasso*.

Table 1: Experimental results in Bleu (%) on the English→German data. We evaluate changes to each region of the network separately. In combination with sparse output projection, we also evaluate a *fixed* selection of parameters chosen by thresholding and a set selected dynamically for each data set using group *lasso*. The two bottom rows show repetition rates in % for the source and target sides of the test data.

5 Experiments

5.1 Data

We first evaluate all techniques on an English→German Transformer network trained on 98M parallel sentence pairs. We apply byte pair encoding (Sennrich et al., 2016) separately to each language and obtain vocabularies with 40K unique tokens each. We refer to the unadapted model as *Baseline*. We evaluate on four domains. For development, we use a data set labeled *User1* that was gathered from a user of the browser-based CAT (computer-aided translation) tool Lilt[2] and contains documents from the financial domain with 48K segments for batch adaptation and 1790 segments for testing and incremental adaptation. We further evaluate on a second user test set *User2* (technical support, 31k batch adaptation, 1000 test segments); the public Autodesk corpus[3], where we select the first 20k segments for batch adaptation and the next 1000 segments for testing; and the IWSLT corpus[4] (semi-technical talks), where we use all provided 206K sentences for batch adaptation and the *dev2010* set (888 sentences) for testing. The overall best performing compact adaptation technique, group lasso regularization, is further evaluated on six other language pairs trained using production data sets collected from Lilt's user base: English↔French, English↔Russian and English↔Chinese. Adaptation is performed on user data from various domains (technical manuals, finance, legal), each with 8k-10k segments for batch adaptation and 2000 segments for testing and incremental adaptation. Translation quality is evaluated using the cased Bleu (Papineni et al., 2002) measure.

5.2 Results

Table 1 shows English→German results. Full model adaptation, where all offsets are stored, improves over the baseline in all cases to various degrees. This full model contains only 25.8M parameters, as offsets for both embedding matrices are stored as sparse collections of columns for the vocabulary present in the adaptation data. Next, we evaluate the impact of storing offsets only for one region at a time. We observe that among the three vocabulary matrices, the output projection Y_o has the strongest impact on quality, which is not dimin-

Table 2: Experimental results in BLEU (%) on six production language pairs. We compare the unadapted baseline model with a full model and the model with sparse output projection and group lasso, both with application of batch and incremental adaptation.

ished by storing a sparse variant that is restricted only to observed vocabulary.

In addition, we evaluate two methods of choosing a subset of tensors procedurally. We first experiment with a fixed subset of tensor offsets that was chosen by selecting all tensors for which parameters were offset by more than 0.002 on average after batch adaptation on the *User1* data set. This simple procedure approaches the performance of full model adaptation, but stores only 27% of its parameters. Dynamically selecting tensor offsets for each data set using group lasso regularization improves performance on 6 out of 8 data conditions.

The combination of batch and incremental adaptation yields further improvements, with the exception of the *User2* and *IWSLT* tasks, where incremental adaptation overall performs not as well as batch adaptation. For these tasks, both tests sets exhibit lower repetition rates[5] (Cettolo et al., 2014) than the test sets for the two other tasks (see the two bottom lines in Table 1). The *User2* test set is furthermore a random sample of non-consecutive text from a translation memory, which is suboptimal for incremental learning.

Altogether, we are able to achieve translation performance similar to full model adaptation with 25% of the total network parameters. Note that due to the selection of entire tensors with groupwise regularization, there is nearly zero space overhead incurred by storing a sparse set of offset tensors.

Table 2 confirms our main findings on six other language pairs. We observe average improvements of 14.3 BLEU with our final compact model, which compares to 15.5 BLEU for full model adaptation.

6 Conclusion

We describe an efficient approach to personalized machine translation that stores a sparse set of tensor offsets for each user domain. Group lasso regularization applied to the offsets during adaptation achieves high space and time efficiency while yielding translation performance close to a full adapted model, for both batch and incremental adaptation and their combination.

Abstract

Deep neural networks reach state-of-the-art performance for wide range of natural language processing, computer vision and speech applications. Yet, one of the biggest challenges is running these complex networks on devices such as mobile phones or smart watches with tiny memory footprint and low computational capacity. We propose on-device Self-Governing Neural Networks (SGNNs), which learn compact projection vectors with local sensitive hashing. The key advantage of SGNNs over existing work is that they surmount the need for pre-trained word embeddings and complex networks with huge parameters. We conduct extensive evaluation on dialog act classification and show significant improvement over state-of-the-art results. Our findings show that SGNNs are effective at capturing low-dimensional semantic text representations, while maintaining high accuracy.

1 Introduction

Deep neural networks are one of the most successful machine learning methods outperforming many state-of-the-art machine learning methods in natural language processing (Sutskever et al., 2014), speech (Hinton et al., 2012) and visual recognition tasks (Krizhevsky et al., 2012). The availability of high performance computing has enabled research in deep learning to focus largely on the development of deeper and more complex network architectures for improved accuracy. However, the increased complexity of the deep neural networks has become one of the biggest obstacles to deploy deep neural networks on-device such as mobile phones, smart watches and IoT (Iandola et al., 2016). The main challenges with developing and deploying deep neural network models on-device are (1) the tiny memory footprint, (2) inference latency and (3) significantly low computational capacity compared to high performance computing systems such as CPUs, GPUs and TPUs on the cloud.

There are multiple strategies to build lightweight text classification models for on-device. One can create a small dictionary of common *input* → *category* mapping on the device and use a naive look-up at inference time. However, such an approach does not scale to complex natural language tasks involving rich vocabularies and wide language variability. Another strategy is to employ fast sampling techniques (Ahmed et al., 2012; Ravi, 2013) or incorporate deep learning models with graph learning like (Bui et al., 2017, 2018), which result in large models but have proven to be extremely powerful for complex language understanding tasks like response completion (Pang and Ravi, 2012) and Smart Reply (Kannan et al., 2016).

In this paper, we propose Self-Governing Neural Networks (SGNNs) inspired by projection networks (Ravi, 2017). SGNNs are on-device deep learning models learned via embedding-free projection operations. We employ a modified version of the locality sensitive hashing (LSH) to reduce input dimension from millions of unique words/features to a short, fixed-length sequence of bits. This allows us to compute a projection for an incoming text very fast, on-the-fly, with a small memory footprint on the device since we do not need to store the incoming text and word embeddings. We evaluate the performance of our SGNNs on Dialogue Act classification, because (1) it is an important step towards dialog interpretation and conversational analysis aiming to understand the intent of the speaker at every utterance of the conversation and (2) deep learning methods reached state-of-the-art (Lee and Dernoncourt, 2016; Khanpour et al., 2016; Tran et al., 2017; Ortega and Vu, 2017).

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 887–893
Brussels, Belgium, October 31 - November 4, 2018.

The main contributions of the paper are:

- Novel Self-Governing Neural Networks (SGNNs) for on-device deep learning for short text classification.
- Compression technique that effectively captures low-dimensional semantic text representation and produces compact models that save on storage and computational cost.
- On the fly computation of projection vectors that eliminate the need for large pre-trained word embeddings or vocabulary pruning.
- Exhaustive experimental evaluation on dialog act datasets, outperforming state-of-the-art deep CNN (Lee and Dernoncourt, 2016) and RNN variants (Khanpour et al., 2016; Ortega and Vu, 2017).

2 Self-Governing Neural Networks

We model the Self-Governing network using a *projection* model architecture (Ravi, 2017). The *projection* model is a simple network with dynamically-computed layers that encodes a set of efficient-to-compute operations which can be performed directly on device for inference. The model defines a set of efficient "projection" functions $\mathbb{P}(\vec{x}_i)$ that project each input instance $\vec{x}_i$ to a different space $\Omega_{\mathbb{P}}$ and then performs learning in this space to map it to corresponding outputs y_i^p. A very simple projection model comprises just few operations where the inputs $\vec{x}_i$ are transformed using a series of T projection functions $\mathbb{P}^1, ..., \mathbb{P}^T$ followed by a single layer of activations.

2.1 Model Architecture

In this work, we design a Self-Governing Neural Network (SGNN) using multi-layered locality-sensitive projection model. Figure 1 shows the model architecture of the on-device SGNN network. The *self-governing* property of this network stems from its ability to learn a model (e.g., a classifier) without having to initialize, load or store any feature or vocabulary weight matrices. In this sense, our method is a truly **embedding-free** approach unlike majority of the widely-used state-of-the-art deep learning techniques in NLP whose performance depends on embeddings pre-trained on large corpora. Instead, we use the projection functions to dynamically transform each input to a low-dimensional representation. Furthermore, we stack this with additional layers and non-linear activations to achieve deep, non-linear combinations of projections that permit the network to learn complex mappings from inputs x_i to outputs y_i. An SGNN network is shown below:

$$
\begin{aligned}
i_p &= [\mathbb{P}^1(x_i), ..., \mathbb{P}^T(x_i)] && (1)\\
h_p &= \sigma(W_p \cdot i_p + b_p) && (2)\\
h_t &= \sigma(W_t \cdot h_{t-1} + b_t) && (3)\\
y_i &= \texttt{softmax}(W_o \cdot h_k + b_o) && (4)
\end{aligned}
$$

where, i_p refers to the output of projection operation applied to input x_i, h_p is applied to projection output, h_t is applied at intermediate layers of the network with depth k followed by a final `softmax` activation layer at the top. In a k-layer SGNN, h_t, where $t = p, p+1, ..., p+k-1$ refers to the k subsequent layers after the projection layer. W_p, W_t, W_o and b_p, b_t, b_o represent trainable weights and biases respectively.

The projection transformations use pre-computed parameterized functions, i.e., they are not trained during the learning process, and their outputs are concatenated to form the hidden units for subsequent operations. Each input text x_i is converted to an intermediate feature vector (via raw text features such as skip-grams) followed by projections.

$$x_i \xrightarrow{\mathbb{F}} \vec{x_i} \xrightarrow{\mathbb{P}} [\mathbb{P}^1(x_i), ..., \mathbb{P}^T(x_i)] \qquad (5)$$

On-the-fly Computation. The transformation step $\mathbb{F}$ dynamically extracts features from the raw input. Text features (e.g., skip-grams) are converted into feature-ids f_j (via hashing) to generate a sparse feature representation $\vec{x_i}$ of feature-id, weight pairs (f_j, w_j) . This intermediate feature representation is passed through projection functions $\mathbb{P}$ to construct projection layer i_p in SGNN. For this last step, a projection vector $\mathbb{P}^k$ is first constructed on-the-fly using a hash function with feature ids f_j in $\vec{x_i}$ and fixed seed as input, then dot product of the two vectors $< \vec{x_i}, \mathbb{P}^k >$ is computed and transformed into binary representation $\mathbb{P}^k(\vec{x_i})$ using $sgn(.)$ of the dot product.

As shown in Figure 1, both $\mathbb{F}$ and $\mathbb{P}$ steps are computed on-the-fly, i.e., no word-embedding or vocabulary/feature matrices need to be stored and looked up during training or inference. Instead feature-ids and projection vectors are dynamically computed via hash functions. For intermediate feature weights w_j, we use observed counts in

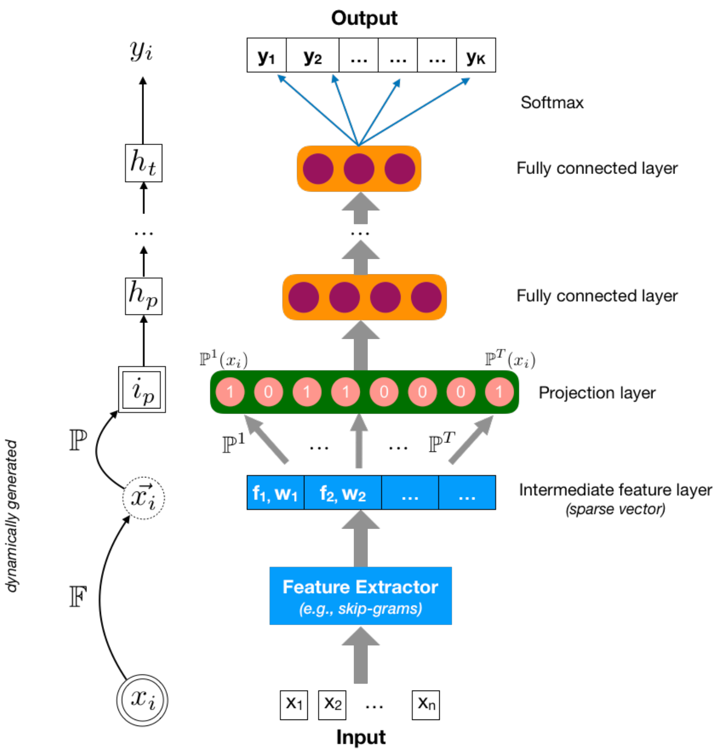

Figure 1: Self-Governing Neural Network (SGNN) architecture.

each input text and do not use pre-computed statistics like idf. Hence the method is embedding-free.

Model Optimization. The SGNN network is trained from scratch on the task data using a supervised loss defined wrt ground truth $\hat{y}_i$:

$$\mathcal{L}(.) = \sum_{i \in N} \texttt{cross}-\texttt{entropy}(y_i, \hat{y}_i) \quad (6)$$

During training, the network learns to choose and apply specific projection operations $\mathbb{P}^j$ (via activations) that are more predictive for a given task. The choice of the type of projection matrix $\mathbb{P}$ as well as representation of the projected space $\Omega_{\mathbb{P}}$ has a direct effect on computation cost and model size. We leverage an efficient randomized projection method and use a binary representation $\{0, 1\}^d$ for $\Omega_{\mathbb{P}}$. This yields a drastically lower memory footprint both in terms of number and size of parameters.

Computing Projections. We employ an efficient randomized projection method for the projection step. We use locality sensitive hashing (LSH) (Charikar, 2002) to model the underlying projection operations in SGNN. LSH is typically used as a dimensionality reduction technique for clustering (Manning et al., 2008). LSH allows us to project similar inputs $\vec{x}_i$ or intermediate network layers into hidden unit vectors that are nearby in metric space. We use repeated binary hashing for $\mathbb{P}$ and apply the projection vectors to transform the input $\vec{x}_i$ to a binary hash representation denoted by $\mathbb{P}_k(\vec{x}_i) \in \{0, 1\}$, where $[\mathbb{P}_k(\vec{x}_i)] := sgn[\langle \vec{x}_i, \mathbb{P}_k \rangle]$. This results in a d-bit vector representation, one bit corresponding to each projection row $\mathbb{P}_{k=1 \ldots d}$.

The same projection matrix $\mathbb{P}$ is used for training and inference. We never need to explicitly store the random projection vector $\mathbb{P}_k$ since we can compute them on the fly using hash functions over feature indices with a fixed row seed rather than invoking a random number generator. This also permits us to perform projection operations that are linear in the *observed* feature size rather than the *overall* feature or vocabulary size which can be prohibitively large for high-dimensional data, thereby saving both memory and computation cost. Thus, SGNN can efficiently model high-dimensional sparse inputs and large vocabulary sizes common for text applications instead of relying on feature pruning or other pre-processing heuristics employed to restrict input sizes in standard neural networks for feasible training. The binary representation is significant since this results in a significantly compact representation for the *projection* network parameters that in turn considerably reduces the model size.

SGNN Parameters. In practice, we employ T different projection functions $\mathbb{P}^{j=1\dots T}$, each resulting in d-bit vector that is concatenated to form the projected vector i_p in Equation 5. T and d vary depending on the *projection* network parameter configuration specified for $\mathbb{P}$ and can be tuned to trade-off between prediction quality and model size. Note that the choice of whether to use a single projection matrix of size $T \cdot d$ or T separate matrices of d columns depends on the type of projection employed (dense or sparse). For the intermediate feature step $\mathbb{F}$ in Equation 5, we use skip-gram features (3-grams with skip-size=2) extracted from raw text.

2.2 Training and Inference

We use the compact bit units to represent the *projection* in SGNN. During training, the network learns to move the gradients for points that are nearby to each other in the projected bit space $\Omega_{\mathbb{P}}$ in the same direction. SGNN network is trained end-to-end using backpropagation. Training can progress efficiently with stochastic gradient descent with distributed computing on high-performance CPUs or GPUs.

Complexity. The overall complexity for SGNN inference, governed by the projection layer, is $O(n \cdot T \cdot d)$, where n is the observed feature size (*not* overall vocabulary size) which is linear in input size, d is the number of LSH bits specified for each projection vector $\mathbb{P}_k$, and T is the number of projection functions used in $\mathbb{P}$. The model size (in terms of number of parameters) and memory storage required for the *projection* inference step is $O(T \cdot d \cdot C)$, where C is the number of hidden units in h_p in the multi-layer projection network and typically smaller than $T \cdot d$.

3 Datasets and Experimental Setup

3.1 Data Description

We conduct our experimental evaluation on two dialog act benchmark datasets.

- **SWDA:** Switchboard Dialog Act Corpus (Godfrey et al., 1992; Jurafsky et al., 1997) is a popular open domain dialogs corpus between two speakers with 42 dialogs acts.
- **MRDA:** ICSI Meeting Recorder Dialog Act Corpus (Adam et al., 2003; Shriberg et al., 2004) is a dialog corpus of multiparty meetings with 5 tags of dialog acts.

Datasets	Class	Vocab.	Train	Validation	Test
SwDA	42	20K	193K	23K	5K
MRDA	5	12K	78K	16K	15K

Table 1: Dialog Act Datasets Statistics

Table 1 summarizes dataset statistics. We use the train, validation and test splits as defined in (Lee and Dernoncourt, 2016; Ortega and Vu, 2017).

3.2 Experimental Setup

We setup our experimental evaluation, as follows: given a classification task and a dataset, we generate an on-device model. The size of the model can be configured (by adjusting the projection matrix $\mathbb{P}$) to fit in the memory footprint of the device, i.e. a phone has more memory compared to a smart watch. For each classification task, we report $Accuracy$ on the test set.

3.3 Hyperparameter and Training

For both datasets we used the following: 2-layer SGNN ($\mathbb{P}_{T=80,d=14}$ $\times$ FullyConnected$_{256}$ $\times$ FullyConnected$_{256}$), mini-batch size of 100, dropout rate of 0.25, learning rate was initialized to 0.025 with cosine annealing decay (Loshchilov and Hutter, 2016). Unlike prior approaches (Lee and Dernoncourt, 2016; Ortega and Vu, 2017) that rely on pre-trained word embeddings, we learn the projection weights on the fly during training, i.e word embeddings (or vocabularies) do not need to be stored. Instead, features are computed on the fly and are dynamically compressed via the projection matrices into projection vectors. These values were chosen via a grid search on development sets, we do not perform any other dataset-specific tuning. Training is performed through stochastic gradient descent over shuffled mini-batches with Nesterov momentum optimizer (Sutskever et al., 2013), run for 1M steps.

4 Results

Tables 2 and 3 show results on the SwDA and MRDA dialog act datasets. Overall, our SGNN model consistently outperforms the baselines and prior state-of-the-art deep learning models.

4.1 Baselines

We compare our model against a majority class baseline and Naive Bayes classifier (Lee and Dernoncourt, 2016). Our model significantly outperforms both baselines by 12 to 35% absolute.

4.2 Comparison against State-of-art Methods

We also compare our performance against prior work using HMMs (Stolcke et al., 2000) and recent deep learning methods like CNN (Lee and Dernoncourt, 2016), RNN (Khanpour et al., 2016) and RNN with gated attention (Tran et al., 2017).

To the best of our knowledge, (Lee and Dernoncourt, 2016; Ortega and Vu, 2017; Tran et al., 2017) are the latest approaches in dialog act classification, which also reported on the same data splits. Therefore, we compare our research against these works. According to (Ortega and Vu, 2017), prior work by (Ji and Bilmes, 2006) achieved promising results on the MRDA dataset, but since the evaluation was conducted on a different data split, it is hard to compare them directly.

For both SwDA and MRDA datasets, our SGNNs obtains the best result of 83.1 and 86.7 accuracy outperforming prior state-of-the-art work. This is very impressive given that we work with very small memory footprint and we do not rely on pre-trained word embeddings. Our study also shows that the proposed method is very effective for such natural language tasks compared to more complex neural network architectures such as deep CNN (Lee and Dernoncourt, 2016) and RNN variants (Khanpour et al., 2016; Ortega and Vu, 2017). We believe that the compression techniques like locality sensitive projections jointly coupled with non-linear functions are effective at capturing low-dimensional semantic text representations that are useful for text classification applications.

4.3 Discussion on Model Size and Inference

LSTMs have millions of parameters, while our on-device architecture has just 300K parameters (order of magnitude lower). Most deep learning methods also use large vocabulary size of 10K or higher. Each word embedding is represented as 100-dimensional vector leading to a storage requirement of $10,000 \times 100$ parameter weights just in the first layer of the deep network. In contrast, SGNNs in all our experiments use a fixed 1120-dimensional vector regardless of the vocabulary or feature size, dynamic computation results in further speed up for high-dimensional feature spaces. This amounts to a huge savings in storage and computation cost wrt FLOPs (floating point operations per second).

Method	Acc.
Majority Class (baseline) (Ortega and Vu, 2017)	33.7
Naive Bayes (baseline) (Khanpour et al., 2016)	47.3

5 Conclusion

We proposed Self-Governing Neural Networks for on-device short text classification. Experiments on multiple dialog act datasets showed that our model outperforms state-of-the-art deep leaning methods (Lee and Dernoncourt, 2016; Khanpour et al., 2016; Ortega and Vu, 2017). We introduced a compression technique that effectively captures low-dimensional semantic representation and produces compact models that significantly save on storage and computational cost. Our approach does not rely on pre-trained embeddings and efficiently computes the projection vectors on the fly. In the future, we are interested in extending this approach to more natural language tasks. For instance, we built a multilingual SGNN model for customer feedback classification (Liu et al., 2017) and obtained 73% on Japanese, close to best performing system on the challenge (Plank, 2017). Unlike their method, we did not use any pre-processing, tagging, parsing, pre-trained embeddings or other resources.

Supervised Domain Enablement Attention for Personalized Domain Classification

Joo-Kyung Kim **Young-Bum Kim**
Amazon Alexa
`{jookyk,youngbum}@amazon.com`

Abstract

In large-scale domain classification for natural language understanding, leveraging each user's domain enablement information, which refers to the preferred or authenticated domains by the user, with attention mechanism has been shown to improve the overall domain classification performance. In this paper, we propose a supervised enablement attention mechanism, which utilizes sigmoid activation for the attention weighting so that the attention can be computed with more expressive power without the weight sum constraint of softmax attention. The attention weights are explicitly encouraged to be similar to the corresponding elements of the ground-truth's one-hot vector by supervised attention, and the attention information of the other enabled domains is leveraged through self-distillation. By evaluating on the actual utterances from a large-scale IPDA, we show that our approach significantly improves domain classification performance.

1 Introduction

Due to recent advances in deep learning techniques, intelligent personal digital assistants (IPDAs) such as Amazon Alexa, Google Assistant, Microsoft Cortana, and Apple Siri have been widely used as real-life applications of natural language understanding (Sarikaya et al., 2016; Sarikaya, 2017).

In natural language understanding, domain classification is a task that finds the most relevant domain given an input utterance (Tur and de Mori, 2011). For example, "make a lion sound" and "find me an apple pie recipe" should be classified as `ZooKeeper` and `AllRecipe`, respectively. Recent IPDAs cover more than several thousands of diverse domains by including third-party developed domains such as Alexa Skills (Kumar et al., 2017; Kim et al., 2018a; Kim and Kim, 2018), Google Actions, and Cortana Skills, which makes domain classification to be a more challenging task.

Given a large number of domains, leveraging user's enabled domain information[1] has been shown to improve the domain classification performance since enabled domains reflect the user's context in terms of domain usage (Kim et al., 2018b). For an input utterance, Kim et al. (2018b) use attention mechanism so that a weighted sum of the enabled domain vectors are used as an input signal as well as the utterance vector. The enabled domain vectors and the attention weights are automatically trained in an end-to-end fashion to be helpful for the domain classification.

In this paper, we propose a supervised enablement attention mechanism for more effective attention on the enabled domains. First, we use logistic sigmoid instead of softmax as the attention activation function to relax the constraint that the weight sum over all the enabled domains is 1 to the constraint that each attention weight is between 0 and 1 regardless of the other weights (Martins and Astudillo, 2016; Kim et al., 2017). Therefore, all the attention weights can be very low if there are no enabled domains relevant to a ground-truth so that we can disregard the irrelevant enabled domains, and multiple attention weights can have high values when multiple enabled domains are helpful for disambiguating an input utterance. Second, we encourage each attention weight to be high if the corresponding enabled domain is a ground-truth domain and if otherwise, to be low, by a supervised attention method (Mi et al., 2016) so that the attention weights can be directly tuned for the downstream classification task. Third, we

---

[1] Enabled domain information specifically refers to preferred or authenticated domains in Amazon Alexa, but it can be extended to other information such as the list of recently used domains.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 894–899
Brussels, Belgium, October 31 - November 4, 2018.

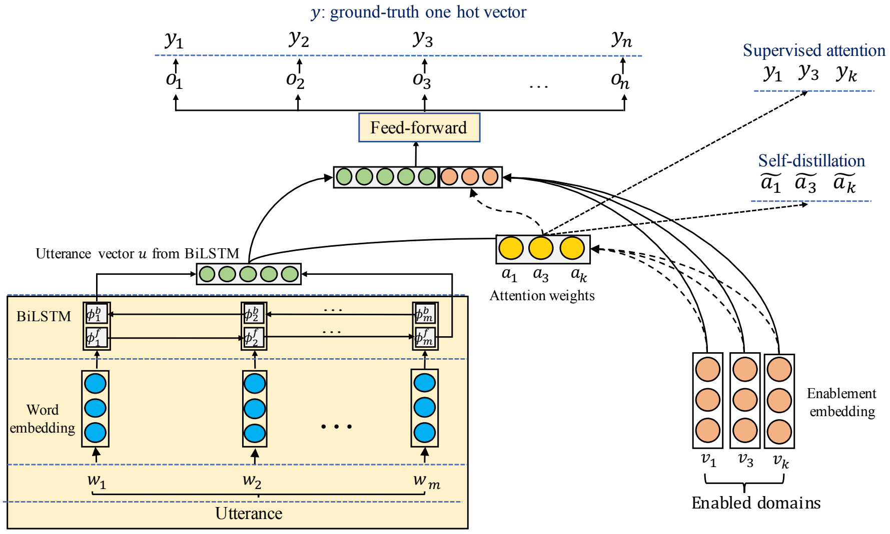

Figure 1: Model architecture: the input utterance is represented as a dense vector through word embedding and BiLSTM. Domain enablement vector is computed as a weighted sum of enabled domain vectors through the proposed attention mechanism. The two vectors are concatenated for the final domain prediction thorough a feed-forward neural network.

apply self-distillation (Furlanello et al., 2018) on top of the enablement attention weights so that we can better utilize the enabled domains that are not ground-truth domains but still relevant.

Evaluating on datasets obtained from real usage in a large-scale IPDA, we show that our approach significantly improves domain classification performance by utilizing the domain enablement information effectively.

2 Model

Figure 1 shows the overall architecture of the proposed model.

Given an input utterance, each word of the utterance is represented as a dense vector through word embedding followed by bidirectional long short-term memory (BiLSTM) (Graves and Schmidhuber, 2005). Then, an utterance vector is composed by concatenating the last outputs of the forward LSTM and the backward LSTM.[2]

To represent the domain enablement information, we obtain a weighted sum of domain enablement vector where the weights are calculated by logistic sigmoid function on top of the multiplicative attention (Luong et al., 2015) for the utterance vector and the domain enablement vectors. The attention weight of an enabled domain e is formulated as follows:

$$a_e = \sigma\left(u \cdot v_e\right),$$

where u is the utterance vector, v_e is the enablement vector of enabled domain e, and σ is sigmoid function. Compared to conventional attention mechanism using softmax function, which constraints the sum of the attention weights to be 1, sigmoid attention has more expressive power, where each attention weight can be between 0 and 1 regardless of the other weights. We show that using sigmoid attention is actually more effective for improving prediction performance in Section 3.

The utterance vector and the weighted sum of the domain enablement vectors are concatenated to represent the utterance and the domain enablement as a single vector. Given the concatenated vector, a feed-forward neural network with a single hidden layer[3] is used to predict the confidence score by logistic sigmoid function for each domain.

One issue of the proposed architecture is that the domain enablement can be trained to be a very strong signal, where one of the enabled domains would be the predicted domains regardless of the relevancy of the utterances to the predicted domains in many cases. To reduce this prediction bias, we use randomly sampled enabled domains

---

[2] We have also evaluated word vector summation, CNN (Kim, 2014), BiLSTM mean-pooling, and BiLSTM max-pooling (Conneau et al., 2017) as alternative utterance representation methods, but they did not show better performance on our task.

[3] We utilize scaled exponential linear units (SeLU) as the activation function for the hidden layer(Klambauer et al., 2017).

instead of the correct enabled domains of an input utterance with 50% probability during training so that the domain enablement is used as an auxiliary signal rather than determining signal. During inference, we always use the correct domain enablements of the given utterances.

The main loss function of our model is formulated as binary log loss between the confidence score and the ground-truth vector as follows:

$$\mathcal{L}_m = -\sum_{i=1}^{n} y_i \log o_i + (1 - y_i) \log (1 - o_i) ,$$

where n is the number of all domains, o is an n-dimensional confidence score vector from the model, and y is an n-dimensional one-hot vector whose element corresponding to the position of the ground-truth domain is set to 1.

2.1 Supervised Enablement Attention

Attention weights are originally intended to be automatically trained in an end-to-end fashion (Bahdanau et al., 2015), but it has been shown that applying proper explicit supervision to the attention improves the downstream tasks such as machine translation given the word alignment and constituent parsing given annotations between surface words and nonterminals (Mi et al., 2016; Liu et al., 2016; Kamigaito et al., 2017).

We hypothesize that if the ground-truth domain is one of the enabled domains, the attention weight for the ground-truth domain should be high and vice versa. To apply this hypothesis in the model training as a supervised attention method, we formulate an auxiliary loss function as follows:

$$\mathcal{L}_a = -\sum_{e \in E} y_e \log a_e + (1 - y_e) \log (1 - a_e) ,$$

where E is a set of enabled domains and a_e is the attention weight for the enabled domain e.

2.2 Self-Distilled Attention

One issue of supervised attention in Section 2.1 is that enabled domains that are not ground-truth domains are encouraged to have lower attention weights regardless of their relevancies to the input utterances and the ground-truth domains. Distillation methods utilize not only the ground-truth but also all the output activations of a source model so that all the prediction information from the source model can be utilized for more effective knowledge transfer between the source model and the target model (Hinton et al., 2014). Self-distillation, which trains a model leveraging the outputs of the source model with the same architecture or capacity, has been shown to improve the target model's performance with a distillation method (Furlanello et al., 2018).

We use a variant of self-distillation methods, where the model outputs at the previous epoch with the best dev set performance are used as the soft targets for the distillation,[4] so that the enabled domains that are not ground-truths can also be used for the supervised attention. While conventional distillation methods utilize softmax activations as the target values, we show that distillation on top of sigmoid activations is also effective without loss of generality. The loss function for the self-distillation on the attention weights is formulated as follows:

$$\mathcal{L}_d = -\sum_{e \in E} \tilde{a_e} \log a_e + (1 - \tilde{a_e}) \log (1 - a_e) ,$$

where $\tilde{a_e}$ is the attention weight of the model showing the dev set performance in the previous epochs. It is formulated as:

$$\tilde{a_e} = \sigma \left(\frac{u \cdot v_e}{T} \right) ,$$

where T is the temperature for sufficient usage of all the attention weights as the soft target. In this work, we set T to be 16, which shows the best dev set performance.

We have also evaluated soft-target regularization (Aghajanyan, 2017), where a weighted sum of the hard ground-truth target vector and the soft target vector is used as a single target vector, but it did not show better performance than self-distillation.

All the described loss functions are added to compose a single loss function as follows:

$$\mathcal{L} = \mathcal{L}_m + \alpha \left\{ (1 - \beta) \mathcal{L}_a + \beta^t \mathcal{L}_d \right\} ,$$

where α is a coefficient representing the degree of supervised enablement attention and β^t denotes the degree of the self-distillation. We set α to be 0.01 in this work. Following Hu et al. (2016), $\beta^t = 1 - 0.95^t$, where t denotes the current training epoch starting from 0 so that the hard ground-truth targets are more influential in the early epochs and the self-distillation is more utilized in the late epochs.

Table 2: Sample utterances correctly predicted with model (4) but not with model (1) and (2).

3 Experiments

We evaluate our proposed model on domain classification leveraging enabled domains. The enabled domains can be a crucial disambiguating signal especially when there are multiple similar domains. For example, assume that the input utterance is *"what's the weather"* and there are multiple weather-related domains such as `NewYorkWeather`, `AccuWeather`, and `WeatherChannel`. In this case, if `WeatherChannel` is included as an enabled domain of the current user, it is likely to be the most relevant domain to the user.

3.1 Datasets

Following the data collection methods used in Kim et al. (2018b), our models are trained using utterances with explicit invocation patterns. For example, given a user's utterance, *"Ask* {`ZooKeeper`} *to* {*play peacock sound*}*," "play peacock sound"* and `ZooKeeper` are extracted to compose a pair of the utterance and the ground-truth, respectively. In this way, we have generated train, development, and test sets containing 4.4M, 500K, and 500K utterances, respectively. All the utterances are from the usage log of Amazon Alexa and the ground-truth of each utterance is one of 1K frequently used domains. The average number of enabled domains per utterance in the test sets is 8.47.

One issue of this collected data sets is that the ground-truth is included in the enabled domains for more than 90% of the utterances, where the ground-truths are biased to enabled domains.[5] For more correct and unbiased evaluation of the models on the input utterances from real live traffic, we also evaluate the models on the same sized train, development, and test sets where the utterances are sampled to set the ratio of ground-truth inclusion in enabled domains to be 70%, which is closer to the ratio for actual input traffic.

3.2 Results

Table 1 shows the accuracies of our proposed models on the two test sets. We also show mean reciprocal rank (MRR) and top-3, accuracy[6] which is meaningful when utilizing post reranker, but we do not cover reranking issues in this paper (Robichaud et al., 2014; Kim et al., 2018a).

From Table 1, we can first see that changing softmax attention to sigmoid attention significantly improves the performance. This means that having more expressive power for the domain enablement information by relaxing the softmax constraint is effective in terms of leveraging the domain enablement information for domain classification. Along with sigmoid attention, supervised attention leveraging ground-truth slightly improves the performance, and supervised attention combined with self-distillation shows significant performance improvement. It demon-

---

(Laine and Aila, 2017), but we just leverage the model outputs at the previous epoch rather than accumulating the outputs over multiple epochs.

[5] Since the data collection method leverages utterances where users already know the exact domain names, such domains are likely to be the enabled domains of the users.

[6] Top-3 accuracy is calculated as # (utterances one of whose top three predictions is a ground-truth) / # (total utterances).

strates that supervised domain enablement attention leveraging ground-truth enabled domains is helpful, and utilizing attention information from other enabled domains is synergistic.

Kim et al. (2018b)'s model also adds a domain enablement bias vector to the final output, which is helpful when the ground-truth domain is one of the enabled domains. Such models (5) and (6) also show good performance for the test set where the ground-truth is one of the enabled domains with more than 90% probability. However, for the unbiased test set where the ground-truth is included in the enabled domains with a smaller probability, not adding the bias vector is shown to be better overall.

Table 2 shows sample utterances correctly predicted with model (4) but not with model (1) and (2). For the first two utterances, the ground-truths are included in the enabled domains, but there were only hundreds or fewer training instances whose ground-truths are `CryptoPrice` or `Expedia`. In these cases, we can see that model (1) attends to unrelated domains, model (2) attends to none of the enabled domains, but model (4), which uses supervised attention, is shown to attend to the ground-truth even without many training examples. "*find my phone*" has a single enabled domain which is not a ground-truth. In this case, model (1) still fully attends to the unrelated domain because of softmax attention while model (2) and (4) do not highly attend to it so that the unrelated enabled domain is not impactive.

3.3 Implementation Details

The word vectors are initialized with off-the-shelf GloVe vectors (Pennington et al., 2014), and all the other model parameters are initialized with Xavier initialization (Glorot and Bengio, 2010). Each model is trained for 25 epochs and the parameters showing the best performance on the development set are chosen as the model parameters. We use ADAM (Kingma and Ba, 2015) for the optimization with the initial learning rate 0.0002 and the mini-batch size 128. We use gradient clipping, where the threshold is set to 5. We use a variant of LSTM, where the input gate and the forget gate are coupled and peephole connections are used (Gers and Schmidhuber, 2000; Greff et al., 2017). We also use variational dropout for the LSTM regularization (Gal and Ghahramani, 2016). All the models are implemented with DyNet (Neubig et al., 2017).

4 Conclusion

We have introduced a novel domain enablement attention mechanism improving domain classification performance utilizing domain enablement information more effectively. The proposed attention mechanism uses sigmoid attentions for more expressive power of the attention weights, supervised attention leveraging ground-truth information for explicit guidance of the attention weight training, and self-distillation for the attention supervision leveraging enabled domains that are not ground truth domains. Evaluating on utterances from real usage in a large-scale IPDA, we have demonstrated that our proposed model significantly improves domain classification performance by better utilizing domain enablement information.

Abstract

In the sentence classification task, context formed from sentences adjacent to the sentence being classified can provide important information for classification. This context is, however, often ignored. Where methods do make use of context, only small amounts are considered, making it difficult to scale. We present a new method for sentence classification, Context-LSTM-CNN, that makes use of potentially large contexts. The method also utilizes long-range dependencies within the sentence being classified, using an LSTM, and short-span features, using a stacked CNN. Our experiments demonstrate that this approach consistently improves over previous methods on two different datasets.

1 Introduction

Artificial neural networks (ANN) and especially Deep Neural Networks (DNN) give state-of-the art results for sentence classification tasks. Usually, sentences are treated as separate instances for the task. However, in many situations the sentence that is the focus of classification appears in a context that can provide additional information. For example, in the below sentences from the IEMOCAP dataset, it is difficult to classify M02 as showing excitement, without the prior context:

- M01: I got it. I got accepted to U.S.C..
- F01: Oh, for real?
- M02: Yes! I just found out today. I just got the letter.

Our work is motivated by sentence classification in the text of medical records, in which complex judgements may be made across several sentences, each adding weight and nuance to a point. We believe, however, that the techniqe is more widely applicable. In order to test generalisability and to allow reproducibility, we therefore present an evaluation of the method with publicy available, non-medical corpora.

Previous work on using context for sentence classification used LSTM and CNN network layers to encode the surrounding context, giving an improvement in classification accuracy (Lee and Dernoncourt, 2016). However, the use of CNN and LSTM layers imposes a significant computational cost when training the network, especially if the size of the context is large. For this reason, the approach presented in (Lee and Dernoncourt, 2016) is explicitly intended for sequential, short-text classification.

In many cases, however, the context available is of significant size. We therefore introduce a new method, **Context-LSTM-CNN**[1], which is based on the computationally efficient FOFE (Fixed Size Ordinally Forgetting) method (Zhang et al., 2015), and an architecture that combines an LSTM and CNN for the focus sentence. The method consistently improves over results obtained from either LSTM alone, CNN alone, or these two combined, with little increase in training time.

This paper makes three contributions: 1) a demonstration of the importance of context in some sentence classification tasks; 2) an adaptation of existing datasets for such sentence classification tasks, in order to support reproducibility of evaluations; 3) a neural architecture for sentence classification that outperforms previous methods, and can include context of arbitrary size without incurring a large computational cost.

2 Related work

Since their introduction (Collobert et al., 2011), CNNs with word embedding language models have become common for text classification tasks (Kim, 2014; Conneau et al., 2017). One limitation of the original CNN approach is the loss

of long distance dependencies. In order to deal with this in image and speech recognition tasks, Xu et al. (2015); Sainath et al. (2015) combined CNNs with a Recurrent Neural Network (RNN) layer. Zhou et al. (2015) subsequently applied this to text classification. However, the CNN-RNN approach was originally devised for sequence labelling, is biased towards later words in the sequence, and does not perform better than CNN alone. Huynh et al. (2016) suggested reversing the architecture to first apply the RNN followed by a CNN with pooling to obtain global features. This gave results that improved over CNN-RNN, but not over CNN alone. In this paper, we build on Huynh et al. (2016)'s approach by replacing the GRU-based RNN (Cho et al., 2014) with an LSTM (Hochreiter and Schmidhuber, 1997) and by using multiple kernel sizes and more features in the subsequent CNN layer.

Lee and Dernoncourt (2016) showed that when classifying short texts, accuracy can be boosted by adding a CNN or LSTM derived vector representation of the surrounding context. For long contexts (such as patient records which may include well over 100 sentences), however, this will incur a significant additional computational cost. In this paper, we therefore apply an adaptation of the FOFE encoding (Zhang et al., 2015) to encode context.

3 Model

The Context-LSTM-CNN model is shown in Figure 1. It is based on the following components:

1. Input layer using word embeddings to encode the words of the focus sentence.
2. Bi-directional LSTM applied to the word embeddings of the focus sentence.
3. CNN on the outputs of the LSTM.
4. FOFE applied to word embeddings of both left and right context.
5. A final output layer.

In brief, an LSTM layer is used to encode the focus sentence. This is followed by convolutional layers with small-size kernels and max-pooling to extract local features at specific points from the LSTM outputs. In addition to processing the focus sentence, we also encode the full left and right contexts using an adaptation of FOFE applied to our embeddings. This encodes any variable length context into a fixed length embedding, thus allowing us to include large contexts without rapidly increasing the computational cost. The output of the FOFE layers are then each passed through separate fully connected layers, before being concatenated and connected to output layer.

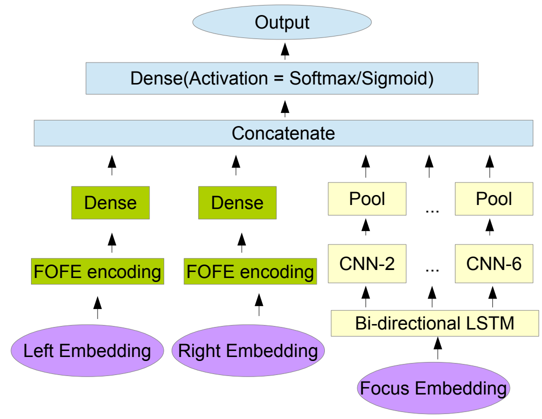

Figure 1: Structure of the C-LSTM-CNN model

In detail, the full network takes three inputs. The first is the sequence of words $X = (x_1, x_2, ...x_T)$, where T is the length of the sentence to be classified, and where each x_i is a word embedding for the respective word in this sentence. Embeddings are pre-trained by Word2Vec (Mikolov et al., 2013) on the corpus used for the respective experiment. The embeddings are not updated during the training of our network.

The second and third inputs are the left and right context, which will connect to the FOFE encoders. Each context is a sequence of sentences $X_C = (s_1, s_2, ...s_N)$, where each sentence is a sequence of word embeddings $s_n = (x_1, x_2, ...x_U)$ from the same embedding space as X.

The first component of the inputs, derived from the focus sentence, is processed by a bi-directional LSTM with one layer, in order to capture long-distance dependencies within the sentence. Since LSTMs impose a significant computational cost for very long sequences we only use this layer for the input representing the focus sentence, and not for the left and right contexts.

The LSTM generates outputs $h_{lstm} = (h_1, h_2..., h_T)$ which are passed on to the convolutional layer (CNN) in order to learn local features for different kernel sizes l from the history-aware outputs of the LSTM. For each of several kernel sizes, we generate f different features, to give CNN outputs $c^l_{cnn} = (c_1, c_2, \cdots, c_{T-l+1})$. For each CNN output c^l_{cnn}, we use max-overtime pooling to extract the most significant feature, and dropout to make the learned features more robust.

We use an adapted version of FOFE to provide information about the left and right contexts of the focus. Instead of the original 1 of k FOFE representation, we apply FOFE encoding to word2vec embeddings. This gives a weighted sum of the context word embeddings, with weights decreasing exponentially with distance from the focus.

The embedding z for a sentence $(x_1, x_2, ...x_U)$ is initialised to $z_1 = x_1$, and then calculated recursively for $u \in 2 \cdots U$ as $z_u = \alpha \cdot z_{u-1} + x_u$. The parameter α is the forgetting factor, which controls how fast the weights used for words farther away from the start of the sentence diminish. This method is fast and compactly encodes the words of a sentence in a single embedding vector.

For our use of FOFE, we encode all sentences in the document to left and right of the focus sentence, in two hierarchical steps. First we encode each context sentence into a FOFE embedding z^{sent}, with a slowly-decreasing α_{sent}. Following this, the left context FOFE encodings are themselves encoded into a single context embedding using a rapidly decreasing α_{cont}. This is calculated starting with $z_1^{cont} = z_1^{sent}$ and is calculated for $m \in 2 \cdots |C_{left}|$ as $z_m^{cont} = \alpha_{cont} \cdot z_{m-1}^{cont} + z_m^{sent}$. The right context FOFE encodings are encoded in the same way, starting with $z_{|C_{right}|}^{cont} = z_{|C_{right}|}^{sent}$ and recursively applying the same formula for $m \in |C_{right}| \cdots 2$. This gives a heavy bias towards sentences more local to the focus sentence, but only slightly decreases the importance of words within each sentence. The final FOFE embeddings for the left and right contexts are then put through a dense linear layer to obtain the hidden layer outputs, which are combined with the LSTM-CNN outputs. The concatenated outputs from the dense FOFE layers and from the CNN layer for all kernel sizes are then used as input to a final softmax output layer.

4 Experiments

We compare the performance of four different network architectures: 1) CNN only; 2) LSTM only; 3) LSTM-CNN; 4) LSTM context encoded LSTM-CNN (L-LSTM-CNN), in which the one left and right context sentence are encoded by LSTM; and 5) Context-LSTM-CNN (C-LSTM-CNN). We use the following two datasets for evaluation:

Interactive Emotional Dyadic Motion Capture Database (Busso et al., 2008)[2] (IEMOCAP). Originally created for the analysis of human emotions based on speech and video, a transcript of the speech component is available for NLP research. Each sentence in the dialogue is annotated with one of 10 types of emotion. There is a class imbalance in the labelled data, and so we follow the approach of (Chernykh et al., 2017), and only use sentences classified with one of four labels ('Anger', 'Excitement', 'Neutral' and 'Sadness'). For this dataset, instead of using left and right contexts, we assign all sentences from one person to one context and all sentences from the other person to the other context. While only the sentences with the four classes of interest are used for classification, all sentences of the dialog are used as the context. This results in a set of 4936 labelled sentences with average sentence length 14, and average document length is 986.

Drug-related Adverse Effects (Gurulingappa et al., 2012)[3] (ADE). This dataset contains sentences sampled from the abstracts of medical case reports. For each sentence, the annotation indicates whether adverse effects of a drug are being described ('Positive') or not ('Negative'). The original release of the data does not contain the document context, which we reconstructed from PubMed[4]. Sentences for which the full abstract could not be found were removed, resulting in 20,040 labelled sentences, with average sentence length 21 and average document length 129.

rithm. To deal with label imbalance in the data, class weights w_i for class i were set proportional to $\max(f_i)/f_i$ where f_i is the frequency of class i.

We used word2vec embeddings with 50 dimensions (suggesed as sufficient by (Lai et al., 2016)). For the LSTM, 64 hidden units were used. For the CNN, layers for kernel sizes 2 to 6 were included in the network, and 64 features were used for each.

4.1 Effect of Forgetting Factors

We examined the effect of the two context encoder hyperparameters: α_{cont} (context level forgetting factor) and α_w (sentence level forgetting factor) on classification performance over the IEMOCAP dataset. We tested both in the range of 0.1 to 1 with an incremental step of 0.1. Results are shown in Figure 2. Accuracy improves as α_{cont} increases, but drops at $\alpha_{cont} = 1$, at which point all context sentence are given equal weight. This may be because context closest to the focus sentence is more important than distant context. Therefore, we select $\alpha_{cont} = 0.9$ in all experiments.

For α_{sent}, performance always increases as α_{sent} increases, with best results at $\alpha_{sent} = 1$, at which point all words in the sentence contribute equally in the context code. This implies that for individual sentences in the context, it is more preferable to lose word order, than to down weight any individual word. In all experiments, we therefore set the sentence level forgetting factor to $\alpha_{sent} = 1$

4.2 Evaluation Results

Table 1 shows the mean and standard deviations for accuracy over the cross validation folds, and training time, for both data sets. CNN alone performs better than LSTM alone in both tasks. The combined LSTM-CNN network consistently improves performance beyond both CNN alone and LSTM alone. Both context based models (L-LSTM-CNN and C-LSTM-CNN) perform better than non context based models, but note that L-LSTM-CNN increases training time by approximately 1.5x, whereas C-LSTM-CNN shows only a marginal increase in training time, with a large increase in accuracy on the IEMOCAP corpus.

Table 2 shows the F1-measure for each class in the two datasets. Again, Context-LSTM-CNN outperforms the other models on all classes for all data sets. C-LSTM-CNN improves on average by 6.28 over L-LSTM-CNN, 10.16 over LSTM-CNN, 11.4 over CNN and 13.29 over LSTM.

We conducted a t-test between L-LSTM-CNN and C-LSTM-CNN. On IEMOCAP, C-LSTM-CNN is significantly better than L-LSTM-CNN ($p = 0.002$). On ADE, C-LSTM-CNN is not significantly better than L-LSTM-CNN ($p = 0.128$). This may because ADE sentences are less context dependent. Alternatively, as the ADE task is relatively easy, with all models able to achieve about 90% accuracy, a context based approach might not be able to further improve the accuracy.

5 Conclusion

In this paper we introduced a new ANN model, **Context-LSTM-CNN**, that combines the strength of LSTM and CNN with the lightweight context encoding algorithm, FOFE. Our model shows a consistent improvement over either a non-context based model and a LSTM context encoded model, for the sentence classification task.

Abstract

Deep NLP models benefit from underlying structures in the data—*e.g.*, parse trees—typically extracted using off-the-shelf parsers. Recent attempts to jointly learn the latent structure encounter a tradeoff: either make factorization assumptions that limit expressiveness, or sacrifice end-to-end differentiability. Using the recently proposed SparseMAP inference, which retrieves a sparse distribution over latent structures, we propose a novel approach for end-to-end learning of latent structure predictors jointly with a downstream predictor. To the best of our knowledge, our method is the first to enable unrestricted dynamic computation graph construction from the *global* latent structure, while maintaining differentiability.

1 Introduction

Latent structure models are a powerful tool for modeling compositional data and building NLP pipelines (Smith, 2011). An interesting emerging direction is to **dynamically** adapt a network's computation graph, based on structure inferred from the input; notable applications include learning to write programs (Bosnjak et al., 2017), answering visual questions by composing specialized modules (Hu et al., 2017; Johnson et al., 2017), and composing sentence representations using latent syntactic parse trees (Yogatama et al., 2017).

But how to learn a model that is able to condition on such combinatorial variables? The question then becomes: how to marginalize over *all* possible latent structures? For tractability, existing approaches have to make a choice. Some of them eschew *global* latent structure, resorting to computation graphs built from smaller local decisions: *e.g.*, structured attention networks use local posterior marginals as attention weights (Kim et al., 2017; Liu and Lapata, 2018), and Maillard et al. (2017) construct sentence representations from parser chart entries. Others allow more flexibility at the cost of losing end-to-end differentiability, ending up with reinforcement learning problems (Yogatama et al., 2017; Hu et al., 2017; Johnson et al., 2017; Williams et al., 2018). More traditional approaches employ an off-line structure predictor (*e.g.*, a parser) to define the computation graph (Tai et al., 2015; Chen et al., 2017), sometimes with some parameter sharing (Bowman et al., 2016). However, these off-line methods are unable to *jointly* train the latent model and the downstream classifier via error gradient information.

We propose here a new strategy for building **dynamic computation graphs** with latent structure, through **sparse structure prediction**. Sparsity allows selecting and conditioning on a tractable number of global structures, eliminating the limitations stated above. Namely, our approach is the first that:

A) is **fully differentiable**;

B) supports **latent structured variables**;

C) can marginalize over full **global structures**.

This contrasts with off-line and with reinforcement learning-based approaches, which satisfy **B** and **C** but not **A**; and with local marginal-based methods such as structured attention networks, which satisfy **A** and **B**, but not **C**. Key to our approach is the recently proposed **SparseMAP inference** (Niculae et al., 2018), which induces, for each data example, a very sparse posterior distribution over the possible structures, allowing us to compute the expected network output efficiently and explicitly in terms of a small, interpretable set of latent structures. Our model can be trained end-to-end with gradient-based methods, without the need for policy exploration or sampling.

We demonstrate our strategy on inducing latent dependency TreeLSTMs, achieving competitive results on sentence classification, natural language inference, and reverse dictionary lookup.

2 Sparse Latent Structure Prediction

We describe our proposed approach for learning with combinatorial structures (in particular, non-projective dependency trees) as latent variables.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 905–911
Brussels, Belgium, October 31 - November 4, 2018.

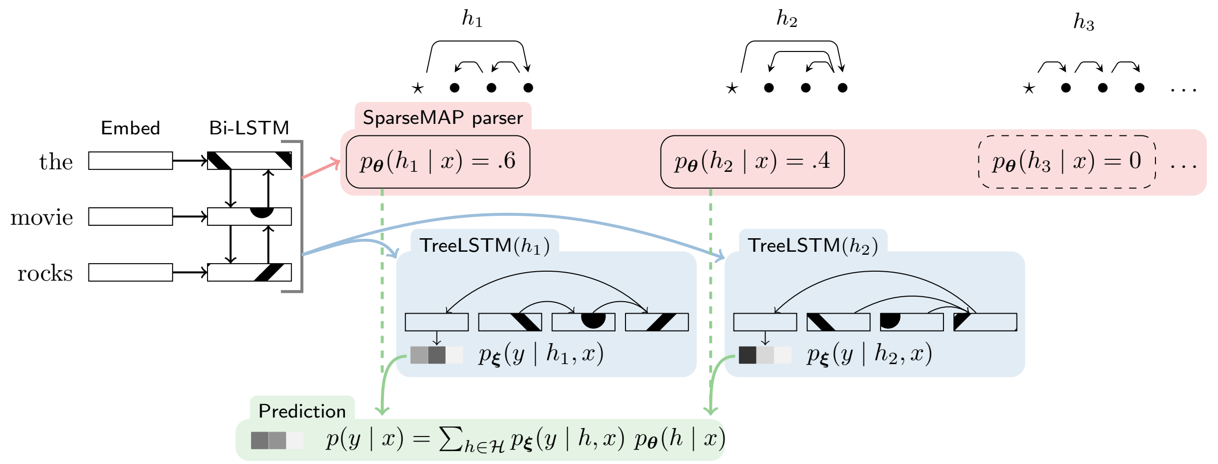

Figure 1: Our method computes a sparse probability distribution over all possible latent structures: here, only two have nonzero probability. For each selected tree h, we evaluate $p_{\boldsymbol\xi}(y \mid h, x)$ by dynamically building the corresponding computation graph (*e.g.*, a TreeLSTM). The final, posterior prediction is a sparse weighted average.

2.1 Latent Structure Models

Let x and y denote classifier inputs and outputs, and $h \in \mathcal{H}(x)$ a latent variable; for example, $\mathcal{H}(x)$ can be the set of possible dependency trees for x. We would like to train a neural network to model

$$p(y \mid x) := \sum_{h \in \mathcal{H}(x)} p_{\boldsymbol\theta}(h \mid x)\, p_{\boldsymbol\xi}(y \mid h, x), \qquad (1)$$

where $p_{\boldsymbol\theta}(h \mid x)$ is a structured-output parsing model that defines a distribution over trees, and $p_{\boldsymbol\xi}(y \mid h, x)$ is a classifier whose computation graph may depend **freely and globally** on the structure h (*e.g.*, a TreeLSTM). The rest of this section focuses on the challenge of defining $p_{\boldsymbol\theta}(h \mid x)$ such that Eqn. 1 remains tractable and differentiable.

2.2 Global Inference

Denote by $f_{\boldsymbol\theta}(h;\, x)$ a scoring function, assigning each tree a non-normalized score. For instance, we may have an *arc-factored* score $f_{\boldsymbol\theta}(h; x) := \sum_{a \in h} s_{\boldsymbol\theta}(a; x)$, where we interpret a tree h as a set of directed arcs a, each receiving an atomic score $s_{\boldsymbol\theta}(a; x)$. Deriving $p_{\boldsymbol\theta}$ given $f_{\boldsymbol\theta}$ is known as *structured inference*. This can be written as a Ω-regularized optimization problem of the form

$$p_{\boldsymbol\theta}(\cdot \mid x) := \operatorname*{argmax}_{q \in \triangle^{|\mathcal{H}(x)|}} \sum_{h \in \mathcal{H}(x)} q(h) f_{\boldsymbol\theta}(h; x) - \Omega(q),$$

where $\triangle^{|\mathcal{H}(x)|}$ is the set of all possible probability distributions over $\mathcal{H}(x)$. Examples follow.

Marginal inference. With negative entropy regularization, *i.e.*, $\Omega(q) := \sum_{h \in \mathcal{H}(x)} q(h) \log q(h)$, we recover marginal inference, and the probability of a tree becomes (Wainwright and Jordan, 2008)

$$p_{\boldsymbol\theta}(h \mid x) \propto \exp(f_{\boldsymbol\theta}(h; x)).$$

This closed-form derivation, detailed in Appendix A, provides a differentiable expression for $p_{\boldsymbol\theta}$. However, crucially, since $\exp(\cdot) > 0$, every tree is assigned strictly nonzero probability. Therefore—unless the downstream $p_{\boldsymbol\xi}$ is constrained to also factor over arcs, as in Kim et al. (2017); Liu and Lapata (2018)—the sum in Eqn. 1 requires enumerating the exponentially large $\mathcal{H}(x)$. This is generally intractable, and even hard to approximate via sampling, even when $p_{\boldsymbol\theta}$ is tractable.

MAP inference. At the polar opposite, setting $\Omega(q) := 0$ yields **maximum a posteriori (MAP) inference** (see Appendix A). MAP assigns a probability of 1 to the highest-scoring tree, and 0 to all others, yielding a very sparse $p_{\boldsymbol\theta}$. However, since the top-scoring tree (or top-k, for fixed k) does not vary with small changes in $\boldsymbol\theta$, error gradients cannot propagate through MAP. This prevents end-to-end gradient-based training for MAP-based latent variables, which makes them more difficult to use. Related reinforcement learning approaches also yield only one structure, but sidestep non-differentiability by instead introducing more challenging search problems.

2.3 Sparse Inference

In this work, we propose using **SparseMAP inference** (Niculae et al., 2018) to sparsify the set $\mathcal{H}$ while preserving differentiability. SparseMAP uses a quadratic penalty on the posterior marginals

$$\Omega(q) := \|\boldsymbol{u}(q)\|_2^2, \quad \text{where} \quad [\boldsymbol{u}(q)]_a := \sum_{h:a \in h} q(h).$$

Situated between marginal inference and MAP inference, SparseMAP assigns nonzero probability to only a small set of plausible trees $\bar{\mathcal{H}} \subset \mathcal{H}$, of size at most equal to the number of arcs (Martins et al., 2015, Proposition 11). This guarantees that the summation in Eqn. 1 can be computed efficiently by iterating over $\bar{\mathcal{H}}$: this is depicted in Figure 1 and described in the next paragraphs.

Forward pass. To compute $p(y \mid x)$ (Eqn. 1), we observe that the SparseMAP posterior $p_{\boldsymbol{\theta}}$ is nonzero only on a small set of trees $\bar{\mathcal{H}}$, and thus we only need to compute $p_{\boldsymbol{\xi}}(y \mid h, x)$ for $h \in \bar{\mathcal{H}}$. The support and values of $p_{\boldsymbol{\theta}}$ are obtained by solving the SparseMAP inference problem, as we describe in Niculae et al. (2018). The strategy, based on the active set algorithm (Nocedal and Wright, 1999, chapter 16), involves a sequence of MAP calls (here: maximum spanning tree problems.)

Backward pass. We next show how to compute end-to-end gradients efficiently. Recall from Eqn. 1 $p(y \mid x) = \sum_{h \in \mathcal{H}} p_{\boldsymbol{\theta}}(h \mid x)\, p_{\boldsymbol{\xi}}(y \mid h, x)$, where h is a discrete index of a tree. To train the classifier, we have $\partial p(y|x)/\partial \boldsymbol{\xi} = \sum_{h \in \mathcal{H}} p_{\boldsymbol{\theta}}(h \mid x) \partial p_{\boldsymbol{\xi}}(y|h,x)/\partial \boldsymbol{\xi}$, therefore only the terms with nonzero probability (*i.e.*, $h \in \bar{\mathcal{H}}$) contribute to the gradient. $\partial p_{\boldsymbol{\xi}}(y|h,x)/\partial \boldsymbol{\xi}$ is readily available by implementing $p_{\boldsymbol{\xi}}$ in an automatic differentiation library.[1] To train the latent parser, the total gradient $\partial p(y|x)/\boldsymbol{\theta}$ is the sum $\sum_{h \in \bar{\mathcal{H}}} p_{\boldsymbol{\xi}}(y \mid h, x)\ \partial p_{\boldsymbol{\theta}}(h|x)/\partial \boldsymbol{\theta}$. We derive the expression of $\partial p_{\boldsymbol{\theta}}(h|x)/\partial \boldsymbol{\theta}$ in Appendix B. **Crucially, the gradient sum is also sparse, like $p_{\boldsymbol{\theta}}$, and efficient to compute,** amounting to multiplying by a $|\bar{\mathcal{H}}(x)|$-by-$|\bar{\mathcal{H}}(x)|$ matrix. The proof, given in Appendix B, is a novel extension of the SparseMAP backward pass (Niculae et al., 2018).

Generality. Our description focuses on probabilistic classifiers, but our method can be readily applied to networks that output any representation, not necessarily a probability. For this, we define a function $\boldsymbol{r}_{\boldsymbol{\xi}}(h, x)$, consisting of any auto-differentiable computation w.r.t. x, conditioned on the discrete latent structure h in arbitrary, non-differentiable ways. We then compute

$$\bar{\boldsymbol{r}}(x) := \sum_{h \in \mathcal{H}(x)} p_{\boldsymbol{\theta}}(h \mid x) \boldsymbol{r}_{\boldsymbol{\xi}}(h, x) = \mathbb{E}_{h \sim p_{\boldsymbol{\theta}}} \boldsymbol{r}_{\boldsymbol{\xi}}(h, x).$$

Table 1: Accuracy scores for classification and NLI.

This strategy is demonstrated in our reverse-dictionary experiments in §3.4. In addition, our approach is not limited to trees: any structured model with tractable MAP inference may be used.

3 Experiments

We evaluate our approach on three natural language processing tasks: sentence classification, natural language inference, and reverse dictionary lookup.

3.1 Common aspects

Word vectors. Unless otherwise mentioned, we initialize with 300-dimensional GloVe word embeddings (Pennington et al., 2014) We transform every sentence via a bidirectional LSTM encoder, to produce a context-aware vector $\boldsymbol{v}_i$ encoding word i.

Dependency TreeLSTM. We combine the word vectors $\boldsymbol{v}_i$ in a sentence into a single vector using a tree-structured Child-Sum LSTM, which allows an arbitrary number of children at any node (Tai et al., 2015). Our baselines consist in extreme cases of dependency trees: where the parent of word i is word $i+1$ (resulting in a **left-to-right** sequential LSTM), and where all words are direct children of the root node (resulting in a **flat** additive model). We also consider **off-line** dependency trees precomputed by Stanford CoreNLP (Manning et al., 2014).

Neural arc-factored dependency parsing. We compute arc scores $s_{\boldsymbol{\theta}}(a; x)$ with one-hidden-layer perceptrons (Kiperwasser and Goldberg, 2016).

Experimental setup. All networks are trained via stochastic gradient with 16 samples per batch. We tune the learning rate on a log-grid, using a decay factor of 0.9 after every epoch at which the validation performance is not the best seen, and stop after five epochs without improvement. At test time, we scale the arc scores $s_{\boldsymbol{\theta}}$ by a temperature t

---

[1] Here we assume $\boldsymbol{\theta}$ and $\boldsymbol{\xi}$ to be disjoint, but weight sharing is easily handled by automatic differentiation via the product rule. Differentiation w.r.t. the summation index h is not necessary: $p_{\boldsymbol{\xi}}$ may use the discrete structure h freely and globally.

Following the authors, for an input definition, we rank a shortlist of approximately 50k candidate words according to the cosine similarity to the output vector, and report median rank of the expected word, accuracy at 10, and at 100.

chosen on the validation set, controlling the sparsity of the SparseMAP distribution. All hidden layers are 300-dimensional.[2]

3.2 Sentence classification

We evaluate our models for sentence-level subjectivity classification (Pang and Lee, 2004) and for binary sentiment classification on the Stanford Sentiment Treebank (Socher et al., 2013). In both cases, we use a softmax output layer on top of the Dependency TreeLSTM output representation.

3.3 Natural language inference (NLI)

We apply our strategy to the SNLI corpus (Bowman et al., 2015), which consists of classifying premise-hypothesis sentence pairs into entailment, contradiction or neutral relations. In this case, for each pair (x_P, x_H), the running sum is over *two* latent distributions over parse trees, *i.e.*, $\sum_{h_P \in \mathcal{H}(x_P)} \sum_{h_H \in \mathcal{H}(x_H)} p_{\boldsymbol{\xi}}(y \mid x_{\{P,H\}}, h_{\{P,H\}}) p_{\boldsymbol{\theta}}(h_P \mid x_P) p_{\boldsymbol{\theta}}(h_H \mid x_H)$. For each pair of trees, we independently encode the premise and hypothesis using a TreeLSTM. We then concatenate the two vectors, their difference, and their element-wise product (Mou et al., 2016). The result is passed through one *tanh* hidden layer, followed by the softmax output layer.[3]

3.4 Reverse dictionary lookup

The reverse dictionary task aims to compose a dictionary definition into an embedding that is close to the defined word. We therefore used *fixed* input and output embeddings, set to unit-norm 500-dimensional vectors provided, together with training and evaluation data, by Hill et al. (2016). The network output is a projection of the TreeLSTM encoding back to the dimension of the word embeddings, normalized to unit ℓ_2 norm. We maximize the cosine similarity of the predicted vector with the embedding of the defined word.

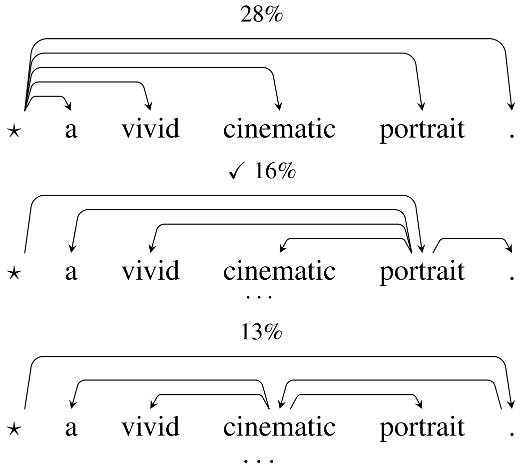

Figure 2: Three of the sixteen trees with nonzero probability for an SST test example. Flat representations, such as the first tree, perform well on this task, as reflected by the baselines. The second tree, marked with ✓, agrees with the off-line parser.

4 Discussion

Experimental performance. Classification and NLI results are reported in Table 1. Compared to the latent structure model of Yogatama et al. (2017), our model performs better on SNLI (80.5%) but worse on SST (86.5%). On SNLI, our model also outperforms Maillard et al. (2017) (81.6%). To our knowledge, latent structure models have not been tested on subjectivity classification. Surprisingly, the simple flat and left-to-right baselines are very strong, outperforming the off-line dependency tree models on all three datasets. The latent TreeLSTM model reaches the best accuracy on two out of the three datasets. On reverse dictionary lookup (Ta-

---

[2] Our `dynet` (Neubig et al., 2017) implementation is available at `https://github.com/vene/sparsemap`.

[3] For NLI, our architecture is motivated by our goal of evaluating the impact of latent structure for learning compositional sentence representations. State-of-the-art models conditionally transform the sentences to achieve better performance, *e.g.*, 88.6% accuracy in Chen et al. (2017).

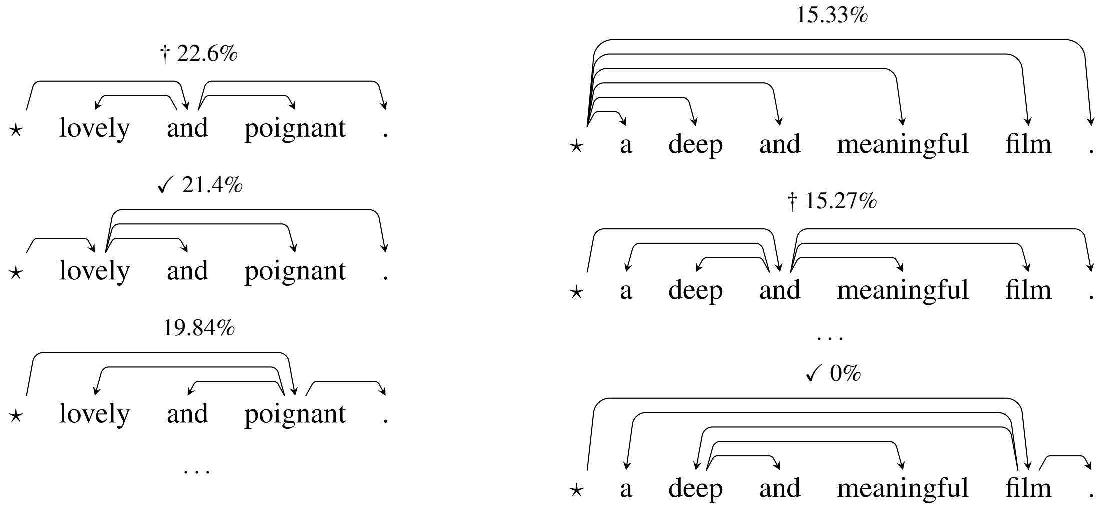

Figure 3: Examples of coordinate structures where our model assigns high probability to a symmetric parse (marked †). While not consistent with the standard asymmetrical parse produced by CoreNLP (marked with ✓), the symmetric analysis may be more appropriate for TreeLSTM composition.

ble 2), our model also performs well, especially on concept classification, where the input definitions are more different from the ones seen during training. For context, we repeat the scores of the CKY-based latent TreeLSTM model of Maillard et al. (2017), as well as of the LSTM from Hill et al. (2016); these different-sized models are not entirely comparable. We attribute our model's performance to the latent parser's flexibility, investigated below.

Selected latent structures. We analyze the latent structures selected by our model on SST, where the flat composition baseline is remarkably strong. We find that our model, to maximize accuracy, prefers flat or nearly-flat trees, but not exclusively: the average posterior probability of the flat tree is 28.9%. In Figure 2, the highest-ranked tree is flat, but deeper trees are also selected, including the projective CoreNLP parser output. Syntax is not necessarily an optimal composition order for a latent TreeLSTM, as illustrated by the poor performance of the off-line parser (Table 1). Consequently, our (fully unsupervised) latent structures tend to disagree with CoreNLP: the average probability of CoreNLP arcs is 5.8%; Williams et al. (2018) make related observations. Indeed, some syntactic conventions may be questionable for recursive composition. Figure 3 shows two examples where our model identifies a plausible symmetric composition order for coordinate structures: this analysis disagrees with CoreNLP, which uses the asymmetrical Stanford / UD convention of assigning the left-most conjunct as head (Nivre et al., 2016). Assigning the conjunction as head instead seems preferable in a Child-Sum TreeLSTM.

Training efficiency. Our model must evaluate at least one TreeLSTM for each sentence, making it necessarily slower than the baselines, which evaluate exactly one. Thanks to sparsity and autobatching, the actual slow-down is not problematic; moreover, as the model trains, the latent parser gets more confident, and for many unambiguous sentences there may be only one latent tree with nonzero probability. On SST, our average training epoch is only 4.7× slower than the off-line parser and 6× slower than the flat baseline.

5 Conclusions and future work

We presented a novel approach for training latent structure neural models, based on the key idea of sparsifying the set of possible structures, and demonstrated our method with competitive latent dependency TreeLSTM models. Our method's generality opens up several avenues for future work: since it supports any structure for which MAP inference is available (*e.g.*, matchings, alignments), and we have no restrictions on the downstream $p_{\boldsymbol{\xi}}(y \mid h, x)$, we may design latent versions of more complicated state-of-the-art models, such as ESIM for NLI (Chen et al., 2017). In concurrent work, Peng et al. (2018) proposed an approximate MAP backward pass, relying on a relaxation and a gradient projection. Unlike our method, theirs does not support multiple latent structures; we intend to further study the relationship between the methods.

Convolutional Neural Networks with Recurrent Neural Filters

Yi Yang

Abstract

We introduce a class of convolutional neural networks (CNNs) that utilize recurrent neural networks (RNNs) as convolution filters. A convolution filter is typically implemented as a linear affine transformation followed by a non-linear function, which fails to account for language compositionality. As a result, it limits the use of high-order filters that are often warranted for natural language processing tasks. In this work, we model convolution filters with RNNs that naturally capture compositionality and long-term dependencies in language. We show that simple CNN architectures equipped with recurrent neural filters (RNFs) achieve results that are on par with the best published ones on the Stanford Sentiment Treebank and two answer sentence selection datasets.[1]

1 Introduction

Convolutional neural networks (CNNs) have been shown to achieve state-of-the-art results on various natural language processing (NLP) tasks, such as sentence classification (Kim, 2014), question answering (Dong et al., 2015), and machine translation (Gehring et al., 2017). In an NLP system, a convolution operation is typically a sliding window function that applies a convolution filter to every possible window of words in a sentence. Hence, the key components of CNNs are a set of convolution filters that compose low-level word features into higher-level representations.

Convolution filters are usually realized as linear systems, as their outputs are affine transformations of the inputs followed by some non-linear activation functions. Prior work directly adopts a linear convolution filter to NLP problems by utilizing a concatenation of embeddings of a window of words as the input, which leverages word order information in a shallow additive way. As early CNN architectures have mainly drawn inspiration from models of the primate visual system, the necessity of coping with language compositionality is largely overlooked in these systems. Due to the linear nature of the convolution filters, they lack the ability to capture complex language phenomena, such as compositionality and long-term dependencies.

To overcome this, we propose to employ recurrent neural networks (RNNs) as convolution filters of CNN systems for various NLP tasks. Our recurrent neural filters (RNFs) can naturally deal with language compositionality with a recurrent function that models word relations, and they are also able to implicitly model long-term dependencies. RNFs are typically applied to word sequences of moderate lengths, which alleviates some well-known drawbacks of RNNs, including their vulnerability to the gradient vanishing and exploding problems (Pascanu et al., 2013). As in conventional CNNs, the computation of the convolution operation with RNFs can be easily parallelized. As a result, RNF-based CNN models can be 3-8x faster than their RNN counterparts.

We present two RNF-based CNN architectures for sentence classification and answer sentence selection problems. Experimental results on the Stanford Sentiment Treebank and the QASent and WikiQA datasets demonstrate that RNFs significantly improve CNN performance over linear filters by 4-5% accuracies and 3-6% MAP scores respectively. Analysis results suggest that RNFs perform much better than linear filters in detecting longer key phrases, which provide stronger cues for categorizing the sentences.

2 Approach

The aim of a convolution filter is to produce a local feature for a window of words. We describe a novel approach to learning filters using RNNs, which is especially suitable for NLP problems.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 912–917
Brussels, Belgium, October 31 - November 4, 2018.

We then present two CNN architectures equipped with RNFs for sentence classification and sentence matching tasks respectively.

2.1 Recurrent neural filters

We briefly review the linear convolution filter implementation by Kim (2014), which has been widely adopted in later works. Consider an m-gram word sequence $[\mathbf{x}_i, \cdots, \mathbf{x}_{i+m-1}]$, where $\mathbf{x}_i \in \mathbb{R}^k$ is a k-dimensional word vector. A linear convolution filter is a function applied to the m-gram to produce a feature $c_{i,j}$:

$$\begin{aligned} c_{i,j} &= f(\mathbf{w}_j^\top \mathbf{x}_{i:i+m-1} + b_j), \\ \mathbf{x}_{i:i+m-1} &= \mathbf{x}_i \oplus \mathbf{x}_{i+1} \oplus \cdots \oplus \mathbf{x}_{i+m-1}, \end{aligned} \quad (1)$$

where $\oplus$ is the concatenation operator, b_j is a bias term, and f is a non-linear activation function. We typically use multiple independent linear filters to yield a feature vector $\mathbf{c}_i$ for the word sequence. Linear convolution filters make strong assumptions about language that could harm the performance of NLP systems. First, linear filters assume local compositionality and ignore long-term dependencies in language. Second, they use separate parameters for each value of the time index, which hinders parameter sharing for the same word type (Goodfellow et al., 2016). The assumptions become more problematic if we increase the window size m.

We propose to address the limitations by employing RNNs to realize convolution filters, which we term *recurrent neural filters* (RNFs). RNFs compose the words of the m-gram from left to right using the same recurrent unit:

$$\mathbf{h}_t = \mathrm{RNN}(\mathbf{h}_{t-1}, \mathbf{x}_t), \quad (2)$$

where $\mathbf{h}_t$ is a hidden state vector that encoded information about previously processed words, and the function RNN is a recurrent unit such as Long Short-Term Memory (LSTM) unit (Hochreiter and Schmidhuber, 1997) or Gated Recurrent Unit (GRU) (Cho et al., 2014). We use the last hidden state $\mathbf{h}_{i+m-1}$ as the RNF output feature vector $\mathbf{c}_i$. Features learned by RNFs are interdependent of each other, which permits the learning of complementary information about the word sequence. The left-to-right word composing procedure in RNFs preserves word order information and implicitly models long-term dependencies in language. RNFs can be treated as simple drop-in replacements of linear filters and potentially adopted in numerous CNN architectures.

2.2 CNN architectures

Sentence encoder We use a CNN architecture with one convolution layer followed by one max pooling layer to encode a sentence. In particular, the RNFs are applied to every possible window of m words in the sentence $\{\mathbf{x}_{1:m}, \mathbf{x}_{2:m+1}, \cdots, \mathbf{x}_{n-m+1:n}\}$ to generate feature maps $\mathbf{C} = [\mathbf{c}_1, \mathbf{c}_2, \cdots, \mathbf{c}_{n-m+1}]$. Then a max-over-time pooling operation (Collobert et al., 2011) is used to produce a fixed size sentence representation: $\mathbf{v} = \max\{\mathbf{C}\}$.

Sentence classification We use a CNN architecture that is similar to the CNN-static model described in Kim (2014) for sentence classification. After obtaining the sentence representation $\mathbf{v}$, a fully connected softmax layer is used to map $\mathbf{v}$ to an output probability distribution. The network is optimized against a cross-entropy loss function.

Sentence matching We exploit a CNN architecture that is nearly identical to the CNN-Cnt model introduced by Yang et al. (2015). Let $\mathbf{v}_1$ and $\mathbf{v}_2$ be the vector representations of the two sentences. A bilinear function is applied to $\mathbf{v}_1$ and $\mathbf{v}_2$ to produce a sentence matching score. The score is combined with two word matching count features and fed into a sigmoid layer. The output of the sigmoid layer is used by binary cross-entropy loss to optimize the model.

3 Experiments

We evaluate RNFs on some of the most popular datasets for the sentence classification and sentence matching tasks. After describing the experimental setup, we compare RNFs against both linear filters and conventional RNN models, and report our findings in § 3.2.

3.1 Experimental settings

Data We use the Stanford Sentiment Treebank (Socher et al., 2013) in our sentence classification experiments. We report accuracy results for both binary classification and fine-grained classification settings. Two answer sentence selection datasets, QASent (Wang et al., 2007) and WikiQA (Yang et al., 2015), are adopted in our sentence matching experiments. We use MAP and MRR to evaluate the performance of answer sentence selection models.

Competitive systems We consider CNN variants with linear filters and RNFs. For RNFs, we adopt two implementations based on GRUs and LSTMs respectively. We also compare against the following RNN variants: GRU, LSTM, GRU with max pooling, and LSTM with max pooling.[2] We use the publicly available 300-dimensional GloVe vectors (Pennington et al., 2014) pre-trained with 840 billion tokens to initialize the word embeddings for all the models. The word vectors are fixed during downstream training. Finally, we report best published results for each dataset.[3]

Parameter tuning For all the experiments, we tune hyperparameters on the development sets and report results obtained with the selected hyperparameters on the test sets. After the preliminary search, we choose the number of hidden units (feature maps) from $\{200, 300, 400\}$, and the filter window width from $\{2, 3, 4, 5\}$ for linear filters and from $\{5, 6, 7, 8\}$ for RNFs. Linear filters tend to perform well with small window widths, while RNFs work better with larger window widths. We apply dropout to embedding layers, pooling layers, RNN input layers, and RNN recurrent layers. The dropout rates are selected from $\{0, 0.2, 0.4\}$, where 0 indicates that dropout is not used for the specific layer. Optimization is performed by Adam (Kingma and Ba, 2015) with early stopping. We conduct random search with a budget of 100 runs to seek the best hyperparameter configuration for each system.

3.2 Results

The evaluation results on sentiment classification and answer sentence selection are shown in Table 1 and Table 2 respectively. RNFs significantly outperform linear filters on both tasks. In fact, we find that CNN-RNF variants significantly outperform CNN-linear-filter on nearly every hyperparameter configuration in our experiments. On the Stanford Sentiment Treebank, CNN-RNF-LSTM outperforms CNN-linear-filter by 5.4% and 3.9% accuracies on the fine-grained and binary classification settings respectively. We observe similar performance boosts by adopting RNFs for CNNs on the QASent and WikiQA test sets. CNN-RNF-GRU improves upon CNN-linear-filter by 3.7% MRR score on QASent and CNN-RNF-LSTM performs better than CNN-linear-filter by 6.1% MAP score on WikiQA. In particular, CNN-RNF-LSTM achieves 53.4% and 90.0% accuracies on the fine-grained and binary sentiment classification tasks respectively, which match the state-of-the-art results on the Stanford Sentiment Treebank. CNN-RNF-LSTM also obtains competitive results on answer sentence selection datasets, despite the simple model architecture compared to state-of-the-art systems.

LSTM-maxpool	51.6	89.8
Best published results		
(Lei et al., 2017)	53.2	89.9

Table 1: Accuracy results on the Stanford Sentiment Treebank. The best results obtained from our implementations are in **bold**. The best published results are underlined.

Conventional RNN models clearly benefit from max pooling, especially on the task of answer sentence selection. Like RNF-based CNN models, max-pooled RNNs also consist of two essential layers. The recurrent layer learns a set of hidden states corresponding to different time steps, and the max pooling layer extracts the most salient information from the hidden states. However, a hidden state in RNNs encodes information about all the previous time steps, while RNFs focus on detecting local features from a window of words that can be more relevant to specific tasks. As a result, RNF-based CNN models perform consistently better than max-pooled RNN models.

CNN-RNF models are much faster to train than their corresponding RNN counterparts, despite they have the same numbers of parameters, as RNFs are applied to word sequences of shorter lengths and the computation is parallelizable. The training of CNN-RNF-LSTM models takes 10-20 mins on the Stanford Sentiment Treebank, which is 3-8x faster than the training of LSTM models, on an NVIDIA Tesla P100 GPU accelerator.

---

[2] Max pooling performed better than mean pooling in our preliminary experiments.

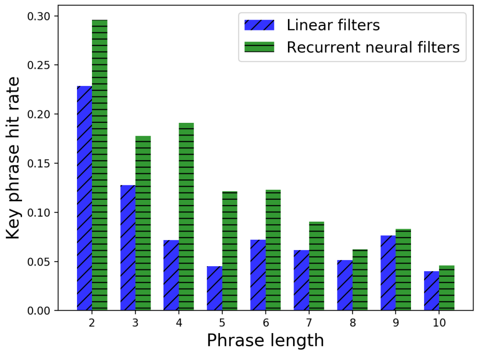

Figure 2: Key phrase hit rate results computed on SST dev set. The RNFs are implemented with LSTMs.

4 Analysis

We now investigate why RNFs are more effective than linear convolution filters on the binary sentiment classification task. We perform quantitative analysis on the development set of the Stanford Sentiment Treebank (SST), in which sentiment labels for some phrases are also available.

Local label consistency (LLC) ratio We first inspect whether longer phrases have a higher tendency to express the same sentiment as the entire sentence. We define the *local label consistency (LLC) ratio* as the ratio of m-grams that share the same sentiment labels as the original sentences. The LLC ratios with respect to different phrase lengths are shown in Figure 1. Longer phrases are more likely to convey the same sentiments as the original sentences. Therefore, the ability to model long phrases is crucial to convolution filters.

Key phrase hit rate We examine linear filters and RNFs on the ability to detect a key phrase in a sentence. Specifically, we define the key phrases for a sentence to be the set of phrases that are labeled with the same sentiment as the original sentence. The *key phrase hit rate* is then defined as the ratio of filter-detected m-grams that fall into the corresponding key phrase sets. The filter-detected m-gram of a sentence is the one whose convolution feature vector has the shortest Euclidean distance to the max-pooled vector. The hit rate results computed on SST dev set are presented in Figure 2. As shown, RNFs consistently perform better than linear filters on identifying key phrases across different phrase lengths, especially on phrases of moderate lengths (4-7). The results suggest that RNFs are superior to linear filters, as they can better model longer phrases whose labels are more consistent with the sentences.[4]

5 Related work

Linear convolution filters are dominated in CNN-based systems for both computer vision and natural language processing tasks. One exception is the work of Zoumpourlis et al. (2017), which proposes a convolution filter that is a function with quadratic forms through the Volterra kernels. However, this non-linear convolution filter is developed in the context of a computational model of the visual cortex, which is not suitable for NLP problems. In contrast, RNFs are specifically derived for NLP tasks, in which a different form of non-linearity, language compositionality, often plays a critical role.

Several works have employed neural network architectures that contain both CNN and RNN components to tackle NLP problems. Tan et al. (2016) present a deep neural network for answer sentence selection, in which a convolution layer is applied to the output of a BiLSTM layer for extracting sentence representations. Ma and Hovy (2016) propose to compose character representations of a word using a CNN, whose output is then fed into a BiLSTM for sequence tagging. Kalchbrenner and Blunsom (2013) introduce a neural architecture that uses a sentence model based on CNNs and a discourse model based on RNNs. Their system achieves state-of-the-art results on the task of dialogue act classification. Instead of treating an RNN and a CNN as isolated components, our work directly marries RNNs with the convolution operation, which illustrates a new direction in mixing RNNs with CNNs.

6 Conclusion and future work

We present RNFs, a new class of convolution filters based on recurrent neural networks. RNFs sequentially apply the same recurrent unit to words of a phrase, which naturally capture language compositionality and implicitly model long-term dependencies. Experiments on sentiment classification and answer sentence selection tasks demonstrate that RNFs give a significant boost in performance compared to linear convolution filters. RNF-based CNNs also outperform a variety of RNN-based models, as they focus on extracting local information that could be more relevant to particular problems. The quantitive analysis reveals that RNFs can handle long phrases much better than linear filters, which explains their superiority over the linear counterparts. In the future, we would like to investigate the effectiveness of RNFs on a wider range of NLP tasks, such as natural language inference and machine translation.

Abstract

Existing neural semantic parsers mainly utilize a sequence encoder, i.e., a sequential LSTM, to extract word order features while neglecting other valuable syntactic information such as dependency or constituent trees. In this paper, we first propose to use the *syntactic graph* to represent three types of syntactic information, i.e., word order, dependency and constituency features; then employ a graph-to-sequence model to encode the syntactic graph and decode a logical form. Experimental results on benchmark datasets show that our model is comparable to the state-of-the-art on Jobs640, ATIS, and Geo880. Experimental results on adversarial examples demonstrate the robustness of the model is also improved by encoding more syntactic information.

1 Introduction

The task of *semantic parsing* is to translate text to its formal meaning representations, such as logical forms or structured queries. Recent neural semantic parsers approach this problem by learning soft alignments between natural language and logical forms from (text, logic) pairs (Jia and Liang, 2016; Dong and Lapata, 2016; Krishnamurthy et al., 2017). All these parsers follow the conventional encoder-decoder architecture that first encodes the text into a distributional representation and then decodes it to a logical form. These parsers may differ in the choice of the decoders, such as sequence or tree decoders, but they utilize the same encoder which is essentially a sequential Long Short-Term Memory network (SeqLSTM). This encoder only extracts word order features while neglecting useful syntactic information, such as dependency parse and constituency parse.

However, the syntactic features capture important structural information of the natural language input, which complements the simple word sequence. For example, a dependency graph presents grammatical relations that hold among the words; and a constituent tree provides a phrase structure representation. Intuitively, by incorporating such additional information, the encoder could produce a more meaningful and robust sentence representation. The combination of these features (i.e., sequence + trees) forms a general graph structure (see Figure 1). This inspires us to apply a graph encoder to produce a representation of a graph-structured input. The graph encoder also has the advantages that it could simultaneously encode all types of syntactic contexts, and incorporate multiple types of syntactic structures in a unified way.

In this paper, we first introduce a structure, namely *syntactic graph*, to represent three types of syntactic information, i.e., word order, dependency and constituency features (see §2). We then employ a novel graph-to-sequence (Graph2Seq) model (Xu et al., 2018), which consists of a graph encoder and a sequence decoder, to learn the representation of the syntactic graph (see §3). Specifically, the graph encoder learns the representation of each node by aggregating information from its K-hop neighbors. Given the learned node embeddings, the graph encoder uses a pooling-based method to generate the graph embedding. On the decoder side, a Recurrent Neural Network (RNN) decoder takes the graph embedding as its initial hidden state to generate the logical form while employing an attention mechanism over the node embeddings. Experimental results show that our model achieves the competitive performance on Jobs640, ATIS, and Geo880 datasets.

Different from existing works, we also investigate the robustness of our model by evaluating the model on two types of adversarial examples (Belinkov and Bisk, 2017; Cheng et al., 2018).

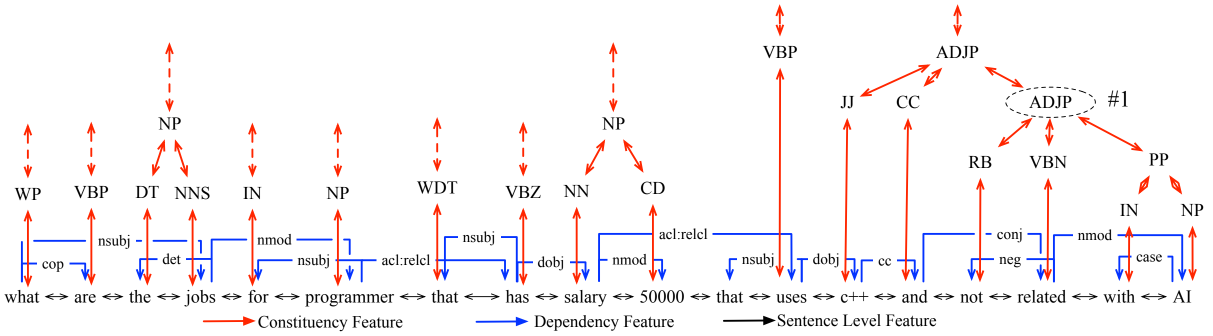

Figure 1: The syntactic graph for the Jobs640 question *what are the jobs for programmer that has salary 50000 that uses c++ and not related with AI*. Due to the space limitation, the constituent tree is partially shown here.

Experimental results show that the model coupling all syntactic features has the best robustness, achieving the best performance. Our code and data is available at `https://github.com/IBM/Text-to-LogicForm`.

2 Syntactic Graph

We represent three types of syntactic features, i.e., word order, dependency parse and constituency parse, as the syntactic graph (see Figure 1).

- **Word Order Features.** Previous neural semantic parsers mainly use these features by building a SeqLSTM that works on the word sequence. Our syntactic graph also incorporates this information by generating a node for each word and connecting them in the chain form. In order to capture the forward and backward contextual information, we link these nodes in two directions, that is, from left to right and from right to left.
- **Dependency Features.** A dependency parse describes the grammatical relations that hold among words. Reddy et al. (2016, 2017) have demonstrated that the dependency parse tree could be directly transformed to a logical form, which indicates that the dependency information (i.e., tree structure and dependency labels) is critical to the semantic parsing task. We incorporate this information into the syntactic graph by adding directed edges between the word nodes and assign them with dependency labels.
- **Constituency Features.** Similar to the dependency parse, the constituency parse represents the phrase structure, which is also important to the semantic parsing task. Take Figure 1 as an example: given the constituent tree that explicitly annotates "*not related with AI*" (node #1) is a proposition phrase, the model could learn a meaningful embedding for this phrase by encoding this structure into the model. Motivated by this observation, we add the non-terminal nodes of the constituent tree and the edges describing their parent-child relationships into the syntactic graph.

3 Graph-to-sequence Model for Semantic Parsing

After building the syntactic graph for the input text, we employ a novel graph-to-sequence model (Xu et al., 2018), which includes a graph encoder and a sequence decoder with attention mechanism, to map the syntactic graph to the logical form. Conceptually, the graph encoder generates node embeddings for each node by accumulating information from its K-hop neighbors, and then produces a graph embedding for the entire graph by abstracting all these node embeddings. Next, the sequence decoder takes the graph embedding as the initial hidden state, and calculates the attention over all node embeddings on the encoder side to generate logical forms. Note that this graph encoder does not explicitly encode the edge label information, therefore, for each labeled edge, we add a node whose text attribute is the edge's label.

Node Embedding. Given the syntactic graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, we take the embedding generation process for node $v \in \mathcal{V}$ as an example to explain the node embedding generation algorithm[1]:

(1) We first transform node v's text attribute to a feature vector, $\mathbf{a}_v$, by looking up the embedding matrix W_e;

(2) The neighbors of v are categorized into forward neighbors $\mathcal{N}_{\vdash}(v)$ and backward neighbors $\mathcal{N}_{\dashv}(v)$ according to the edge direction. In particular, $\mathcal{N}_{\vdash}(v)$ returns the nodes that v directs to and $\mathcal{N}_{\dashv}(v)$ returns the nodes that direct to v;

(3) We aggregate the **forward** representations of v's forward neighbors $\{\mathbf{h}_{u\vdash}^{k-1}, \forall u \in \mathcal{N}_{\vdash}(v)\}$ into

---

[1] Interested readers may refer to (Xu et al., 2018) for more implementation details.

a single vector, $\mathbf{h}^{k}_{\mathcal{N}_{\vdash}(v)}$, where $k\in\{1, ..., K\}$ is the iteration index. Specifically, this aggregator feeds each neighbor's vector to a fully-connected neural network and applies an element-wise max-pooling operation to capture different aspects of the neighbor set. Notice that, at iteration k, this aggregator only uses the representations generated at $k-1$. The initial forward representation of each node is its feature vector calculated in step (1);

(4) We concatenate v's current **forward** representation $\mathbf{h}^{k-1}_{v\vdash}$ with the newly generated neighborhood vector $\mathbf{h}^{k}_{\mathcal{N}_{\vdash}(v)}$. The resulted vector is fed into a fully connected layer with nonlinear activation function σ, which updates the **forward** representation of v, $\mathbf{h}^{k}_{v\vdash}$, to be used at the next iteration;

(5) We update the **backward** representation of v, $\mathbf{h}^{k}_{v\dashv}$ using the similar procedure as introduced in step (3) and (4) except that operating on the backward representations;

(6) We repeat steps (3)$\sim$(5) K times, and the concatenation of the final forward and backward representations is used as the final representation of v. Since the neighbor information from different hops may have different impacts on the node embedding, we learn a distinct aggregator at each iteration.

Graph Embedding. We feed the obtained node embeddings into a fully-connected neural network, and apply the element-wise *max*-pooling operation on all node embeddings. We did not find substantial performance improvement using *mean*-pooling.

Sequence Decoding. The decoder is an RNN which predicts the next token y_i given all the previous words $y_{<i} = y_1, ..., y_{i-1}$, the RNN hidden state s_i for time-step i and the context vector c_i that captures the attention of the encoder side. In particular, the context vector c_i depends on a set of node representations ($\mathbf{h}_1$,...,$\mathbf{h}_{\mathcal{V}}$) to which the encoder maps the input graph. The context vector c_i is dynamically computed using an attention mechanism over the node representations. The whole model is jointly trained to maximize the conditional log-probability of the correct description given a source graph. In the inference phase, we use the beam search algorithm to generate a description with beam size = 3.

4 Experiments

We evaluate our model on three datasets: Jobs640, a set of 640 queries to a database of job listings; Geo880, a set of 880 queries to a database of U.S. geography; and ATIS, a set of 5,410 queries to a flight booking system. We use the standard train/development/test split as previous works, and the logical form accuracy as our evaluation metric.

Method	Jobs	Geo	ATIS
Zettlemoyer and Collins (2007)	79.3	86.1	84.6

BASELINE	88.1	84.9	83.0

Table 1: Exact-match accuracy on Jobs640, Geo880 and ATIS.

The model is trained using the Adam optimizer (Kingma and Ba, 2014), with mini-batch size 30. Our hyper-parameters are cross-validated on the training set for Jobs640 and Geo880, and tuned on the development set for ATIS. The learning rate is set to 0.001. The decoder has 1 layer, and its hidden state size is 300. The dropout strategy (Srivastava et al., 2014) with the ratio of 0.5 is applied at the decoder layer to avoid overfitting. W_e is initialized using GloVe word vectors from Pennington et al. (2014) and the dimension of word embedding is 300. For the graph encoder, the hop size K is set to 10, the non-linearity function σ is implemented as ReLU (Glorot et al., 2011), the parameters of the aggregators are randomly initialized. We use the Stanford CoreNLP tool (Manning et al., 2014) to generate the dependency and constituent trees.

Results and Discussion. Table 1 summarizes the results of our model and existing semantic parsers on three datasets. Our model achieves competitive performance on Jobs640, ATIS and Geo880. Our work is the first to use both multiple trees and the word sequence for semantic parsing, and it outperforms the Seq2Seq model reported in Dong and Lapata (2016), which only uses limited syntactic information.

Comparison with Baseline. To better demonstrate that our work is an effective way to utilize both multiple trees and the word sequence for semantic parsing, we compare with an additional straightforward baseline method (referred as BASELINE in Table 1). To deal with the graph input, the BASELINE decomposes the graph embedding to two steps and applies different types of encoders sequentially: (1) a SeqLSTM to extract word order features, which results in word embeddings, W_{seq}; (2) two TreeLSTMs (Tai et al., 2015) to extract the dependency tree and constituency features while taking W_{seq} as initial word embeddings. The resulted word embeddings and nonterminal node embeddings (from TreeLSTMs) are then fed into a sequence decoder.

We can see that our model significantly outperforms the BASELINE. One possible reason is that our graph encoder jointly extracts these features in a unified model by propagating the dependency and constituency information to all nodes in the syntactic graph. However, BASELINE separately models these features using two distinct TreeLSTMs. As a result, the non-terminal tree nodes only retain only one type of syntactic information propagated from their descendants in the tree.

Ablation Study. In Table 1, we also report the results of three ablation variants of our model, i.e., without word order features/dependency features/constituency features. We find that Graph2Seq is superior to Seq2Seq (Dong and Lapata, 2016) which is expected since Graph2Seq exploits more syntactic information. Among these features, the word order feature have more impact on the performance than other two syntactic features. By incorporating either the dependency or the constituency features, the model could gain further performance improvement, which underlines the importance of utilizing more aspects of syntactic information. Finally, removing both syntactic features (w/ ONLY word order) performs slightly worse compared to the Seq2Seq baseline. This shows that using K=10 hops is good enough for memorizing the sentences in our benchmarks, although still weaker compared to a bidirectional LSTM encoder.

A natural question here is on which type of queries our model could benefit from incorporating these parse features. By analyzing the queries and our predicted logical forms, we find that the parse features mainly improve the prediction accuracy for the queries with complex logical forms. Table 2 gives some running examples of complicated queries in three datasets. We find that the model that exploits three syntactic information could correctly predict these logical forms while the model that only uses word order features may fail.

Complicated Query & Predicted Logical Forms
Jobs Q: *what are the jobs for programmer that has salary 50000 that uses c++ and not related with AI*
Pred: answer(J,(job(J),-((area(J,R),const(R,'ai'))), language(J,L),const(L,'c++'), title(J,P), const(P,'Programmer'),salary_greater_than(J, 50000,year)))).
Geo Q: *which is the density of the state that the largest river in the united states run through*
Pred: answer(A,(density(B,A),state(B), longest(C,(river(C),loc(C,D),const(D,id(usa)))), traverse(C,B))))
ATIS Q: *please find a flight round trip from los angeles to tacoma washington with a stopover in san francisco not exceeding the price of 300 dollars for june tenth 1993*
Pred: (lambda \$0 e (and (flight \$0) (round_trip \$0) (from \$0 *los angeles*) (to \$0 *tacoma washington*) (stop \$0 *san francisco*) (< (cost \$0) 300) (day_number \$0 *tenth*) (month \$0 *june*) (year \$0 1993)))

Table 2: Examples of complicated query and predicted logical forms.

Robustness Study. Different from previous works, we evaluate the robustness of our model by creating adversarial examples with the hope to investigate the impact of introducing more syntactic information on robustness. Specifically, we create two types of adversarial examples and conduct experiments on the ATIS dataset. Following Belinkov and Bisk (2017), we first experiment with the synthetic noise, **SWAP**, which swaps two letters (e.g. noise→nosie). It is common to see such noisy information when typing quickly. Given a text, we randomly perform swap on $m \in \{1, 2, 3, 4, 5\}$ words that **not** correspond to the operators or arguments in logical forms, ensuring the meaning of the text is not changed. We train Graph2Seq on the training data and first evaluate it on the original development data, Dev_{ori}. Then we use the same model but evaluate it on a variant of Dev_{ori}, whose queries contain m swapped words.

Figure 2 summarizes the results of our model on the first type of adversarial examples, i.e., the ATIS development set with the SWAP noise. From Figure 2, we can see that (1) the performance of our model on all combinations of features degrade significantly when increasing the number of swapped words; (2) the model that uses three syntactic features (our default model) always achieves the best performance, and the performance gap

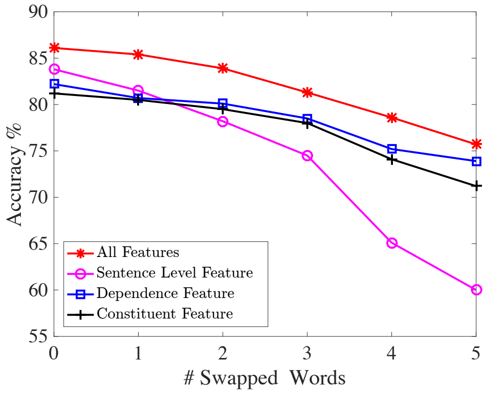

Figure 2: The logical form accuracy on the development set of ATIS with various swapped words number.

compared to others increases when rising the number of swapped words; (3) word order features are the most sensitive to the word sequence while the dependency and constituency features seem more robust to such noisy information; (4) thanks to the robustness of the dependency and constituency features, the default model performs significantly better than the one that only uses word order features on the noisy sentences. These findings demonstrate that incorporating more aspects of syntactic information could enhance the robustness of the model.

We also experiment with the paraphrase of the input text as the second type of adversarial examples. More specifically, we collect the paraphrase of a text by first translating it to the other language such as Chinese and then translating it back to English, using the Google Translate service. We use this method to collect a new variant of Dev$_{ori}$ whose queries are the paraphrases of the original ones. By manually reading these queries, we find 94% queries convey the same meaning as original ones. Similar to the first experiment, we still train the model on Dev$_{ori}$ and evaluate it on the newly created dataset.

Feature	Acc$_{ori}$	Acc$_{para}$	Diff.
Word Order	84.8	78.7	-6.1
Dep	83.5	80.1	-3.4
Cons	82.9	77.3	-5.6
Dep + Cons	84.0	80.7	-3.3
Word Order + Dep	85.2	82.3	-2.9
Word Order + Cons	84.9	79.9	-5.0
Word Order + Dep + Cons	**86.0**	**83.5**	**-2.5**

Table 3: Evaluation results on ATIS where Acc$_{ori}$ and Acc$_{para}$ denote the accuracy on the original and paraphrased development set of ATIS, respectively.

Table 3 shows the results of our model on the second type of adversarial examples, i.e., the paraphrased ATIS development set. We also report the result of our model on the original ATIS development set. We can see that (1) no matter which feature our model uses, the performance degrades at least 2.5% on the paraphrased dataset; (2) the model that only uses word order features achieves the worst robustness to the paraphrased queries while the dependency feature seems more robust than other two features. (3) simultaneously utilizing three syntactic features could greatly enhance the robustness of our model. These results again demonstrate that our model could benefit from incorporating more aspects of syntactic information.

5 Related Work

Existing works of generating text representation has evolved into two main streams. The first one is based on the word order, that is, either generating general purpose and domain independent embeddings of word sequences (Wu et al., 2018a; Arora et al., 2017), or building Bi-directional LSTMs over the text (Zhang et al., 2018). These methods neglect other syntactic information, which, however, has been proved to be useful in shallow semantic parsing, e.g., semantic role labeling (Punyakanok et al., 2008). To address this, recent works attempt to incorporate these syntactic information into the text representation. For example, Xu et al. (2016) builds separated neural networks for different types of syntactic annotation. Gormley et al. (2015); Wu et al. (2018b) decompose a graph to simpler sub-graphs and embed these subgraphs independently. Our approach, compared to the above methods, provided a unified solution to arbitrary combinations of syntactic graphs. In parallel to syntactic features, other works leverage additional information such as dialogue and paraphrasing for semantic parsing (Su and Yan, 2017; Gur et al., 2018).

6 Conclusions

Existing neural semantic parsers mainly leverage word order features while neglecting other valuable syntactic information. To address this, we propose to build a syntactic graph which represents three types of syntactic information, and further apply a novel graph-to-sequence model to map the syntactic graph to a logical form. Experimental results show that the robustness of our model is improved due to the incorporating more aspects of syntactic information, and our model outperforms previous semantic parsing systems.

Abstract

In models to generate program source code from natural language, representing this code in a tree structure has been a common approach. However, existing methods often fail to generate complex code correctly due to a lack of ability to memorize large and complex structures. We introduce RECODE, a method based on subtree retrieval that makes it possible to explicitly reference existing code examples within a neural code generation model. First, we retrieve sentences that are similar to input sentences using a dynamic-programming-based sentence similarity scoring method. Next, we extract n-grams of action sequences that build the associated abstract syntax tree. Finally, we increase the probability of actions that cause the retrieved n-gram action subtree to be in the predicted code. We show that our approach improves the performance on two code generation tasks by up to +2.6 BLEU.[1]

1 Introduction

Natural language to code generation, a subtask of semantic parsing, is the problem of converting natural language (NL) descriptions to code (Ling et al., 2016; Yin and Neubig, 2017; Rabinovich et al., 2017). This task is challenging because it has a well-defined structured output and the input structure and output structure are in different forms.

A number of neural network approaches have been proposed to solve this task. Sequential approaches (Ling et al., 2016; Jia and Liang, 2016; Locascio et al., 2016) convert the target code into a sequence of symbols and apply a sequence-to-sequence model, but this approach does not ensure that the output will be syntactically correct. Tree-based approaches (Yin and Neubig, 2017; Rabinovich et al., 2017) represent code as Abstract Syntax Trees (ASTs), which has proven effective in improving accuracy as it enforces the well-formedness of the output code. However, representing code as a tree is not a trivial task, as the number of nodes in the tree often greatly exceeds the length of the NL description. As a result, tree-based approaches are often incapable of generating correct code for phrases in the corresponding NL description that have low frequency in the training data.

In machine translation (MT) problems (Zhang et al., 2018; Gu et al., 2018; Amin Farajian et al., 2017; Li et al., 2018), hybrid methods combining retrieval of salient examples and neural models have proven successful in dealing with rare words. Following the intuition of these models, we hypothesize that our model can benefit from querying pairs of NL descriptions and AST structures from training data.

In this paper, we propose RECODE, and adaptation of Zhang et al. (2018)'s retrieval-based approach neural MT method to the code generation problem by expanding it to apply to generation of tree structures. Our main contribution is to introduce the use of retrieval methods in neural code generation models. We also propose a dynamic programming-based sentence-to-sentence alignment method that can be applied to similar sentences to perform word substitution and enable retrieval of imperfect matches. These contributions allow us to improve on previous state-of-the-art results.

2 Syntactic Code Generation

Given an NL description q, our purpose is to generate code (e.g. Python) represented as an AST a. In this work, we start with the syntactic code gen-

Brussels, Belgium, October 31 - November 4, 2018.

eration model by Yin and Neubig (2017), which uses sequences of actions to generate the AST before converting it to surface code. Formally, we want to find the best generated AST $\hat{a}$ given by:

$$\hat{a} = \arg\max_{a} p(a|q)$$

$$p(a|q) = \prod_{t=1}^{T} p(y_t|y_{<t}, q)$$

where y_t is the action taken at time step t and $y_{<t} = y_1 ... y_{t-1}$ and T is the number of total time steps of the whole action sequence resulting in AST a.

We have two types of actions to build an AST: APPLYRULE and GENTOKEN. APPLYRULE(r) expands the current node in the tree by applying production rule r from the abstract syntax grammar[2] to the current node. GENTOKEN(v) populates terminal nodes with the variable v which can be generated from vocabulary or by COPYing variable names or values from the NL description. The generation process follows a preorder traversal starting with the `root` node. Figure 1 shows an action tree for the example code: the nodes correspond to actions per time step in the construction of the AST.

Interested readers can reference Yin and Neubig (2017) for more detail of the neural model, which consists of a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) encoder-decoder with action embeddings, context vectors, parent feeding, and a copy mechanism using pointer networks.

3 RECODE: Retrieval-Based Neural Code Generation

We propose RECODE, a method for retrieval-based neural syntactic code generation, using retrieved action subtrees. Following Zhang et al. (2018)'s method for neural machine translation, these retrieved subtrees act as templates that bias the generation of output code. Our pipeline at test time is as follows:

- retrieve from the training set NL descriptions that are most similar with our input sentence (§3.1),
- extract **n-gram action subtrees** from these retrieved sentences' corresponding target ASTs (§3.2),
- alter the copying actions in these subtrees, by substituting words of the retrieved sentence with corresponding words in the input sentence (§3.3), and
- at every decoding step, increase the probability of actions that would lead to having these subtrees in the produced tree (§3.4).

3.1 Retrieval of Training Instances

For every retrieved NL description q_m from training set (or *retrieved sentence* for short), we compute its similarity with input q, using a sentence similarity formula (Gu et al., 2016; Zhang et al., 2018):

$$\text{sim}(q, q_m) = 1 - \frac{d(q, q_m)}{\max(|q|, |q_m|)}$$

where d is the edit distance. We retrieve only the top M sentences according to this metric where M is a hyperparameter. These scores will later be used to increase action probabilities accordingly.

3.2 Extracting N-gram Action Subtrees

In Zhang et al. (2018), they collect n-grams from the output side of the retrieved sentences and encourage the model to generate these n-grams. Word n-grams are obvious candidates when generating a sequence of words as output, as in NMT. However, in syntax-based code generation, the generation target is ASTs with no obvious linear structure. To resolve this problem, we instead use *retrieved pieces* of n-gram subtrees from the target code corresponding to the retrieved NL descriptions. Though we could select successive nodes in the AST as retrieved pieces, such as `[assign; expr*(targets); expr]` from Figure 1, we would miss important structural information from the rules that are used. Thus, we choose to exploit actions in the generation model rather than AST nodes themselves to be candidates for our retrieved pieces.

In the action tree (Figure 1), we considered only successive actions, such as subtrees where each node has one or no children, to avoid overly rigid structures or combinatorial explosion of the number of retrieved pieces the model has to consider. For example, such an action subtree would be given by `[assign → expr*(targets), expr(value) ; expr(value) → List; List → epsilon]`.

As the node in the action tree holds structural information about its children, we set the subtrees

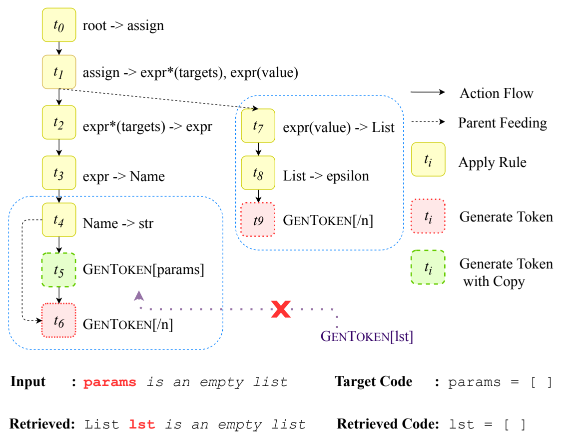

Figure 1: The action sequence used to generate AST for the target code given the input example. Dashed nodes represent terminals. Each node is labeled with time steps. APPLYRULE action is represented as rule in this figure. Blue dotted boxes denote 3-gram action subtrees. Italic words are unedited words. Red bold words are different object names.

to have a fixed depth, linear in the size of the tree. These can be considered "n-grams of actions", emphasizing the comparison with machine translation which uses n-grams of words. n is a hyperparameter to be tuned.

3.3 Word Substitution in Copy Actions

Using the retrieved subtree without modification is problematic if it contains at least one node corresponding to a COPY action because copied tokens from the retrieved sentence may be different from those in the input. Figure 1 shows an example when the input and retrieved sentence have four common words, but the object names are different. The extracted action n-gram would contain the rule that copies the second word ("lst") of the retrieved sentence while we want to copy the first word ("params") from the input.

By computing word-based edit distance between the input description and the retrieved sentence, we implement a one-to-one sentence alignment method that infers correspondences between uncommon words. For unaligned words, we alter all COPY rules in the extracted n-grams to copy tokens by their aligned counterpart, such as replace "params" with "lst", and delete the n-gram subtree, as it is not likely to be relevant in the predicted tree. Thus, in the example in Figure 1, the GENTOKEN(LST) action in t_5 will not be executed.

3.4 Retrieval-Guided Code Generation

N-gram subtrees from all retrieved sentences are assigned a score, based on the best similarity score of all instances where they appeared. We normalize the scores for each input sentence by subtracting the average over the training dataset.

At decoding time, incorporate these retrieval-derived scores into beam search: for a given time step, all actions that would result in one of the retrieved n-grams u to be in the prediction tree has its log probability $\log(p(y_t \mid y_1^{t-1}))$ increased by $\lambda * \text{score}(u)$ where λ is a hyperparameter, and $\text{score}(u)$ is the maximal $\text{sim}(q, q_m)$ from which u is extracted. The probability distribution is then renormalized.

Dataset	HS	Django
Train	533	16,000
Dev	66	1,000
Test	66	1,805
Avg. tokens in description	39.1	14.3
Avg. number of nodes of AST	136.6	17.2

Table 1: Dataset statistics as reported Yin and Neubig (2017)

4 Datasets and Evaluation Metrics

We evaluate RECODE with the Hearthstone (HS) (Ling et al., 2016) and Django (Oda et al., 2015) datasets, as preprocessed by Yin and Neubig (2017). HS consists of Python classes that implement Hearthstone card descriptions while Django contains pairs of Python source code and English pseudo-code from Django web framework. Table 1 summarizes dataset statistics.

For evaluation metrics, we use accuracy of exact match and the BLEU score following Yin and Neubig (2017).

5 Experiments

For the neural code generation model, we use the settings explained in Yin and Neubig (2017). For the retrieval method, we tuned hyperparameters and achieved best result when we set $n_{max} = 4$ and $\lambda = 3$ for both datasets[3]. For HS, we set $M = 3$ and $M = 10$ for Django.

We compare our model with Yin and Neubig (2017)'s model that we call YN17 for brevity, and a sequence-to-sequence (SEQ2SEQ) model that we implemented. SEQ2SEQ is an attention-enabled encoder-decoder model (Bahdanau et al., 2015). The encoder is a bidirectional LSTM and the decoder is an LSTM.

5.1 Results

Table 2 shows that RECODE outperforms the baselines in both BLEU and accuracy, providing ev-

---

[3] n-gram subtrees are collected up to n_{max}-gram

idence for the effectiveness of incorporating retrieval methods into tree-based approaches.

	HS		Django	
	Acc	**BLEU**	**Acc**	**BLEU**
SEQ2SEQ	0.0	55.0	13.9	67.3
YN17	16.2	75.8	71.6	84.5
ASN[†]	18.2	77.6	-	-
ASN + SUPATT[†]	*22.7*	*79.2*	-	-
RECODE	**19.6**	**78.4**	**72.8**	**84.7**

Table 2: Results compared to baselines. YN17 result is taken from Yin and Neubig (2017). ASN result is taken from Rabinovich et al. (2017)

.

We ran statistical significance tests for RECODE and YN17, using bootstrap resampling with N = 10,000. For the BLEU scores of both datasets, $p < 0.001$. For the exact match accuracy, $p < 0.001$ for Django dataset, but for Hearthstone, $p > 0.3$, showing that the retrieval-based model is on par with YN17. It is worth noting, though, that HS consists of long and complex code, and that generating exact matches is very difficult, making exact match accuracy a less reliable metric.

We also compare RECODE with Rabinovich et al. (2017)'s Abstract Syntax Networks with supervision (ASN+SUPATT) which is the state-of-the-art system for HS. RECODE exceeds ASN without extra supervision though ASN+SUPATT has a slightly better result. However, ASN+SUPATT is trained with supervised attention extracted through heuristic exact word matches while our attention is unsupervised.

5.2 Discussion and Analysis

From our observation and as mentioned in Rabinovich et al. (2017), HS contains classes with similar structure, so the code generation task could be simply matching the tree structure and filling the terminal tokens with correct variables and values. However, when the code consists of complex logic, partial implementation errors occur, leading to low exact match accuracy (Yin and Neubig, 2017). Analyzing our result, we find this intuition to be true not only for HS but also for Django.

Example 1	
"if offset is lesser than integer 0, sign is set to '-', otherwise sign is '+' "	**Input**
`sign = offset < 0 or '-'`	**YN17**
`sign = '-' if offset < 0 else '+'`	**RECODE**
`sign = '-' if offset < 0 else '+'`	**Gold**
Example 2	
"evaluate the function timesince with d, now and reversed set to boolean true as arguments, return the result."	**Input**
`return reversed(d, reversed=now)`	**YN17**
`return timesince(d, now, reversed=now)`	**RECODE**
`return timesince(d, now, reversed=True)`	**Gold**
Example 3	
"return an instance of SafeText , created with an argument s converted into a string ."	**Input**
`return SafeText(bool(s))`	**YN17**
`return SafeText(s)`	**RECODE**
`return SafeString(str(s))`	**Gold**
