Abstract

We present a Few-Shot Relation Classification Dataset (FewRel), consisting of $70,000$ sentences on 100 relations derived from Wikipedia and annotated by crowdworkers. The relation of each sentence is first recognized by distant supervision methods, and then filtered by crowdworkers. We adapt the most recent state-of-the-art few-shot learning methods for relation classification and conduct thorough evaluation of these methods. Empirical results show that even the most competitive few-shot learning models struggle on this task, especially as compared with humans. We also show that a range of different reasoning skills are needed to solve our task. These results indicate that few-shot relation classification remains an open problem and still requires further research. Our detailed analysis points multiple directions for future research. All details and resources about the dataset and baselines are released on `http://zhuhao.me/fewrel`.

Supporting Set	
(A) capital_of	(1) *London* is the capital of *the U.K.* (2) *Washington* is the capital of *the U.S.A.*
(B) member_of	(1) *Newton* served as the president of *the Royal Society*. (2) *Leibniz* was a member of *the Prussian Academy of Sciences*.
(C) birth_name	(1) *Samuel Langhorne Clemens*, better known by his pen name *Mark Twain*, was an American writer. (2) *Alexei Maximovich Peshkov*, primarily known as *Maxim Gorky*, was a Russian and Soviet writer.
Test Instance	
(A) or (B) or (C)	*Euler* was elected a foreign member of *the Royal Swedish Academy of Sciences*.

Table 1: An example for a 3 way 2 shot scenario. Different colors indicate different entities, blue for head entity, and red for tail entity.

1 Introduction

Relation classification (RC) is an important task in NLP, aiming to determine the correct relation between two entities in a given sentence. Many works have been proposed for this task, including kernel methods (Zelenko et al., 2002; Mooney and Bunescu, 2006), embedding methods (Gormley et al., 2015), and neural methods (Zeng et al., 2014). The performance of these conventional models heavily depends on time-consuming and labor-intensive annotated data, which make themselves hard to generalize well. Adopting distant supervision is a primary approach to alleviate this problem for RC (Mintz et al.; Riedel et al.; Hoffmann et al., 2011; Surdeanu et al., 2012; Zeng et al., 2015; Lin et al., 2016), which heuristically aligns knowledge bases (KBs) and text to automatically annotate adequate amounts of training instances. We evaluate the model proposed by Lin et al. (2016), which is followed by the recent state-of-the-art methods (Zeng et al., 2017; Ji et al., 2017; Huang and Wang, 2017; Wu et al., 2017; Liu et al., 2017; Feng et al., 2018; Zeng et al., 2018), on the benchmark dataset NYT-10 (Riedel et al.). Though it achieves promising results on common relations, the performance of a relation drops dramatically when its number of training instances decrease. About 58% of the relations in NYT-10 are long-tail with fewer than 100 instances. Furthermore, distant supervision suffers from the wrong labeling problem, which makes it harder to classify long-tail relations. Hence, it is necessary to study training RC models with insufficient training instances.

We formulate RC as a few-shot learning task in

---

Brussels, Belgium, October 31 - November 4, 2018.

this paper, which requires models capable of handling classification task with a handful of training instances, as shown in Table 1. Many efforts have devoted to few-shot learning. The early works (Caruana, 1995; Bengio, 2012; Donahue et al., 2014) apply transfer learning methods to fine-tune pre-trained models from the common classes containing adequate instances to the uncommon classes with only few instances. Then metric learning methods (Koch et al., 2015; Vinyals et al., 2016; Snell et al., 2017) have been proposed to learn the distance distributions among classes. Similar classes are adjacent in the distance space. The metric methods also take advantage of non-parametric estimation to make models efficient and general. Recently, the idea of meta-learning is proposed, which encourages the models to learn fast-learning abilities from previous experience and rapidly generalize to new concepts. Many meta-learning models (Ravi and Larochelle, 2017; Santoro et al., 2016; Finn et al., 2017; Munkhdalai and Yu, 2017) achieve the state-of-the-art results on several few-shot benchmarks.

Though meta-learning methods develop fast, most of these works evaluate on two popular datasets, Omniglot (Lake et al., 2015) and mini-ImageNet (Vinyals et al., 2016). Both the datasets concentrate on image classification. Many works in NLP mainly focus on the zero-shot/semi-supervised scenario (Xie et al., 2016; Ma et al., 2016; Carlson et al., 2009), which incorporate extra information to classify objects never appearing in the training sets. However, the few-shot scenario needs models to classify objects with few instances without any extra information. Recently, Yu et al. (2018) propose a multi-metric method for few-shot text classification. However, there lack systematic researches about adopting few-shot learning for NLP tasks. We propose FewRel: a new large-scale supervised **Few**-shot **Rel**ation Classification dataset. To address the wrong labeling problem in most distantly supervised RC datasets, we apply crowd-sourcing to manually remove the noise.[i]

Besides constructing the dataset, we systematically implement the most recent state-of-the-art few-shot learning methods and adapt them for RC. We conduct a detailed evaluation for all these models on our dataset. Though the state-of-the-art few-shot learning methods have much lower results than humans on our challenging dataset, they significantly outperform the vanilla RC models, indicating that incorporating few-shot learning is promising and needs further research. In summary, our contribution is three-fold:

(1) We formulate RC as a few-shot learning task, and propose a new large supervised few-shot RC dataset.

(2) We systematically adapt the most recent state-of-the-art few-shot learning methods for RC, which may further benefit other NLP tasks.

(3) We conduct a comprehensive evaluation of few-shot learning methods on our dataset, which indicates some promising research directions for RC.

2 FewRel Dataset

In this section, we describe the process of creating FewRel in detail. The whole procedure can be divided into two steps: (1) We create a large candidate set of sentences aligned to relations via distant supervision. (2) We ask human annotators to filter out the wrong labeled sentences for each relation to finally achieve a clean RC dataset.

2.1 Distant Supervision

For the first step, We use Wikipedia as the corpus[ii] and Wikidata as the KB. Wikidata is a large-scale KB where many entities are already linked to Wikipedia articles. The articles in Wikipedia also contain anchors linking to each other. Thus it is convenient to align sentences in Wikipedia articles to KB facts in Wikidata. We also employ entity linking technique to extract more unanchored entities in articles. We first adopt named entity recognition via spaCy[iii] to find possible entity mentions, then match each mention with the name of an entity in KBs, and link the mention to the entity if successfully matched.

For each sentence s in Wikipedia articles containing head and tail entities e_1 and e_2, if there exists a Wikidata statement (e_1, e_2, r) meaning e_1 and e_2 have the relation r, we denote the (s, e_1, e_2, r) tuple as an instance and add it to the candidate set. Empirically, many instances of a given relation contain the same entity pair. For

---

[i] Many previous works, such as (Roth et al., 2013; Luo et al., 2017; Xin et al., 2018) have worked on automatically removing noise from distantly supervision. Instead, we use crowd-sourcing methods to achieve a high accuracy.

[ii] We use whole Wikipedia articles as corpus, not just the first sentence.

[iii] `https://spacy.io/`

such relation, classifiers may prefer memorizing the entity pairs in the training instances rather than grasping the sentence semantics. Therefore, in the candidate set of each relation, we only keep 1 instance for each unique entity pair. Finally, we remove relations with fewer than 1000 instances, and randomly keep 1000 instances for the rest of the relations. As a result, we get a candidate set of 122 relations and 122, 000 instances.

2.2 Human Annotation

Next, we invite some well-educated annotators to filter the raw data on a platform similar to Amazon MTurk developed by ourselves. The platform presents each annotator with one instance each time, by showing the sentence, two entities in the sentence, and the corresponding relation labeled by distant supervision. The platform also provides the name of the entities and relation in Wikidata accompanied with the detailed description of that relation. Then the annotator is asked to judge whether the relation could be deduced only from the sentence semantics. We also ask the annotator to mark an instance as negative if the sentence is not complete, or the mention is falsely linked with the entity.

Relations are randomly assigned to annotators from the candidate set, and each annotator will consecutively annotate 20 instances of the same relation before switching to next relation. To ensure the labeling quality, each instance is labeled by at least two annotators. If the two annotators have disagreements on this instance, it will be assigned to a third annotator. As a result, each instance has at least two same annotations, which will be the final decision. After the annotation, we remove relations with fewer than 700 positive instances. For the remaining 105 relations, we calculate the inter-annotator agreement for each relation using the free-marginal multirater kappa (Randolph, 2005), and keep the top 100 relations.

2.3 Dataset Statistics

The final FewRel dataset consists of 100 relations, each has 700 instances. A full list of relations, including their names and descriptions, is provided in Appendix A.2. The average number of tokens in each sentence is 24.99, and there are 124, 577 unique tokens in total. Following recent meta-learning tasks (Vinyals et al., 2016), which use separate sets of classes for training and testing, we use 64, 16, and 20 relations for training, validation, and testing respectively. Table 2 provides a comparison of our FewRel dataset to two other popular few-shot classification datasets, Omniglot and mini-ImageNet. Table 3 provides a comparison of FewRel to the previous RC datasets, including SemEval-2010 Task 8 dataset (Hendrickx et al., 2009), ACE 2003-2004 dataset (Strassel et al., 2008), TACRED dataset (Zhang et al., 2017), and NYT-10 dataset (Riedel et al., 2010). While some RC datasets contain instances with no relations (negative), we ignore such instances for comparison.

Dataset	#cls.	#inst./cls	#insts.
Omniglot	1, 623	20	32, 460
mini-ImageNet	100	600	60, 000
FewRel	100	700	70, 000

Table 2: Comparison of FewRel with Omniglot and mini-ImageNet.

Dataset	#cls.	#insts.
SemEval-2010 Task 8	9	6, 674
ACE 2003-2004	24	16, 771
TACRED	42	21, 784
NYT-10	57	143, 391
FewRel	100	70, 000

Table 3: Comparison of FewRel with existing RC datasets. Note that negative (no relation) instances in some datasets are ignored.

3 Experiments

We conduct comprehensive evaluations of vanilla RC models with simple strategies such as finetune or kNN on our new dataset. We also evaluate the recent state-of-the-art few-shot learning methods.

3.1 Task Formulation

In few-shot relation classification, we intend to obtain a function $F : (\mathcal{R}, \mathcal{S}, x) \mapsto y$. Here $\mathcal{R} = \{r_1, \ldots, r_m\}$ defines the relations that the instances are classified into. $\mathcal{S}$ is a support set

$$\begin{aligned} \mathcal{S} = \{&(x_1^1, r_1), (x_1^2, r_1), \ldots, (x_1^{n_1}, r_1), \\ &\ldots, \\ &(x_m^1, r_m), (x_m^2, r_m), \ldots, (x_m^{n_m}, r_m)\} \end{aligned} \tag{1}$$

including n_i instances for each relation $r_i \in \mathcal{R}$. For relation classification, a data instance x_i^j is a sentence accompanied with a pair of entities. The query data x is an unlabeled instance to classify, and $y \in \mathcal{R}$ is the prediction of x given by F.

Model	5 Way 1 Shot	5 Way 5 Shot	10 Way 1 Shot	10 Way 5 Shot
Finetune (CNN)	44.21 ± 0.44	68.66 ± 0.41	27.30 ± 0.28	55.04 ± 0.31
Finetune (PCNN)	45.64 ± 0.62	57.86 ± 0.61	29.65 ± 0.40	37.43 ± 0.42
kNN (CNN)	54.67 ± 0.44	68.77 ± 0.41	41.24 ± 0.31	55.87 ± 0.31
kNN (PCNN)	60.28 ± 0.43	72.41 ± 0.39	46.15 ± 0.31	59.11 ± 0.30
Meta Network (CNN)	64.46 ± 0.54	80.57 ± 0.48	53.96 ± 0.56	69.23 ± 0.52
GNN (CNN)	66.23 ± 0.75	81.28 ± 0.62	46.27 ± 0.80	64.02 ± 0.77
SNAIL (CNN)	67.29 ± 0.26	79.40 ± 0.22	53.28 ± 0.27	68.33 ± 0.25
Prototypical Network (CNN)	69.20 ± 0.20	84.79 ± 0.16	56.44 ± 0.22	75.55 ± 0.19
Human performance	92.22 ± 5.53	-	85.88 ± 7.40	-

Table 4: Accuracies (%) of all models on FewRel under four different settings.

In recent research on few-shot learning, N way K shot setting is widely adopted. We follow this setting for the few-shot relation classification problem. To be exact, for N way K shot learning

$$N = m = |\mathcal{R}|, K = n_1 = \ldots = n_m \qquad (2)$$

3.2 Experiment Settings

We consider four types of few-shot tasks in our experiments: 5 way 1 shot, 5 way 5 shot, 10 way 1 shot, 10 way 5 shot. Under this setting, we evaluate different few-shot training strategies and state-of-the-art few-shot learning methods built upon two widely used instance encoders, CNN (Zeng et al., 2014) and PCNN (Zeng et al., 2015).

For both CNN and PCNN, the sentence is first represented to the input vectors by transforming each word into concatenation of word embeddings and position embeddings. In CNN, the input vectors pass a convolution layer, a max-pooling layer, and a non-linear activation layer to get the final output sentence embedding. PCNN is a variant of CNN, which replaces the max-pooling operation with a piecewise max-pooling operation.

To evaluate this two vanilla models in few-shot RC task, we first consider two training strategies, namely Finetune and kNN. For the Finetune baseline, it learns to classify all relations on the training set with CNN/PCNN, and tune parameters on the support set. We only tune the parameters of output layer, and keep other parameters unchanged. For the kNN baseline, it also jointly classifies all relations during training, while at the test time, it uses the neural networks to embed all the instances and then adopts k-nearest-neighbor (kNN) to classify the test instances.

By adapting them to relation classification, we also evaluate four recently proposed few-shot learning methods, including Meta Network (Munkhdalai and Yu, 2017), GNN (Satorras and Estrach, 2018), SNAIL (Mishra et al., 2018), and Prototypical Network (Snell et al., 2017). We describe briefly about these baselines in Sec. 3.3. If you are familiar with these methods, you can safely skip that subsection. The hyperparameters of each model are selected via grid search against the validation set.

Human performance is also evaluated under 5 way 1 shot setting and 10 way 1 shot setting. A human labeler is given $5/10$ instances from different relations and one extra test instance. Human labelers are asked to decide which relation the test instance belongs to. Note that these labelers are not provided the name of the relations and any extra information. Since 5 way 5 shot and 10 way 5 shot settings are easier, we only evaluate performance of 5 way 1 shot and 10 way 1 shot.

3.3 Baselines of Few-shot Learning Models

Meta Network Meta Network (Munkhdalai and Yu, 2017) is a meta learning algorithm utilizing a high level *meta learner* on top of the traditional classification model, or *base learner*, to supervise the training process. The weights of base learner are divided into two groups, fast weights and slow weights. Fast weights are generated by the meta learner, whereas slow weights are simply updated by minimizing classification loss. The fast weights are expected to help the model generalize to new tasks with very few training instances.

GNN GNN (Satorras and Estrach, 2018) tackles the few-shot learning problem by considering each supporting instance or query instance as a node in the graph. For those instances in the support sets, label information is also embedded into the corresponding node representations. Graph neural networks are then employed to propagate the information between nodes. A query instance is expected to receive information from support sets in order to make the classification. In our adaption, while the instances are encoded by CNNs, labels are represented by one-hot encoding.

SNAIL SNAIL (Mishra et al., 2018) is a meta learning model that utilizes temporal convolutional neural networks and attention modules for fast learning from past experience. SNAIL arranges all the supporting instance-label pairs into a sequence and appends the query instance behind them. Such an order agrees with the temporal order of learning process where we learn information by reading supporting instances before making predictions for unlabeled instances. Temporal convolution (a 1-D convolution) is then performed along the sequence to aggregate information across different time steps and a causally masked attention model is used over the sequence to aggregate useful information from former instances to latter ones.

Prototypical Networks Prototypical Network (Snell et al., 2017) is a few-shot classification model based on the assumption that for each class there exists a prototype. The model tries to find the prototypes for classes from supporting instances, and compares the distance between the query instance and each prototype under certain distance metric. Prototypical network learns a embedding function u to embed each class's instances, and computes each prototype by averaging over all the output embeddings of instances in the support set S that are labeled with the corresponding class.

4 Result Analysis and Future Work

We report evaluation results in Table 4. From our preliminary experiments, PCNN with few-shot learning methods perform 3-10 percentages worse than CNN, therefore only CNN results are shown in our experimental results. From the results, we observe that integrating few-shot learning methods into CNN significantly outperforms CNN/PCNN with finetune or kNN, which means adapting few-shot learning methods for RC is promising. However, there are still huge gaps between their performance and humans', which means our dataset is a challenging testbed for both relation classification and few-shot learning.

Sentence	Reasoning
Chris Bohjalian graduated from *Amherst College* Summa Cum Laude, where he was a member of the Phi Beta Kappa Society.	Simple Pattern
James Alty obtained a 1st class honours (Physics) at *Liverpool University*.	Commonsense Reasoning
He was a professor at *Reed College*, where he taught *Steve Jobs*, and replaced Lloyd J. Reynolds as the head of the calligraphy program.	Logical Reasoning
He and *Cesare Borgia* were thought to be close friends since childhood, going on to accompany one another during their studies at the *University of Pisa*.	Co-reference Reasoning

Table 5: Examples from relation "educated_at". Different colors indicate different entities, blue for head entity, and red for tail entity.

In this paper, we propose a new large and high quality dataset, FewRel, for few-shot relation classification task. This dataset provides a new point of view for RC, and also a new benchmark for few-shot learning. Through the evaluation of different few-shot learning methods, we find even the best model performs much worse than humans, which suggests there is still large space for few-shot learning methods to improve.

The most challenging characteristic of our dataset is the diversity in expressing the same relation. We provide some examples from FewRel in Table 5, showing different reasoning modes needed for classifying some instances. Future researches may consider incorporating commonsense knowledge or improved causal modules.

A strong baseline for question relevancy ranking

Ana V. González-Garduño and Isabelle Augenstein and Anders Søgaard
Dpt. of Computer Science
University of Copenhagen
`{ana|augenstein|soegaard}@di.ku.dk`

Abstract

The best systems at the SemEval-16 and SemEval-17 community question answering shared tasks – a task that amounts to *question relevancy ranking* – involve complex pipelines and manual feature engineering. Despite this, many of these still fail at beating the IR baseline, i.e., the rankings provided by Google's search engine. We present a strong baseline for question relevancy ranking by training a simple multi-task feed forward network on a bag of 14 distance measures for the input question pair. This baseline model, which is fast to train and uses only language-independent features, outperforms the best shared task systems on the task of retrieving relevant previously asked questions.

1 Introduction

Community question-answer fora are great resources, collecting answers to frequently and less-frequently asked questions on specific topics, but these are often not moderated and contain many irrelevant answers. Community Question Answering (CQA), cast as a question relevancy ranking problem, was the topic of two shared tasks at SemEval 2016-17. This is a non-trivial retrieval task, typically evaluated using mean average precision (MAP). We present a strong baseline for this task, on par with or surpassing state-of-the-art systems.

The English subtasks of the SemEval CQA (Nakov et al., 2015, 2017) consist of Question-Question Similarity, Question-Comment Similarity, and Question-External Comment Similarity. In this study, we focus on the core subtask of Question-Question similarity, defined as follows: Given a question, rank other relevant questions by their relevancy to that question. This proved to be a difficult task in both SemEval-16 and SemEval-17 as it is the one with the least amount of data available. The baseline was the ranking retrieved by performing a Google search, which proved to be a strong baseline beating a large portion of the systems submitted.

Contribution Our baseline is a simple multi-task feed-forward neural network taking distance measures between pairs of questions as input. We use a question-answer dataset as auxiliary task; but we also experiment with datasets for pairwise classification tasks such as natural language inference and fake news detection. This simple, easy-to-train model is on par or better than state-of-the-art systems for question relevancy ranking. We also show that this simple model outperforms a more complex model based on recurrent neural networks.

2 Our Model

We present a simple baseline model for question relevancy ranking.[1] It is a deep feed-forward network with a hidden layer that is shared with an auxiliary task model. The input to the network is extremely simple and consists of five distance measures of the input question-question pair. §2.1 discusses these distance measures, and how they relate. §2.2 introduces the multi-task learning architecture that we propose.

2.1 Features

We use four similarity metrics and three sentence representations (averaged word embeddings, binary unigram vectors, and trigram vectors). The **cosine distance** between the sentence representations of query x and query y is

$$\frac{\sum_i \mathbf{x}_i \mathbf{y}_i}{\sqrt{\sum_i \mathbf{x}^2} + \sqrt{\sum_i \mathbf{y}^2}}$$

---

[1] Code available at http://anavaleriagonzalez/FAQ_rank.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4810–4815
Brussels, Belgium, October 31 - November 4, 2018. ©2018 Association for Computational Linguistics

The **Manhattan distance** is

$$\sum_i |\mathbf{x}_i - \mathbf{y}_i|$$

The **Bhattacharya distance** is

$$-\ln(\sum_i \sqrt{\mathbf{x}_i \mathbf{y}_i})$$

and is a measure of divergence, and the **Euclidean distance** is

$$\sqrt{\sum_i (\mathbf{x}_i - \mathbf{y}_i)^2}$$

Note that the squared Euclidean distance is proportional to cosine distance and Manhattan distance. The Bhattacharya and Jaccard metrics, on the other hand, are sensitive to the number of types in the input (the ℓ_1 norm of the vector encodings). So, for example, *only* the cosine, Euclidean, and Manhattan distances will be the same for

$$\mathbf{x} = \langle 1,1,0,0,1,0,1,1,0,1 \rangle, \mathbf{y} = \langle 0,0,1,0,1,0,0,0,1,1 \rangle$$

and

$$\mathbf{x} = \langle 0,0,0,0,0,1,0,0,1,1 \rangle, \mathbf{y} = \langle 1,1,1,1,0,0,0,0,0,1 \rangle$$

The **Jaccard index** is the only metric that can only be applied to two of our representations, unigrams and n-grams: It is defined over m-dimensional *binary* (indicator) vectors and therefore not applicable to averaged embeddings. It is defined as

$$\frac{\mathbf{x} \cdot \mathbf{y}}{m}$$

We represent each query pair by these 14 numerical features.

2.2 MTL Architecture

Our architecture is a simple feed-forward, multi-task learning (MTL) architecture. Our architecture is presented in Figure 1 and is a Multi-Layer Perceptron (MLP) that takes a pair of sequences as input. The sequences can be sampled from the main task or the auxiliary task. The MLP has one shared hidden layer, a task-specific hidden layer and, finally, a task-specific classification layer for each output. The hyper-parameters, after doing grid search, optimizing performance on the validation data, are given in Figure 2.

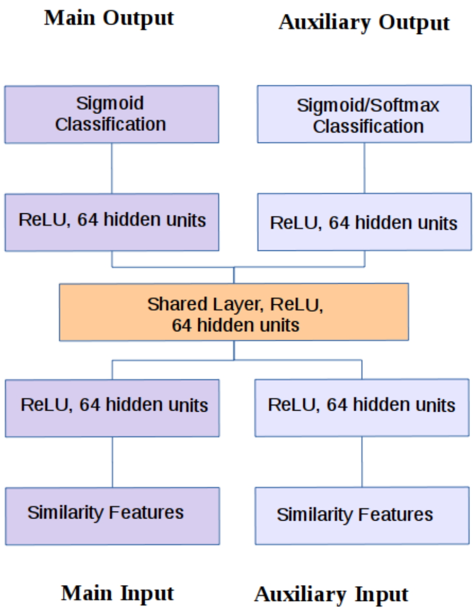

Figure 1: The architecture of the multi task learning MLP

2.3 LSTM baseline

We compare our MLP ranker to a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) model. It takes two sequences inputs: sequence 1 and sequence 2, and a stack of three bidirectional LSTM layers, which encode sequence 1 and sequence 2, respectively. The outputs are then concatenated, to enable representing the differences between the two sequences. Instead of relying only on this presentation (Bowman et al., 2015; Augenstein et al., 2016), we also concatenate our distance features and feed everything into our MLP ranker described above.

3 Datasets

For our experiments, we use data from SemEval shared tasks, but we also take advantage of potential synergies with other existing datasets for classification of sentence pairs. Below we present the datasets used for our main and auxiliary tasks. We provide some summary statistics for each dataset in Table 3.

SemEval 2016 and 2017 As our main dataset we use the queries from SemEval's subtask B which consists of an original query and 10 possibly related queries. As an auxiliary task, we use the data from subtask A, which is a question-related comment ranking task.

Table 1: The results show that learning pairwise classification tasks simultaneously with the main task leads to improvements over the baselines and the best SemEval systems. We show results for three auxiliary tasks, Question-Comment relevancy prediction, Fake News detection and Natural Language Inference. The asterisks for the MTL results represent the significance of the improvements over the STL systems with ** representing a p-value of < 0.01 and * representing a p-value between 0.01 and 0.05

Natural Language Inference Natural Language Inference (NLI), consists in predicting ENTAILMENT, CONTRADICTION or NEUTRAL, given a hypothesis and a premise. We use the MNLI dataset as opposed to the SNLI data (Bowman et al., 2015; Nangia et al., 2017), since it contains different genres. Our model is not built to be a strong NLI system; we use the similarity between premise and hypothesis as a weak signal to improve the generalization on our main task.

Fake News Challenge The Fake News Challenge[2] (FNC) was introduced to combat misleading and false information online. This task has been used before in a multi-task setting as a way to utilize general information about pairwise relations (Augenstein et al., 2018). Formally, the FNC task consists in, given a headline and the body of text which can be from the same news article or not, classify the stance of the body of text relative to what is claimed in the headline. There are four labels:

- AGREES: The body of the article is in agreement with the headline
- DISAGREES: The body of the article is in disagreement with the headline
- DISCUSSES: The body of the article does not take a position
- UNRELATED: the body of the article discusses a different topic

We include fake news detection as a weak auxiliary signal that can lead to better generalization of our question-question ranking model.

3.1 Evaluation

We evaluate our performance on the main task of question relevancy ranking using the official

---

Dataset	Train	Dev	Test
SemEval 16	2000	500	700
SemEval 17	-	-	880
FNC	49k	-	-
MNLI	433k	-	-

Figure 3: Size of datasets used for the experiments. Here we present the full size of FNC and MultiNLI training sets, however for our MTL experiments we used a random sample of the same size of the train, test and dev sets of the SemEval data as auxiliary data. The SemEval 17 shared task uses the same train and dev set as SemEval 16

SemEval-2017 Task 3 evaluation scripts (Nakov et al., 2017). The scripts provide a variety of metrics; however, in accordance with the shared task, we report Mean Average Precision (MAP) (the official metric for the SemEval 2016 and 2017 shared tasks); Mean Reciprocal Rank (MRR), which has being thoroughly used for IR and QA; Average Recall; and, finally, the accuracy of predicting relevant documents.

4 Results

The results from our experiments are shown in Table 1. We present the official metric from the SemEval task, as well as other common metrics. For the SemEval-16 data, our multitask MLP architecture with a question-answer auxiliary task performed best on all metrics, except accuracy, where the multi-task MLP using all auxiliary tasks performed best. We outperform the winning systems of both the SemEval 2016 and 2017 campaigns. In addition, our improvements from single-task to multi-task are significant ($p < 0.01$). We also outperform the official IR baseline used in the SemEval 2016 and 2017 shared tasks. We discuss the STL-LSTM-SIM results in §5. Furthermore, in Table 2, we show the performance of our models when training on feature combinations, while in Table 3, we present an ablation test where we remove one feature at a time.

Learning curve In Figure 4, we also present our learning curves for the development set when incrementally increasing the training set size. We observe that when using an auxiliary task, the learning is more stable across training set size.

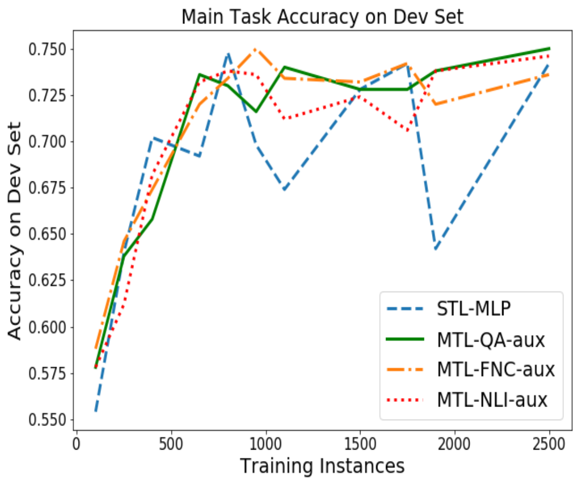

Figure 4: Learning curves for single- and multi-task learning. All MTL models outperform the STL model with very few training samples, and learning curves are more stable for MTL models than for STL.

	STL		MTL

Table 2: Performance on development set of SemEval-16 when training *only* on certain feature combinations. MTL uses QA as auxiliary data.

5 Discussion

For the SemEval shared tasks on CQA, several authors used complex recurrent and convolutional neural network architectures (Severyn and Moschitti, 2015; Barrón-Cedeno et al., 2016). For example, Barrón-Cedeno et al. used a convolutional neural network in combination with feature vectors representing lexical, syntactic, and semantic similarity as well as tree kernels. Their performance was slightly lower than the best system (SemEval-Best for 2016 in Table 1). The best system used lexical and semantic similarity measures in combination with a ranking model based on support vector machines (SVMs) (Filice et al., 2016; Franco-Salvador et al., 2016). Both systems are harder to implement and train than the model we propose here. For SemEval-17, Franco-Salvador et al. (2016), the winning team used

FEATURE REMOVED		MAP	ACC
COSINE	unigram	69.25	**74.99**
	trigram	69.93	76.28
	embedding	69.11	76.40
MANHATTAN	unigram	70.33	76.71
	trigram	69.29	76.28
	embedding	66.90	75.28
BHATTACHARYA	unigram	70.83	75.85
	trigram	71.14	77.50
	embedding	71.72	77.28
EUCLIDEAN	unigram	71.43	76.57
	trigram	**65.55**	76.14
	embedding	70.60	75.57
JACCARD	unigram	67.41	75.70
	trigram	69.27	75.98

Table 3: We perform an ablation test, where we remove one feature at a time and report performance on development data of our single-task baseline. We observe that our baseline suffers most from removing the Euclidean distance over trigrams and the cosine similarity over unigrams. Note also that the Jaccard index over unigrams seems to carry a strong signal, albeit a very simple feature.

distributed representations of words, knowledge graphs and frames from FrameNet (Baker et al., 1998) as some of their features, and used SVMs for ranking.

For a more direct comparison, we also train a more expressive model than the simple MTL-based model we propose. This architecture is based on bi-directional LSTMs (Hochreiter and Schmidhuber, 1997). For this model, we input sequences of embedded words (using pre-trained word embeddings) from each query into independent BiLSTM blocks and output a vector representation for each query. We then concatenate the vector representations with the similarity features from our MTL model and feed it into a dense layer and a classification layer. This way we can evaluate the usefulness of the flexible, expressive LSTM network directly (as our MTL model becomes an ablation instance of the full, more complex architecture). We use the same dropout regularization and SGD values as for the MLP. Tuning all parameters on the development data, we do not manage to outperform our proposed model, however. See lines MTL-LSTM-SIM in Table 1 for results.

6 Conclusion

We show that simple feature engineering, combined with an auxiliary task and a simple feedforward neural architecture is appropriate for a small dataset and manages to beat the baseline and the best performing systems for the Semeval task of question relevancy ranking. We observe that introducing pairwise classification tasks leads to significant improvements in performance and a more stable model. Overall, our simple model introduces a new strong baseline which is particularly useful when there is a lack of labeled data.

Abstract

Research on link prediction in knowledge graphs has mainly focused on static multi-relational data. In this work we consider temporal knowledge graphs where relations between entities may only hold for a time interval or a specific point in time. In line with previous work on static knowledge graphs, we propose to address this problem by learning latent entity and relation type representations. To incorporate temporal information, we utilize recurrent neural networks to learn time-aware representations of relation types which can be used in conjunction with existing latent factorization methods. The proposed approach is shown to be robust to common challenges in real-world KGs: the sparsity and heterogeneity of temporal expressions. Experiments show the benefits of our approach on four temporal KGs. The data sets are available under a permissive BSD-3 license[1].

1 Introduction

Knowledge graphs (KGs) are used to organize, manage, and retrieve structured information. The incompleteness of most real-world KGs has stimulated research on predicting missing relations between entities. A KG is of the form $\mathcal{G} = (\mathcal{E}, \mathcal{R})$, where $\mathcal{E}$ is a set of entities and, $\mathcal{R}$ is a set of relation types or predicates. One can represent $\mathcal{G}$ as a set of triples of the form (subject, predicate, object), denoted as $(\mathtt{s}, \mathtt{p}, \mathtt{o})$. The link prediction problem seeks the most probable completion of a triple $(\mathtt{s}, \mathtt{p}, ?)$ or $(?, \mathtt{p}, \mathtt{o})$ (Nickel et al., 2016). We focus on temporal KGs where some triples are augmented with time information and the link prediction problem asks for the most probable completion given time information. More formally, a temporal KG $\mathcal{G} = (\mathcal{E}, \mathcal{R}, \mathcal{T})$ is a KG where facts can also have the form (subject, predicate, object, timestamp) or (subject, predicate, object, time predicate, timestamp), in addition to $(\mathtt{s}, \mathtt{p}, \mathtt{o})$ triples. For instance, facts such as (Barack Obama, born, US, 1961) or (Barack Obama, president, US, occursSince, 2009-01) express temporal information about the facts associated with Barack Obama. While the former expresses that a relation type occurred at a specific point in time, the latter expresses an (open) time interval using the time predicate "occursSince." The latter example also illustrates a common challenge posed by the heterogeneity of time expressions due to variations in language and serialization standards.

Most approaches to link prediction are characterized by a scoring function that operates on the entity and relation type embeddings of a triple (Bordes et al., 2013; Yang et al., 2014; Guu et al., 2015). Learning representations that carry temporal information is challenging due to the sparsity and irregularities of time expressions. It is possible, however, to turn time expressions into sequences of tokens expressing said temporal information. Moreover, character-level architectures for language modeling (Zhang et al., 2015; Kim et al., 2016) operate on characters as atomic units to derive word embeddings. Inspired by these models, we propose a method to incorporate time information into standard embedding approaches for link prediction. We learn time-aware representations by training a recursive neural network with sequences of tokens representing the time predicate and the digits of the timestamp, if they exist. The last hidden state of the recurrent network is combined with standard scoring functions from the KG completion literature.

2 Related Work

Reasoning with temporal information in knowledge bases has a long history and has resulted in numerous temporal logics (van Benthem, 1995). Several recent approaches extend statistical relational learning frameworks with temporal reasoning capabilities (Chekol et al., 2017; Chekol and Stuckenschmidt, 2018; Dylla et al., 2013).

There is also prior work on incorporating temporal information in knowledge graph completion methods. Jiang et al. (2016) capture the temporal ordering that exists between some relation types as well as additional common-sense constraints to generate more accurate link predictions. Esteban et al. (2016) introduce a prediction model for link prediction that assumes that changes to a KG are introduced by incoming events. These events are modeled as a separate event graph and used to predict the existence of links in the future. Trivedi et al. (2017) model the occurrence of a fact as a point process whose intensity function is influenced by the score assigned to the fact by an embedding function. Leblay and Chekol (2018) develop scoring functions that incorporate time representations into a TransE-type scoring function. Prior work has also incorporated numerical but non-temporal entity information for knowledge base completion (Garcia-Duran and Niepert, 2017).

Contrary to all previous approaches, we encode sequences of temporal tokens with an RNN. This facilitates the encoding of relation types with temporal tokens such as “since,” ”until,” and the digits of timestamps. Moreover, the RNN encoding provides an inductive bias for parameter sharing among similar timestamps (e.g., those occurring in the same century). Finally, our method can be combined with all existing scoring functions.

3 Time-Aware Representations

Embedding approaches for KG completion learn a scoring function f that operates on the embeddings of the subject $\mathbf{e}_s$, the object $\mathbf{e}_o$, and the predicate $\mathbf{e}_p$ of the triples. The value of this scoring function on a triple (s, p, o), $f(s,p,o)$, is learned to be proportional to the likelihood of the triples being true. Popular examples of scoring functions are

- TRANSE (Bordes et al., 2013)

$$f(s,p,o) = ||\mathbf{e}_s + \mathbf{e}_p - \mathbf{e}_o||_2. \quad (1)$$

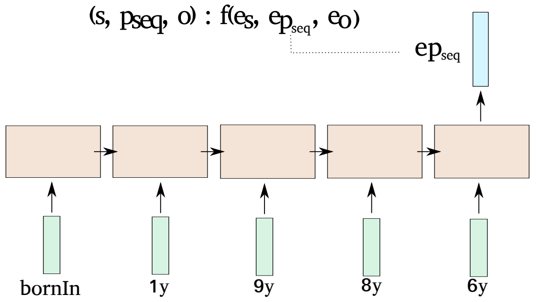

Figure 1: Learning time-aware representations.

- DISTMULT (Yang et al., 2014):

$$f(s,p,o) = (\mathbf{e}_s \circ \mathbf{e}_o)\mathbf{e}_p^T, \quad (2)$$

where $\mathbf{e}_s, \mathbf{e}_o \in \mathbb{R}^d$ are the embeddings of the *subject* and *object* entities, $\mathbf{e}_p \in \mathbb{R}^d$ is the embedding of the relation type *predicate*, and $\circ$ is the element-wise product. These scoring functions do not take temporal information into account.

Given a temporal KG where some triples are augmented with temporal information, we can decompose a given (possibly incomplete) timestamp into a sequence consisting of some of the following *temporal tokens*

$$\overbrace{0 \cdot 1 \cdot 2 \cdot 3 \cdot 4 \cdot 5 \cdot 6 \cdot 7 \cdot 8 \cdot 9}^{year}$$

$$\overbrace{01 \cdot 02 \cdot 03 \cdot 04 \cdot 05 \cdot 06 \cdot 07 \cdot 08 \cdot 09 \cdot 10 \cdot 11 \cdot 12}^{month}$$

$$\overbrace{0 \cdot 1 \cdot 2 \cdot 3 \cdot 4 \cdot 5 \cdot 6 \cdot 7 \cdot 8 \cdot 9}^{day}$$

Hence, temporal tokens have a vocabulary size of 32. Moreover, for each triple we can extract a sequence of *predicate tokens* that always consists of the relation type token and, if available, a temporal modifier token such as “since” or “until.” We refer to the concatenation of the predicate token sequence and (if available) the sequence of temporal tokens as the predicate sequence p_{seq}. Now, a temporal KG can be represented as a collection of triples of the form (s, p_{seq}, o), wherein the predicate sequence may include temporal information. Table 1 lists some examples of such facts from a temporal KG and their corresponding predicate sequence. We use the suffix y, m and d to indicate whether the digit corresponds to year, month or day information. It is these sequences of tokens that are used as input to a recurrent neural network.

3.1 LSTMs for Time-Encoding Sequences

A long short-term memory (LSTM) is a neural network architecture particularly suited for modeling sequential data. The equations defining an

Fact	Predicate Sequence
(Barack Obama, country, US)	[country]
(Barack Obama, born, US, 1961)	[born, $1y$, $9y$, $6y$, $1y$]
(Barack Obama, president, US, since, 2009-01)	[president, since, $2y$, $0y$, $0y$, $9y$, $01m$]

Table 1: Facts and their corresponding predicate sequence.

LSTM are

$$\begin{aligned}\mathbf{i} &= \sigma_g(\mathbf{h}_{n-1}\mathbf{U}_i + \mathbf{x}_n\mathbf{W}_i)\\ \mathbf{f} &= \sigma_g(\mathbf{h}_{n-1}\mathbf{U}_f + \mathbf{x}_n\mathbf{W}_f)\\ \mathbf{o} &= \sigma_g(\mathbf{h}_{n-1}\mathbf{U}_o + \mathbf{x}_n\mathbf{W}_o)\\ \mathbf{g} &= \sigma_c(\mathbf{h}_{n-1}\mathbf{U}_g + \mathbf{x}_n\mathbf{W}_g)\\ \mathbf{c}_n &= \mathbf{f}\circ\mathbf{c}_{n-1} + \mathbf{i}\circ\mathbf{g}\\ \mathbf{h}_n &= \mathbf{o}\circ\sigma_h(\mathbf{c}_n)\end{aligned} \tag{3}$$

where $\mathbf{i}$, $\mathbf{f}$, $\mathbf{o}$ and $\mathbf{g}$ are the input, forget, output and input modulation gates, respectively. $\mathbf{c}$ and $\mathbf{h}$ are the cell and hidden state, respectively. All vectors are in $\mathbb{R}^h$. $\mathbf{x}_n \in \mathbb{R}^d$ is the representation of the n-th element of a sequence. In this paper we set $h = d$. σ_g, σ_c and σ_h are activation functions.

Each token of the input sequence p_{seq} is first mapped to its corresponding d-dimensional embedding via a linear layer and the resulting sequence of embeddings used as input to the LSTM. Each predicate sequence of length N is represented by the last hidden state of the LSTM, that is, $\boxed{\mathbf{e}_{p_{seq}} = \mathbf{h}_N}$. The predicate sequence representation, which carries time information, can now be used in conjunction with *subject* and *object* embeddings in standard scoring functions. For instance, temporal-aware versions of TRANSE and DISTMULT, which we refer to as TA-TRANSE and TA-DISTMULT, have the following scoring function for triples (s, p_{seq}, o):

$$\text{TA-TRANSE: } f(s, p_{seq}, o) = ||\mathbf{e}_s + \mathbf{e}_{p_{seq}} - \mathbf{e}_o||_2$$
$$\text{TA-DISTMULT: } f(s, p_{seq}, o) = (\mathbf{e}_s \circ \mathbf{e}_o)\mathbf{e}^T_{p_{seq}}.$$

All parameters of the scoring functions are learned jointly with the parameters of the LSTMs using stochastic gradient descent.

The advantages of character level models to encode time information for link prediction are: (1) the usage of digits and modifiers such as “since” as atomic tokens facilitates the transfer of information across similar timestamps, leading to higher efficiency (e.g. small vocabulary size); (2) at test time, one can obtain a representation for a timestamp even though it is not part of the training set; (3) the model can use triples with and without temporal information as training data. Figure 1 illustrates the generic working of our approach.

4 Experiments

We conducted experiments on four different KG completion data sets where a subset of the facts are augmented with time information.

4.1 Datasets

Integrated Crisis Early Warning System (ICEWS) is a repository that contains political events with a specific timestamp. These political events relate entities (e.g. countries, presidents...) to a number of other entities via logical predicates (e.g. ’Make a visit’ or ’Express intent to meet or negotiate’). Additional information can be found at `http://www.icews.com/`. The repository is organized in dumps that contain the events that occurred each year from 1995 to 2015. We created two temporal KGs out of this repository, i) a short-range version that contains all events in 2014, and ii) a long-range version that contains all events occurring between 2005-2015. We refer to these two data sets as ICEWS 2014 and ICEWS 2005-15, respectively. Due to the large number of entities we selected a subset of the most frequently occurring entities in the graph and all facts where both the *subject* and *object* are part of this subset of entities. We split the facts into training, validation and test in a proportion of 80%/10%/10%, respectively. The protocol for the creation of these data sets is identical to the onw followed in previous work (Bordes et al., 2013). To create YAGO15K, we used FREEBASE15K (Bordes et al., 2013) (FB15K) as a blueprint. We aligned entities from FB15K to YAGO (Hoffart et al., 2013) with SAMEAS relations contained in a YAGO dump[2], and kept all facts involving those entities. Finally, we augment this collection of facts with time information from the “yagoDateFacts”[3] dump. Contrary to the

Table 4: Results (filtered setting) of the temporal knowledge graph completion experiments for the data sets ICEWS 2014 and ICEWS 2005-15. The best results are written bold.

ICEWS data sets, YAGO15k does contain temporal modifiers; namely, 'occursSince' and 'occursUntil'. Contrary to previous work (Leblay and Chekol, 2018), all facts maintain time information in the same level of granularity as one can find in the original dumps these data sets come from.

We also experimented with the temporal facts from the Wikidata data set[4] extracted in (Leblay and Chekol, 2018). Only information regarding the year is available for these facts, since the authors discarded information of finer granularity. All facts are framed in a time interval (i.e. they contain the temporal modifiers 'occursSince' and 'occursUntil'). Facts annotated with a single point-in-time are associated with that time-point as start and end time. Due to the large number of entities of this data set, which hinders the computation of standard KG completion metrics, we selected a subset of the most frequent entities and kept all facts where both the *subject* and *object* are part of this subset of entities. This set of filtered facts was split into training, validation and test in the same proportion as before.

Table 2 lists some statistics of the temporal KGs. All four data sets, with their corresponding training, validation, and test splits are available at `https://github.com/nle-ml/mmkb`.

4.2 General Set-up

We evaluate various methods by their ability to answer completion queries where i) all the arguments of a fact are known except the *subject* entity, and ii) all the arguments of a fact are known except the *object* entity. For the former we replace the subject by each of the KBs entities $\mathcal{E}$ in turn, sort the triples based on the scores returned by the different methods, and computed the rank of the correct entity. We repeated the same process for the second completion task and average the results.

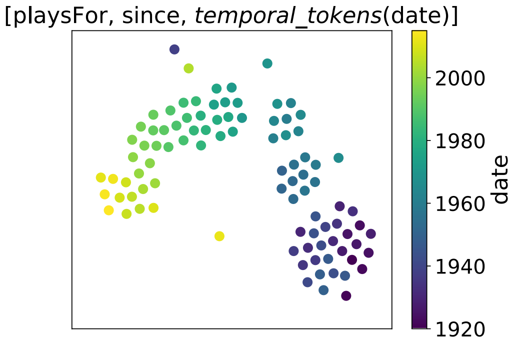

Figure 2: T-SNE visualization of the embeddings learned for the predicate sequence p_{seq} = [playsFor, occursSince, *date*], where *date* corresponds to the date token sequence.

This is standard procedure in the KG completion literature. We also report the filtered setting as described in (Bordes et al., 2013). The mean of all computed ranks is the Mean Rank (lower is better) and the fraction of correct entities ranked in the top n is called hits@n (higher is better). We also compute the Mean Reciprocal Rank (higher is better) which is less susceptible to outliers.

Recent work (Leblay and Chekol, 2018) evaluates different approaches for performing link prediction in temporal KGs. The approach that learns independent representations for each timestamp and use these representations as translation vectors, similarly to (Bordes et al., 2013), leads to the best results. This approach is called Vector-based TTransE, though for the shake of simplicity in the paper we refer to it as TTransE. We compare our approaches TA-TransE and TA-distMult against TTransE, and the standard embedding methods TransE and distMult. For all approaches, we used ADAM (Kingma and Ba, 2014) for parameter learning in a mini-batch setting with a learning rate of 0.001, the categorical cross-entropy (Kadlec et al., 2017) as loss function and the number of epochs was set to 500. We validated every 20 epochs and stopped learning whenever the MRR values on the validation set decreased. The batch size was set to 512 and the number of negative samples to 500 for all experiments. The embedding size is d=100. We apply dropout (Srivastava et al., 2014) for all embeddings. We validated the dropout from the values $\{0, 0.4\}$ for all experiments. For TA-TransE and TA-distMult, the activation gate σ_g is the sigmoid function; σ_c and σ_h were chosen to be linear activation functions.

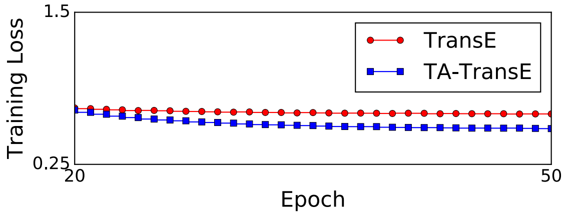

Figure 3: Training loss in YAGO15k. TA-TransE's ability to learn from time information leads to a lower loss.

4.3 Results

Table 3 and 4 list the results for the KG completion tasks. TA-TransE and TA-distMult systematically improve TransE and distMult in MRR, hits@10 and hits@1 in almost all cases. Mean rank is a metric that is very susceptible to outliers and hence these improvements are not consistent. TTransE learns independent representations for each timestamp contained in the training set. At test time, timestamps unseen during training are represented by null vectors. This explains that TTransE is only competitive in YAGO15k, wherein the number of distinct timestamps is very small (see #Distinct TS in Table 2) and thus enough training examples exist to learn robust timestamp embeddings. TTransE's performance is similar to that of TA-TransE, our time-aware version of TransE, in Wikidata. Similarly, TTransE can learn robust timestamp representations because of the small number of distinct timestamps of this data set.

Figure 3 shows a comparison of the training loss of TransE and TA-TransE for YAGO15k. Under the same set-up, TA-TransE's ability to learn from time information leads to a training loss lower than that of TransE.

Figure 2 shows a t-SNE (Maaten and Hinton, 2008) visualization of the embeddings learned for the predicate sequence p_{seq} = [playsFor, occursSince, *date*], where *date* corresponds to the date token sequence. This illustrates that the learned relation type embeddings carry temporal information.

5 Conclusions

We propose a digit-level LSTM to learn representations for time-augmented KG facts that can be used in conjunction with existing scoring functions for link prediction. Experiments in four temporal knowledge graphs show the effectiveness of the approach.

Similar but not the Same: Word Sense Disambiguation Improves Event Detection via Neural Representation Matching

Abstract

Event detection (ED) and word sense disambiguation (WSD) are two similar tasks in that they both involve identifying the classes (i.e. event types or word senses) of some word in a given sentence. It is thus possible to extract the knowledge hidden in the data for WSD, and utilize it to improve the performance on ED. In this work, we propose a method to transfer the knowledge learned on WSD to ED by matching the neural representations learned for the two tasks. Our experiments on two widely used datasets for ED demonstrate the effectiveness of the proposed method.

1 Introduction

An important aspect of natural language processing involves understanding events mentioned in text. Towards this end, event detection (ED) is the task of locating event triggers (usually verbs or nouns) within a given text, and classifying them among a given set of event types. This task remains challenging due to the inherent ambiguity and flexibility of natural languages. The current state-of-the-art methods for ED have involved applying deep learning (DL) models to automatically extract feature representations of the text, and then treating the task as a classification problem (Chen et al., 2015; Nguyen and Grishman, 2015b).

The major intuition in this paper is that the task of ED is closely related to the task of word sense disambiguation (WSD) whose datasets can help to improve the performance of the DL models for ED. This is due to the goal of WSD to determine the sense of a word within a particular context, given a set of possible senses that the word can take on. Our intuition is based on the two following aspects:

(i) Similar Context Modeling: Given a word in a context/sentence, both ED and WSD models need to select/predict a correct label in a list of candidate labels for the word. For WSD, the candidate labels are the possible senses (e.g, sense ids in WordNet) that the word of interest can have, while for ED, they are the set of predetermined event types (e.g, the event subtypes in the ACE 2005 dataset[1]). Consider the word "*fired*" in the following sentence as an example:

The boss ***fired*** *his secretary today.*

For WSD, there are 12 possible senses for the verb "*fire*" in WordNet in which the correct label for the word "*fired*" in this case is the sense id "*fire%2:41:00::*" (i.e, "*terminate the employment of*"). The ED task in the ACE 2005 dataset, on the other hand, involves 33 possible event subtypes with "*End-Position*" as the correct event subtype/label for the word "*fired*" in our example.

In order to make such label predictions, both ED and WSD need to model the word itself and its context (i.e, the words "*fired*", "*boss*", and "*secretary*" in the example). This similar modeling allows the same DL model to be adopted for both ED and WSD, facilitating the use of WSD data to improve the feature representations for ED via parameter/representation tying.

(ii) Close Semantic Consideration: As there are some overlaps between the semantic differentiation in WSD and ED, the knowledge/information from WSD about a particular word in a context can help to make a better prediction for that word in ED. For instance, in the example above, the knowledge from WSD that the word "*fired*" is referring to a termination of employment would clearly help ED to identify "*End-Position*" as the correct event type (rather than the incorrect event type "*Attack*") for "*fired*" in this case.

How can we exploit this intuition to improve the performance of the DL models for ED with WSD

---

Brussels, Belgium, October 31 - November 4, 2018.

data? In this work, we propose a novel method based on representation matching to transfer the knowledge learned from the WSD data to the DL models for ED. In particular, two separate deep learning models are employed to model the context for WSD and ED. The two models share the network architecture, but involve different parameters that are specific to the tasks. We then transfer the knowledge from the WSD network to the ED network by ensuring that the feature representations learned by the two networks on the same contexts are similar to each other.

We demonstrate the effectiveness of the proposed method on two widely used datasets for ED. To the best of our knowledge, this is the first work to study the transfer learning/multi-task learning methods for WSD and ED with DL.

2 Model

We consider the typical setting where we have two separate datasets $D^{wsd} = \{W_i^{wsd}, p_i^{wsd}, y_i^{wsd}\}$ for WSD and $D^{ed} = \{W_i^{ed}, p_i^{ed}, y_i^{ed}\}$ for ED. Here, W_i^{ed} is the i-the sentence of D^{ed}, p_i^{ed} is the index of the word of interest for event type prediction in W_i^{ed}, and y_i^{ed} is the corresponding event type label. The same conventions apply for $W_i^{wsd}, p_i^{wsd}, y_i^{wsd}$. Also, let Y^{wsd} and Y^{ed} be the label sets for WSD and ED respectively (i.e, $y_i^{wsd} \in Y^{wsd}$ and $y_i^{ed} \in Y^{ed}$). Our goal is to transfer the knowledge learned from the D^{wsd} dataset to improve the performance of the ED models trained on the D^{ed} dataset (multi-task learning).

In the following, we will first describe the deep learning architectures to transform the sentences W in the datasets D^{wsd} and D^{ed} into representation vectors. We only focus on the deep learning architectures proposed for ED in the literature to achieve compatible comparisons for ED. The proposed multi-task learning method for ED with the WSD dataset will follow.

2.1 Computing the Feature Representations

Consider a sentence W in the datasets D^{wsd} or D^{ed} that is represented as a sequence of tokens $W = [w_0, w_1, \ldots, w_t]$. Let p be the index of the word of interest in this sentence. The context for w_p in W is constructed by taking the word itself, the n preceding words, and the n following words (padding or truncating when necessary). The tokens in the context are re-indexed to form an instance $V = [v_0, v_1, \ldots, v_n, \ldots, v_{2n-1}, v_{2n}]$, where v_n corresponds to w_p in W.

Encoding

The first step to prepare the instance V for the deep learning models is to map each token v_j in V into two real-valued vectors, which are then concatenated to form a vector representation x_j for v_j (Nguyen and Grishman, 2015b; Chen et al., 2015):

1. The word embedding of v_j obtained by looking up the token v_j in the pre-trained word embedding table (Mikolov et al., 2013a).

2. The position embedding vector for v_j: obtained by looking up the relative distance $j - n$ of v_j with respect to the token of interest v_n in a position embedding table (randomly initialized) (Chen et al., 2015; Nguyen and Grishman, 2015a).

It is important to note that, different from the prior works (Nguyen and Grishman, 2015b; Liu et al., 2017), we do not include the entity type label of each token into its representation. This is a more realistic setting for our work as the golden entity mentions do not always exist in practice, especially for the datasets in WSD.

Once each token v_j is converted into the representation vector x_j, the instance V becomes a sequence of vectors $X = [x_0, x_1, \ldots, x_n, \ldots, x_{2n-1}, x_{2n}]$ that would be fed into the one of the following deep learning models to learn a feature representation R for V.

Typical Deep Learning Models for ED

1. *CNN*: This is the convolutional neural networks in(Nguyen and Grishman, 2015b; Chen et al., 2015). It features convolution operations that are performed over the k consecutive vectors (k-grams) in X and followed by a max-pooling layer to generate the representation vector R for V. Multiple window values k are used to enhance the coverage of the model over the hidden k-grams in the context.

2. *NCNN* (Nguyen and Grishman, 2016d): This model is similar to *CNN*. The only difference is instead of running the convolution over the k consecutive vectors, *NCNN* convolutes over the k arbitrarily non-consecutive k vectors in V. This helps *NCNN* to explicitly model the non-consecutive words in the context to improve ED.

3. *BiRNN*: This is the bidirectional recurrent neural network (RNN) for event extraction in (Nguyen et al., 2016a). The model is

composed of two recurrent neural networks (RNN), where one runs forward and the other runs backward through the input sequence V. The hidden vectors produced by the two networks are then concatenated at each position in the context. The vector at the position of n for the word of interest is used as the representation vector R for V. Due to the property of RNN, R encodes the information over the whole input V with a greater focus on v_n.

4. *CNN+BiRNN*: In this model (Feng et al., 2016), X is passed through both a *CNN* and a *BiRNN* whose results are concatenated to produce the hidden representation R for ED. The expectation is to take advantage of the modeling abilities from both the *CNN* and *BiRNN* architectures for ED.

In practice, the representation vector R (obtained from one of the deep learning models above) is also concatenated with the word embeddings of the tokens surrounding the token of interest w_n to improve its expressiveness (Chen et al., 2015; Nguyen and Grishman, 2016d). We would use this extended version when we refer to R in the following.

In the final step, the representation vector R is fed into a feed-forward neural network followed by a softmax layer to perform predictions for ED and WSD.

For convenience, we denote the whole process that a DL model M is used to compute the representation vector R for the input sentence W with the token index p of interest as: $R = M(W, p)$.

2.2 Multi-task Learning Models

The previous section has described the deep learning methods that can be employed to train the models for ED and WSD separately. This section presents our proposed method to transfer the knowledge from the WSD dataset to improve the performance for ED.

A typical method for transfer learning/multi-task learning in NLP is to alternate the training process for the parameter-shared models of the related tasks (possibly with different datasets) (Guo et al., 2016; Li et al., 2015; Liu et al., 2016). For instance, in (Guo et al., 2016), the authors use the same deep learning model to learn the feature representations for the text inputs of two related tasks. This is then followed by task-specific output layers to perform the corresponding tasks. Note that the two tasks in (Guo et al., 2016) are provided with two different datasets of different text inputs, thereby being similar to the setting we consider in this work. In order to learn the parameters for this model, in each iteration, (Guo et al., 2016) select one of the tasks with some probabilities, sample a mini-batch of examples in the dataset of the chosen task, and update the model parameters using the objective function specific to the chosen task. Consequently, the model parameters for feature representation learning are updated at every iteration while only the model parameters in the output layer for the chosen task are updated at the current iteration.

It has been demonstrated in (Guo et al., 2016) that the alternating method (called *ALT*) is more effective than pre-training the network on a related task and fine-tuning it on the expected task. We thereby consider *ALT* as the baseline for multi-task learning in our work. However, we argue that this baseline is not effective enough to transfer the knowledge from the WSD dataset to ED in our case. This stems from its employment of a single DL model to induce the representations for the text inputs in both tasks. In our case of WSD and ED, although there are some overlap between the semantic differentiation of the two tasks, the labels in the WSD datasets (i.e, the sense ids) tend to be more fine-grained and exhaustive than those in ED. For instance, for the word "*fire*", there might be 12 WSD labels for it in WordNet while the number of possible event types for "*fire*" in the ACE 2005 dataset is only 2 (i.e, "*End-Position*" and "*Attack*"). Eventually, if a single DL model is used to compute the representations for the text inputs in both WSD and ED, the model would suffer from a confusion to distinguish such subtlety in the semantic differentiation.

In order to overcome this issue, we propose to employ two versions M^{wsd} and M^{ed} of the same DL model (with different model parameters) to compute the feature representations for WSD and ED respectively. We then transfer the knowledge from M^{wsd} to M^{ed} by encouraging the representations generated by the two versions M^{wsd} and M^{ed} on the same text inputs to be similar. Formally, let (W^t, p^t, y^t) be an example in the D^{wsd} or D^{ed} dataset ($t \in \{wsd, ed\}$). Also, let R^{wsd} and R^{ed} be the representations for (W^t, p^t) induced by M^{wsd} and M^{ed} respectively:

$$R^{wsd} = M^{wsd}(W^t, p^t), R^{ed} = M^{ed}(W^t, p^t)$$

Such representation vectors are then followed by a task-specific output layer F^t (i.e, feed-forward neural networks followed by a softmax layer) to compute the probability distribution over the possible labels for (W^t, p^t): $P^t(Y^t|R^t) = F^t(R^t)$ where Y^t is the label set for the t task.

If the two models M^{wsd} and M^{ed} were trained separately, the objective function for the t task for the current example would be the negative log-likelihood: $C^t(W^t, p^t, y^t) = -\log P^t(y^t|R^t)$. In this work, instead of just optimizing this objective, we optimize the joint function:

$$C^t(W^t, p^t, y^t) = -\log P^t(y^t|R^t) + \lambda \frac{1}{d_R} \sum_{i=0}^{d_R} \left(R_i^{wsd} - R_i^{ed} \right)^2$$

where λ is a trade-off parameter and d_R is the dimension of the representation vectors.

The second term in the joint objective function enforces that the feature representations learned by M^{wsd} and M^{ed} on the same input context (W^t, p^t) are close to each other ($t \in \{wsd, ed\}$). One the one hand, this representation matching schema helps the two models to communicate to each other so the knowledge from one model can be passed to the other one. On the other hand, the use of two separate models leaves a flexibility for the models to induce the task-specific structures.

Presumably, the objective function (2.2) can simultaneously improve the performance for both tasks of consideration. However, in our case of ED and WSD, it turns out this mechanism actually worsen the performance of the WSD models that were trained separately. We attribute this to the fact that the semantic differentiation in ED is more coarse-grained that that of WSD, causing the ineffectiveness of the datasets for ED to improve WSD performance. Eventually, we will just focus on the ED performance in the experiments.

3 Experiments

3.1 Parameters and Datasets

We use the Semcor dataset (Miller et al., 1994) as the dataset for WSD in this work. This dataset was extracted from the Brown Corpus, and manually annotated with WordNet senses. We evaluate the models on two different datasets for ED:

1. **ACE 2005**: This dataset has 33 event subtypes. We use the same data split with the prior work (Chen et al., 2015; Nguyen and Grishman, 2015b). In particular, 40 newswire documents are used for testing, 30 other documents are reserved for validation, and the 529 remaining documents form the training data.
2. **TAC 2015**: This dataset was released in the Event Nugget Detection Evaluation of the 2015 Text Analysis Conference (TAC) (Mitamura et al., 2015). It comes with 38 event subtypes. We follow the data split in the official evaluation to achieve compatible comparison. As TAC 2015 does not have a development set, we use the best parameters tuned on ACE 2005 for the experiments with TAC 2015.

We use the pre-trained word embeddings provided by (Nguyen and Grishman, 2016d). For *CNN*, *NCNN* and *CNN+BiRNN*, we employ filter sizes of $\{2, 3, 4, 5\}$ with 300 filters for each size as in (Nguyen and Grishman, 2015b), while Gated Recurrent Units (Cho et al., 2014) with 300 hidden units are applied in *BiRNN* and *CNN+BiRNN* (as do (Nguyen and Grishman, 2016d)). For the other parameters, the best values suggested by the development data include: a dropout rate of 0.5, a feed-forward neural network with one hidden layer of 1200 hidden units for the output layers, and the penalty rate λ of 0.01 for both CNN and BiRNN, 0.6 for NCNN, and 0.7 for CNN+BiRNN in the proposed transfer learning method (called *MATCHING*). For simplicity, the same hyper-parameters are used for the two versions of the same network architecture in the *MATCHING* method. We utilize Adadelta (Zeiler, 2012) with back-propagation to train the models in this work.

3.2 Experiments

In this section, we compare the proposed *MATCHING* method with the transfer learning baseline *ALT* in (Guo et al., 2016) and the separate training mechanism for ED (called *SEPARATE*) employed in the previous work for ED (Chen et al., 2015; Nguyen and Grishman, 2015b). Note that in the *SEPARATE* method, the models are only trained on the datasets for ED without utilizing any transfer learning techniques with external datasets. We report the performance when each of the DL methods in Section 2.1 is used as the network to learn the feature representations for ED and WSD.

Tables 1 and 2 present the performance (i.e, F1 scores) of the models on the ACE 2005 and TAC 2015 datasets respectively. The first observation is that the proposed transfer learning method *MATCHING* is consistently better than the baseline method *ALT* across different deep learning models and datasets with large performance gap. This is significantly with $p < 0.05$ and confirms our hypothesis in Section 2.2 about the advantage of the proposed *MATCHING* over the alternating training method *ALT* for ED and WSD. In fact, the performance of the *ALT* method is even worse than the traditional *SEPARATE* method also over different network architectures and datasets. Consequently, training a single deep learning model on a combination of ED and WSD data (as in *ALT*) does not automatically enable the model to learn to exploit the similar structures of the two tasks. In contrast, it hinders the model's ability to effectively extract hidden representations for ED.

Comparing *MATCHING* and *SEPARATE*, we see that *MATCHING* helps to improve *SEPARATE* with respect to difference choices of the DL models. The performance improvement is significant for *CNN* and *BiRNN* on ACE 2005 and for all the models on TAC 2015. Such results demonstrate the effectiveness of the WSD dataset for ED and the ability of the proposed method *MATCHING* to promote knowledge transferring between WSD and ED to improve ED performance.

Regarding the best reported performance, our best performance on ACE (i.e, 71.2% with *CNN*) is comparable with the recent state-of-the-art performance (i.e, Table 1). However, we note that such work heavily relies on the manual annotation of the entity mentions in the documents. Our current work do not employ such information to better reflect the realistic setting. For the TAC 2015 dataset, our best performance is 60.7% with *CNN+BiRNN* although the performance of the other models is also very close. This performance is better than the best performance that has been reported on the TAC 2015 (i.e, Table 2).

4 Related Work

Prior works on ED include statistical models with manual feature engineering(Ahn, 2006; Ji and Grishman, 2008; Hong et al., 2011; Li et al., 2013; Venugopal et al., 2014; Li et al., 2015), followed by neural network models, such as CNNs (Nguyen and Grishman, 2015b; Chen et al., 2015; Nguyen et al., 2016b,e; Chen et al., 2017), RNNs (Nguyen et al., 2016a; Jagannatha and Yu, 2016), and attention-based methods (Liu et al., 2017; Nguyen and Nguyen, 2018b).

A similar trend exists in methods proposed for WSD, with feature based methods (Miller et al., 1994; Zhong and Ng, 2010; Taghipour and Ng, 2015) succeeded recently by deep learning methods (Yuan et al., 2016; Raganato et al., 2017).

For multi-task learning in NLP, methods have been proposed for jointly modeling structured prediction tasks (Hatori et al., 2012; Li et al., 2011; Bohnet and Nivre, 2012; Henderson et al., 2013; Lluís et al., 2013; Duong et al., 2015), and for sequence-to-sequence problems (Dong et al., 2015; Luong et al., 2015; Liu et al., 2016; Klerke et al., 2016). The prior work to solve multiple NLP tasks using an unified architecture includes (Collobert and Weston, 2008; Guo et al., 2016).

5 Conclusion

We present a method that improves the performance of deep learning models for ED by training two different versions of the same network architecture for ED and WSD, while encouraging the knowledge transfer between the two versions via representation matching. The proposed method produces better results across a variety of deep learning models.

Learning Word Representations with Cross-Sentence Dependency for End-to-End Co-reference Resolution

`glass@mit.edu`

Abstract

In this work, we present a word embedding model that learns cross-sentence dependency for improving end-to-end co-reference resolution (E2E-CR). While the traditional E2E-CR model generates word representations by running long short-term memory (LSTM) recurrent neural networks on each sentence of an input article or conversation separately, we propose linear sentence linking and attentional sentence linking models to learn cross-sentence dependency. Both sentence linking strategies enable the LSTMs to make use of valuable information from context sentences while calculating the representation of the current input word. With this approach, the LSTMs learn word embeddings considering knowledge not only from the current sentence but also from the entire input document. Experiments show that learning cross-sentence dependency enriches information contained by the word representations, and improves the performance of the co-reference resolution model compared with our baseline.

1 Introduction

Co-reference resolution requires models to cluster mentions that refer to the same physical entities. The models based on neural networks typically require different levels of semantic representations of input sentences. The models usually need to calculate the representations of word spans, or mentions, given pre-trained character and word-level embeddings (Turian et al., 2010; Pennington et al., 2014) before predicting antecedents. The mention-level embeddings are used to make co-reference decisions, typically by scoring mention pairs and making links (Lee et al., 2017; Clark and Manning, 2016a; Wiseman et al., 2016). Long short-term memories (LSTMs) are often used to encode the syntactic and semantic information of input sentences.

Articles and conversations include more than one sentences. Considering the accuracy and efficiency of co-reference resolution models, the encoder LSTM usually processes input sentences separately as a batch (Lee et al., 2017). The disadvantage of this method is that the models do not consider the dependency among words from different sentences, which plays a significant role in word representation learning and co-reference predicting. For example, pronouns are often linked to entities mentioned in other sentences, while their initial word vectors lack dependency information. As a result, a word representation model cannot learn an informative embedding of a pronoun without considering cross-sentence dependency in this case.

It is also problematic if we encode the input document considering cross-sentence dependency and treat the entire document as one sentence. An input article or conversation can be too long for a single LSTM cell to memorize. If the LSTM updates itself for too many steps, gradients will vanish or explode (Pascanu et al., 2013), and the co-reference resolution model will be very difficult to optimize. Regarding the entire input corpus as one sequence instead of a batch also significantly increases the time complexity of the model.

To solve the problem that traditional LSTM encoders, which treat the input sentences as a batch, lack an ability to capture cross-sentence dependency, and to avoid the time complexity and difficulties of training the model concatenating all input sentences, we propose a cross-sentence encoder for end-to-end co-reference (E2E-CR). Borrowing the idea of an external memory module from Sukhbaatar et al. (2015), an external memory block containing syntactic and semantic information from context sentences is added to the standard LSTM model. With this context memory block, the proposed model is able to encode

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4829–4833
Brussels, Belgium, October 31 - November 4, 2018.

input sentences as a batch, and also calculate the representations of input words by taking both target sentences and context sentences into consideration. Experiments showed that this approach improved the performance of co-reference resolution models.

2 Related Work

2.1 Co-reference Resolution

A popular method of co-reference resolution is mention ranking (Durrett and Klein, 2013). Reading each mention, the model calculates co-reference scores for all antecedent mentions, and picks the mention with the highest positive score to be its co-reference. Many recent works are based on this approach. Durrett and Klein (2013) designed a set of feature templates to improve the mention-ranking model. Peng et al. (2015) proposed a mention-ranking model by jointly learning mention heads and co-references. Clark and Manning (2016a) proposed a reinforcement learning framework for the mention ranking approach. Based on similar ideas but without using parsing features, the authors of Lee et al. (2017) proposed the current state-of-the-art model which uses neural networks to embed mentions and calculate mention and antecedent scores. Lee et al. (2018) applied ELMo embeddings (Peters et al., 2018) to improve within-sentence dependency modeling and word representation learning. Wiseman et al. (2016) and Clark and Manning (2016b) proposed models using global entity-level features.

2.2 Language Representation Learning

Distributed word embeddings has been used as the basic unit of language representation for over a decade (Bengio et al., 2003). Pre-trained word embeddings, for example GloVe (Pennington et al., 2014) and Skip-Gram (Mikolov et al., 2013) are widely used as the input of natural language processing models.

Long short-term memory (LSTM) networks (Hochreiter and Schmidhuber, 1997) are widely used for sentence modeling. A single-layer LSTM network was applied in the previous state-of-the-art co-reference model (Lee et al., 2017) to generate word and mention representations. To capture dependency of longer distances, Campos et al. (2017) proposed a recurrent model that outputs hidden states by skipping input tokens.

Recently, memory networks (Sukhbaatar et al., 2015) have been applied in language modeling (Cheng et al., 2016; Tran et al., 2016). Applying an attention mechanism on memory cells, memory networks allow the model to focus on significant words or segments for classification and generation tasks. Previous works have shown that applying memory blocks in LSTMs also improves long-distance dependency extraction (Yogatama et al., 2018).

3 Learning Cross-Sentence dependency

To improve the word representation learning model for better co-reference resolution performance, we propose two word representation models that learn cross-sentence dependency.

3.1 Linear Sentence Linking

Instead of treating the entire input document as separate sentences and encode the sentences as a batch with an LSTM, the most direct way to consider cross-sentence dependency is to initialize LSTM states with the encodings of adjacent sentences. We name this method linear sentence linking (LSL).

In LSL, we encode input sentences with a 2-layer bidirectional LSTM. Give input sentences $[s_1, s_2 \dots s_n]$, the outputs of the first layer are $[[\overrightarrow{s}_1; \overleftarrow{s}_1], [\overrightarrow{s}_2; \overleftarrow{s}_2], \dots [\overrightarrow{s}_n; \overleftarrow{s}_n]]$. In the second LSTM layer, the initial state of the forward LSTM of s_i is initialized as

$$\overrightarrow{S}_i = [\overrightarrow{c}_0^2; [\overrightarrow{s}_{i-1}; \overleftarrow{s}_{i-1}]]$$

while the backward state is initialized as

$$\overleftarrow{S}_i = [\overleftarrow{c}_0^2; [\overrightarrow{s}_{i-1}; \overleftarrow{s}_{i-1}]]$$

where c_0^i stands for the initial cell of the i-th layer, and x stands for the final output of the LSTMs in first layer. We then concatenate the outputs of the forward and backward LSTMs in the second layer as the word representations for co-reference prediction.

3.2 Attentional Sentence Linking

It is difficult for LSTMs to embed enough information about a long sentence into a low-dimensional distributed vector. To collect richer knowledge from neighbor sentences, we propose a long short-term recurrent memory module and an attention mechanism to improve sentence linking.

To describe the architecture of the proposed model, we focus on adjacent input sentences s_{i-1}

and s_i. We present the input embeddings of the j-th word in the i-th sentence with $x_{i,j}$.

3.2.1 Long Short-Term Memory RNNs

To solve the traditional recurrent neural networks, Hochreiter and Schmidhuber (1997) proposed the LSTM architecture. The detail of recurrent state updating in LSTMs $h_t = f_{lstm}(x_t, h_{t-1}, c_{t-1})$ is shown in following equations.

$$\begin{aligned}
i_t &= \sigma(W_{xi}x_t + W_{hi}h_{t-1} + b_i) \\
f_t &= \sigma(W_{xf}x_t + W_{hf}h_{t-1} + b_f) \\
c_t &= f_t \odot c_{t-1} + i_t \odot tanh(W_{xc}x_t + W_{hc}h_{t-1} + b_c) \\
o_t &= \sigma(W_{xo}x_t + W_{ho}h_{t-1} + b_o) \\
h_t &= o_t \odot tanh(c_t)
\end{aligned}$$

where x_t is the input embedding and h_t is the output representation of the t-th word.

3.2.2 LSTMs with Cross-Sentence Attention

We design an LSTM module with cross-sentence attention for capturing cross-sentence dependency. We name this method attentional sentence linking (ASL). Considering input word $x_{i,t}$ in the i-th sentence and all words from the previous sentence $X_{i-1} = [x_{i-1,1}, x_{i-1,2}, \dots, x_{i-1,m}]$, we regard the matrix X_{i-1} as an external memory module and calculate an attention on its cells, where each cell contains a word embedding.

$$\alpha_j = \frac{e^{c_j}}{\sum_k e^{c_k}} \tag{1}$$

$$c_k = f_c([x_{i,t}; h_{t-1}; x_{i-1,k}]^T) \tag{2}$$

With the attention distribution $\boldsymbol{\alpha}$, we can get a vector summarizing related information from s_{i-1},

$$v_{i-1} = \sum_j \alpha_j \cdot x_{i-1,j} \tag{3}$$

The model decides if it needs to pay more attention on the current input or cross-sentence information with a context gate.

$$g_t = \sigma(f_g([x_{i,t}; h_{t-1}; v_{i-1}]^T)) \tag{4}$$

$$\hat{x}_{i,t} = g_t \cdot x_{i,t} + (1 - g_t) \cdot v_{i-1} \tag{5}$$

$\sigma(\cdot)$ stands for the Sigmoid function. The word representation of the target word is calculated as

$$h_{i,t} = f_{lstm}(\hat{x}_{i,t}, h_{i,t-1}, c_{i,t-1}) \tag{6}$$

where f_{lstm} stands for standard LSTM update described in section 3.2.1.

3.3 Co-reference Prediction

In this work, we apply the mention-ranking end-to-end co-reference resolution (E2E-CR) model proposed by Lee et al. (2017) for co-reference prediction. The word representations applied in E2E-CR model is formed by concatenating pre-trained word embeddings and the outputs of LSTMs. In our work, we represent words by concatenating pre-trained word embeddings and the outputs of LSL- and ASL-LSTMs.

4 Experiments

We train and evaluate our model on the English corpus of the CoNLL-2012 shared task (Pradhan et al., 2012). We implement our model based on the published implementation of the baseline E2E-CR model (Lee et al., 2017) [1]. Our implementation is also available online for reproducing the results reported in this paper [2]. In this section, we first describe our hyperparameter setup, and then show the experimental results of previous work and our proposed models.

4.1 Model and Hyperparameter Setup

In practice, the LSTM modules applied in our model have 200 output units. In ASL, we calculate cross-sentence dependency using a multilayer perceptron with one hidden layer consisting of 150 hidden units. The initial learning rate is set as 0.001 and decays 0.001% every 100 steps. The model is optimized with the Adam algorithm (Kingma and Ba, 2014). We randomly select up to 40 continuous sentences for training if the input is too long. In co-reference prediction, we select 250 candidate antecedents as our baseline model.

4.2 Experiment Results and Discussion

We evaluate our model on the test set of the CoNLL-2012 shared task. The performance of previous work and our model are shown in Table 1. We mainly focus on the average F1 score of MUC, B^3, and CEAF metrics. Comparing with the baseline model that achieved 67.2% F1 score, the ASL model improved the performance by 0.6% and achieved 67.8% average F1. Experiments

- **Reporters** are tired of the usual stand ups. - **They** want to be riding on a train or walking in the rain or something to get attention .
- Planned terrorist bombing that ripped a 20 x 40 - foot hole in the **Navy destroyer USS Cole** in the Yemeni port of Aden. - **The ship** was there for refueling.
- Yemeni authorities claimed they have detained **over 70 people** for questioning. - **These** include some Afghan - Arab volunteers.

Table 2: Examples predictions of the ASL model and the baseline model.

show that the models that consider cross-sentence dependency significantly outperform the baseline model, which encodes each sentence from the input document separately.

Experiments also indicated that the ASL model has better performance than the LSL model, since it summarizes extracts context information with an attention mechanism instead of simply viewing sentence-level embeddings. This gives the model a better ability to model cross-sentence dependency.

Examples for comparing the performance of the ASL model and the baseline are shown in Table 2. Each example contains two continuous sentences with co-references distritubed in different sentences. Underlined spans in bold are target mentions and annotated co-references. Spans in green are ASL predictions, and spans in red are baseline predictions. A prediction on "-" means that no mention is predicted as a co-reference.

Table 2 shows that the baseline model, which does not consider cross-sentence dependency, has difficulty in learning the semantics of pronouns whose co-references are not in the same sentence. The pretrained embeddings of pronouns are not informative enough. In the first example, "it" is not semantically similar with "SMS" in GloVe without any context, and in this case, "it" and "SMS" are in different sentences. As a result, if reading this two sentences separately, it is hard for the encoder to represent "it" with the semantics of "SMS". This difficulty makes the co-reference resolution model either prediction a wrong antecedent mention, or cannot find any co-reference.

However, with ASL, the model learns the semantics of pronouns with an attention to words in other sentences. With the proposed context gate, ASL takes knowledge from context sentences if local inputs are not informative enough. Based on word represents enhanced with cross-sentence dependency, the co-reference scoring model can make better predictions.

5 Conclusion and Future Work

We proposed linear and attentional sentence linking models for learning word representations that captures cross-sentence dependency. Experiments showed that the embeddings learned by proposed models successfully improved the performance of the state-of-the-art co-reference resolution model, indicating that cross-sentence dependency plays an important role in semantic learning in articles and conversations consists of multiple sentences. It worth exploring if our model can improve the performance of other natural language processing applications whose inputs contain multiple sentences, for example, reading comprehension, dialog generation, and sentiment analysis.

Abstract

Lexicon relation extraction given distributional representation of words is an important topic in NLP. We observe that the state-of-the-art projection-based methods cannot be generalized to handle unseen hypernyms. We propose to analyze it in the perspective of pollution, that is, the predicted hypernyms are limited to those appeared in training set. We propose a word relation autoencoder (WRAE) model to address the challenge and construct the corresponding indicator to measure the pollution. Experiments on several hypernym-like lexicon datasets show that our model outperforms the competitors significantly.

1 Introduction

This paper discusses the inference of relations between words. For the hypernym *beer IsA drink*, , denoted as *IsA(x, y)*, *beer* is the hyponym x and *drink* serves as the hypernym y. Relation lexicons are precious resource for NLP systems, while constructing the semantic graphs such as WordNet (Fellbaum, 1998) and ConceptNet (Speer and Havasi, 2012) requires expensive human efforts for labeling.

Recently, researchers have started working on extracting word relations based on pre-trained word embedding without the need of an existing corpus, thanks to the success of distributional word representation models such as GloVe (Pennington et al., 2014).

Query	Answer
$beef \rightarrow meat \approx crab \rightarrow ?$	seafood
$tiger \rightarrow zoo \approx dolphin \rightarrow ?$	aquarium
$paint \rightarrow artist \approx book \rightarrow ?$	writer
$japan \rightarrow asia \approx italy \rightarrow ?$	europe

Table 1: Unseen relation extraction examples for IsA, AtLocation, CreatedBy, and PartOf (top row to bottom row) in ConceptNet. The answers are not appeared in training.

Comparing with hypernym classification models (Lenci and Benotto, 2012; Weeds et al., 2014; Levy et al., 2015; Vylomova et al., 2016) that take a pair of entities *(x,y)* as inputs and output a binary decision about the existence of relation, there has been less work focusing on hypernym extraction task. It is a challenging task to automatically extract all possible hypernyms of a given hyponym query, especially the unlabeled ones, from the vocabularies.

Classification-based models are not applicable for this task because the complexity of inference is $\mathcal{O}(V)$, where V is the size of vocabulary that often scales to billions.

Among the existing solutions, projection-based methods (Fu et al., 2014; Yamane et al., 2016; Espinosa-Anke et al., 2016; Ustalov et al., 2017) emphasize on hypernym extraction which intuitively represent a relation as $y - x$ according to the linear structure of word embedding. By directly learning a linear mapping Φ between two words such that $x\Phi = y$, the prediction $\hat{y}$ can be obtained with nearest neighbor search for $x\Phi$ in the word embedding space. Moreover, the potential candidates of y are not required to be seen in advance so that the method can be used to predict unseen hypernym directly.

Fu et al. (2014) further observe the existence of

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4834–4839
Brussels, Belgium, October 31 - November 4, 2018.

cluster structures in relation representation $y - x$ and propose to learn a piecewise linear mapping such that $x\Phi_k = y$ for each cluster C_k. Their experiments show that domain clustering on training offset is very useful for hypernym identification.

However, we observe that each cluster contains very few distinct hypernyms. For instance, about 83% of the clusters contain fewer than 5 hypernyms for ConceptNet-IsA in our experiments. Hypernyms can be seen as the collections of related word pairs, e.g., *IsA(dog, animal)*, *IsA(cat, animal)*, *IsA(horse, animal)*, ... etc. The piecewise projection matrices can hardly learn the inference between hyponyms and hypernyms but only *memorize* some words which serve as the hypernyms in the training data. Inevitably, the state-of-the-art models using piecewise projection learning face generalization problem and fail to predict unseen hypernyms correctly.

We design a novel **Word Relation Autoencoder (WRAE)** framework, which adopts the conditional autoencoder structure ($x \rightarrow r \rightarrow x'$) that encodes hyponyms and reconstructs itself by decoding from $r = y - x$. The weights of encoder are further tied with decoder which is imposed to learn how to separate the hypernym and the hyponym from the relation vectors and extract the hyponym x with the intention to optimize reconstruction loss, thus effectively mitigates the mentioned generalization problem.

We summarize our main contributions as follows: (1) We propose a novel, yet more general scenario for relation extraction to handle unseen hypernyms. (2) We propose an intuitive pollution indicator that allows us to empirically measure whether the model learns the inference between a relation pair or not. (3) We propose a novel Word Relation Autoencoder (WRAE) which can effectively reduce pollution. We conduct thorough experiments to show that our model outperforms the competitors, and can be applied to other hypernym-like relations.

2 Related Work

Fu et al. (2014) first apply projection learning for generalized hypernym extraction by learning a linear transformation from a hyponym word embedding to the corresponding hypernym word vector. They further conduct piecewise projection learning, i.e., learning a projection matrix for each cluster and harvest significant improvements by first applying k-means clustering. They perform training with stochastic gradient descent methods, implying good potential for attaching different regularizers for optimization. Several recent works also follow the schema as the one proposed by Espinosa-Anke et al. (2016) and operate the similar model at the sense level and took advantage of domain clustering to discover hypernyms through domain adaption between different topics. Yamane et al. (2016) focus on improving the performance through better cluster assignments by learning clustering and the projections jointly. Ustalov et al. (2017) propose several regularization terms in addition to the original loss function (Fu et al., 2014) using extra synonym pairs or the asymmetric property of hypernym. Nayak (2015) provides detailed technical studies on piecewise projection models.

Our work differs from all of them, as we emphasize on the setting that all hyponyms and hypernyms in testing vocabulary are not seen in training.

3 Model Formulation

3.1 Piecewise Projection

Piecewise projection learning (Fu et al., 2014) serves as our baseline. The objective is to learn a relation transform from x to y on training pairs (x, y). Piecewise projection matrix Φ_k is learned separately for each cluster, after applying k-means clustering on the offset of training using $y - x$ between each pair.

$$\min_{\Phi_k} \frac{1}{|C_k|} \sum_{(x,y)\in C_k} \|x\Phi_k - y\|_2^2 , \qquad (1)$$

where C_k represents the size of the k^{th} cluster. In addition, we also examine a simple solution of L2-penalized projection learning model which imposes a L2 constraint on Φ in Equation 1, i.e., $\alpha \|\Phi_k\|_2^2$.

3.2 Word Relation Autoencoder (WRAE)

Our model takes the form of an autoencoder. As shown in Equation 2,

$$\min_{\Phi_k} \frac{1}{|C_k|} \sum_{(x,y)\in C_k} \|x - x\Phi_k\Phi_k^*\|_2^2 , \qquad (2)$$

where $x\Phi_k = y - x$. Here we adopt the simplifying trick (Kodirov et al., 2017a) to tie with the constraint (Ranzato et al., 2008) $\Phi^* = \Phi^T$. Note that the L2-norm regularization term is not necessary for WRAE to avoid overfitting since the constraint of $\Phi^* = \Phi^T$ guarantees $\|\Phi\|_2^2$ cannot be large otherwise the reconstruction loss will be bad. Also, the learning process is more efficient.

To release the constraint of $x\Phi_k = y - x$, the objective can be further split into two terms:

$$\min_{\Phi_k} \frac{1}{|C_k|} \sum_{(x,y)\in C_k} (\|x\Phi_k - (y-x)\|_2^2 + \lambda \left\|(y-x)\Phi_k^T - x\right\|_2^2), \tag{3}$$

where λ is a weighting constant.

We find that learning relation mapping from $x \to (y-x)$ instead of $x \to y$ effectively mitigates the pollution problem (Lazaridou et al., 2015). A prediction is said to be polluted if the nearest neighbor of predicted $\hat{y}$ matches a hypernym appeared in training set. The operation fundamentally solves the cause of pollution since each pair of input and output becomes $(x, y-x)$ instead of (x, y). Unlike projecting to a small number of target y, the target $y-x$ obviously differs from pair to pair thus avoiding simply overfitting the lexicons.

Conceptually, WRAE learns to extract the hyponym x from the relation vectors $r = y - x$ to optimize on the reconstruction loss. By encouraging the projection to learn the relationship between a word pair, WRAE effectively mitigates the mentioned generalized problem.

Our model is related to Semantic Autoencoder (SAE) (Kodirov et al., 2017b). With the latent relation directly associates with input x, WRAE can be regarded as a special conditional SAE where the condition is the input itself and is incorporated into the middle layer.

Relation	#Pair	#Head	#Tail

AtLocation	39916	10100	11311
PartOf	14231	9784	5519
CreatedBy	503	385	414

Table 2: Relations from ConceptNet. For a relation pair $x \to y$, x is the *head* and y is the *tail*.

4 Experiments

4.1 Setup

Different from the experimental setup in previous works (Fu et al., 2014; Ustalov et al., 2017; Yamane et al., 2016) that do not assume the candidate hypernyms are unseen, in our experiments the vocabulary sets for training and testing are completely disjoint, i.e., all vocabularies in testing are not seen in training at all.

To further examine the generality of our model, we collect several hypernym-like relations listed in Table 2 from ConceptNet semantic graph. Considering the property of these relations, we treat the head and tail words of a pair as the x and y for our models similar to hyponym and hypernym, respectively. Examples are in Table 1.

We split the datasets with ratios 0.7, 0.2, and 0.1 for training, testing, and validation, respectively. For all results, we report the mean of 30 random splits. We test two different settings, one uses k-means clustering and one does not ($k = 1$). We tune the number of cluster k unsupervisedly with the Silhouette score (Rousseeuw, 1987) on validation. The projection matrices are optimized with the Adam method (Kingma and Ba, 2014) with learning rate = $1e^{-3}$. We adopt the GloVe (Pennington et al., 2014) 300d pre-trained word embeddings[1] which are trained on 6B token corpus (Wikipedia 2014 + Gigaword 5) with 400,000 words.

4.2 Evaluation Metrics

Hit Rate

To evaluate the precision of returned hypernyms, we follow Ustalov et al. (2017) and Kodirov et al. (2017a) using the hit rate measure (Frome et al., 2013). We also adopt area under curve (AUC) measure which computes the averaged area under the $l - 1$ trapezoids of hit@l to take the ranks of ground truth into consideration:

$$AUC_l = \frac{1}{2(l-1)} \sum_{i=1}^{l-1} (hit@i + hit@(i+1)), \tag{4}$$

Soft Pollution

To evaluate the degree of pollution of the extracted hypernym, we adopt a metric similar to Lazaridou et al. (2015). A prediction is said to be polluted if the nearest neighbor of predicted $\hat{y}$ matches a hypernym appears in the training set, noted as a binary function $pol_1(\hat{y})$.

However, it is possible that ground truth unseen hypernyms are be very close to some seen hypernyms in Y_{train} in real cases. We take ground truths

Table 3: Performance on ConceptNet relation dataset. †: all results pass the hypothesis test against the other models with $p < 0.01$. *: for IsA, we report hit@5 and hit@10. For hit rates, the higher the better. For pollution, the lower the better.

into consideration:

$$pol_l^{soft}(\hat{y}, y) = \rho \cdot pol_1(\hat{y}), y \in Y_{test},$$
$$\rho = \begin{cases} 1, & if \quad NN_l(y) \cap Y_{train} = \phi, \\ 2^{\frac{n-1}{l-1}} - 1, & otherwise, \end{cases} \tag{5}$$

where n is for the top n nearest neighbors (from 1 to l) of y that appears in Y_{train} and ρ is a factor term exponentially decreases from 1 to 0 along with the increase of n therefore provides a smoother estimation. With pollution indications, one can understand to what degree the model suffers from overfitting on the seen examples. ϕ is the empty set. Note that it is reasonable to set l equal for both hit rate and soft pollution.

4.3 Results: Unseen General Hypernym-Like Relation Extraction

We report two sets of results for all models, one with clustering and one without (k = 1). As shown in Table 3, WRAE outperforms the competitors significantly with and without clustering. The naive application of Equation 2 which set $x\Phi_k = y$, denoted as *WRAE-Y*, consistently ranks second. The $y - x$ operation is crucial to avoid pollution thus guarantees the generalization power of the mapping. Apply simple L2-norm regularization Equation 1 for *Proj.*, denoted as *Proj.+L2*, only slightly improves the performance. The results in Table 3 supports our hypothesis that Proj. models deteriorate significantly for larger k, due to lack of training examples for hypernyms in each cluster. We prove that WRAE is effective against pollution. The role of regularizer is important for decoders to optimize towards better objective.

The negative effects derived from pollution impact accuracy. We observe severe pollution problem in simple projection learning. Take *IsA* as example, in $k = 1$ group the pol_1 is about 71% for Proj., which implies about two of out of three returned predictions are data points from training data. Our WRAE reduces the pollution pol_1 to 60% and 12% after clustering. The improvement on accuracy supports that pollution indication reflects the inherent overfitting problem. In general, results are consistent with our claims that pollution can be viewed as valid negative indicators.

Across the board, the performance should benefit from domain clustering if pollution is handled properly as the experiments showed.

5 Conclusion

We present an unseen hypernym extraction framework and analyze the pollution problem with this setup. Consequently we argue that only by using unseen candidates in evaluation can truly test whether the model learns the true relation representation, instead of being polluted by the seen training examples. Future work includes relation discovery, which is to identify new relations besides hypernyms in an unsupervised manner.

Abstract

In this paper, we propose a simple method for refining pretrained word embeddings using layer-wise relevance propagation. Given a target semantic representation one would like word vectors to reflect, our method first trains the mapping between the original word vectors and the target representation using a neural network. Estimated target values are then propagated backward toward word vectors, and a relevance score is computed for each dimension of word vectors. Finally, the relevance score vectors are used to refine the original word vectors so that they are projected into the subspace that reflects the information relevant to the target representation. The evaluation experiment using binary classification of word pairs demonstrates that the refined vectors by our method achieve the higher performance than the original vectors.

1 Introduction

The recent success of neural NLP is partially but largely due to the development of word embedding techniques (Goldberg, 2017). Although a considerable number of studies have been made on training word embeddings from distributional information of language (Mikolov et al., 2013; Pennington et al., 2014; Bojanowski et al., 2017; Nickel and Kiela, 2017), one recent research trend is to refine or fine-tune pretrained word embeddings. One promising approach is the use of other information such as multimodal information (Bruni et al., 2014; Kiela et al., 2014; Kiela and Clark, 2015; Kiela et al., 2015a; Silberer et al., 2017) and language resources (Faruqui et al., 2015; Faruqui and Dyer, 2015; Kiela et al., 2015b; Rothe and Schütze, 2017; Yu and Dredze, 2014). Other refinement methods include task-specific embeddings (Bolukbasi et al., 2016; Yu et al., 2017) and the selective use of multiple embeddings (Bollegala et al., 2017; Kiela et al., 2018).

In this paper, we propose a different approach to refining pretrained word embeddings so that word vectors reflect the information relevant for a specific knowledge. Our method utilizes layer-wise relevance propagation (Bach et al., 2015; Samek et al., 2017), which has been proposed as a general framework for decomposing predictions of modern AI systems, in particular deep learning systems. The basic idea of layer-wise relevance propagation is to quantitatively measure the contribution of each fragment of an input vector (e.g., a single pixel of an image) to the prediction as a relevance score. Using relevance scores, our method projects word vectors into the subspace that better reflects the target knowledge. The assumption underlying our approach is that the information for any given target knowledge is contained in pretrained word embeddings. Our method attempts to make the best use of the information contained in word vectors by estimating the importance in reflecting a target knowledge.

To the best of our knowledge, this paper is the first to employ the technique of layer-wise relevance propagation for refining word embeddings. Our method can be applied to word vectors $\boldsymbol{x}$ trained by any word embedding method. This implies that our method does not compete with other refinement methods, but they are complementary; it can be used for word vectors refined by other methods. In addition, our method can refine word vectors for any target knowledge $\boldsymbol{y}$, from a single binary value to a structured representation, as long as a function $\boldsymbol{y} = f(\boldsymbol{x})$ can be learned.

2 Method for Refining Word Vectors

Our method comprises the following three steps: (1) it trains a prediction function from a pretrained word vector to a target representation; (2) computes a relevance score for each dimension of the

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4840–4846
Brussels, Belgium, October 31 - November 4, 2018.

word vector; and (3) projects word vectors into the subspace using the relevance scores. In this section, these three steps are explained in detail.

2.1 Training the Prediction Function

Given pairs of an input word vector $\boldsymbol{x}^{(i)}$ to be refined and a target knowledge representation $\boldsymbol{y}^{(i)}$ for a word $w^{(i)}$, the proposed method trains a function $\boldsymbol{y}^{(i)} = f(\boldsymbol{x}^{(i)})$. In this paper, we use a neural network as a learning method, but other learning methods such as linear transformation and SVM can also be used. Note that a scalar value or a class label can be used as a target representation $\boldsymbol{y}^{(i)}$.

2.2 Computing Relevance Scores

This step derives an explanation of the prediction in terms of input variables, namely the importance of each dimension of a word vector $\boldsymbol{x}^{(i)}$ for the prediction $\hat{\boldsymbol{y}}^{(i)} = f(\boldsymbol{x}^{(i)})$. In layer-wise relevance propagation, the score of the correct prediction $\hat{y}_j^{(i)}$ is redistributed backward using relevance propagation rules. By repeatedly applying propagation rules, it assigns a relevance score $r_k^{(i,j)}$ to each dimension $x_k^{(i)}$ of a word vector $\boldsymbol{x}^{(i)}$. As a result, a relevance score vector $\boldsymbol{r}^{(i,j)}$ is obtained for each word vector $\boldsymbol{x}^{(i)}$ and target dimension $y_j^{(i)}$.

Among a number of propagation rules (Bach et al., 2015), we use the "alpha-beta" rule for multilayer neural networks. The relevance score $R_i^{(l)}$ of the i-th unit $u_i^{(l)}$ in the l-th layer is a function of upper-layer relevances $R_j^{(l+1)}$ defined by:

$$R_{i\leftarrow j}^{(l,l+1)} = R_j^{(l+1)} \cdot \left(\alpha \frac{z_{ij}^{+}}{\sum_i z_{ij}^{+}} + \beta \frac{z_{ij}^{-}}{\sum_i z_{ij}^{-}} \right) \quad (1)$$

$$R_i^{(l)} = \sum_j R_{i\leftarrow j}^{(l,l+1)} \quad (2)$$

$$z_{ij}^{(l,l+1)} = x_i^{(l)} w_{ij}^{(l,l+1)} \quad (3)$$

where $x_i^{(l)}$ is an activation of the unit $u_i^{(l)}$, $w_{ij}^{(l,l+1)}$ is a weight connecting $u_i^{(l)}$ to $u_j^{(l+1)}$, and z_{ij}^{+} and z_{ij}^{-} denote the positive and negative part of $z_{ij}^{(l,l+1)}$. As a result, relevance scores $r_k^{(i,j)}$ of the word vector $\boldsymbol{x}^{(i)}$ and the target dimension $y_j^{(i)}$ are obtained as relevance scores $R_k^{(1)}$ of the input layer. The parameters α and β denote the importance of positive and negative evidence for predicting a target representations and should be chosen such that $\alpha + \beta = 1$. In this paper, we assume that positive and negative evidence equally contributes to the prediction and thus set $\alpha = \beta = 0.5$.

2.3 Projecting Word Vectors into a Subspace

The basic idea of projection is that n-dimensional word vectors are projected into m-dimensional vectors whose relevance scores are more than or equal to a threshold θ_R.

First, for a target dimension j of $\boldsymbol{y}$, relevance score vectors are averaged over words relevant to the target dimension as follows:

$$\overline{\boldsymbol{r}}^{(j)} = g_2\left(\frac{\sum_{w_i \in V_j} g_1(\boldsymbol{r}^{(i,j)})}{|V_j|} \right) \quad (4)$$

$$\{g_1(\boldsymbol{x})\}_i = \begin{cases} x_i & (x_i \geq \theta_{R_1}) \\ 0 & (\text{otherwise}) \end{cases}$$

$$\{g_2(\boldsymbol{x})\}_i = \begin{cases} \frac{x_i}{\max_i x_i} & (\frac{x_i}{\max_i x_i} \geq \theta_{R_2}) \\ 0 & (\text{otherwise}) \end{cases}$$

where V_j is a set of words $w^{(i)}$ such that $\hat{y}_j^{(i)} \geq \theta_T$. The functions g_1 and g_2 are used for downplaying irrelevant dimensions. For example, the target knowledge is the property of *Visually dark* and $V_{visually\_dark}$ is {*chocolate, crow, night*}. By averaging relevance score vectors of these words, we obtain the mean relevance vector $\overline{\boldsymbol{r}}^{(visually\_dark)}$ that represents the importance of word vector dimension in predicting whether a given word has the property of *Visually dark*.

Finally, using the mean relevance vector $\overline{\boldsymbol{r}}^{(j)}$, word vectors $\boldsymbol{x}_i$ is transformed into vectors $\boldsymbol{z}_i^{(j)}$ of a subspace for the target dimension. This is achieved by weighting $\boldsymbol{x}_i$ by component-wise multiplication of $\boldsymbol{x}_i$ and $\overline{\boldsymbol{r}}^{(j)}$ and removing the dimensions of zero relevance. Formally, the projection is defined by the n by m projection matrix $\boldsymbol{T}^{(j)}$ as follows:

$$\boldsymbol{z}_i^{(j)} = \boldsymbol{x}_i \boldsymbol{T}^{(j)} \quad (5)$$

$$T_{ik}^{(j)} = \begin{cases} \overline{r}_i^{(j)} & (\overline{r}_i^{(j)} > 0 \text{ and it is the } k\text{-th} \\ & \ \text{nonzero dimension of } \overline{\boldsymbol{r}}^{(j)}) \\ 0 & (\text{otherwise}) \end{cases} \quad (6)$$

3 Evaluation Experiment

In order to justify the effectiveness of the proposed method, we conducted an evaluation experiment using binary classification of word pairs.

Corpus: All word vectors were trained on the Corpus of Contemporary American English

Domain	Properties
Vision	Vision, Bright, Dark, Color, Pattern, Large, Small, Motion, Biomotion, Fast, Slow, Shape, Complexity, Face, Body
Somatic	Touch, Temperature, Texture, Weight, Pain
Audition	Audition, Loud, Low, High, Sound, Music, Speech
Gustation	Taste
Olfaction	Smell
Motor	Head, UpperLimb, LowerLimb, Practice
Spatial	Landmark, Path, Scene, Near, Toward, Away, Number
Temporal	Time, Duration, Long, Short
Causal	Caused, Consequential
Social	Social, Human, Communication, Self
Cognition	Cognition
Emotion	Benefit, Harm, Pleasant, Unpleasant, Happy, Sad, Angry, Disgusted, Fearful, Surprised
Drive	Drive, Needs
Attention	Attention, Arousal

Table 1: 65 properties in Binder et al.'s (2016) dataset

(COCA), which includes 0.56G word tokens. Words that occurred less than 30 times in the corpus were ignored, resulting in the vocabulary of 108,230 words. Three context windows of size 3, 5, and 10 were used for training.

Word embedding: We used two representative models, namely skip-gram with negative sampling (SGNS) (Mikolov et al., 2013) and GloVe (Pennington et al., 2014). We trained 100-, 200- and 300-dimensional word vectors from the corpus.

Target knowledge representation: We used Binder et al.'s (2016) brain-based semantic vectors of 535 words as a target representation. [1] This representation comprises 65 properties in Table 1, which are based entirely on functional divisions in the human brain. Each word is represented as a 65-dimensional vector and each dimension corresponds to one of these properties. Each value of the brain-based vectors represents the salience of the corresponding property, which is calculated as a mean salience rating on a 7-point scale ranging from 0 to 6. Because these properties are based on not only perceptual properties but also a variety of other properties such as affective, social, and cognitive ones, this dataset is suitable for evaluation.

Refining word vectors: The prediction function f was trained using a three-layer neural network comprising an input layer for n-dimensional word vectors, one hidden layer with $n/2$ sigmoid units, and a linear output layer. The parameters θ_T, θ_{R_1} and θ_{R_2} for projection were estimated using 10-fold cross-validation and grid search. [2]

Bright, Dark, Color, Pattern, Large, Small, Motion, Fast, Slow, Shape, Temperature, Texture, Weight, Loud, Sound, Taste, Smell, Fearful

Table 2: 18 properties in CSLB dataset

Task: We used a binary classification task of judging whether a pair of words is similar or not with respect to each property of Table 1. For example, *night* and *chocolate* should be judged as similar with respect to the property of *Dark*, while *night* and *ice* should be judged as dissimilar with respect to that property. For each property, we chose 10 words with the highest salience and 10 words with the lowest salience from the vocabulary of brain-based vectors, and generated 45 high-salience word pairs and 100 pairs of high-salience and low-salience words. Note that we did not consider low-score word pairs because it does not make sense to ask whether words (e.g., *peace* and *wit*) that do not have a property (e.g., *Dark*) are similar with respect to that property.

To confirm the generality of our method, we also generated another evaluation dataset for untrained words (i.e., words not included in Binder et al.'s vocabulary) using CSLB concept property norms of 638 words (Devereux et al., 2014). [3] After removing words contained in Binder et al.'s vocabulary, we chose properties that were closely related to Binder et al.'s properties and possessed by at least 10 words. As a result, the generated dataset contained 18 properties listed in Table 2, because the property norm mainly includes perceptual and functional properties.

Binary classification was carried out by computing cosine similarity between vectors of paired words and classifying the n highest pairs into similar pairs. Hence, the classification performance was measured by average precision.

4 Results

Table 3 shows mean average precisions across 65 properties for the original word embeddings (Orig) and the refined embeddings by our method (Refn). The asterisk indicates that the mean average precision of the refined vectors is signifi-

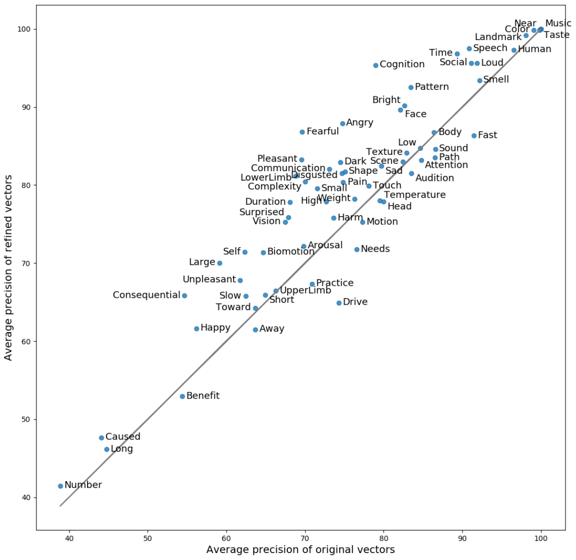

Figure 1: A scatterplot of average precision of the original versus refined vectors for 65 properties in the case of SGNS with `win`$=5$ and `dim`$=200$. The diagonal reference line $y = x$ indicates that the original and refined vectors have equal precision.

cantly higher than that of the original vectors by Wilcoxon signed-rank test ($p < .05$). For all word embeddings, the refined vectors achieved higher mean average precision than the original ones. Furthermore, in almost all cases, the improvement is statistically significant. This result demonstrates that the proposed method is successful in refining word embeddings so that vector similarity better reflects the target knowledge.

Figure 1 depicts the difference of average precision between the original word vectors and the refined vectors for each target property. Most of the properties are plotted above the diagonal reference line, indicating that these properties are better represented by the refined vectors. Note that properties plotted below the diagonal line, for which refined word vectors yielded lower precision than the original vectors, are sensorimotor or spatiotemporal properties. This result is consistent with Utsumi's (2018) finding that these kinds of knowledge are less likely to be encoded in word vectors.

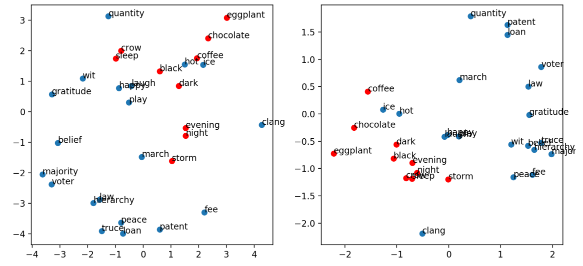
Table 4: Mean average precision for CSLB property norm dataset

Table 4 shows the result of binary classification for CSLB property norm dataset. In most cases, the refined vectors of untrained words also yielded better performance than the original vectors. In some cases, however, refinement did not improve the performance. One of the reasons for this failure would be that a small set of vocabulary words in Binder et al.'s (2016) dataset is not enough for the subspace to generalize to untrained words.

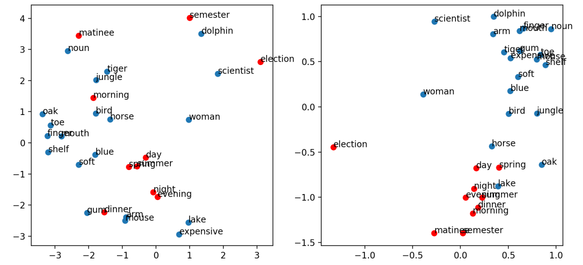
To confirm whether the projected subspace better reflects the target knowledge than the original space, we visualize both spaces using MDS in Figure 2. Although all 535 words are embedded into the two-dimensional space, Figure 2 only shows words used in binary classification task, namely words with the 10 highest salience (denoted by red dots) and 20 lowest salience for a given property. As shown in Figure 2, our method refines the vectors of salient words to be more similar in the subspace, while preserving the other similarity of words.

5 Related Work

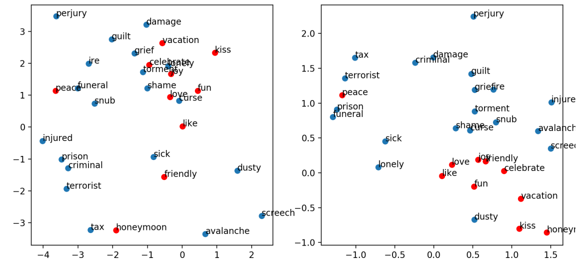
Prior work on word embedding refinement can be classified into general purpose refinement and specific target refinement. Many existing studies have attempted to refine word vectors to improve the performance of general-purpose similarity computation. These studies generally re-



(a) Property *Dark*



(b) Property *Time*



(c) Property *Pleasant*

Figure 2: Two-dimensional MDS visualization of the original space (trained by SGNS with `win`$=5$ and `dim`$=200$) and the projected subspace ($\theta_T = 3.0$, $\theta_{R_1} = 0.026$ and $\theta_{R_2} = 0.10$). Left: Original space, Right: Projected subspace

fine word vectors by solving an optimization problem whose objective function reflects the similarity obtained by language resources, such as WordNet (Faruqui et al., 2015; Yu and Dredze, 2014; Rothe and Schütze, 2017), Freebase (Rothe and Schütze, 2017), Paraphrase Database (Faruqui et al., 2015; Yu and Dredze, 2014), free association norm (Kiela et al., 2015b), and dictionary (Wang et al., 2015). Our method differs from them in that it is proposed for specific target refinement. In other words, the refined vectors by general purpose refinement method can be further refined to extract a specific knowledge by our method.

Most prior studies for specific purpose refinement propose a method specialized for a specific task such as sentiment analysis (Labutov and Lipson, 2013; Tang et al., 2016; Yu et al., 2017) and lexical entailment (Mrkšić et al., 2016; Vulić and Mrkšić, 2018). On the other hand, our method refines word vectors for a specific knowledge or task, but it is not specialized for a knowledge or task.

Rothe et al. (2016) and Rothe and Schütze (2016) are conceptually similar to our approach; their method refines word vectors for a specific knowledge but it is not specialized for a certain task. The merit of our method is that any types of representation can be used as a target, while their method is limited to binary labels. Furthermore, while their method learns an orthogonal transformation of pretrained word vectors by directly optimizing the objective function, our method can project word vectors to a subspace independent of training method for a prediction function.

6 Conclusion

In this paper, we propose a method for refining pretrained word vectors using layer-wise relevance propagation. We demonstrated that the proposed method can refine word vectors so that they better reflect the target knowledge. One of our motivation is to make embeddings more interpretable and useful. In other studies (Utsumi, 2015, 2018), we have analyzed the internal knowledge encoded in text-based word embeddings, while this study is the first step toward a general method for utilizing the internal knowledge of word embeddings.

In future work, we have to modify the refinement method by relevance propagation to be more effective by exploring the mechanism of how the internal knowledge of word vectors is extracted by multilayer neural networks and examining the effectiveness of other relevance propagation methods. It would also be vital for future work to explore efficient combinations with other refinement methods using language resources.

Learning Gender-Neutral Word Embeddings

Abstract

Word embedding models have become a fundamental component in a wide range of Natural Language Processing (NLP) applications. However, embeddings trained on human-generated corpora have been demonstrated to inherit strong gender stereotypes that reflect social constructs. To address this concern, in this paper, we propose a novel training procedure for learning gender-neutral word embeddings. Our approach aims to preserve gender information in certain dimensions of word vectors while compelling other dimensions to be free of gender influence. Based on the proposed method, we generate a Gender-Neutral variant of GloVe (GN-GloVe). Quantitative and qualitative experiments demonstrate that GN-GloVe successfully isolates gender information without sacrificing the functionality of the embedding model.

1 Introduction

Word embedding models have been designed for representing the meaning of words in a vector space. These models have become a fundamental NLP technique and have been widely used in various applications. However, prior studies show that such models learned from human-generated corpora are often prone to exhibit social biases, such as gender stereotypes (Bolukbasi et al., 2016; Caliskan et al., 2017). For example, the word "programmer" is neutral to gender by its definition, but an embedding model trained on a news corpus associates "programmer" closer with "male" than "female".

Such a bias substantially affects downstream applications. Zhao et al. (2018) show that a coreference resolution system is sexist due to the word embedding component used in the system. This concerns the practitioners who use the embedding model to build gender-sensitive applications such as a resume filtering system or a job recommendation system as the automated system may discriminate candidates based on their gender, as reflected by their name. Besides, biased embeddings may implicitly affect downstream applications used in our daily lives. For example, when searching for "computer scientist" using a search engine, as this phrase is closer to male names than female names in the embedding space, a search algorithm using an embedding model in the backbone tends to rank male scientists higher than females', hindering women from being recognized and further exacerbating the gender inequality in the community.

To alleviate gender stereotype in word embeddings, Bolukbasi et al. (2016) propose a post-processing method that projects gender-neutral words to a subspace which is perpendicular to the gender dimension defined by a set of gender-definition words.[1] However, their approach has two limitations. First, the method is essentially a pipeline approach and requires the gender-neutral words to be identified by a classifier before employing the projection. If the classifier makes a mistake, the error will be propagated and affect the performance of the model. Second, their method completely removes gender information from those words which are essential in some domains such as medicine and social science (Back et al., 2010; McFadden et al., 1992).

To overcome these limitations, we propose a learning scheme, Gender-Neutral Global Vectors (GN-GloVe) for training word embedding models with protected attributes (e.g., gender) based on GloVe (Pennington et al., 2014).[2] GN-GloVe represents protected attributes in certain dimen-

---

[1] Gender-definition words are the words associated with gender by definition (e,g., mother, waitress); the remainder are gender-neutral words.

[2] The code and data are released at `https://github.com/uclanlp/gn_glove`

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4847–4853
Brussels, Belgium, October 31 - November 4, 2018.

sions while neutralizing the others during training. As the information of the protected attribute is restricted in certain dimensions, it can be removed from the embedding easily. By jointly identifying gender-neutral words while learning word vectors, GN-GloVe does not require a separate classifier to identify gender-neutral words; therefore, the error propagation issue is eliminated. The proposed approach is generic and can be incorporated with other word embedding models and be applied in reducing other societal stereotypes.

Our contributions are summarized as follows: 1) To our best knowledge, GN-GloVe is the first method to learn word embeddings with protected attributes; 2) By capturing protected attributes in certain dimensions, our approach ameliorates the interpretability of word representations; 3) Qualitative and quantitative experiments demonstrate that GN-GloVe effectively isolates the protected attributes and preserves the word proximity.

2 Related Work

Word Embeddings Word embeddings serve as a fundamental building block for a broad range of NLP applications (dos Santos and Gatti, 2014; Bahdanau et al., 2014; Zeng et al., 2015) and various approaches (Mikolov et al., 2013b; Pennington et al., 2014; Levy et al., 2015) have been proposed for training the word vectors. Improvements have been made by leveraging semantic lexicons and morphology (Luong et al., 2013; Faruqui et al., 2014), disambiguating multiple senses (Šuster et al., 2016; Arora et al., 2018; Upadhyay et al., 2017), and modeling contextualized information by deep neural networks (Peters et al., 2018). However, none of these works attempts to tackle the problem of stereotypes exhibited in embeddings.

Stereotype Analysis Implicit stereotypes have been observed in applications such as online advertising systems (Sweeney, 2013), web search (Kay et al., 2015), and online reviews (Wallace and Paul, 2016). Besides, Zhao et al. (2017) and Rudinger et al. (2018) show that coreference resolution systems are gender biased. The systems can successfully predict the link between "the president" with male pronoun but fail with the female one. Rudinger et al. (2017) use pointwise mutual information to test the SNLI (Bowman et al., 2015) corpus and demonstrate gender stereotypes as well as varying degrees of racial, religious, and age-based stereotypes in the corpus. A temporal analysis about word embeddings (Garg et al., 2018) captures changes in gender and ethnic stereotypes over time. Researchers attributed such problem partly to the biases in the datasets (Zhao et al., 2017; Yao and Huang, 2017) and word embeddings (Garg et al., 2017; Caliskan et al., 2017) but did not provide constructive solutions.

3 Methodology

In this paper, we take GloVe (Pennington et al., 2014) as the base embedding model and gender as the protected attribute. It is worth noting that our approach is general and can be applied to other embedding models and attributes. Following GloVe (Pennington et al., 2014), we construct a word-to-word co-occurrence matrix X, denoting the frequency of the j-th word appearing in the context of the i-th word as $X_{i,j}$. $w, \tilde{w} \in \mathbb{R}^d$ stand for the embeddings of a center and a context word, respectively, where d is the dimension.

In our embedding model, a word vector w consists of two parts $w = [w^{(a)}; w^{(g)}]$. $w^{(a)} \in \mathbb{R}^{d-k}$ and $w^{(g)} \in \mathbb{R}^k$ stand for neutralized and gendered components respectively, where k is the number of dimensions reserved for gender information.[3] Our proposed gender neutralizing scheme is to reserve the gender feature, known as "protected attribute" into $w^{(g)}$. Therefore, the information encoded in $w^{(a)}$ is independent of gender influence. We use $v_g \in \mathbb{R}^{d-k}$ to denote the direction of gender in the embedding space. We categorize all the vocabulary words into three subsets: male-definition Ω_M, female-definition Ω_F, and gender-neutral Ω_N, based on their definition in WordNet (Miller and Fellbaum, 1998).

Gender Neutral Word Embedding Our minimization objective is designed in accordance with above insights. It contains three components:

$$J = J_G + \lambda_d J_D + \lambda_e J_E, \qquad (1)$$

where λ_d and λ_e are hyper-parameters.

The first component J_G is originated from GloVe (Pennington et al., 2014), which captures the word proximity:

$$J_G = \sum_{i,j=1}^{V} f(X_{i,j}) \left(w_i^T \tilde{w}_j + b_i + \tilde{b}_j - \log X_{i,j} \right)^2 .$$

---

[3] We set $k = 1$ in this paper.

Here $f(X_{i,j})$ is a weighting function to reduce the influence of extremely large co-occurrence frequencies. b and $\tilde{b}$ are the respective linear biases for w and $\tilde{w}$.

The other two terms are aimed to restrict gender information in $w^{(g)}$, such that $w^{(a)}$ is neutral. Given male- and female-definition seed words Ω_M and Ω_F, we consider two distant metrics and form two types of objective functions.

In J_D^{L1}, we directly minimizing the negative distances between words in the two groups:

$$J_D^{L1} = -\left\| \sum_{w \in \Omega_M} w^{(g)} - \sum_{w \in \Omega_F} w^{(g)} \right\|_1 .$$

In J_D^{L2}, we restrict the values of word vectors in $[\beta_1, \beta_2]$ and push $w^{(g)}$ into one of the extremes:

$$J_D^{L2} = \sum_{w \in \Omega_M} \left\| \beta_1 \boldsymbol{e} - w^{(g)} \right\|_2^2 + \sum_{w \in \Omega_F} \left\| \beta_2 \boldsymbol{e} - w^{(g)} \right\|_2^2 ,$$

where $\boldsymbol{e} \in \mathcal{R}^k$ is a vector of all ones. β_1 and β_2 can be arbitrary values, and we set them to be 1 and -1, respectively.

Finally, for words in Ω_N, the last term encourages their $w^{(a)}$ to be retained in the null space of the gender direction v_g:

$$J_E = \sum_{w \in \Omega_N} \left(v_g^T w^{(a)} \right)^2 ,$$

where v_g is estimating on the fly by averaging the differences between female words and their male counterparts in a predefined set,

$$v_g = \frac{1}{|\Omega'|} \sum_{(w_m, w_f) \in \Omega'} (w_m^{(a)} - w_f^{(a)}),$$

where Ω' is a set of predefined gender word pairs.

We use stochastic gradient descent to optimize Eq. (1). To reduce the computational complexity in training the wording embedding, we assume v_g is a fixed vector (i.e., we do not derive gradient w.r.t v_g in updating $w^{(a)}, \forall w \in \Omega'$) and estimate v_g only at the beginning of each epoch.

4 Experiments

In this section, we conduct the following qualitative and quantitative studies: 1) We visualize the embedding space and show that GN-GloVe separates the protected gender attribute from other latent aspects; 2) We measure the ability of GN-GloVe to distinguish between gender-definition words and gender-stereotype words on a newly annotated dataset; 3) We evaluate GN-GloVe on standard word embedding benchmark datasets and show that it performs well in estimating word proximity; 4) We demonstrate that GN-Glove reduces gender bias on a downstream application, coreference resolution.

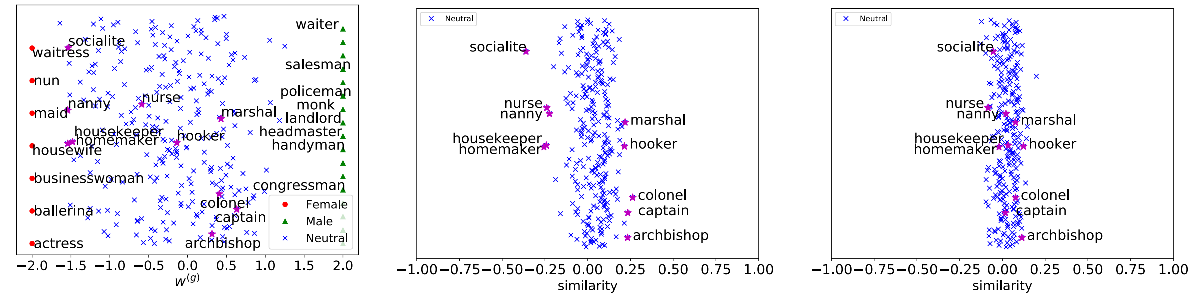
We compare GN-GloVe with two embedding models, GloVe and Hard-GloVe. GloVe is a widely-used model (Pennington et al., 2014), and we apply the post-processing step introduced in (Bolukbasi et al., 2016) to reduce gender bias in GloVe and name it after Hard-GloVe. All the embeddings are trained on *2017 English Wikipedia dump* with the default hyper-parameters decribed in (Pennington et al., 2014). When training GN-GloVe, we constrain the value of each dimension within $[-1, 1]$ to avoid numerical difficulty. We set λ_d and λ_e both to be 0.8. In our preliminary study on development data, we observe that the model is not sensitive to these parameters. Unless other stated, we use J_D^{L1} in the GN-GloVe model.

Separate protected attribute First, we demonstrate that GN-GloVe preserves the gender association (either definitional or stereotypical associations) in $w^{(g)}$[4]. To illustrate the distribution of gender information of different words, we plot Fig. 1a using $w^{(g)}$ for the x-axis and a random value for the y-axis to spread out words in the plot. As shown in the figure, the gender-definition words, e.g. "waiter" and "waitress", fall far away from each other in $w^{(g)}$. In addition, words such as "housekeeper" and "doctor" are inclined to different genders and their $w^{(g)}$ preserves such information.

Next, we demonstrate that GN-GloVe reduces gender stereotype using a list of profession titles from (Bolukbasi et al., 2016). All these profession titles are neutral to gender by definition. In Fig. 1b and Fig. 1c, we plot the cosine similarity between each word vector $w^{(a)}$ and the gender direction v_g (i.e., $\frac{w^T v_g}{\|w\| \|v_g\|}$). Result shows that words, such as "doctor" and "nurse", possess no gender association by definition, but their GloVe word vectors exhibit strong gender stereotype. In contrast, the gender projects of GN-GloVe word vectors $w^{(a)}$ are closer to zero. This demonstrates

---

[4] We follow the original GloVe implementation using the summation of word vector and context vector to represent a word. Therefore, the elements of the word vectors are constrained in [-2, 2]



(a) $w^{(g)}$ dimension for all the professions

(b) Gender-neutral profession words projected to gender direction in GloVe

(c) Gender-neutral profession words projected to gender direction in GN-GloVe

Figure 1: Cosine similarity between the gender direction and the embeddings of gender-neutral words. In each figure, negative values represent a bias towards female, otherwise male.

the gender information has been substantially diminished from $w^{(a)}$ in the GN-GloVe embedding.

We further quantify the gender information exhibited in the embedding models. For each model, we project the word vectors of occupational words into the gender sub-space defined by "he-she" and compute their average size. A larger projection indicates an embedding model is more biased. Results show that the average projection of GloVe is 0.080, the projection of Hard-GloVe is 0.019, and the projection of Gn-Glove is 0.052. Comparing with GloVe, GN-GloVe reduces the bias by 35%. Although Hard-GloVe contains less gender information, we will show later GN-GloVe can tell difference between gender-stereotype and gender-definition words better.

Gender Relational Analogy To study the quality of the gender information present in each model, we follow SemEval 2012 Task2 (Jurgens et al., 2012) to create an analogy dataset, *SemBias*, with the goal to identify the correct analogy of "he - she" from four pairs of words. Each instance in the dataset consists of four word pairs: a gender-definition word pair (Definition; e.g., "waiter - waitress"), a gender-stereotype word pair (Stereotyp; e.g., "doctor - nurse") and two other pairs of words that have similar meanings (None; e.g., "dog - cat", "cup - lid")[5]. We consider 20 gender-stereotype word pairs and 22 gender-definition word pairs and use their Cartesian product to generate 440 instances. Among the 22 gender-definition word pairs, there are 2 word pairs that are not used as a seed word during the training. To test the generalization ability of the model, we generate a subset of data (SemBias (subset)) of 40 instances associated with these 2 pairs.

Dataset	Embeddings	Definition	Stereotype	None
SemBias	GloVe	80.2	10.9	8.9
	Hard-Glove	84.1	6.4	9.5
	GN-GloVe	97.7	1.4	0.9
SemBias (subset)	GloVe	57.5	20	22.5
	Hard-Glove	25	27.5	47.5
	GN-GloVe	75	15	10

Table 1: Percentage of predictions for each category on gender relational analogy task.

Table 1 lists the percentage of times that each class of pair is on the top based on a word embedding model (Mikolov et al., 2013c). GN-GloVe achieves 97.7% accuracy in identifying gender-definition word pairs as an analogy to "he - she". In contrast, GloVe and Hard-GloVe makes significantly more mistakes. On the subset, GN-GloVe also achieves significantly better performance than Hard-Glove and GloVe, indicating that it can generalize the gender pairs on the training set to identify other gender-definition word pairs.

Word Similarity and Analogy In addition, we evaluate the word embeddings on the benchmark tasks to ensure their quality. The word similarity tasks measure how well a word embedding model captures the similarity between words comparing to human annotated rating scores. Embeddings are tested on multiple datasets: WS353-ALL (Finkelstein et al., 2001), RG-65 (Rubenstein and Goodenough, 1965), MTurk-287 (Radinsky et al., 2011), MTurk-771 (Halawi et al., 2012), RW (Luong et al., 2013), and MEN-TR-3k (Bruni et al., 2012)

---

[5] The pair is sampled from the list of word pairs with "SIMILAR: Coordinates" relation annotated in (Jurgens et al., 2012). The original list has 38 pairs. After removing gender-definition word pairs, 29 are left.

Embeddings	Analogy		Similarity					
	Google	MSR	WS353-ALL	RG-65	MTurk-287	MTurk-771	RW	MEN-TR-3k
GloVe	**70.8**	**45.8**	62.0	75.3	64.8	64.9	37.3	72.2
Hard-GloVe	**70.8**	**45.8**	61.2	74.8	64.4	64.8	37.3	72.2
GN-GloVe-L1	68.9	43.7	**62.8**	74.1	66.2	**66.2**	**40.0**	**74.5**
GN-GloVe-L2	68.8	43.6	62.5	**76.4**	**66.8**	65.6	39.3	74.4

Table 2: Results on the benchmark datasets. Performance is measured in accuracy and in Spearman rank correlation for word analogy and word similarity tasks, respectively.

datasets. The analogy tasks are to answer the question "*A* is to *B* as *C* is to _?" by finding a word vector w that is closest to $w_A - w_B + w_C$ in the embedding space. Google (Mikolov et al., 2013a) and MSR (Mikolov et al., 2013c) datasets are utilized for this evaluation. The results are shown in Table 2, where the suffix "-L1" and "-L2" of GN-GloVe stand for the GN-GloVe using J_D^{L1} and J_D^{L2}, respectively. Compared with others, GN-GloVe achieves a higher accuracy in the similarity tasks and its analogy score slightly drops indicating that GN-GloVe is capable of preserving proximity among words.

Coreference Resolution Finally, we investigate how the gender bias in word embeddings affects a downstream application, such as coreference resolution. Coreference resolution aims at clustering the denotative noun phrases referring to the same entity in the given text. We evaluate our models on the Ontonotes 5.0 (Weischedel et al., 2012) benchmark dataset and the WinoBias dataset (Zhao et al., 2018).[6] In particular, the WinoBias dataset is composed of pro-stereotype (PRO) and anti-stereotype (ANTI) subsets. The PRO subset consists of sentences where a gender pronoun refers to a profession, which is dominated by the same gender. Example sentences include "The CEO raised the salary of the receptionist because he is generous." In this sentence, the pronoun "he" refers to "CEO" and this reference is consistent with societal stereotype. The ANTI subset contains the same set of sentences, but the gender pronoun in each sentence is replaced by the opposite gender. For instance, the gender pronoun "he" is replaced by "she" in the aforementioned example. Despite the sentence is almost identical, the gender pronoun now refers to a profession that is less represented by the gender. Details about the dataset are in (Zhao et al., 2018).

Embeddings	OntoNotes-test	PRO	ANTI	Avg	Diff
GloVe	66.5	76.2	46.0	61.1	30.2
Hard-Glove	66.2	70.6	54.9	62.8	15.7
GN-GloVe	66.2	72.4	51.9	62.2	20.5
GN-GloVe(w_a)	65.9	70.0	53.9	62.0	16.1

Table 3: F1 score (%) on the coreference system.

We train the end-to-end coreference resolution model (Lee et al., 2017) with different word embeddings on OntoNote and report their performance in Table 3. For the WinoBias dataset, we also report the average (Avg) and absolute difference (Diff) of F1 scores on two subsets. A smaller Diff value indicates less bias in a system. Results show that GN-GloVe achieves comparable performance as Glove and Hard-GloVe on the OntoNotes dataset while distinctly reducing the bias on the WinoBias dataset. When only the $w^{(a)}$ potion of the embedding is used in representing words, GN-GloVe($w^{(a)}$) further reduces the bias in coreference resolution.

5 Conclusion and Discussion

In this paper, we introduced an algorithm for training gender-neutral word embedding. Our method is general and can be applied in any language as long as a list of gender definitional words is provided as seed words (e.g., gender pronouns). Future directions include extending the proposed approach to model other properties of words such as sentiment and generalizing our analysis beyond binary gender.

Abstract

We introduce a weakly supervised approach for inferring the property of abstractness of words and expressions in the complete absence of labeled data. Exploiting only minimal linguistic clues and the contextual usage of a concept as manifested in textual data, we train sufficiently powerful classifiers, obtaining high correlation with human labels. The results imply the applicability of this approach to additional properties of concepts, additional languages, and resource-scarce scenarios.

1 Introduction

During the last decades, the influence of psycholinguistic properties of words on cognitive processes has become a major topic of scientific inquiry. Among the most studied psycholinguistic attributes are concreteness, familiarity, imagery, and average age of acquisition. *Abstractness* (the opposite of concreteness) quantifies the degree to which an expression denotes an entity that can be directly perceived by human senses.

Word abstractness ratings were first collected by Spreen and Schulz (1966) and Paivio et al. (1968), and made available in the MRC database (Coltheart, 1981) for 4,292 English words. Since its release, this database has stimulated research in a wide range of linguistic tasks, as well as artificial intelligence and cognitive studies. Despite their evident usefulness, resources providing abstractness ratings are relatively rare and of limited size. Here, we address the task of *automatically* inferring the abstractness rating of a concept by applying a *weakly supervised* approach that exploits minimal linguistic clues.

Studies on derivational morphological processes indicate that word meaning is often entailed by its morphology. As an example, word suffixation by *-ant* or *-ent* is used to denote a person, as in *assistant*, while the suffix *-hood* yields nouns meaning "condition of being", as in *childhood*. A wide range of word-formation processes was described by Huddleston and Pullum (2002); in particular, the authors detail categories of suffixes that are used to derive words, broadly perceived as abstract, e.g., *-ism* as in *feminism*, or *-ness* as in *agreeableness*.

Concept abstractness indicators are also likely to be manifested in its contextual usage. Consider the two sentences below, each embedding abstract and concrete words – one describing *feminism* and the other *screwdriver* – respectively:

> *Second- and third-wave* ***feminism*** *in China involved a reexamination of women's roles during the communist revolution and other reform movements, and new discussions about whether women's equality has been fully achieved.*

> *Many* ***screwdriver*** *handles are not smooth and often not round, but have bumps or other irregularities to improve grip and to prevent the tool from rolling when on a flat surface.*

We hypothesize that the immediate neighborhood of a word as reflected in embedding sentences captures the signal of abstractness. In the examples above, several potential clues for the degree of word abstractness are underlined.

Correspondingly, we propose a method for inferring the degree of abstractness of concepts in the complete absence of labeled data, by exploiting (1) a minimal set of morphological word-formation clues; and (2) a text corpus for learning the context in which words tend to appear.

We demonstrate that this method allows us to infer the abstractness ratings of unigram, bigram and trigram Wikipedia concepts (titles) – the task that, to the best of our knowledge, was only addressed through manual labeling so far (Brysbaert et al., 2014). The main contribution of this work is, therefore, in the proposal and evaluation of a

Brussels, Belgium, October 31 - November 4, 2018.

weakly supervised methodology for inferring the abstractness rating of concepts, potentially applicable to additional languages. The suggested approach may also be applicable for predicting other word and concept properties, when those are manifested in both morphology and context. Finally, we release a dataset of 300K Wikipedia concepts automatically rated for their degree of abstractness, and additional 1500 unigram, bigram and trigram concepts annotated with both manual and predicted scores.[1]

2 Related work

A large body of research addressed the relations of word abstractness and cognitive processes (Connell and Lynott, 2012; Gianico-Relyea and Altarriba, 2012; Oliveira et al., 2013; Nishiyama, 2013; Paivio, 2013; Barber et al., 2013). Computational investigation of word abstractness and concreteness has been a prolific field of recent research, laying out an empirical foundation for the theoretically motivated hypotheses on the characteristics of these properties. A ranker trained on psycholinguistic features extracted from the MRC database (in combination with other features) reached first place in the English Lexical Simplification task at SemEval 2012 (Jauhar and Specia, 2012). Hill and Korhonen (2014) achieved state-of-the-art performance in Semantic Composition and Semantic Modification prediction by including concreteness in the set of features used by the model.

Along the years, several works extended the seed MRC dataset by employing various *supervised* machine learning techniques, further utilizing the extended dataset for tasks of lexical simplification (Paetzold and Specia, 2016b,a), cross-lingual metaphor detection (Tsvetkov et al., 2013), literal and metaphorical sense identification (Turney et al., 2011), as well as readability assessment of Brazilian Portuguese (dos Santos et al., 2017). Feng et al. (2011) exploited word attributes from WordNet, properties extracted from the CELEX database, and Latent Semantic Analysis over a large text corpus for building a linear regression model predicting abstractness rate; the model accounted for 64% variance of human annotations.

A comprehensive survey of psycholinguistic and memory research on word concreteness is presented in Brysbaert et al. (2014) (BWK), who conducted a large-scale manual annotation of concreteness ratings for over 40K concepts, further used by Rothe et al. (2016) to infer concreteness ratings for the whole Google News lexicon. To the best of our knowledge, our work is the first attempt to automatically infer the property of concept abstractness in the complete absence of labeled data.

3 Predicting concept abstractness

3.1 Abstractness indicators

Nominalization is a word-formation process that involves the formation of nouns from bases of other classes by means of affixation. As an example, a derivational suffix can be added to an adjective (capable+*ity* for *capability*) or a verb (react+*tion* for *reaction*) to create a noun. Various word-formation processes often enrich words with meaning associated with certain semantic grouping. Huddleston and Pullum (2002) detail nominalization processes that serve to form nouns denoting a “state” or “condition of being”, which in turn are broadly associated with abstractness. As such, the suffixes *-ety, -ity* and *-ness* carry over the general meaning of “quality or state of being” and the suffix *-ism* is used to form nouns denoting a range of doctrines, beliefs and movements (Huddleston and Pullum, 2002). Additional suffixes that tend to form English nouns with high degree of abstractness include *-ance, -ence, -ation, -ution, -dom, -hood, -ship* and *-y*.

3.2 Dataset

We used the English Wikipedia[2] article titles as a proxy for retrieving frequently used single- and multi-word expressions, thereby associating over 5M Wikipedia titles with concepts.

Training data We chose two abstractness signals, manifested by the suffixes *-ism* and *-ness*, representing different types of abstract meanings. We extracted 1,040 potentially abstract unigram Wikipedia titles suffixed by either of the two (the positive class). The – admittedly noisy – concrete (negative) class was generated by randomly selecting the same number of unigram concepts from the complementary set of titles.In both cases, we set a threshold[3] on the frequency of a concept in the

---

[1] The datasets are available for download at `https://www.research.ibm.com/haifa/dept/vst/debating_data.shtml`

[2] We used the Wikipedia May 2017 dump.

[3] The minimum of 20 occurrences for a concept.

corpus, and filtered out non-alphabetic unigrams and unigrams containing special characters. We assessed the quality of the positive and negative weakly-labeled training unigrams by manual annotation of their level of abstractness, obtaining abstractness prior of 93% in the set of presumably abstract concepts, and concreteness prior of 81% for the opposite class.

Given this set of weakly-labeled positive and negative concepts, we randomly selected a set of Wikipedia sentences that include any of these concepts (equally split by positive and negative unigrams), to be used in the training phase, while limiting sentence length to the range of 10 to 70 tokens. This step resulted in about 400K train sentences in each class, 800K in total. The final preprocessing phase involved masking a sentence concept with a generic token, aiming to prevent the classifier from training on the concept itself, and instead training on its contextual usage.

Evaluation data A randomly selected set of 1500 Wikpedia concepts (with the minimum of 500 occurrences per concept), split equally between unigrams, bigrams and trigrams, and distinct from the training set, was used for testing prediction. We henceforth refer to this set of concepts as the *evaluation set*. Each of these concepts was manually annotated for abstractness on the 1–7 scale by seven in-house labelers, using an adaptation of the guidelines by Spreen and Schulz (1966) to the multi-word scenario:

> *Words or phrases may refer to persons, places and things that can be seen, heard, felt, smelled or tasted or to more abstract concepts that cannot be experienced by our senses. The purpose of this task is to rate a list of concepts with respect to "concreteness" in terms of sense-experience. Any expression that refers to objects, materials or persons should receive a high concreteness rating; any expression that refers to an abstract concept that cannot be experienced by the senses should receive a low concreteness rating. Concrete concepts typically have physical or concrete existence, while abstract do not. Think of the concepts "onion" and "nationalism" – "onion" can be experienced by our senses and therefore should be rated as concrete (1); "nationalism" cannot be experienced by the senses as such and therefore should be rated as abstract (7).*

Word polysemy is a common challenge in tasks related to lexical semantics. As such, our perception of the concreteness rate of the concept *bank* may vary depending on whether a financial institution or a river bank is concerned. While we could not avoid this issue altogether (since working with pre-trained word representations that do not carry disambiguation information), we ensured that all in-house labelers annotated the same word sense by providing them with Wikipedia definition of the most frequent sense of a concept.

The final abstractness score was computed as the average over individual annotations. The average pairwise weighted Kappa agreement[4] on the entire set of 1500 concepts was 0.65.

3.3 Classification models

We hypothesize that words that share similar degree of abstractness tend to share certain similarities in their contextual usage; that, in contrast to concepts that exhibit opposite abstractness rate. Indeed, a statistical significance test applied to the (weak) positive and negative training data (Section 3.2) reveals markers such as {*parish, movement, century, spiritual, life, doctrine, nature, regime*} sharing excessive frequency in sentences containing abstract concepts. The very essence of this phenomenon is captured by distributed word representations (Mikolov et al., 2013; Pennington et al., 2014), a.k.a. word embeddings, learned based on the contextual usage of words. We therefore trained three classifiers, each exploiting different language properties, as described below.

Naive Bayes (NB) Using solely word counts in textual data, we used a simple probabilistic Naive Bayes classifier, with a bag-of-words feature set extracted from the 800K sentences containing positive and negative training concepts. Given a sentence containing a test concept, its degree of abstractness was defined as the posterior probability assigned by the classifier. Aiming at robust classification, we retrieved 500 sentences containing each test concept from the corpus. Consequently, the final abstractness score of a concept was calculated by averaging the predictions assigned by the classifier to individual sentences.

Nearest neighbor We used the nearest neighbors algorithm, specifically, its *radius-based* version (NN-RAD), using the pre-trained GloVe embeddings (Pennington et al., 2014). This classifier

---

[4] We used the implementation in `http://scikit-learn.org`, with "quadratic" scheme.

estimates the degree of concept abstractness given only its distributional representation.

The abstractness score of a test concept was computed by the ratio of its abstract neighbors to the total number of concepts within the predefined radius, where the entire set of neighbors is limited to the concepts in the weakly-labeled training set. The proximity threshold (radius) was set to 0.25, w.r.t. the cosine similarity between two embedding vectors.[5] Multi-word concepts were subject to more careful processing, where the classifier computed a multi-word concept representation as an average of representations of its individual words, and further estimated the abstractness score of the obtained embedding. In case that one of a concept constituents was not found in embeddings, we excluded the concept from computation.

RNN Aiming at exploiting both embeddings and textual data, we utilized a bidirectional recurrent neural network (RNN) with one layer of forward and backward LSTM cells. Each cell has width of 128, and is wrapped by a dropout wrapper with keep probability 0.85. An attention layer was created in order to weigh words according to their proximity to the train/test concept. The output of the LSTM cells is passed to the attention layer which reduces it to the size of 100. The output of the attention layer is passed to a fully connected layer which produces the final prediction of the abstractness level of a concept. GloVe embeddings with 300 dimensions were used as word representations. Given a set of sentences containing a test concept, its final abstractness score was computed by applying the averaging procedure described for the Naive Bayes classifier.

4 Results

We demonstrate that trained models discover linguistic patterns associated with abstract meaning (beyond those known at training), and furthermore yield abstractness scores that correlate significantly with human annotations.

4.1 Revealing abstractness markers

We automatically scored 100K unigram Wikipedia concepts for abstractness with all classifiers and extracted the set of suffixes that share excessive frequency in the top-k abstract concepts using the statistical proportion test. More specifically, we applied the test to the exhaustive list of all three-character English suffixes (e.g., *-aaa, -aab*), counting their occurrences in the subset of concepts with the highest abstractness scores[6] (the population under test) and in the remainder (the background). Our hypothesis was that suffixes associated with abstract meaning in the literature will be over-represented in the population of concepts ranked as abstract by the classifiers. The top-10 suffixes, scored by their statistical significance p-value[7] were {***-ism***, *-ity, -ion, -sis, -ics,* ***-ess***, *-phy, -nce, -ogy, -ing*} – suffixes broadly associated with abstractness in the literature (where all suffixes but two are distinct from the training data). The underlying concept examples included {*illegalism, modernity, antireligion, henosis, politics, lawlessness, ecosophy, conscience, ideology, enabling*} – words broadly perceived as abstract.

4.2 Abstractness rating

Table 1 presents a few examples of abstract and concrete concepts, as identified by manual annotation, along with their abstractness score as predicted by the RNN classifier (Section 3.3).

abstract		concrete	
concept	score	concept	score
marxism	0.972	plywood	0.000
islamophobia	0.969	Wiltshire	0.000
affirmative action	0.844	moonlight	0.058
absolute monarchy	0.842	convoy	0.112
sincerity	0.836	gadget	0.120

Table 1: Examples of concepts found as abstract/concrete (above/below the average score of 0.5) via manual annotation, along with their score as predicted by RNN.

Table 2 presents the Pearson correlation between the abstractness scores as assigned by the classifiers and the manual annotations over the evaluation set. We also present the correlation of scores produced by our classifiers to the set of Wikipedia concepts from the manually annotated MRC database (MRC-seed, Section 1), and to the set of 5883 noun concepts[8] from manually annotated BWK dataset (Brysbaert et al., 2014).

Evidently, the best results are obtained by the RNN classifier, yielding up to 0.740 correlation

---

[5] The radius was tuned on the set of 500 unigrams.

[6] We used the set of 18% highest ranked concepts – the fraction of abstract concepts in a sample population, as estimated by manual labeling.

[7] In all cases the obtained p-value was practically zero.

[8] Only concepts that can be mapped to a corresponding Wikipedia page were considered.

test set	Naive Bayes	NN-RAD	RNN
BWK	**0.657**	0.622	0.634
MRC-seed	**0.674**	0.576	0.669
1-grams	0.679	0.638	**0.740**
2-grams	0.565	0.515	**0.666**
3-grams	0.412	0.467	**0.490**

Table 2: Correlation of abstractness scores assigned by the classifiers to manual annotations.

with human annotations. Notably, the simple Naive Bayes, utilizing only textual data, yields results of reasonable quality; the broad implication of this outcome lies in the potential applicability of this approach to resource-scarce scenarios where high quality word embeddings are not available. Interestingly, while using Google word2vec embeddings (instead of Glove) yielded similar results, utilizing fastText pre-trained representations (Joulin et al., 2016) obtained more accurate ranking, e.g., the NN-RAD classifier yielded correlation of 0.688 for the BWK dataset, compared to 0.622 obtained using Glove (Table 2). We attribute this improvement to the fact that fastText embeddings better capture morphological word properties and cover more extensive vocabulary.

The relatively low correlation obtained with trigram concepts can be explained by the inherent complexity introduced by the multi-word scenario, challenging still further the subjective human perception of abstractness. While inter-labeler agreement for unigrams and bigrams was 0.72 and 0.66, respectively, it only reached 0.54 for trigrams, supporting the aforementioned hypothesis.

4.3 Varying the size of a test set

How many sentences containing a test concept suffice for a reliable prediction? We address this question by limiting the number of (randomly chosen) sentences used for rating. While the correlation obtained by RNN with 500 sentences containing a test concept reached 0.740 (Table 2), as little as 10, and even 5 sentences yielded correlation of 0.706 and 0.675, respectively, implying the efficiency and effectiveness of the presented approach in the availability of only little data. The plot in Figure 1 presents the correlation of the RNN and NB classifiers to label as function of number of (randomly sampled) sentences used for evaluation. Each such experiment (e.g., using 1, 5, 10 sentences) was averaged over 50 runs; the average correlation to label, as well as standard deviation, are plotted on the chart. The constant correlation yield by the (text-independent) NN-RAD algorithm is illustrated by the vertical line.

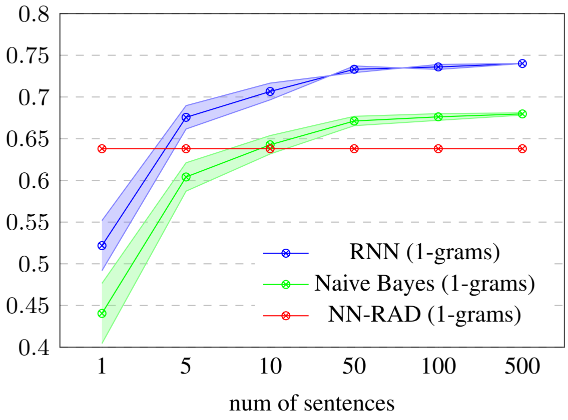

Figure 1: Average correlation (and standard deviation) to manual annotation as function of number of sentences used for evaluation.

4.4 Comparison to supervised models

Tsvetkov et al. (2013) used supervised learning algorithm to propagate abstractness scores to words using pre-trained word representations. Utilizing vector elements as features, they trained a supervised classifier, and predicted the degree of abstractness for unseen words. Abstractness rankings from the MRC database were used as a training set, and the classifier predictions were binarized into abstract-concrete boolean indicators using predefined thresholds. The authors obtained 94% accuracy when tested on held-out data.

5 Conclusions

We presented a weakly supervised approach for inferring the degree of concept abstractness. Our results demonstrate that a minimal morphological signal and a textual corpus are sufficient to train classifiers that yield relatively accurate predictions, that in turn can be used to unravel additional linguistic patterns indicative of the same property. Our future plans include exploring the value of the proposed methodology with other languages and additional properties.

Word Sense Induction with Neural biLM and Symmetric Patterns

Asaf Amrami † and **Yoav Goldberg** † ‡

Abstract

An established method for Word Sense Induction (WSI) uses a language model to predict probable substitutes for target words, and induces senses by clustering these resulting substitute vectors.

We replace the ngram-based language model (LM) with a recurrent one. Beyond being more accurate, the use of the recurrent LM allows us to effectively query it in a creative way, using what we call *dynamic symmetric patterns*. The combination of the RNN-LM and the dynamic symmetric patterns results in strong substitute vectors for WSI, allowing to surpass the current state-of-the-art on the SemEval 2013 WSI shared task by a large margin.

1 Introduction

We deal with the problem of *word sense induction* (WSI): given a target lemma and a collection of within-sentence usages it, cluster the usages (**instances**) according to the different senses of the target lemma. For example, for the sentences:

(a) We spotted a large ***bass*** in the ocean.

(b) The ***bass*** player did not receive the acknowledgment she deserves.

(c) The black sea ***bass***, is a member of the wreckfish family.

We would like to cluster (a) and (c) in one group and (b) in another.[1] Note that some mentions are ambiguous. For example, (d) matches both the music and the fish senses:

(d) ***Bass*** scales are the worst.

This calls for a *soft clustering*, allowing to probabilistically associate a given mention to two senses.

The problem of WSI has been extensively studied with a series of shared tasks on the topic (Agirre and Soroa, 2007; Manandhar et al., 2010; Jurgens and Klapaftis, 2013), the latest being SemEval 2013 Task 13 (Jurgens and Klapaftis, 2013). Recent state-of-the-art approaches to WSI rely on generative graphical models (Lau et al., 2013; Wang et al., 2015; Komninos and Manandhar, 2016). In these works, the sense is modeled as a latent variable that influences the context of the target word. The later models explicitly differentiate between local (syntactic, close to the disambiguated word) and global (thematic, semantic) context features.

Substitute Vectors Baskaya et al. (2013) take a different approach to the problem, based on *substitute vectors*. They represent each instance as a distribution of possible substitute words, as determined by a language model (LM). The substitute vectors are then clustered to obtain senses.

Baskaya et al. (2013) derive their probabilities from a 4-gram language model. Their system (AI-KU) was one of the best performing at the time of SemEval 2013 shared task. Our method is inspired by the AI-KU use of substitution based sense induction, but deviate from it by moving to a recurrent language model. Besides being more accurate, this allows us to further improve the quality of the derived substitutions by the incorporation of *dynamic symmetric patterns.*

BiLM Bidirectional RNNs were shown to be effective for word-sense disambiguation and lexical substitution tasks (Melamud et al., 2016; Yuan et al., 2016; Raganato et al., 2017). We adopt the

---

[1] This example shows *homonymy*, a case where the same word form has two distinct meaning. A more subtle case is *polysemy*, where the senses share some semantic similarity. In "She played a low bass note", the sense of *bass* is related to the sense in (b), but distinct from it. The WSI task we tackle in this work deals with both cases.

Brussels, Belgium, October 31 - November 4, 2018.

ELMo biLM model of Peters et al. (2018), which was shown to produce very competitive results for many NLP tasks. We use the pre-trained ELMo biLM provided by Peters et al. (2018).[2] However, rather than using the LSTM state vectors as suggested in the ELMo paper, we opt instead to use the predicted word probabilities. Moving from continuous and opaque state vectors to discrete and transparent word distributions allows far better control of the resulting representations (e.g. by sampling, re-weighting and lemmatizing the words) as well as better debugging opportunities.

As expected, the move to the neural biLM already outperforms the AI-KU system, and matches the previous state-of-the-art. However, we observe that the substitute vectors do not take into account the disambiguated word itself. We find that this often results in noisy substitutions. As a motivating example, consider the sentence "the doctor recommends *oranges* for your health". Here, *running* is a perfectly good substitution, as the "fruitness" of the target word itself isn't represented in the context. We would like the substitutes word distribution representing the target word to take both kinds of information—the context as well as the target word—into account.

Dynamic Symmetric Patterns Our main proposal incorporates such information. It is motivated by Hearst patterns (Hearst, 1992; Widdows and Dorow, 2002; Schwartz et al., 2015), and made possible by neural LMs. Neural LMs are better in capturing long-range dependencies, and can handle and predict unseen text by generalizing from similar contexts. Conjunctions, and in particular the word *and*, are known to combine expressions of the same kind. Recently, Schwartz et al. (2015) used conjunctive symmetric patterns to derive word embeddings that excel at capturing word similarity. Similarly, Kozareva et al. (2008) search for doubly-anchored patterns including the word *and* in a large web-corpus to improve semantic-class induction. The method of Schwartz et al. (2015) result in context-independent embeddings, while that of Kozareva et al. (2008) takes some context into account but is restricted to exact corpus matches and thus suffers a lot from sparsity.

We make use of the rich sequence representation capabilities of the neural biLM to derive *context-dependent symmetric pattern substitutions*. Relying on the generalization properties of neural language models and the abundance of the "X and Y" pattern, we present the language model with a dynamically created incomplete pattern, and ask it to predict probable completion candidates. Rather than predicting the word distribution following *the doctor recommends* __, we instead predict the distribution following *the doctor recommends oranges and* __. This provides substantial improvement, resulting in state-of-the-art performance on the SemEval 2013 shared task.

The code for reproducing the experiments and our analyses is available at `https://github.com/asafamr/SymPatternWSI`.

2 Method

Given a target word (lemma and its part-of-speech pair), together with several sentences in which the target word is used (instances), our goal is to cluster the word usages such that each cluster corresponds to a different sense of the target word. Following the SemEval 2013 shared task and motivating example (d) from the introduction, we seek a soft (probabilistic) clustering, in which each word instance is assigned with a probability of belonging to each of the sense-clusters.

Our algorithm works in three stages: (1) We first associate each instance with a probability distribution over in-context word-substitutes. This probability distribution is based on a neural biLM (section 2.1). (2) We associate each instance with k representatives, each containing multiple samples from its associated word distributions (section 2.3). (3) Finally, we cluster the representatives and use the hard clustering to derive a soft-clustering over the instances (section 2.4).

We use the pre-trained neural biLM as a black-box, but use linguistically motivated processing of both its input and its output: we rely on the generalization power of the biLM and query it using *dynamic symmetric patterns* (section 2.2); and we lemmatize the resulting word distributions.

Running example In what follows, we demonstrate the algorithm using a running example of inducing senses from the word *sound*, focusing on the instance sentence:

*I liked the **sound** of the harpsichord.*

2.1 biLM Derived Substitutions

We follow the ELMo biLM approach (Peters et al., 2018) and consider two separately trained

---

[2] We thank the ELMo team for sharing the pre-trained models.

language models, a forward model trained for predicting $p_{\rightarrow}(w_i|w_1, ..., w_{i-1})$ and a backward model $p_{\leftarrow}(w_i|w_n, ..., w_{i+1})$. Rather than combining the two models' predictions into a single distribution, we simply associate the target word with two distributions, one from $p_{\rightarrow}$ and one from $p_{\leftarrow}$. For convenience, we use $LM_{\rightarrow}(w_1 w_2 ... w_{i-1}\_\_)$ to denote the distribution $p_{\rightarrow}(w_i|w_1, ..., w_{i-1})$ and $LM_{\leftarrow}(\_\_w_{i+1} w_{i+2} ... w_n)$ to denote $p_{\leftarrow}(w_i|w_n, ..., w_{i+1})$.

Context-based substitution In the purely context-based setup (the one used in the AI-KU system) we represent the target word *sounds* by the two distributions:

$LM_{\rightarrow}$(`<s>` I liked the __)
$LM_{\leftarrow}$(__ of the harpsichord `</s>`)

The resulting top predictions from each distribution are:
{*idea:0.12, fact:0.07, article: 0.05, guy: 0.04, concept: 0.02*} and
{*sounds:0.04, version: 0.03, rhythm: 0.03, strings: 0.03, piece: 0.02*} respectively.

2.2 Dynamic Symmetric Patterns

As discussed in the introduction, conditioning solely on context is ignoring valuable information. This is evident in the resulting word distributions. We use the coordinative symmetric pattern *X and Y* in order to produce a substitutes vector incorporating both the word and its context. Concretely, we represent a target word w_i by $p_{\rightarrow}(w'|w_1, ..., w_i, \texttt{and})$ and $p_{\leftarrow}(w'|w_n, ..., w_i, \texttt{and})$. For our running example, this translates to:

$LM_{\rightarrow}$(`<s>` I liked the sound and __)
$LM_{\leftarrow}$(__ and sound of the harpsichord . `</s>`)

with resulting top words: {*feel: 0.15, felt: 0.11, thought: 0.07, smell: 0.06, sounds: 0.05*} and {*sight: 0.16, sounds: 0.11, rhythm: 0.04, tone: 0.03, noise: 0.03*}.

The distributions predicted using the *and* pattern exhibit a much nicer behavior, and incorporate global context (resulting in sensing related substitutes) as well as local and syntactic information that resulting from the target word itself. Table 1 compares the context-only and symmetric-pattern substitutes for two senses of the word *sound*.

2.3 Representative Generation

To perform fuzzy clustering, we follow AI-KU and associate each instance with k representatives, but deviate in the way the representatives are generated. Specifically, each representative is a set of size 2ℓ , containing ℓ samples from the forward distribution and ℓ samples from the backward distribution. In the symmetric pattern case above, a plausible representative, assuming $\ell = 2$, would be: {*feel, sounds, sight, rhythm*} where two words were predicted by each side LM. In this work, we use $\ell = 4$ and $k = 20$.

2.4 Sense Clustering

After obtaining k representatives for each of the n word instances, we cluster the nk representatives into distinct senses and translate this hard-clustering of representatives into a probabilistic clustering of the originating instances.

Hard-clustering of representatives Let V be the vocabulary obtained from all the representatives. We associate each representative with a sparse $|V|$ dimensional bag-of-features vector, and arrange the representatives into a $nk \times |V|$ matrix M where each row corresponds to a representative. We now cluster M's rows into senses. We found it is beneficial to transform the matrix using TF-IDF. Treating each representative as a document, TF-IDF reduces the weight of uninformative words shared by many representatives. We use agglomerative clustering (cosine distance, average linkage) and induce a fixed number of clusters.[3] We use `sklearn` (Pedregosa et al., 2011) for both TF-IDF weighting and clustering.

Inducing soft clustering over instances After clustering the representatives, we induce a soft-clustering over the instances by associating each instance j to sense i based on the proportion of representatives of j that are assigned to cluster i.

2.5 Additional Processing

Lemmatization The WSI task is defined over lemmas, and some target words have morphological variability within a sense. This is especially common with verb tenses, e.g., "I **booked** a flight" and "I am **booking** a flight". As the conjunctive

---

[3] In this work, we use 7 clusters, which roughly matches the number of senses for each target word in the corpus. Dynamically selecting the number of clusters is left for future work. The effect of changing the number of clusters is explored in the supplementary material.

Context Only		Symmetric Pattern	
Forward dist.	Backward dist.	Forward dist.	Backward dist.
This is a ***sound*** idea, I like it.			
sad 0.02	bad 0.12	welcome 0.09	funny 0.10
great 0.02	good 0.09	practical 0.03	beautiful 0.05
huge 0.02	great 0.06	comprehensive 0.03	fun 0.04
very 0.02	wonderful 0.05	light 0.02	simple 0.04
lesson 0.02	nice 0.04	balanced 0.02	interesting 0.03
I liked the ***sound*** of the harpsichord			
idea 0.12	sounds 0.04	feel 0.15	sight 0.16
fact 0.07	version 0.03	felt 0.11	sounds 0.11
article 0.05	rhythm 0.03	thought 0.07	rhythm 0.04
guy 0.04	strings 0.03	smell 0.06	tone 0.03
concept 0.02	piece 0.03	sounds 0.05	noise 0.03

Table 1: Predicted substitutes for two senses of sound, for context-only and the symmetric-pattern approaches.

symmetric pattern favors morphologically-similar words, the resulting substitute vectors for these two sentences will differ, each of them agreeing with the tense of its source instance. To deal with this, we lemmatize the predictions made by the language model prior to adding them to the representatives. Such removal of morphological inflection is straightforward when using the word distributions but much less trivial when using raw LM state vectors, further motivating our choice of working with the word distributions. The substantial importance of the lemmatization is explored in the ablation experiments in the next section, as well as in the supplementary material.

Distribution cutoff and bias Low ranked LM prediction tend to become noisier. We thus consider only the top 50 word predicted by each LM, re-normalizing their probabilities to sum to one. Additionally, we ignore the final bias vector during prediction (words are predicted via $softmax(Wx)$ rather than $softmax(Wx + b)$). This removes unconditionally probable (frequent) words from the top LM predictions.

3 Experiments and Results

We evaluate our method on the SemEval 2013 Task 13 dataset (Jurgens and Klapaftis, 2013), containing 50 ambiguous words each with roughly 100 in-sentence instances, where each instance is soft-labeled with one or more WordNet senses.

Experiment Protocol Due to the stochastic nature of the algorithm, we repeat each experiment 30 times and report the mean scores together with the standard deviation.

Evaluation metrics We follow previous work (Wang et al., 2015; Komninos and Manandhar, 2016) and evaluate on two measures: ***Fuzzy Normalized Mutual Information (FNMI)*** and ***Fuzzy B-Cubed (FBC)*** as well as their geometric mean (**AVG**).

Systems We compare against three graphical-model based systems which, as far as we know, represent the current state of the art: **MCC-S** (Komninos and Manandhar, 2016), **Sense-Topic** (Wang et al., 2015) and **unimelb** (Lau et al., 2013). We also compare against the **AI-KU** system. Wang et al. also present a method for dataset enrichment that boosted their model performance. We didn't use the suggested methods and compare ourselves to the vanilla settings, but report the enrichment numbers as well.

Results Table 2 summarizes the results. Our system using symmetric patterns outperforms all other setups with an AVG score of 25.4, establishing a new state-of-the-art on the task.

Ablation and analysis We perform ablations to explore the contribution of the different components (Symmetric Patterns (SP), Lemmatization (LEM) and TF-IDF re-weighting). Figure (1) shows the results for the entire dataset (ALL, top), as well as broken-down by part-of-speech. All components are beneficial and are needed for obtaining the best performance in all cases. However, their relative importance differs across parts-of-speech. Adjectives gain the most from the use of the dynamic symmetric patterns, while nouns gain the least. For verbs, the lemmatization is

Model	FNMI	FBC	AVG
Original task dataset			
Ours	**11.26** ± 0.48	57.49 ± 0.23	**25.43** ± 0.48
MCC-S	7.62	55.6	20.58
Sense-Topic (SW)	7.14	55.4	19.89
Sense-Topic	6.96	53.5	19.30
AI-KU	6.5	39.0	15.92
unimelb	6.0	48.3	17.02
With data enrichment			
Sense-Topic (AAC)	9.39	**59.1**	23.56
Sense-Topic (AUC)	9.74	54.5	23.04

Table 2: Evaluation Results on the SemEval 2013 Task 13 Dataset. SW: Embeddings similarity based feature weighting. AAC: Extending instance sentences from their traced source. AUC: Adding similar sentences from the dataset originating corpus. We report our mean scores over 30 runs ± standard deviation

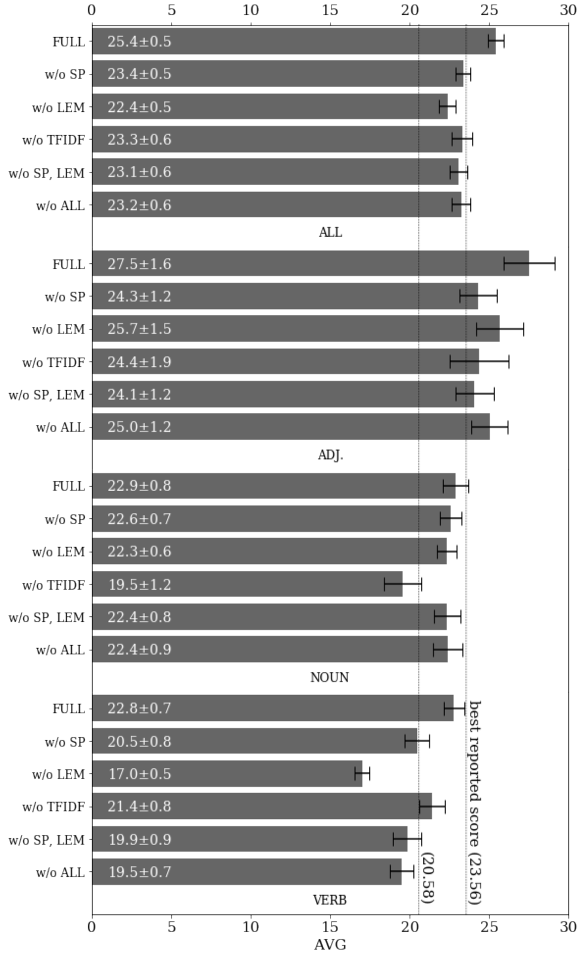

Figure 1: Ablation break down by part of speech, each part of speech was averaged across run. Bars are mean of means and error bars are standard deviations.

crucial for obtaining good performance, especially when symmetric patterns are used: using symmetric patterns without lemmatization, the mean score drops to 17.0. Lemmatization without symmetric patterns achieves a higher mean score of 20.5, while using both yields 22.8. Finally, for nouns it is the TF-IDF scoring that plays the biggest role.

4 Conclusions

We describe a simple and effective WSI method based on a neural biLM and a novel dynamic application of the *X and Y* symmetric pattern. The method substantially improves on the state-of-the-art. Our results provide further validation that RNN-based language models contain valuable semantic information.

The main novelty in our proposal is querying the neural LM in a creative way, in what we call *dynamic symmetric patterns*. We believe that the use of such dynamic symmetric patterns (or more generally *dynamic Hearst patterns*) will be beneficial to NLP tasks beyond WSI.

In contrast to previous work, we used discrete predicted word distributions rather than the continuous RNN states. This paid off by allowing us to inspect and debug the representation, as well to control it in a meaningful way by injecting linguistic knowledge in the form of lemmatization, and by distributional cutoff and TF-IDF re-weighing. We encourage others to consider using explicit, discrete representations when appropriate.

Supplementary Material

Statistics of the SemEval 2013 Task 13 Dataset

SemEval 2013 Task 13 consists of 50 targets, each has a lemma and a part of speech (20 verbs, 20 nouns and 10 adjectives). We use the dataset only for evaluation. Most targets have around 100 labeled instances (sentences containing a usage of the target in its designated part of speech together with one or more WordNet senses assigned by human labeler). Exceptions are the targets of trace.n and book.v which have 37 and 22 labeled instances accordingly. Leaving out the two anomalous targets mentioned above we are left with 4605 instances from 48 targets: 19 verb, 19 noun and 10 adjective targets. We note that the small size of the dataset should make one cautious to draw quick conclusions, yet, our results seem to be consistent.

Effect of the Choice of Number of Clusters

An important statistic of the dataset is the number of senses per target. The average number of senses per target in the dataset is 6.94 (stdev:2.71). Breaking down by part of speech, the means and standard deviations of target senses are: verbs: 5.90 (±1.37), nouns: 7.32 (±2.21), adjectives: 7.11 (±3.54). In this work we follow this statistic and always look for 7 clusters. Figure 2 shows the accuracy as a function of the number of clusters. While 7 clusters indeed produces the highest scores, all numbers in the range 4 to 15 produce state-of-the-art results. We leave the selection of per-instance number of clusters to future work.

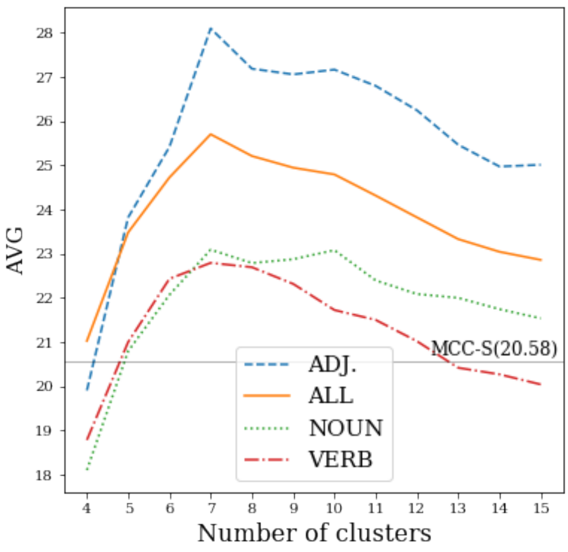

Figure 2: AVG score by number of clusters.

Figure 2 also tells us our system is better at inducing senses for adjectives, at least according to task score.

The Importance of Lemmatization

The ablation results in the paper indicate that for verbs, using symmetric patterns without lemmatization yields poor results. We present the analysis the motivated our use of lemmatization. Consider the samples from the biLM with and without symmetric patterns, for the instance *It was when I was a high-school student that I* ***became*** *convinced of this fact for the first time.*

fw LM, no SP:	didn, write, 'd, learnt, start
bw LM, no SP:	seem, be, grow, be, be
fw LM, with SP:	went, got, started, wasn, loved
bw LM, with SP:	1990s, decade, 1980s, afterwards, changed

Another sentence, in another tense: *The issue will* ***become*** *more pressing as an estimated 40,000 to 50,000 Chinese, mostly unskilled, come to settle each year.*

fw LM, no SP:	be, be, remain, likely, be
bw LM, no SP:	becoming, grown becoming, much, becomes
fw LM, with SP:	remains, remain, which, continue, how
bw LM, with SP:	rising, overseas, booming, abroad, expanded

When using the symmetric patterns, the predicted verbs tend to share the tense of the target word.

This results in targets of different tenses having nearly distinct distributions, even when the targets share the same sense, splitting the single sense cluster to two (or more) tense clusters. We quantify this intuition by computing the correlation between tense and induced clusters (senses), as given by the Normalized Mutual Information (NMI). We measure NMI between verb instance tense in sentence and their most probable induced cluster in the different settings, as well as the NMI of the verb instances and the gold clusters. Table 3 summarize the results. We see that in the gold clusters there is indeed very little correlation (0.15) between the the tense and the sense. When using SP but not lemmatization (w/o LEM), the correlation is substantially higher (0.67). When not using either lemmatization of SP (w/o LEM and SP) the correlation is 0.27, much closer to the gold one. Performing explicit lemmatization naturally reduces the correlation with tense, and using the full model (Final model) results in a correlation to 0.22, close to the gold number of 0.15.

Some Failure Modes of Dynamic Symmetric Patterns

While the use of dynamic symmetric patterns improves performance and generally produces good substitutes for contextualized words, we also identify some failure modes and unexpected behavior.

Common phrases involving conjunctions Some target words have a strong prior to appear in common phrases involving a conjunction, causing the strong local pattern to override context-based hints. For example, when the LM is asked to complete ... *state and* __, its prior on *church* makes it a very probable completion, regardless of context and sense. This phenomena motivated our use TF-IDF for weighing of too common words. Relatedly, a common completion for symmetric patterns is the word *then*, as *and then* is a very common phrase. This completion even ignores the target word and could be troublesome if a global, cross-lemma, clustering is attempted.

Multi word phrases substitutes Sometime the LM does interpret the *and* as a trigger for a symmetric relation, but on a chunk extending beyond the target word. For example, when presented with the query *The human heart not only makes heart sounds and* __, the forward LM predicted in its top twenty suggestions the word *muscle*, followed by a next-word prediction of *movements*. That is, the symmetry extends beyond "sounds" to the phrase "heart sounds" which could be substitutes by "muscle movements". We didn't specifically address this in the current work, but note that restricting the prediction to agree with the target word on part-of-speech and plurality may help in mitigating this. Furthermore, this suggests an exciting direction for moving from single words towards handling of multi-word units.

Settings	NMI (mean ± STD)
Gold labels	0.15 ± 0.07
Final model	0.22 ± 0.12
w/o SP	0.19 ± 0.08
w/o TFIDF	0.18 ± 0.07
w/o LEM	**0.67± 0.12**
w/o LEM and SP	0.26 ± 0.09
w/o ALL	0.24 ± 0.08

Table 3: Correlation between tense and sense. NMI is averaged on all verbs, using best matching sense. SP: Symmetric Patterns, LEM: Lemmatizing predictions, ALL: LEM, SP, TFIDF. The bold line show symmetric patterns without lemmatization excessively correlates tense and sense and provides additional validation to our hypothesis, suggesting its essential to lemmatizate when symmetric patterns are used.

InferLite: Simple Universal Sentence Representations from Natural Language Inference Data

Jamie Ryan Kiros
Google Brain Toronto

William Chan
Google Brain Toronto
`williamchan@google.com`

Abstract

Natural language inference has been shown to be an effective supervised task for learning generic sentence embeddings. In order to better understand the components that lead to effective representations, we propose a lightweight version of InferSent (Conneau et al., 2017), called InferLite, that does not use any recurrent layers and operates on a collection of pre-trained word embeddings. We show that a simple instance of our model that makes no use of context, word ordering or position can still obtain competitive performance on the majority of downstream prediction tasks, with most performance gaps being filled by adding local contextual information through temporal convolutions. Our models can be trained in under 1 hour on a single GPU and allows for fast inference of new representations. Finally we describe a semantic hashing layer that allows our model to learn generic binary codes for sentences.

1 Introduction

Distributed representations of words have become immensely successful as the building blocks for deep neural networks applied to a wide range of natural language processing tasks (Pennington et al., 2014). Learning representations of sentences, however, has largely been done in a task-dependent way. In recent years, a growing body of research has emerged for learning general purpose sentence embeddings. These methods aim to learn a universal encoding function that can map arbitrary sentences into vectors which can then be applied to downstream prediction tasks without fine-tuning. Much of the motivation behind this work is to mimic the successful use of feature transfer in computer vision.

Recently, Conneau et al. (2017) showed that a bidirectional LSTM with max pooling trained to perform Natural Language Inference (NLI), called InferSent, outperforms several other encoding functions on a suite of downstream prediction tasks. This method could match or outperform existing models that learns generic embeddings in an unsupervised setting, often requiring several days or weeks to train (Kiros et al., 2015). However, a better understanding of what properties induce a useful generic embedding remains illusive.

In this work we propose a lightweight version of InferSent, called InferLite. InferLite deviates from InferSent in that it does not use any recurrent connections and can generalize to multiple pre-trained word embeddings. Our method uses a controller to dynamically weight embeddings for each word followed by max pooling over components to obtain the final sentence representation. Despite its simplicity, our method obtains performances on par with InferSent (Conneau et al., 2017) when using Glove representations (Pennington et al., 2014) as the source of pre-trained word vectors. To our surprise, the majority of evaluations can be done competitively without any notion of context, word ordering or position. For tasks where this is useful, much of the performance gap can be made up through a stack of convolutional layers to incorporate local context. Finally, we describe a semantic hashing layer that allows our model to be extended to learning generic binary vectors. The final result is a method that is both fast at training and inference and offers a strong baseline for future research on general purpose embeddings.

1.1 Why learn lightweight encoders?

Our proposed model naturally raises a question: why consider lightweight sentence encoders? If a generic encoder only needs to be trained once, why would training times be relevant? We argue our direction is important for two reasons. One is inference speed. With a lightweight encoder, we can encode millions of sentences efficiently without requiring extensive computational resources. The appendix includes inference speeds of our models. The second, perhaps more importantly, is to gain a better understanding of what prop-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4868–4874
Brussels, Belgium, October 31 - November 4, 2018.

erties lead to high quality generic embeddings. When models take several days or weeks to train, an ablation analysis becomes prohibitively costly. Since our models can be trained quickly, it allows for a more extensive analysis of architectural and data necessities. Moreover, we include an ablation study in the appendix that shows even innocent or seemingly irrelevant model decisions can have a drastic effect on performance. Such observations could not be observed when models take orders of magnitude longer to train.

2 Related Work

A large body of work on distributional semantics have considered encoding phrase and sentence meaning into vectors e.g. (Mitchell and Lapata, 2008; Grefenstette et al., 2013; Paperno et al., 2014). The first attempt at using neural networks for learning generic sentence embeddings was Kiros et al. (2015), who proposed a sequence-to-sequence extension of the skip-gram model but applied at the sentence level. This method was taught to encode a sentence and predict its neighbours, harnessing a large collection of books for training (Zhu et al., 2015). A similar approach, FastSent, was proposed by (Hill et al., 2016) which replaced the RNN encoder of skip-thoughts with word embedding summation. Methods using RNN encoders tend to perform poorly on STS evaluations, as shown by Wieting et al. (2015). Arora et al. (2017) showed a simple weighted bag of words with the first principal component subtracted, can be competitive on many sentencing encoding tasks.

Attempts to learn generic encoders with discriminative objectives were considered by Nie et al. (2017) and Logeswaran and Lee (2018) who replaced the decoder of skip-thoughts with classification tasks based on discourse relations and prediction of target sentences from an encoded candidate. All of the above methods relied on a large corpus of unlabelled data. Conneau et al. (2017) showed that similar or improved performance can be obtained using NLI datasets as a source of supervisory information. The state of the art sentence encoders utilize multi-task learning (Subramanian et al., 2018) by training an encoder to simultaneously do well on a collection of tasks such as NLI, next sentence prediction and translation.

The use of gating for selecting word representations has been considered in previous work. Yang et al. (2017) introduced a method for choosing between word and character embeddings while Kiela et al. (2018) describe a contextual gating method for word embedding selection. Gating has also been widely applied to multimodal fusion (Arevalo et al., 2017; Wang et al., 2018b; Kiros et al., 2018).

Feature	dataset	dim	method
Glove	Common Crawl	300	
News	Google News	500	CBOW
Query	Google Search	800	CBOW

Table 1: Comparison of word representations used.

Our work is also related to recent methods that induce contextualized word representations (McCann et al., 2017; Peters et al., 2018) as well as pre-training language models for task-dependent fine-tuning (Dai and Le, 2015; Howard and Ruder, 2018; Radford et al., 2018). We differ from these approaches in that we aim to infer a transferable sentence vector without any additional fine-tuning.

3 Method

Our method operates on a collection of pre-trained word representations and is then trained on the concatenation of SNLI (Bowman et al., 2015) and MultiNLI (Williams et al., 2018) datasets as in Conneau et al. (2017). Table 1 summarizes the properties of the embeddings we consider. At a high level, our method takes as input a collection of embeddings for each word and learns a gated controller to decide how to weight each representation. After encoding each word in a sentence, the sentence embedding is obtained by max pooling the transformed word representations. Unlike Subramanian et al. (2018), which learn a shared encoder in a multi-task setting, we instead fix the prediction task to NLI but use embeddings obtained from alternative tasks. Figure 1 illustrates our model.

We begin by defining notation. Suppose we are given a sentence of words $S = w^1, \ldots, w^T$ which we would like to encode into a vector. Let K be the number of embedding types (e.g. Glove, News, Query) and let E^k denote the word embedding matrix for type k. Define $E^c = [E^1; \ldots; E^K]$ to be the concatenation of word embedding matrices of all K types.

We break our model description into four modules: Encoder, Controller, Fusion and Reduction. In the appendix we include an ablation study that analyzes the effect of our design choices.

Encoder. The encoder computes $M + 1$ layers $H_0^k, \ldots, H_M^k$ for $k = 1, \ldots, K$ embedding types.

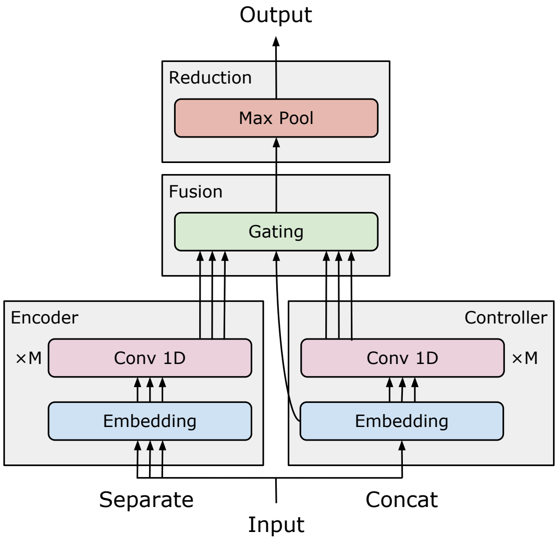

Figure 1: Illustration of the InferLite model. Separate and Concat refer to the embedding types used.

The first layer is computed as:

$$H_0^k = \phi_{0,h}(W_{0,h}^k E^k + b_{0,h}^k) \tag{1}$$

where $W_{0,g}^k E^k$ is a time distributed matrix multiply [1] and $\phi_{0,h}$ is the activation function. Each subsequent layer is given by:

$$H_i^k = \phi_{i,h}(W_{i,h}^k * H_{i-1}^k + b_{i,h}^k) \tag{2}$$

where $*$ denotes the 1-D convolution operator that preserves dimensions. Note that if the convolutional filter length is 1, the model reduces to a bag-of-words encoder. We use ReLU activation functions for $\phi_{i,h}$ where $i = 0, \ldots, M-1$ and a tanh activation for the last layer $\phi_{M,h}$.

Controller. The controller first computes a shared layer G_0^c along with M heads $G_1^k, \ldots, G_M^k$ for $k = 1, \ldots, K$ embedding types. The first layer is computed as:

$$G_0^c = \phi_{0,g}(W_{0,g}^c E^c + b_{0,g}^c) \tag{3}$$

where $W_{0,g}^c E^c$ is a time distributed matrix multiply and $\phi_{0,g}$ is the activation function. Define $G_0^k = G_0^c, k = 1, \ldots, K$. Each subsequent layer is given by:

$$G_i^k = \phi_{i,g}(W_{i,g}^k * G_{i-1}^k + b_{i,g}^k) \tag{4}$$

We use ReLU activation functions for $\phi_{i,g}$ where $i = 0, \ldots, M-1$ and a sigmoid activation for the last layer $\phi_{M,g}$.

Fusion. The fusion layer combines the encoder and controller layers as follows:

$$\begin{aligned} F' &= \left(\sum_{k=1}^{K} H_M^k \odot G_M^k \right) + G_0^c &(5) \\ F &= \phi_f(W_f F' + b_f) &(6) \end{aligned}$$

where $\odot$ denotes a component-wise product, $W_f F'$ is a time distributed matrix multiply, ϕ_f is a ReLU activation function and G_0^c is added as a skip connection. In the appendix we demonstrate that the added skip connection is crucial to the success of the model.

Reduction. The final reduction operation simply applies max pooling across tokens:

$$s = \text{maxpool}\{F\}_T \tag{7}$$

resulting in a sentence vector s. This resulting vector corresponds to the embedding for which we evaluate all downstream tasks with.

For training on NLI, we follow existing work and compute the concatenation of the embeddings of premise and hypothesis sentences along with their componentwise and absolute difference (Conneau et al., 2017). This joint vector is fed into a 2 hidden layer feedforward network with ReLU activations, followed by a softmax layer to predict whether the sentence pairs are neutral, entailed or contradictory. After training on NLI, the weights of the model are frozen and used for encoding new sentences.

3.1 Relationship to other work

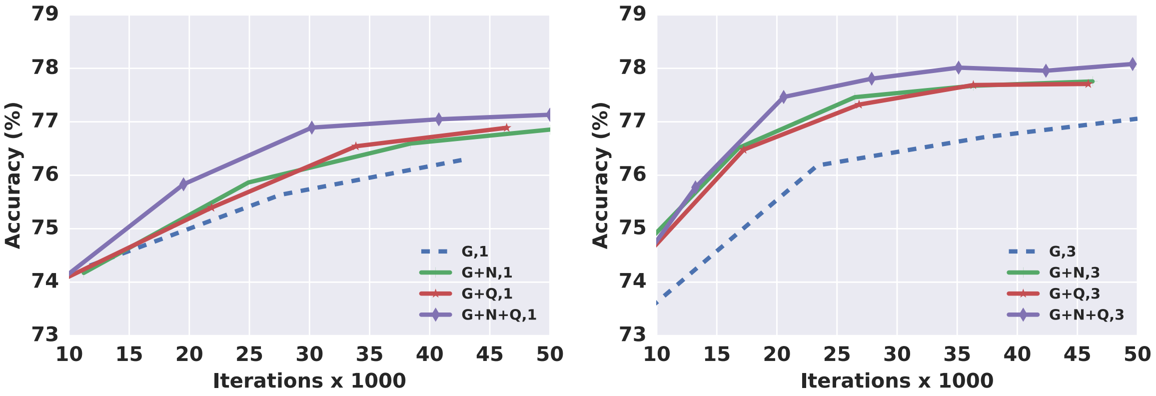
Our model shares similarities to two other works, namely the gated convolutional layers from Dauphin et al. (2016); Gehring et al. (2017) and van den Oord et al. (2016). There are three main differences: 1) we generalize to multiple embedding types 2) we only apply gating at the end of the last layer as a way of weighting all embedding types (instead of each layer) and 3) we use a skip connection from the controller's transformed input to the fusion layer. We note that our encoder module can be reduced to the gated convolutional encoder in van den Oord et al. (2016) if we use one embedding type, remove the time distributed layers and only use a single convolutional layer.

3.2 Semantic hashing

We can augment a semantic hashing (Salakhutdinov and Hinton, 2009) layer to InferLite as a way of learning binary codes for sentences. Binary codes allow for efficient storage and retrieval

---

[1] Sometimes referred to as a "translation layer" (see https://github.com/Smerity/keras_snli).



(a) NLI: no context (Conv length 1).

(b) NLI: with context (Conv length 3).

Figure 2: NLI accuracy using models that (a) have no context (convolution length of 1) and b) local context (convolution length of 3). Performance is reported on the concatenation of SNLI and MultiNLI development sets. **G** stands for Glove, **N** stands for News and **Q** stands for Query embeddings.

over massive corpora. To do this, we append the following layer:

$$h(s) = \sigma\left(\frac{\mathrm{LN}(W_x s + b_x)}{\tau}\right) \quad (8)$$

where LN is Layer Normalization (Ba et al., 2016), σ is the sigmoid activation and τ is a temperature hyperparameter. We initialize $\tau = 1$ at the beginning of training and exponentially decay τ towards 0 over the course of training. At inference time, we threshold at 0.5 to obtain codes. We found Layer Normalization was important for obtaining good codes as otherwise many dead units would form. In the appendix we include downstream performance results for 256, 1024 and 4096-bit codes. The combination of fast inference and efficient storage allows InferLite to be an effective generic encoder for large-scale retrieval and similarity search.

4 Experiments

We use the SentEval toolkit (Conneau and Kiela, 2018) for evaluating our sentence embeddings. All of our models are trained to optimize performance on the concatenation of SNLI and MultiNLI, using the concatenated development sets for early stopping. We use 4096-dimensional embeddings as in Conneau et al. (2017). We consider encoders that use convolutional filters of length 1 (no context) or length 3 (local context), with a stack of $M = 3$ convolutional layers. All word embeddings are pre-trained, normalized to unit length and held fixed during training. Full hyperparameter details are included in the appendix, including an ablation study comparing the effect of the choice of M.

We first analyze performance of our model on NLI prior to evaluating our models on downstream tasks. Figure 2 shows development set accuracy on NLI for models with and without context, using various feature combinations. Here we observe that a) using local context improves NLI performance and b) adding additional embedding types leads to improved performance.

Tables 2 and 3 show results on downstream evaluation tasks. Here several observations can be made. First note the effectiveness of the basic (glove,1) model, which is essentially a deep bag-of-unigram encoder. We also observe our models outperform all previous bag of words baselines. Next we observe that adding local context helps significantly on MR, CR, SST2 and TREC tasks. Furthermore, fusing embeddings from query and news models matches or improves performance over a glove-only model on 12 out of 15 tasks. Our (glove+news+query,3) model is best on 5 tasks and is a generally strong performer across all evaluations. Finally observe that our models significantly improves over previous work on STS tasks.

Next we compare training times of our models to previous work. All of our models can be trained in one GPU hour or less. QuickThoughts and InferSent can be trained on the order of a day while Multitask requires 1 week of training. This demonstrates the trade-off of these approaches.

In the appendix we include results from several other experiments including COCO image-sentence retrieval, downstream performance of InferLite with semantic hashing and results on 10 probing tasks introduced in Conneau et al. (2018). We also do an extensive ablation study

of model components and illustrate gate activation values qualitatively for sentences from the (glove+news+query,3) model.

4.1 Limitations

We also experimented with additional embedding types, including Picturebook (Kiros et al., 2018), knowledge graph and neural machine translation based embeddings. While adding these embeddings improved performance on NLI, they did not lead to any performance gains on downstream tasks. This is in contrast to Subramanian et al. (2018) who showed adding additional tasks in a multi-task objective led to better downstream performance. This demonstrates the limitations of solely using NLI as an objective, even if we transfer embeddings from additional tasks.

5 Future Work

In future work, we would like to explore using contextualized word embeddings, such as CoVe (McCann et al., 2017) and ELMo (Peters et al., 2018), as input to our models as opposed to non-contextualized representations. We also intend to evaluate on additional benchmark tasks such as GLUE (Wang et al., 2018a), explore using the learned word representations as contextualized embeddings and perform downstream fine-tuning.

Acknowledgments

The authors would like to thank Geoffrey Hinton, George Dahl and the EMNLP anonomous reviewers for their valuable feedback.

Similarity-Based Reconstruction Loss for Meaning Representation

Abstract

This paper addresses the problem of representation learning. Using an autoencoder framework, we propose and evaluate several loss functions that can be used as an alternative to the commonly used cross-entropy reconstruction loss. The proposed loss functions use similarities between words in the embedding space, and can be used to train any neural model for text generation. We show that the introduced loss functions amplify semantic diversity of reconstructed sentences, while preserving the original meaning of the input. We test the derived autoencoder-generated representations on paraphrase detection and language inference tasks and demonstrate performance improvement compared to the traditional cross-entropy loss.

1 Introduction

Natural language processing (NLP) tasks that use an encoder-decoder architecture tend to rely on the cross-entropy reconstruction loss to generate the target output. A great majority of deep learning models used at present for state-of-the-art machine translation, question answering, summarization, and dialogue generation employ this type of architecture.

The standard cross-entropy loss penalizes the model whenever it fails to produce the exact word from the ground truth data used for training. However, in many NLP tasks that deal with generating text from semantic representation, recovering the exact word is not necessarily optimal, and often generating a near-synonym or just a semantically close word is nearly as good or even better from the point of view of model performance. Consider a situation when a decoder model generates a word by sampling from a softmax over the vocabulary-sized final layer to produce an output. Since cross-entropy loss forces a model to generate the exact words corresponding to those in the input text, the model will be penalized when semantically close but distinct outputs are generated. This is clearly undesirable in many cases when the exact output is not required.

In this paper, we introduce and experiment with a series of distance-based reconstruction losses. Using an auto-encoder derived representation of sentence meaning, we test their impact on model performance in several tasks that require building a semantic representation, including paraphrase detection and entailment / inference. We show that the loss functions that take into account distributional similarity between the word embeddings of the generated output and the ground truth tokens lead to a substantial improvement in performance on such tasks in an unsupervised setting.

2 Related Work

The encoder-decoder setting was first used in deep learning by Sutskever et al. (2014) and has been successfully adapted to a problem of representation learning since then. To date, numerous approaches based on the encoder-decoder idea have been suggested for unsupervised feature extraction from textual data.

Cer et al. (2018) modify the Transformer architecture (Vaswani et al., 2017) originally suggested for machine translation to produce sentence embeddings that target transfer learning to other NLP tasks. Arora et al. (2016) claim that sentence representation as simple weighted averaging of word vectors beats more sophisticated recurrent network-based models. McCann et al. (2017) show that adding machine translation-learned vectors to models designed for other NLP tasks improves their performance. Nangia et al. (2017) in RepEval-2017 report that in-sentence attention and biLSTM-based models extract represen-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4875–4880
Brussels, Belgium, October 31 - November 4, 2018.

tation of meaning from text reasonably well. Logeswaran and Lee (2018) and Kiros et al. (2015) change the problem of learning sentence representations to a classification task for predicting context sentences. Subramanian et al. (2018) demonstrate that sharing the same sentence encoder across different tasks leads to performance improvements.

All the listed works, however, propose methods that either develop task-specific architectures, or use large corpora of labeled data to learn embeddings at a sentence level. Unlike the mentioned papers, the simple modification we propose does not require data annotation and can be used with any state-of-the-art neural models for text generation.

Surprisingly, we have not found other work that uses the proposed idea despite its simplicity.

3 Experiments

The objective of a classic autoencoder is to minimize the difference between the given input $\mathbf{X}$ and the reconstructed output $\hat{\mathbf{X}}$.

$$\mathcal{L}(\mathbf{X}, g(f(\mathbf{X}))) \tag{1}$$

where f is the encoder function and g is the decoder function. We propose and compare several modifications of distance-based losses, that apply different penalties to the model depending on the similarity of the produced words to the targets in the embedding space.

- *Weighted similarity loss*

$$\mathcal{L} = -\sum_{i=1}^{V} \text{sim}(y_t, y_i) p_i \tag{2}$$

where p_i is the softmax probability over vocabulary size, $-1 \leq \text{sim} \leq 1$ is the similarity between the tokens embeddings vectors, y_t and y_i are the ground-truth token and the predicted token, respectively, and V is the total vocabulary size. Intuitively, this loss encourages the model to produce high probabilities for words that are close to the target word. In the present experiments, we use cosine as the similarity measure.

- *Weighted cross-entropy loss*

$$\mathcal{L} = -\sum_{i=1}^{V} \text{sim}(y_t, y_i) \log p_i \tag{3}$$

Here the optimization function can be seen as the "weighted" cross-entropy, meaning that every ground-truth token is represented with similarities to other words in the vocabulary rather than with a traditional one-hot-encoding scheme. The schematic illustration of the true label encoding for the weighted similarity and weighted cross-entropy loss functions is shown in Figure 1 (right).

- *Soft label loss*

$$\mathcal{L} = -\sum_{i=1}^{V} y_i^* logp_i \tag{4}$$

This cost function is similar to the previous one in terms of true label y_i representation: we encode ground-truth tokens as their similarities across the vocabulary, but we consider only the top N closest words in the vocabulary and normalize the similarities so that they add up to one $\sum_{i=1}^{V} y_i^* = 1$. Essentially, the loss function can be interpreted as cross-entropy with soft targets. We vary N from 3 to 10 in our experiments. We also exclude common English stop-words from soft target encoding, i.e. we apply a regular cross entropy loss for reconstructing of these words. The schematic illustration is given in Figure 1 (center).

$$y_i^* = \begin{cases} \frac{\text{sim}(y_t, y_i)}{\sum_{j=1}^{N} \text{sim}(y_t, y_j)}, & y_i \in \text{top N} \\ 0, & y_i \notin \text{top N} \end{cases} \tag{5}$$

We use pre-trained fastText (Bojanowski et al., 2016) word vectors to compute similarities between words. Note that the more recently proposed ELMo embeddings (Peters et al., 2018), for example, can not be used in our case, since they are context-dependent, which means that similarities between individual words can not be precomputed.

To find out how the proposed loss functions affect the quality of the derived representations, we trained several autoencoder models using the regular cross-entropy, as well as the three variants of the similarity-based reconstruction loss described above. In these experiments, we use the Yelp restaurant reviews dataset (Shen et al., 2017). This dataset was originally introduced for a sentiment classification task and consists of 600K sentences.

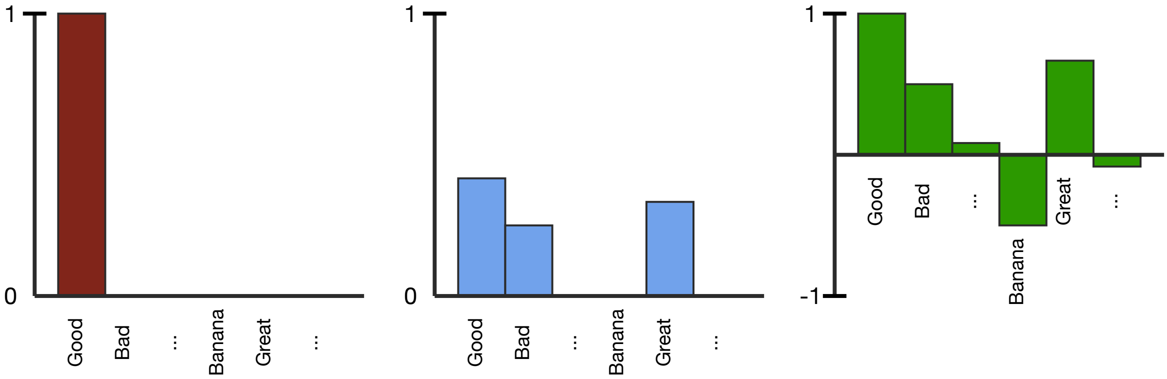

Figure 1: Schematic illustration of true-label encoding using the standard cross-entropy loss (left), soft label loss for $N = 3$ (center) and weighted similarity/weighted cross-entropy loss (right). All the three examples "good", "great" and "bad" are close in the embedding space, since they appear in similar contexts. Note that all the soft labels add up to 1, while weighted similarity labels for the third loss can vary in the range from -1 to 1.

Model	MSRP		SNLI	SICK-E
	F1	Acc	Acc	Acc
Cross-entropy (vanilla AE)	79.0	66.9	44.8	56.8
Soft label, $N = 3$	77.6	67.1	57.8	71.8
Soft label, $N = 5$	79.1	67.3	57.2	71.6
Soft label, $N = 10$	77.9	66.5	57.9	**72.4**
Weighted similarity	77.5	65.6	**69.1**	56.6
Weighted cross-entropy	**79.4**	**68.2**	57.2	70.2

Table 1: Results of transfer learning tasks performance of the proposed autoencoder models. All the models are trained on the Yelp reviews dataset with the use of fastText pre-trained word embeddings.

Our autoencoder model is implemented using the PyTorch deep learning framework (Paszke et al., 2017). In our architecture, both the encoder and the decoder are implemented as single layer LSTMs, each with the hidden size of 256 units. We divide our dataset into train/dev/test splits in 70/10/20 ratio. The resulting vocabulary size of the training dataset is 9.5K tokens. For our training, we use the Adam optimizer (Kingma and Ba, 2014) with the learning rate that varies depending on the tested loss between 0.001 and 0.0001.

We test our learned representations using the SentEval toolkit (Conneau et al., 2017). SentEval is an open-source Python library for evaluating sentence embeddings on a diverse set of language tasks. This toolkit provides a cluster of downstream tasks taken from various competitions such as SemEval as well as a set of probing tasks. In current paper, we focus on the paraphrase detection task using the Microsoft Research Paraphrase Corpus (MSRP) (Dolan et al., 2004), as well as the inference/entailment tasks using the Stanford Natural Language Inference corpus (SNLI) (Bowman et al., 2015) and the SICK-Entailment dataset from SemEval-2014 (Marelli et al., 2014). We selected these tasks because they seem to be likely to benefit from capturing word-level semantic similarity. Table 1 shows the scores averaged over three (3) runs.

4 Discussion

We find that almost all of the proposed loss functions outperform the vanilla autoencoder trained with cross-entropy on all three tasks (see Table 1). The only exception is the weighted similarity loss function. Compared to the logarithm-based losses, this loss applies softer penalties when the ground-truth tokens are predicted to have lower probabilities. We conclude that the non-linearity introduced by a logarithm function contributes to more efficient training.

Among the models we tested, the best scores were achieved by the weighted cross-entropy loss for MSRP (68.2%), the weighted similarity loss for SNLI (69.1%) and by the soft label loss for

Configuration	Autoencoder outputs	
	Input sentence	Reconstructed sentence
Cross-entropy	you can trust this business	you can trust this business
Soft label, $N = 3$	the taste was so good	the flavor was so good
Soft label, $N = 5$	her tone was incredibly rude	her attitude was incredibly unprofessional
Soft label, $N = 10$	a very nice spot for a quiet lunch	a very nice slot for a tranquil lunchtime
Weighted similarity	once again the staff were wonderful	that so that service and great
Weighted cross-entropy	great breakfast option	great food place

Table 2: Sample autoencoder reconstruction outputs for the tested loss configurations.

SICK-E (72.4%). We observe that for the paraphrase task, all the soft label losses behaved similarly, while for the inference/entailment, increasing the number of neighbors improved performance.

In order to better understand how different modifications of the soft label loss affected model performance on transfer tasks, we conducted some additional experiments. Specifically, we investigated the effects of (a) varying the number N of word neighbors used to compute the loss function, and (b) removing the normalization factor by getting rid of the denominator in Eq. 5 (i.e. soft label similarities no longer sum up to 1). Note that when $N = 1$, the soft label loss becomes identical to cross-entropy. When the normalization factor is removed, having $N = V$ makes the soft label loss identical to the weighted similarity loss.

We found that the normalization factor slightly reduced the accuracy for all of the three tasks (see Figure 2). Interestingly, we have not established a universal tendency for the optimal choice of N: for the language inference tasks, the best accuracy was achieved at N close to 10, while for the paraphrasing task the suitable choice for N was in the range of 3-5.

The performance figures obtained for each loss are well illustrated by the quality of the reconstructed examples in Table 2. The standard cross-entropy, as expected, aims at the accurate word-by-word reconstruction of the input sentence. The autoencoder with our least successful weigthed similarity loss function manages to learn most frequent corpus-specific words (e.g. "great service"), but the overall meaning is not conveyed well. he rest of the models succeed in reconstructing synonyms at the word-level. This results in a slightly different expression style (e.g. "her tone was incredibly rude" becomes "her attitude was incredibly unprofessional"), but the overall meaning is reconstructed correctly.

Obviously, the quality of the generated representations depends to a large extent on the selection of pre-trained word embeddings. The related drawback that we observe in our choice of the fastText vectors is that the target ground-truth tokens can be replaced with word inflections as well as with antonyms, which in certain cases can change the meaning of the sentence to the opposite.

For a subset of configurations, we conducted exploratory testing on additional tasks, including different subsets of STS and SICK-Relatedness data. For nearly all tasks tested, we recorded better performance compared to cross-entropy, with the minimum relative gain being 1%. The only performance reduction was in plagiarism detection, which may be expected to favor exact replication.

Although the scores we obtained are below the state-of-the-art for the considered tasks, our goal was to demonstrate that in a traditional encoder-decoder setting, which is extensively used for a number of NLP problems, the proposed loss functions beat the conventional cross-entropy. The major advantage of our proposal is that it is very simple and highly generalizable, i.e. without a sophisticated model architecture, our model is able to produce diversified outputs and can be easily integrated in any existing encoder-decoder architectures.

5 Conclusion

In this paper, we introduced the loss functions that leverage word-level distributional similarity between the generated output and the ground truth. Compared to the representations learned by a

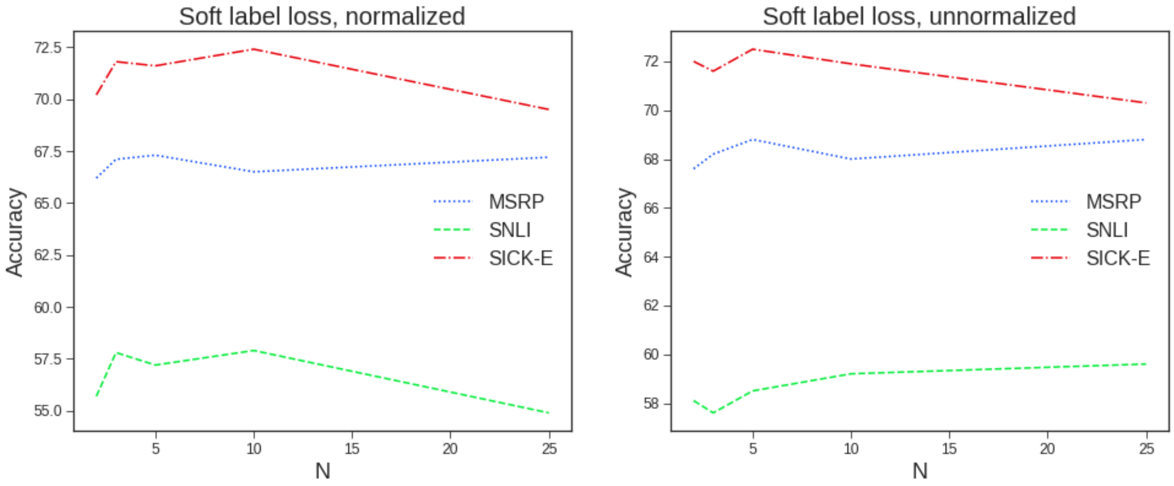

Figure 2: The effect of the soft label loss modifications on task performance. N is the number of closest words neighbors used to compute the loss function.

vanilla autoencoder, the proposed reconstruction loss variants show substantially improved performance on several semantic representation tasks. Further, relative to the conventional cross-entropy, the tested loss variants produce more diverse output while preserving the underlying semantics.

We focused on the autoencoder architecture which requires no pre-annotated data to generate the representations. The major benefit of our proposal is that the proposed loss functions can be plugged directly into any NLP model that generates text word-by-word and that may benefit from more diverse output. The potential applications of our proposal therefore include any of the common NLP problems where language diversity is desirable, including conversational agents, paraphrase generation and text summarization.

The next step for this work is to evaluate the performance of the proposed loss functions in state-of-the-art models for the NLP tasks that leverage sentence-level semantic representation, such as the ones we explored in the present study. Further experiments with the proposed loss functions are also needed to evaluate the effects of different word embedding models on the quality of derived representations.

Abstract

We investigate the effects of multi-task learning using the recently introduced task of semantic tagging. We employ semantic tagging as an auxiliary task for three different NLP tasks: part-of-speech tagging, Universal Dependency parsing, and Natural Language Inference. We compare full neural network sharing, partial neural network sharing, and what we term the *learning what to share* setting where negative transfer between tasks is less likely. Our findings show considerable improvements for all tasks, particularly in the *learning what to share* setting, which shows consistent gains across all tasks.

1 Introduction

Multi-task learning (MTL) is a recently resurgent approach to machine learning in which multiple tasks are simultaneously learned. By optimising the multiple loss functions of related tasks at once, multi-task learning models can achieve superior results compared to models trained on a single task. The key principle is summarized by Caruana (1998) as "MTL improves generalization by leveraging the domain-specific information contained in the training signals of related tasks". Neural MTL has become an increasingly successful approach by exploiting similarities between Natural Language Processing (NLP) tasks (Collobert and Weston, 2008; Søgaard and Goldberg, 2016; Plank et al., 2016). Our work builds upon Bjerva et al. (2016), who demonstrate that employing semantic tagging as an auxiliary task for Universal Dependency (McDonald et al., 2013) part-of-speech tagging can lead to improved performance.

The objective of this paper is to investigate whether learning to predict lexical semantic categories can be beneficial to other NLP tasks. To achieve this we augment single-task models (ST)[1] with an additional classifier to predict semantic tags and jointly optimize for both the original task and the auxiliary semantic tagging task. Our hypothesis is that learning to predict semantic tags as an auxiliary task can improve performance of single-task systems. We believe that this is, among other factors, due to the following:

- Providing the main task's model with a useful inductive bias, encouraging it to prefer representations that lead to semantically plausible hypotheses over those that are not.
- Putting the focus of the main task model's attention on features that actually matter by providing additional evidence for the relevance or irrelevance of those features.
- Reducing the risk of overfitting by minimizing the model's *Rademacher Complexity*[2] Representations which are learned for multiple tasks have been shown to generalize better (Baxter et al., 2000).

We test our hypothesis on three disparate NLP tasks: (i) Universal Dependency part-of-speech tagging (UPOS), (ii) Universal Dependency parsing (UD DEP), a complex syntactic task; and (iii) Natural Language Inference (NLI), a complex task requiring deep natural language understanding.

2 Background and Related work

2.1 Semantic Tagging

Semantic tagging (Bjerva et al., 2016; Abzianidze and Bos, 2017) is the task of assigning language-neutral semantic categories to words. It is designed to overcome a lack of semantic information syntax-oriented part-of-speech tagsets, such as the

Brussels, Belgium, October 31 - November 4, 2018.

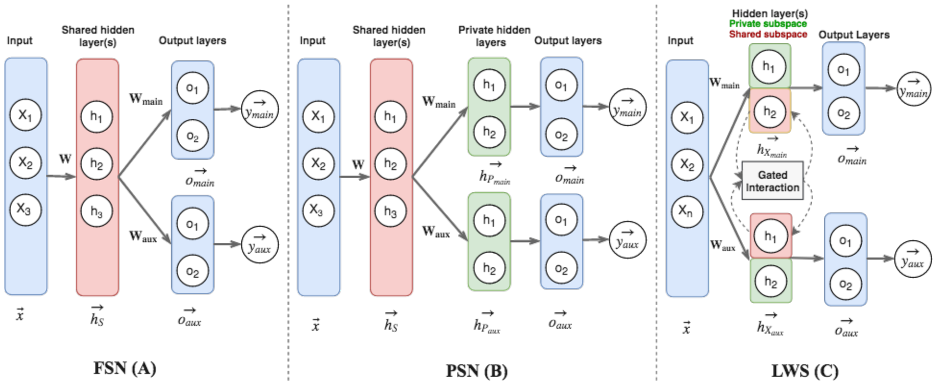

Figure 1: Our three multi-task learning settings: (A) fully shared networks, (B) partially shared networks, and (C) *Learning What to Share*. Layers are mathematically denoted by vectors and the connections between them, represented by arrows, are mathematically denoted by matrices of weights. S indicates a shared layer, P a private layer, and X a layer with shared and private subspaces.

Penn Treebank tagset(Marcus et al., 1993), usually have. Such tagsets exclude important semantic distinctions, such as negation and modals, types of quantification, named entity types, and the contribution of verbs to tense, aspect, or event.

The semantic tagset is language-neutral, abstracts over part-of-speech and named-entity classes, and includes fine-grained semantic information. The tagset consists of 80 semantic tags grouped in 13 coarse-grained classes. The tagset originated in the Parallel Meaning Bank (PMB) project (Abzianidze et al., 2017), where it contributes to compositional semantics and cross-lingual projection of semantic representations. Recent work has highlighted the utility of the tagset as a conduit for evaluating the semantics captured by vector representations (Belinkov et al., 2018), or employed it in an auxiliary tagging task (Bjerva et al., 2016), as we do in this work.

2.2 Learning What to Share

Recently, there has been an increasing interest in the development of models which are trained to learn what to (and what not to) share between a set of tasks, with the general aim of preventing negative transfer when the tasks are not closely related (Meyerson and Miikkulainen, 2017; Ruder et al., 2017; Lu et al., 2017; Misra et al., 2016). Our *Learning What to Share* setting is based on this idea and closely related to Liu et al. (2016)'s shared layer architecture.

Specifically, a layer $\vec{h}_X$ which is shared between the main task and the auxiliary task is split into two subspaces: a shared subspace $\vec{h}_{X_S}$ and a private subspace $\vec{h}_{X_P}$. The interaction between the shared subspaces is modulated via a sigmoidal gating unit applied to a set of learned weights, as seen in Equations (1) and (2) where $\vec{h}_{X_{S(main)}}$ and $\vec{h}_{X_{S(aux)}}$ are the main and auxiliary tasks' shared layers, $W_{a \to m}$ and $W_{m \to a}$ are learned weights, and σ is a sigmoidal function.

$$\vec{h}_{X_{S(main)}} = \vec{h}_{X_{S(main)}} \sigma(\vec{h}_{X_{S(aux)}} W_{a \to m}) \quad (1)$$

$$\vec{h}_{X_{S(aux)}} = \vec{h}_{X_{S(aux)}} \sigma(\vec{h}_{X_{S(main)}} W_{m \to a}) \quad (2)$$

Unlike Liu et al. (2016)'s Shared-Layer Architecture, in our setup each task has its own shared subspace rather than one common shared layer. This enables the sharing of different parameters in each direction (i.e., from main to auxiliary task and from auxiliary to main task), allowing each task to choose what to learn from the other, rather than having "one shared layer to capture the shared information for all the tasks" as in Liu et al. (2016).

3 Multi-Task Learning Settings

We implement three neural MTL settings, shown in Figure 1. They differ in the way the network's parameters are shared between the tasks:

- **Fully shared network (FSN):** All hidden layers are entirely shared among the tasks, each task has a separate output layer. The transformation of our input vector $\vec{x}$ into a shared hidden layer $\vec{h}_S$ is described by Equation (3):

$$\vec{h}_S = \sigma(\vec{x}W) \quad (3)$$

- **Partially shared network (PSN):** A subset of hidden layers is shared among the tasks;

each task has at least one private hidden layer and a separate output layer. The transformation of a *shared* hidden layer $\vec{h}_S$ into *private* hidden layers, denoted by $\vec{h}_{P_{(main)}}$ and $\vec{h}_{P_{(aux)}}$ is described in Equations (4) and (5).

$$\vec{h}_{P_{(main)}} = \sigma(\vec{h_S} W_{(main)}) \tag{4}$$

$$\vec{h}_{P_{(aux)}} = \sigma(\vec{h_S} W_{(aux)}) \tag{5}$$

- **Learning What to Share (LWS):** Each task has a dedicated set of hidden layers. For sharing, a hidden layer is split into a shared subspace and a private subspace. A gating unit modulates the transfer of information between the shared subspaces as shown in Equations (1) and (2).

4 Data

In the UPOS tagging experiments, we utilize the UD 2.0 English corpus (Nivre et al., 2017) for the POS tagging and the semantically tagged PMB release 0.1.0 (sem-PMB)[3] for the MTL settings. Note that there is no overlap between the two datasets. Conversely, for the UD DEP and NLI experiments there is a complete overlap between the datasets of main and auxiliary tasks, i.e., each instance is labeled with both the main task's labels and semantic tags. We use the Stanford POS Tagger (Toutanova et al., 2003) trained on sem-PMB to tag the UD corpus and NLI datasets with semantic tags, and then use those assigned tags for the MTL settings of our dependency parsing and NLI models. We find that this approach leads to better results when the main task is only loosely related to the auxiliary task. The UD DEP experiments use the English UD 2.0 corpus, and the NLI experiments use the SNLI (Bowman et al., 2015) and SICK-E[4] datasets (Marelli et al., 2014). The provided train, development, and test splits are used for all datasets. For sem-PMB, the silver and gold parts are used for training and testing respectively.

5 Experiments

We run four experiments for each of the four tasks (UPOS, UD DEP, SNLI, SICK-E), one using the ST model and one for each of the three MTL settings. Each experiment is run five times, and the average of the five runs is reported. We briefly describe the ST models and refer the reader to the original work for further details due to a lack of space.[5] For reproducibility, detailed diagrams of the MTL models for each task and their hyperparameters can be found in Appendix A.

5.1 Universal Dependency POS Tagging

Our tagging model uses a basic contextual one-layer bi-LSTM (Hochreiter and Schmidhuber, 1997) that takes in word embeddings and produces a sequence of recurrent states which can be viewed as contextualized representations. The recurrent r_n state from the bi-LSTM corresponding to each time-step t_n is passed through a dense layer with a softmax activation to predict the token's tag.

In each of the MTL settings a softmax classifier is added to predict a token's semantic tag and the model is then jointly trained on the concatenation of the sem-PMB and UPOS tagging data to minimize the sum of softmax cross-entropy losses of both the main (UPOS tagging) and auxiliary (semantic tagging) tasks.

5.2 Universal Dependency Parsing

We employ a parsing model that is based on Dozat and Manning (2016). The model's embeddings layer is a concatenation of randomly initialized word embeddings[6] and character-based word representations added to pre-trained word embeddings, which are passed through a 4-layer stacked bi-LSTM. Unlike Dozat and Manning (2016), our model jointly learns to perform UPOS tagging and parsing, instead of treating them as separate tasks. Therefore, instead of tag embeddings, we add a softmax classifier to predict UPOS tags after the first bi-LSTM layer. The outputs from that layer and the UPOS softmax prediction vectors are both concatenated to the original embedding layer and passed to the second bi-LSTM layer. The output of the last bi-LSTM is then used as input for four dense layers with a ReLU activation, producing four vector representations: a word as a dependent seeking its head; a word as a head seeking all its dependents; a word as a dependent deciding on its label; a word as head deciding on the labels of its dependents. These representations are then passed to biaffine and affine softmax classifiers to produce a fully-connected labeled probabilistic dependency graph (Dozat and Manning,

---

[3] `http://pmb.let.rug.nl/data.php`

[4] SICK-E refers to the entailment part of the SICK dataset.

[5] This applies to UD DEP and NLI only, as the POS tagger is not based on any one particular work.

[6] This replaces the holistic word embeddings for frequent words in Dozat and Manning (2016).

2016). Finally, a non-projective maximum spanning tree parsing algorithm (Chu, 1965; Edmonds, 1967) is used to obtain a well-formed dependency tree.[7]

Similarly to UPOS tagging, an additional softmax classifier is used to predict a token's semantic tag in each of the MTL settings, as both tasks are jointly learned. In the FSN setting, the 4-layer stacked bi-LSTM is entirely shared. In the PSN setting the semantic tags are predicted from the second layer's hidden states, and the final two layers are devoted to the parsing task. In the LWS setting, the first two layers of the bi-LSTM are split into a private bi-LSTM$_{private}$ and a shared bi-LSTM$_{shared}$ for each of the tasks with the interaction between the shared subspaces being modulated via a gating unit. Then, two bi-LSTM layers that are devoted to parsing only are stacked on top.

5.3 Natural Language Inference

We base our NLI model on Chen et al. (2017)'s Enhanced Sequential Inference Model which uses a bi-LSTM to encode the premise and hypothesis, computes a soft-alignment between premise and hypothesis' representations using an attention mechanism, and employs an inference composition bi-LSTM to compose local inference information sequentially.[8] The MTL settings are implemented by adding a softmax classifier to predict semantic tags at the level of the encoding bi-LSTM, with rest of the model unaltered. In the FSN setting, the hidden states of the encoding bi-LSTM are directly passed as input to the softmax classifier. In the PSN setting an earlier bi-LSTM layer is used to predict the semantic tags and the output from that is passed on to the encoding bi-LSTM which is stacked on top. This follows Hashimoto et al. (2016)'s hierarchical approach. In the LWS setting, a bi-LSTM layer with private and shared subspaces is used for semantic tagging and for the ESIM model's encoding layer. In all MTL settings, the bi-LSTM used for semantic tagging is pre-trained on the sem-PMB data.

6 Results and Discussion

Results for all tasks are shown in Table 1. In line with Bjerva et al. (2016)'s findings, the FSN setting leads to an improvement for UPOS tagging. POS tagging, a sequence labeling task, can be seen as the most closely related to semantic tagging, therefore negative transfer is minimal and the full sharing of parameters is beneficial. Surprisingly, the FSN setting also leads improvements for UD DEP. Indeed, for UD DEP, all of the MTL models outperform the ST model by increasing margins. For the NLI tasks, however, there is a clear degradation in performance.

The PSN setting shows mixed results and does not show a clear advantage over FSN for UPOS and UD DEP. This suggests that adding task-specific layers after fully-shared ones does not always enable sufficient task specialization. For the NLI tasks however, PSN is clearly preferable to FSN, especially for the small-sized SICK-E dataset where the FSN model fails to adequately learn.

Model	SNLI	SICK-E	UPOS	UD DEP
ST	87.01	81.30	92.12	80.24 / 84.87
FSN	84.96	56.69	92.95	81.03 / 85.54
PSN	87.08	77.92	92.34	80.92 / 85.81
LWS	**87.51**	**84.57**	**95.54**	**81.39 / 86.00**

Table 1: Results for single-task models (ST), fully-shared networks (FSN), partially-shared networks (PSN), and *learning what to share* (LWS). All scores are reported as accuracy, except UD DEP for which we report LAS/UAS F_1 score.

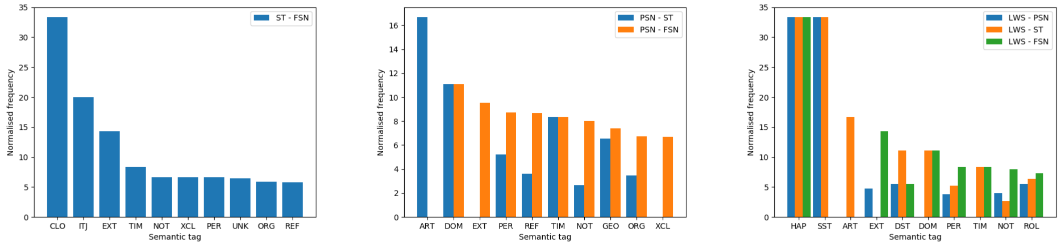
As a sentence-level task, NLI is functionally dissimilar to semantic tagging. However, it is a task which requires deep understanding of natural language semantics and can therefore conceivably benefit from the signal provided by semantic tagging. Our results demonstrate that it is possible to leverage this signal given a selective sharing setup where negative transfer can be minimized. Indeed, for the NLI tasks, only the LWS setting leads to improvements over the ST models.[9] The improvement is larger for the SICK-E task which has a much smaller training set and therefore stands to learn more from the semantic tagging signal. For all tasks, it can be observed that the LWS models outperform the rest of the models. This is in line with our expectations with the findings from previous work (Ruder et al., 2017; Liu et al.,

---

[7] This is recommended but not implemented by Dozat et al. (2017).

[8] We do not implement the additional tree-LSTM model used in Chen et al. (2017) as we focus on the effect of MTL with semantic tagging rather than on absolute performance.

[9] Demonstrative examples of the SNLI models' outputs can be found in Appendix B.



(a) Single-task network (b) Partially shared network (c) Learning what to share

Figure 2: Normalized semantic tag frequencies for all six sets of sentences. `X - Y` denotes the set of sentences correctly classified by model X but misclassified by model Y.

2016) that selective sharing outperforms full network and partial network sharing.

7 Analysis

In addition to evaluating performance directly, we attempt to qualify how semtags affect performance with respect to each of the SNLI MTL settings[10].

7.1 Qualitative analyses

The fact that NLI is a sentence-level task, while semantic tags are word-level annotations presents a difficulty in measuring the effect of semantic tags on the systems' performance, as there is no one-to-one correspondence between a correct label and a particular semantic tag. We therefore employ the following method in order to assess the contribution of semantic tags. Given the performance ranking of all our systems — $FSN < ST < PSN < LWS$ — we make a pairwise comparison between the output of a superior system S_{sup} and an inferior system S_{inf}. This involves taking the pairs of sentences that every S_{sup} classifies correctly, but some S_{inf} does not. Given that FSN is the worst performing system and, as such, has no 'worse' system for comparison, we are left with six sets of sentences: ST-FSN, PSN-FSN, PSN-ST, LWS-PSN, LWS-ST, and LWS-FSN. To gain insight as to where a given system S_{sup} performs better than a given S_{inf}, we then sort each comparison sentence set by the frequency of semtags predicted therein, which are normalized by dividing by their frequency in the full SNLI test set.

We notice interesting patterns, visible in Figure 2. Specifically, PSN appears markedly better at sentences with named entities (`ART`, `PER`, `GEO`, `ORG`) and temporal entities (`DOM`) than both ST and the FSN. Marginal improvements are also observed for sentences with negation and reflexive pronouns. The LWS setting continues this pattern, with additional improvements observable for sentences with the `HAP` tag for names of events, `SST` for subsective attributes, and the `ROL` tag for role nouns.

7.2 Contribution of semantic tagging

To assess the contribution of the semantic tagging auxiliary task independent of model architecture and complexity we run three additional SNLI experiments — one for each MTL setting — where the model architectures are unchanged but the auxiliary tasks are assigned no weight (i.e. do not affect the learning). The results confirm our previous findings that, for NLI, the semantic tagging auxiliary task only improves performance in a selective sharing setting, and hurts it otherwise: i) the FSN system which had performed below ST improves to equal it and ii) the PSN and LWS settings both see a drop to ST-level performance.

8 Conclusions

We present a comprehensive evaluation of MTL using a recently proposed task of semantic tagging as an auxiliary task. Our experiments span three types of NLP tasks and three MTL settings. The results of the experiments show that employing semantic tagging as an auxiliary task leads to improvements in performance for UPOS tagging and UD DEP in all MTL settings. For the SNLI tasks, requiring understanding of phrasal semantics, the selective sharing setup we term *Learning What to Share* holds a clear advantage. Our work offers a generalizable framework for the evaluation of the utility of an auxiliary task.

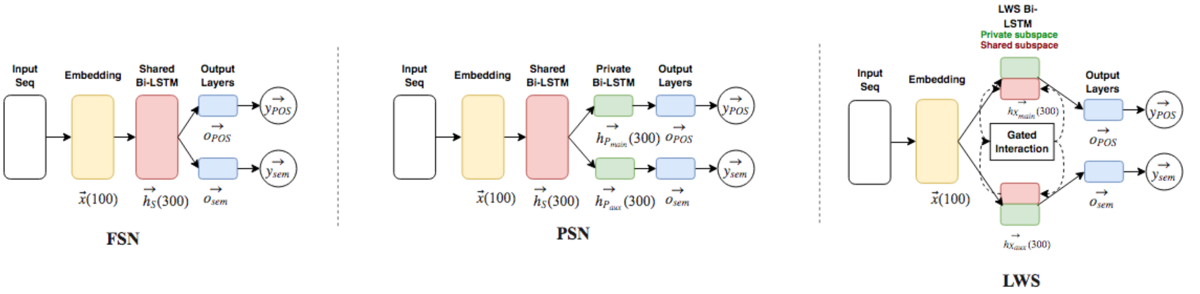
A MTL setting Diagrams, Preprocessing, and Hyperparameters

UPOS Tagging

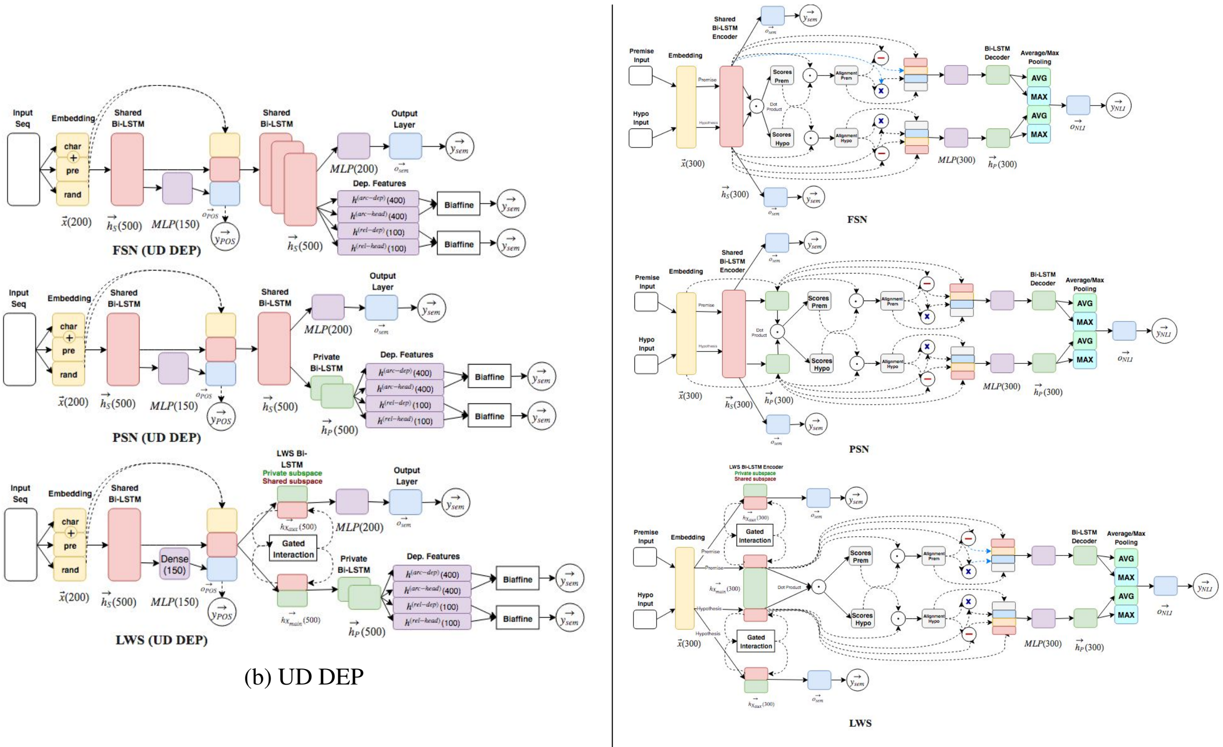
Figure 3a shows the three MTL models used for UPOS. All hyperparameters were tuned with respect to loss on the English UD 2.0 UPOS validation set. We trained for 20 epochs with a batch size of 128 and optimized using Adam (Kingma and Ba, 2014) with a learning rate of 0.0001. We weight the auxiliary semantic tagging loss with $\lambda = 0.1$. The pre-trained word embeddings we used are GloVe embeddings (Pennington et al., 2014) of dimension 100 trained on 6 billion tokens of Wikipedia 2014 and Gigaword 5. We applied dropout and recurrent dropout with a probability of 0.3 to all bi-LSTMs.

UD DEP

Figure 3b shows the three MTL models for UD DEP. We use the gold tokenization. All hyperparameters were tuned with respect to loss on the English UD 2.0 UD validation set. We trained for 15 epochs with a batch size of 50 and optimized using Adam with a learning rate of $2e-3$. We weight the auxiliary semantic tagging loss with λ = 0.5. The pre-trained word embeddings we use are GloVe embeddings of dimension 100 trained on 6 billion tokens of Wikipedia 2014 and Gigaword 5. We applied dropout with a probability of 0.33 to all bi-LSTM, embedding layers, and non-output dense layers.



(a) UPOS



(b) UD DEP

(c) NLI

Figure 3: The three MTL settings for each task. Layers dimensions are displayed in brackets.

NLI

Figure 3c shows the three MTL models for NLI. All hyperparameters were tuned with respect to loss on the SNLI and SICK-E validation datasets (separately). For the SNLI experiments, we trained for 37 epochs with a batch size of 128. For the SICK-E experiments, we trained for 20 epochs with a batch size of 8. Note that the ESIM model was designed for the SNLI dataset, therefore performance is non-optimal for SICK-E. For both sets of experiments: we optimized using Adam with a learning rate of 0.00005; we weight the auxiliary semantic tagging loss with $\lambda = 0.1$; the pre-trained word embeddings we use are GloVe embeddings of dimension 300 trained on 840 billion tokens of Common Crawl; and we applied dropout and recurrent dropout with a probability of 0.3 to all biLSTM, and non-output dense layers.

B SNLI model output analysis

Table 2 shows demonstrative examples from the SNLI test set on which the *Learning What to Share* (LWS) model outperforms the single-task (ST) model. The examples cover all possible combinations of entailment classes. Table 3 explains the relevant part of the semantic tagset. Table 4 shows the per-label precision and recall scores.

Tag category	Semantic tag with examples
Anaphoric	`DEF`: definite; *the, lo*^{IT}*, der*^{DE}
	`HAS`: possessive pronoun; *my, her*
Attribute	`COL`: colour; *red, crimson, light_blue, chestnut_brown*
	`QUC`: concrete quantity; *two, six_million, twice*
	`IST`: intersective; *open, vegetarian, quickly*
	`REL`: relation; *in, on, 's, of, after*
Unnamed entity	`CON`: concept; *dog, person*
Logical	`ALT`: alternative & repetitions; *another, different, again*
	`DIS`: disjunction & exist. quantif.; *a, some, any, or*
Discourse	`SUB`: subordinate relations; *that, while, because*
Events	`ENS`: present simple; *we walk, he walks*
	`EPS`: past simple; *ate, went*
	`EXG`: untensed progessive; *is running*
	`EXS`: untensed simple; *to walk, is eaten, destruction*
Tense & aspect	`NOW`: present tense; *is skiing, do ski, has skied, now*

Abstract

Conventional word embedding models do not leverage information from document metadata, and they do not model uncertainty. We address these concerns with a model that incorporates document covariates to estimate conditional word embedding distributions. Our model allows for (a) hypothesis tests about the meanings of terms, (b) assessments as to whether a word is near or far from another conditioned on different covariate values, and (c) assessments as to whether estimated differences are statistically significant.

1 Introduction

Whether a word's meaning varies across contexts has become a major focus of NLP, linguistics, and social science research in recent years. For example, since the early 20th century, the word "gay" has evolved from describing an emotion to being more aligned with sexual orientation (Hamilton et al., 2016b). Popular word embedding techniques (e.g., Mikolov et al., 2013a; Pennington et al., 2014) have proven useful for analyzing language evolution. But to use these models for such research, scholars often divide a corpus into distinct training sets (e.g., train independent language models on different decades of text) and compare model output across specifications in an *ad hoc* way (Garg et al., 2018). Such splitting inhibits many within- and across-word comparisons, since embeddings are only comparable within a given model. Additionally, most methods ignore the *variance* of words, mechanically treating words equally regardless of the volatility, or uncertainty, in their meanings. If one inspects semantics with only point estimates of embeddings, it is hard to tell whether embeddings represent meaningful traits or are simply noise in the data.

We address these concerns in three ways. First, we estimate a vector for each distinct value of the document covariates, using a multilayer perceptron (MLP) with a non-linear activation function. Second, we parametrize the covariance matrix of each embedding vector explicitly in the model, adopting the Bayes-by-Backprop algorithm (Blundell et al., 2015). Third, we utilize Hotelling T^2 statistics (Hotelling, 1931) to assess whether estimated differences in word vectors are statistically differentiable under a null χ^2 distribution (Ito, 1956). To our knowledge, no prior work evaluates word embeddings with this statistical framework.

2 Related Work

Drift Analysis using Word Embeddings There are several ways to measure drifts in word meanings. Hamilton et al. (2016c) propose the use of cosine similarities of words in different contexts to detect changes. Hamilton et al. (2016b) provide an alternative measure based on the distance of words from their nearest neighbors. Rudolph and Blei (2018) analyze absolute drift of words using Euclidean distance in (two discrete) slices of data. All of these methods compute the word distance based only on the point (i.e., mean) estimates of the word embeddings.

Conditional Word Embedding Rudolph and Blei (2018) estimate dynamic Bernoulli embeddings (DBE), extending the exponential family embedding (Rudolph et al., 2016) generalization of Mikolov et al. (2013a), to learn conditional word embeddings over time. Their amortized approach builds a separate neural network that transforms a global word vector into a covariate-specific vector, and is closely related to our approach in this paper. However, a noticeable omission in their model is that they do not explicitly model parameter covariance or uncertainty.

Word Embedding with Uncertainty Vilnis and McCallum (2017) earlier proposed an energy-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4890–4895
Brussels, Belgium, October 31 - November 4, 2018.

based learning framework in which each word is represented as a multivariate Gaussian distribution with a diagonal covariance. The energy function is defined by the divergence (e.g., KL) between two Gaussian embeddings, and the margin ranking loss (Weston et al., 2011) is minimized. A related model is the Bayesian skip-gram in Brazinskas et al. (2017), which posits a generative model where words are associated with multivariate Gaussian latent variables that generate context words. The parameters of those prior distributions over the multivariate Gaussian latent variables are estimated by maximizing the variational lowerbound, and act as word embeddings.

These works replace mean estimates of embeddings with Gaussian distributions, similar to our proposal here. However, they arrive at this differently; Vilnis and McCallum (2017) from the energy-based learning (LeCun et al., 2006), and Brazinskas et al. (2017) from generative modeling. We provide yet another angle: via (approximate) Bayesian neural networks.

3 Conditional Word Embedding

Adopting Bayes-by-Backprop for Estimation Given a tuple of a word v, a covariate x and a context word v_c, we define the conditional log-probability as

$$\log p(v_c|v,x) = \theta_{v|x}^{\top}\theta_{v_c}^{c} - \log \sum_{v'_c \in V} \exp\left(\theta_{v|x}^{\top}\theta_{v'_c}^{c}\right),$$

where $\theta_{v|x}$ and $\theta_{v_c}^{c}$ are the conditional word embedding of v given x and the context embedding of v_c, respectively. V is the vocabulary of all unique words. To avoid the expensive computation of the partition function, we use negative sampling (Mikolov et al., 2013b), which stochastically approximates the log-probability above by:

$$\begin{aligned}\log p(v_c|v,x) \approx & \log \sigma(\theta_{v|x}^{\top}\theta_{v_c}^{c}) \\ & + \frac{1}{M}\sum_{m=1}^{M} \log(1-\sigma(\theta_{v|x}^{\top}\theta_{v_c^m}^{c})),\end{aligned} \tag{1}$$

where $v_c^m \in V$ is the m-th negative sample drawn from a unigram distribution estimated from D.

We define a prior distribution over each parameter θ to be a scaled mixture of two Gaussians, as suggested by Blundell et al. (2015):

$$\begin{aligned}\log p(\theta_i) = & \log\left(u\mathcal{N}(\theta_i|0,\sigma_1^2)\right. \\ & \left.+(1-u)\mathcal{N}(\theta_i|0,\sigma_2^2)\right),\end{aligned} \tag{2}$$

where σ_1, σ_2 and u are the hyperparameters.

As exactly marginalizing out the parameters $\theta_{\cdot}$ and $\theta_{\cdot}^{c}$ is not scalable, we maximize the variational lowerbound of the marginal probability. To do so, we introduce a variational posterior $q(\theta|\phi)$ parametrized by its own parameter set ϕ. Then, the variational lowerbound is defined as $-\mathcal{F}(\theta,D) = \mathbb{E}_q\left[\log p(D|\theta)\right] - \mathrm{KL}(q(\theta)\|p(\theta))$, where $\log p(D|\theta) = \sum_{(v,x,v_c)\in D} \log p(v_c|v,x)$ in our case. This is stochastically approximated by

$$\begin{aligned}-\mathcal{F}(\theta,D) \approx & \frac{1}{M}\sum_{m=1}^{M} \log p(D|\theta^{(m)}) \\ & - \log q(\theta^{(m)}|\phi) + \log p(\theta^{(m)}),\end{aligned} \tag{3}$$

where $\theta^{(m)}$ is the m-th sample from the variational posterior q (Blundell et al., 2015) via the Gaussian reparametrization in Kingma and Welling (2013). We formulate the variational posterior as a multivariate Gaussian with diagonal covariance.

We use stochastic gradient descent (SGD) to minimize $\mathcal{F}$ with respect to the variational parameters ϕ. At each SGD step, we compute the gradient of the following per-example cost given an example $(v, v_c, x) \in D$:

$$\begin{aligned}f(\theta,(v,v_c,x)) \approx & -\log p(v_c|v,x) + \log q(\tilde{\theta}_{v|x}|\phi) \\ & + \log q(\tilde{\theta}_{v_c}^{c}) + \log q(\tilde{\theta}_{v'_c}^{c}) - \log p(\tilde{\theta}),\end{aligned}$$

where $\tilde{\theta}$ is a single sample from the approximate posterior, and $\log p(v_c|v,x)$ and $\log p(\tilde{\theta})$ are from Eqs. (1)–(2). We then estimate the (approximate) posterior distribution of each conditional word embedding $\theta_{v|x}$ rather than its point estimate, by minimizing $\mathcal{F}$. See Sec. A of the supplementary material for the detailed steps for computing the per-example cost.

Parametrized Conditional Word Embedding An issue with the approach described so far is the number of parameters grows linearly in the size of the vocabulary and in the number of covariate partitions, i.e., $O(|V| \times |C|)$, where C is the set of all partitions. This effectively excludes any potential sharing of structures underlying words across different covariate values and decreases the number of examples per parameter. To avoid this issue, we use a single parametrized function to compute the variational parameters ϕ of each conditional word embedding $\theta_{v|x}$.

For each covariate-word $v|x$, there are two variational parameters $\mu_{v|x}$ and $\sigma_{v|x}$. We use an MLP without any hidden layer and tanh output layer, i.e., the affine transformation followed by pointwise tanh, that takes as input both a global word vector $\mu_v^{(v)}$ and a covariate vector $\mu_x^{(x)}$ and outputs $\mu_{v|x}$, i.e., $\mu_{v|x} = f_\psi(\left[\mu_v^{(v)}; \mu_x^{(x)}\right])$, where ψ is the parameters of this mean-transformation network. The diagonal covariance $\sigma_{v|x}$ is parametrized as $\sigma_{v|x} = \log(1 + \exp(\rho_v))$, where ρ_v is a parameter shared across all covariate configurations. We then minimize $\mathcal{F}$ w.r.t. these parameters ψ, $\left\{\mu_v^{(v)}, \rho_v\right\}_{v \in V}$ and $\left\{\mu_x^{(x)}\right\}_{x \in C}$.

This approach of parametrized conditional word embeddings significantly reduces the number of parameters from $O(|V| \times |C|)$ to $O(|V| + |C|)$, while maintaining posterior uncertainty of the estimated conditional word embedding $\theta_{v|x}$.

4 Divergences for Word Embeddings

As we estimate the approximate posterior uncertainty of conditional word vectors, we can estimate richer relations between vectors (e.g., KL) in addition to more common comparisons (e.g., cosine or Euclidean distance). Moreover, we can explicitly test for whether two vectors are (un)likely to have the same mean in the population. Below, we introduce how Hotelling's T^2 may be used for word-drift or across-word hypothesis testing.

Hotelling's T^2 Statistic We use the estimated posterior mean vector $\mu_{v|x}$ and the diagonal covariance vector $\sigma_{v|x}$ of two word-covariate pairs $v|x_i$ and $v|x_j$ to compute the T^2 statistic, as if they were estimates from two sets of samples: $T^2 = (\mu_i - \mu_j)^\top \mathrm{diag}(s)^{-1}(\mu_i - \mu_j)$. The pooled (diagonal) covariance s of word pairs is computed by $s = \frac{(n_i-1)\cdot\sigma_i^2+(n_j-1)\cdot\sigma_j^2}{n_i+n_j-2}$, where n_i and n_j are the numbers of occurrences of $v|x_i$ and $v|x_j$ in D, respectively.[1] Unlike other divergence measures, this T^2 statistic explicitly takes into account the frequencies of the word-covariate pairs.

Under general conditions, e.g., D is large, the sampling distribution of T^2 converges to a χ_d^2 distribution (Ito, 1956) with d equal to the embedding dimensionality. This allows us to statistically test such a null hypothesis as $\mathrm{Diff}(v_i|x, v_j|x) = 0$ and $\mathrm{Diff}(v|x_i, v|x_j) = 0$.

5 Application: Political Speech in UK

Data We use U.K. Parliament speech records from 1935-2012 as our training data (Rheault et al., 2016). Our conditioning variable of interest is the decade in which a speech occurred. More details are in Sec. B of the supplementary file.

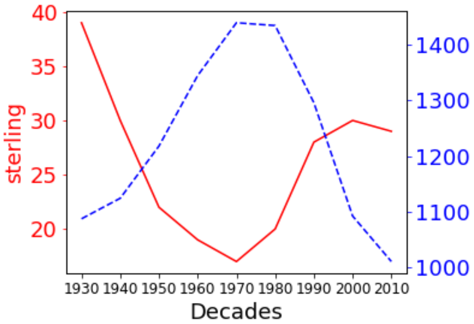

Figure 1: The ranks of "sterling" (solid line) and "pound" (dotted line) w.r.t. "currency" across the decades according to KL divergence.

Model and Learning For each word in the corpus, we consider six surrounding words as its context. The size of embedding is set to 100. We use six negative samples to compute Eq. (1). We use Adagrad (Duchi et al., 2011) with the initial learning rate 0.05 for learning.[2] For other hyperparameters, see the supplementary material. We refer to our approach by BBP. For comparison, we also train analogous DBE embeddings using code from the authors.

6 Result and Analysis

Impact of Covariates To demonstrate how document covariates influence conditional word embeddings, we compare the vector for "currency" against "sterling" and "pound" according to the KL divergence in each decade, which is shown in Fig. 1. In each time period we report the ranking of each w.r.t "currency". Here, we observe that pivotal points for both "sterling" and "pound" occur in the 1970s, which coincides with the moment the UK began to abandon the 'sterling area' (Part III in Schenk, 2010). As such, this financial policy appears to have encouraged semantic drift of the word "pound" towards "currency". See Sec. D in the supplementary material for more details.

We also show a few more examples in Figure 2 and Figure 3 from the Dictionary Induction section below.

Dictionary Induction As a quantitative comparison between the proposed approach and the DBE, we take a dictionary of (British) political terms by Laver and Garry (2000) and look at the

---

[1] T^2 is valid only when $n_i > 1$ and $n_j > 1$.

[2] https://github.com/rhan1207/ConditionalEmbeddings

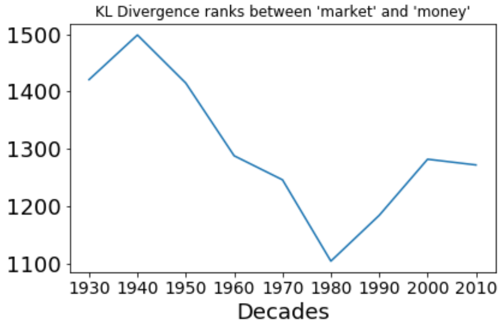

Figure 2: The ranks between "market" and "money" across the decades according to KL divergence.

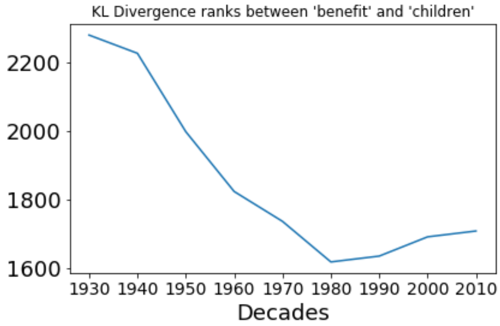

Figure 3: The ranks between "benefit" and "children" across the decades according to KL divergence.

average pair-wise, directional rank in each category ("pro-state", "con-state" and "neutral-state"). We only consider the 2,000 most frequent words in the vocabulary and embeddings with the covariate (decade) set to 2000s. We observed that the proposed model using KL divergence has significantly smaller average pair-wise ranks in "pro-state" (4052 vs. 5047) and "con-state" (2578 vs. 3758) while performs slightly worse than DBE in "neutral-state" category (5414 vs. 5031) suggesting that the proposal approach can cluster words from similar semantic group into closer neighbors than DBE.

Furthermore, we pick 5 most frequent words from "pro-state" and "con-state" and show their average pair-wise rankings and percentile in Table 1. Out of 25K words, our proposed model is able to rank most chosen words within top 10% percentile.

Statistical Word Drift Analysis Our BBP approach permits meaningful downstream hypothesis tests of word drift, i.e, Diff$(v|x_i, v|x_j) = 0$, and across-word similarity, i.e., Diff$(v_i, v_j) = 0$. Among the 2,000 most frequent words in our sample, we perform hypothesis tests of word drifts, comparing vectors from the 1940s against those from the 2000s. We compare results from BBP against the top-100 estimated drifts via DBE. We first observe that most of the top-ranked words by L2 distance in the DBE model are not statistically significant. With the p-value threshold of $\alpha = 0.1$, only eleven words were deemed to have had significant drift, including "council", "labour", "european" and "defence". Sec. E of the supplement includes entire lists of this drift analysis.

Pro-state			Con-state		
Words	Ranks	Pctl	Words	Ranks	Pctl
benefit	1437	5.7	market	1783	7.1
children	2432	9.8	money	1623	6.5

health	996	4.0	private	1670	6.7
transport	4247	17.0	value	1693	6.8

Table 1: Average pair-wise rankings of most frequent words in "pro-state" and "con-state" from a British political dictionary.

	DBE	No Covariance		Covariance	
Words	Ranks	L2	cosine	KL	T^2
uk	1	1.60	0.81	61.4	99.7
eu	2	1.58	0.84	44.6	89.2
war	6	1.52	0.85	48.4	96.8
council	8	1.66	0.84	71.0	142.0^{**}
labour	15	1.63	0.82	62.4	124.8^{*}

Table 2: Top word drifts selected based on DBE model and estimated by BBP. * and ** indicate p-value ≤ 0.05 and 0.01, respectively.

In Table 1, we show results from five illustrative tests, drawn from the top-100 word drifts estimated by the DBE model. We report words' drift ranks in DBE against their corresponding L2 distance, cosine similarity, KL divergence and Hotelling T^2 using the embeddings estimated in our BBP model. Based on the distance metrics that ignore the covariance matrix, these words do not appear to change much over time as their cosine similarities are fairly large and their L2 distances are relatively small with little variation across the five words. This suggests their mean vectors are projected into close space between 1940s and 2000s. However, by taking into account their uncertainty, we observe greater variation in both KL divergence and T^2 statistic. For example, "council" has the eighth largest drift in DBE by L2, but shows the largest T^2 statistic among the five words and is statistically significant at $\alpha = 0.01$. So too, the largest DBE drift ("uk") is insignificant once you take into account the covariance structure.

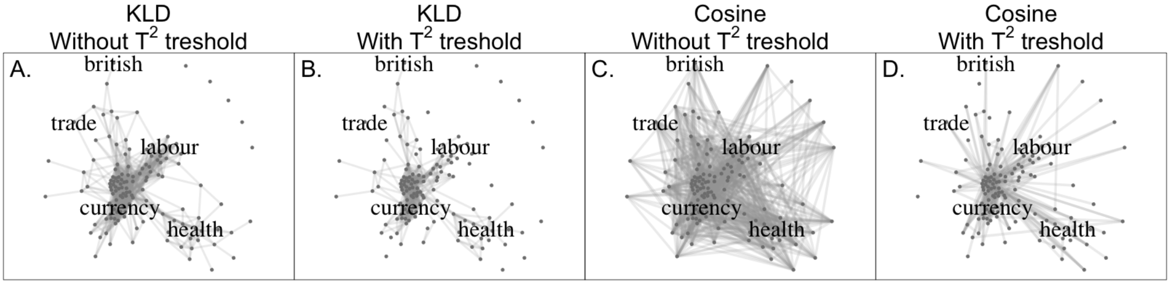

Figure 4: Semantic Graphs with KLD vs. Cosine Similarity

Cosine Similarity vs. KL Divergence In contrast to cosine distance, our proposed method allows computation of the KLD between two vectors that takes into account their covariance. Figure 2 presents semantic graphs estimated in the spirit of Hamilton et al. (2016a). The set of words is given by the union set of the 10 nearest neighbors, measured by cosine similarity and KLD, for the five seed words: "currency", "british", "health", "trade" and "labour". This results in 130 unique words including the seed words and we compute their pair-wise KLD matrix, W_{KL} and pairwise cosine similarity matrix, W_{cos}. We convert W_{KL} to a symmetric matrix as $W'_{KL} = (W_{KL} + W^T_{KL})/2$. Both W_{KL} and W_{cos} have dimensions of 130×130.

Edge weights in Figures 2.A and 2.B are computed by taking a sigmoid transformation of normalized entries in W'_{KL}, i.e., $\sigma(normalize(w'_{KL_{i,j}}))$. Edge weights in 2.C and 2.D are computed by $\arccos(w_{cos_{i,j}})$, following Hamilton et al. (2016a). Edges with weights below 90th percentiles are dropped for visual clarity. Note that with the same number of edges being eliminated, the KLD charts appear more clustered around seed words, implying that incorporating covariance matrix creates useful segregation of words within local contexts; graphs constructed via cosine similarity seem to disperse edge weights in a more diffuse manner.

T^2-based Significance In the context of uncertainty-aware word embeddings, we can use the T^2 statistic to filter out additional words from a nearest neighbor set. For instance, in Figure 2.B and 2.D, we drop edges for word pairs that fall below the 90th percentile of computed T^2 statistics. Filtering with Hotelling T^2 results in more sparse semantic graphs.

7 Conclusion

We proposed an uncertainty-aware conditional word embedding model that combines two ideas; (1) variational Bayesian learning for estimating parameter uncertainty, and (2) structured embeddings conditioned on covariates. This provides a principled direction to investigate hypothesis tests of word vectors in various forms. We evaluated various aspects of the proposed approach on U.K. Parliament speech records from 1935-2012. We believe the proposed approach will serve as a more rigorous tool in social science and other domains.

Classifying Referential and Non-referential *It* Using Gaze

Victoria Yaneva, Le An Ha, Richard Evans, and Ruslan Mitkov

Abstract

When processing a text, humans and machines must disambiguate between different uses of the pronoun *it*, including non-referential, nominal anaphoric or clause anaphoric ones. In this paper, we use eye-tracking data to learn how humans perform this disambiguation. We use this knowledge to improve the automatic classification of *it*. We show that by using gaze data and a POS-tagger we are able to significantly outperform a common baseline and classify between three categories of *it* with an accuracy comparable to that of linguistic-based approaches. In addition, the discriminatory power of specific gaze features informs the way humans process the pronoun, which, to the best of our knowledge, has not been explored using data from a natural reading task.

1 Introduction

Anaphora resolution is both one of the most important and one of the least developed tasks in Natural Language Processing (Lee et al., 2016). A particularly difficult case for anaphora resolution systems is the pronoun *it*, as it may refer to a specific noun phrase or an entire clause, or it may even refer to nothing at all, as in sentences 1 - 3 below[1].

1. *"I couldnt say exactly, sir, but it wasnt tea-time by a long way."* (Pleonastic *it* (non-referential)).
2. *Now, as to this quarrel. When was the first time you heard of it?* (Nominal anaphoric)
3. *You have been with your mistress many years, is it not so?* (Clause anaphoric[2].)

This phenomenon is not specific only to English; pronouns that can be used both referentially and non-referentially exist in a variety of language groups such as the pronoun *'het'* in Dutch, *'det'* in Danish, *'ello'* in Spanish, *'il'* in French, etc.

In NLP, there has been active research in the area of automatic classification of *it* during the past four decades but the issue is far from being solved (Section 2). According to corpus statistics, the pronoun it is by far the most frequently used pronoun in the English language (Li et al., 2009), and as recently as 2016, incorrect classification of different cases of *it* and their antecedents is highlighted as one of the major reasons for the failure of question-answering systems (Lee et al., 2016). In the state of the art, the best approaches to classifying *it* achieve between 2% and 15% improvement over a majority baseline when assigning examples of the pronoun to more than two classes.

In contrast with the extensive research in NLP, very little is known about the way humans approach the disambiguation of *it*. To the best of our knowledge, Foraker and McElree (2007) is the only study on this subject that uses online measures of reading. It proves empirically that the pronoun *it* is resolved more slowly and less accurately than gendered pronouns due to its ambiguity. So far there have been no studies investigating the subject using natural reading data as opposed to artificially created controlled sentences.

In this paper we approach these two problems as one and hypothesise that obtaining information on the way humans disambiguate the pronoun can improve its automatic classification.

We propose a new method for classifying the pronoun *it* that does not rely on linguistic processing. Instead, the model leverages knowledge about the way in which humans disambiguate the pronoun based on eye tracking data. We

---

[1] Extracted from the GECO corpus (Cop et al., 2016)

[2] Some authors also distinguish other, less-common types of the pronoun it such as proaction, cataphoric, discourse topic, and idiomatic, among others (Evans, 2001).

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4896–4901
Brussels, Belgium, October 31 - November 4, 2018.

show that by using gaze data and a POS tagger we are able to achieve classification accuracy of three types of *it* that is comparable to the performance of linguistic-based approaches and that outperforms a common baseline with a statistically significant difference. In addition, examining the discriminatory power of specific gaze features provides valuable information about the human processing of the pronoun. We make our data, code and annotation available at `https://github.com/victoria-ianeva/It-Classification`. The GECO eye-tracking corpus is available at `http://expsy.ugent.be/downloads/geco/`.

2 Related Work

Gaze data in NLP While eye-movement data has been traditionally used to gain understanding of the cognitive processing of text, it was recently applied to a number of technical tasks such as part-of-speech tagging (Barrett et al., 2016), detection of multi-word expressions (Rohanian et al., 2017; Yaneva et al., 2017), sentence compression (Klerke et al., 2016), complex-word identification (Štajner et al., 2017), and sentiment analysis (Rotsztejn, 2018). Eye movements were also shown to carry valuable information about the reader and were used to detect specific conditions affecting reading such as autism (Yaneva et al., 2018, 2016) and dyslexia (Rello and Ballesteros, 2015). The motivation behind these approaches is two-fold. First, eye tracking is already making its way into everyday use with interfaces and devices that feature eye-tracking navigation (e.g. Windows Eye Control[3]). Second, linguistic annotation by gaze is faster than traditional annotation techniques, does not require trained annotators, and provides a language-independent approach that can be applied to under-resourced languages (Barrett et al., 2016). This is particularly interesting for the case of non-referential pronouns, as the phenomenon exists in different languages.

Classification of *it* The majority of the machine learning approaches to classifying the pronoun *it* in different languages are based on linguistic features capturing token, syntactic and semantic context. Different papers report varying majority baseline metrics (between 50% and 75%) depending on the annotated corpora, and an improvement over the majority baselines of between 2% and 15% for classification of more than two classes of *it* (Loáiciga et al., 2017; Uryupina et al., 2016; Lee et al., 2016; Müller, 2006; Boyd et al., 2005; Hoste et al., 2007; Evans, 2001). For example, Loáiciga et al. (2017) train a bidirectional recurrent neural network (RNN) to classify three classes of *it* in the ParCor corpus (Guillou et al., 2014) and compare its performance to a feature-based maximum entropy classifier. The RNN achieves accuracy of 62% compared to a majority baseline of 54% and is significantly outperformed by the linguistic-feature classifier which obtained 68.7% accuracy. Lee et al. (2016) compare several statistical models and report 75% accuracy for four-class classification over a majority baseline of around 62% using linguistic features and a stochastic adaptive gradient algorithm. They also report that experimenting with word embeddings did not lead to more accurate classification. So far, approaches using linguistic features still represent the state of the art in the classification of *it*.

3 Data

Corpus: The eye-tracking data was extracted from the GECO corpus (see Cop et al. (2016) for full corpus specifications) which is the largest and most recent eye-tracking corpus for English at present. The text of the corpus is a novel by Agatha Christie entitled "The Mysterious Affair at Styles", the English version of which contains 54,364 tokens and 5,012 unique types. The entire novel was read by 14 native English undergraduates from the University of Southampton using an eye-tracker with a sampling rate of 1 kHz.

Annotation scheme: A total of 1,052 instances of *it* were found in the corpus[4]. Each of the instances of *it* was annotated by two annotators and assigned to one of three categories: *Pleonastic, Nominal anaphoric* and *Clause anaphoric*, following the scheme used by Lee et al. (2016). The annotators were free to view as much of the previous text as necessary to decide on a label. The inter-annotator agreement for the three categories was $\kappa = 0.636$, $p < 0.0005$, indicating substantial agreement between the annotators. This number corresponds to a percentage agreement of 77.47% for the three categories and is comparable to the

---

[3] https://support.microsoft.com/en-gb/help/4043921/windows-10-get-started-eye-control

[4] This number does not include the possessive pronoun *its*. There are also several tokenisation errors in the GECO corpus (e.g. "it?..ah," and "it...the" misidentified as single tokens.). These cases were excluded.

	Annotat. 1	Annotat. 2	Final
Pleonastic	339 (33%)	406 (38%)	272 (33%)
Nom. anaph.	492 (46%)	527 (50%)	453 (56%)
Clause anaph.	221 (21%)	119 (11%)	89 (11%)

Table 1: Annotation categories

	Prev.	“It”	Next	It + Next
Early	61.1	60.3	61.7	61
Medium	60.9	60.5	60.6	61.2
Late	58.9	60.2	61	61.4

Table 2: Weighted F1 scores for an ablation study for different gaze feature groups over the Previous and Next word baseline (60.4)

81% agreement reported in Lee et al. (2016). We perceived adjudication between cases of disagreement (237 instances) to be extremely arbitrary, so those cases were excluded rather than resolved. Examples of such arbitrary cases include:

- *”Sit down here on the grass, do. It’s ever so much nicer.”* (nominal vs. clause anaphoric)
- *It’s a jolly good life taking it all round...if it weren’t for that fellow Alfred Inglethorp!”* (pleonastic vs. clause anaphoric)

The distribution of each class of the retained data by annotator is presented in Table 1. We make the full annotations of both annotators available.

4 Experiments

Overview In order to test the extent to which gaze data can help the classification of different cases of *it*, we trained and compared three separate classifiers. The first classifier is based on gaze features, the second one is based on linguistic features and finally, we trained a combined classifier using both gaze and linguistic features. We compared the performance of these classifiers to a majority baseline of 55.7 and to another baseline obtained by using the tokens surrounding the pronoun (previous and next word) as features (60.4). We also experimented with adding word embeddings[6] for the surrounding tokens as features. While the full exploration of word embeddings for the classification of *it* remains outside of the scope of this work, it would be interesting to explore whether the embeddings add value to the models by encoding information that was not otherwise captured.

The features that do not have marks in the last three columns were not retained in any of the three best models.

Gaze features We use the gaze features as provided in GECO and we average the data from all 14 readers per token. We extract gaze data for each case of *it*, as well as for the preceding and following word. The full list of gaze features used in the

---

experiments can be seen in Table 3.

Different eye-tracking measures (usually divided into *early* and *late*) are indicative of different aspects of cognitive processing. Early gaze measures such as *First_Fixation_Duration* give information about the early stages of lexical access and syntactic processing, while late measures such as *Total_Reading_Time* or *Number_of_Fixations* give information about processes such as textual integration and disambiguation (see Rayner et al. (2012) for a review). In Table 3, the distinction between *Early, Medium* and *Late* gaze features is mainly based on the run during which the fixations were made (i.e. whether the eyes were passing through the text for the first, second or third time). For each run we report count measures, percentage measures (as part of the trial) and duration measures (in milliseconds). Additional late features reported include *Last_Fixation_Duration* and *Last_Fixation_Run* (the run during which the last fixation in a given region occurred), *Total_Reading_Time* (in msec and %), and *Trial_Fixation_Count* (the overall number of fixations within the trial). *Go_Past_Time* refers to the summation of all fixation durations on the current word during the first pass. *Spillover* refers to the duration of the first fixation made on the next word after leaving the current word in the first run. Finally, a word is considered skipped if no fixation occurred during the first run (*Skip*). A complete legend explaining each feature can be found within the corpus metadata.

An ablation study on the contributions of individual groups of gaze features towards the classification of *it* is presented in Table 2.

Linguistic features We implemented a set of features originally proposed by Evans (2001) and subsequently used extensively in the studies presented in Section 2. In terms of features and categories of *it*, the study by Evans (2001) is the most fine-grained one we could find, classifying 7 categories of *it* with 69% accuracy. The set of features from Evans (2001) is presented in Table 3. These features synthesize information based on corpus studies of the pronoun *it* and thus aim to capture positional, part-of-speech and proximity information, as well as specific patterns of usage. For example, Evans (2001) notes that pleonastic pronouns rarely appear immediately after a prepositional word and that complementisers or adjectives often follow pleonastic instances. Another pattern that distinguishes the pleonastic use of *it* is associated with certain sequences of elements such as 'adjective + noun phrase' and 'complementiser + noun phrase' (Evans, 2001). Therefore, the linguistic features proposed by Evans (2001) and used in our experiments make possible the utilization of corpus-based knowledge for the automatic classification of *it*.

Table 4: Precision, Recall and Weighted F1 for the various classifiers. The * symbol marks statistical significance compared to the baseline model of Previous + Next Word (60.4).

Classification We use simple logistic regression as implemented in WEKA (Hall et al., 2009) with 10-fold cross validation and a random seed parameter 20. Since logistic regression is an interpretable method, we are able to assess the performance of individual features and gain insight into the psycholinguistic processing of the pronoun.

We experimented with gaze features for the individual words but as gaze data is inherently very noisy, we found that smoothing the features by adding the ones that correspond to the pronoun and the next word stabilized the results. Adding the gaze features for the previous word significantly reduced the performance but using them separately in a model with the added *It* + *Next* features maximised our results. For the role of individual features in the models see Table 3.

In order to account for class imbalance we compute and report a weighted F1 score, as opposed to the harmonic mean between precision and recall. First, the F1 for each class is weighted by multiplying it by the number of instances in the class. Then the F1 scores for all classes are summed up and divided by the total number of instances. The resulting weighted F1 score is lower than the traditionally reported mean F1 score, but it represents the effects of class imbalance more accurately.

5 Results and Discussion

The results from the classification experiments presented in Table 4 have implications for language processing by both humans and machines.

From the NLP perspective, the potential of gaze data to not only improve but also, to a certain extent, substitute text processing approaches is an exciting new frontier. Our results show that the gaze-based classifier performs on par with the one using linguistic features and both of them perform significantly better[7] than the baseline of 60.4. An improvement of 13% over the majority baseline is achieved when combining the two but this difference is not a significant improvement over the individual best classifiers. A possible reason for this is that the gaze data and linguistic features encode similar information about the disambiguation of *it* and adding them together leads to overlap instead of complementation. In all three classifiers, the clause-anaphoric class was consistently predicted with lowest accuracy (Table 5), which is not surprising given that it only accounts for 11% of the retained data. In line with the observation of Lee et al. (2016) (Section 2), the embeddings do not show a stable contribution. In our case, this is likely related to the small amount of data, to which we add 300 dimensions per word.

Overall, the improvement achieved by the classifiers is comparable with the current state-of-the-art (Section 2). It is important to note that this is the first study to use text from the domain of literature and that this may have influenced the extraction of the linguistic features. At the same time, literature can be regarded as a more challenging domain than the declarative texts used in previous research, owing to the creative use of language.

From a psycholinguistic perspective, we provide evidence that, indeed, the three classes of *it* are processed differently. We observe that medium and late gaze features related to disambiguation are more discriminative than the early ones. For example, measures such as first fixation duration were not included in any of the models, while revisits as late as the third run (the third time the eyes pass over the region of interest) occurred in these regions and provided a strong signal. Particularly useful features were the durations of the second and last fixations, as well as the information about the run (pass) during which they occur.

NomAnaph	ClauseAnaph	Pleon

53	11	25	ClauseAnaph
93	3	176	Pleon

Table 5: Confusion matrix for the best combined model (Weighted F1 = 68.8)

The significance of these features in the best classifiers somewhat contradicts the ablation study presented in Table 2. According to that table, early processing features for the preceding and next words are expected to outperform the late ones. A possible explanation for this are predictability and spillover effects, as the pronoun *it* is both highly predictable and easy to skip, because of its high frequency and shortness. Indeed, the gaze features from the it-region itself are not as useful as the ones from the surrounding words.

The results from this study showed that: i) gaze features encode information about the way humans disambiguate the pronoun *it*, ii) that this information partially overlaps with the information carried by linguistic features, and that iii) gaze can be used for automatic classification of the pronoun with accuracy comparable to that of linguistic-based approaches. In our future work we will attempt to identify specific patterns of cognitive processing for the individual classes, as well as explore factors related to the readers.

6 Conclusion

We presented the first study on the use of gaze data for disambiguating categories of *it*, exploring a wide range of gaze and linguistic features. The model based on gaze features and part-of-speech information achieved accuracy similar to that of the linguistic-based model and state-of-the-art systems, without the need for text processing. Late gaze features emerged as the most discriminative ones, with disambiguation effort indicators as late as third pass revisits.

State-of-the-art Chinese Word Segmentation with Bi-LSTMs

Ji Ma **Kuzman Ganchev** **David Weiss**
Google AI Language
{maji,kuzman,djweiss}@google.com

Abstract

A wide variety of neural-network architectures have been proposed for the task of Chinese word segmentation. Surprisingly, we find that a bidirectional LSTM model, when combined with standard deep learning techniques and best practices, can achieve better accuracy on many of the popular datasets as compared to models based on more complex neural-network architectures. Furthermore, our error analysis shows that out-of-vocabulary words remain challenging for neural-network models, and many of the remaining errors are unlikely to be fixed through architecture changes. Instead, more effort should be made on exploring resources for further improvement.

1 Introduction

Neural networks have become ubiquitous in natural language processing. For the word segmentation task, there has been a growing body of work exploring novel neural network architectures for learning useful representation and thus better segmentation prediction (Pei et al., 2014; Ma and Hinrichs, 2015; Zhang et al., 2016a; Liu et al., 2016; Cai et al., 2017; Wang and Xu, 2017).

We show that properly training and tuning a relatively simple architecture with a minimal feature set and greedy search achieves state-of-the-art accuracies and beats more complex neural-network architectures. Specifically, the model itself is a straightforward stacked bidirectional LSTM (Figure 1) with just two input features at each position (character and bigram). We use three widely recognized techniques to get the most performance out of the model: pre-trained embeddings (Yang et al., 2017; Zhou et al., 2017), dropout (Srivastava et al., 2014), and hyperparameter tuning (Weiss et al., 2015; Melis et al., 2018). These results have important ramifications for further model development. Unless best practices are followed, it is difficult to compare the impact of modeling decisions, as differences between models are masked by choice of hyperparameters or initialization.

In addition to the simpler model we present, we also aim to provide useful guidance for future research by examining the errors that the model makes. About a third of the errors are due to annotation inconsistency, and these can only be eliminated with manual annotation. The other two thirds are those due to out-of-vocabulary words and those requiring semantic clues not present in the training data. Some of these errors will be almost impossible to solve with different model architectures. For example, while 抽象概念 (abstract concept) appears as one word at test time, any model trained only on the MSR dataset will segment it as two words: 抽象 (abstract) and 概念 (concept), which are seen in the training set 28 and 90 times, respectively, and never together. Thus, we expect that iterating on model architectures will give diminishing returns, while leveraging external resources such as unlabeled data or lexicons is a more promising direction.

In sum, this work contributes two significant pieces of evidence to guide further development in Chinese word segmentation. First, comparing different model architectures requires careful tuning and application of best practices in order to obtain rigorous comparisons. Second, iterating on neural architectures may be insufficient to solve the remaining classes of segmentation errors without further efforts in data collection.

2 Model

Our model is relatively simple. Our approach uses long short-term memory neural networks architectures (LSTM) since previous work has found success with these models (Chen et al., 2015; Zhou et al., 2017, inter alia). We use two features: uni-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4902–4908
Brussels, Belgium, October 31 - November 4, 2018.

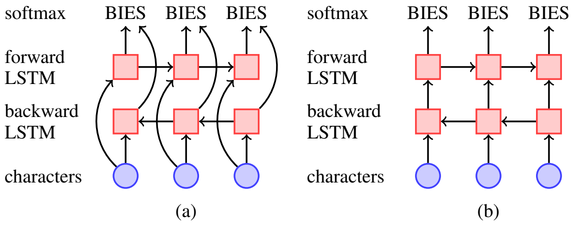

Figure 1: Bi-LSTM models: (a) non-stacking, (b) stacking. Blue circles are input (char and char bigram) embeddings. Red squares are LSTM cells. BIES is a 4-way softmax.

grams and bi-grams of characters at each position. These features are embedded, concatenated, and fed into a stacked bidirectional LSTM (see Figure 1) with two total layers of 256 hidden units each. The softmax layer of the bi-LSTM predicts Begin/Inside/End/Single tags encoding the relationship from characters to segmented words.

In the next sections we describe the best practices we used to achieve state-of-the-art performance from this architecture. Note that all of these practices and techniques are derived from related work, which we describe.

Recurrent Dropout. Contrary to the recommendation of Zaremba et al. (2014), we apply dropout to the recurrent connections of our LSTMs, and we see similar improvements when following the recipe of Gal and Ghahramani (2016) or simply sample a new dropout mask at every recurrent connection.

Hyperparameters. We use the momentum-based averaged SGD procedure from (Weiss et al., 2015) to train the model, with few additions. We normalized each gradient to be at most unit norm, and used asynchronous SGD updates to speed up training time. For each configuration we evaluated, we trained different settings of a manually tuned hyperparameter grid, varying the initial learning rate, learning rate schedule, and input and recurrent dropout rates. We fixed the momentum parameter $\mu = 0.95$. The full list of hyperparameters is given in Table 2. We show the impact of this tuning procedure in Table 7, which we found was crucial to measure the best performance of the simple architecture.

Pretrained Embeddings. Pre-training embedding matrices from automatically gathered data is a powerful technique that has been applied to many NLP problems for several years (e.g. Collobert et al. (2011); Mikolov et al. (2013)). We pretrain the character embeddings and character-bigram embeddings using wang2vec[1] (Ling et al., 2015), which modifies word2vec by incorporating character/bigram order information during training. Note that this idea has been used in segmentation previously by Zhou et al. (2017), but they also augment the contexts by adding the predictions of a baseline segmenter as an additional context. We experimented with both treating the pretrained embeddings as constants or fine-tuning on the particular datasets.

Other Related Work. Recently, a number of different neural network based models have been proposed for word segmentation task. One common approach is to learn word representation through the characters of that word. For example, Liu et al. (2016) runs bi-directional LSTM over characters of the word candidate and then concatenate bi-directional LSTM outputs at both end points. Cai et al. (2017) adopts a gating mechanism to control relative importance of each character in the word candidate.

Besides modeling word representation directly, sequential labeling is another popular approach. For instance, Zheng et al. (2013) and Pei et al. (2014) predict the label of a character based context of a fixed sized local window. Chen et al. (2015) extends the approach by using LSTMs to capture potential long distance information. Both Chen et al. (2015) and Pei et al. (2014) use a transition matrix to model interaction between adjacent tags. Zhou et al. (2017) conduct rigorous comparison and show that such transition matrix rarely improves accuracy. Our model is similar to Zhou et al. (2017), except that we stack the backward LSTM on top of the forward one, which improves accuracy as shown in later section.

Our model is also trained via a simple maximum likelihood objective. In contrast, other state-

of-the-art models use a non-greedy approach to training and inference, e.g. Yang et al. (2017) and Zhang et al. (2016b).

3 Experiments

Data. We conduct experiments on the following datasets: Chinese Penn Treebank 6.0 (CTB6) with data split according the official document; Chinese Penn Treebank 7.0 (CTB7) with recommended data split (Wang et al., 2011); Chinese Universal Treebank (UD) from the Conll2017 shared task (Zeman et al., 2017) with the official data split; Dataset from SIGHAN 2005 bake-off task (Emerson, 2005). Table 1 shows statistics of each data set. For each of the SIGHAN 2005 dataset, we randomly select 10% training data as development set. We convert all digits, punctuation and Latin letters to half-width, to handle full/half-width mismatch between training and test set. We train and evaluate a model for each of the dataset, rather than train one model on the union of all dataset. Following Yang et al. (2017), we convert AS and CITYU to simplified Chinese.

3.1 Main Results

Table 2 contains the state-of-the-art results from recent neural network based models, together with the performance of our model. Table 3 contains results achieved without using any pretrained embeddings.

Our model achieves the best results among NN models on 6/7 datasets. In addition, while the majority of datasets work the best if the pretrained embedding matrix is treated as constant, the MSR dataset is an outlier: fine-tuning embeddings yields a very large improvement. We observe that the likely cause is a low OOV rate in the MSR evaluation set compared to other datasets.

3.2 Ablation Experiments

To see which decisions had the greatest impact on the result, we performed ablation experiments on the holdout sets of the different corpora. Starting with our proposed system[2], we remove one decision, perform hyperparameter tuning, and see the change in performance. The results are summarized in Table 6. Negative numbers in Table 6 correspond to decreases in performance for the ablated system. Note that although each of the components help performance on average, there are cases where we observe no impact. For example using recurrent dropout on AS and MSR rarely af-

---

[2] Based on development set accuracy, we keep the pretrained embedding fixed for all datasets except MSR and AS.

Parameter	Values

Table 5: Test set OOV rate, together with OOV recall achieved with randomly initialized and pretrained embeddings, respectively.

fects accuracy.

We next investigate how important the hyperparameter tuning is to this ablation. In the main result, we tuned each model separately for each dataset. What if instead, each model used a single hyperparameter configuration for all datasets? In Table 7, we compare fully tuned models with those that share hyperparameter configurations across dataset for three settings of the model. We can see that hyperparameter tuning consistently improves model accuracy across all settings.

3.3 Error Analysis

In order to guide future research on Chinese word segmentaion, it is important to understand the types of errors that the system is making. To get a sense of this, we randomly selected 54 and 50 errors from the CTB-6 and MSR test set, respectively. We then manually analyzed them.

The model learns to remember words it has seen, especially for high frequency words. It also learns the notion of prefixes/suffixes, which aids predicting OOV words, a major source of segmentation errors (Huang and Zhao, 2007). Using pretrained embeddings enables the model to expand the set of prefixes/suffixes through their nearest neighbors in the embedding spaces, and therefore further improve OOV recall (on average, using pretrained embeddings contributes to 10% OOV recall improvement, also see Table 5 for more details).

Nevertheless, OOV remains challenging especially for those that can be divided into words frequently seen in the training data, and most (37 out of 43) of the oversegmentation errors are due to this. For instance, the model incorrectly segmented the OOV word 抽象概念 (abstract concept) as 抽象 (abstract) and 概念 (concept). 抽象 and 概念 are seen in the training set for 28 times and 90 times, respectively. Unless high coverage dictionaries are used, it is difficult for any supervised model to learn not to follow this trend in the training data.

In addition, the model sometimes struggles when a prefix/suffix can also be a word by itself. For instance, 权 (right/power) frequently serves as a suffix, such as 管理权 (right of management), 立法权 (right of legislation) and 终审权 (right of final judgment). When the model encounters 下放 (delegate/transfer) 权(power), it incorrectly merges them together.

Similarly, the model segments 居 (in/at) + 中 (middle) as 居中 (in the middle), since the training data contains words such as 居首 (in the first place) and 居次 (in the second place). This example also hints at the ambiguity of word delineation in Chinese, and explains the difficulty in keeping annotations consistent.

As another example, 县 is often attached to another proper noun to become a new word, e.g., 高雄 (Kaohsiung) + 县 becomes 高雄县 (county of Kaohsiung), 新竹(Hsinchu) + 县 becomes 新竹县 (county of Hsinchu). When seeing 银行县支行 (bank's county branch), which should be 银行 (bank) + 县支行 (county branch), the model outputs 银行县 + 支行 (i.e. a county named bank).

PKU	994,822	0.53
UD	98,608	0.46

Table 8: Automatically computed inconsistency in the corpus training data. See text for methodology.

Fixing the above errors requires semantic level knowledge such as ‘Bank’ (银行) is unlikely to be the name of a county (县), and likewise, transfer power (下放权) is not a type of right (权).

Previous work (Huang and Zhao, 2007) also pointed out that OOV is a major obstacle to achieving high segmentation accuracy. They also mentioned that machine learning approaches together with character-based features are more promising in solving OOV problem than rule based methods. Our analysis indicate that learning from the training corpus alone can hardly solve the above mentioned errors. Exploring other sources of knowledge is essential for further improvement. One potential way to acquire such knowledge is to use a language model that is trained on a large scale corpus (Peters et al., 2018). We leave this to future investigation.

Unfortunately, a third (34 out of 104) of the errors we have looked at were due to annotation inconsistency. For example, 建筑系 (Department of Architecture) is once annotated as 建筑 (Architecture) + 系 (Department) and once as 建筑系 under exactly the same context 建筑系教授喻肇青 (Zhaoqing Yu, professor of Architecture). 高新技术 (advanced technology) is annotated as 高 (advanced) + 新 (new) + 技术 (technology) for 37 times, and is annotated as 高新 (advanced and new) + 技术 (technology) for 19 times.

In order to augment the manual verification we performed above, we also wrote a script to automatically find inconsistent annotations in the data. Since this is an automatic script, it cannot distinguish between genuine ambiguity and inconsistent annotations. The heuristic we use is the following: for all word bigrams in the training data, we see if they also occur as single words or word trigrams. We ignore the dominant analysis and count the number of occurrences of the less frequent analyses and report this number as a fraction of the number of tokens in the corpus. Table 8 shows the results of running the script. We see that the AS corpus is the least consistent (according to this heuristic) while MSR is the most consistent. This might explain why both our system and prior work have relatively low performance on AS even though this has the largest training set. By contrast results are much stronger on MSR, and this might be in part because it is more consistently annotated. The ordering of corpora by inconsistency roughly mirrors their ordering by accuracy.

4 Conclusion

In this work, we showed that further research in Chinese segmentation must overcome two key challenges: (1) rigorous tuning and testing of deep learning architectures and (2) more effort should be made on exploring resources for further performance gain.

Abstract

In Sanskrit, small words (morphemes) are combined to form compound words through a process known as *Sandhi*. Sandhi splitting is the process of splitting a given compound word into its constituent morphemes. Although rules governing word splitting exists in the language, it is highly challenging to identify the location of the splits in a compound word. Though existing Sandhi splitting systems incorporate these pre-defined splitting rules, they have a low accuracy as the same compound word might be broken down in multiple ways to provide syntactically correct splits.

In this research, we propose a novel deep learning architecture called Double Decoder RNN (DD-RNN), which (i) predicts the location of the split(s) with 95% accuracy, and (ii) predicts the constituent words (learning the Sandhi splitting rules) with 79.5% accuracy, outperforming the state-of-art by 20%. Additionally, we show the generalization capability of our deep learning model, by showing competitive results in the problem of Chinese word segmentation, as well.

1 Introduction

Compound word formation in Sanskrit is governed by a set of deterministic rules following a well-defined structure described in *Pāṇini's Aṣṭādhyāyī*, a seminal work on Sanskrit grammar. The process of merging two or more morphemes to form a word in Sanskrit is called *Sandhi* and the process of breaking a compound word into its constituent morphemes is called *Sandhi splitting*. In Japanese, *Rendaku* ('sequential voicing') is similar to Sandhi. For example, *'origami'* consists of *'ori'* (paper) + *'kami'* (folding), where *'kami'* changes to *'gami'* due to *Rendaku*.

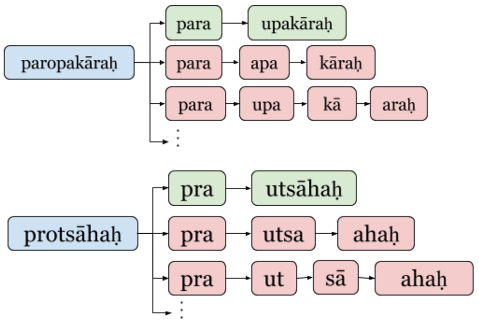

Figure 1: Different possible splits for the word *paropakāraḥ* and *protsāhaḥ*, provided by a standard Sandhi splitter.

Learning the process of sandhi splitting for Sanskrit could provide linguistic insights into the formation of words in a wide-variety of Dravidian languages. From an NLP perspective, automated learning of word formations in Sanskrit could provide a framework for learning word organization in other Indian languages, as well (Bharati et al., 2006). In literature, past works have explored sandhi splitting (Gillon, 2009) (Kulkarni and Shukl, 2009), as a rule based problem by applying the rules from *Aṣṭādhyāyī* in a brute force manner. Consider the example in Figure 1 illustrating the different possible splits of a compound word *paropakāraḥ*. While the correct split is *para* + *upakāraḥ*, other forms of splits such as, *para* + *apa* + *kāraḥ* are syntactically possible while semantically incorrect[1]. Thus, knowing all the rules of splitting is insufficient and it is essential to identify the location(s) of split(s) in a given compound word.

In this research, we propose an approach for au-

tomated generation of split words by first learning the potential split locations in a compound word. We use a deep bi-directional character RNN encoder and two decoders with attention, ***seq*2(*seq*)^2**. The accuracy of our approach on the benchmark dataset for split location prediction is 95% and for split words prediction is 79.5% respectively. To the best of our knowledge, this is the first research work to explore deep learning techniques for the problem of Sanskrit Sandhi splitting, along with producing state-of-art results. Additionally, we show the performance of our proposed model for Chinese word segmentation to demonstrate the model's generalization capability.

2 *seq*2(*seq*)^2: Model Description

In this section, we present our double decoder model to address the Sandhi splitting problem. We first outline the issues with basic deep learning architectures and conceptually highlight the advantages of the double decoder model.

2.1 Issues with standard architectures

Consider an example of splitting a sequence *abcdefg* as *abcdx* + *efg*. The primary task is to identify *d* as the split location. Further, for a given location *d* in the character sequence, the algorithm should take into account (i) the context of character sequence *abc*, (ii) the immediate previous character *c*, (iii) the immediate succeeding character *e*, to make an effective split. For such sequence learning problems, RNNs have become the most popular deep learning model (Pascanu et al., 2013) (Sak et al., 2014).

A basic RNN encoder-decoder model (Cho et al., 2014) with LSTM units (Hochreiter and Schmidhuber, 1997), similar to a machine translation model, was trained initially. The compound word's characters is fed as input to the encoder and is translated to a sequence of characters representing the split words ('+' symbol acts as a separator between the generated split words). However, the model did not yield adequate performance as it encoded only the context of the characters that appeared before the potential split location(s). Though we tried making the encoder bi-directional (referred to as B-RNN), the model's performance only improved marginally. Adding global attention (referred to as B-RNN-A) to the decoder enabled the model to attend to the characters surrounding the potential split location(s) and improved the split prediction performance, making it comparable with some of the best performing tools in the literature.

2.2 Double Decoder RNN (DD-RNN) model

The critical part of learning to split compound words is to correctly identify the location(s) of the split(s). Therefore, we added a two decoders to our bi-directional encoder-decoder model: (i) *location decoder* which learns to predict the split locations and (ii) *character decoder* which generates the split words. A compound word is fed into the encoder character by character. Each character's embedding x_i is passed to the encoders LSTM units. There are two LSTM layers which encode the word, one in forward direction and the other backward. The encoded context vector e_i is then passed to a global attention layer.

In the first phase of training, only the *location decoder* is trained and the *character decoder* is frozen. The character embeddings are learned from scratch in this phase along with the attention weights and other parameters. Here, the model learns to identify the split locations. For example, if the inputs are the embeddings for the compound word *protsāhaḥ*, the location decoder will generate a binary vector $[0, 0, 1, 0, 0, 0, 0, 0, 0]$ which indicates that the split occurs between the third and fourth characters. In the second phase, the *location decoder* is frozen and the *character decoder* is trained. The encoder and attention weights are allowed to be fine-tuned. This decoder learns the underlying rules of Sandhi splitting. Since the attention layer is already pre-trained to identify potential split locations in the previous phase, the *character decoder* can use this context and learn to split the words more accurately. For example, for the same input word *protsāhaḥ*, the *character decoder* will generate [p, r, a, +, u, t, s, ā, h, a, ḥ] as the output. Here the character *o* is split into two characters *a* and *u*.

In both the training phases, we use negative log likelihood as the loss function. Let X be the sequence of the input compound word's characters and Y be the binary vector which indicates the location of the split(s) in the first phase and the true target sequence of characters which form the split words in the second phase. If $Y = y_1, y_2, ..., y_n$, then the loss function is defined as:

$$loss = -\sum_{i=1}^{|Y|} \log P(y_i | y_{i-1}, \cdots, y_1, X)$$

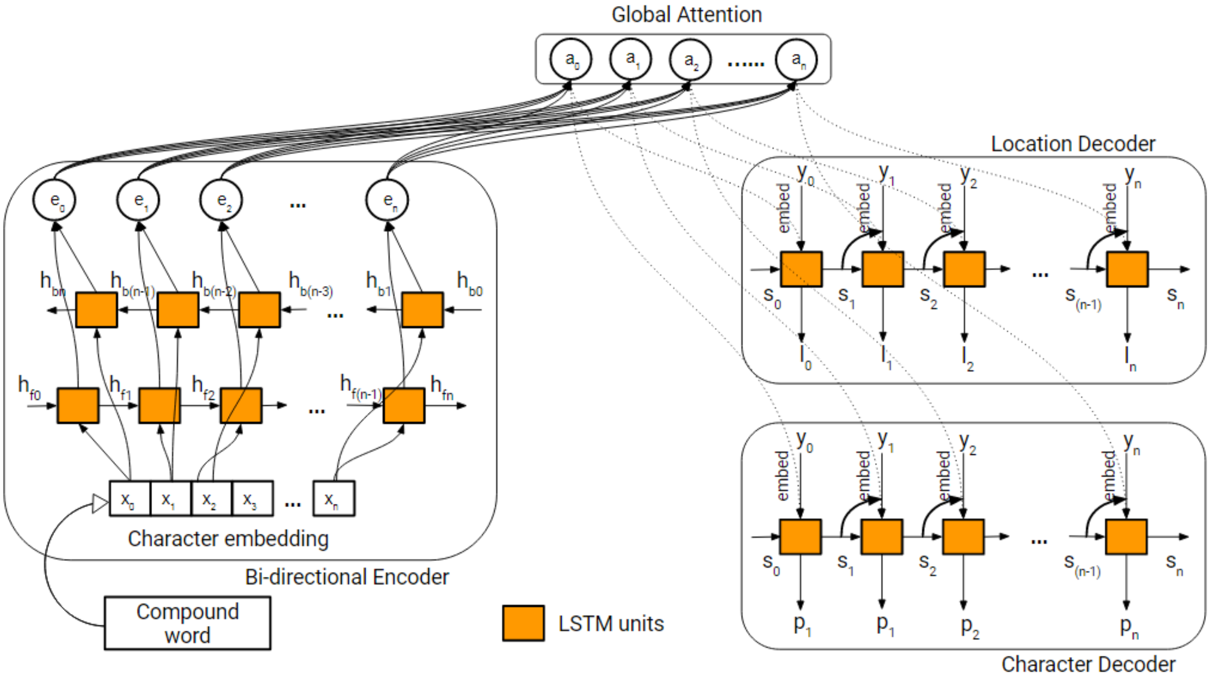

Figure 2: The bi-directional encoder and decoders with attention

We evaluate the DD-RNN and compare it with other tools and architectures in Section 4.

2.3 Implementation details

The architecture of the DD-RNN is shown in Figure 2. We used a character embedding size of 128. The bi-directional encoder and the two decoders are 2 layers deep with 512 LSTM units in each layer. A dropout layer with $p = 0.3$ is applied after each LSTM layer. The entire network is implemented in Torch [2].

Of the 71,747 words in our benchmark dataset, we randomly sampled 80% of the data for training our models. The remaining 20% was used for testing. We used stochastic gradient descent for optimizing the model parameters with an initial learning rate of 1.0. The learning rate was decayed by a factor of 0.5 if the validation perplexity did not improve after an epoch. We used a batch size of 64 and trained the network for 10 epochs on four Tesla K80 GPUs. This setup remains the same for all the experiments we conduct.

3 Existing Datasets and Tools

In this section, we briefly introduce various Sanskirt Sandhi datasets and splitting tools available in literature. We also discuss the tools' drawbacks and the major challenges faced while creating such tools.

Datasets: The *UoH corpus*, created at the University of Hyderabad[3] contains 113,913 words and their splits. This dataset is noisy with typing errors and incorrect splits. The recent *SandhiKosh corpus* (Shubham Bhardwaj, 2018) is a set of 13,930 annotated splits. We combine these datasets and heuristically prune them to finally get 71,747 words and their splits. The pruning is done by considering a data point to be valid only if the compound word and it's splits are present in a standard Sanskrit dictionary (Monier-Williams, 1970). We use this as our benchmark dataset and run all our experiments on it.

Tools: There exist multiple Sandhi splitters in the open domain such as (i) *JNU splitter* (Sachin, 2007), (ii) *UoH splitter* (Kumar et al., 2010) and (iii) *INRIA sanskrit reader companion* (Huet, 2003) (Goyal and Huet, 2013). Though each tool addresses the splitting problem in a specialized way, the general principle remains constant. For a given compound word, the set of all rules are applied to every character in the word and a large potential candidate list of word splits is obtained. Then, a morpheme dictionary of Sanskrit words is used with other heuristics to remove infeasible

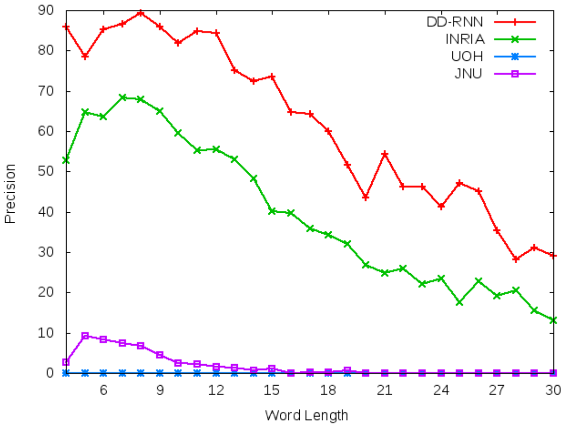

Figure 3: Top-1 split prediction accuracy comparison of different publicly available tools with DD-RNN

word split combinations. However, none of the approaches address the fundamental problem of identifying the location of the split before applying the rules, which will significantly reduce the number of rules that can be applied, hence resulting in more accurate splits.

4 Evaluation and Results

We evaluate the performance of our DD-RNN model by: (i) comparing the **split prediction** accuracy with other publicly available sandhi splitting tools, (ii) comparing the **split prediction** accuracy with other standard RNN architectures such as RNN, B-RNN, and B-RNN-A, and (iii) comparing the **location prediction** accuracy with the RNNs used for Chinese word segmentation (as they only predict the split locations and do not learn the rules of splitting)

4.1 Comparison with publicly available tools

The tools discussed in Section 3 take a compound word as input and provide a list of all possible splits as output (UoH and INRIA splitters provide weighted lists). Initially, we compared only the top prediction in each list with the true output. This gave a very low precision for the tools as shown in Figure 3. Therefore, we relaxed this constraint and considered an output to be correct if the true split is present in the top ten predictions of the list. This increased the precision of the tools as shown in Figure 4 and Table 1.

Even though DD-RNN generates only one output for every input, it clearly out-performs the other publicly available tools by a fair margin.

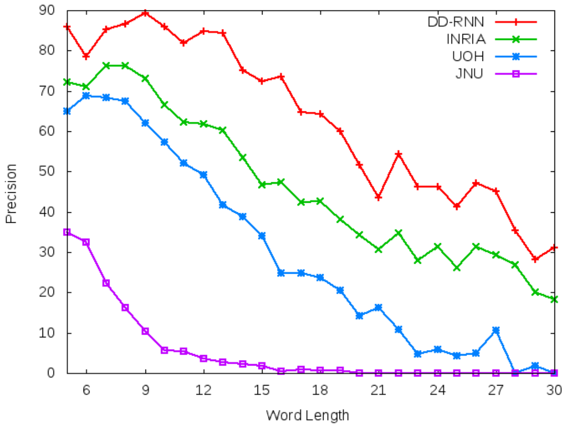

Figure 4: Split prediction accuracy comparison of different publicly available tools (Top-10) with DD-RNN (Top-1)

	Accuracy (%)	
Model	**Location Prediction**	**Split Prediction**
JNU (Top 10)	-	8.1
UoH (Top 10)	-	47.2
INRIA (Top 10)	-	59.9
RNN	79.10	56.6
B-RNN	84.62	58.6
B-RNN-A	88.53	69.3
DD-RNN	**95.0**	**79.5**
LSTM-4	70.2	-
GRNN-5	67.7	-

Table 1: Location and split prediction accuracy of all the tools and models under comparison

4.2 Comparison with standard RNN architectures

To compare the performance of DD-RNN with other standard RNN architectures, we trained the following three models to generate the split predictions on our benchmark dataset: (i) unidirectional encoder and decoder without attention (RNN), (ii) bi-directional encoder and decoder without attention (B-RNN), and (iii) bi-directional encoder and decoder with attention (B-RNN-A)

As seen from the middle part of Table 1, the DD-RNN performs much better than the other architectures with an accuracy of **79.5%**. It is to be noted that B-RNN-A is the same as DD-RNN without the *location decoder*. However, the accuracy of DD-RNN is 14.7% more than that the B-RNN-A and consistently outperforms B-RNN-A on almost all word lengths (Figure 5). This in-

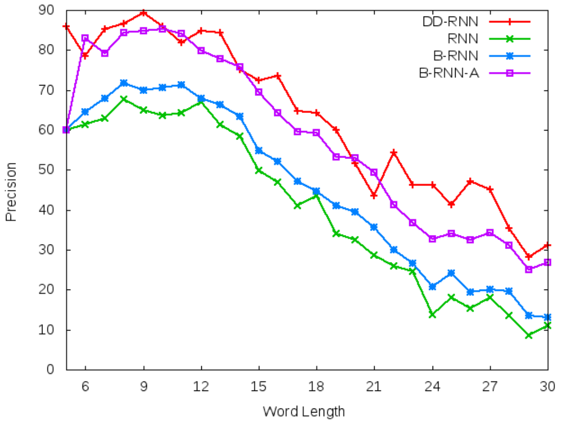

Figure 5: Split prediction accuracy comparison of different variations of RNN on words of different lengths

dicates that the attention mechanism of DD-RNN has learned to better identify the split location(s) due to its pre-training with the *location decoder*.

4.3 Comparison with similar works

(Reddy et al., 2018) propsed a *seq2seq* model using RNN with attention to tackle the Sandhi problem. Their model is similar to B-RNN-A and is outperformed by our proposed DD-RNN by $\tilde{6}$.47%. We also compared our proposed DD-RNN with a uni-directional LSTM with a depth of 4 (Chen et al., 2015b) (**LSTM-4**) and a Gated Recursive Neural Network with a depth of 5 (Chen et al., 2015a) (**GRNN-5**). These models were used to get state of the art results for Chinese word segmentation and their source code is made available online.[4] Since these models can only predict the location(s) of the split(s) and cannot generate the split words themselves, we used the location prediction accuracy as the metric. We trained these models on our benchmark dataset and the results are shown in Table 1. DD-RNN's precision is 35.3% and 40.3% better than LSTM-4 and GRNN-5 respectively. Conversely, we trained the DD-RNN for the Chinese word segmentation task to test the generalizability of the model. Since there are no morphological changes during segmentation in Chinese, the character decoder is redundant and the model collapses to simple *seq2seq*. We used the PKU dataset which is also used in (Chen et al., 2015b) & (Chen et al., 2015a) and obtained an accuracy of 64.25% which is comparable to the results of other standard models.

To summarize, we have used our benchmark dataset to compare the DD-RNN model with existing publicly available Sandhi splitting tools, other RNN architectures and models used for Chinese word segmentation task. Among the existing tools, the INRIA splitter gives the highest split prediction accuracy of 59.9%. Among the standard RNN architectures, B-RNN-A performs the best with a split prediction accuracy of 69.3%. LSTM-4 performs the best among the Chinese word segmentation models with a location prediction accuracy of 70.2%. DD-RNN outperforms all the models both in location and split predictions with 95% and 79.5% accuracies, respectively.

5 Research Impact

This work can be foundational to other Sanskrit based NLP tasks. Let us consider translation as an example. In Sanskrit, arbitrary number of words can be joined together to form a compound word. Literary works, especially from the *Vedic* era often contain words which are a concatenation of three or more simpler words. Presence of such compound words will increase the vocabulary size exponentially and hinder the translation process. However, as a pre-processing step, if all the compound words are split before training a translation model, the number of unique words in the vocabulary reduces which will ease the learning process.

6 Conclusion

In this research, we propose a novel double decoder RNN architecture with attention for Sanskrit Sandhi splitting. Learning such a model would provide further insights into the fundamental linguistic word formation rules of the language. A deep bi-directional encoder is used to encode the character sequence of a Sanskrit word. Using this encoded context vector, a *location decoder* is first used to learn the location(s) of the split(s). Then the *character decoder* is used to generate the split words. We evaluate the performance of the proposed approach on the benchmark dataset in comparison with other publicly available tools, standard RNN architectures and with prior work which tackle similar problems in other languages. As future work, we intend to tackle the harder *Samasa* problem which requires semantic information of a word in addition to the characters' context.

Zhi-Hong Deng
Peking University
`zhdeng@pku.edu.cn`

Abstract

Previous traditional approaches to unsupervised Chinese word segmentation (CWS) can be roughly classified into discriminative and generative models. The former uses the carefully designed goodness measures for candidate segmentation, while the latter focuses on finding the optimal segmentation of the highest generative probability. However, while there exists a trivial way to extend the discriminative models into neural version by using neural language models, those of generative ones are non-trivial. In this paper, we propose the segmental language models (SLMs) for CWS. Our approach explicitly focuses on the segmental nature of Chinese, as well as preserves several properties of language models. In SLMs, a context encoder encodes the previous context and a segment decoder generates each segment incrementally. As far as we know, we are the first to propose a neural model for unsupervised CWS and achieve competitive performance to the state-of-the-art statistical models on four different datasets from SIGHAN 2005 bakeoff.

1 Introduction

Unlike English and many other languages, Chinese sentences have no explicit word boundaries. Therefore, Chinese Word Segmentation (CWS) is a crucial step for many Chinese Natural Language Processing (NLP) tasks such as syntactic parsing, information retrieval and word representation learning (Grave et al., 2018).

Recently, neural approaches for supervised CWS are attracting huge interest. A great quantities of neural models, e.g., tensor neural network (Pei et al., 2014), recursive neural network (Chen et al., 2015a), long-short-term-memory (RNN-LSTM) (Chen et al., 2015b) and convolutional neural network (CNN) (Wang and Xu, 2017), have been proposed and given competitive results to the best statistical models (Sun, 2010). However, the neural approaches for unsupervised CWS have not been investigated.

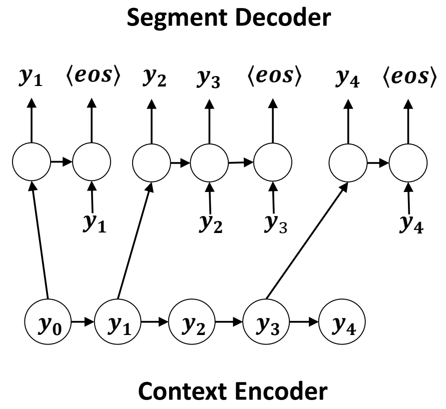

Figure 1: A Segmental Language Model (SLM) works on $\mathbf{y} = \mathbf{y}_1\mathbf{y}_2\mathbf{y}_3\mathbf{y}_4$ with the candidate segmentation $\mathbf{y}_1$, $\mathbf{y}_{2:3}$ and $\mathbf{y}_4$, where $\mathbf{y}_0$ is an additional start symbol which is kept same for all sentences.

Previous unsupervised approaches to CWS can be roughly classified into discriminative and generative models. The former uses carefully designed goodness measures for candidate segmentation, while the latter focuses on designing statistical models for Chinese and finds the optimal segmentation of the highest generative probability.

Popular goodness measures for discriminative models include Mutual Information (MI) (Chang and Lin, 2003), normalized Variation of Branching Entropy (nVBE) (Magistry and Sagot, 2012) and Minimum Description Length (MDL) (Magistry and Sagot, 2013). There is a trivial way to extend these statistical discriminative approaches, because we can simply replace the n-gram language models in these approaches by neural language models (Bengio et al., 2003). There may

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4915–4920
Brussels, Belgium, October 31 - November 4, 2018. ©2018 Association for Computational Linguistics

exists other more sophisticated neural discriminative approaches, but it is not the focus of this paper.

For generative approaches, typical statistical models includes Hidden Markov Model (HMM) (Chen et al., 2014), Hierarchical Dirichlet Process (HDP) (Goldwater et al., 2009) and Nested Pitman-Yor Process (NPY) (Mochihashi et al., 2009). However, none of them can be easily extended into a neural model. Therefore, neural generative models for word segmentation are remaining to be investigated.

In this paper, we proposed the Segmental Language Models (SLMs), a neural generative model that explicitly focuses on the segmental nature of Chinese: SLMs can directly generate segmented sentences and give the corresponding generative probability. We evaluate our methods on four different benchmark datasets from SIGHAN 2005 bakeoff (Emerson, 2005), namely PKU, MSR, AS and CityU. To our knowledge, we are the first to propose a neural model for unsupervised Chinese word segmentation and achieve competitive performance to the state-of-the-art statistical models on four different datasets.[1]

2 Segmental Language Models

In this section, we present our segmental language models (SLMs). Notice that in Chinese NLP, characters are the atom elements. Thus in the context of CWS, we use “character” instead of “word” for language modeling.

2.1 Language Models

The goal of language modeling is to learn the joint probability function of sequences of characters in a language. However, This is intrinsically difficult because of the curse of dimensionality. Traditional approaches obtain generalization based on n-grams, while neural approaches introduce a distributed representation for characters to fight the curse of dimensionality.

A neural Language Model (LM) can give the conditional probability of the next character given the previous ones, and is usually implemented by a Recurrent Neural Network (RNN):

$$\mathbf{h}_t = f(\mathbf{y}_{t-1}, \mathbf{h}_{t-1}) \tag{1}$$

$$p(\mathbf{y}_t|\mathbf{y}_{1:t-1}) = g(\mathbf{h}_t, \mathbf{y}_t) \tag{2}$$

where $\mathbf{y}_t$ is the distributed representation for the t^{th} character and $\mathbf{h}_t$ represents the information of the previous characters.

2.2 Segmental Language Models

Similar to neural language modeling, the goal of segmental language modeling is to learn the joint probability function of the segmented sequences of characters. Thus, for each segment, we have:

$$\hat{p}(\mathbf{y}_t^{(i)}|\mathbf{y}_{1:t-1}^{(i)}, \mathbf{y}^{(1:i-1)}) = g(\mathbf{h}_t^{(i)}, \mathbf{y}_t^{(i)}) \tag{3}$$

where $\mathbf{y}_t^{(i)}$ is the distributed representation for the t^{th} character in the i^{th} segment and $\mathbf{y}^{(1:i-1)}$ is the previous segments. And the concatenation of all segments $\mathbf{y}_{1:T_i}^{(i)}$ is exactly the whole sentence $\mathbf{y}_{1:T}$, where T_i is the length of the i^{th} segment $\mathbf{y}^{(i)}$, T is the length of the sentence $\mathbf{y}$.

Moreover, we introduce a context encoder RNN to process the character sequence $\mathbf{y}^{(1:i-1)}$ in order to make $\mathbf{y}_t^{(i)}$ conditional on $\mathbf{y}^{(1:i-1)}$. Specifically, we initialize $\mathbf{h}_0^{(i)}$ with the context encoder's output of $\mathbf{y}^{(1:i-1)}$.

Notice that although we have an encoder and the segment decoder g, SLM is not an encoder-decoder model. Because the content that the decoder generates is not the same as what the encoder provides.

Figure 1 illustrates how SLMs work with a candidate segmentation.

2.3 Properties of SLMs

However, in unsupervised scheme, the given sentences are not segmented. Therefore, the probability for SLMs to generate a given sentence is the joint probability of all possible segmentation:

$$\begin{aligned} p(\mathbf{y}_{1:T}) &= \sum_{T_1,T_2,\dots} \prod_i \hat{p}(\mathbf{y}_{1:T_i}^{(i)}) \\ &= \sum_{T_1,T_2,\dots} \prod_i \prod_{t=1}^{T_i+1} \hat{p}(\mathbf{y}_t^{(i)}|\mathbf{y}_{0:t-1}^{(i)}) \end{aligned} \tag{4}$$

where $\mathbf{y}_{T_i+1}^{(i)} = \langle eos \rangle$ is the **end of segment** symbol at the end of each segment, and $\mathbf{y}_0^{(i)}$ is the context representation of $\mathbf{y}^{(1:i-1)}$.

Moreover, for sentence generation, SLMs are able to generate arbitrary sentences by generating

---

[1] Our implementation can be found at `https://github.com/Edward-Sun/SLM`

segments one by one and stopping when generating **end of sentence** symbol $\langle EOS \rangle$. In addition, the time complexity is linear to the length of the generated sentence, as we can keep the hidden state of the context encoder RNN and update it when generating new words.

Last but not least, it is easy to verify that SLMs preserve the probabilistic property of language models:

$$\sum_i P(\mathbf{s}_i) = 1 \tag{5}$$

where $\mathbf{s}_i$ enumerates all possible sentences.

In summary, the segmental language models can perfectly substitute vanilla language models.

2.4 Training and Decoding

Similar to language model, the training is achieved by maximizing the training corpus log-likelihood:

$$L = -\log p(\mathbf{y}_{1:T}) \tag{6}$$

Luckily, we can compute the loss objective function in linear time complexity using dynamic programming, given the initial condition that $p(\mathbf{y}_{1:0}) = 1$:

$$p(\mathbf{y}_{1:n}) = \sum_{k=1}^{K} p(\mathbf{y}_{1:n-k}) \hat{p}(\mathbf{y}_{n-k+1:n}) \tag{7}$$

where $p(\cdot)$ is the joint probability of all possible segmentation, $\hat{p}(\cdot)$ is the probability of one segment and K is the maximal length of the segments.

We can also find the segmentation with maximal probability (namely, decoding) in linear time using dynamic programming in the similarly way with $\bar{p}(\mathbf{y}_{1:0}) = 1$:

$$\bar{p}(\mathbf{y}_{1:n}) = \max_{k=1}^{K} \bar{p}(\mathbf{y}_{1:n-k}) \hat{p}(\mathbf{y}_{n-k+1:n}) \tag{8}$$

$$\delta(\mathbf{y}_{1:n}) = \arg\max_{k=1}^{K} \bar{p}(\mathbf{y}_{1:n-k}) \hat{p}(\mathbf{y}_{n-k+1:n}) \tag{9}$$

where $\bar{p}$ is the probability of the best segmentation and δ is used to trace back the decoding.

3 Experiments

3.1 Experimental Settings and Detail

We evaluate our models on SIGHAN 2005 bakeoff (Emerson, 2005) datasets and replace all the punctuation marks with $\langle punc \rangle$, English characters with $\langle eng \rangle$ and Arabic numbers with $\langle num \rangle$ for all text and only consider segment the text between punctuations. Following Chen et al. (2014) , we use both training data and test data for training and only test data are used for evaluation. In order to make a fair comparison with the previous works, we do not consider using other larger raw corpus.

Table 1: Main results on SIGHAN 2005 bakeoff datasets with previous state-of-the-art models (Chen et al., 2014; Wang et al., 2011; Mochihashi et al., 2009; Magistry and Sagot, 2012)

We apply word2vec (Mikolov et al., 2013) on Chinese Gigaword corpus (LDC2011T13) to get pretrained embedding of characters.

A 2-layer LSTM (Hochreiter and Schmidhuber, 1997) is used as the segment decoder and a 1-layer LSTM is used as the context encoder.

We use stochastic gradient decent with a minibatch size of 256 and a learning rate of 16.0 to optimize the model parameters in the first 400 steps, then we use Adam (Kingma and Ba, 2014) with a learning rate of 0.005 to further optimize the models. Model parameters are initialized by normal distributions as Glorot and Bengio (2010) suggested. We use a gradient clip $= 0.1$ and apply a dropout with dropout rate $= 0.1$ to the character embedding and RNNs to prevent over-fit.

The standard word precision, recall and F1 measures (Emerson, 2005) are used to evaluate segmentation performance.

3.2 Results and Analysis

Our final results are shown in Table 1, which lists the results of several previous state-of-the-art methods[2], where we mark the best results in

---

[2] Magistry and Sagot (2012) evaluated their nVBE on the training data, and the joint model of Chen et al. (2014) combine HDP+HMM and is initialized with nVBE, so in principle these results can not be compared directly.

Table 2: Results of SLM-4 incorporating ad hoc guidelines, where † represents using additional 1024 segmented setences for training data and * represents using a rule-based post-processing

boldface. We test the proposed SLMs with different maximal segment length $K = 2, 3, 4$ and use "SLM-K" to denote the corresponding model. We do not try $K > 4$ because there are rare words that consist more than 4 characters.

As can be seen, it is hard to predict what choice of K will give the best performance. This is because the exact definition of what a word remains hard to reach and different datasets follow different guidelines. Zhao and Kit (2008) use cross-training of a supervised segmentation system in order to have an estimation of the consistency between different segmentation guidelines and the average consistency is found to be as low as 85 (f-score). Therefore, this can be regarded as a top line for unsupervised CWS.

Table 1 shows that SLMs outperform previous best discriminative and generative models on PKU and AS datasets. This might be due to that the segmentation guideline of our models are closer to these two datasets.

Moreover, in the experiments, we observe that Chinese particles often attach other words, for example, "的" following adjectives and "了" following verbs. It is hard for our generative models to split them apart. Therefore, we propose a rule-based post-processing module to deal with this problem, where we explicitly split the attached particles from other words.[3] The post-processing is applied on the results of "SLM-4". In addition, we also evaluate "SLM-4" using the first 1024 sentences of the segmented training datasets (about 5.4% of PKU, 1.2% of MSR, 0.1% of AS and 1.9% of CityU) for training, in order to teach "SLM-4" the corresponding ad hoc segmentation guidelines. Table 2 shows the results.

We can find from the table that only 1024 guideline sentences can improve the performance of "SLM-4" significantly. While rule-based post-processing is very effective, "SLM-4†" can outperform "SLM-4*" on all the four datasets. Moreover, performance drops when applying the rule-based post-processing to "SLM-4†" on three datasets. These indicate that SLMs can learn the empirical rules for word segmentation given only a small amount of training data. And these guideline data can improve the performance of SLMs naturally, superior to using explicit rules.

Error	SLM-2	SLM-3	SLM-4
Insertion	7866	4803	3519
Deletion	3855	7518	8851

Table 3: Statistics of insertion errors and deletion errors that SLM-K produces on PKU dataset

3.3 The Effect of the Maximal Segment Length

The maximal segment length K represents the prior knowledge we have for Chinese word segmentation. For example $K = 3$ represents that there are only unigrams, bigrams and trigrams in the text. While there do exist words that contain more than four characters, most of the Chinese words are unigram or bigram. Therefore, K denotes a trade-off between the accuracy of short words and long words.

Specifically, we investigate two major segmentation problems that might affect the accuracy of word segmentation performance, namely, insertion errors and deletion errors. An insertion error insert a segment in a word, which split a correct word. And an deletion error delete the segment between two words, which results in a composition error (Li and Yuan, 1998). Table 3 shows the statistics of different errors on PKU of our model with different K. We can observe that insertion error rate decrease with the increase of K, while the deletion error rate increase with the increase of K.

We also provide some examples in Table 4, which are taken from the results of our models. It clearly illustrates that different K could result in different errors. For example, there is an insertion error on "反过来" by SML-2, and a deletion error on "促进" and "了" by SLM-4.

4 Related Work

Generative Models for CWS Goldwater et al. (2009) are the first to proposed a generative model for unsupervised word segmentation. They

built a nonparametric Bayesian bigram language model based on HDP (Teh et al., 2005). Mochihashi et al. (2009) proposed a Bayesian hierarchical language model using Pitman-Yor (PY) process, which can generate sentences hierarchically. Chen et al. (2014) proposed a Bayesian HMM model for unsupervised CWS inspired by the character-based scheme in supervised CWS task, where the hidden state of charaters are set to $\{\mathbf{S}\text{ingle}, \mathbf{B}\text{egin}, \mathbf{E}\text{nd}, \mathbf{M}\text{iddle}\}$ to represents their corresponding positions in the words. The segmental language model is not a neural extension of the above statistical models, as we model the segments directly.

Segmental Sequence Models Sequence modeling via segmentations has been well investigated by Wang et al. (2017), where they proposed the Sleep-AWake Network (SWAN) for speech recognition. SWAN is similar to SLM. However, SLMs do not have sleep-awake states. And SLMs predict the following segment given the previous context while SWAN tries to recover the information in the encoded state. Therefore, the key difference is that SLMs are unsupervised language models while SWANs are supervised seq2seq models. Thereafter, Huang et al. (2017) successfully apply SWAN in their phrase-based machine translation. Another related work in machine translation is the online segment to segment neural transduction (Yu et al., 2016), where the model is able to capture unbounded dependencies in both the input and output sequences. Kong (2017) also proposed a Segmental Recurrent Neural Network (SRNN) with CTC to solve segmental labeling problems.

5 Conclusion

In this paper, we proposed a neural generative model for fully unsupervised Chinese word segmentation (CWS). To the best of knowledge, this is the first neural model for CWS. Our segmental language model is an intuitive generalization of vanilla neural language models that directly modeling the segmental nature of Chinese. Experimental results show that our models achieve competitive performance to the previous state-of-the-art statistical models on four datasets from SIGHAN 2005. We also show the improvement of incorporating ad hoc guidelines into our segmental language models. Our future work may include the following two directions.

- In this work, we only consider the sequential segmental language modeling. In the future, we are interested in build a hierarchical neural language model like the Pitman-Yor process.
- Like vanilla language models, the segmental language models can also provide useful information for semi-supervised learning tasks. It would also be interesting to explore our models in the semi-supervised schemes.

Abstract

We present LemmaTag, a featureless neural network architecture that jointly generates part-of-speech tags and lemmas for sentences by using bidirectional RNNs with character-level and word-level embeddings. We demonstrate that both tasks benefit from sharing the encoding part of the network, predicting tag subcategories, and using the tagger output as an input to the lemmatizer. We evaluate our model across several languages with complex morphology, which surpasses state-of-the-art accuracy in both part-of-speech tagging and lemmatization in Czech, German, and Arabic.

1 Introduction

Morphologically rich languages are often difficult to process in many NLP tasks (Tsarfaty et al., 2010). As opposed to analytical languages like English, morphologically rich languages encode diverse sets of grammatical information within each word using inflections, which convey characteristics such as case, gender, and tense. The addition of several inflectional variants across many words dramatically increases the vocabulary size, which results in data sparsity and out-of-vocabulary (OOV) issues.

Due to these issues, morphological part-of-speech (POS) tagging and lemmatization are heavily used in NLP tasks such as machine translation (Fraser et al., 2012) and sentiment analysis (Abdul-Mageed et al., 2014). In morphologically rich languages, the POS tags typically consist of multiple morpho-syntactic subcategories providing additional information (see Figure 1). Closely related to POS tagging is lemmatization, which involves transforming each word to its root or dictionary form. Both tasks require context-sensitive awareness to disambiguate words with the same form but different syntactic or semantic features and behavior. Furthermore, lemmatization of a word form can benefit substantially from the information present in morphological tags, as grammatical attributes often disambiguate word forms using context (Müller et al., 2015).

We address context-sensitive POS tagging and lemmatization using a neural network model that jointly performs both tasks on each input word in a given sentence.[1] We train the model in a supervised fashion, requiring training data containing word forms, lemmas, and POS tags. In addition, we incorporate the ideas from Inoue et al. (2017) to optionally allow the network to predict the subcategories of each tag to improve accuracy. Our model is related to the work of Müller et al. (2015), which use conditional random fields (CRF) to jointly tag and lemmatize words for morphologically rich languages. The idea of jointly predicting several dimensions of categories has been explored prior to this work, for example, joint morphological and syntactic analysis (Bohnet et al., 2013) or joint parsing and semantic role labeling (Gesmundo et al., 2009).

Our model consists of three parts: (1) The **shared encoder**, which creates an internal representation for every word based on its character se-

Brussels, Belgium, October 31 - November 4, 2018.

quence and the sentence context. We adopt the encoder architecture of Chakrabarty et al. (2017), utilizing character-level (Heigold et al., 2017) and word-level embeddings (Mikolov et al., 2013b; Santos and Zadrozny, 2014) processed through several layers of bidirectional recurrent neural networks (BRNN/BiRNN) (Schuster and Paliwal, 1997; Chakrabarty et al., 2017). (2) The **tagger decoder**, which applies a fully-connected layer to the outputs of the shared encoder to predict the POS tags. (3) The **lemmatizer decoder**, which applies an RNN sequence decoder to the combined outputs of the shared encoder and tagger decoder, producing a sequence of characters that predict each lemma (similar to Bergmanis and Goldwater (2018)).

The main advantages over other proposed models are: (i) The model is featureless, requiring little to no text preprocessing or morphological analysis postprocessing. (ii) The model shares the word embeddings, character embeddings, and RNN encoder weights in the tagger and lemmatizer, improving both tagging and lemmatization accuracy while reducing the number of parameters required for both tasks. (iii) The model predicts tag subcategories and provides the output of the tagger as features for the input of the lemmatizer, further improving accuracy.

We evaluate the accuracy of our model in POS tagging and lemmatization across several languages: Czech, Arabic, German, and English. For each language, we also compare the performance of a fully separate tagger and lemmatizer to the proposed joint model. Our results show that our joint model is able to improve the accuracy for both tasks, and achieves state-of-the-art performance in both POS tagging and lemmatization in Czech, German, and Arabic, while closely matching state-of-the-art performance for English.

2 The Joint LemmaTag Model

Given a sequence of words in a sentence $w_1, \ldots, w_k$, the task of the model is to produce a sequence of associated tags $t_1, \ldots, t_k$ and lemmas $\ell_1, \ldots, \ell_k$. For a word w_i at position i, we denote $c_{i,1}, c_{i,2} \ldots c_{i,m_i}$ to be the sequence of characters that make up w_i, where m_i indicates the length of the word string at position i. Analogously, we define $l_{i,1}, \ldots l_{i,\lambda_i}$ to be the sequence of characters that make up the lemma ℓ_i.

Our proposed model (shown in Figures 2 and 3) is split into three parts: the shared encoder, the tagger, and the lemmatizer. The initial layers of the model are shared between the tagger and lemmatizer, encoding the words, characters, and context in a given sentence. The encoder then passes its outputs to two networks, which perform a classification task to predict tags by the tagger and a sequence prediction task to output lemmas (character-by-character) in the lemmatizer.

2.1 Shared Encoder

In the encoder shown in Figure 2, each character $c_{i,1}, c_{i,2} \ldots c_{i,m_i}$ of a word w_i is indexed into an embedding layer to produce fixed-length embedded vectors representing each character. These vectors are further passed into a layer of BRNNs composed of gated recurrent units (GRU) (Cho et al., 2014) producing outputs $\mathbf{e}_1^c, \ldots, \mathbf{e}_m^c$, and whose final states are concatenated to produce the character-level embedding $\mathbf{s}_i^c$ of the word. Similarly, we index w_i into a word-level embedding layer to compute vector $\mathbf{e}_i^b$. Then we sum these results to produce the final word embedding $\mathbf{e}_i^w = \mathbf{s}_i^c + \mathbf{e}_i^b$.

We repeat this process independently for all the words in the sentence and feed the resulting sequence $\mathbf{e}_1^w \ldots \mathbf{e}_k^w$ into another two BRNN layers composed of long short-term memory units (LSTM) with residual connections. This produces word-level outputs $\mathbf{o}_1^w, \ldots \mathbf{o}_k^w$ that encode sentence-level context for each word (we ignore the final hidden states).

2.2 Tagger

The task of the tagger is to predict a tag $t_i \in \mathcal{T}$ given a word w_i and its context, where $\mathcal{T}$ is a set of possible tags. As explained the introduction, morphologically rich languages typically subdivide tags further into several subcategories $t_i = (t_{i,1}, \ldots, t_{i,\tau})$, where $t_{i,j} \in \mathcal{T}_j$, the j-th subcategory. See Figure 1 for an illustration taken from the Czech PDT tagset where $\tau = 15$.

Having the encoded words of a sentence available, the tagger consists of a fully-connected layer with $|\mathcal{T}|$ neurons whose input is the output of the word feature RNN $\mathbf{o}_i^w$ (see figure 2). This layer produces the logits $\mathbf{t}_i$ of the tag values and the predictions t_i as the maximum-likelihood value (i.e., softmax).

To obtain the information about categorical nature of each tag, we also predict every category $t_{i,j}$ of the tag independently (if they exist in the

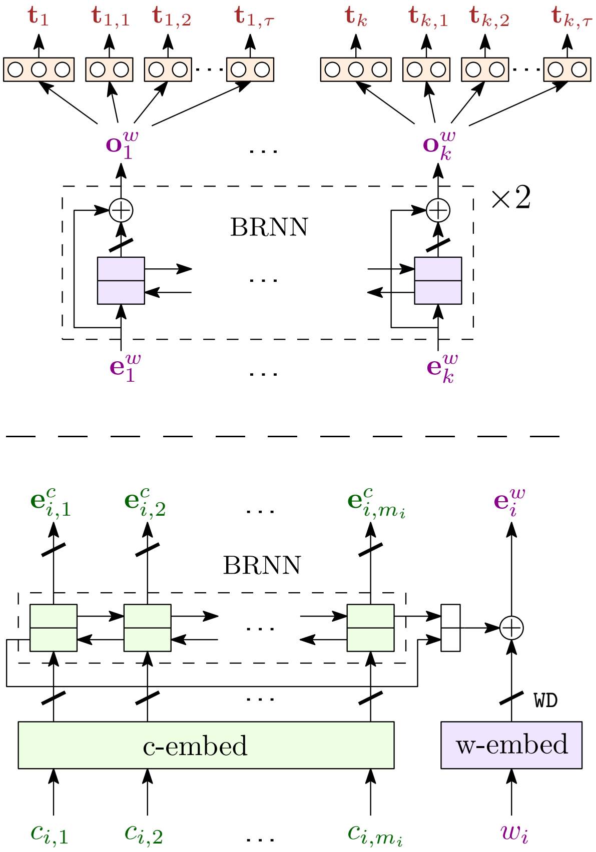

Figure 2: *Bottom:* Word-level encoder. The characters of every input word are embedded with a look-up table (c-embed) and encoded with a BRNN. The outputs $\mathbf{e}_{i,j}^c$ are used in decoder attention, and the final states are summed with the word-level embedding (w-embed) to produce $\mathbf{e}_i^w$. `WD` denotes word dropout.
Top: Sentence-level encoder and tag classifier. Two BRNN layers with residual connections act on the embedded words $\mathbf{e}_i^w$ of a sentence, providing context. The output of the tag classification are the logits for both the whole tags $\mathbf{t}_i$ and their components $\mathbf{t}_{i,j}$.
Both: Thick slanted lines denote training dropout.

dataset) with τ dense layers similar to Inoue et al. (2017). The j-th layer has $|\mathcal{T}_j|$ neurons and outputs the logits $\mathbf{t}_{i,j}$ for the category values. While these values are trained for, their value is not used in tag prediction. All tag values $\mathbf{T}_i = (\mathbf{t}_i, \mathbf{t}_{i,1} \dots, \mathbf{t}_{i,\tau})$ are concatenated into a flat vector and fed into the lemmatizer as an additional set of potentially useful features.

2.3 Lemmatizer

The task of the lemmatizer is to produce a sequence of characters $l_{i,1}, \dots, l_{i,\lambda_i}$ and the lemma length λ_i for each lemma ℓ_i. We use a recurrent sequence decoder, a setup typical of many sequence-to-sequence (seq2seq) tasks such as in neural machine translation (Sutskever et al., 2014).

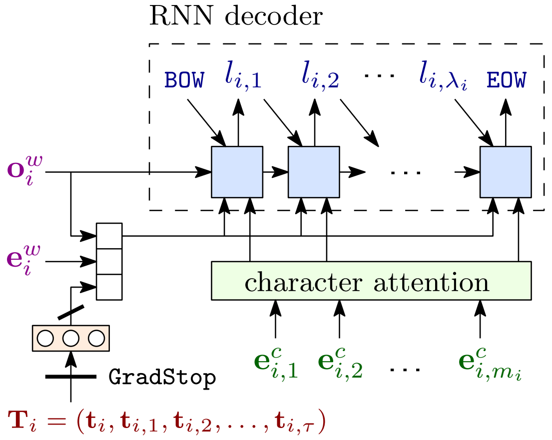

Figure 3: Lemma decoder, consisting of a standard seq2seq autoregressive decoder with Luong attention on character encodings, and with additional inputs of processed tagger features $\mathbf{T}_i$, embeddings $\mathbf{e}_i^w$ and sentence-level outputs $\mathbf{o}_i^w$. Gradients from the lemmatizer are stopped from flowing into the tagger (denoted `GradStop`).

The lemmatizer consists of a recurrent LSTM layer whose initial state is taken from word-level output $\mathbf{o}_i^w$ and whose inputs consist of three parts. The first part is the embedding of the previous output character (initially a *beginning-of-word* character `BOW`).

The second part is a character-level attention mechanism (Bahdanau et al., 2014) on the outputs of the character-level BRNN $\mathbf{e}_{i,1}^c, \dots, \mathbf{e}_{i,m_i}^c$. We employ the multiplicative attention mechanism described in Luong et al. (2015), which allows the LSTM cell to compute an attention vector that selectively weights character-level information in $\mathbf{e}_{i,j}^c$ at each time step j based on the input state of the LSTM cell.

The third and final part of the RNN input allows the network to receive the information about the embedding of the word, the surrounding context of the sentence, and the output of the tagger. This output is the same for all time steps of a lemma and is a concatenation of the following: the output of the encoder $\mathbf{o}_i^w$, the embedded word $\mathbf{e}_i^w$ and processed tag features $\mathbf{T}_i^f$. The tag features are obtained by projecting the concatenated outputs of the tagger $\mathbf{T}_i$ through a fully connected layer with ReLU activation. During training, we do not pass the gradients back through $\mathbf{T}_i$ to prevent the distortion of the tagger output.

The decoder performs greedy decoding to predict the character outputs. It runs until it produces the *end-of-word* character `EOW` or reaches a character limit of $m_i + 10$.

2.4 Loss Function

We define the final loss function as the weighted sum of the losses of the tagger and the lemmatizer:

$$L(\hat{y}, y) = \boldsymbol{\alpha} L(\hat{\mathbf{y}}^t, \mathbf{y}^t) + \beta L(\hat{\mathbf{y}}^\ell, \mathbf{y}^\ell)$$

where $\mathbf{y}$ are the predicted outputs, $\hat{\mathbf{y}}$ the expected outputs, $\mathbf{y}^t$, the tag components and $\mathbf{y}^\ell$ are the lemma characters. The tagger and lemmatizer losses are separately computed as the softmax cross entropy of the output logits. The weight hyperparameters $\boldsymbol{\alpha}, \beta$ scale the training losses so that the subtag and lemmatizer losses do not overpower the unfactored tag predictor gradients. The vector $\boldsymbol{\alpha}$ contains $\tau + 1$ weights: one for the whole tag and one for every component.[2]

3 Experiments

In this section, we show the outcomes of evaluation when running our joint tagger and lemmatizer and compare with the current state of the art in Czech, German, Arabic, and English datasets. Additionally, we evaluate the lemmatizer and tagger separately to compare the relative increase in tagging and lemmatization accuracy.

3.1 Datasets

Our datasets consist of the Czech Prague Dependency Treebank (PDT) (Hajič et al., 2006, 2018), the German TIGER corpus (Brants et al., 2004), the Universal Dependencies Prague Arabic Dependency Treebank (UD-PADT) (Hajic et al., 2004), the Universal Dependencies English Web Treebank (UD-EWT) (Silveira et al., 2014), and the WSJ portion of the English Penn Treebank (tags only) (Marcus et al., 1993). In all datasets, we use the tags specific to their respective language. Of these datasets, only Czech and Arabic provide subcategorical tags, and we use unfactored tags for the rest. See Table 1 for tagger and lemmatizer accuracies.

Note that the PDT dataset disambiguates lemmas with the same textual representation by appending a number as lemma sense indicator. For example, the dataset contains disambiguated lemmas `moc-1` (as *power*) and `moc-2` (as *too much*). About 17.5% of the PDT tokens have such sense-disambiguated lemmas. LemmaTag predicts the lemmas including the senses and the accuracies in Table 1 take that into account. Ignoring the sense ambiguity, the lemmatization accuracy of the joint LemmaTag model is 98.94% for Czech-PDT.

3.2 Hyperparameters

We use loss weights $\boldsymbol{\alpha}_0 = 1.0$ for the whole tags, $\boldsymbol{\alpha}_{1,\ldots,\tau} = 0.1$ for the tag component losses and $\beta = 0.5$ for the lemmatizer loss.[3] The RNNs and word embedding tables have dimensionality 768 except for character-level embeddings and the character-level RNN, which are of dimension 384. The fully-connected layer whose inputs are $\mathbf{T}_i$ is of dimension 256.

We train the models for 40 epochs with random permutations of training sentences and batches of 16 sentences. The starting learning rate is $\eta = 0.001$ and we scale this by 0.25 at epochs 20 and 30 to increase accuracy. We train the network using the lazy variant of the Adam optimizer (Kingma and Ba, 2014), which only updates accumulators for variables that appear in the current batch (TensorFlow, 2018), with parameters $\beta_1 = 0.9$ and $\beta_2 = 0.99$. We clip the global gradient norm to 3.0 to reduce the risk of exploding gradients.

To prevent the tagger from overfitting, we devise several strategies for regularization. We apply dropouts with rate 0.5 as indicated in Figures 2 and 3. The word dropout (`WD`) replaces 25% of words by the unknown token `<unk>` to force the network to rely more on context, combatting data sparsity issues. Lastly, we employ label smoothing (Pereyra et al., 2017) which is a way to prevent the network from being too confident in any one class. The label smoothing parameter is set to 0.1 for the tagger logits (both whole tags and the tag components).

Note that we did not perform any complex hyperparameter search. For additional information on real-world performance and additional techniques which have not improved evaluation accuracy, see Appendix A.

4 Conclusion

The evaluation results show that performing lemmatization and tagging jointly by sharing encoder parameters and utilizing tag features is

---

[2] If no components are available, $\tau = 0$.

[3] These are reasonable values to prevent gradients from overpowering one another. The lemmatizer tends to influence the tagger heavily.

Approach	**Czech-PDT***		**German-TIGER**		**Arabic-PADT***		**Eng-EWT**		**Eng-WSJ**

Table 1: Final accuracies on the test sets comparing the LemmaTag architecture as described (joint), LemmaTag neither sharing the encoder nor providing tagger features (sep), and the state-of-the-art results (SoTA). The state-of-the-art results are taken from the following papers: *(a)* Hajič et al. (2009), *(b)* Straková et al. (2014), *(c)* Eger et al. (2016), *(d)* Inoue et al. (2017), *(e)* Straka et al. (2016), *(f)* Ling et al. (2015). The results marked with a plus$_+$ use additional resources apart from the dataset, and datasets marked with a star* indicate the availability of subcategorical tags.

mutually beneficial in morphologically rich languages. We have shown that incorporating these ideas results in excellent performance, surpassing state-of-the-art in Czech, German, and Arabic POS tagging and lemmatization by a substantial margin, while closely matching state-of-the-art English POS tagging accuracy.

However, in languages with weak morphology such as English (and German to a lesser extent), sharing the encoder parameters may even hurt the performance of the tagger. We believe this is a consequence of tags correlating less with word-level morphology, and more with sentence-level syntax in morphologically poor languages. Lemma prediction could benefit from the syntactic information in the tags, but the tag predictions rely more on syntactic structure (i.e., word order) rather than on root forms of individual words which could be ambiguous.

There are some possible performance improvements and additional metrics which we leave for future work. For simplicity, one improvement we intentionally left out is the use of additional data. We can incorporate word2vec (Mikolov et al., 2013a) or ELMo (Peters et al., 2018) word representations, which have shown to reduce out-of-domain issues and provide semantic information (Eger et al., 2016). A second improvement is to integrate information from a morphological dictionary to resolve certain ambiguities (Hajič et al., 2009; Inoue et al., 2017). A third improvement can be to replace the seq2seq lemmatizer decoder with a classifier that chooses a corresponding edit tree to modify (reduce) the word form to its lemma (Chakrabarty et al., 2017). A fourth possible improvement would be to experiment with the Transformer model (Vaswani et al., 2017), which utilizes non-recurrent multi-headed self-attention and has been shown to achieve state-of-the-art performance in several related sequence tasks (Dehghani et al., 2018). Lastly, we would like to evaluate LemmaTag on a wider range of languages, e.g., on the Universal Dependencies (Nivre et al., 2016) languages and treebanks which employ lemmatization, and to analyze the use of different types of POS tags in the model.

The code we used for LemmaTag is available at `https://github.com/hyperparticle/LemmaTag`.

A Appendix

A.1 GPU Performance

We ran all the tests on an NVIDIA GTX 1080 Ti GPU. The joint LemmaTag training takes about 3 hours for Arabic PADT, 4.5 hours for English EWT, 12 hours for German TIGER, and 22 hours for Czech PDT. The separate models take about 50% more time. After training, the lemma and tag predictions of 219,000 test tokens of the Czech PDT take about 100 seconds.

A.2 Other Techniques

We briefly summarize some of the additional techniques we have tried but which do not improve the results. While some of those techniques do help on smaller models or earlier in the training, the effect on the fully trained network seems to be marginal or even detrimental.

Separate sense prediction. Instead of predicting the sense disambiguation with the lemmatizer (Czech only), we tried to predict sense as an additional classification problem with one dense layer based on $\mathbf{o}_i^w$ and $\mathbf{T}_i$, but it seems to perform slightly worse (0.2%).

Beam search decoder. We have implemented a beam search decoder for the lemmatizer instead of the standard greedy one, but the improvement was marginal (around 0.01%).

Variational dropout. While the dropouts in the LemmaTag are completely random, variational dropout erases the same channels across the time steps of the RNN. While this generally improves training in convolutional networks and RNNs, we saw no significant difference.

Layer normalization. Layer normalization applied to the encoding RNNs did not bring significant gain and also slowed down the training.

Recovering Missing Characters in Old Hawaiian Writing

Abstract

In contrast to the older writing system of the 19th century, modern Hawaiian orthography employs characters for long vowels and glottal stops. These extra characters account for about one-third of the phonemes in Hawaiian, so including them makes a big difference to reading comprehension and pronunciation. However, transliterating between older and newer texts is a laborious task when performed manually. We introduce two related methods to help solve this transliteration problem automatically. One approach is implemented, end-to-end, using finite state transducers (FSTs). The other is a hybrid deep learning approach, which approximately composes an FST with a recurrent neural network language model.

1 Introduction

From 1834 to 1948, more than 125,000 newspaper pages were published in the Hawaiian language (Nogelmeier, 2010). Yet by 1981, many expected this once flourishing language to die (Benton, 1981). Hawaiian has since defied expectations and experienced the beginnings of a remarkable recovery (Warner, 2001; Wilson and Kamanā, 2001). However much of the literary inheritance that is contained in the newspapers has become difficult for modern Hawaiians to read, since the newspapers were written in an orthography that failed to represent about one-third of the language's phonemes. This orthography, which we will refer to as the *missionary orthography*, excluded Hawaiian phonemes that did not have equivalents in American English (see Schütz, 1994), including Hawaiian's long vowels /iː eː aː oː uː/ and glottal stop /ʔ/. By contrast, the *modern Hawaiian orthography*, an innovation of Pukui and Elbert's Hawaiian dictionary (Pukui and Elbert, 1957), presents a nearly perfect, one-to-one mapping between graphemes and phonemes (see Appendix A.1). The process of manual transliteration from missionary to modern Hawaiian orthography is extremely labor intensive. Yet the cultural benefits are so great that hundreds of pages of newspaper-serials have already been transliterated by hand, such as Nogelmeier's new edition of the epic tale of *Hiʻiakaikapoliopele*, the volcano goddess's sister (Hoʻoulumāhiehie, 2007). Critically important as such efforts are to the continued revitalization of this endangered language, they are still only an introduction to the material that could be translated for a modern Hawaiian audience.

In this paper, we propose to automate, or semi-automate, the transliteration of old Hawaiian texts into the modern orthography. Following a brief review of related work (Section 2), we begin by describing a dataset of modern Hawaiian (Section 3). In Section 4, we present two methods for recovering missing graphemes (and hence phonemes) from the missionary orthography. The first composes a series of weighted FSTs; the second approximately composes a FST with a recurrent neural network language model (RNNLM) using a beam search procedure. Both approaches require only modern Hawaiian texts for training, which are much more plentiful than parallel corpora. Section 5 reports the results of our transliteration experiments using a simulated parallel corpus, as well as two 19th century newspaper articles for which we also have modern Hawaiian transcriptions. Being based on FSTs, both approaches are modular and extensible. We observe useful and promising results for both of our methods, with the best results obtained by the hybrid FST-RNNLM. These results showcase the strength of combining established hand-engineering methods with deep learning in a smaller data regime, with practical applications for an endangered language.

2 Related work

Many of the themes that we address relate to existing literature. For example, Hajič et al. (2000) and Scannell (2014) have written on machine translation (MT) for closely related languages and on multilingual text normalization. Though language-relatedness makes MT easier (Kolovratník et al., 2010), state-of-the-art techniques such as neural machine translation (NMT) have not performed well for languages with little data (Östling and Tiedemann, 2017). So while the Hawaiian transliteration problem could be cast as an instance of MT or of NMT, we chose to sidestep the scarcity of parallel data by not considering such approaches.

Hybrid approaches that combine expert knowledge for well-understood structures with deep learning for data-plentiful subproblems offer rich opportunities for data-efficient modelling. Prior work has combined FSTs with RNNs, although not using the approximate FST-to-RNN composition algorithm that we introduce here (in Appendix A.4). For example, Sproat and Jaitly (2016) used an FST to restrict the search space when decoding from an RNN and Rastogi et al. (2016) incorporated RNN information into an FST.

3 Data

3.1 Missionary & modern orthography

The primary difference between the missionary and modern Hawaiian orthographies is that the missionary orthography does not encode long vowels or the glottal stop (see Appendix A.1). For example, the following Hawaiian phrases were recorded by a 19th-century German traveller in the missionary orthography: *Ua oia au*, *E ue ae oe ia Ii*, *E ao ae oe ia ia* (Chamisso, 1837, p. 7). In the modern orthography these become: *Ua ʻō ʻia au* ‘I am speared’, *E uē aʻe ʻoe iā ʻĪʻī* ‘You must weep for ‘Īʻī (a person)’, and *E aʻo aʻe ʻoe iā ia* ‘You teach him’ (Elbert and Pukui, 1979, p. 3).

We can convert text in the modern Hawaiian orthography *backward* chronologically to an approximate missionary orthography by mapping each glottal stop ⟨ʻ⟩ to the empty string ε, and each long vowel, e.g. ⟨ā ē ī ō ū⟩, to its corresponding short vowel, ⟨a e i o u⟩. As a first approximation, we may treat mappings from the modern-to-missionary orthographies as unambiguously many-to-one; thus there is information loss. We will return to secondary differences between the orthographies in Section 6. To illustrate, the following four words in the modern orthography all map to the same missionary string *aa*: *aʻa* (root), *ʻaʻa* (brave), *ʻaʻā* (crumbly lava rock), and *ʻāʻā* (stutter).

The *forward* mapping from missionary-to-modern orthographies is one-to-many. Thus the missionary string *aa* could map to *aʻa*, *ʻaʻa*, *ʻaʻā*, or *ʻāʻā*. The *transliteration problem* we address here seeks to discover how we can use context to recover the information not present in the missionary orthography that modern Hawaiian orthography retains.

Source	Chars	Words
Ulukau(160 texts)	6,518,451	1,334,451
Hiʻiakaikapoliopele	1,272,935	259,947
Wikipedia	577,794	10,221
Total	8,369,180	1,604,619

Figure 1: Modern data sources and their sizes.

3.2 Data sources

We draw on three sources for modern Hawaiian text: the main text of *Hiʻiakaikapoliopele* (Hoʻoulumāhiehie, 2007), 160 short texts from *Ulukau: The Hawaiian Electronic Library*, and the full Hawaiian Wikipedia (see Figure 1).[1]

For evaluation, we simulate a missionary-era version of the modern texts using the backward mapping described above. In addition, we evaluated our models on a couple of 19th century newspaper samples for which we have parallel missionary-era and modern text. Both simulated and real parallel corpora will be described in Section 5.

4 Models

We can frame the task of transliterating from missionary-to-modern Hawaiian orthographies as a sequence transduction problem. Many deep learning approaches (e.g. Sutskever et al., 2014; Graves, 2012) are not easily applicable to this task since we do not have a sufficiently large dataset of parallel texts. Instead, we focus on approaches that mix hand-designed finite state transducers with trained language models, including deep learning approaches like RNNLMs (Mikolov et al., 2010).

---

[1] *Ulukau: The Hawaiian Electronic Library*: `http://ulukau.org/`, Hawaiian Wikipedia: `https://haw.wikipedia.org/`. Both accessed 19 May 2018.

4.1 Finite state transducers

Our initial approach represents the mapping from missionary to modern orthography using a composition of (weighted) FSTs. For a thorough review of FSTs, see Mohri (1997).

First, we construct a finite state acceptor, I, from the input text. Here we construct a trivial chain-shaped acceptor that accepts only the input text. Each symbol in the input text is represented by a state which emits this symbol on a single transition that moves to the next state. The transition emitting the final symbol in the string leads to the sole accepting state.

Second, we construct a missionary-to-modern orthography conversion FST which we call C, which models potential orthography changes that can occur when transliterating from the missionary to modern Hawaiian orthography. For example, two non-deterministic transitions introduce an optional long-vowel map (a : ā) and (a : a). Another transition inserts glottal stops: (ϵ : ‘). By capturing the orthographic changes we know to occur, the composition $I \circ C$ produces a large set of candidates to be narrowed using the language model.

Third, we use the modern Hawaiian text from Section 3.2 to construct and evaluate a number of character-level n-gram language models, of various combinations of order and Katz backoff and Kneser-Ney (KN) smoothing (Katz, 1987; Kneser and Ney, 1995); see Appendix A.5 for details. N-gram language models can be expressed as weighted FSTs. We denote the n-gram or weighted FST language model as G. Character-level models are used as we wanted to generalize to out-of-vocabulary words, which we expected to occur frequently in a small corpus like the one we have for Hawaiian.

Finally, we use this model to infer modern orthography given a piece of text in missionary orthography as input, then compose the FSTs to form the *search graph* FST: $S = I \circ C \circ G$. The minimum cost path through S gives the predicted modern orthography. Of these n-gram-based approached, we found the Kneser-Ney-based models to perform best; these approaches are called FST-C-NGRAM-KN and FST-C_{wb}-NGRAM-KN.

We circumvent the lack of a large, non-simulated parallel corpus by training the language model exclusively on text in the modern Hawaiian orthography. In turn, the orthographic transliteration FST C produces candidates which are disambiguated by the language model. The result is finally evaluated against the ground-truth modern text.

Although the orthographic transliteration model is an approximation, and thus not exhaustive, it embodies an explicit and interpretable representation that can be easily extended independently of the rest of the model. To illustrate how the approach can be extended, we constructed a variant C_{wb} (where wb stands for word boundary). C_{wb} optionally inserts a space after each vowel using an additional arc that maps (ϵ : *space*), as diagrammed in Appendix A.2. This variant is able to model some changes in Hawaiian's word-boundary conventions (Wilson, 1976), such as *alaila* becoming *a laila* which demarcates the preposition *a* ‘until’ and noun *laila* ‘then’. We employ this variant to predict modern equivalents from 19th century newspaper samples in Section 5. Pseudocode summarizing this method is shown in Appendix A.3. Example predictions can be found in Appendix A.6.

4.2 FSTs with LSTM language models

As an alternative approach, we combined the FST C in the previous section with an RNNLM (Mikolov et al., 2010). RNNLMs often generalize better than n-gram models.

An RNN is a neural network that models temporal or sequential data, by iterating a function mapping a state and input to a new state and output. These can be stacked to form a deep RNN. For language modelling, each step of the final RNN layer models a word or character sequence via $p(w_1, \ldots, w_n) = \prod_{i=1}^{n} p(w_i | w_{1:i-1})$ and can be trained by maximum likelihood. Recent language modeling work has typically used the long short-term memory (LSTM) unit (Hochreiter and Schmidhuber, 1997) for its favorable gradient propagation properties. All RNNs in this paper are LSTMs.

Our goal is to replace the n-gram language model in the end-to-end FST approach with an RNNLM. While the minimum cost path through an FST can be computed exactly as done in the previous section, it is not straightforward to compose the relation defined by an FST with an arbitrary one like that defined by an RNNLM. A minimum cost path through the composition of the FST and the RNNLM can be defined as a path (i.e. label sequence) that minimizes the sum of the FST path cost and the RNNLM cost.

We can approximately find a minimum cost path of the composition of the two models by a breadth-first search over the FST graph, or using a beam search, as follows. At any particular iteration, consider a single beam element. The beam element holds the current FST and RNN states, and the path taken through the FST so far. We follow each possible arc from the current FST state, each producing a new child beam element, and feed the output symbol into the RNN (unless it is ϵ). There may be duplicate beam elements due the nondeterminicity of the FST; in this case, the lower cost edge wins. We sort by the sum of the FST and RNN costs, keep the lowest-cost K, and then proceed to the next iteration. If a beam element is on an accepting state of the FST, it is kept as-is between iterations. Detailed pseudocode is provided in Appendix A.4.

In the following we will refer to the hybrid models as FST-RNNLM—or as FST-RNNLM-C and FST-RNNLM-C_{wb} if we want to distinguish between which FST we used. Similarly, the FST-only models will be referred to as FST-C and FST-C_{wb}, with suffixes denoting what kind of n-gram and smoothing were used. For example, FST-C-7GRAM-KN denotes a FST-only model with an 7-gram language model and Kneser-Ney smoothing. Details of the language models trained can be found in Appendix A.5.

5 Results

Evaluation. Since we were unable to find a sufficiently large corpus of parallel texts in the missionary and modern Hawaiian orthographies, we instead used a corpus of modern Hawaiian texts (*ground-truth*) as summarized in Section 3.2 and Figure 1. Note that training the n-gram and RNN language models required only this modern corpus.

To evaluate the accuracy of our approaches, we derived a synthetic parallel corpus from these modern Hawaiian texts. We also used a small but real parallel corpus, based on two 19th century newspaper texts and their hand-edited modern equivalents.

Simulated parallel corpus. To produce a simulated parallel corpus (*input-missionary*), we systematically reduced the orthography in the modern texts using the backward mapping described in Section 3.1. We then applied the two approaches described in Section 4, with the aim of recovering the information lost.

We evaluated the predicted modern text (*predictions*) by computing

$$\text{CERR} = \frac{d(\text{prediction}, \text{ground-truth})}{d(\text{input-missionary}, \text{ground-truth})},$$

where d denotes character-level edit distance. This is a modification of character error rate, normalized by the distance of the input and target rather than by the length of the target. We note that CERR may be high even when the predictions are very accurate as $d(\text{input-missionary}, \text{ground-truth})$ is small when the text is similar in both orthographies.

Table 1 reports the results of the approaches we described in Section 4. Out of the Kneser-Ney n-gram models, we found that the FST-C-9GRAM-KN and the version modelling word boundaries (FST-C_{wb}-9GRAM-KN) to perform best on the synthetic parallel corpus and newspapers, respectively. C_{wb} was not applied to the synthetic parallel corpus as we did not model word splitting. The hybrid models (FST-RNNLM) outperformed all FST-only approaches.

Real parallel corpus (newspaper texts). Not content to evaluate the model on simulated missionary orthography, we also evaluated it on two newspaper texts, using selections originally published in 1867 and 1894 for which we had 19th century and manually-edited modern equivalents. The newspaper selections discuss *Kahahana*, one of the last kings of Oʻahu (Kamakau and Perreira, 2002), and *Uluhaimalama*, a garden party and secret political gathering, held after the deposition of Hawaiʻi's last queen (Pukui et al., 2006). Unlike the synthetic missionary corpus evaluation where we did not model word splitting, we found that replacing C with C_{wb} on the newspaper texts significantly improved the output, especially on the FST-RNNLM model. Thus, we found the word-splitting hybrid model (FST-RNNLM-C_{wb}) to be the best performing model overall (Table 1).

6 Conclusions and future work

With this paper we introduced a new transliteration problem to the field, that of mapping between old and new Hawaiian orthographies—where the modern Hawaiian orthography represents linguistic information that is missing from older missionary-era texts. One difficulty of this problem is that there is a limited amount of Hawaiian data, making data-hungry solutions like end-to-end deep learning

	LM perplexity		Transliteration performance (%CERR)		
Transliteration model	Valid.	Test	Corpus	Newspaper 1	Newspaper 2
FST-(C/C_{wb})-7GRAM-KN	3.07	3.13	27.3%	50.1% / 38.7%	52.0% / 47.5%
FST-(C/C_{wb})-9GRAM-KN	2.95	3.02	26.6%	50.7% / 39.3%	52.5% / 47.2%
FST-(C/C_{wb})-11GRAM-KN	2.94	3.02	27.8%	53.9% / 41.3%	54.1% / 48.7%
FST-RNNLM-(C/C_{wb})	**2.65**	**2.69**	**16.3%**	47.2% / **34.3%**	49.8% / **41.2%**

Table 1: Performance (%CERR). Slash-separated pairs denote FSTs incapable/capable of inserting word boundaries, respectively; see Section 4. The -KN suffix denotes Kneser-Ney smoothing. The data from Section 3.2 is used for evaluating the modern-orthography language model perplexity, and "Corpus" evaluates test-set transliteration performance from the synthetic missionary text back to the original modern text.

Input	Ua lawe ola ia o Keawehano imua o Kahekili, a ua hai aku o Kapohu...
Prediction	Ua lawe ola ʻia ʻo Keawehano i mua o Kahekili, a ua haʻi aku ʻo Kapohu...
Ground-truth	Ua lawe ola ʻia ʻo Keawehano i mua o Kahekili, a ua haʻi aku ʻo Kapohū...

Figure 2: An example of (missionary input, predicted modern text, ground-truth), from each newspaper. Note the correctly split word in the second example. Incorrect characters, which are quite rare, are shown as red and underlined. More sample predictions can be found in Appendix A.6.

unlikely to work. To solve the transliteration problem, we therefore proposed two models: the first was implemented end-to-end using weighted FSTs; the second was a hybrid deep learning approach that combined an FST and an RNNLM. Both models gave promising results, but the hybrid approach, which allowed us to use a more powerful recurrent neural network-based language model despite our dataset's small size, performed best. Factoring a problem like ours into one part that can be modelled exactly using expert domain knowledge and into another part that can be learned directly from data using deep learning is not novel; however it is a promising research direction for data-efficient modelling. To our knowledge, this paper is the first to describe a procedure to compose an FST with an RNN by approximately performing beam search over the FST.

While the role of the RNNLM part of the hybrid approach may be obvious, the FST component plays an important role too. For example, the hand-designed FST component can be replaced without needing to retrain the RNNLM. We tried to showcase this modularity by constructing two FSTs which we referred to as C and C_{wb}, where only the latter allowed the insertion of spaces. Future work could extend the FST to model orthographic changes suggested by an error analysis of the current model's predictions (see Appendix A.6). These errors motivate new mappings for consonant substitutions like (r : l) and (s : k) observed in loanword adaptations (e.g. *rose* ⇒ *loke*). The error analysis also motivates mappings to delete spaces ($\sqcup : \epsilon$) and to handle contractions, like *na'lii* ⇒ *nā aliʻi*. We could further incorporate linguistic knowledge of Hawaiian into the FST, which tells us, for example, that a consonant is typically followed by a vowel (Parker Jones, 2010). Additional improvements to the hybrid model might be obtained by increasing the amount of modern Hawaiian text used to train the RNNLM. One way to do this would be to accelerate the rate at which missionary-era Hawaiian texts are modernized. To this end, we hope that the present models will be used within the Hawaiian community to semi-automate, and thereby accelerate, the modernization of old Hawaiian texts.

When data permutations are pathological: the case of neural natural language inference

Natalie Schluter and Daniel Varab

Abstract

Consider two competitive machine learning models, one of which was considered state-of-the art, and the other a competitive baseline. Suppose that by just permuting the examples of the training set, say by reversing the original order, by shuffling, or by mini-batching, you could report substantially better/worst performance for the system of your choice, by multiple percentage points. In this paper, we illustrate this scenario for a trending NLP task: Natural Language Inference (NLI). We show that for the two central NLI corpora today, the learning process of neural systems is far too sensitive to permutations of the data. In doing so we reopen the question of how to judge a good neural architecture for NLI, given the available dataset and perhaps, further, the soundness of the NLI task itself in its current state.

1 Introduction

There is increased interest today in the detection of information quality: whether a statement is true or false, or equivalently, whether one statement (the premise) is entailed by, contradicts or has no relation to another statement (the hypothesis). This is the Natural Language Inference task. The timely development of the Stanford Natural Language Inference (SNLI) corpus (Bowman et al., 2015) and more recently the Multi-Genre NLI (MULTI-NLI) corpus (Williams et al., 2017) has lead to a steady increase in contributions to research on NLI. Recent research, however, indicates these central datasets to be trivially annotated to a large degree (Gururangan et al., 2018). In this paper, we give evidence of an unrelated problem.

Deep neural network approaches provide the state-of-the-art today for the tasks. We show a pathological sensitivity of these systems to permutations of the training set. This calls into question the soundness of the task in its current state and corresponding development and benchmarking of NLI neural systems.

Given the approximate iterative optimisation methods required to induce models, a common practice for statistical learning is to first randomly shuffle the training set. This serves to offset unwanted bias due to accidental ordering of the examples (for example, with respect to time or class). Probably because of this, there is very little literature or understanding of the effect of order among the training examples–strict ordering of examples has simply been known to be undesirable. However, as neural network approaches increasingly dominate in performance across many NLP tasks, the notion of random shuffling has become overshadowed by that of computational efficiency. This seems to lead back to experiment parameters from Sutskever et al. (2014)'s work, which demonstrates that grouping examples of similar sentence length into batches results in a halved training time. But what is the effect on accuracy? Indeed, a curiosity of neural network models induced over the NLI datasets is the ease in acquiring rather instable results as a result of simple example order permutations of the training set.

In this paper, we present an investigation into these questions. In particular, we consider two simple but competitive neural network topologies in order to investigate the effect of training example order from these datasets on performance. One of these achieves close to state-of-art results over SNLI and state-of-the-art for MULTI-NLI (for simple systems, Cf. Section 4.1), while the other is a simpler variant of the first, characterised by fewer parameters. Out of the standard deep learning, standard machine learning and other plausi-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4935–4939
Brussels, Belgium, October 31 - November 4, 2018.

ble orderings of the dataset, we show that only the original ordering of the training examples leads to state-of-the-art model induction. We also show that the gap in performance between the two neural architectures described here generally drops over all other permutations.

2 NLI task and datasets

The NLI task input is two sentences, $\mathbf{a} = (a_1, \ldots, a_{l_a})$ and $\mathbf{b} = (b_1, \ldots, b_{l_b})$ of lengths l_a and l_b respectively. Each a_i (resp. b_j) for $i \in [l_a]$ (resp. $j \in [l_b]$) corresponds to the word embedding with dimension d for the ith (resp. jth) word. The task dataset consists of labeled pairs of sentences, $\{\mathbf{a^{(n)}}, \mathbf{b^{(n)}}, \mathbf{y^{(n)}}\}_{n=1}^{N}$, where $y^{(n)} \in \{\text{entailment}, \text{contradiction}, \text{neutral}\}$ is the class.

We use two central datasets for our study here: SNLI and MULTI-NLI (Bowman et al., 2015; Williams et al., 2017), containing over 570K and 433K sentence pairs respectively.

3 Our neural network architectures

For the research presented in this paper, we choose two related and relatively simple neural network architectures corresponding roughly to Parikh et al. (2016) and a simplified version of Chen et al. (2017) consisting of five components.[1] Note that we also downloaded Chen et al. (2017)'s code[2] and ran it over the datasets; since it did not perform with the same accuracy reported in the paper for our run (87.77% instead of the reported 88%), and since it took several hours longer than our implementation to run (+7 hours longer), we concentrated on our own implementation. We also attempted to run Gong et al. (2017)'s system[3]; for our runs, the system halted without completion after several hours. Moreover, there are reports on the difficulty in getting the architecture to achieve the accuracy score of 88% reported in the original paper, Mirakyan et al. (2018) reporting that their re-implementation could only achieve 86.38%. This is significantly worst-performing than our best system, which we present now.

(1) Pre-projection. To compensate approximately for not updating the original embeddings during learning, we first carry out a preliminary projection of the embeddings, to the same dimensions using a feed-forward network.

(2) Embedding projection. We further project embeddings via either a simple feed-forward (FF) with a ReLU activation function or a bidirectional LSTM (BiLSTM) layer. The result is then sent to the attention component. This corresponds precisely therefore to Parikh et al. (2016)'s computationally efficient approximation of the vector product before soft-alignment.

(3) Attention. The attention mechanism, first introduced by Bahdanau et al. (2015), is based on a matrix of all-pairs scores between the elements of two sequences $\mathbf{a_i}$ and $\mathbf{b_j}$:[4]

$$e_{ij} := F'(\mathbf{a_i}, \mathbf{b_j}) := F(\mathbf{a_i})^T F(\mathbf{b_j})$$

We follow (Parikh et al., 2016) and later attention-based models for NLI, by representing the importance of $\mathbf{a_i}$ with respect to $\mathbf{b}$ as the normalised sum

$$\beta_i := \sum_{j=1}^{l_b} \frac{exp(e_{ij})}{\sum_{k=1}^{l_b} exp(e_{ik})} b_j.$$

The result is concatenated with $\mathbf{a_i}$, to create $[\mathbf{a_i}, \beta_i]$ which is then projected down to original embedding dimension. The same is done for $\mathbf{b_j}$ with respect to $\mathbf{a}$.

(4) Aggregation. Following the attention mechanism we aggregate over words for a sentence representation. Either we sum over the attended word vectors Parikh et al. (2016) or use the final state of a single LSTM layer (Chen et al., 2017)[5].

(5) Prediction. Finally we feed a vector concatenation of both sentence vectors as input to a component consisting of three feed-forward layers with dropout and regularisation, followed by a linear softmax layer for prediction.

Instantiated architectures. The two topologies we adopt for this study consist of the above components with embedding projection and aggregation as follows:

- FF/SUM corresponding to the embedding projection instantiated with a feed-forward network and the aggregation carried out through vector summation, and

---

[1] We make the systems publicly available `https://github.com/natschluter/nli-data-permutations`.

[2] `https://github.com/lukecq1231/nli`

[3] `https://github.com/YichenGong/Densely-Interactive-Inference-Network`

[4] Note that we also experimented with $e_{ij} := F'(\mathbf{a_i}, \mathbf{b_j})$ where F' was a component-wise multiplication and F' a feed-forward network with ReLU activations. However, we observed no benefits to doing so performance-wise, and substantial loss in computational efficiency.

[5] For Chen et al. (2017), aggregation consists of several layers of BiLSTMS as opposed to our single LSTM layer.

- Bi/LSTM corresponding to the embedding projection instantiated with a BiLSTM and the aggregation carried out via an LSTM.

Other hyperparameters. We use 300 dimensional GloVe embeddings trained on the Common Crawl 840B tokens dataset (Pennington et al., 2014), which remain fixed during training. Out of vocabulary (OOV) words are represented as zero vectors.[6] We use a 0.2 dropout rate and L2 regularisation, applied in all feed-forward layers. We optimise the network using categorical cross-entropy loss and employ the RMSprop optimizer with ρ set to 0.9, a 0.001 learning rate, with a batch size of 512 and use early stopping over the development set after no improvement in accuracy after 4 epochs.

State-of-the-art for simple systems. The models are **simple** in that no information above word embeddings is taken as input, for example, no POS-tags or syntactic relations (See Section 4.1). Our Bi/LSTM system also currently sets the state-of-the-art for simple systems on the MULTI-NLI dataset (See Section 4.1).

4 Related work

Previous work is related either in terms of the neural architectures for NLI (Section 4.1), or in terms of work on training data permutations in learning (Section 4.2).

4.1 State-of-the-art NLI

There are different types of neural network systems in the literature with respect to the simplicity of input data required for modeling and interdependence of the internal modules. In this work, we only consider simple system approaches that use only word embeddings (no character representations, POS-tags, word-position, syntactic tree, external resources, etc.) and consist only of interdependent modules (not ensembles). We make no claims regarding linguistic or ensemble-complex systems, but make the straightforward hypothesis that the conclusions presented here can be extended to cover more complex frameworks as well, especially given that our systems are strongly competitive or even better performing than two highly complex state-of-the-art neural systems (Cf. Section 3).

For simple systems, the state-of-the-art is currently set by Sha et al. (2016) at 87.5%, on SNLI. They use a standard BiLSTM to read the premise, and propose a Bi-rLSTM to read the hypothesis. Their proposed rLSTM–“re-read” LSTM unit–takes the attention vector of one sentence as an inner state while reading the other sentence. The output of the standard BiLSTM is also taken as the general input of the bidirectional rLSTM. The currently published next best performing simple system, Parikh et al. (2016) at 86.3% accuracy, introduced use of the attention mechanism for the NLI task, the way it is generally being used today.[7]

4.2 Example permutation in learning

Morishita et al. (2017) explored the effect of mini-batching on the learning of Neural Machine Translation models, carrying out their experiments on two datasets (two language-pairs). In particular, they studied the strategies of (1) sorting by length of the source sentence, (2) target sentence, or (3) both, among other things. They empirically compare their efficiency on two translation tasks and find that some strategies in wide use are not necessarily optimal for accuracy and convergence-wise. In contrast to the work described here however, one of the sorting strategies produced best results, though no comparison was made with the original ordering of examples. By contrast, we show that it is by making non-canonical (semi-non-random) orderings of the data that best results are achieved in NLI, for the two available datasets.

---

[6] We experimented with alternative OOV representations, such as the the mean vector of most frequent words and random vectors, with insignificant effects.

[7] Parikh et al. (2016) also have a result with intra-sentential attention that performs with 86.8% accuracy. However this attention model is dependent on word positional information.

Table 2: Performance of the FF/SUM and Bi/LSTM neural networks for the training example permutations, evaluated over the development set, along with the difference (diff) in performance between the two architectures.

5 Experiments

Data permutations. We consider the following original and sorted orderings of the training set examples to learn our models.

orig: The original order in which the dataset is currently distributed.

prem: Sorting by increasing premise length.

hypo: Sorting by increasing hypothesis length.

lengths: Sorting by increasing premise + hypothesis length.

conf: Sorting by increasing score, where the scores for each example are generating in training Bi/LSTM over orig.

shuffle-once: Randomly shuffle once before training, averaged over 5 runs.

shuffle-epoch: Randomly shuffle on each epoch during training, for a single run.

In addition to each of these, we consider the reversal of the order (indicated by the suffix **-r**.)

In order to not exhaust the test set, we generate the results over data permutations on the development set. These are given in Table 2.

Discussion. For both datasets, we observe that all other training example permutations result in a substantial drop in performance, by approximately 3-4% on SNLI and 1-6% on MULTI-NLI. Even a simple reversal of the original order leads to a substantial drop in performance. Shuffling consistently the data provides the strongest alternative training conditions to the original ordering.

Moreover, the difference in performance of the two separate architectures is generally much lower on all other permutations of the training data, calling into question the significance of the more complex components. These observations apply to both randomly shuffling (as advised in statistical learning practise) and ordering the data by length (as advised in deep learning for NLP practise).

For an analysis of the sorting permutations, we looked into whether hypothesis sentence lengths differed by class to such an extent that the dataset became sorted by class label. We cannot include the results here due to space constraints. However, we observed that ordering by class results in small (and quite interesting) drops in performance, so long as the original order is preserved. If we first randomly shuffle the examples before ordering them by class, similar drops in performance result to those in Table 2.

6 Conclusions

We have shown that models induced over the SNLI and MULTI-NLI datasets are greatly affected by the permutation of the training data instances at hand: recommended statistical learning or deep learning engineering strategies for ordering the training examples result in significantly and even substantially worse performance over these datasets. Our models are simple (no information over word embedding representations of sentences and no ensembles), but strongly competitive with (or better performing than) both SOTA (re-)implementations of much more complex neural systems. We make the straightforward hypothesise that these observations will extend to more complex models; we leave this to be verified by future work.

Bridging Knowledge Gaps in Neural Entailment via Symbolic Models

Abstract

Most textual entailment models focus on lexical gaps between the premise text and the hypothesis, but rarely on knowledge gaps. We focus on filling these knowledge gaps in the Science Entailment task, by leveraging an external structured knowledge base (KB) of science facts. Our new architecture combines standard neural entailment models with a knowledge lookup module. To facilitate this lookup, we propose a fact-level decomposition of the hypothesis, and verifying the resulting sub-facts against both the textual premise and the structured KB. Our model, NSnet, learns to aggregate predictions from these heterogeneous data formats. On the SciTail dataset, NSnet outperforms a simpler combination of the two predictions by 3% and the base entailment model by 5%.

1 Introduction

Textual entailment, a key challenge in natural language understanding, is a sub-problem in many end tasks such as question answering and information extraction. In one of the earliest works on entailment, the PASCAL Recognizing Textual Entailment Challenge, Dagan et al. (2005) define entailment as follows: text (or premise) P entails a hypothesis H if *typically* a human reading P would infer that H is *most likely* true. They note that this informal definition is “based on (and assumes) common human understanding of language as well as *common background knowledge*”.

While current entailment systems have achieved impressive performance by focusing on the language understanding aspect, these systems, especially recent neural models (e.g. Parikh et al., 2016; Khot et al., 2018), do not directly address the need for filling knowledge gaps by leveraging common background knowledge.

Figure 1 illustrates an example of P and H from SciTail, a recent science entailment dataset (Khot et al., 2018), that highlights the challenge of *knowledge gaps*—sub-facts of H that aren’t stated in P but are universally true. In this example, an entailment system that is strong at filling lexical gaps may align *large blood vessel* with *major artery* to help conclude that P entails H. Such a system, however, would equally well—but incorrectly—conclude that P entails a hypothetical variant H’ of H where *artery* is replaced with *vein*. A typical human, on the other hand, could bring to bear a piece of background knowledge, that aorta is a major artery (not a vein), to break the tie.

P: The aorta is a large blood vessel that moves blood away from the heart to the rest of the body.

H (entailed): Aorta is the major artery carrying recently oxygenated blood away from the heart.

H’ (not entailed): Aorta is the major vein carrying recently oxygenated blood away from the heart.

Figure 1: Knowledge gap: Aorta is a major artery (not a vein). *Large blood vessel* soft-aligns with *major artery* but also with *major vein*.

Motivated by this observation, we propose a new entailment model that combines the strengths of the latest neural entailment models with a structured knowledge base (KB) lookup module to bridge such knowledge gaps. To enable KB lookup, we use a fact-level decomposition of the hypothesis, and verify each resulting sub-fact against both the premise (using a standard entailment model) and against the KB (using a structured scorer). The predictions from these two modules are combined using a multi-layer “aggregator” network. Our system, called NSnet, achieves 77.9% accuracy on SciTail, substantially improving over the baseline neural entailment model, and comparable to the structured entailment model proposed by Khot et al. (2018).

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4940–4945
Brussels, Belgium, October 31 - November 4, 2018.

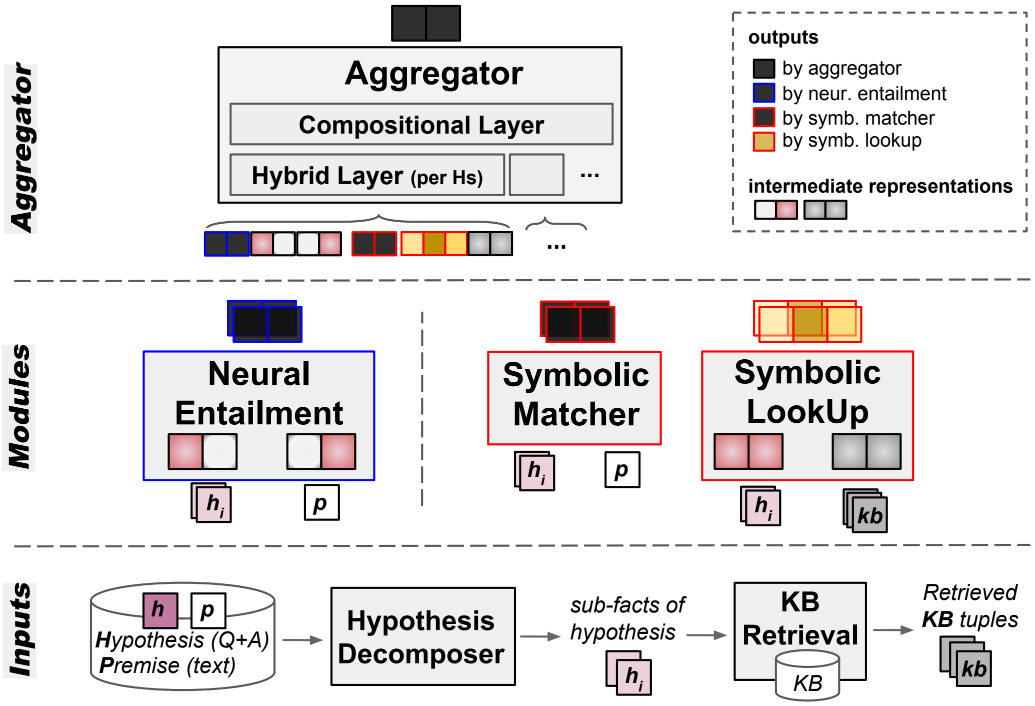

Figure 2: Neural-symbolic learning in NSnet. The bottom layer has QA and their supporting text in SciTail, and the knowledge base (KB). The middle layer has three modules: Neural Entailment (blue) and Symbolic Matcher and Symbolic Lookup (red). The top layer takes the outputs (black and yellow) and intermediate representation from the middle modules, and hierarchically trains with the final labels. All modules and aggregator are jointly trained in an end-to-end fashion.

2 Neural-Symbolic Learning

A general solution for combining neural and symbolic modules remains a challenging open problem. As a step towards this, we present a system in the context of neural entailment that demonstrates a successful integration of the KB lookup model and simple overlap measures, opening up a path to achieve a similar integration in other models and tasks. The overall system architecture of our neural-symbolic model for textual entailment is presented in Figure 2. We describe each layer of this architecture in more detail in the following sub-sections.

2.1 Inputs

We decompose the hypothesis and identify relevant KB facts in the bottom "inputs" layer (Fig. 2).

Hypothesis Decomposition: To identify knowledge gaps, we must first identify the facts stated in the hypothesis $h = (h_1, h_2..)$. We use ClausIE (Del et al., 2013) to break h into sub-facts. ClausIE tuples need not be verb-mediated and generate multiple tuples derived from conjunctions, leading to higher recall than alternatives such as Open IE (Banko et al., 2007). [1]

Knowledge Base (KB): To verify these facts, we use the largest available clean knowledge base for the science domain (Dalvi et al., 2017), with 294K simple facts, as input to our system. The knowledge base contains subject-verb-object (SVO) tuples with short, one or two word arguments (e.g., hydrogen; is; element). Using these simple facts ensures that the KB is only used to fill the basic knowledge gaps and not directly prove the hypothesis irrespective of the premise.

KB Retrieval: The large number of tuples in the knowledge base makes it infeasible to evaluate each hypothesis sub-fact against the entire KB. Hence, we retrieve the top-100 relevant knowledge tuples, K', for each sub-fact based on a simple Jaccard word overlap score.

---

[1] While prior work on question answering in the science domain has successfully used Open IE to extract facts from sentences (Khot et al., 2017), one of the key reasons for errors was the lossy nature of Open IE.

2.2 Modules

We use a Neural Entailment model to compute the entailment score based on the premise, as well as two symbolic models, Symbolic Matcher and Symbolic Lookup, to compute entailment scores based on the premise and the KB respectively (middle layer in Fig. 2).

Neural Entailment We use a simple neural entailment model, Decomposable Attention (Parikh et al., 2016), one of the state-of-the-art models on the SNLI entailment dataset (Bowman et al., 2015). However, our architecture can just as easily use any other neural entailment model. We initialize the model parameters by training it on the Science Entailment dataset. Given the sub-facts from the hypothesis, we use this model to compute an entailment score $n(h_i, p)$ from the premise to each sub-fact h_i.

Symbolic Matcher In our initial experiments, we noticed that the neural entailment models would often either get distracted by similar words in the distributional space (false positives) or completely miss an exact mention of h_i in a long premise (false negatives). To mitigate these errors, we define a Symbolic Matcher model that compares exact words in h_i and p, via a simple asymmetric bag-of-words overlap score:

$$m(h_i, p) = \frac{|h_i \cap p|}{|p|}$$

One could instead use more complex symbolic alignment methods such as integer linear programming (Khashabi et al., 2016; Khot et al., 2017).

Symbolic Lookup This module verifies the presence of the hypothesis sub-fact h_i in the retrieved KB tuples K', by comparing the sub-fact to each tuple and taking the maximum score. Each field in the KB tuple kb_j is scored against the corresponding field in h_i (e.g., subject to subject) and averaged across the fields. To compare a field, we use a simple word-overlap based Jaccard similarity score, $Sim(a, b) = \frac{|a \cap b|}{|a \cup b|}$. The lookup match score for the entire sub-fact and kb-fact is:

$$Sim_f(h_i, kb_j) = \left(\sum_k Sim(h_i[k], kb_j[k]) \right) / 3$$

and the final lookup module score for h_i is:

$$l(h_i) = \max_{kb_j \in K'} Sim_f(h_i, kb_j)$$

Note that the Symbolic Lookup module assesses whether a sub-fact of H is universally true. Neural models, via embeddings, are quite strong at mediating between P and H. The goal of the KB lookup module is to complement this strength, by verifying universally true sub-facts of H that may not be stated in P (e.g. "aorta is a major artery" in our motivating example).

2.3 Aggregator Network

For each sub-fact h_i, we now have three scores: $n(h_i, p)$ from the neural model, $m(h_i, p)$ from the symbolic matcher, and $l(h_i)$ from the symbolic lookup model. The task of the Aggregator network is to combine these to produce a single entailment score. However, we found that using only the final predictions from the three modules was not effective. Inspired by recent work on skip/highway connections (He et al., 2016; Srivastava et al., 2015), we supplement these scores with intermediate, higher-dimensional representations from two of the modules.

From the Symbolic Lookup model, we use the representation of each sub-fact $h_i^{enc} = Enc(h_i)$ obtained by averaging word embeddings (Pennington et al., 2014) and individual similarity scores over the top-100 KB tuples $emb_i = [\ldots, Sim_f(h_i, kb_j), \ldots]$. From the neural entailment model, we use the intermediate representation of both the sub-fact of hypothesis and premise text from the final layer (before the softmax computation), $n^v(h_i, p) = [v_1; v_2]$.

We define a hybrid layer that takes as input a simple concatenation of these representation vectors from the different modules:

$$\begin{aligned} in(h_i, p) =& [h_i^{enc}; l(h_i); m(h_i, p); n(h_i, p); \\ & emb_i; n^v(h_i, p)] \end{aligned}$$

The hybrid layer is a single layer MLP for each sub-fact h_i that outputs a sub-representation $out_i = MLP(in(h_i, p))$. A compositional layer then uses a two-layer MLP over a concatenation of the hybrid layer outputs from different sub-facts, $\{h_1, \ldots, h_I\}$, to produce the final label,

$$label = \text{MLP}([out_1; out_2; \cdots out_I])$$

Finally, we use the cross-entropy loss to train the Aggregator network jointly with representations in the neural entailment and symbolic lookup models, in an end-to-end fashion. We refer to this entire architecture as the NSnet network.

Table 1: Entailment accuracies on the SciTail dataset. NSnet substantially improves upon its base model and marginally outperforms DGEM.

Entailment Model	**Valid.**	**Test**
Majority classifier	63.3	60.3
DecompAttn (Base model)	73.1	74.3
DecompAttn + HypDecomp	71.8	72.7
DGEM	**79.6**	77.3
ENSEMBLE (this work)	75.2	74.8
NSnet (this work)	77.4	**77.9**

To assess the effectiveness of the aggregator network, we also use a simpler baseline model, ENSEMBLE, that works as follows. For each sub-fact h_i, it combines the predictions from each model using a probabilistic-OR function, assuming the model score P_m as a probability of entailment. This function computes the probability of at least one model predicting that h_i is entailed, i.e. $P(h_i) = 1 - \Pi_m(1 - P_m)$ where $m \in n(h_i, p), m(h_i, p), l(h_i)$. We average the probabilities from all the facts to get the final entailment probability.[2]

3 Experiments

We use the SciTail **dataset**[3] (Khot et al., 2018) for our experiments, which contains 27K entailment examples with a 87.3%/4.8%/7.8% train/dev/test split. The premise and hypothesis in each example are natural sentences authored independently as well as independent of the entailment task, which makes the dataset particularly challenging. We focused mainly on the SciTail dataset, since other crowd-sourced datasets, large enough for training, contained limited linguistic variation (Gururangan et al., 2018) leading to limited gains achievable via external knowledge.

For **background knowledge**, we use version v4 of the aforementioned Aristo TupleKB[4] (Dalvi et al., 2017), containing 283K basic science facts. We compare our proposed models to Decomposed Graph Entailment Model (DGEM) (Khot et al., 2018) and Decomposable Attention Model (DecompAttn) (Parikh et al., 2016).

3.1 Results

Table 1 summarizes the validation and test accuracies of various models on the SciTail dataset. The DecompAttn model achieves 74.3% on the test set but drops by 1.6% when the hypotheses are decomposed. The ENSEMBLE approach uses the same hypothesis decomposition and is able to recover 2.1% points by using the KB. The end-to-end NSnet network is able to further improve the score by 3.1% and is statistically significantly (at p-value 0.05) better than the baseline neural entailment model. The model is marginally better than DGEM, a graph-based entailment model proposed by the authors of the SciTail dataset We show significant gains over our base entailment model by using an external knowledge base, which are comparable to the gains achieved by DGEM through the use of hypothesis structure. These are orthogonal approaches and one could replace the base DecompAttn model with DGEM or more recent models (Tay et al., 2017; Yin et al., 2018).

Table 2: Ablation: Both Symbolic Lookup and Symbolic Matcher have significant impact on NSnet performance.

	Valid.	**Test**
NSnet	77.39	77.94
- Symbolic Matcher	76.46	74.73 (**-3.21%**)
- Symbolic Lookup	75.95	75.80 (**-2.14%**)
- Both	75.10	73.98 (**-3.96%**)

In Table 2, we evaluate the impact of the Symbolic Matcher and Symbolic Lookup module on the best reported model. As we see, removing the symbolic matcher, despite its simplicity, results in a 3.2% drop. Also, the KB lookup model is able to fill some knowledge gaps, contributing 2.1% to the final score. Together, these symbolic matching models contribute 4% to the overall score.

3.2 Qualitative Analysis

Figure 3 shows few randomly selected examples in test set. The first two examples show cases when the symbolic models help to change the neural alignment's prediction (F) to correct prediction (T) by our proposed ENSEMBLE or NSnet models. The third question shows a case where the NSnet architecture learns a better combination of the neural and symbolic methods to correctly identify the entailment relation while ENSEMBLE fails to do so.

---

[2] While more intuitive, performing an AND aggregation resulted in worse performance (cf. Appendix **??** for details).

[3] `http://data.allenai.org/scitail`

[4] `http://data.allenai.org/tuple-kb`

Table 3: Few randomly selected examples in the test set between symbolic only, neural only, Ensemble and NSnet inference. The symbolic only model shows its the most similar knowledge from knowledge base inside parenthesis. The first two example shows when knowledge helps fill the gap where neural model can't. The third example shows when NSnet predicts correctly while Ensemble fails.

4 Related Work

Compared to neural only (Bowman et al., 2015; Parikh et al., 2016) or symbolic only (Khot et al., 2017; Khashabi et al., 2016) systems, our model takes advantage of both systems, often called neural-symbolic learning (Garcez et al., 2015). Various neural-symbolic models have been proposed for question answering (Liang et al., 2016) and causal explanations (Kang et al., 2017). We focus on end-to-end training of these models specifically for textual entailment.

Contemporaneous to this work, Chen et al. (2018) have incorporated knowledge-bases within the attention and composition functions of a neural entailment model, while Kang et al. (2018) generate adversarial examples using symbolic knowledge (e.g., WordNet) to train a robust entailment model. We focused on integrating knowledge-bases via a separate symbolic model to fill the knowledge gaps.

5 Conclusion

We proposed a new entailment model that attempts to bridge knowledge gaps in textual entailment by incorporating structured knowledge base lookup into standard neural entailment models. Our architecture, NSnet, can be trained end-to-end, and achieves a 5% improvement on SciTail over the baseline neural model used here. The methodology can be easily applied to more complex entailment models (e.g., DGEM) as the base neural entailment model. Accurately identifying the subfacts from a hypothesis is a challenging task in itself, especially when dealing with negation. Improvements to the fact decomposition should further help improve the model.

Abstract

This paper introduces the Bank Question (BQ) corpus, a Chinese corpus for sentence semantic equivalence identification (SSEI). The BQ corpus contains 120,000 question pairs from 1-year online bank custom service logs. To efficiently process and annotate questions from such a large scale of logs, this paper proposes a clustering based annotation method to achieve questions with the same intent. First, the deduplicated questions with the same answer are clustered into stacks by the Word Mover's Distance (WMD) based Affinity Propagation (AP) algorithm. Then, the annotators are asked to assign the clustered questions into different intent categories. Finally, the positive and negative question pairs for SSEI are selected in the same intent category and between different intent categories respectively. We also present six SSEI benchmark performance on our corpus, including state-of-the-art algorithms. As the largest manually annotated public Chinese SSEI corpus in the bank domain, the BQ corpus is not only useful for Chinese question semantic matching research, but also a significant resource for cross-lingual and cross-domain SSEI research. The corpus is available in public[1].

1 Introduction

As the semantic matching task, sentence semantic equivalence identification (SSEI) is a fundamental task of natural language processing (NLP) in question answering (QA), automatic customer service and chat-bots. In customer service systems, two questions are defined as semantically equivalent if they convey the same intent or they could be answered by the same answer. Because of rich expressions in natural languages, SSEI is really a challenging NLP task.

Compared with other NLP tasks, the lack of large-scale SSEI corpora is one of the biggest obstacles for SSEI algorithm development. To address this issue, several corpora have been provided in recent years, including the Microsoft Research Paraphrase (MSRP) Corpus (Dolan et al., 2004; Dolan and Brockett, 2005), the Twitter Paraphrase Corpus (PIT-2015 corpus) (Xu et al., 2014, 2015), the Twitter URL corpus (Lan et al., 2017) and the Quora dataset [2].

In the early stage, the MSRP corpus was used to validate paraphrase identification algorithms based on a set of linguistic features (Kozareva and Montoyo, 2006; Mihalcea et al., 2006; Rus et al., 2008). Then, MSRP was also used to validate the deep models within a long duration. The deep convolutional neural networks (DCNNs), recurrent neural networks (RNNs), and their variants, such as Arc-I, Arc-II and BiMPM etc., have been developed and verified on it, even though it contains only thousands of sentence pairs (Hu et al., 2014; Yin and Schütze, 2015; Wang et al., 2016, 2017). Until 2015, the SemEval 2015 released a larger corpus, the PIT-2015 corpus for paraphrase and semantic similarity identification tasks. On this corpus, participants adopted SVM classifiers, logistic regression models, referential translation machines (RTM) and neural networks (Xu et al., 2015). In 2017, a large-scale SSEI corpus named Quora was released, which greatly boost the development of deep matching algorithms. Tomar et al. (2017) proposed a variant of the decomposable attention model. Gong et al.(2018) proposed a Densely Interactive Inference Network (DIIN) by hierarchically extracting semantic features from interaction space. However, the Quora corpus comes from social network sites. Consider-

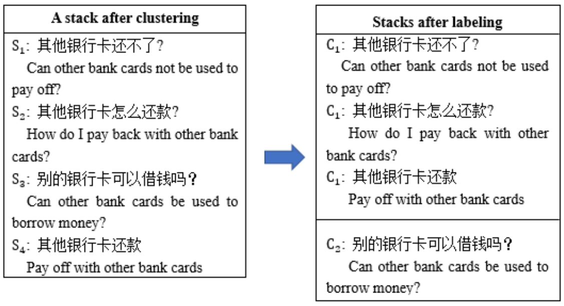
ing the request for specific domains and real context in SSEI, there still lacks corpora from different domains and corpora with features of non-English languages.

In this paper, we present a large-scale Chinese SSEI corpus constructed from real bank customer service logs. The main contributions of this paper include: 1) we present a large-scale domain-specific Chinese SSEI corpus, which contains 120,000 manually annotated sentence pairs; 2)we propose the Affinity Propagation (AP) (Frey and Dueck, 2007) clustering based method for SSEI corpus construction from a large number of sentences; 3)we provide the benchmark performance of 5 representative algorithms on our corpus. Hopefully, these contributions are useful in promoting the research on Chinese SSEI methods and the transferring methods for cross languages or cross domains.



A stack after clustering

2 The Bank Question Corpus

2.1 Features of the Bank Corpus

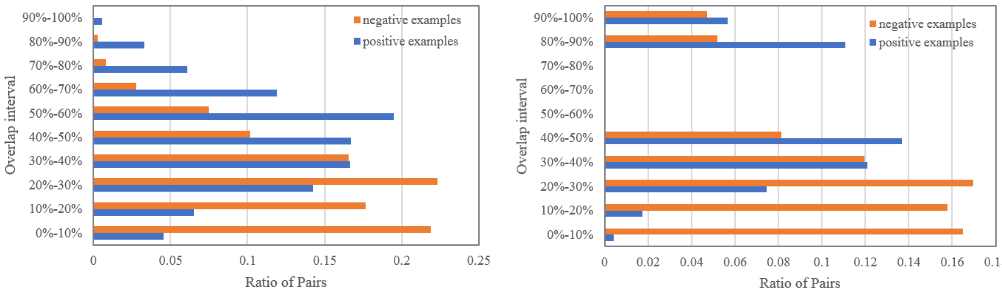
As the first domain-specific large-scale Chinese SSEI corpus, the Bank Corpus contains 120,000 question pairs. It is split into three parts: 100,000 pairs for training, 10,000 pairs for validation, and 10,000 pairs for test. There is no sentence overlap among training, validation and test sets. The last line in Table 1 shows the main features of our corpus. We also highlight features of the most popular SSEI corpus from line 1 to 4 in Table 1. The further analysis of the Bank Corpus will be shown in following sections.

2.2 Construction of the Bank Corpus

The original data came from the 1-year customer service logs with more than 20 millions of questions provided by a Chinese bank. To manually annotate so many questions is unimaginable, so we conducted three steps to get the SSEI corpus, including the clustering of questions, the intent-based annotation and the combination of semantic equivalent question pairs.

Grouping and Clustering At first, two definitions are given: a set of questions replied by the same answer is called a *group*; The clusters generated by an automatic clustering algorithm in a group is called a *stack*. Here, a stack is a subset of a group with questions have the same intent. First, the users' questions were divided into *groups* by their respective answers. The de-duplication is then executed on each group. Next, we used the Word Mover's Distance (WMD) (Kusner et al., 2015) based Affinity Propagation (AP) clustering algorithm to split the questions within each group into multiple question *stacks*. After filtering some emoijs and sentences which are standard answers from the questions, we finally got 799 distinct groups and selected total of 55724 questions from all groups for annotation.

Annotation We adopted two steps to annotate the question stacks. First, we recruited 12 annotators to categorize questions in each clustered stack into different intent classes. Here, if the questions express the same intent, we think that they belong to an intent class. For each labeled stack, the classes of intent are the same. If a question is chit-chat or it can not be combined with other questions into an intent class, it will be put into a specific class called ”other”. Second, the experts related to this specific domain were requested to check and correct the annotated intent classes. After annotation, we got 953 groups and 18002 questions. Among the questions, 16680



(a) The overlap distribution of our corpus (b) The overlap distribution of the Quora corpus

Figure 2: The overlap distribution of positive and negative data

Examples			
most common:	一次性还完可以继续借吗 Can I continue to borrow money when I repay the loan at one time	一笔借款提前还清还可以借款吗 Can I borrow money again when a loan be pay off ahead of time	1
low overlap:	这是什么公司的产品 What's the company of the product	企业名称 the enterprise name	1
most common:	我几号还款 When should I repay my loan	今天的还款，可以推迟么? Can I postpone today's repayment?	0
high overlap:	能不能取消申请 Can I cancel the application	能不能取消，重新申请 Can I cancel the application and reapply	0

Table 2: The most common examples, the positive example with low overlap and the negative example with high overlap. Chinese sentences are original-form examples and English sentences below them are their corresponding translations.

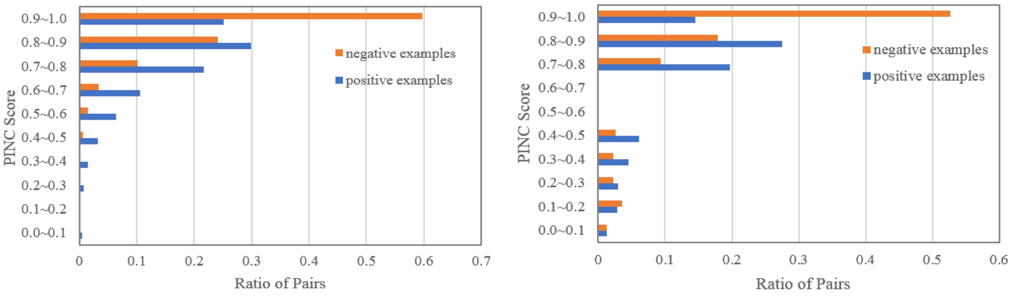
questions are with meaningful intents and can be used to create semantic pairs. There are average 9 stacks in each group. The annotation process from clustering examples to labeled examples is shown as Figure 1. From the clustering results, we find the clustering algorithm cluster the word ”借(borrow)” and the word ”还(pay back)” together. Actually, they convey different intentions and we need to distinguish them.

Generation Based on the labeled stacks, we combine the questions in each stack which have the same intention to create the positive question pairs, and select questions from different stacks in each group which have different intentions to create the negative question pairs.

2.3 Quality of the Corpus

To verify the quality of the corpus, we analyze the word overlap (Dolan et al., 2004) distribution and the PINC (Paraphrase In N-gram Changes) (Kim, 2014) distribution in the positive pairs and the negative pairs respectively.

The overlap is defined as the number of common words between two sentences divided by the average length of them. As shown in Figure 2, the overlap ratio of positive samples on the intervals appears a normal distribution on our new corpus, while the Quora corpus has no examples on overlaps between 50% and 80%. The positive question pairs with overlap ratio below 50% account for 58.67% and the negative question pairs with overlap ratio above 50% account for 11.36%. Here, we just give some examples with the largest ratio among the overlap intervals, some positive examples with low overlap and some negative examples with high overlap as shown in Table 2. For example, the positive question pair (“这是什么公司的产品(What's the company of the product)” and “企业名称(the enterprise name)”) expresses the same intention while they have low overlap, where “什么公司(what company)” has the same meaning as “企业名称(the enterprise name)”. The negative pair(“能不能取消申请(Can I cancel the application)” and “能不能取消，重新申请(Can I cancel the application and reapply)”) is different only on the word “重新(again)” while they nearly convey the contrary meaning. The statistics and examples indicate that except common examples we also have some difficult examples especially the positive pairs with low overlap and our new corpus is meaningful for research on learning methods.



(a) The PINC distribution of our corpus

(b) The PINC distribution of the Quora corpus

Figure 3: The PINC score distribution of positive and negative data

PINC (Kim, 2014) is a score of n-gram differences to measure lexical dissimilarity of sentence pairs. In essence, it is the inverse of BLEU (Papineni et al., 2002). As shown in Figure 3, most of the PINC scores on our corpus are between 0.7 and 1.0 which reveals that our corpus contains more lexical dissimilar question pairs. It contains rich expressions for the same user intention and it is challenging for machine learning methods to identify the semantic equivalence of the question pairs automatically.

3 Semantic Equivalence Identification

For this new public corpus, we provide a benchmark on the question semantic equivalence identification task to better understand its characteristic and provide further evidence for its value.

3.1 Models

Text-CNN (Kim, 2014) is a typical Convolutional Neural Network (CNN) model for sentence classification. We respectively feed each sentence of the question pair into the model with 300-dimensional word vectors and concatenate the sentence representation for SSEI. Here, we trained the word vectors on our new corpus by gensim[4].

BiLSTM (Graves and Schmidhuber, 2005) is an variant of RNN which considers both long and short dependency in context from forward and backward. We use the same structure but constitute the CNN with BiLSTM to model the sentence representation.

BiMPM (Wang et al., 2017) is a bilateral multi-perspective matching model of well performance for natural language sentence matching. The model uses the BiLSTM to learn the sentence representation, matches two sentences from two directions and multi-perspectives, aggregates the matching results with BiLSTM and finally predicts through a fully connected layer.

DIIN (Gong et al., 2018) is a Densely Interactive Inference Network (DIIN) for Natural Language Inference (NLI). It hierarchically extracts semantic features from interaction space to achieve the high-level understanding of sentence pairs. It achieves the state-of-the-art performance on large-scale NLI copora and Quora corpus.

3.2 Results and Discussion

The benchmark performance on our new corpus is shown in Table 3. The performace on the Quora corpus is shown in Table 4. The random method achieves 50.43% which indicates that our new corpus is balanced and meets the basic requirements for SSEI model research.

The TF-IDF method just models the surface features of sentences according to the vocabulary frequency. It can not learn the dependency features in the word sequences and the synonym or near-synonym according to the word meanings. Therefore, it performs not so well, which indicates that the new corpus can not be learned by simple surface features and the deep semantic relationsn need to be mined by deep models.

Here, we use four deep neural network models to verify the new constructed corpus, including two basic and representative models (Text-CNN and BiLSTM) and two latest and well-used models (BiMPM and DIIN) which perform well on the natural language sentence matching task. The results show that the BiLSTM model can learn the dependency features between words in the sentences better than the Text-CNN model. The Accuracy of BiMPM is 81.85% and that of DIIN is 81.41%. Compared with the performance on the Quora corpus, the performance on the BQ corpus

is lower, which reveals that our new corpus is challenging for semantic matching model research.

4 Conclusion and Future Work

In this paper, we present a large-scale Chinese corpus for question semantic equivalence identification in the bank domain. The construction procedure and benchmark performance are given. To the best of our knowledge, this corpus is the largest manually annotated public Chinese SSEI corpus in the bank domain. Compared with existing corpora, it is of high quality and challenging, and is hopefully useful for research on SSEI, cross-lingual and cross-domain learning.

Abstract

Deep learning models have achieved remarkable success in natural language inference (NLI) tasks. While these models are widely explored, they are hard to interpret and it is often unclear how and why they actually work. In this paper, we take a step toward explaining such deep learning based models through a case study on a popular neural model for NLI. In particular, we propose to interpret the intermediate layers of NLI models by visualizing the saliency of attention and LSTM gating signals. We present several examples for which our methods are able to reveal interesting insights and identify the critical information contributing to the model decisions.

1 Introduction

Deep learning has achieved tremendous success for many NLP tasks. However, unlike traditional methods that provide optimized weights for human understandable features, the behavior of deep learning models is much harder to interpret. Due to the high dimensionality of word embeddings, and the complex, typically recurrent architectures used for textual data, it is often unclear how and why a deep learning model reaches its decisions.

There are a few attempts toward explaining/interpreting deep learning-based models, mostly by visualizing the representation of words and/or hidden states, and their importances (via saliency or erasure) on shallow tasks like sentiment analysis and POS tagging (Bahdanau et al., 2014; Denil et al., 2014; Li et al., 2016; Arras et al., 2017; Li et al., 2017; Rei and Søgaard, 2018). In contrast, we focus on interpreting the gating and attention signals of the intermediate layers of deep models in the challenging task of Natural Language Inference. A key concept in explaining deep models is saliency, which determines what is critical for the final decision of a deep model. So far, saliency has only been used to illustrate the impact of word embeddings. In this paper, we extend this concept to the intermediate layer of deep models to examine the saliency of attention as well as the LSTM gating signals to understand the behavior of these components and their impact on the final decision.

We make two main contributions. First, we introduce new strategies for interpreting the behavior of deep models in their intermediate layers, specifically, by examining the saliency of the attention and the gating signals. Second, we provide an extensive analysis of the state-of-the-art model for the NLI task and show that our methods reveal interesting insights not available from traditional methods of inspecting attention and word saliency.

In this paper, our focus was on NLI, which is a fundamental NLP task that requires both understanding and reasoning. Furthermore, the state-of-the-art NLI models employ complex neural architectures involving key mechanisms, such as attention and repeated reading, widely seen in successful models for other NLP tasks. As such, we expect our methods to be potentially useful for other natural understanding tasks as well.

2 Task and Model

In NLI (Bowman et al., 2015), we are given two sentences, a premise and a hypothesis, the goal is to decide the logical relationship (*Entailment*, *Neutral*, or *Contradiction*) between them.

Many of the top performing NLI models (Ghaeini et al., 2018b; Tay et al., 2018; Peters et al., 2018; McCann et al., 2017; Gong et al., 2017; Wang et al., 2017; Chen et al., 2017), are variants of the ESIM model (Chen et al., 2017), which we choose to analyze in this paper. ESIM reads the sentences independently using LSTM at first, and then applies attention to align/contrast

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4952–4957
Brussels, Belgium, October 31 - November 4, 2018.

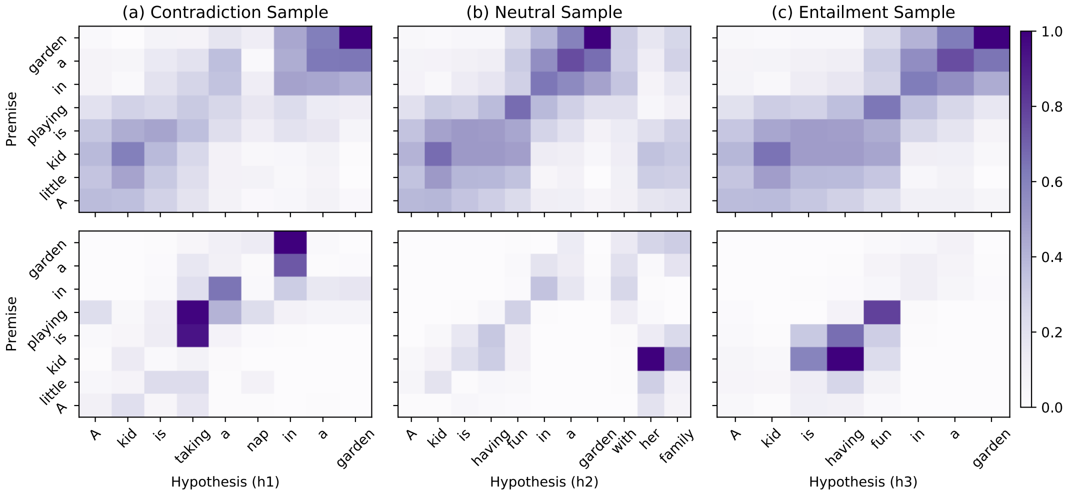

Figure 1: Normalized attention and attention saliency visualization. Each column shows visualization of one sample. Top plots depict attention visualization and bottom ones represent attention saliency visualization. Predicted (the same as Gold) label of each sample is shown on top of each column.

the sentences. Another round of LSTM reading then produces the final representations, which are compared to make the prediction. Detailed description of ESIM can be found in the Supplementary Materials.

Using the SNLI (Bowman et al., 2015) data, we train two variants of ESIM, with dimensionality 50 and 300 respectively, referred to as ESIM-50 and ESIM-300 in the remainder of the paper.

3 Visualization of Attention and Gating

In this work, we are primarily interested in the internal workings of the NLI model. In particular, we focus on the attention and the gating signals of LSTM readers, and how they contribute to the decisions of the model.

3.1 Attention

Attention has been widely used in many NLP tasks (Ghaeini et al., 2018a; Dhingra et al., 2017; Bahdanau et al., 2014) and is probably one of the most critical parts that affects the inference decisions. Several pieces of prior work in NLI have attempted to visualize the attention layer to provide some understanding of their models (Ghaeini et al., 2018b; Parikh et al., 2016). Such visualizations generate a heatmap representing the similarity between the hidden states of the premise and the hypothesis (Eq. 3 of the Supplementary Materials). Unfortunately the similarities are often the same regardless of the decision.

Let us consider the following example, where the same premise *“A kid is playing in the garden”*, is paired with three different hypotheses:

h1: *A kid is taking a nap in the garden*
h2: *A kid is having fun in the garden with her family*
h3: *A kid is having fun in the garden*

Note that the ground truth relationships are Contradiction, Neutral, and Entailment, respectively.

The first row of Fig. 1 shows the visualization of normalized attention for the three cases produced by ESIM-50, which makes correct predictions for all of them. As we can see from the figure, the three attention maps are fairly similar despite the completely different decisions. The key issue is that the attention visualization only allows us to see how the model aligns the premise with the hypothesis, but does not show *how such alignment impacts the decision.* This prompts us to consider the saliency of attention.

3.1.1 Attention Saliency

The concept of saliency was first introduced in vision for visualizing the spatial support on an image for a particular object class (Simonyan et al., 2013). In NLP, saliency has been used to study the importance of words toward a final decision (Li et al., 2016) .

We propose to examine the saliency of attention. Specifically, given a premise-hypothesis pair and the model’s decision y, we consider the similarity between a pair of premise and hypothesis hidden states e_{ij} as a variable. The score of the decision $S(y)$ is thus a function of e_{ij} for all i and j. The saliency of e_{ij} is then defined to be $|\frac{\partial S(y)}{\partial e_{ij}}|$.

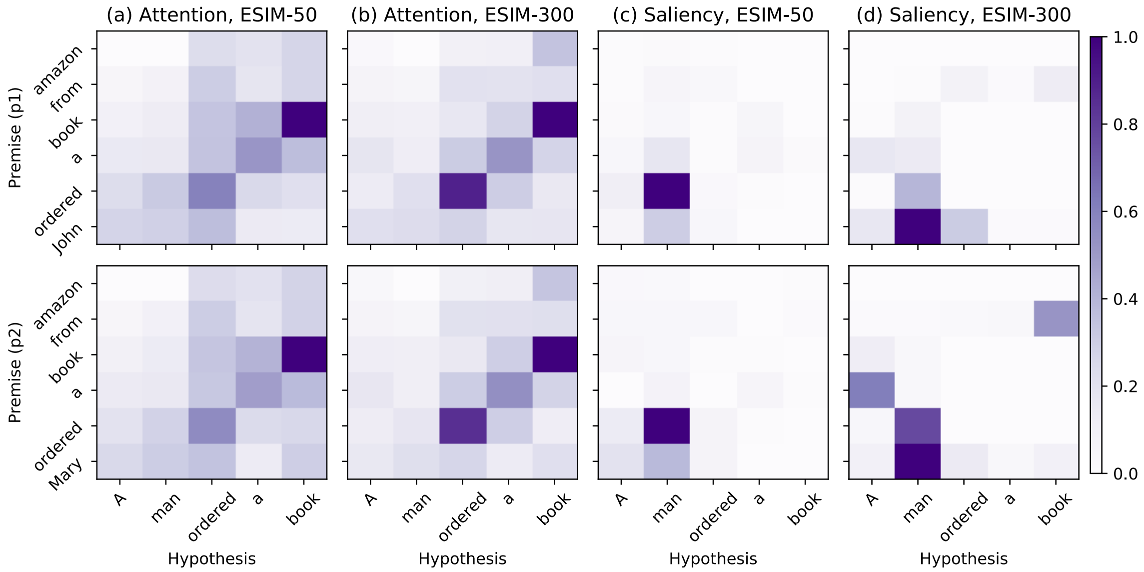

Figure 2: Normalized attention and attention saliency visualizations of two examples (p1 and p2) for ESIM-50 (a) and ESIM-300 (b) models. Each column indicates visualization of a model and each row represents visualization of one example.

The second row of Fig. 1 presents the attention saliency map for the three examples acquired by the same ESIM-50 model. Interestingly, the saliencies are clearly different across the examples, each highlighting different parts of the alignment. Specifically, for h1, we see the alignment between "is playing" and "taking a nap" and the alignment of "in a garden" to have the most prominent saliency toward the decision of Contradiction. For h2, the alignment of "kid" and "her family" seems to be the most salient for the decision of Neutral. Finally, for h3, the alignment between "is having fun" and "kid is playing" have the strongest impact toward the decision of Entailment.

From this example, we can see that by inspecting the attention saliency, we effectively pinpoint which part of the alignments contribute most critically to the final prediction whereas simply visualizing the attention itself reveals little information.

3.1.2 Comparing Models

In the previous examples, we study the behavior of the same model on different inputs. Now we use the attention saliency to compare the two different ESIM models: ESIM-50 and ESIM-300.

Consider two examples with a shared hypothesis of *"A man ordered a book"* and premise:

p1: *John ordered a book from amazon*

p2: *Mary ordered a book from amazon*

Here ESIM-50 fails to capture the gender connections of the two different names and predicts Neutral for both inputs, whereas ESIM-300 correctly predicts Entailment for the first case and Contradiction for the second.

In the first two columns of Fig. 2 (column a and b) we visualize the attention of the two examples for ESIM-50 (left) and ESIM-300 (right) respectively. Although the two models make different predictions, their attention maps appear qualitatively similar.

In contrast, columns 3-4 of Fig. 2 (column c and d) present the attention saliency for the two examples by ESIM-50 and ESIM-300 respectively. We see that for both examples, ESIM-50 primarily focused on the alignment of "ordered", whereas ESIM-300 focused more on the alignment of "John" and "Mary" with "man". It is interesting to note that ESIM-300 does not appear to learn significantly different similarity values compared to ESIM-50 for the two critical pairs of words ("John", "man") and ("Mary", "man") based on the attention map. The saliency map, however, reveals that the two models use these values quite differently, with only ESIM-300 correctly focusing on them.

3.2 LSTM Gating Signals

LSTM gating signals determine the flow of information. In other words, they indicate how LSTM reads the word sequences and how the information from different parts is captured and combined. LSTM gating signals are rarely analyzed, possibly

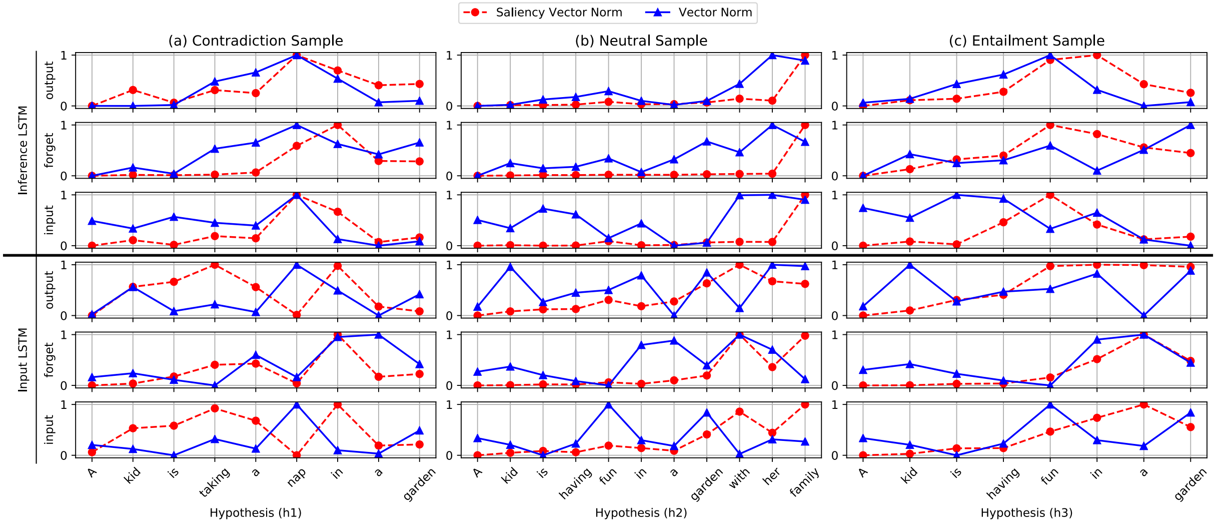

Figure 3: Normalized signal and saliency norms for the input and inference LSTMs (forward) of ESIM-50 for three examples. The bottom (top) three rows show the signals of the input (inference) LSTM. Each row shows one of the three gates (input, forget and output).

due to their high dimensionality and complexity. In this work, we consider both the gating signals and their saliency, which is computed as the partial derivative of the score of the final decision with respect to each gating signal.

Instead of considering individual dimensions of the gating signals, we aggregate them to consider their norm, both for the signal and for its saliency. Note that ESIM models have two LSTM layers, the first (input) LSTM performs the input encoding and the second (inference) LSTM generates the representation for inference.

In Fig. 3 we plot the normalized signal and saliency norms for different gates (input, forget, output)[1] of the Forward input (bottom three rows) and inference (top three rows) LSTMs. These results are produced by the ESIM-50 model for the three examples of Section 3.1, one for each column.

From the figure, we first note that the saliency tends to be somewhat consistent across different gates within the same LSTM, suggesting that we can interpret them jointly to identify parts of the sentence important for the model's prediction.

Comparing across examples, we see that the saliency curves show pronounced differences across the examples. For instance, the saliency pattern of the Neutral example is significantly different from the other two examples, and heavily concentrated toward the end of the sentence ("with her family"). Note that without this part of the sentence, the relationship would have been Entailment. The focus (evidenced by its strong saliency and strong gating signal) on this particular part, which presents information not available from the premise, explains the model's decision of Neutral.

Comparing the behavior of the input LSTM and the inference LSTM, we observe interesting shifts of focus. In particular, we see that the inference LSTM tends to see much more concentrated saliency over key parts of the sentence, whereas the input LSTM sees more spread of saliency. For example, for the Contradiction example, the input LSTM sees high saliency for both "taking" and "in", whereas the inference LSTM primarily focuses on "nap", which is the key word suggesting a Contradiction. Note that ESIM uses attention between the input and inference LSTM layers to align/contrast the sentences, hence it makes sense that the inference LSTM is more focused on the critical differences between the sentences. This is also observed for the Neutral example as well.

It is worth noting that, while revealing similar general trends, the backward LSTM can sometimes focus on different parts of the sentence (e.g., see Fig. 8 of the Supplementary Materials), suggesting the forward and backward readings provide complementary understanding of the sentence.

---

[1] We also examined the memory cell but it shows very similar behavior with the output gate and is hence omitted.

4 Conclusion

We propose new visualization and interpretation strategies for neural models to understand how and why they work. We demonstrate the effectiveness of the proposed strategies on a complex task (NLI). Our strategies are able to provide interesting insights not achievable by previous explanation techniques. Our future work will extend our study to consider other NLP tasks and models with the goal of producing useful insights for further improving these models.

Abstract

Neural models have shown several state-of-the-art performances on Semantic Role Labeling (SRL). However, the neural models require an immense amount of semantic-role corpora and are thus not well suited for low-resource languages or domains. The paper proposes a semi-supervised semantic role labeling method that outperforms the state-of-the-art in limited SRL training corpora. The method is based on explicitly enforcing syntactic constraints by augmenting the training objective with a syntactic-inconsistency loss component and uses SRL-unlabeled instances to train a joint-objective LSTM. On CoNLL-2012 English section, the proposed semi-supervised training with 1%, 10% SRL-labeled data and varying amounts of SRL-unlabeled data achieves +1.58, +0.78 F1, respectively, over the pre-trained models that were trained on SOTA architecture with ELMo on the same SRL-labeled data. Additionally, by using the syntactic-inconsistency loss on inference time, the proposed model achieves +3.67, +2.1 F1 over pre-trained model on 1%, 10% SRL-labeled data, respectively.

1 Introduction

Semantic role labeling (SRL), a.k.a shallow semantic parsing, identifies the arguments corresponding to each clause or proposition, i.e. its semantic roles, based on lexical and positional information. SRL labels non-overlapping text spans corresponding to typical semantic roles such as Agent, Patient, Instrument, Beneficiary, etc. This task finds its use in many downstream applications such as question-answering (Shen and Lapata, 2007), information extraction (Bastianelli et al., 2013), machine translation, etc.

Several SRL systems relying on large annotated corpora have been proposed (Peters et al., 2018; He et al., 2017), and perform relatively well. A more challenging task is to design an SRL method for low resource scenarios (e.g. rare languages or domains) where we have limited annotated data but where we may leverage annotated data from related tasks. Therefore, in this paper, we focus on building effective systems for low resource scenarios and illustrate our system's performance by simulating low resource scenarios for English.

SRL systems for English are built using large annotated corpora of verb predicates and their arguments provided as part of the PropBank and OntoNotes v5.0 projects (Kingsbury and Palmer, 2002; Pradhan et al., 2013). These corpora are built by adding semantic role annotations to the constituents of previously-annotated syntactic parse trees in the Penn Treebank (Marcus et al., 1993). Traditionally, SRL relies heavily on using syntactic parse trees either from shallow syntactic parsers (chunkers) or full syntactic parsers and Punyakanok et al. shows significant improvements by using syntactic parse trees.

Recent breakthroughs motivated by end-to-end deep learning techniques (Zhou and Xu, 2015; He et al., 2017) achieve state-of-the-art performance without leveraging any syntactic signals, relying instead on ample role-label annotations. We hypothesize that by leveraging syntactic structure while training neural SRL models, we may achieve robust performance, especially for low resource scenarios. Specifically, we propose to leverage syntactic parse trees as hard constraints for the SRL task i.e., we explicitly enforce that the predicted argument spans of the SRL network must agree with the spans implied by the syntactic parse of the sentence via scoring function in the training objective. Moreover, we present a semi-supervised learning (SSL) based formulation, wherein we leverage syntactic parse trees for SRL-unlabeled data to build effective SRL for low

resource scenarios.

We build upon the state-of-the-art SRL system by (Peters et al., 2018; He et al., 2017), where we formulate SRL as a BIO tagging problem and use multi-layer highway bi-directional LSTMs. However, we differ in terms of our training objective. In addition to the log-likelihood objective, we also include syntactic inconsistency loss (defined in Section 2.3) which quantifies the hard constraint (spans implied by syntactic parse) violations in our training objective. In other words, while training our model, we enforce the outputs of our system to agree with the spans implied by the syntactic parse of the sentence as much as possible. In summary, our contributions to low-resource SRL are:

1. A novel formulation which leverages syntactic parse trees for SRL by introducing them as hard constraints while training the model.
2. Experiments with varying amounts of SRL-unlabeled data that point towards semi-supervised learning for low-resource SRL by leveraging the fact that syntactic inconsistency loss does not require labels.

2 Proposed Approach

We build upon an existing deep-learning approach to SRL (He et al., 2017). First we revisit definitions introduced by (He et al., 2017) and then discuss about our formulation.

2.1 Task definition

Given a sentence-predicate pair $(\mathbf{x}, v)$, SRL task is defined as predicting a sequence of tags $\mathbf{y}$, where each y_i belongs to a set of BIO tags (Ω). So, for an argument span with semantic role ARG$_i$, B-ARG$_i$ tag indicates that the corresponding token marks the beginning of the argument span and I-ARG$_i$ tag indicates that the corresponding token is inside of the argument span and O tag indicates that token is outside of all argument spans. Let $n = |\mathbf{x}| = |\mathbf{y}|$ be the length of the sentence. Further, let *srl-spans*$(\mathbf{y})$ denote the set of all argument spans in the SRL tagging $\mathbf{y}$. Similarly, *parse-spans*$(\mathbf{x})$ denotes the set of all unlabeled parse constituents for the given sentence $\mathbf{x}$. Lastly, SRL-labeled/unlabeled data refers to sentence-predicate pairs with/without gold SRL tags.

2.2 State-of-the-Art (SOTA) Model

He et al. proposed a deep bi-directional LSTM to learn a locally decomposed scoring function conditioned on the entire input sentence- $\sum_{i=1}^{n} \log p(y_i|\mathbf{x})$. To learn the parameters of a network, the conditional negative log-likelihood $\mathcal{L}(\mathbf{w})$ of a sample of training data $\mathcal{T} = \{\mathbf{x}^{(t)}, \mathbf{y}^{(t)}\}_{\forall t}$ is minimized, where $\mathcal{L}(\mathbf{w})$ is

$$\mathcal{L}(\mathbf{w}) = -\sum_{(\mathbf{x},\mathbf{y})\in\mathcal{T}} \sum_{i=1}^{|\mathbf{y}|} \log p(y_i|\mathbf{x};\mathbf{w}). \quad (1)$$

Since Eq.(1) does not model any dependencies between the output tags, the predicted output tags tend to be structurally inconsistent. To alleviate this problem, (He et al., 2017) searches for the best $\hat{\mathbf{y}}$ over the space of all possibilities (Ω^n) using the scoring function $f(x, y)$, which incorporates log probability and structural penalty terms. The details of scoring function is on Appendix Eq.(7).

$$\hat{\mathbf{y}} = \arg\max_{\mathbf{y}'\in\Omega^n} \mathbf{f}(\mathbf{x}, \mathbf{y}') \quad (2)$$

2.3 Structural Constraints

There are different types of structural constraints: BIO, SRL and syntactic constraints. BIO constraints define valid BIO transitions for sequence tagging. For example, B-ARG0 cannot be followed by I-ARG1. SRL constraints define rules on the role level and has three particular constraints: unique core roles (U), continuation roles (C) and reference roles (R) (Punyakanok et al., 2008). Lastly, syntactic constraints state that *srl-spans*$(\mathbf{y})$ have to be subset of *parse-spans*$(\mathbf{x})$.

(He et al., 2017) use BIO and syntactic constraints at decoding time by solving Eq.(2) where $f(x, y)$ incorporates those constraints and report that SRL constraints do not show significant improvements over the ensemble model. In particular, by using syntactic constraints, (He et al., 2017) achieves up to +2 F1 score on CoNLL-2005 dataset via A* decoding.

Improvements of SRL system via use of syntactic constraints is consistent with other observations (Punyakanok et al., 2008). However, all previous works enforce syntactic consistency only during decoding step. We propose that enforcing syntactic consistency during training time would also be beneficial and show the efficacy experimentally on Section 3.3.

Enforcing Syntactic Consistency To quantify syntactic inconsistency, we define *disagreeing-spans*$(\mathbf{x}, \mathbf{y}) = \{span_i \in \text{srl-spans}(\mathbf{y}) \mid span_i \notin \text{parse-spans}(\mathbf{x})\}$. Further, we define *disagreement* *rate*, $d(\mathbf{x},\mathbf{y}) \in [0,1]$, and *syntactic inconsistency score*, $s(\mathbf{x},\mathbf{y}) \in [-1,1]$, as follows:

$$d(\mathbf{x},\mathbf{y}) = \frac{|\text{disagreeing-spans}(\mathbf{x},\mathbf{y})|}{|\text{srl-spans}(\mathbf{y})|} \quad (3)$$

$$s(\mathbf{x},\mathbf{y}) = 2 \times d(\mathbf{x},\mathbf{y}) - 1 \quad (4)$$

Syntactic Inconsistency Loss (SI-Loss) For a given $(\mathbf{x}, v)$, let us consider $\hat{\mathbf{y}}^{(t)}$ to be the best possible tag sequence (according to Eq.(2) during epoch t of model training. Ideally, if our model is syntax-aware, we would have $d(\mathbf{x},\hat{\mathbf{y}}^{(t)}) = 0$ or $r(\mathbf{x},\hat{\mathbf{y}}^{(t)}) = 1$. We define a loss component due to syntactic inconsistency (*SI-Loss*) as follows:

$$\text{SI-Loss} = s(\mathbf{x},\hat{\mathbf{y}}^{(t)}) \sum_{i=1}^{|\hat{\mathbf{y}}^{(t)}|} \log p(\hat{y}_i^{(t)}|\mathbf{x};\mathbf{w}^{(t)}) \quad (5)$$

During training, we want to minimize SI-Loss.

2.4 Training with Joint Objective

Based on Eq.(1), a supervised loss, and Eq.(5), the SI-Loss, we propose a joint training objective. For a given sentence-predicate pair $(\mathbf{x}, v)$ and SRL tags $\mathbf{y}$, our joint training objective (at epoch t) is defined as:

$$\text{Joint loss} = -\alpha_1 \sum_{i=1}^{|\mathbf{y}|} \log p(y_i|\mathbf{x};\mathbf{w})$$
$$+\alpha_2\, r(\mathbf{x},\hat{\mathbf{y}}^{(t)}) \sum_{i=1}^{|\hat{\mathbf{y}}^{(t)}|} \log p(\hat{y}_i^{(t)}|\mathbf{x};\mathbf{w}^{(t)}) \quad (6)$$

Here, α_1 and α_2 are weights (hyper-parameters) for different loss components and are tuned using a development set. During training, we minimize joint loss - i.e., negative log-likelihood (or cross-entropy loss) and syntactic inconsistency loss.

2.5 Semi-supervised learning formulation

In low resource scenarios, we have limited labeled data and larger amounts of unlabeled data. The obvious question is how to leverage large amounts of unlabeled data for training accurate models. In context of SRL, we propose to leverage SRL-unlabeled data in terms of parse trees.

Observing Eq.(5), one can notice that our formulation of SI-Loss is only dependent upon model's predicted tag sequence $\hat{\mathbf{y}}^{(t)}$ at a particular time point t during training and the given sentence and it does not depend upon gold SRL tags. We leverage this fact in our SSL formulation to compute SI-loss from SRL-unlabeled sentences.

Model/ Legend	Test F1	Average disagreement rate (%)
B100	84.40	14.69
B10	**78.56**	**17.01**
B1	**67.28**	**21.17**
J100	84.75 (+0.35)	14.48 (−1.43%)
J10	79.09 (+0.53)	16.25 (−4.47%)
J1	68.02 (+0.74)	20.49 (−3.21%)

Table 1: Comparison of baseline models (**B**) with the models trained with joint objective (**J**).

Let *sup-s* be a batch of SRL-labeled sentences and *usup-s* be a batch SRL-unlabeled sentences only with parse information. In SSL setup, we propose to train our model with joint objective where *sup-s* only contributes to supervised loss Eq.(1) and *unsup-s* contributes in terms of syntactic inconsistency objective Eq.(5) and combine them according to Eq.(6) to train them with joint loss.

3 Experiments

3.1 Dataset

We evaluate our model's performance on span-based SRL dataset from CoNLL-2012 shared task (Pradhan et al., 2013). This dataset contains gold predicates as part of the input sentence and also gold parse information corresponding to each sentence which we use for defining hard constraints for SRL task. We use standard train/development/test split containing 278K/38.3K/25.6K sentences. Further, there is approx. 10% disagreement between gold SRL-spans and gold parse-spans (we term these as noisy syntactic constraints). During training, we do not preprocess data to handle these noisy constraints but for the analysis related to enforcing syntactic constraints during inference, we study both cases: with and without noisy constraints. [1]

3.2 Model configurations

For the SOTA system proposed in (Peters et al., 2018), we use code from Allen AI[2] to implement our approach. We follow their initialization and training configurations. Let **B**$\underline{X}$**, J**$\underline{X}$ denote model trained with $\underline{X}$% of the SRL-labeled data with cross-entropy and joint training objective, re-

---

[1] We preprocessed data for inference by simply deleting syntactic parse trees for the sentences where we have disagreement and perform standard Viterbi decoding for those sentences and note that this preprocessing scheme was never used during training.

Gradient-based	80.18 (+1.62)	**80.66** **(+1.32)**	69.97 (+2.69)	70.94 (+2.08)

Table 4: Comparison of different decoding techniques: Viterbi, A* (He et al., 2017) and gradient based inference (Lee et al., 2017) with noisy and noise-free syntactic constraints[1]. Note that the (+/-) F1 are reported w.r.t Viterbi decoding on the same column.

spectively. B$\underline{X}$-SI$\underline{U}$x and B$\underline{X}$-J$\underline{U}$x denote model trained with SI-loss and Joint loss, respectively, on the pre-trained B$\underline{X}$ model where $\underline{X} \times \underline{U}$ amount of SRL-unlabeled data were used for further training. To satisfy BIO constraints, we run Viterbi decoding by default for inference.

3.3 Results

We are interested in answering following questions. (Q1) how well does the baseline model produce syntactically consistent outputs, (Q2) does our approach actually enforce syntactic constraints, (Q3) does our approach enforce syntactic constraints without compromising the quality of the system, (Q4) how well does our SSL formulation perform, especially in low-resource scenarios, and lastly (Q5) what is the difference in using the syntactic constraints in training time compared to using it at decoding time. To answer (Q1-2) favorably we report average disagreement rate computed over test split. To answer (Q3-5), we report overall F1-scores on CoNLL-2012 test set (using standard evaluation script). For experiments using SRL-unlabeled data, we report average results after running multiple experiments with different random samples of it.

Does training with joint objective help? We trained 3 models with random 1%, 10% and whole 100% of the training set with joint objective (α_1 = α_2 = 0.5). For comparison, we trained 3 SOTA models with the same training sets. All models were trained for max 150 epochs and with a patience of 20 epochs. Table 1 reports the results of this experiment. We see that models trained with joint objective (JX) improve over baseline models (BX), both in terms of F1 and average disagreement rate. These improvements provide evidence for answering (Q1-3) favorably. Further, gains are more in low resource scenarios because by training models jointly to satisfy syntactic constraints helps in better generalization when trained with limited SRL corpora.

Does SSL based training work for low-resource scenarios? To enforce syntactic constraints via SI-loss on SRL-unlabeled data, we further train pre-trained model with two objectives in SSL set up: (a) SI-loss (Table 2) and (b) joint objective (Table 3)

For experiment (a), we use square loss, $\beta \| W - W_{\text{pre-train}} \|^2$ regularizer to keep the model W close to the pre-trained model $W_{\text{pre-train}}$ to avoid catastrophic forgetting (β set to 0.005). We optimize with SGD with learning rate of 0.01, $\alpha_2 = 1.0$, patience of 10 epochs. We see that with SI-loss improvements are significant in terms of average disagreement rate as compared to F1.

For experiment (b), we train B1 and B10 with joint objective in SSL set-up (as discussed in Section 2.5). We use SGD with learning rate of 0.05, $\alpha_1 = \alpha_2 = 1.0$ and patience of 10 epochs. We report +1.58 F1 and +0.78 F1 improvement over

B1 and B10, trained with 5% and 100% SRL-unlabeled data, respectively. Note that we cannot achieve these improvements with simply fine-tunning B$\underline{X}$ with supervised loss, as seen with B$\underline{X}$-further on Table 3. This provides evidence to answer (Q4) favorably. In general, the performance gains increase as the size of the SRL-unlabeled data increases.

Is it better to enforce syntactic consistency on decoding or on training time? To answer (Q5), we conducted three experiments: using syntactic constraints on (a) inference only, i.e. structured prediction, (b) training only, and (c) both training and inference steps. For the structured prediction, we consider A* decoding, as used in (He et al., 2017) and gradient-based inference (Lee et al., 2017), which optimizes loss function similar to SI-loss on Eq.(5) per example basis. If neither A* decoding nor gradient-based inference is used, we use Viterbi algorithm to enforce BIO constraints. The performance is the best (bold on Table 4) when syntactic consistency is enforced both on training and inference steps, +3.67, +2.1 F1 score improvement over B1 and B10 respectively, and we conclude that the effort of enforcing syntactic consistency on inference time is complementary to the same effort on training time. However, note that the overall performance increases as the benefit from enforcing syntactic consistency with SSL is far greater compared to marginal decrement on structured prediction.

While syntactic constraints help both train and inference, injecting constraints on train time is far more robust compared to enforcing them on decoding time. The performance of the structured prediction drops rapidly when the noise in the parse information is introduced (x column of Table 4). On the other hand, SSL was trained on CoNLL2012 data where about 10% of the gold SRL-spans do not match with gold parse-spans and even when we increase noise level to 20% the performance drop was only around 0.1 F1 score.

4 Related Work

The traditional approaches for SRL (Pradhan et al., 2005; Koomen et al., 2005) constituted of cascaded system with four subtasks: pruning, argument identification, argument labeling, and inference. Recent approaches (Zhou and Xu, 2015; He et al., 2017) proposed end-to-end system for SRL using deep recurrent or bi-LSTM-based architecture with no syntactic inputs and have achieved SOTA results on English SRL. Lastly, (Peters et al., 2018) proposed ELMo, a deep contextualized word representations, and improved the SOTA English SRL by 3.2 F1-points.

Even on the end-to-end learning, inference still remains as a separate subtask and would be formalized as a constrained optimization problem. To solve this problem ILP (Punyakanok et al., 2008), *A* algorithm* (He et al., 2017) and gradient-based inference (Lee et al., 2017) were employed. Further, all of these works leveraged syntactic parse during inference and was never used during training unless used as a cascaded system.

To the best of our knowledge, this work is the first attempt towards SSL span-based SRL model. Nonetheless, there were few efforts in SSL in dependency-based SRL systems (Fürstenau and Lapata, 2009; Deschacht and Moens, 2009; Croce et al., 2010). (Fürstenau and Lapata, 2009) proposed to augment the dataset by finding similar unlabeled sentences to already labeled set and annotate accordingly. While interesting, the similar augmentation technique is harder to apply to span-based SRL as one requires to annotate the whole span. (Deschacht and Moens, 2009; Croce et al., 2010) proposed to leverage the relation between words by learning latent word distribution over the context, i.e. language model. Our paper also incorporates this idea by using ELMo as it is trained via language model objective.

5 Conclusion and Future Work

We presented a SI-loss to enforce SRL systems to produce syntactically consistent outputs. Further, leveraging the fact that SI-loss does not require labeled data, we proposed a SSL formulation with joint objective constituting of SI-loss and supervised loss together. We show the efficacy of the proposed approach on low resource settings, +1.58, +0.78 F1 on 1%, 10% SRL-labeled data respectively, via further training on top of pre-trained SOTA model. We further show the structured prediction can be used as a complimentary tool and show performance gain of +3.67, +2.1 F1 over pre-trained model on 1%, 10% SRL-labeled data, respectively. Semi-supervised training from the scratch and examination of semi-supervised setting on large dataset remains as part of the future work.

Abstract

When the semantics of a sentence are not representable in a semantic parser's output schema, parsing will inevitably fail. Detection of these instances is commonly treated as an out-of-domain classification problem. However, there is also a more subtle scenario in which the test data is drawn from the same domain. In addition to formalizing this problem of *domain-adjacency*, we present a comparison of various baselines that could be used to solve it. We also propose a new simple sentence representation that emphasizes words which are unexpected. This approach improves the performance of a downstream semantic parser run on in-domain and domain-adjacent instances.

Air Travel Domain	
Example In-Domain Predicates	
buyTicket	Buy ticket LGA to SFO on 3/12
flightStatus	What's the status of my SF flight?
switchFlight	Change it to the 8am SFO flight
cancelFlight	Cancel my flight to SFO
awardTravel	I want to fly to SFO with miles
Example Domain-Adjacent Predicates	
changeSeat	Change my seat to 23A
milesUpgrade	Upgrade my flight with my miles
arrivalGate	Gate that my SFO flight arrives at
mileageStatus	What's my miles status
Example Out-of-Domain Predicates	
transferMoney	Transfer $200 to checking
addTimer	Add a timer for 3 minutes
restaurantSearch	Thai restaurants in SF
scheduleMeeting	Set up a 9am meeting with Amy

Figure 1: In this example, an **air travel** semantic parser is trained on data containing in-domain predicates. A test instance cannot be parsed correctly if it contains any domain-adjacent or out-of-domain predicates.

1 Introduction

Semantic parsers map text to logical forms, which can then be used by downstream components to fulfill an action. Consider, for example, a system for booking air travel, in which a user provides natural language input, and a downstream subsystem is able to make or cancel flight reservations. Users of the system typically have a general understanding of its purpose, so the input will revolve around the correct topic of **air travel**. However, they are unlikely to know the limits of the system's functionality, and may provide inputs for which the expected action is beyond its capabilities, such as asking to change seats on a flight reservation. Because the logical schema is designed with fulfillment in mind, no logical form can capture the semantics of these sentences, making it impossible for the parser to generate a correct parse. Any output the parser generates will cause unintended actions to be executed downstream. For example, asking to change seats might be misparsed and executed as changing flights. Instead, the parser should identify that this input is beyond its scope so the condition can be handled.[1] In this paper, we formalize this pervasive problem, which we call *domain-adjacent instance identification*.

While this task is similar to that of identifying *out-of-domain* input instances (e.g., **banking** with respect to **air travel**), it is much more subtle — the instances come from roughly the same domain as the parser's training examples, and thus use very similar language. Domain adjacency is a property with respect to the parser's output schema, independent of the data used to train it.

In this paper, we formalize this task, and propose a simple approach for representing sentences in which words are weighted by how likely they are to differentiate between in-domain and domain-adjacent instances. Note that while this approach can also be applied to out-of-domain

---

[1] In the final page of the paper, we suggest a few immediate downstream system behaviors when a domain-adjacent instance is identified, but others have investigated the related problem of teaching the system new behavior (Azaria et al., 2016).

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4964–4969
Brussels, Belgium, October 31 - November 4, 2018. ©2018 Association for Computational Linguistics

instances, in this paper we are interested in its performance on domain-adjacent instances. We describe an evaluation framework for this new task and, finally, evaluate our proposed method against a set of baselines, comparing performance on the domain-adjacent classification problem and a downstream semantic parsing task.

2 Problem Setting

A semantic parser can be seen as a function φ that maps sentences x in a natural language $\mathcal{L}$ to logical forms $y \in \mathcal{Y}$. Assuming the existence of an oracle parser $\hat{\varphi}$, the problem we propose in this paper is that of determining, for a given test instance x, whether it belongs to the *domain* Φ of $\hat{\varphi}$, i.e., if its semantics can be encoded in the schema $\mathcal{Y}$.

In real-world usage, the input sentences x will be generated by a human user, who associates the capabilities of the parser to a particular topic (e.g., **air travel**). Thus most of the $x \in \mathcal{L} \setminus \Phi$ will share topic with the $\hat{x} \in \Phi$. Because of the similarity between these x and $\hat{x}$, we call this task *identification of domain-adjacent instances*.

3 Approach

Our goal is to identify input instances whose semantics are not representable in the parser's output schema, and we assume only an in-domain dataset is available at training time. Our approach is based on determining similarity to these training instances. We split the task in two parts: 1) encode the sentences to a compact representation that preserves the needed information, and 2) given these representations, identify which sentences are so dissimilar that they are unlikely to be parseable with any schema that covers the training set.

3.1 Sentence Representation

Among recent work in distributional semantics, averaging the word vectors to represent a sentence (Wieting et al., 2016; Adi et al., 2017) has proven to be a simple and robust approach. However, we have an intuition that words which are *unexpected* in their context given the training data may be a strong signal that an instance is domain-adjacent. To incorporate this signal, we propose a weighted average, in which the weight corresponds to how unexpected the word is in its context. For example, given in-domain predicates from Figure 1, in the domain-adjacent sentence "Upgrade my flight to SFO with my miles", *upgrade* should receive a much higher weight than *flight* or *SFO*.

Our weighting scheme is as follows: We use the cosine distance between the expected ($\bar{v}_i$) and the actual ($\hat{v}_i$) domain-specific word embedding at a given position (i) in a sentence to compute its weight: $w_i = 1 - cos(\bar{v}_i, \hat{v}_i)$. The expected word embedding is computed using the context embeddings, $\bar{v}_i = \sum_{j=i-c, j\neq i}^{i+c} \hat{v}_j$, where $\hat{v}_j$ is a domain-specific word embedding, in a window of size c around position i. Intuitively, w_i represents how surprising the word is in the context.

Since our training set is too small to directly learn domain-specific embeddings, we learn a mapping from general pre-trained embeddings. We train a continuous bag-of-words model (Mikolov et al., 2013) in which we pass pre-trained embeddings (v_i) instead of 1-hot vectors, as input to the embedding layer. The layer thus learns a mapping from pre-trained to domain-specific embeddings ($\hat{v}_i$). We use this mapping to compute new embeddings for words that are missing from the training set. Only words that do not have pre-trained embeddings are ignored.

Finally, for a sentence with n words, we take the weighted average of the pre-trained embeddings of the words in the sentence, using the weights from above: $S = (\sum_{i=1}^{n} w_i v_i) \,/\, (\sum_{i=1}^{n} w_i)$.

This approach assigns high weight to words that differ significantly from what is expected based on the training data. By combining these weights with the pre-trained word embeddings, we allow the model to incorporate external information, improving generalization beyond the training set.

3.2 Domain-Adjacent Model

A number of techniques can be applied to predict whether a sentence is domain-adjacent from its continuous representation. Of the methods we tried, we found k-nearest neighbors (Angiulli and Pizzuti, 2002) to perform best: to classify a sentence, we calculate the average cosine distance between its embedding and its k nearest neighbors in the training data, and label it domain-adjacent if this value is greater than some threshold. This simpler model relies more heavily on the external information brought in by pre-trained word embeddings, while more complex models seem to overfit to the training data.

Recipes	*preparationTime*
Restaurants	*starRating*
Social	*educationStartDate*, *employmentEndDate*

Table 1: Predicates excluded from training and considered domain-adjacent. Domains have 5-20 predicates.

4 Evaluation

In this section, we introduce an evaluation framework for this new task. We consider training and test sets from a single domain, with only the latter containing domain-adjacent instances. Test instances are classified individually, and we measure performance on in-domain/domain-adjacent classification and semantic parsing.

4.1 Dataset and Semantic Parser

We simulate this setting by adapting the OVERNIGHT dataset (Wang et al., 2015). This dataset is composed of queries drawn from eight domains, each having a set of seven to eighteen distinct semantic predicates. Queries consist of a crowd-sourced textual sentence and its corresponding logical form containing one or more of these domain-specific semantic predicates.

For each domain, we select a set of predicates to exclude from the logical schema (see Table 1), and remove all instances containing these predicates from the training set (since they are now domain-adjacent). We then train a domain-adjacent model and semantic parser on the remaining training data and attempt to identify the domain-adjacent examples in the test data. We use the train/test splits from Wang et al. (2015). In all experiments, we use the SEMPRE parser (Berant et al., 2013).

4.2 Baselines

Because this is a novel task, and results are not comparable to previous work, we report results from a variety of baseline systems. The first baseline, CONFIDENCE, identifies instances as domain-adjacent if the semantic parser's confidence in its predictions is below some threshold.

The remaining baselines follow the two-part approach from Section 3. AUTOENCODER is inspired by Ryu et al. (2017)'s work on identifying *out-of-domain* examples. For the sentence representation, this method uses a bi-LSTM with self-attention, trained to predict the semantic predicates, and concatenates the final hidden state from each direction as the sentence representation. An autoencoder is used as the domain-adjacent classifier.

The remaining methods use the nearest neighbor model discussed in Section 3.2. For sentence representations, we include baselines drawn from different neural approaches. In CBOW, we simply average the pre-trained word embeddings in the sentence. In CNN, we train a two-layer CNN with a final softmax layer to predict the semantic predicates for a sentence. We concatenate the mean pooling of each layer as the sentence representation. In LSTM, we use the same sentence representation as in AUTOENCODER, with the nearest neighbor domain-adjacent model. Finally, SURPRISE is the approach presented in Section 3.1.

4.3 Direct Evaluation

We first directly evaluate the identification of domain-adjacent instances: Table 2 reports the area under a receiver operating characteristic curve (AUC) for the considered models (Fawcett, 2006). SURPRISE generally performs the best on this evaluation; and, in general, the simpler models tend to perform better, suggesting that more complex approaches tune too much to the training data.

Qualitatively, for domains where the SURPRISE model performs better, it places higher weight on words we would consider important for distinguishing domain-adjacent sentences. For example in “show me recipes with longer preparation times than rice pudding” from **Recipes**, “longer” and “preparation” have the highest weights. In **Social**, there are two in-domain predicates (*employmentStartDate* and *educationEndDate*) which use very similar wording to those that are domain-adjacent, making it difficult to isolate surprising words. The weights in this domain seem to instead emphasize unusual wordings such as “soonest” in “employees with the soonest finish date”.

4.3.1 Ablation Analysis

In order to determine the contribution of each one of the components of SURPRISE, we performed an ablation analysis comparing the following modifications of the method: CBOW, as described above, using an unweighted average of pre-trained embeddings; FREQUENCY, using a

	Basketball	Blocks	Calendar	Housing	Publications	Recipes	Restaurants	Social
Autoencoder	0.801	0.479	0.766	0.781	0.874	0.722	0.581	0.774
Confidence	0.660	0.738	0.697	0.648	0.631	0.651	0.730	0.573
CBOW	0.743	0.782	0.662	0.910	0.884	0.670	0.911	0.675
CNN	**0.916**	0.654	**0.862**	0.792	0.908	0.505	0.840	**0.813**
LSTM	0.826	0.571	0.741	0.912	0.827	0.487	0.593	0.754
Surprise	0.755	**0.827**	0.817	**0.933**	**0.978**	**0.758**	**0.941**	0.545

Table 2: AUC for domain-adjacent instance identification, using kNN as the domain-adjacent model.

	Basketball	Blocks	Calendar	Housing	Publications	Recipes	Restaurants	Social
CBOW	0.743	0.782	0.662	0.910	0.884	0.670	0.911	**0.675**
Frequency	0.656	0.703	0.771	0.884	0.887	0.667	0.834	0.591
PreTrained	0.612	0.636	0.512	0.819	0.842	0.526	0.858	0.538
Surprise	**0.755**	**0.827**	**0.817**	**0.933**	**0.978**	**0.758**	**0.941**	0.545

Table 3: AUC for domain-adjacent instance identification, using ablated versions of Surprise with kNN.

weighted average of pre-trained embeddings, with weights based on inverse document frequency in the training set; PreTrained, using the surprise schema but with weights determined using pre-trained embeddings; and the full Suprise as presented above. Each approach adds one component (weighting, surprise-based weights, and domain-specific embeddings) with respect to the previous one.

The results of the experiment are shown in Table 3. We can see that Frequency performs slightly worse than CBOW and PreTrained performs even worse than that. We can conclude that the combination of the weighting schema and the tuned vectors is what makes Suprise effective.

4.4 Downstream Task Evaluation

We next evaluate how including the domain-adjacent predictions affects the performance of a semantic parser. In a real setting, when the semantic parser is presented with domain-adjacent input that is beyond its scope, the correct behavior is to label it as such so that it can be handled properly by downstream components. To simulate this behavior, we set the gold parse for domain-adjacent instances to be an empty parse, and automatically assign an empty parse to any instance that is identified as domain-adjacent. We report accuracy of the semantic parser with 20% domain-adjacent test data. We include two additional models: NoFilter, in which nothing is labeled domain-adjacent, and Oracle, in which all the domain-adjacent instances are correctly identified. For each baseline requiring a threshold, we set it such that 3% of the instances in the dev set would be marked as domain-adjacent (intuitively, this represents the error-tolerance of the system).

Table 4 shows the results for this experiment. In general, the relative performance is similar to that in the direct evaluation (e.g. Surprise tends to do well on most domains, but performs poorly on Basketball and Social in particular). However, in this evaluation, misclassifying an instance as domain-adjacent if the semantic parser would have accurately parsed it is worse than misclassifying the instance if the semantic parser could not have accurately parsed it. For example, in Social we can thus infer that Surprise is marking some instances as domain-adjacent that would otherwise be accurately parsed as the performance there is actually worse than for NoFilter.

5 Related Work

Domain-adjacency identification is a new task, but relatively little effort has been devoted to even the related task of identifying out-of-domain instances (i.e., from completely separate domains) for semantic parsers. Hakkani-Tur et al. (2015) approached the problem by clustering sentences based on shared subgraphs in their general semantic parses; Ryu et al. (2017) classify sentences with autoencoder reconstruction error.

Prior distributional semantics work to create compact sentential representations generated specific embeddings for downstream tasks (Kalchbrenner et al., 2014; Kim, 2014; Socher et al., 2013). Recently, work has focused on domain-

Table 4: Accuracy for a semantic parser evaluated on a test set in which 20% is domain adjacent.

independent embeddings, learned without downstream task supervision. Kiros et al. (2015), Hill et al. (2016), and Kenter et al. (2016) learn representations by predicting the surrounding sentences. Wieting et al. (2016) use paraphrases as supervision. Mu et al. (2017) represent sentences by the low-rank subspace spanned by the embeddings of the words in them; Arora et al. (2017) use a weighted average of word embeddings, with their projection onto the first principal component across all sentences in the corpus removed.

Another relatively sparse area of related work is handling the domain-adjacent instances once they have been identified. The simplest thing to do is to return a generic error. For user-facing applications, one such message might state that the system can't handle that specific query. Azaria et al. (2016) approach this problem by having the user break down the domain-adjacent instance into a sequence of simpler textual instructions and then attempting to map those to known logical forms.

6 Conclusion

Identifying domain-adjacent instances is a practical issue that can improve downstream semantic parsing precision, and thus provide a smoother and more reliable user experience. In this paper, we formalize this task, and introduce a novel sentence embedding approach which outperforms baselines. Future work includes exploring alternative ways of incorporating information outside of the given training set and experimenting with various combinations of semantic parsers and upstream domain-adjacency models. Another area of future research is how the underlying system should recover when domain-adjacent instances are detected.

Mapping natural language commands to web elements

Panupong Pasupat **Tian-Shun Jiang** **Evan Liu** **Kelvin Guu** **Percy Liang**
Stanford University
`{ppasupat,jiangts,evanliu,kguu,pliang}@cs.stanford.edu`

Abstract

The web provides a rich, open-domain environment with textual, structural, and spatial properties. We propose a new task for grounding language in this environment: given a natural language command (e.g., "click on the second article"), choose the correct element on the web page (e.g., a hyperlink or text box). We collected a dataset of over 50,000 commands that capture various phenomena such as functional references (e.g. "find who made this site"), relational reasoning (e.g. "article by john"), and visual reasoning (e.g. "top-most article"). We also implemented and analyzed three baseline models that capture different phenomena present in the dataset.

1 Introduction

Web pages are complex documents containing both structured properties (e.g., the internal tree representation) and unstructured properties (e.g., text and images). Due to their diversity in content and design, web pages provide a rich environment for natural language grounding tasks.

In particular, we consider the task of mapping natural language commands to web page elements (e.g., links, buttons, and form inputs), as illustrated in Figure 1. While some commands refer to an element's text directly, many others require more complex reasoning with the various aspects of web pages: the text, attributes, styles, structural data from the document object model (DOM), and spatial data from the rendered web page.

Our task is inspired by the semantic parsing literature, which aims to map natural language utterances into actions such as database queries and object manipulation (Zelle and Mooney, 1996; Chen and Mooney, 2011; Artzi and Zettlemoyer, 2013; Berant et al., 2013; Misra et al., 2015; Andreas and Klein, 2015). While these actions usually act on an environment with a fixed and known schema, web pages contain a larger variety of structures, making the task more open-ended. At the same time, our task can be viewed as a reference game (Golland et al., 2010; Smith et al., 2013; Andreas and Klein, 2016), where the system has to select an object given a natural language reference. The diversity of attributes in web page elements, along with the need to use context to interpret elements, makes web pages particularly interesting.

Figure 1: Examples of natural language commands on the web page `appleinsider.com`.

Identifying elements via natural language has several real-world applications. The main one is providing a voice interface for interacting with web pages, which is especially useful as an assistive technology for the visually impaired (Zajicek et al., 1998; Ashok et al., 2014). Another use case is browser automation: natural language commands are less brittle than CSS or XPath selectors (Hammoudi et al., 2016) and could generalize across different websites.

We collected a dataset of over 50,000 natural language commands. As seen in Figure 1, the

element description	The command describes a property of the element.	"click blue button"	2.0 %
relational reasoning	The command requires reasoning with another element or its surrounding context.	"show cookies info" → "More Info" in the cookies warning bar, not in the news section	2.5 %
ordinal reasoning	The command uses an ordinal.	"click on the first article"	3.5 %
spatial reasoning	The command describes the element's position.	"click the three slashes at the top left of the page"	2.0 %
image target	The target is an image (no text).	"select the favorites button"	11.5 %
form input target	The target is an input (text box, check box, drop-down list, etc.).	"in the search bar, type testing"	6.5 %

Table 1: Phenomena present in the commands in the dataset. Each example can have multiple phenomena.

commands contain many phenomena, such as relational, visual, and functional reasoning, which we analyze in greater depth in Section 2.2. We also implemented three models for the task based on retrieval, element embedding, and text alignment. Our experimental analysis shows that functional references, relational references, and visual reasoning are important for correctly identifying elements from natural language commands.

2 Task

Given a web page w with elements $e_1, \dots, e_k$ and a command c, the task is to select the element $e \in \{e_1, \dots, e_k\}$ described by the command c. The training and test data contain (w, c, e) triples.

2.1 Dataset

We collected a dataset of 51,663 commands on 1,835 web pages. To collect the data, we first archived home pages of the top 10,000 websites[1] by rendering them in Google Chrome. After loading the dynamic content, we recorded the DOM trees and the geometry of each element, and stored the rendered web pages. We filtered for web pages in English that rendered correctly and did not contain inappropriate content. Then we asked crowdworkers to brainstorm different actions for each web page, requiring each action to reference exactly one element (of their choice) from the filtered list of interactive elements (which include visible links, inputs, and buttons). We encouraged the workers to avoid using the exact words of the elements by granting a bonus for each command that did not contain the exact wording of the selected element. Finally, we split the data into 70% training, 10% development, and 20% test data. Web pages in the three sets do not overlap.

The collected web pages have an average of 1,051 elements, while the commands are 4.1 tokens long on average.

2.2 Phenomena present in the commands

Apart from referring to the exact text of the element, commands can refer to elements in a variety of ways. We analyzed 200 examples from the training data and broke down the phenomena present in these commands (see Table 1).

Even when the command directly references the element's text, many other elements on the page also have word overlap with the command. On average, commands have word overlap with 5.9 leaf elements on the page (not counting stop words).

3 Models

3.1 Retrieval-based model

Many commands refer to the elements by their text contents. As such, we first consider a simple retrieval-based model that uses the command as a search query to retrieve the most relevant element based on its TF-IDF score.

Specifically, each element is represented as a bag-of-tokens computed by (1) tokenizing and stemming its text content, and (2) tokenizing the

---

[1] `https://majestic.com/reports/majestic-million`

attributes (id, class, placeholder, label, tooltip, aria-text, name, src, href) at punctuation marks and camel-case boundaries. When computing term frequencies, we downweight the attribute tokens from (2) by a factor of α. We use $\alpha = 3$ tuned on the development set for our experiments.

The document frequencies are computed over the web pages in the training dataset. If multiple elements have the same score, we heuristically pick the most prominent element, i.e., the one that appears earliest in the pre-order traversal of the DOM hierarchy.

3.2 Embedding-based model

A common method for matching two pieces of text is to embed them separately and then compute a score from the two embeddings (Kiros et al., 2015; Tai et al., 2015). For a command c and elements $e_1, \ldots, e_k$, we define the following conditional distribution over the elements:

$$p\left(e_i \mid c\right) \propto \exp\left[s(f(c), g(e_i))\right]$$

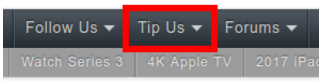
where s is a scoring function, $f(c)$ is the embedding of c, and $g(e_i)$ is the embedding of e_i, described below. The model is trained to maximize the log-likelihood of the correct element in the training data.

Command embedding. To compute $f(c)$, we embed each token of c into a fixed-dimensional vector and take an average[2] over the token embeddings. (The token embeddings are initialized with GloVe vectors.)

Element embedding. To compute $g(e)$, we embed the properties of e, concatenate the results, and then apply a linear layer to obtain a vector of the same length as $f(c)$. Figure 2 shows an example of the properties that the model receives. The properties include:

- *Text content.* We apply the command embedder f on the text content of e. As the text of most elements of interest (links, buttons, and inputs) are short, we find it sufficient to limit the text to the first 10 tokens to save memory.

- *Text attributes.* Several attributes (aria, title, tooltip, placeholder, label, name) usually contain natural language. We concatenate their values and then apply the command embedder f on the resulting string.



```
<a class="dd-head" id="tip-link"
 href="submit_story/">Tip Us</a>
```

Text content: tip us
String attributes: tip link dd head
Visual features: location = (0.53, 0.08)
visible = true

Figure 2: Example of properties used to compute the embedding $g(e)$ of the element e.

- *String attributes.* We tokenize other string attributes (tag, id, class) at punctuation marks and camel-case boundaries. Then we embed them with separate lookup tables and average the resulting vectors.

- *Visual features.* We form a vector consisting of the coordinates of the element's center (as fractions of the page width and height) and visibility (as a boolean).

Scoring function. To compute the score $s(f(c), g(e))$, we first let $\hat{f}(c)$ and $\hat{g}(e)$ be the results of normalizing the two embeddings to unit norm. Then we apply a linear layer on the concatenated vector $[\hat{f}(c); \hat{g}(e); \hat{f}(c) \circ \hat{g}(e)]$ (where $\circ$ denotes the element-wise product).

Incorporating spatial context. Context is critical in certain cases; for example, selecting a text box relies on knowing the neighboring label text, and selecting an article based on the author requires locating the author's name nearby. Identifying which related element should be considered based on the command is a challenging task.

We experiment with adding *spatial context* to the model. For each direction $d \in$ {top, bottom, left, right}, we use g to embed a neighboring element $n_d(e)$ directly adjacent to e in that direction. (If there are multiple such elements, sample one; if there is no such element, use a zero vector.) After normalizing the results to get $\hat{g}(n_d(e))$, we concatenate $\hat{g}(n_d(e))$ and $\hat{f}(c) \circ \hat{g}(n_d(e))$ to the linear layer input in the scoring function.

3.3 Alignment-based model

One downside of the embedding-based model is that the text tokens from c and e do not directly interact. Previous works on sentence matching usually employ either unidirectional or bidirectional attention to tackle this issue (Seo et al., 2016; Yin

---

[2] We tried applying LSTM but found no improvement.

et al., 2016; Xiong et al., 2017; Yu et al., 2018). We opt for a simple method based on a single alignment matrix similar to Hu et al. (2014) as described below.

Let $t(e)$ be the concatenation of e's text content and text attributes of e, trimmed to 10 tokens. We construct a matrix $A(c, e)$ where each entry $A_{ij}(c, e)$ is the dot product between the embeddings of the ith token of c and the jth token of $t(e)$. Then we apply two convolutional layers of size 3×3 on the matrix, apply a max-pooling layer of size 2×2, concatenate a tag embedding, and then apply a linear layer on the result to get a 10-dimensional vector $h(c, e)$.

We apply a final linear layer on $h(c, e)$ to compute a scalar score, and then train on the same objective function as the encoding-based model. To incorporate context, we simply concatenate the four vectors $h(c, n_d(e))$ of the neighbors $n_d(e)$ to the final linear layer input.

4 Experiments

We evaluate the models on *accuracy*, the fraction of examples that the model selects the correct element. We train the neural models using Adam (Kingma and Ba, 2014) with initial learning rate 10^{-3}, and apply early stopping based on the development set. The models can choose any element that is visible on the page at rendering time.

The experimental results are shown in Table 2. Both neural models significantly outperform the retrieval model.

4.1 Ablation analysis

To measure the importance of each type of information in web pages, we perform an ablation study where the model does not observe one of the following aspects of the elements: text contents, attributes, and spatial context.

Unsurprisingly, the results in Table 2 show that text contents are the most important input signal. However, attributes also play an important role in both the embedding and alignment models. Finally, while spatial context increases alignment model performance, the gain is very small, suggesting that incorporating appropriate contexts to the model is a challenging task due to the variety in the types of context, as well as the sparsity of the signals.

Model	Accuracy (%)
retrieval	36.55
embedding	56.05
no texts	23.62
no attributes	55.43
no spatial context	58.87
alignment	50.74
no texts	15.94
no attributes	48.51
no spatial context	50.66

Table 2: Accuracies of the models and their ablations.

Error Type	Embed	Align
Fail to match strings	26.8%	11.6%
Incorrectly match strings	3.8%	14.2%
Fail to understand paraphrases	8.9%	7.9%
Fail to understand descriptions	12.1%	17.4%
Fail to perform reasoning	15.9%	13.7 %
Select a less prominent element	19.8%	24.8%
Noisy annotation	12.7%	10.5%

Table 3: Error breakdowns of the embedding and alignment models on 100 examples. The embedding model handles implicit descriptions well, while the alignment model excels at string matching.

4.2 Error analysis

To get a better picture of how the models handle different phenomena, we analyze the predictions of the embedding-based and alignment-based models on 100 development examples where at least one model made an error. The errors, summarized in Table 3, are elaborated below:

Fail to match strings. Many commands simply specify the text content of the element (e.g., "click customised garages" → the link with text "Customised Garages, Canopies & Carports"). The encoding model, which encodes the whole command as a single vector, occasionally fails to select the element with partially matching texts. In contrast, the alignment model explicitly models text matching, and thus is better at this type of commands.

Incorrectly match strings. Due to its reliance on text matching, the alignment model struggles when many elements share substrings with the command (e.g., "shop for knitwear" when many elements contain the word "shop"), or when an element with a matching substring is not the correct target (e.g., "get the program" → the "Download" link, not the "Microsoft developer program" link).

Fail to understand descriptions. As seen in Table 1, many commands indirectly describe the elements using paraphrases, goal descriptions, or properties of the elements. The encoding model, which summarizes various properties of the elements as an embedding vector, is better at handling these commands than the alignment model, but still makes a few errors on harder examples (e.g., "please close this notice for me" → the "X" button with hidden text "Hide").

Fail to perform reasoning. For the most part, the models fail to handle relational, ordinal, or spatial reasoning. The most frequent error mode is when the element is a text box, and the command uses nearby label as the reference. While a few text boxes have semantic annotations which the model can use (e.g., tooltip or aria attributes), many web pages do not provide such annotations. To handle these cases, a model would have to identify the label of the text box based on logical or visual contexts.

Other errors. Apart from the annotation noise, occasionally multiple elements on the web page satisfy the given command (e.g., "log in" can match any "Sign In" button on the web page). In these cases, the annotation usually gives the most *prominent* element among the possible candidates. To provide a natural interface for users, the model should arguably learn to predict such prominent elements instead of more obscure ones.

5 Related work and discussion

Mapping natural language to actions. Previous work on semantic parsing learns to perform actions described by natural language utterances in various environments. Examples of such actions include API calls (Young et al., 2013; Su et al., 2017; Bordes and Weston, 2017), database queries (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2007; Berant et al., 2013; Yih et al., 2015), navigation (Artzi and Zettlemoyer, 2013; Janner et al., 2018), and object manipulation (Tellex et al., 2011; Andreas and Klein, 2015; Guu et al., 2017; Fried et al., 2018).

For web pages and graphical user interfaces, there are previous works on using natural language to perform computations on web tables (Pasupat and Liang, 2015; Zhong et al., 2017) and submit web forms (Shi et al., 2017). Our task is similar to previous works on interpreting instructions on user interfaces (Branavan et al., 2009, 2010; Liu et al., 2018). While their works focuses on learning from distant supervision, we consider shallower interactions but on a much broader domain.

Previous work also explores the reverse problem of generating natural language description of objects (Vinyals et al., 2014; Karpathy and Fei-Fei, 2015; Zarriaiß and Schlangen, 2017). We hope that our dataset could also be useful for exploring the reverse task of describing actions on web pages.

Reference games. In a reference game, the system has to select the correct object referenced by the given utterance (Frank and Goodman, 2012). Previous work on reference games focuses on a small number of objects with similar properties, and applies pragmatics to handle ambiguous utterance (Golland et al., 2010; Smith et al., 2013; Çelikyilmaz et al., 2014; Andreas and Klein, 2016; Yu et al., 2017). Our task can be viewed as a reference game with several challenges: higher number of objects, diverse object properties, and the need to interpret objects based on their contexts.

Interacting with web pages. Automated scripts are used to interact with web elements. While most scripts reference elements with logical selectors (e.g., CSS and XPath), there have been several alternatives such as images (Yeh et al., 2009) and simple natural language utterances (Soh, 2017). Some other interfaces for navigating web pages include keystrokes (Spalteholz et al., 2008), speech (Ashok et al., 2014), haptics (Yu et al., 2005), and eye gaze (Kumar et al., 2007).

6 Conclusion

We presented a new task of grounding natural language commands on open-ended and semi-structured web pages. With different methods of referencing elements, mixtures of textual and non-textual element attributes, and the need to properly incorporate context, our task offers a challenging environment for language understanding with great potential for real-world applications.

Our dataset and code are available at `https://github.com/stanfordnlp/phrasenode`. Reproducible experiments are available on the CodaLab platform at `https://worksheets.codalab.org/worksheets/0x0097f249cd944284a81af331093c3579/`.

Wronging a Right: Generating Better Errors to Improve Grammatical Error Detection

Sudhanshu Kasewa and **Pontus Stenetorp** and **Sebastian Riedel**
{sudhanshu.kasewa.16, p.stenetorp, s.riedel}@ucl.ac.uk
University College London

Abstract

Grammatical error correction, like other machine learning tasks, greatly benefits from large quantities of high quality training data, which is typically expensive to produce. While writing a program to automatically generate realistic grammatical errors would be difficult, one could learn the distribution of naturally-occurring errors and attempt to introduce them into other datasets. Initial work on inducing errors in this way using statistical machine translation has shown promise; we investigate cheaply constructing synthetic samples, given a small corpus of human-annotated data, using an off-the-rack attentive sequence-to-sequence model and a straight-forward post-processing procedure. Our approach yields error-filled artificial data that helps a vanilla bi-directional LSTM to outperform the previous state of the art at grammatical error detection, and a previously introduced model to gain further improvements of over 5% $F_{0.5}$ score. When attempting to determine if a given sentence is synthetic, a human annotator at best achieves 39.39 F_1 score, indicating that our model generates mostly human-like instances.

1 Introduction

There is an ever-growing number of people learning English as a second language; providing them with quick feedback to facilitate their learning is a crucial, labour-intensive endeavour. Part of this process is identifying and correcting grammatical errors, and several computational techniques have been developed to automate it (Rozovskaya and Roth, 2014; Junczys-Dowmunt and Grundkiewicz, 2016). For example, given an erroneous sentence *"I wanted to **goes** to the beach"*, the grammatical error correction task is to output the valid sentence *"I wanted to **go** to the beach"*. The task can be cast as a two-stage process, detection and correction, which can either be performed sequentially (Yannakoudakis et al., 2017), or jointly (Napoles and Callison-Burch, 2017).

Automated error correction performance is arguably still too low for practical consideration, perhaps limited by the amount of training data (Rei et al., 2017). High quality annotations are expensive to procure, and foreign language learners and commercial entities may feel uncomfortable granting access to their data. Instead, one could attempt to supplement existing manual annotations with synthetic instances. Such artificial samples are beneficial only when they share structure with the true distribution from which human errors are generated. Generative Adversarial Networks (Goodfellow et al., 2014) could be used for this purpose, but they are difficult to train, and require a large collection of sentences that are incorrect. One might attempt self-training (McClosky et al., 2006), where new instances are generated by applying a trained model to unannotated data, using high-confidence predictions as ground truth labels. However, in such a scheme, the expectation is that the unlabelled text already contains errors, which is not usually the case for most freely available text such as Wikipedia articles as they strive towards correctness.

In place of using machine translation (MT) to *correct* grammatical mistakes (Yuan and Felice, 2013; Junczys-Dowmunt and Grundkiewicz, 2014; Yuan and Briscoe, 2016), one might consider swapping the input and output streams, and instead learn to *induce errors* into error-free text, for the purpose of creating a synthetic training dataset (Felice and Yuan, 2014). Recently, Rei et al. (2017) used a statistical MT (SMT) system to induce errors into error-free text. Building on this work, and leveraging recent advances in neural MT (NMT), we used an off-the-shelf attentive sequence-to-sequence model (Britz et al., 2017), eliminating the need of specialised soft-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4977–4983
Brussels, Belgium, October 31 - November 4, 2018.

ware such as a phrase-table generator, decoder, and part-of-speech tagger. We created multiple synthetic datasets from in-domain and out-of-domain sources, and found that stochastic token sampling, and pruning redundant and low-likelihood sentences, were helpful in generating meaningful corruptions. Using the artificial samples thus generated, we improved upon detection results with simply a vanilla bi-directional LSTM (Hochreiter and Schmidhuber, 1997). Using a more powerful model, we established new state-of-the-art results, that improve on previously published $F_{0.5}$ scores by over 5%. Additionally, we confirm that our generated instances are human-like, as an annotator identifying generated sentences achieved a maximum F_1 score of 39.39.

2 Related work

In computer vision, images are blurred, rotated, or otherwise deformed inexpensively to create new training instances (Wang and Perez, 2017), because such manipulation does not significantly alter the image semantics. Similar coarse processes do not work in NLP since mutating even a single letter or a word can change a sentence's meaning, or render it nonsensical. Nonetheless, Vinyals et al. (2015) employed a kind of self-training where they use noisy predictions for unlabelled instances output by existing state-of-the-art parsers as ground-truth labels, and improved syntactic parsing performance. Sennrich et al. (2016) synthesised training instances by round-trip-translating a monolingual corpus with weaker versions of an NMT learner, and used them to improve the translation. Bouchard et al. (2016) developed an efficient algorithm to blend generated and true data for improving generalisation.

Grammar correction is a well-studied task in NLP, and early systems were rule-based pattern recognisers (Macdonald, 1983) and dictionary-based linguistic analysis engines (Richardson and Braden-Harder, 1988). Later systems used statistical approaches, addressing specific kinds of errors such as article insertion (Knight et al., 1994) and spelling correction (Golding and Roth, 1996). Most recently, architectural innovations in neural sequence labelling (Rei et al., 2016; Rei, 2017) raised error detection performance through improved ability to process unknown words and jointly learning a language model.

Early efforts for artificial error generation included generating specific types of errors, such as mass noun errors (Brockett et al., 2006) and article errors (Rozovskaya and Roth, 2010), and leveraging linguistic information to identify error patterns and transfer them onto grammatically correct text (Foster and Andersen, 2009; Yuan and Felice, 2013). Imamura et al. (2012) investigated methods to generate pseudo-erroneous sentences for error correction in Japanese. Recently, Rei et al. (2017) corrupted error-free text using SMT to create training instances for error detection.

3 Neural error generation

To learn to introduce errors, we use an off-the-shelf attentive sequence-to-sequence neural network (Bahdanau et al., 2014). Given an input sequence, the *encoder* generates context vectors for each token. Then, the *attention mechanism* and the *decoder* work in tandem to emit a distribution over the target vocabulary. At every decoder time-step, the encoder context vectors are scored by the attention mechanism, and a weighted sum is supplied to the decoder, along with its propagated internal state and last output symbol.

Corruption: Tokens from this distribution are sampled at every decoder time-step, either by $argmax$ (AM), which emits the most likely word, or by a stochastic alternative such as *temperature sampling* (TS) as $argmax$ cannot be relied on to generate rare words. A temperature parameter $\tau > 0$ sharpens or softens the distribution:

$$\tilde{p}_i = \boldsymbol{f}_\tau(p)_i = \frac{p_i^{\frac{1}{\tau}}}{\sum_j p_j^{\frac{1}{\tau}}}$$

where i are the components of the probability distribution corresponding to words in the vocabulary. As one interpolates τ from 0 to 1, the behaviour of $\tilde{p}$ transitions from *argmax* to p, controlling the diversity of the generated tokens.

The sentence generated by TS might be a low probability sequence from the joint conditional distribution $P(\mathbf{v}|\mathbf{u})$, where $\mathbf{u}$ is the input sentence and $\mathbf{v}$ is the output sentence. One way around this is to use *beam search* (BS), which checks the likelihood of every possible continuation of a sentence fragment, and maintains a list of the n best translations generated up to the current time-step. AM, TS, and BS are indicative of the trade-off between increasing levels of model flexibility at the cost of computation; we compare them to assess whether

Table 2: $F_{0.5}$ scores on various tests contrasted with published results and unaugmented baseline models.

the additional computations were helpful in creating high-quality synthetic instances.

Post-processing: Original and corrupted sentences are aligned at a word-level using Levenshtein distance. Using the minimal alignment, words in the corrupted sentence are labelled *correct*, 'c', or *incorrect*, 'i', as follows:

If the word is not aligned with itself, then 'i'. *Else*, if following a gap, then 'i', as at this point a human reader would notice that there is a word missing in the sentence. *Else*, if it is the last word, but it is not aligned to the last word of the source sentence, then 'i', as a human would realise that this sentence ends abruptly, *Else*, 'c'.

These token-labelled corrupted sentences now form an artificial dataset for training an error detector. Duplicate instances and corrupted sentences with more than 5 errors were dropped to remove noise from the downstream training.

4 Experiments

We evaluated our approach on the First Certificate of English (FCE) error detection dataset (Rei and Yannakoudakis, 2016), as well as on two human-annotated test sets (CoNLL1, CoNLL2) from the CoNLL 2014 shared task (Ng et al., 2014). The CoNLL data sets pose a unique challenge; as they are different in style and domain from FCE, we have no matching training data. We compared the effect of different neural generation procedures (AM, TS, BS) and contrasted the downstream performance of a bidirectional LSTM with an elaborate sequence labeller.

4.1 Implementation details

NMT training and corruption: We minimally modified the open source implementation[1] of Britz et al. (2017) to implement TS and BS.[2] We trained our NMT with a single-layered encoder and decoder with cell size 256, on the parallel corpus version of FCE (Yannakoudakis et al., 2011), with early stopping after the FCE development set score dropped consistently for 20 epochs. We introduced errors into three datasets: FCE itself (450K tokens), the English Vocabulary Profile or EVP (270K tokens) and a subset of Simple Wikipedia or SW (8.4M tokens); of these, FCE and EVP were both used in artificial error generation via SMT and pattern extraction (PAT) by Rei et al. (2017), enabling us to make a fair experimental comparison. Ten corrupted versions using each of AM, TS ($\tau = 0.05$) and BS were sampled for FCE and EVP corruptions, while one sufficed for SW. The theoretical time complexity of BS is O(bn) for each sentence, where b is num-

ber of candidates, and n is the maximum length of a sentence. Empirically, BS with $b = 11$ took a factor of 11.3 more time than AM. Examples of generated errors are provided in Table 1.

Error detection: We compare two error detection models: a vanilla bi-directional LSTM (BiLSTM) (Schuster and Paliwal, 1997), and the state-of-the-art sequence labeller (SL) neural network used by Rei et al. (2017). These models were trained on the binary-labelled FCE training set augmented with the corrupted instances. Wherever no model is explicitly stated, the SL model was used. During training, we alternate between the annotated FCE dataset and the synthetic collection. This alternating protocol prevents overfitting on FCE; once it shifts back, it reinforces connections made from the helpful synthetic corruptions while forgetting about the noisy ones.

4.2 Results

The results for our baselines and data augmentation strategies can be found in Table 2. Augmented with our NMT generated data, even our vanilla downstream BiLSTM outperforms the SMT+PAT artificial error augmentation approach of Rei et al. (2017), indicating that our process better generalises the error information in the source dataset. Using the more powerful SL network bests the previous state of the art by over 5% on the FCE test. Most intriguingly, we note a significant improvement for the CoNLL tests using corruptions from out-of-domain SW. Figure 2 illustrates how we gain performance on these tests with increasing amounts of corrupted SW, which does not hold true for corrupted FCE. This shows that we were able to induce useful errors into a corpus with a large unseen vocabulary and different syntactic biases, and this in turn proved valuable for detecting errors in a third domain, suggesting that our method can transfer learned distributions across stylistic genres.

Using EVP as a standard source, Figure 1 illustrates the variance of the different sampling methods. All generation methods yield corruptions that significantly improve test performance, with instances sampled by beam-search consistently outperforming the alternatives.

5 Discussion

5.1 Error distribution

The original FCE dataset was annotated using the error taxonomy specified in Nicholls (2003), and contains 75 unique error codes. We annotated samples of EVP corrupted by all three sampling methods, at a reduced resolution, to compare the distribution of errors across FCE and the synthetic corpora. These are presented in Table 3.

At a high level, NMT generates errors more often among more common parts-of-speech, favouring errors in verbs and nouns, rather than in adverbs and conjunctions. It did not make spelling errors as often as in the source dataset; this is likely because it only observed the specific spelling errors present in FCE, and as the vocabulary is restricted to that dataset, it does not encounter those words as frequently in EVP, and thus rarely makes the same spelling mistakes.

Additionally, the differences in these distributions can partially be attributed to the implicit differences between us and the annotators of FCE.

Spelling	FCE	AM	TS	BS
Spelling errors	11	1	1	4

Part-of-speech	FCE	AM	TS	BS
Verb	34	16	26	16
Preposition	18	16	10	14
Determiner	16	7	6	10
Noun	13	36	35	43
Pronoun	7	3	3	1
Adverb	5	5	3	5
Adjective	3	15	16	12
Conjunction	2	2	2	1
Quantifier	1	0	0	0

Remedy Type	FCE	AM	TS	BS
Replacement	49	35	34	32
Inclusion	23	30	27	35
Removal	14	33	36	32
Word form	9	2	2	1
Word order	5	0	0	0

Table 3: Error distribution across FCE and manually annotated samples of artificial data. Spelling errors are a % of all errors, while Part-of-speech, and Remedy Type are compared within their own categories to sum to 100%.

5.2 Comparison with human errors

To check if the synthetic instances passed for human-like, we mixed 50 generated sentences among an equal number of actual ungrammatical instances from FCE-dev and tasked a human evaluator to identify the artificial statements, in a simple Turing-style test. We created three such sets, one for each of our sampling techniques, and the test subject aimed to identify synthetic samples with high confidence. Results of this test are presented in Table 4.

The high precision but low recall scores suggest that while it is still possible to spot some corruptions that are quite clearly artificial, the bulk of our samples do not betray their synthetic nature and are indistinguishable from naturally occurring erroneous sentences. In order to fairly compare our work with earlier results, we intended to conduct such a test for sentences generated by the SMT of Rei et al. (2017). Unfortunately, we were only able to source corruptions of FCE-train via this method; therefore, we decided not to perform this test as its results cannot be compared to ours.

	AM	TS	BS
Precision	81.25	63.63	50.00
Recall	26.00	28.00	14.00
F1	39.39	38.89	22.22

Table 4: Results of a Turing-style test, where a subject was asked to distinguish between real and fake sentences, sampled from each of the different generated corpora.

6 Conclusions and future work

We presented a novel data augmentation technique for grammatical error detection using neural machine translation to learn the distribution of language-learner errors, and induce such errors into grammatically correct text. We explored several different variants of sampling to improve the quality of our synthetic errors. After creating artificial training instances with an off-the-shelf NMT, we bettered previous state-of-the-art results on the canonical test with even a basic BiLSTM, and established a new state of the art using a stronger model. Additionally, we demonstrated that we were able to leverage corruptions of an out-of-domain dataset to set new benchmarks on separate, also out-of-domain tests, without specifically optimising for either.

Our work indicates that neural error generation warrants further investigation with different datasets and architectures, both for error detection and error correction. Among possible future work is using generative adversarial networks as corruption engines, and developing better sequence alignment methods. Some preliminary results with simple corruptions using word substitution and word dropout (Iyyer et al., 2015) appear to be promising, and may feature as components of a future corruption system. Finally, one could use such artificial error-prone corpora as source text for self-training an error detection system.

Abstract

Recently introduced neural network parsers allow for new approaches to circumvent data sparsity issues by modeling character level information and by exploiting raw data in a semi-supervised setting. Data sparsity is especially prevailing when transferring to non-standard domains. In this setting, lexical normalization has often been used in the past to circumvent data sparsity. In this paper, we investigate whether these new neural approaches provide similar functionality as lexical normalization, or whether they are complementary.

We provide experimental results which show that a separate normalization component improves performance of a neural network parser even if it has access to character level information as well as external word embeddings. Further improvements are obtained by a straightforward but novel approach in which the top-N best candidates provided by the normalization component are available to the parser.

1 Introduction

Recently, neural network dependency parsers (Chen and Manning, 2014; Dyer et al., 2015; Kiperwasser and Goldberg, 2016) obtained state-of-the-art performance for dependency parsing. These parsers incorporate character level information (de Lhoneux et al., 2017a; Ballesteros et al., 2015; Nguyen et al., 2017) and can more easily exploit raw text in a semi-supervised setup. These new methods are especially beneficial for words not occurring in the training data. In practice, such unseen words often are spelling mistakes, or alternative spellings of known words. In more classical parsing models, these unseen words were usually clustered using ad-hoc rules. For non-standard domains, the number of unseen words is much larger. To minimize the degradation in performance, lexical normalization is often used. Lexical normalization is the task of converting non-standard input to a more standard format. Previous work has shown that this is beneficial, in particular for parsing social media data (Foster, 2010; Zhang et al., 2013; van der Goot and van Noord, 2017b).

This leads to the question whether normalization is indeed no longer required for these modern character-based neural network parsers, or whether normalization is capable of solving problems beyond the scope of this type of neural network parsers.

Our main contributions are:

- We show that using normalization as pre-processing improves parser performance for non-standard language, even if pre-trained embeddings and character level information are used.
- We propose a novel technique to exploit the top-N candidates provided by the normalization component, and we show that this technique leads to a further increase in parser performance.
- A treebank containing non-standard language is created to evaluate the effect of normalization on parser performance. The treebank consists of 10,005 tokens annotated with lexical normalization and Universal Dependencies (Nivre et al., 2017). The treebank has been made publicly available.

2 Related Work

Early work on parser adaptation focused on relatively canonical domains, like biomedical data (McClosky and Charniak, 2008). More recently, there has been an increasing interest in parsing of the notoriously noisy domain of social media. A lot of previous work is orthogonal to our

approach, as it focuses on adaptation of the training data (Foster et al., 2011; Khan et al., 2013; Kong et al., 2014; Blodgett et al., 2018). In the remainder of this section we will shortly review work which evaluated the effect of normalization on dependency parsing.

Zhang et al. (2013) tune a normalization model for the parsing task, and show performance improvement on a silver treebank obtained from manually normalized data. Daiber and van der Goot (2016) use an existing normalization model as pre-processing for a graph-based dependency parser, and show a small but significant performance improvement. In the shared task of parsing the web (Petrov and McDonald, 2012) held at SANCL 2012, some teams used a simple rule-based normalization, but the effect on final performance remained untested.

Baldwin and Li (2015) examined the theoretical impact of different normalization actions on parsing performance. To this end they use manual normalization. They show that edits beyond the word level can also be crucial for parsing (e.g. insertion of copulas and subjects). However, these are difficult to obtain automatically.

Note that all this previous work, except for Blodgett et al. (2018), is based on traditional feature-based dependency parsers, whereas we focus on neural network parsing.

3 Method

In this section we will first shortly review the two models we will combine: a lexical normalization model and a neural network parser. Then we describe how they can be combined.

3.1 Normalization

In this work we use an existing normalization model: MoNoise (van der Goot and van Noord, 2017a)[1]. This model is based on the observation that normalization requires a variety of different replacement actions. For these different actions, different modules are used to generate candidates, including: the Aspell spell checker[2], word embeddings and a lookup list generated from the training data. Features from these generation modules are complemented with N-gram features from canonical data and non-canonical data. A random forest classifier is used to score and rank the candidates. In this work, we use the top-N candidates and convert the confidence scores of the classifier to probabilities. An example of this output is shown in Table 1.

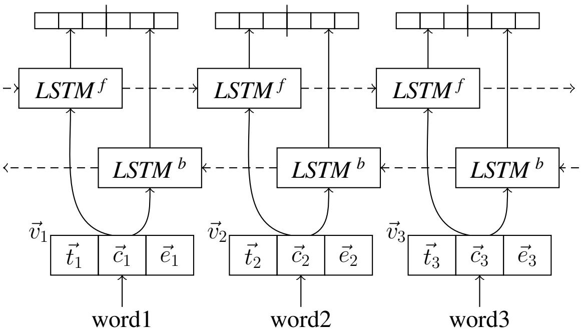

Figure 1: Overview of the conversion of input words to vectors which are used in the shift-reduce algorithm.

We train MoNoise on 2,577 tweets annotated with normalization by Li and Liu (2014), which only contains word-word replacements. In our inital experiments, we noted that the normalization model wrongfully normalized some words due to the different tokenization in the treebank (e.g. "ca n't"), because these do not occur in the normalization data. We manually created a list of exceptions, which are not considered for normalization process.

3.2 Neural Network Parser

As a starting point, we use the shift-reduce UUParser 2.0 (de Lhoneux et al., 2017b; Kiperwasser and Goldberg, 2016). This parser uses the Arc-Hybrid Transition system (Kuhlmann et al., 2011). Words are first converted to continu-

---

[1] `https://bitbucket.org/robvanderg/monoise`

[2] `www.aspell.net`

ous vectors, which are then processed through a Bidirectional Long-Short Term Memory network (BiLSTM) (Graves and Schmidhuber, 2005) before they are passed on to the parsing algorithm. The decision whether to shift, reduce or swap is made by a multi-layer perceptron with one hidden layer. The BiLSTM is trained jointly with the parsing objective, so that the vectors are optimized for the parsing task.

Figure 1 shows an overview of how the input words are converted to vectors which are used in the shift-reduce algorithm. We denote the vector used as input to the BiLSTM for word i by $\vec{v}_i$. This vector is a concatenation of three vectors which are derived from the input word. $\vec{t}_i$ is optimized on the training data, $\vec{c}_i$ is the result of a separate BiLSTM ran over the characters of word i and $\vec{e}_i$ is the external vector; it is obtained from external embeddings which are trained on huge amounts of raw texts. In this work we use the same word embeddings as used by the normalization model (van der Goot and van Noord, 2017a), which are trained on 760,744,676 tweets using word2vec (Mikolov et al., 2013).

3.3 Adaptation Strategy

Notation We use $\vec{w}_0 ... \vec{w}_n$ to represent the vectors of the original words of a sentence. The vectors of the normalization candidates are represented by $\vec{n}_{ij}$, where i is the index of the original word in the sentence, and j is the rank of the candidate. The corresponding probability as given by the normalization model is p_{ij}. We use $\vec{g}_i$ for the vector of the manual normalization of word i

Our baseline setup is to simply use the vector of the original word:

$$\text{ORIG:} \quad \vec{v}_i = \vec{w}_i$$

The most straightforward use of normalization is to use the best normalization sequence as input to the parser. In our setup, this means that we use the vector of the best normalization candidate for each position:

$$\text{NORM:} \quad \vec{v}_i = \vec{n}_{i0}$$

To give more information to the parser, we will exploit the top-n candidates of the normalization model. The vectors of the top-N candidates are merged using linear interpolation:

$$\text{INTEGRATED:} \quad \vec{v}_i = \sum_{j=0}^{n} p_{ij} * \vec{n}_{ij}$$

An interesting property of this integration approach is that it does not influence the size of the search space, so the effect on complexity of the parsing algorithm is negligible. The only extra runtime compared to ORIG originates from running the normalization model.

Finally, we include a theoretical upperbound of the effect of normalization, which uses manually annotated normalization:

$$\text{GOLD:} \quad \vec{v}_i = \vec{g}_i$$

4 Data

To test the effect of normalization, we need a treebank containing non-standard language, preferably with a corresponding training treebank from a more standard domain. Since the existing treebanks are not noisy enough (Foster et al., 2011; Kaljahi et al., 2015)[3] or do not have a corresponding training treebank in the same annotation format (Kong et al., 2014; Daiber and van der Goot, 2016) we annotate a small treebank for development and testing purposes[4]. We choose to use the Universal Dependencies 2.1 annotation format (Nivre et al., 2017), since the annotation efforts on the the English Web Treebank (Silveira et al., 2014) provide suitable training data. This treebank already contains web specific phenomena like URL's, E-Mail addresses and emoticons, so we do not have to create special annotation guidelines and the parser can learn these phenomena from the training data.

Our treebank consists of tweets, taken from Li and Liu (2015). The tweets in this dataset originate from two sources: the LexNorm corpus (Han and Baldwin, 2011), which was originally annotated with normalization, and a corpus originally annotated with POS tags (Owoputi et al., 2013). Li and Liu (2015) complemented this annotation for both datasets, so that they both have a normalization layer and a POS layer. To avoid overfitting on a specific filtering or time-frame we use the data collected by Owoputi et al. (2013) as development data and LexNorm as test data. We only keep the tweets which are still available on Twitter, resulting in a dataset of 305 development and

---

[3] Kaljahi et al. (2015) only normalize 3.6%, and we manually normalized the development data from Foster et al. (2011), were even less words were in need of normalization.

[4] It should be noted that two other suitable Twitter treebanks in the UD format where created in parallel to our treebank (Liu et al., 2018; Blodgett et al., 2018), which were released after submission of this paper.

327 test tweets (10,005 tokens in total). It should be noted that these corpora were filtered to contain domain-specific phenomena and non-standard language, and thus provide an ideal testbed for our experiments but are not representative of the whole Twitter domain.

Tokenization and normalization are first re-annotated, because the Universal Dependencies format requires treebank specific tokenization. To avoid parser bias, dependency relations are annotated from scratch. For more details on annotation decisions for domain-specific structures, we refer to the appendix.

MoNoise reaches 90% accuracy on the word level for the normalization task for our development data. In this dataset, 18% of all words are in need of normalization, so a baseline which simply copies the original words would reach an accuracy of 82%. The most common mistakes made by MoNoise are due to treebank specific normalizations, like ‘na’ ↦ go. However, these also occur in the training treebank, so normalization is not crucial.

5 Evaluation

In this section, we first use the development data to compare the effect of the different normalization settings with the use of character level information and external embeddings. Secondly, we confirm our main results on the test set. Thirdly, we test if our model is sensitive to over-normalization on standard data. Finally, we perform some analysis to examine why normalization is beneficial. All scores reported in this section are obtained using the CoNLL 2017 evaluation script (Zeman et al., 2017). In Section 5.1 the results are the average over ten runs, using a different seed for the BiLSTM and the shuffling of the training data. In the remainder of this section, the best model is used to simplify interpretation. The parser is trained using default settings (de Lhoneux et al., 2017b).

In our initial experiments, it became apparent that the parser often considered a username mention or retweet in the beginning of the tweet as root, resulting in a propagation of errors. Because we want to exclude any influences from this simple construction, we added an heuristic to our parser which exclude usernames and retweets in the beginning of a tweet, and connects them to the root after parsing. We use this heuristic in all experiments.

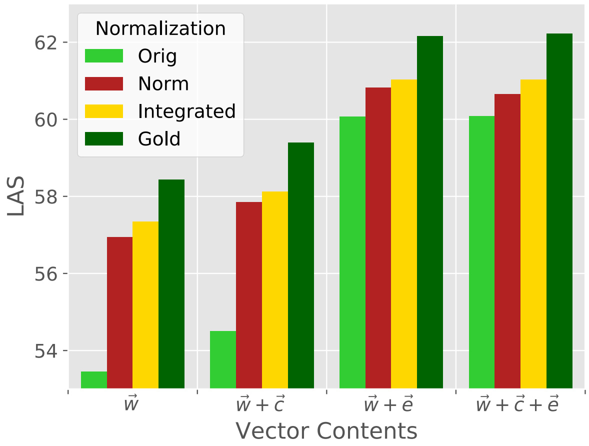

Figure 2: The effect of normalization on LAS for the different parsing models on the development data.

5.1 Normalization Strategies

The results of the different parser and normalization settings on the development data are plotted in Figure 2. Using external embeddings ($\vec{e}$) results in a much bigger performance improvement compared to using character level information ($\vec{c}$). Adding character level embeddings on top of external embeddings only leads to a very minor improvement. This can partly be explained by the coverage of 98.4% of the embeddings on the development data.

In the settings without external embeddings, the direct use of normalization (NORM) results in a improvement of approximately 3 LAS points. However, when external embeddings are included the improvement becomes more than twice as small, indicating that the approaches target some common issues, but are also complementary to each other. When external embeddings and normalization are already used, the character level embeddings slightly harm performance. Integration of the normalization (INTEGRATED) consistently results in a slightly higher LAS compared to direct normalization. Interestingly, gold normalization still performs substantially better compared to automatic normalization.

5.2 Test Data

Table 2 shows the results of the parser with external embeddings and character embeddings (using the best seed from the development data), for the different normalization strategies on the test data. These results confirm the observations on the development data: normalization helps on top of ex-

Model	UAS	LAS
ORIG	69.63	59.64
NORM	70.51	61.76*
INTEGRATED	70.62	62.30*
GOLD	70.71	62.33

Table 2: LAS scores for the Twitter test data. *Statistically significant compared to the previous row at $P < 0.05$ using a paired t-test.

ternal embeddings, and integrating normalization results in an even higher score. In contrast to the development data, the integrated approach almost reaches the theoretical upper bound of gold normalization on the test data. However, since this is only the case on the test data, not too strong conclusions can be drawn from this result. The performance difference between the datasets is probably partly due to the differences in filtering[5]. Interestingly, integrating normalization is especially beneficial for the LAS, meaning that it is most useful for choosing the type of relation.

5.3 Robustness

As stated in Section 4, our development and test data is filtered to be very non-standard. However, it is undesirable to have a parser that performs bad on more standard texts. Hence, we also tested performance on the English Web Treebank development set. This dataset also consists of data from the web, however, it contains much less words in need of normalization; MoNoise normalizes less than 0.5% of all words. We compared the performance using no normalization (ORIG) versus our INTEGRATED approach, which showed a very minor performance improvement from 81.42 to 81.43 LAS. This is a direct effect of the normalization model giving high probabilities to the original words on this more canonical data.

5.4 Analysis

To gain insights into which constructions are parsed better when using normalization, we compared the predictions of the vanilla parser with our NORM and INTEGRATED methods on the development data. Starting with NORM, the first observation is that the incoming arcs of the words which are normalized are responsible for 44.1% of all improvements, whereas the outgoing arcs are responsible for 17.6% of al improvements. So, the direct context of the normalized words is responsible for only 61.7% of all improvements. Considering the type of syntactic constructions for which parsing improved, it is hard to identify trends, because the improvements are based on the output of the normalization model, which normalizes a wide variety of words. One clearly influential effect of using normalization, was that the parser improved upon finding the root. When multiple unknown words occured in the beginning of a sentence, the vanilla parser often failed at identifying the root, which improved considerably after normalizing.

For the INTEGRATED method, almost all the improvements made by NORM remained. On top of these, some additional improvements where made. Manual inspection revealed that these improvements often originated from a non-standard word, for which the correct normalization was ranked high. This then leads to improvements for the non-standard word as well as its context. In some cases, even incorrect normalization candidates lead to performance improvements. For example for 'Gma', where the normalization model ranked the original word first, but 'mom' second. Even though 'grandma' is the correct normalization, 'mom' occurs in similar contexts, and is much easier for the parser to process.

6 Conclusion

We showed that normalization can improve performance of a neural network parser, even when making use of character level information and external word embeddings. Integrating multiple normalization candidates into the parser leads to an even larger performance increase. Normalization has shown to be complementary to external embeddings, in contrast to character embeddings, which add no additional information. Our experiments revealed that our approach is robust, and it does not harm performance on more canonical data. However, when comparing our approach to the theoretical upperbound of using gold normalization, we saw that on different datasets the performance gain is of a different magnitude. Furthermore, we release a dataset containing 636 tweets annotated with both normalization and Universal Dependencies. The data and all code to reproduce the results in this paper is available at: `https://bitbucket.org/robvanderg/normpar`

---

[5] Even when using the best seed on the development data, INTEGRATED results in two-thirds of the performance improvement compared to GOLD.

Abstract

Previous work has suggested that parameter sharing between transition-based neural dependency parsers for related languages can lead to better performance, but there is no consensus on what parameters to share. We present an evaluation of 27 different parameter sharing strategies across 10 languages, representing five pairs of related languages, each pair from a different language family. We find that sharing transition classifier parameters always helps, whereas the usefulness of sharing word and/or character LSTM parameters varies. Based on this result, we propose an architecture where the transition classifier is shared, and the sharing of word and character parameters is controlled by a parameter that can be tuned on validation data. This model is linguistically motivated and obtains significant improvements over a mono-lingually trained baseline. We also find that sharing transition classifier parameters helps when training a parser on unrelated language pairs, but we find that, in the case of unrelated languages, sharing too many parameters does not help.

1 Introduction

The idea of sharing parameters between parsers of related languages goes back to early work in cross-lingual adaptation (Zeman and Resnik, 2008), and the idea has recently received a lot of interest in the context of neural dependency parsers (Duong et al., 2015; Ammar et al., 2016; Susanto and Lu, 2017). Modern neural dependency parsers, however, use different sets of parameters for representation and scoring, and it is not clear what parameters it is best to share.

The Universal Dependencies (UD) project (Nivre et al., 2016), which is seeking to harmonize the annotation of dependency treebanks across languages, has seen a steady increase in languages that have a treebank in a common standard. Many of these languages are low resource and have small UD treebanks. It seems interesting to find out ways to leverage the wealth of information contained in these treebanks, especially for low resource languages.

In this paper, we evaluate 27 different parameter sharing strategies. We focus on a particular transition-based neural dependency parser (de Lhoneux et al., 2017a,b), which performs close to the state of the art. This parser has three sets of parameters: i) the parameters of a character-based one-layer, bidirectional LSTM; ii) the parameters of a word-based two-layer, bidirectional LSTM; iii) and the parameters of a multi-layered perceptron (MLP) with a single hidden layer. The two first sets are for learning to represent configurations; the third for selecting the next transition. We consider all combinations of sharing these sets of parameters; and in addition, we consider two ways of sharing each set of parameters, namely with and without a prefixed language embedding. The latter enables partial, soft sharing. In sum, we consider all 3^3 combinations of no sharing, hard sharing and soft sharing of the three sets of parameters. We evaluate the 27 multilingual parsers on 10 languages from the UD project, representing five pairs of related languages, each pair from a different language family. We repeat the experiment with the same set of languages, but using pairs of unrelated languages.

Contributions This paper is, to the best of our knowledge, the first to evaluate different parameter sharing strategies for exploiting synergies between neural dependency parsers of related languages. We evaluate the different strategies on 10 languages, representing five different language families. We find that sharing (MLP) transition

Table 1: Dataset characteristics

classifier parameters always helps, whereas the usefulness of sharing LSTM parameters depends on the language pair. This reflects the intuition that the transition classifier learns hierarchical structures that are likely to transfer across languages, based on parser configurations that abstract away from several linguistic differences. The similarity of the input to character- and word-level LSTMs, on the other hand, will vary depending on the phonological and morphosyntactic similarity of the languages in question. Motivated by this observation, we propose an architecture with hard-wired transition classifier parameter sharing, but in which sharing of LSTM parameters is tuned. The novel architecture significantly outperforms our monolingual baseline on our set of 10 languages. We additionally investigate parameter sharing of unrelated languages.

2 The Uppsala dependency parser

The Uppsala parser (de Lhoneux et al., 2017a,b) consists of three sets of parameters; the parameters of the character-based LSTM, those of the word-based LSTM, and the parameters of the MLP that predicts transitions. The character-based LSTM produces representations for the word-based LSTM, which produces representations for the MLP. The Uppsala parser is a transition-based parser (Kiperwasser and Goldberg, 2016), adapted to the Universal Dependencies (UD) scheme,[1] and using the arc-hybrid transition system from Kuhlmann et al. (2011) extended with a SWAP transition and a static-dynamic oracle, as described in de Lhoneux et al. (2017b). The SWAP transition is used to generate non-projective dependency trees (Nivre, 2009).

For an input sentence of length n with words $w_1, \dots, w_n$, the parser creates a sequence of vectors $x_{1:n}$, where the vector x_i representing w_i is the concatenation of a word embedding and the final state of the character-based LSTM after processing the characters of w_i. The character vector $ch(w_i)$ is obtained by running a (bi-directional) LSTM over the characters ch_j $(1 \leq j \leq m)$ of w_i. Each input element is represented by the word-level, bi-directional LSTM, as a vector $v_i = \textsc{BiLstm}(x_{1:n}, i)$. For each configuration, the feature extractor concatenates the LSTM representations of core elements from the stack and buffer. Both the embeddings and the LSTMs are trained together with the model.

A configuration c is represented by a feature function $\phi(\cdot)$ over a subset of its elements. For each configuration, transitions are scored by a classifier, in this case an MLP, and $\phi(\cdot)$ is a concatenation of BiLSTM vectors on top of the stack and the beginning of the buffer. The MLP scores transitions together with the arc labels for transitions that involve adding an arc. In practice, we use two interpolated MLPs, one which only scores the transitions, and one which scores transitions together with the arc label. For simplicity, we refer to that interpolated MLP as the MLP.

3 Parameter sharing

Since our parser has three basic sets of model parameters, we consider sharing all combinations of those three sets. We also introduce two ways of sharing, namely, with or without the addition of a vector representing the language. This language embedding enables the model, in theory, to learn what to share between the two languages in question. Since for all three model parameter sets, we now have three options – not sharing, sharing, or sharing in the context of a language embedding – we are left with $3^3 = 27$ parameter sharing strategies; see Table 2.

In the setting where we do not share (✗) word parameters (**W**), we construct a different word lookup table and a different word-level BiLSTM for each language. In the setting where we do hard parameter sharing (✓) of word parameters, we only construct one lookup table and one word BiLSTM for the languages involved. In the setting where we do soft sharing (ID) of word pa-

Table 2: Performance on development data (LAS; in %) across select sharing strategies. Mono is our single-task baseline; Language-best is using the best sharing strategy for each language (as evaluated on development data); Best is the overall best sharing strategy, across languages; Char shares only the character-based LSTM parameters; Word shares only the word-based LSTM parameters; All shares all parameters. ✓ refers to hard sharing, ID refers to soft sharing, using an embedding of the language ID and ✗ refers to not sharing.

rameters, we share those parameters, and in addition, concatenate a language embedding l_i representing the language of word w_i to the vector of the word w_i at the input of the word BiLSTM: $x_i = e(w_i) \circ ch(w_i) \circ l_i$. Similarly for character parameters (**C**), we construct a different character BiLSTM and one character lookup for each language (✗), create those for all languages and share them (✓) or share them and concatenate a (randomly initialized) language embedding l_i representing the language of word w_i at the input of the character BiLSTM (ID): $ch_j = e(ch_j) \circ l_i$. At the level of configuration or parser states (**S**), we either construct a different MLP for each language (✗), share the MLP (✓) or share it and concatenate a language embedding l_i representing the language of word w_i to the vector representing the configuration, at the input of the MLP (ID): $c = \phi(\cdot) \circ l_i$.

4 Experiments

Language pairs We use 10 languages in our experiments, representing five language pairs from different language families. Our two Semitic languages are Arabic and Hebrew. These two languages differ in that Arabic tends to favour VSO word order whereas Hebrew tends to use SVO, but are similar in their rich transfixing morphology. Our two Finno-Ugric languages are Estonian and Finnish. These two languages differ in that Estonian no longer has vowel harmony, but share a rich agglutinative morphology. Our two Slavic languages are Croatian and Russian. These two languages differ in that Croatian uses gender in plural nouns, but otherwise share their rich inflectional morphology. Our two Romance languages are Italian and Spanish. These two languages differ in that Italian uses a possessive adjective with a definite article, but share a fairly strict SVO order. Finally, our two Germanic languages are Dutch and Norwegian. These two languages differ in morphological complexity, but share word ordering features to some extent.

Datasets For all 10 languages, we use treebanks from the Universal Dependencies project. The dataset characteristics are listed in Table 1. To keep the results comparable across language pairs, we down-sample the training set to the size of the smallest of our languages, Hebrew: we randomly sample 5000 sentences for each training set. Note that while this setting makes the experiment somewhat artificial and will probably overestimate the benefits that can be obtained from sharing parameters when using larger treebanks, we find it interesting to see how much low resource languages can benefit from parameter sharing, as explained in the introduction.

Baselines and systems This is an evaluation paper, and our results are intended to explore a space of sharing strategies to find better ways of sharing parameters between dependency parsers of related languages. Our baseline is the Uppsala parser trained monolingually. Our systems are parsers trained bilingually by language pair where we share subsets of parameters between the languages in the pair, and we report on what sharing strategies seem superior across the 10 languages that we consider.

Implementation details A flexible implementation of parameter strategies for the Uppsala parser was implemented in Dynet.[2] We make the code publicly available.[3]

5 Results and discussion

Our results on development sets are presented in Table 2. We use labeled attachment score (LAS) as our metric for evaluating parsers. Table 2 presents numbers for a select subset of the 27 sharing strategies. The other results can be found in the supplementary material. Our main observations are: **(i)** that, generally, and as observed in previous work, *multi-task learning helps*: all different sharing strategies are on average better than the monolingual baselines, with minor (0.16 LAS points) to major (0.86 LAS points) average improvements; and **(ii)** that sharing the MLP seems to be overall a better strategy than not sharing it: the 10 best strategies share the MLP. Whereas the usefulness of sharing the MLP seems to be quite robust across language pairs, the usefulness of sharing word and character parameters seems more dependent on the language pairs. This reflects the linguistic intuition that character- and word-level LSTMs are highly sensitive to phonological and morphosyntactic differences such as word order, whereas the MLP learns to predict less idiosyncratic, hierarchical relations from relatively abstract representations of parser configurations.

Based on this result, we propose a model (OURS) where *the MLP is shared and the sharing of word and character parameters is controlled by a parameter that can be set on validation data.* Results are given in Table 3. We obtain a 0.6 LAS improvement on average and our proposed model is significantly better than the monolingual baseline with $p < 0.01$. Significance testing is performed using a randomization test, with the script from the CoNLL 2017 Shared Task.[4]

6 Unrelated languages

We repeated the same set of experiments with unrelated language pairs. We hypothesise that parameter sharing between unrelated language pairs will be less useful in general than with related language pairs. However, it can still be useful, it has been shown previously that unrelated languages can benefit from being trained jointly. For example, Lynn et al. (2014) have shown that Indonesian was surprisingly particularly useful for Irish.

The results are presented in Table 4. The table only presents part of the results, the rest can be found in the supplementary material. As expected, there is much less to be gained from sharing parameters between unrelated pairs. However, it is possible to improve the monolingual baseline by sharing some of the parameters. In general, sharing the MLP is still a helpful thing to do. It is most helpful to share the MLP and optionally one of the two other sets of parameters. Results are close to the monolingual baseline when everything is shared. Sharing word and character parameters but not the MLP hurts accuracy compared to the monolingual baseline.

7 Related work

Previous work has shown that sharing parameters between dependency parsers for related languages can lead to improvements (Duong et al., 2015; Ammar et al., 2016; Susanto and Lu, 2017). Smith et al. (2018) recently found that sharing parameters using the same parser as in this paper

Table 4: Performance on development data (LAS; in %) across select sharing strategies for unrelated languages. Mono is our single-task baseline; Language-best is using the best sharing strategy for each language (as evaluated on development data); Best and Worst are the overall best and worst sharing strategy across languages; Char shares only the character-based LSTM parameters; Word shares only the word-based LSTM parameters; All shares all parameters. ✓ refers to hard sharing, ID refers to soft sharing, using an embedding of the language ID and ✗ refers to not sharing.

(soft sharing of word parameters, hard sharing of the rest) improves parsing accuracy when training on related languages, and is especially useful in the low resource case. Similar effects have been observed in machine translation (Dong et al., 2015; Johnson et al., 2017), for example. Most studies have only explored a small number of parameter sharing strategies, however. Vilares et al. (2016) evaluate parsing with hard parameter sharing for 100 language pairs with a statistical parser. Naseem et al. (2012) proposed to selectively share subsets of a parser across languages in the context of a probabilistic parser.

Options we do not explore here are learning the architecture jointly with optimizing the task objective (Misra et al., 2016; Ruder et al., 2017), or learning an architecture search model that predicts an architecture based on the properties of datasets, typically with reinforcement learning (Zoph and Le, 2017; Wong and Gesmundo, 2018; Liang et al., 2018). We also do not explore the option of sharing selectively based on more fine-grained typological information about languages, which related work has indicated could be useful (Bjerva and Augenstein, 2018). Rather, we stick to sharing between languages of the same language families.

The strategies explored here do not exhaust the space of possible parameter sharing strategies. For example, we completely ignore soft sharing based on mean-constrained regularisation (Duong et al., 2015).

8 Conclusions

We present evaluations of 27 parameter sharing strategies for the Uppsala parser across 10 languages, representing five language pairs from five different language families. We repeated the experiment with pairs of unrelated languages. We made several observations: (a) Generally, multi-task learning helps. (b) Sharing the MLP parameters always helps. It helps to share MLP parameters when training a parser on a pair of related languages, and it also helps if the languages are unrelated. (c) Sharing word and character parameters is differently helpful depending on the language. (d) Sharing too many parameters does not help, when the languages are unrelated.

In future work, we plan to investigate what happens when training on more than 2 languages. Here, we focused on a setting with rather small amounts of balanced data. It would be interesting to experiment with using datasets that are not balanced with respect to size. Finally, we have restricted our experiments to a specific architecture, using fixed hyperparameters including word and character embedding dimensions. It would be interesting to experiment with different parsing architectures as well as varying those hyperparameters.

Abstract

A substantial thread of recent work on *latent tree learning* has attempted to develop neural network models with parse-valued latent variables and train them on non-parsing tasks, in the hope of having them discover interpretable tree structure. In a recent paper, Shen et al. (2018) introduce such a model and report near-state-of-the-art results on the target task of language modeling, and the first strong latent tree learning result on constituency parsing. In an attempt to reproduce these results, we discover issues that make the original results hard to trust, including tuning and even training on what is effectively the test set. Here, we attempt to reproduce these results in a fair experiment and to extend them to two new datasets. We find that the results of this work are robust: All variants of the model under study outperform all latent tree learning baselines, and perform competitively with symbolic grammar induction systems. We find that this model represents the first empirical success for latent tree learning, and that neural network language modeling warrants further study as a setting for grammar induction.

1 Introduction and Background

Work on *grammar induction* attempts to find methods for syntactic parsing that do not require expensive and difficult-to-design expert-labeled treebanks for training (Charniak and Carroll, 1992; Klein and Manning, 2002; Smith and Eisner, 2005). Recent work on *latent tree learning* offers a new family of approaches to the problem (Yogatama et al., 2017; Maillard et al., 2017; Choi et al., 2018). Latent tree learning models attempt to induce syntactic structure using the supervision from a downstream NLP task such as textual entailment. Though these models tend to show good task performance, they are often not evaluated using standard parsing metrics, and Williams et al. (2018a) report that the parses they produce tend to be no better than random trees in a standard evaluation on the full Wall Street Journal section of the Penn Treebank (WSJ; Marcus et al., 1993).

This paper addresses the Parsing-Reading-Predict Network (PRPN; Shen et al., 2018), which was recently published at ICLR, and which reports near-state-of-the-art results on language modeling and strong results on grammar induction, a first for latent tree models (though they do not use that term). PRPN is built around a substantially novel architecture, and uses convolutional networks with a form of structured attention (Kim et al., 2017) rather than recursive neural networks (Goller and Kuchler, 1996; Socher et al., 2011) to evaluate and learn trees while performing straightforward backpropagation training on a language modeling objective. In this work, we aim to understand what the PRPN model learns that allows it to succeed, and to identify the conditions under which this success is possible.

Their experiments on language modeling and parsing are carried out using different configurations of the PRPN model, which were claimed to be optimized for the corresponding tasks. PRPN-LM is tuned for language modeling performance, and PRPN-UP for (unsupervised) parsing performance. In the parsing experiments, we also observe that the WSJ data is not split, such that the test data is used without parse information for training. This approach follows the previous works on grammar induction using non-neural models where the entire dataset is used for training (Klein and Manning, 2002). However, this implies that the parsing results of PRPN-UP may not be generalizable in the way usually expected of machine learning evaluation results. Additionally, it is not obvious that the model should be able to learn to parse reliably: (1) Since the parser is trained as part of a language model, it makes pars-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4998–5003
Brussels, Belgium, October 31 - November 4, 2018.

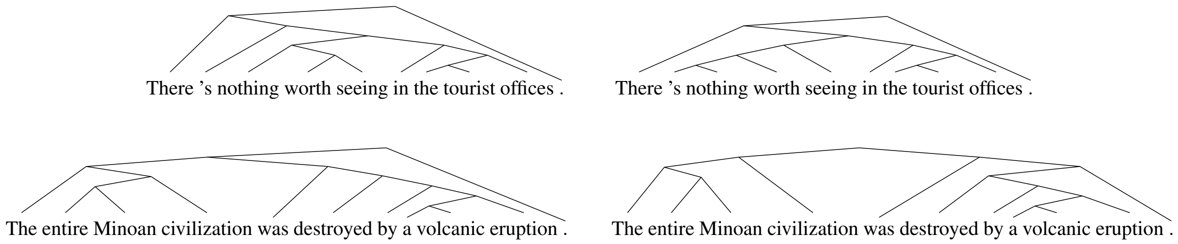

Figure 1: *Left* Parses from PRPN-LM trained on AllNLI. *Right* Parses from PRPN-UP trained on AllNLI (stopping criterion: parsing). We can observe that both sets of parses tend to have roughly reasonable high-level structure and tend to identify noun phrases correctly.

ing decisions greedily and with *no* access to any words to the right of the point where each parsing decision must be made (Collins and Roark, 2004); (2) As RNN language models are known to be insufficient for capturing syntax-sensitive dependencies (Linzen et al., 2016), language modeling as the downstream task may not be well-suited to latent tree learning.

In this replication we train PRPN on two corpora: The full WSJ, a staple in work on grammar induction, and AllNLI, the concatenation of the Stanford Natural Language Inference Corpus (SNLI; Bowman et al., 2015) and the Multi-Genre NLI Corpus (MultiNLI; Williams et al., 2018b), which is used in other latent tree learning work for its non-syntactic classification labels for the task of textual entailment, and which we include for comparison. We then evaluate the constituency trees produced by these models on the WSJ test set, full WSJ10,[1] and the MultiNLI development set.

Our results indicate that PRPN-LM achieves better parsing performance than PRPN-UP on both WSJ and WSJ10 even though PRPN-UP was tuned—at least to some extent—for parsing. Surprisingly, a PRPN-LM model trained on the large out-of-domain AllNLI dataset achieves the best parsing performance on WSJ despite not being tuned for parsing. We also notice that vocabulary size affects the language modeling significantly—the perplexity gets higher as the vocabulary size increases.

Overall, despite the relatively uninformative experimental design used in Shen et al. (2018), we find that PRPN is an effective model. It outperforms all latent tree learning baselines by large margins on both WSJ and MultiNLI, and performs competitively with symbolic grammar induction systems on WSJ10, suggesting that PRPN in particular and language modeling in general are a viable setting for latent tree learning.

2 Methods

PRPN consists of three components: (i) a *parsing network* that uses a two-layer convolution kernel to calculate the *syntactic distance* between successive pairs of words, which can form an indirect representation of the constituency structure of the sentence, (ii) a recurrent *reading network* that summarizes the current memory state based on all previous memory states and the implicit constituent structure, and (iii) a *predict network* that uses the memory state to predict the next token. We refer readers to the appendix and the original work for details.

We do not re-implement or re-tune PRPN, but rather attempt to replicate and understand the results of the work using the author's publicly available code.[2] The experiments on language modeling and parsing are carried out using different configurations of the model, with substantially different hyperparameter values including the size of the word embeddings, the maximum sentence length, the vocabulary size, and the sizes of hidden layers. PRPN-LM is larger than PRPN-UP, with embedding layer that is 4 times larger and the number of units per layer that is 3 times larger. We use both versions of the model in all our experiments.

We use the 49k-sentence WSJ corpus in two settings. To replicate the original results, we re-run an experiment with no train/test split, and for a clearer picture of the model's performance, we run it again with the train (Section 0-21 of WSJ), validation (Section 22 of WSJ), and test (Section 23

Table 1: Unlabeled parsing F1 results evaluated on full WSJ10 and WSJ test set broken down by training data and by early stopping criterion. The *Accuracy* columns represent the fraction of ground truth constituents of a given type that correspond to constituents in the model parses. Italics mark results that are worse than the random baseline. Underlining marks the best results from our runs. Results with RL-SPINN and ST-Gumbel are from Williams et al. (2018a), and are evaluated on the full WSJ. We run the model with 5 different random seeds to calculate the average F1. We use the model with the best F1 score to report ADJP, NP, PP, and INTJ. WSJ10 baselines are from Klein and Manning (2002, CCM), Klein and Manning (2005, DMV+CCM), and Bod (2006, UML-DOP). As the WSJ10 baselines are trained using additional information such as POS tags and dependency parser, they are not strictly comparable with the latent tree learning results.

of WSJ) splits. To compare PRPN to the models studied in Williams et al. (2018a), we also retrain it on AllNLI. As the MultiNLI test set is not publicly available, we follow Williams et al. (2018a) and use the development set for testing. The parsing evaluation code in the original codebase does not support PRPN-LM, and we modify it in our experiments only to add this support.

For early stopping, we remove 10k random sentences from the MultiNLI training set and combine them with the SNLI development set to create a validation set. Our AllNLI training set contains 280.5K unique sentences (1.8M sentences in total including duplicate premise sentences), and covers six distinct genres of spoken and written English. We do not remove the duplicate sentences. We train the model for 100 epochs for WSJ and 15 epochs for AllNLI. We run the model five times with random initializations and average the results from the five runs. The generated parses from the trained models with the best F1 scores and the pre-trained model that provides the highest F1 are available online.[3]

3 Experimental Results

Table 2 shows our results for language modeling. PRPN-UP, configured as-is with parsing criterion and language modeling criterion, performs dramatically worse than the standard PRPN-LM (a vs. d and e). However, this is not a fair comparison as the larger vocabulary gives PRPN-UP a harder task to solve. Adjusting the vocabulary of PRPN-UP down to 10k to make a fairer comparison possible, the PPL of PRPN-UP improves significantly (c vs. d), but not enough to match PRPN-LM (a vs. c). We also observe that early stopping on

Table 3: Unlabeled parsing F1 on the MultiNLI development set for models trained on AllNLI. *F1 wrt.* shows F1 with respect to strictly right- and left-branching (LB/RB) trees and with respect to the Stanford Parser (SP) trees supplied with the corpus; The evaluations of SPINN, RL-SPINN, and ST-Gumbel are from Williams et al. (2018a). SPINN is a supervised parsing model, and the others are latent tree models. Median F1 of each model trained with 5 different random seeds is reported.

parsing leads to incomplete training and a substantial decrease in perplexity (a vs. b and d vs. e). The models stop training at around the 13th epoch when we early-stop on parsing objective, while they stop training around the 65th epoch when we early-stop on language modeling objective. Both PRPN models trained on AllNLI do even worse (f and g), though the mismatch in vocabulary and domain may explain this effect. In addition, since it takes much longer to train PRPN on the larger AllNLI dataset, we train PRPN on AllNLI for only 15 epochs while we train the PRPN on WSJ for 100 epochs. Although the parsing objective converges within 15 epochs, we notice that language modeling perplexity is still improving. We expect that the perplexity of the PRPN models trained on AllNLI could be lower if we increase the number of training epochs.

Turning toward parsing performance, Table 1 shows results with all the models under study, plus several baselines, on WSJ test set and full WSJ10. On full WSJ10, we reproduce the main parsing result of Shen et al. (2018) with their UP model trained on WSJ without a data split. We also find the choice of parse quality as an early stopping criterion does not have a substantial effect and that training on the (unlabeled) test set does not give a significant improvement in performance. In addition and unexpectedly, we observe that PRPN-LM models achieve *higher* parsing performance than PRPN-UP. This shows that any tuning done to separate PRPN-UP from PRPN-LM was not necessary, and more importantly, that the results described in the paper can be largely reproduced by a unified model in a fair setting. Moreover, the PRPN models trained on WSJ achieves comparable results with CCM (Klein and Manning, 2002). The PRPN models are outperformed by DMV+CCM(Klein and Manning, 2005), and UML-DOP(Bod, 2006). However, these models use additional information such as POS and dependency parser so they are not strictly comparable with the PRPN models.

Turning to the WSJ test set, the results look somewhat different: Although the differences in WSJ10 performance across models are small, the same is not true for the WSJ in terms of average F1. PRPN-LM outperforms all the other models on WSJ test set, even the potentially-overfit PRPN-UP model. Moreover, the PRPN models trained on the larger, out-of-domain AllNLI perform better than those trained on WSJ. Surprisingly, PRPN-LM tained on out-of-domain AllNLI achieves the best F1 score on WSJ test set among all the models we experimented, even though its performance on WSJ10 is the lowest of all. This mean that PRPN-LM trained on AllNLI is strikingly good at parsing longer sentences though its performance on shorter sentences is worse than other models. Under all the configurations we tested, the PRPN model yields much better performance than the baselines from Yogatama et al. (2017, called RL-SPINN) and Choi et al. (2018, called ST-Gumbel), despite the fact that the model was tuned exclusively for WSJ10 parsing. This suggests that PRPN is consistently effective at latent tree learning.

We also show detailed results for several specific constituent types, following Williams et al. (2018a). We observe that the accuracy for NP (noun phrases) on the WSJ test set is above 46% (Table 1) for all PRPN models, much higher than any of the baseline models. These runs also perform substantially better than the random baseline in the two other categories Williams et al. (2018a) report: ADJP (adjective phrases) and PP (prepositional phrases). However, as WSJ test set contains only one INTJ (interjection phrases), the results on INTJ are either 0.0% or 100%.

In addition, Table 3 shows that the PRPN-UP models achieve the median parsing F1 scores of 46.3 and 48.6 respectively on the MultiNLI dev set while PRPN-LM performs the median F1 of 45.7; setting the state of the art in parsing performance on this dataset among latent tree models by a large margin. We conclude that PRPN does acquire some substantial knowledge of syntax, and that this knowledge agrees with Penn Treebank (PTB) grammar significantly better than chance.

Qualitatively, the parses produced by most of the best performing PRPN models are relatively balanced (F1 score of 36.5 w.r.t balanced trees) and tend toward right branching (F1 score of 42.0 with respect to balanced trees). They are also shallower than average ground truth PTB parsed trees. These models can parse short sentences relatively well, as shown by their high WSJ10 performance.

For a large proportion of long sentences, most of the best performing models can produce reasonable constituents (Table 1). The best performing model, PRPN-LM trained on AllNLI, achieves the best accuracy at identifying ADJP (adjective phrases), PP (prepositional phrases), and INTJ (interjection phrases) constituents, and a high accuracy on NP (noun phrases). In a more informal inspection, we also observe that our best PRPN-LM and PRPN-UP runs are fairly good at pairing determiners with NPs as we can observe in Figure 1). Although lower level tree constituents appear random in many cases for both PRPN-LM and PRPN-UP, the intermediate and higher-level constituents are generally reasonable. For example, in Figure 1, although the parse for lower level constituents like *The entire Minoan* seem random, the higher-level constituents, such as *The entire Minoan civilization* and *nothing worth seeing in the tourist offices*, are reasonable.

4 Conclusion

In our attempt to replicate the grammar induction results reported in Shen et al. (2018), we find several experimental design problems that make the results difficult to interpret. However, in experiments and analyses going well beyond the scope of the original paper, we find that the PRPN model presented in that work is nonetheless robust. It represents a viable method for grammar induction and the first clear success for latent tree learning with neural networks, and we expect that it heralds further work on language modeling as a tool for grammar induction research.

Abstract

Neural NLP systems achieve high scores in the presence of sizable training dataset. Lack of such datasets leads to poor system performances in the case low-resource languages. We present two simple text augmentation techniques using dependency trees, inspired from image processing. We "crop" sentences by removing dependency links, and we "rotate" sentences by moving the tree fragments around the root. We apply these techniques to augment the training sets of low-resource languages in Universal Dependencies project. We implement a character-level sequence tagging model and evaluate the augmented datasets on part-of-speech tagging task. We show that crop and rotate provides improvements over the models trained with non-augmented data for majority of the languages, especially for languages with rich case marking systems.

1 Introduction

Most recently, various deep learning methods have been proposed for many natural language understanding tasks including sentiment analysis, question answering, dependency parsing and semantic role labeling. Although these methods have reported state-of-the-art results for languages with rich resources, no significant improvement has been announced for low-resource languages. In other words, feature-engineered statistical models still perform better than these neural models for low-resource languages.[1] Generally accepted reason for low scores is the size of the training data, i.e., training labels being too sparse to extract meaningful statistics.

Label-preserving data augmentation techniques are known to help methods generalize better by increasing the variance of the training data. It has been a common practice among researchers in computer vision field to apply data augmentation, e.g., flip, crop, scale and rotate images, for tasks like image classification (Ciresan et al., 2012; Krizhevsky et al., 2012). Similarly, speech recognition systems made use of augmentation techniques like changing the tone and speed of the audio (Ko et al., 2015; Ragni et al., 2014), noise addition (Hartmann et al., 2016) and synthetic audio generation (Takahashi et al., 2016). Comparable techniques for data augmentation are less obvious for NLP tasks, due to structural differences among languages. There are only a small number of studies that tackle data augmentation techniques for NLP, such as Zhang et al. (2015) for text classification and Fadaee et al. (2017) for machine translation.

In this work, we focus on languages with small training datasets, that are made available by the Universal Dependency (UD) project. These languages are dominantly from Uralic, Turkic, Slavic and Baltic language families, which are known to have extensive morphological case-marking systems and relatively free word order. With these languages in mind, we propose an easily adaptable, multilingual text augmentation technique based on dependency trees, inspired from two common augmentation methods from image processing: **cropping** and **rotating**. As images are cropped to focus on a particular item, we **crop** the sentences to form other smaller, meaningful and focused sentences. As images are rotated around a center, we **rotate** the portable tree fragments around the root of the dependency tree to form a synthetic sentence. We augment the training sets of these low-resource languages via crop and rotate operations. In order to measure the impact of augmentation, we implement a unified character-level sequence tagging model. We systematically

---

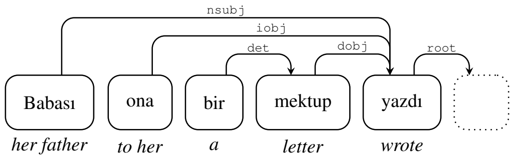
[1] For example, in the case of dependency parsing, recent best results from CoNLL-18 parsing shared task can be compared to the results of traditional language-specific models.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 5004–5009
Brussels, Belgium, October 31 - November 4, 2018.

train separate parts-of-speech tagging models with the original and augmented training sets, and evaluate on the original test set. We show that crop and rotate provide improvements over the non-augmented data for majority of the languages, especially for languages with rich case marking system.

2 Method

We borrow two fundamental label-preserving augmentation ideas from image processing: **cropping** and **rotation**. Image cropping can be defined as removal of some of the peripheral areas of an image to focus on the subject/object (e.g., focusing on the flower in a large green field). Following this basic idea, we aim to identify the parts of the sentence that we want to focus and remove the other chunks, i.e., form simpler/smaller meaningful sentences [2]. In order to do so, we take advantage of dependency trees which provide us with links to focuses, such as subjects and objects. The idea is demonstrated in Fig. 1b on the Turkish sentence given in Fig. 1a. Here, given a predicate *(wrote)* that governs a subject *(her father)*, an indirect object *(to her)* and a direct object *(a letter)*; we form three smaller sentences with a focus on the subject (first row in Fig. 1b: her father wrote) and the objects (second and third row) by removing all dependency links other than the focus (with its subtree). Obviously, cropping may cause semantic shifts on a sentence-level. However it preserves local syntactic tags and even shallow semantic labels.



(a) Dependency analysis

(1) Babası yazdı *(Her father he-wrote)*
(2) Ona yazdı *(He-wrote to her)*
(3) Bir mektup yazdı *(He-wrote a letter)*

(b) Sentence Cropping

(1) Babası yazdı bir mektup ona (SVOIO)
(2) Yazdı babası ona bir mektup (VSIOO)
(3) Bir mektup yazdı babası ona (OVSIO)
(4) Ona bir mektup yazdı babası (IOOVS)

(c) Sentence Rotating

Figure 1: Demonstration of augmentation ideas on the Turkish sentence "Babası ona bir mektup yazdı" *(Her father wrote her a letter)*. S: Subject, V: Verb, O:Object, IO: Indirect Object. Arrows are drawn from dependent to head. Both methods are applied to the *Labels of Interest (LOI)*.

Images are rotated around a chosen center with a certain degree to enhance the training data. Similarly, we choose the root as the center of the sentence and rotate the flexible tree fragments around the root for augmentation. Flexible fragments are usually defined by the morphological typology of the language (Futrell et al., 2015). For instance, languages close to analytical typology such as English, rarely have inflectional morphemes. They do not mark the objects/subjects, therefore words have to follow a strict order. For such languages, sentence rotation would mostly introduce noise. On the other hand, large number of languages such as Latin, Greek, Persian, Romanian, Assyrian, Turkish, Finnish and Basque have no strict word order (though there is a preferred order) due to their extensive marking system. Hence, flexible parts are defined as marked fragments which are again, subjects and objects. Rotation is illustrated in Fig. 1c on the same sentence.

In order to investigate the impact of the augmentation, we design a simple sequence tagging model that operates on the character level. Many low-resource languages we deal with in the Experiments section are morphologically rich. Therefore, we use a character-level model to address the rare word problem and to learn morphological regularities among words.

For each sentence s, we produce a label sequence $\vec{l}$, where l_t refers to POS tag for the t-th token. Given g as gold labels and θ as model parameters we find the values that minimize the negative log likelihood of the sequence:

$$\hat{\theta} = \arg\min_{\theta} \left(-\sum_{t=1}^{n} log(p(g_t|\theta, s)) \right) \quad (1)$$

To calculate $p(l_t|\theta, s)$, we first calculate a word embedding, $\vec{w}$, for each word. We consider words as a sequence of characters $c_0, c_1, .., c_n$ and use a bi-LSTM unit to compose the character sequence into $\vec{w}$, as in Ling et al. (2015):

$$\vec{hw_f}, \vec{hw_b} = \text{bi-LSTM}(c_0, c_1, .., c_n) \quad (2)$$

$$\vec{w} = W_f \cdot \vec{hw_f} + W_b \cdot \vec{hw_b} + b \quad (3)$$

---

[2] Focus should not be confused with the grammatical category FOC.

Later, these embeddings are passed onto another bi-LSTM unit:

$$\vec{h_f}, \vec{h_b} = \text{bi-LSTM}(\vec{w_t}) \tag{4}$$

Hidden states from both directions are concatenated and mapped by a linear layer to the label space. Then label probabilities are calculated by a softmax function:

$$p(\vec{l_t}|s,p) = \text{softmax}(W_l \cdot [\vec{h_f}; \vec{h_b}] + \vec{b_l}) \tag{5}$$

Finally the label with the highest probability is assigned to the input.

3 Experiments and Results

We use the data provided by Universal Dependencies v2.1 (Nivre et al., 2017) project. Since our focus is on languages with low resources, we only consider the ones that have less than 120K tokens. The languages without standard splits and sizes less than 5K tokens, are ignored. We use the universal POS tags defined by UD v2.1.

To keep our approach as language agnostic and simple as possible, we use the following universal dependency labels and their subtypes to extract the focus and the flexible fragment: NSUBJ (nominal subject), IOBJ (indirect object), OBJ (indirect object) and OBL (oblique nominal). These dependency labels are referred to as Label of Interest (LOI). The root/predicate may be a phrase rather than a single token. We use the following relations to identify such cases: FIXED, FLAT, COP (copula) and COMPOUND. Other labels such as ADVMOD can also be considered flexible, however are ignored for the sake of simplicity. We enumerate all flexible chunks and calculate all reordering permutations. Keeping the LOI limited is necessary to reduce the number of permutations. We apply reordering only to the first level in the tree. Our method overgeneralizes, to include sequences that are not grammatical in the language in question. We regard the ungrammatical sentences as noise.

Number of possible cropping operations are limited to the number of items that are linked via an LOI to the root. If we call it n, then the number of possible rotations would be $(n+1)!$ since n pieces and the root are flexible and can be placed anywhere in the sentence. To limit the number of rotations, we calculate all possible permutations for reordering the sentence and then randomly pick n of them. Each operation is applied with a certain probability p to each sentence, (e.g., if $p = 1$, n number of crops; if $p = 0.5$ an average of $n/2$ crops will be done).

We use the model in Sec. 2 to systematically train part-of-speech taggers on original and augmented training data sets. To be able measure the impact of the augmentation, all models are trained with the same hyperparameters. All tokens are lowercased and surrounded with special start-end symbols. Weight parameters are uniformly initialized between -0.1 and $+0.1$. We used one layer bi-LSTMs both for character composition and POS tagging with hidden size of 200. Character embedding size is chosen as 200. We used dropout, gradient clipping and early stopping to prevent overfitting for all experiments. Stochastic gradient descent with an initial learning rate as 1 is used as the optimizer. Learning rate is reduced by half if scores on development set do not improve.

Average of multiple runs for 20 languages are given in Fig. 1. Here, Org column refers to our baseline with non-augmented, original training set, where *Imp%* is the improvement over the baseline by the best crop/flip model for that language. It is evident that, with some minor exceptions, *all* languages have benefited from a type of augmentation. We see that the biggest improvements are achieved on Irish and Lithuanian, the ones with the lowest baseline scores and the smallest training sets [3]. Our result on both languages show that both operations reduced the generalization error surprisingly well in the lack of training data.

Tagging results depend on many factors such as the training data size, the source of the treebank (e.g., news may have less objects and subjects compared to a story), and the language typology (e.g., number/type of case markers it uses). In Fig. 2, the relation between the data size and the improvement by the augmentation is shown. Pearson correlation coefficient for two variables is calculated as -0.35.

Indo-European (IE) : **Baltic** and **Slavic** languages are known to have around 7 distinct case markers, which relaxes the word order. As expectedly, both augmentation techniques improve the scores for Baltic (Latvian, Lithuanian) and Slavic (Belarusian, Slovak, Serbian, Ukranian)

---

[3] Although the total size of the Irish dataset is larger than many, the splits are unbalanced. The training set contains 121 trees while the test has 454 trees.

languages, except for Old Church Slavic (OCS). OCS is solely compiled from bible text which is known to contain longer and passive sentences. We observe that rotation performs slightly better than cropping for Slavic languages. In the presence of a rich marking system, rotation can be considered a better augmenter, since it greatly increases the variance of the training data by shuffling. For **Germanic** (Gothic, Afrikaans, Danish) languages, we do not observe a repeating gain, due to lack of necessary markers.

Uralic and Turkic : Both language types have an extensive marking system. Hence, similar to Slavic languages, both techniques improve the score.

Dravidian : Case system of modern Tamil defines 8 distinct markers, which explains the improved accuracies of the augmented models. We would expect a similar result for Telugu. However Telugu treebank is entirely composed of sentences from a grammar book which may not be expressive and diverse.

4 Related Work

Similar to sentence cropping, Vickrey and Koller (2008) define transformation rules to simplify sentences (e.g., I was not given a chance to eat - I ate) and shows that enrichening training set with simplified sentences improves the results of semantic role labeling. One of the first studies in text augmentation (Zhang et al., 2015), replaces a randomly chosen word with its randomly chosen synonym extracted from a thesaurus. They report improved test scores when a large neural model is trained with the augmented set. Jia and Liang (2016) induce grammar from semantic parsing training data and generate new data points by sampling to feed a sequence to sequence RNN model. Fadaee et al. (2017) chooses low-frequency words instead of a random word, and generate synthetic sentence pairs that contain those rare words.

5 Discussion

Unlike majority of previous NLP augmentation techniques, the proposed methods are meaning-preserving, i.e., they preserve the fundamental meaning of the sentence for most of the tested languages. Therefore can be used for variety of problems such as semantic role labeling, sentiment analysis, text classification. Instead of those problems, we evaluate the idea on the simplest possible task (POS) for the following reasons:

- It gets harder to measure the impact of the idea as the system/task gets complicated due to large number of parameters.

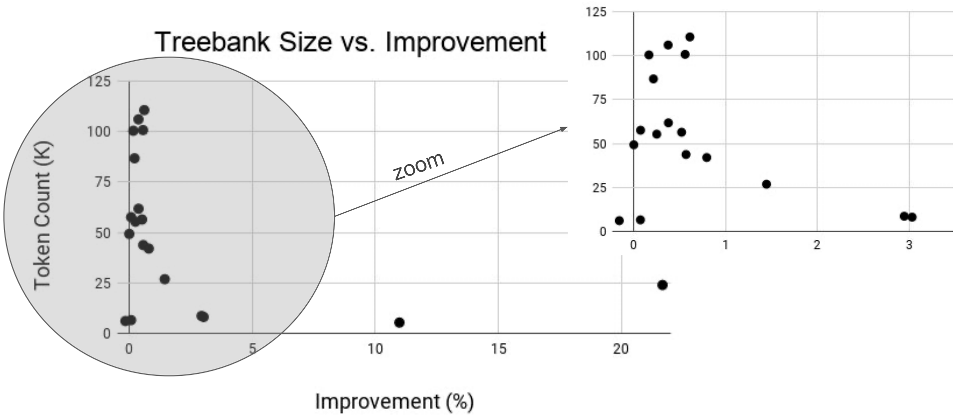

Figure 2: Treebank size versus gain by augmentation

- POS tagging performance is a good indicator of performances of other structured prediction tasks, since POS tags are crucial features for higher-level NLP tasks.

Our research interest was to observe which augmentation technique would improve which language, rather than finding one good model. Therefore we have not used development sets to choose one good augmentation model.

6 Conclusion and Future Work

Neural models have become a standard approach for many NLP problems due to their ability to extract high-level features and generalization capability. Although they have achieved state-of-the-art results in NLP benchmarks with languages with large amount of training data, low-resource languages have not yet benefited from neural models. In this work, we presented two simple text augmentation techniques using dependency trees inspired by image cropping and rotating. We evaluated their impact on parts-of-speech tagging in a number of low-resource languages from various language families. Our results show that:

- Language families with rich case marking systems *(e.g., Baltic, Slavic, Uralic)* benefit both from cropping and rotation. However, for such languages, rotation increases the variance of the data relatively more, leading to slightly better accuracies.

- Both techniques provide substantial improvements over the baseline (non-augmented data) when only a tiny training dataset is available.

This work aimed to measure the impact of the basic techniques, rather than creating the best text augmentation method. Following these encouraging results, method can be improved by (1) considering the preferred chunk order of the language during rotation, (2) taking language-specific flexibilities into account (e.g., Spanish typically allows free subject inversion (unlike object)). Furthermore, we plan to extend this work by evaluating the augmentation on other NLP benchmarks such as language modeling, dependency parsing and semantic role labeling. The code is available at `https://github.com/gozdesahin/crop-rotate-augment`.

How Much *Reading* Does Reading Comprehension Require? A Critical Investigation of Popular Benchmarks

Abstract

Many recent papers address *reading comprehension*, where examples consist of (*question*, *passage*, *answer*) tuples. Presumably, a model must combine information from *both* questions and passages to predict corresponding answers. However, despite intense interest in the topic, with hundreds of published papers vying for leaderboard dominance, basic questions about the difficulty of many popular benchmarks remain unanswered. In this paper, we establish sensible baselines for the bAbI, SQuAD, CBT, CNN, and Who-did-What datasets, finding that question- and passage-only models often perform surprisingly well. On 14 out of 20 bAbI tasks, passage-only models achieve greater than 50% accuracy, sometimes matching the full model. Interestingly, while CBT provides 20-sentence passages, only the last is needed for comparably accurate prediction. By comparison, SQuAD and CNN appear better-constructed.

1 Introduction

Recently, *reading comprehension* (RC) has emerged as a popular task, with researchers proposing various end-to-end deep learning algorithms to push the needle on a variety of benchmarks. As characterized by Hermann et al. (2015); Onishi et al. (2016), unlike prior work addressing question answering from general structured knowledge, RC requires that a model extract information from a given, unstructured passage. It's not hard to imagine how such systems could be useful. In contrast to generic text summarization, RC systems could answer targeted questions about specific documents, efficiently extracting facts and insights.

While many RC datasets have been proposed over the years (Hirschman et al., 1999; Breck et al., 2001; Peñas et al., 2011; Peñas et al., 2012; Sutcliffe et al., 2013; Richardson et al., 2013; Berant et al., 2014), more recently, larger datasets have been proposed to accommodate the data-intensiveness of deep learning. These vary both in the source and size of their corpora and in how they cast the prediction problem—as a classification task (Hill et al., 2016; Hermann et al., 2015; Onishi et al., 2016; Lai et al., 2017; Weston et al., 2016; Miller et al., 2016), span selection (Rajpurkar et al., 2016; Trischler et al., 2017), sentence retrieval (Wang et al., 2007; Yang et al., 2015), or free-form answer generation (Nguyen et al., 2016).[1] Researchers have steadily advanced on these benchmarks, proposing myriad neural network architectures aimed at attending to both questions and passages to produce answers.

In this paper, we argue that amid this rapid progress on empirical benchmarks, crucial steps are sometimes skipped. In particular, we demonstrate that the level of difficulty for several of these tasks is poorly characterized. For example, for many RC datasets, it's not reported, either in the papers introducing the datasets, or in those proposing models, how well one can perform while ignoring either the question or the passage. In other datasets, although the passage might consist of many lines of text, it's not clear how many are actually required to answer the question, e.g., the answer may always lie in the first or the last sentence.

We describe several popular RC datasets and models proposed for these tasks, analyzing their performance when provided with question-only (Q-only) or passage-only (P-only) information. We show that on many tasks, the results obtained are surprisingly strong, outperforming many base-

[1] We note several other QA datasets (Yang et al., 2015; Miller et al., 2016; Nguyen et al., 2016; Paperno et al., 2016; Clark and Etzioni, 2016; Lai et al., 2017; Trischler et al., 2017; Joshi et al., 2017) not addressed in this paper.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 5010–5015
Brussels, Belgium, October 31 - November 4, 2018.

lines, and sometimes even surpassing the same models, supplied with both questions *and* passages.

We note that similar problems were shown for datasets in *visual question answering* by Goyal et al. (2017) and for *natural language inference* by Gururangan et al. (2018); Poliak et al. (2018); Glockner et al. (2018). Several other papers have discussed the weaknesses of various RC benchamrks (Chen et al., 2016; Lee et al., 2016). We discuss these studies in the paragraphs introducing the corresponding datasets below.

2 Datasets

In the following section, we provide context on each dataset that we investigate and then describe our process for corrupting the data as required by our question- and passage-only experiments.

CBT Hill et al. (2016) prepared a cloze-style (*fill in the blank*) RC dataset by using passages from children's books. In their dataset, each passage consists of 20 consecutive sentences, and each question is the 21st sentence with one word removed. The missing word then serves as the answer. The dataset is split into four categories of answers: Named Entities (NE), Common Nouns (CN), Verbs (V) and Prepositions (P). The training corpus contains over $37,000$ candidates and each question is associated with 10 candidates, POS-matched to the correct answer. The authors established LSTM/embedding-based Q-only baselines but did not present the results obtained by their best model using Q-only or P-only information.

CNN Hermann et al. (2015) introduced the CNN/Daily Mail datasets containing more than 1 million news articles, each associated with several highlight sentences. Also adopting the cloze-style dataset preparation, they remove an entity (answer) from a highlight (question). They anonymize all entities to ensure that models rely on information contained in the passage, vs memorizing characteristics of given entities across examples, and thus ignoring passages. On average, passages contain 26 entities, with over 500 total possible answer candidates. Chen et al. (2016) analyzed the difficulty of the CNN and Daily Mail tasks. They hand-engineered a set of eight features for each entity e (does e occur in the question, in the passage, etc.), showing that this simple classifier outperformed many earlier deep learning results.

Who-did-What Onishi et al. (2016) extracted pairs of news articles, each pair referring to the same events. Adopting the cloze-style, they remove a person's name (the answer) from the first sentence of one article (the question). A model must predict the answer based on the question, together with the other article in the pair (passage). Unlike CNN, Who-did-What does not anonymize entities. On average, each question is associated with 3.5 candidate answers. The authors removed several questions from their dataset to thwart simple strategies such as always predicting the name that occurs most (or first) in the passage.

bAbI Weston et al. (2016) presented a set of 20 tasks to help researchers identify and rectify the failings of their reading comprehension systems. Unlike the datasets discussed so far, the questions in this task are not cloze-style and are synthetically generated using templates. This restricts the diversity in clauses appearing in the passages. Further, this also restricts the dataset vocabulary to just 150 words, in contrast, CNN dataset has a vocabulary made of close to $120,000$ words. Memory Networks with adaptive memory, n-grams and non-linear matching were shown to obtain 100% accuracy on 12 out of 20 bAbI tasks. We note that Lee et al. (2016) previously identified that bAbI tasks might fall short as a measure of "AI-complete question answering", proposing two models based on *tensor product representations* that achieve 100% accuracy on many bAbI tasks.

SQuAD More recently, Rajpurkar et al. (2016) released the Stanford Question Answering Dataset (SQuAD) containing over $100,000$ crowd-sourced questions addressing 536 passages. Each question is associated with a paragraph (passage) extracted from an article. These passages are shorter than those in CNN and Who-did-What datasets. Models choose answers by selecting (varying-length) spans from these passages.

Generating Corrupt Data To void any information in either the questions or the passages, while otherwise leaving each architecture intact, we create corrupted versions of each dataset by assigning either questions randomly, while preserving the correspondence between passage and answer, or by randomizing the passage. For tasks where question-answering requires selecting spans or candidates from the passage, we create passages that contain the candidates in random locations but otherwise consist of random gibberish.

3 Models

In our investigations of the various RC benchmarks, we rely upon the following three recently-proposed models: key-value memory networks, gated attention readers, and QA nets. Although space constraints preclude a full discussion of each architecture, we provide references to the source papers and briefly discuss any implementation decisions necessary to reproduce our results.

Key-Value Memory Networks We implement a Key-Value Memory Network (KV-MemNet) (Miller et al., 2016), applying it to bAbI and CBT. KV-MemNets are based on Memory Networks (Sukhbaatar et al., 2015), shown to perform well on both datasets. For bAbI tasks, the keys and values both encode the passage as a bag-of-words (BoW). For CBT, the key is a BoW-encoded 5-word window surrounding a candidate answer and the value is the candidate itself. We fixed the number of hops to 3 and the embedding size to 128.

Gated Attention Reader Introduced by Dhingra et al. (2017), the Gated Attention Reader (GAR)[2] performs multiple hops over a passage, like MemNets. The word representations are refined over each hop and are mapped by an attention-sum module (Kadlec et al., 2016) to a probability distribution over the candidate answer set in the last hop. The model nearly matches best-reported results on many cloze-style RC datasets, and thus we apply it to *Who-did-What, CNN, CBT-NE* and *CBT-CN*.

QA Net Recently introduced by (Yu et al., 2018), the QA-Net[3] was recently demonstrated to outperform all previous models on the SQuAD dataset[4]. Passages and questions are passed as input to separate encoders consisting of depth-wise separable convolutions and global self-attention. This is followed by a passage-question attention layer, followed by stacked encoders. The outputs from these encoders are used to predict an answer span inside the passage.

4 Experimental Results

bAbI tasks Table 1 shows the results obtained by a Key-Value Memory Network on bAbI tasks by nullifying the information present in either questions or passages. On tasks 2, 7, 13 and 20, P-only models obtain over 80% accuracy with questions randomly assigned. Moreover, on tasks 3, 13, 16, and 20, P-only models match performance of those trained on the full dataset. On task 18, Q-only models achieve an accuracy of 91%, nearly matching the best performance of 93% achieved by the full model. These results show that some of bAbI tasks are easier than one might think.

Children's Books Test On the NE and CN CBT tasks, Q-only KV-MemNets obtain an accuracy close to the *full* accuracy and on the Verbs (V) and Prepositions (P) tasks, Q-only models outperform the full model (Table 2). Q-only Gated attention readers reach accuracy of 50.6% and 54% on Named Entities (NE) and Common Nouns (CN) tasks, respectively, while P-only models reach accuracies of 40.8% and 36.7%, respectively. We note that our models can outperform 16 of the 19 reported results on the NE task in Hill et al. (2016) using Q-only information. Table 3 shows that if we make use of just last sentence instead of all 20 sentences in the passage, our sentence memory based KV-MemNet achieve comparable or better performance *w.r.t* the *full* model on most subtasks.

CNN Table 2, shows the performance of Gated Attention Reader on the CNN dataset. Q-only and P-only models obtained 25.6% and 38.3% accuracies respectively, compared to 77.8% on the true dataset. This drop in accuracy could be due to the anonymization of entities which prevents models from building entity-specific information. Notwithstanding the deficiencies noted by Chen et al. (2016), we found that out CNN, out all the cloze-style RC datasets that we evaluated, appears to be the most carefully designed.

Who-did-What P-only models achieve greater than 50% accuracy in both the strict and relaxed setting, reaching within 15% of the accuracy of the *full* model in the strict setting. Q-only models also achieve 50% accuracy on the relaxed setting while achieving an accuracy of 41.8% on the strict setting. Our P-only model also outperforms all the

suppressed baselines and 5 additional baselines reported by Onishi et al. (2016). We suspect that the models memorize attributes of specific entities, justifying the entity-anonymization used by Hermann et al. (2015) to construct the CNN dataset.

SQuAD Our results suggest that SQuAD is an unusually carefully-designed and challenging RC task. The span selection mode of answering requires that models consider the passage thus the abysmal performance of the Q-only QANet (Table 4). Since SQuAD requires answering by span selection, we construct Q-only variants here by placing answers from all relevant questions in random order, filling the gaps with random words. Moreover, Q-only and P-only models achieve F1 scores of only 4% and 14.8% resp. (Table 4), significantly lower than 79.1 on the proper task.

5 Discussion

We briefly discuss our findings, offer some guiding principles for evaluating new benchmarks and algorithms, and speculate on why some of these problems may have gone under the radar. Our goal is not to blame the creators of past datasets but instead to support the community by offering practical guidance for future researchers.

Provide rigorous RC baselines Published RC datasets should contain reasonable baselines that characterize the difficulty of the task, and specifically, the extent to which questions and passages are essential. Moreover, follow-up papers reporting improvements ought to report performance both on the full task and variations omitting questions and passages. While many proposed technical innovations purportedly work by better matching up information in questions and passages, absent these baselines one cannot tell whether gains come for the claimed reason or if the models just do a better job of passage classification (disregarding questions).

Test that *full context* is essential Even on tasks where both questions and passages are required, problems might appear harder than they really are. On first glance the the length-20 passages in CBT, might suggest that success requires reasoning over all 20 sentences to identify the correct answer to each question. However, it turns out that for some models, comparable performance can be achieved by considering only the last sentence. We recommend that researchers provide reasonable ablations to characterize the amount of context that each model truly requires.

Caution with cloze-style RC datasets We note that cloze-style datasets are often created programatically. Thus it's possible for a dataset to be produced, published, and incorporated into many downstream studies, all without many person-hours spent manually inspecting the data. We speculate that, as a result, these datasets tend be subject to less contemplation of what's involved in answering these questions and are therefore especially susceptible to the sorts of overlooked weaknesses described in our study.

A note on publishing incentives We express some concern that the recommended experimental rigor might cut against current publishing incentives. We speculate that papers introducing datasets may be more likely to be accepted at conferences by omitting unfavorable ablations than by including them. Moreover, with reviewers often demanding *architectural novelty*, methods papers may find an easier path to acceptance by providing unsubstantiated stories about the *reasons* why a given architecture works than by providing rigorous ablation studies stripping out spurious explanations and unnecessary model components. For more general discussions of misaligned incentives and empirical rigor in machine learning research, we point the interested reader to Lipton and Steinhardt (2018) and Sculley et al. (2018).

Abstract

Even though machine learning has become the major scene in dialogue research community, the real breakthrough has been blocked by the scale of data available. To address this fundamental obstacle, we introduce the Multi-Domain Wizard-of-Oz dataset (MultiWOZ), a fully-labeled collection of human-human written conversations spanning over multiple domains and topics. At a size of 10k dialogues, it is at least one order of magnitude larger than all previous annotated task-oriented corpora. The contribution of this work apart from the open-sourced dataset labelled with dialogue belief states and dialogue actions is two-fold: firstly, a detailed description of the data collection procedure along with a summary of data structure and analysis is provided. The proposed data-collection pipeline is entirely based on crowd-sourcing without the need of hiring professional annotators; secondly, a set of benchmark results of belief tracking, dialogue act and response generation is reported, which shows the usability of the data and sets a baseline for future studies.

1 Introduction

Conversational Artificial Intelligence (Conversational AI) is one of the long-standing challenges in computer science and artificial intelligence since the Dartmouth Proposal (McCarthy et al., 1955). As human conversation is inherently complex and ambiguous, learning an open-domain conversational AI that can carry on arbitrary tasks is still very far-off (Vinyals and Le, 2015). As a consequence, instead of focusing on creating ambitious conversational agents that can reach human-level intelligence, industrial practice has focused on building task-oriented dialogue systems (Young et al., 2013) that can help with specific tasks such as flight reservation (Seneff and Polifroni, 2000) or bus information (Raux et al., 2005). As the need of hands-free use cases continues to grow, building a conversational agent that can handle tasks across different application domains has become more and more prominent (Ram et al., 2018).

Dialogues systems are inherently hard to build because there are several layers of complexity: the noise and uncertainty in speech recognition (Black et al., 2011); the ambiguity when understanding human language (Williams et al., 2013); the need to integrate third-party services and dialogue context in the decision-making (Traum and Larsson, 2003; Paek and Pieraccini, 2008); and finally, the ability to generate natural and engaging responses (Stent et al., 2005). These difficulties have led to the same solution of using statistical framework and machine learning for various system components, such as natural language understanding (Henderson et al., 2013; Mesnil et al., 2015; Mrkšić et al., 2017a), dialogue management (Gašić and Young, 2014; Tegho et al., 2018), language generation (Wen et al., 2015; Kiddon et al., 2016), and even end-to-end dialogue modelling (Zhao and Eskenazi, 2016; Wen et al., 2017; Eric et al., 2017).

To drive the progress of building dialogue systems using data-driven approaches, a number of conversational corpora have been released in the past. Based on whether a structured annotation scheme is used to label the semantics, these corpora can be roughly divided into two categories: corpora with structured semantic labels (Hemphill et al., 1990; Williams et al., 2013; Asri et al., 2017; Wen et al., 2017; Eric et al., 2017; Shah et al., 2018); and corpora without semantic labels but with an implicit user goal in mind (Ritter et al., 2010; Lowe et al., 2015). Despite these efforts, aforementioned datasets are usually constrained in one or more dimensions such as missing proper annotations, only available in a limited capacity, lacking multi-domain use cases, or having a negli-

gible linguistic variability.

This paper introduces the Multi-Domain Wizard-of-Oz (MultiWOZ) dataset, a large-scale multi-turn conversational corpus with dialogues spanning across several domains and topics. Each dialogue is annotated with a sequence of dialogue states and corresponding system dialogue acts (Traum, 1999). Hence, MultiWOZ can be used to develop individual system modules as separate classification tasks and serve as a benchmark for existing modular-based approaches. On the other hand, MultiWOZ has around 10k dialogues, which is at least one order of magnitude larger than any structured corpus currently available. This significant size of the corpus allows researchers to carry on end-to-end based dialogue modelling experiments, which may facilitate a lot of exciting ongoing research in the area.

This work presents the data collection approach, a summary of the data structure, as well as a series of analyses of the data statistics. To show the potential and usefulness of the proposed MultiWOZ corpus, benchmarking baselines of belief tracking, natural language generation and end-to-end response generation have been conducted and reported. The dataset and baseline models will be freely available online.[1]

2 Related Work

Existing datasets can be roughly grouped into three categories: machine-to-machine, human-to-machine, and human-to-human conversations. A detailed review of these categories is presented below.

Machine-to-Machine Creating an environment with a simulated user enables to exhaustively generate dialogue templates. These templates can be mapped to a natural language by either pre-defined rules (Bordes et al., 2017) or crowd workers (Shah et al., 2018). Such approach ensures a diversity and full coverage of all possible dialogue outcomes within a certain domain. However, the naturalness of the dialogue flows relies entirely on the engineered set-up of the user and system bots. This poses a risk of a mismatch between training data and real interactions harming the interaction quality. Moreover, these datasets do not take into account noisy conditions often experienced in real interactions (Black et al., 2011).

Human-to-Machine Since collecting dialogue corpus for a task-specific application from scratch is difficult, most of the task-oriented dialogue corpora are fostered based on an existing dialogue system. One famous example of this kind is the Let's Go Bus Information System which offers live bus schedule information over the phone (Raux et al., 2005) leading to the first Dialogue State Tracking Challenge (Williams et al., 2013). Taking the idea of the Let's Go system forward, the second and third DSTCs (Henderson et al., 2014b,c) have produced bootstrapped human-machine datasets for a restaurant search domain in the Cambridge area, UK. Since then, DSTCs have become one of the central research topics in the dialogue community (Kim et al., 2016, 2017).

While human-to-machine data collection is an obvious solution for dialogue system develop-

---

[1] `http://dialogue.mi.eng.cam.ac.uk/index.php/corpus/`

ment, it is only possible with a provision of an existing working system. Therefore, this chicken (system)-and-egg (data) problem limits the use of this type of data collection to existing system improvement instead of developing systems in a completely new domain. What is even worse is that the capability of the initial system introduces additional biases to the collected data, which may result in a mismatch between the training and testing sets (Wen et al., 2016). The limited understanding capability of the initial system may prompt the users to adapt to simpler input examples that the system can understand but are not necessarily natural in conversations.

Human-to-Human Arguably, the best strategy to build a natural conversational system may be to have a system that can directly mimic human behaviors through learning from a large amount of real human-human conversations. With this idea in mind, several large-scale dialogue corpora have been released in the past, such as the Twitter (Ritter et al., 2010) dataset, the Reddit conversations (Schrading et al., 2015), and the Ubuntu technical support corpus (Lowe et al., 2015). Although previous work (Vinyals and Le, 2015) has shown that a large learning system can learn to generate interesting responses from these corpora, the lack of grounding conversations onto an existing knowledge base or APIs limits the usability of developed systems. Due to the lack of an explicit goal in the conversation, recent studies have shown that systems trained with this type of corpus not only struggle in generating consistent and diverse responses (Li et al., 2016) but are also extremely hard to evaluate (Liu et al., 2016).

In this paper, we focus on a particular type of human-to-human data collection. The Wizard-of-Oz framework (WOZ) (Kelley, 1984) was first proposed as an iterative approach to improve user experiences when designing a conversational system. The goal of WOZ data collection is to log down the conversation for future system development. One of the earliest dataset collected in this fashion is the ATIS corpus (Hemphill et al., 1990), where conversations between a client and an airline help-desk operator were recorded.

- You are traveling to Cambridge and looking forward to try local restaurants.
- You are looking for a **place to stay**. The hotel should be in the type of **hotel** and should be in the **centre**.
- The hotel should **include free wifi** and should have **a star of 4**.
- Once you find the **hotel** you want to book it for **3 people** and **5 nights** starting from **monday**.
- Make sure you get the **reference number**.
- You are also looking for a **restaurant**. The restaurant should serve **australasian** food and should be in the **moderate** price range.
- The restaurant should be **in the same area as the hotel**.
- If there is no such restaurant, how about one that serves **british** food.
- Once you find the **restaurant** you want to book a table for **the same group of people** at **18:30** on **the same day**.
- Make sure you get the **reference number**

Figure 1: A sample task template spanning over three domains - hotels, restaurants and booking.

More recently, Wen et al. (2017) have shown that the WOZ approach can be applied to collect high-quality typed conversations where a machine learning-based system can learn from. By modifying the original WOZ framework to make it suitable for crowd-sourcing, a total of 676 dialogues was collected via Amazon Mechanical Turk. The corpus was later extended to additional two languages for cross-lingual research (Mrkšić et al., 2017b). Subsequently, this approach is followed by Asri et al. (2017) to collect the Frame corpus in a more complex travel booking domain, and Eric et al. (2017) to collect a corpus of conversations for in-car navigation. Despite the fact that all these datasets contain highly natural conversations comparing to other human-machine collected datasets, they are usually small in size with only a limited domain coverage.

3 Data Collection Set-up

Following the Wizard-of-Oz set-up (Kelley, 1984), corpora of annotated dialogues can be gathered at relatively low costs and with a small time effort. This is in contrast to previous approaches (Henderson et al., 2014a) and such WOZ set-up has been successfully validated by Wen et al. (2017) and Asri et al. (2017).

Therefore, we follow the same process to create a large-scale corpus of natural human-human conversations. Our goal was to collect multi-domain dialogues. To overcome the need of relying the data collection to a small set of trusted workers[2], the collection set-up was designed to provide an

---

[2] Excluding annotation phase.

slots	address* / postcode* / phone* / name^{1234} / no of choices^{1235} / area^{123} / pricerange^{123} / type^{123} / internet^2 / parking^2 / stars^2 / open hours^3 / departure^{45} destination^{45} / leave after^{45} / arrive by^{45} / no of people^{1235} / reference no.^{1235} / trainID^5 / ticket price^5 / travel time^5 / department^7 / day^{1235} / no of days^{123}

easy-to-operate system interface for the Wizards and easy-to-follow goals for the users. This resulted in a bigger diversity and semantical richness of the collected data (see Section 4.3). Moreover, having a large set of workers mitigates the problem of artificial encouragement of a variety of behavior from users. A detailed explanation of the data-gathering process from both sides is provided below. Subsequently, we show how the crowd-sourcing scheme can also be employed to annotate the collected dialogues with dialogue acts.

3.1 Dialogue Task

The domain of a task-oriented dialogue system is often defined by an ontology, a structured representation of the back-end database. The ontology defines all entity attributes called slots and all possible values for each slot. In general, the slots may be divided into *informable* slots and *requestable* slots. *Informable* slots are attributes that allow the user to constrain the search (e.g., area or price range). *Requestable* slots represent additional information the users can request about a given entity (e.g., phone number). Based on a given ontology spanning several domains, a task template was created for each task through random sampling. This results in single and multi-domain dialogue scenarios and domain specific constraints were generated. In domains that allowed for that, an additional booking requirement was sampled with some probability.

To model more realistic conversations, goal changes are encouraged. With a certain probability, the initial constraints of a task may be set to values so that no matching database entry exists. Once informed about that situation by the system, the users only needed to follow the goal which provided alternative values.

3.2 User Side

To provide information to the users, each task template is mapped to natural language. Using heuristic rules, the task is then gradually introduced to the user to prevent an overflow of information. The goal description presented to the user is dependent on the number of turns already performed. Moreover, if the user is required to perform a sub-task (for example - booking a venue), these sub-goals are shown straight-away along with the main goal in the given domain. This makes the dialogues more similar to spoken conversations.[3] Figure 1 shows a sampled task description spanning over two domains with booking requirement. Natural incorporation of co-referencing and lexical entailment into the dialogue was achieved through implicit mentioning of some slots in the goal.

3.3 System Side

The wizard is asked to perform a role of a clerk by providing information required by the user. He is given an easy-to-operate graphical user interface to the back-end database. The wizard conveys the information provided by the current user input through a web form. This information is persistent across turns and is used to query the database. Thus, the annotation of a belief state is performed implicitly while the wizard is allowed to fully focus on providing the required information. Given the result of the query (a list of entities satisfying current constraints), the wizard either requests more details or provides the user with the adequate information. At each system turn, the wizard starts with the results of the query from the previous turn.

To ensure coherence and consistency, the wizard and the user alike first need to go through the

---

[3] However, the length of turns are significantly longer than with spoken interaction (Section 4.3).

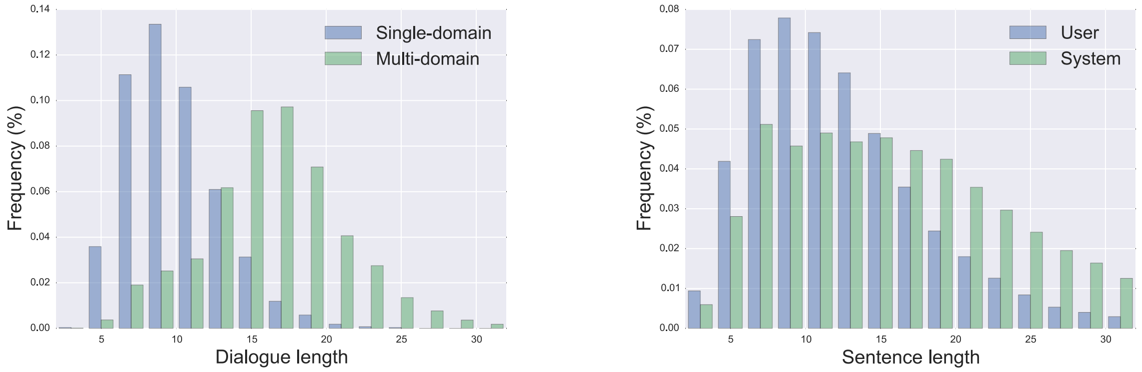

Figure 2: Dialogue length distribution (left) and distribution of number of tokens per turn (right).

dialogue history to establish the respective context. We found that even though multiple workers contributed to one dialogue, only a small margin of dialogues were incoherent.

3.4 Annotation of Dialogue Acts

Arguably, the most challenging and time-consuming part of any dialogue data collection is the process of annotating dialogue acts. One of the major challenges of this task is the definition of a set and structure of dialogue acts (Traum and Hinkelman, 1992; Bunt, 2006). In general, a dialogue act consists of the intent (such as request or inform) and slot-value pairs. For example, the act `inform(domain=hotel,price=expensive)` has the intent *inform*, where the user is informing the system to constrain the search to expensive hotels.

Expecting a big discrepancy in annotations between annotators, we initially ran three trial tests over a subset of dialogues using Amazon Mechanical Turk. Three annotations per dialogue were gathered resulting in around 750 turns. As this requires a multi-annotator metric over a multi-label task, we used Fleiss' kappa metric (Fleiss, 1971) per single dialogue act. Although the weighted kappa value averaged over dialogue acts was at a high level of 0.704, we have observed many cases of very poor annotations and an unsatisfactory coverage of dialogue acts. Initial errors in annotations and suggestions from crowd workers gradually helped us to expand and improve the final set of dialogue acts from 8 to 13 - see Table 2.

The variation in annotations made us change the initial approach. We ran a two-phase trial to first identify set of workers that perform well. Turkers were asked to annotate an illustrative, long dialogue which covered many problematic examples that we have observed in the initial run described above. All submissions that were of high quality were inspected and corrections were reported to annotators. Workers were asked to re-run a new trial dialogue. Having passed the second test, they were allowed to start annotating real dialogues. This procedure resulted in a restricted set of annotators performing high quality annotations. Appendix A contains a demonstration of a created system.

3.5 Data Quality

Data collection was performed in a two-step process. First, all dialogues were collected and then the annotation process was launched. This setup allowed the dialogue act annotators to also report errors (e.g., not following the task or confusing utterances) found in the collected dialogues. As a result, many errors could be corrected. Finally, additional tests were performed to ensure that the provided information in the dialogues match the pre-defined goals.

To estimate the inter-annotator agreement, the averaged weighted kappa value for all dialogue acts was computed over 291 turns. With $\kappa = 0.884$, an improvement in agreement between annotators was achieved although the size of action set was significantly larger.

4 MultiWOZ Dialogue Corpus

The main goal of the data collection was to acquire highly natural conversations between a tourist and a clerk from an information center in a touristic

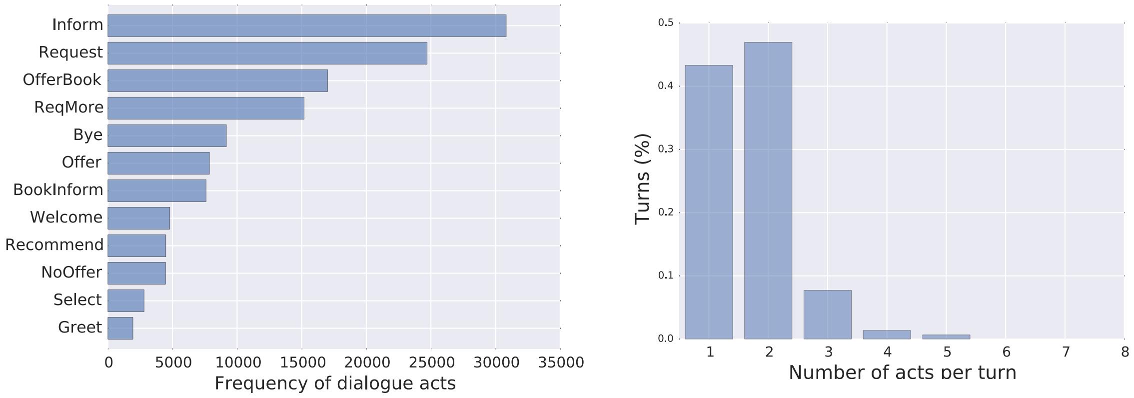

Figure 3: Dialogue acts frequency (left) and number of dialogue acts per turn (right) in the collected corpus.

city. We considered various possible dialogue scenarios ranging from requesting basic information about attractions through booking a hotel room or travelling between cities. In total, the presented corpus consists of 7 domains - *Attraction, Hospital, Police, Hotel, Restaurant, Taxi, Train*. The latter four are extended domains which include the sub-task *Booking*. Through a task sampling procedure (Section 3.1), the dialogues cover between 1 and 5 domains per dialogue thus greatly varying in length and complexity. This broad range of domains allows to create scenarios where domains are naturally connected. For example, a tourist needs to find a hotel, to get the list of attractions and to book a taxi to travel between both places. Table 2 presents the global ontology with the list of considered dialogue acts.

4.1 Data Statistics

Following data collection process from the previous section, a total of $10,438$ dialogues were collected. Figure 2 (left) shows the dialogue length distribution grouped by single and multi domain dialogues. Around 70% of dialogues have more than 10 turns which shows the complexity of the corpus. The average number of turns are 8.93 and 15.39 for single and multi-domain dialogues respectively with $115,434$ turns in total. Figure 2 (right) presents a distribution over the turn lengths. As expected, the wizard replies are much longer - the average sentence lengths are 11.75 and 15.12 for users and wizards respectively. The responses are also more diverse thus enabling the training of more complex generation models.

Figure 3 (left) shows the distribution of dialogue acts annotated in the corpus. We present here a summarized list where different types of actions like *inform* are grouped together. The right graph in the Figure 3 presents the distribution of number of acts per turn. Almost 60% of dialogues turns have more than one dialogue act showing again the richness of system utterances. These create a new challenge for reinforcement learning-based models requiring them to operate on concurrent actions.

In total, $1,249$ workers contributed to the corpus creation with only few instances of intentional wrongdoing. Additional restrictions were added to automatically discover instances of very short utterances, short dialogues or missing single turns during annotations. All such cases were corrected or deleted from the corpus.

4.2 Data Structure

There are $3,406$ single-domain dialogues that include booking if the domain allows for that and $7,032$ multi-domain dialogues consisting of at least 2 up to 5 domains. To enforce reproducibility of results, the corpus was randomly split into a train, test and development set. The test and development sets contain 1k examples each. Even though all dialogues are coherent, some of them were not finished in terms of task description. Therefore, the validation and test sets only contain fully successful dialogues thus enabling a fair comparison of models.

Each dialogue consists of a goal, multiple user and system utterances as well as a belief state and set of dialogue acts with slots per turn. Additionally, the task description in natural language presented to turkers working from the visitor's side is added.

4.3 Comparison to Other Structured Corpora

To illustrate the contribution of the new corpus, we compare it on several important statistics with the DSTC2 corpus (Henderson et al., 2014a), the SFX corpus (Gašić et al., 2014), the WOZ2.0 corpus (Wen et al., 2017), the FRAMES corpus (Asri et al., 2017), the KVRET corpus (Eric et al., 2017), and the M2M corpus (Shah et al., 2018). Figure 1 clearly shows that our corpus compares favorably to all other data sets on most of the metrics with the number of total dialogues, the average number of tokens per turn and the total number of unique tokens as the most prominent ones. Especially the latter is important as it is directly linked to linguistic richness.

5 MultiWOZ as a New Benchmark

The complexity and the rich linguistic variation in the collected MultiWOZ dataset makes it a great benchmark for a range of dialogue tasks. To show the potential usefulness of the MultiWOZ corpus, we break down the dialogue modelling task into three sub-tasks and report a benchmark result for each of them: dialogue state tracking, dialogue-act-to-text generation, and dialogue-context-to-text generation. These results illustrate new challenges introduced by the MultiWOZ dataset for different dialogue modelling problems.

5.1 Dialogue State Tracking

A robust natural language understanding and dialogue state tracking is the first step towards building a good conversational system. Since multi-domain dialogue state tracking is still in its infancy and there are not many comparable approaches available (Rastogi et al., 2017), we instead report our state-of-the-art result on the restaurant subset of the MultiWOZ corpus as the reference baseline. The proposed method (Ramadan et al., 2018) exploits the semantic similarity between dialogue utterances and the ontology terms which allows the information to be shared across domains. Furthermore, the model parameters are independent of the ontology and belief states, therefore the number of the parameters does not increase with the size of the domain itself.[4]

Slot	WOZ 2.0	MultiWOZ (restaurant)
Overall accuracy	96.5	89.7
Joint goals	85.5	80.9

Table 3: The test set accuracies *overall* and for *joint goals* in the restaurant sub-domain.

The same model was trained on both the WOZ2.0 and the proposed MultiWOZ datasets, where the WOZ2.0 corpus consists of 1200 single domain dialogues in the restaurant domain. Although not directly comparable, Table 3 shows that the performance of the model is consecutively poorer on the new dataset compared to WOZ2.0. These results demonstrate how demanding is the new dataset as the conversations are richer and much longer.

5.2 Dialogue-Context-to-Text Generation

After a robust dialogue state tracking module is built, the next challenge becomes the dialogue management and response generation components. These problems can either be addressed separately (Young et al., 2013), or jointly in an end-to-end fashion (Bordes et al., 2017; Wen et al., 2017; Li et al., 2017). In order to establish a clear benchmark where the performance of the composite of dialogue management and response generation is completely independent of the belief tracking, we experimented with a baseline neural response generation model with an *oracle* belief-state obtained from the wizard annotations as discussed in Section 3.3.[5]

Following Wen et al. (2017) which frames the dialogue as a context to response mapping problem, a sequence-to-sequence model (Sutskever et al., 2014) is augmented with a belief tracker and a discrete database accessing component as additional features to inform the word decisions in the decoder. Note, in the original paper the belief tracker was pre-trained while in this work the annotations of the dialogue state are used as an oracle tracker. Figure 4 presents the architecture of the system (Budzianowski et al., 2018).

[5] The model is publicly available at `https://github.com/budzianowski/multiwoz`

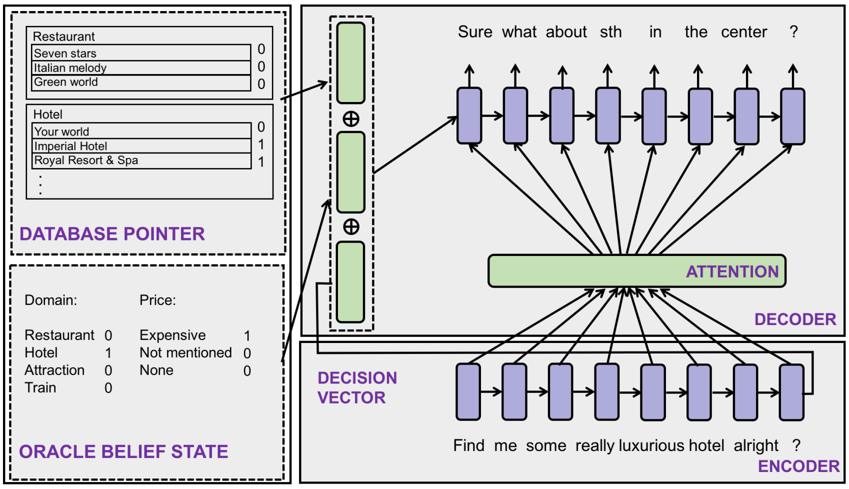

Figure 4: Architecture of the multi-domain response generator. The attention is conditioned on the oracle belief state and the database pointer.

Training and Evaluation Since often times the evaluation of a dialogue system without a direct interaction with the real users can be misleading (Liu et al., 2016), three different automatic metrics are included to ensure the result is better interpreted. Among them, the first two metrics relate to the dialogue task completion - whether the system has provided an appropriate entity (Inform rate) and then answered all the requested attributes (Success rate); while fluency is measured via BLEU score (Papineni et al., 2002). The best models for both datasets were found through a grid search over a set of hyper-parameters such as the size of embeddings, learning rate and different recurrent architectures.

We trained the same neural architecture (taking into account different number of domains) on both MultiWOZ and Cam676 datasets. The best results on the Cam676 corpus were obtained with bidirectional GRU cell. In the case of MultiWOZ dataset, the LSTM cell serving as a decoder and an encoder achieved the highest score with the global type of attention (Bahdanau et al., 2014). Table 4 presents the results of a various of model architectures and shows several challenges. As expected, the model achieves almost perfect score on the Inform metric on the Cam676 dataset taking the advantage of an oracle belief state signal. However, even with the perfect dialogue state tracking of the user intent, the baseline models obtain almost 30% lower score on the Inform metric on the new corpus. The addition of the attention improves the score on the Success metric on the new dataset by less than 1%. Nevertheless, as expected, the best model on MultiWOZ is still falling behind by a large margin in comparison to the results on the Cam676 corpus taking into account both Inform and Success metrics. As most of dialogues span over at least two domains, the model has to be much more effective in order to execute a successful dialogue. Moreover, the BLEU score on the MultiWOZ is lower than the one reported on the Cam676 dataset. This is mainly caused by the much more diverse linguistic expressions observed in the MultiWOZ dataset.

5.3 Dialogue-Act-to-Text Generation

Natural Language Generation from a structured meaning representation (Oh and Rudnicky, 2000; Bohus and Rudnicky, 2005) has been a very popular research topic in the community, and the lack of data has been a long standing block for the field to adopt more machine learning methods. Due to the additional annotation of the system acts, the MultiWOZ dataset serves as a new benchmark for studying natural language generation from a structured meaning representation. In order to verify the difficulty of the collected dataset for the language generation task, we compare it to the SFX dataset (see Table 1), which consists of around 5k dialogue act and natural language sentence pairs. We trained the same Semantically Conditioned Long Short-term Memory network (SC-LSTM) proposed by Wen et al. (2015) on both datasets and used the metrics as a proxy to estimate the difficulty of the two corpora. To make a fair comparison, we constrained our dataset to only the restaurant sub-domain which contains around 25k dia-

	Cam676		MultiWOZ	
	w/o attention	w/ attention	w/o attention	w/ attention
Inform (%)	99.17	99.58	71.29	71.33
Success (%)	75.08	73.75	60.29	60.96
BLEU	0.219	0.204	0.188	0.189

Table 4: Performance comparison of two different model architectures using a corpus-based evaluation.

logue turns. To give more statistics about the two datasets: the SFX corpus has 9 different act types with 12 slots comparing to 12 acts and 14 slots in our corpus. The best model for both datasets was found through a grid search over a set of hyper-parameters such as the size of embeddings, learning rate, and number of LSTM layers.[6]

Table 5 presents the results on two metrics: BLEU score (Papineni et al., 2002) and slot error rate (SER) (Wen et al., 2015). The significantly lower metrics on the MultiWOZ corpus showed that it is much more challenging than the SFX restaurant dataset. This is probably due to the fact that more than 60% of the dialogue turns are composed of at least two system acts, which greatly harms the performance of the existing model.

Metric	SFX	MultiWOZ (restaurant)
SER (%)	0.46	4.378
BLEU	0.731	0.616

Table 5: The test set slot error rate (SER) and BLEU on the SFX dataset and the MultiWOZ restaurant subset.

6 Conclusions

As more and more speech oriented applications are commercially deployed, the necessity of building an entirely data-driven conversational agent becomes more apparent. Various corpora were gathered to enable data-driven approaches to dialogue modelling. To date, however, the available datasets were usually constrained in linguistic variability or lacking multi-domain use cases. In this paper, we established a data-collection pipeline entirely based on crowd-sourcing enabling to gather a large scale, linguistically rich corpus of human-human conversations. We hope that MultiWOZ offers valuable training data and a new challenging testbed for existing modular-based approaches ranging from belief tracking to dialogue acts generation. Moreover, the scale of the data should help push forward research in the end-to-end dialogue modelling.

Abstract

Current state-of-the-art semantic role labeling (SRL) uses a deep neural network with no explicit linguistic features. However, prior work has shown that gold syntax trees can dramatically improve SRL decoding, suggesting the possibility of increased accuracy from explicit modeling of syntax. In this work, we present linguistically-informed self-attention (LISA): a neural network model that combines multi-head self-attention with multi-task learning across dependency parsing, part-of-speech tagging, predicate detection and SRL. Unlike previous models which require significant pre-processing to prepare linguistic features, LISA can incorporate syntax using merely raw tokens as input, encoding the sequence only once to simultaneously perform parsing, predicate detection and role labeling for all predicates. Syntax is incorporated by training one attention head to attend to syntactic parents for each token. Moreover, if a high-quality syntactic parse is already available, it can be beneficially injected at test time without re-training our SRL model. In experiments on CoNLL-2005 SRL, LISA achieves new state-of-the-art performance for a model using predicted predicates and standard word embeddings, attaining 2.5 F1 absolute higher than the previous state-of-the-art on newswire and more than 3.5 F1 on out-of-domain data, nearly 10% reduction in error. On ConLL-2012 English SRL we also show an improvement of more than 2.5 F1. LISA also out-performs the state-of-the-art with contextually-encoded (ELMo) word representations, by nearly 1.0 F1 on news and more than 2.0 F1 on out-of-domain text.

1 Introduction

Semantic role labeling (SRL) extracts a high-level representation of meaning from a sentence, labeling e.g. *who* did *what* to *whom*. Explicit representations of such semantic information have been shown to improve results in challenging downstream tasks such as dialog systems (Tur et al., 2005; Chen et al., 2013), machine reading (Berant et al., 2014; Wang et al., 2015) and translation (Liu and Gildea, 2010; Bazrafshan and Gildea, 2013).

Though syntax was long considered an obvious prerequisite for SRL systems (Levin, 1993; Punyakanok et al., 2008), recently deep neural network architectures have surpassed syntactically-informed models (Zhou and Xu, 2015; Marcheggiani et al., 2017; He et al., 2017; Tan et al., 2018; He et al., 2018), achieving state-of-the art SRL performance with no explicit modeling of syntax. An additional benefit of these end-to-end models is that they require just raw tokens and (usually) detected predicates as input, whereas richer linguistic features typically require extraction by an auxiliary pipeline of models.

Still, recent work (Roth and Lapata, 2016; He et al., 2017; Marcheggiani and Titov, 2017) indicates that neural network models could see even higher accuracy gains by leveraging syntactic information rather than ignoring it. He et al. (2017) indicate that many of the errors made by a syntax-free neural network on SRL are tied to certain syntactic confusions such as prepositional phrase attachment, and show that while constrained inference using a relatively low-accuracy predicted parse can provide small improvements in SRL accuracy, providing a gold-quality parse leads to substantial gains. Marcheggiani and Titov (2017) incorporate syntax from a high-quality parser (Kiperwasser and Goldberg, 2016) using graph convolutional neural networks (Kipf and Welling, 2017), but like He et al. (2017) they attain only small increases over a model with no syntactic parse, and even perform worse than a syntax-free model on out-of-domain data. These works suggest that though syntax has the potential to improve neural network SRL models, we have not

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 5027–5038
Brussels, Belgium, October 31 - November 4, 2018.

yet designed an architecture which maximizes the benefits of auxiliary syntactic information.

In response, we propose *linguistically-informed self-attention* (LISA): a model that combines multi-task learning (Caruana, 1993) with stacked layers of multi-head self-attention (Vaswani et al., 2017); the model is trained to: (1) jointly predict parts of speech and predicates; (2) perform parsing; and (3) attend to syntactic parse parents, while (4) assigning semantic role labels. Whereas prior work typically requires separate models to provide linguistic analysis, including most syntax-free neural models which still rely on external predicate detection, our model is truly end-to-end: earlier layers are trained to predict prerequisite parts-of-speech and predicates, the latter of which are supplied to later layers for scoring. Though prior work re-encodes each sentence to predict each desired task and again with respect to each predicate to perform SRL, we more efficiently encode each sentence only once, predict its predicates, part-of-speech tags and labeled syntactic parse, then predict the semantic roles for all predicates in the sentence in parallel. The model is trained such that, as syntactic parsing models improve, providing high-quality parses at test time will improve its performance, allowing the model to leverage updated parsing models without requiring re-training.

In experiments on the CoNLL-2005 and CoNLL-2012 datasets we show that our linguistically-informed models out-perform the syntax-free state-of-the-art. On CoNLL-2005 with predicted predicates and standard word embeddings, our single model out-performs the previous state-of-the-art model on the WSJ test set by 2.5 F1 points absolute. On the challenging out-of-domain Brown test set, our model improves substantially over the previous state-of-the-art by more than 3.5 F1, a nearly 10% reduction in error. On CoNLL-2012, our model gains more than 2.5 F1 absolute over the previous state-of-the-art. Our models also show improvements when using contextually-encoded word representations (Peters et al., 2018), obtaining nearly 1.0 F1 higher than the state-of-the-art on CoNLL-2005 news and more than 2.0 F1 improvement on out-of-domain text.[1]

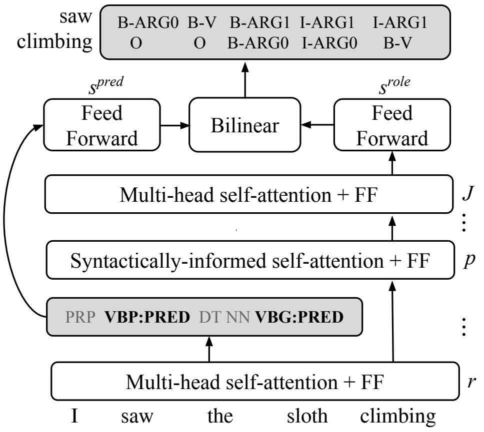

Figure 1: Word embeddings are input to J layers of multi-head self-attention. In layer p one attention head is trained to attend to parse parents (Figure 2). Layer r is input for a joint predicate/POS classifier. Representations from layer r corresponding to predicted predicates are passed to a bilinear operation scoring distinct predicate and role representations to produce per-token SRL predictions with respect to each predicted predicate.

2 Model

Our goal is to design an efficient neural network model which makes use of linguistic information as effectively as possible in order to perform end-to-end SRL. LISA achieves this by combining: (1) A new technique of supervising neural attention to predict syntactic dependencies with (2) multi-task learning across four related tasks.

Figure 1 depicts the overall architecture of our model. The basis for our model is the Transformer encoder introduced by Vaswani et al. (2017): we transform word embeddings into contextually-encoded token representations using stacked multi-head self-attention and feed-forward layers (§2.1).

To incorporate syntax, one self-attention head is trained to attend to each token's syntactic parent, allowing the model to use this attention head as an oracle for syntactic dependencies. We introduce this *syntactically-informed self-attention* (Figure 2) in more detail in §2.2.

Our model is designed for the more realistic setting in which gold predicates are not provided at test-time. Our model predicts predicates and integrates part-of-speech (POS) information into earlier layers by re-purposing representations closer to the input to predict predicate and POS tags us-

---

[1] Our implementation in TensorFlow (Abadi et al., 2015) is available at : `http://github.com/strubell/LISA`

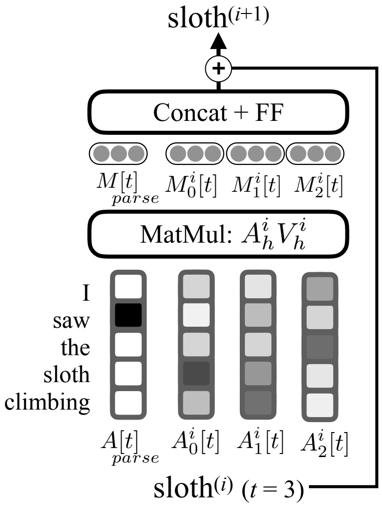

Figure 2: Syntactically-informed self-attention for the query word *sloth*. Attention weights A_{parse} heavily weight the token's syntactic governor, *saw*, in a weighted average over the token values V_{parse}. The other attention heads act as usual, and the attended representations from all heads are concatenated and projected through a feed-forward layer to produce the syntactically-informed representation for *sloth*.

ing hard parameter sharing (§2.3). We simplify optimization and benefit from shared statistical strength derived from highly correlated POS and predicates by treating tagging and predicate detection as a single task, performing multi-class classification into the joint Cartesian product space of POS and predicate labels.

Though typical models, which re-encode the sentence for each predicate, can simplify SRL to token-wise tagging, our joint model requires a different approach to classify roles with respect to each predicate. Contextually encoded tokens are projected to distinct *predicate* and *role* embeddings (§2.4), and each predicted predicate is scored with the sequence's role representations using a bilinear model (Eqn. 6), producing per-label scores for BIO-encoded semantic role labels for each token and each semantic frame.

The model is trained end-to-end by maximum likelihood using stochastic gradient descent (§2.5).

2.1 Self-attention token encoder

The basis for our model is a multi-head self-attention token encoder, recently shown to achieve state-of-the-art performance on SRL (Tan et al., 2018), and which provides a natural mechanism for incorporating syntax, as described in §2.2. Our implementation replicates Vaswani et al. (2017).

The input to the network is a sequence $\mathcal{X}$ of T token representations x_t. In the standard setting these token representations are initialized to pre-trained word embeddings, but we also experiment with supplying pre-trained ELMo representations combined with task-specific learned parameters, which have been shown to substantially improve performance of other SRL models (Peters et al., 2018). For experiments with gold predicates, we concatenate a predicate indicator embedding p_t following previous work (He et al., 2017).

We project[2] these input embeddings to a representation that is the same size as the output of the self-attention layers. We then add a positional encoding vector computed as a deterministic sinusoidal function of t, since the self-attention has no innate notion of token position.

We feed this token representation as input to a series of J residual multi-head self-attention layers with feed-forward connections. Denoting the jth self-attention layer as $T^{(j)}(\cdot)$, the output of that layer $s_t^{(j)}$, and $LN(\cdot)$ layer normalization, the following recurrence applied to initial input $c_t^{(p)}$:

$$s_t^{(j)} = LN(s_t^{(j-1)} + T^{(j)}(s_t^{(j-1)})) \qquad (1)$$

gives our final token representations $s_t^{(j)}$. Each $T^{(j)}(\cdot)$ consists of: (a) multi-head self-attention and (b) a feed-forward projection.

The multi-head self attention consists of H attention heads, each of which learns a distinct attention function to attend to all of the tokens in the sequence. This self-attention is performed for each token for each head, and the results of the H self-attentions are concatenated to form the final self-attended representation for each token.

Specifically, consider the matrix $S^{(j-1)}$ of T token representations at layer $j - 1$. For each attention head h, we project this matrix into distinct key, value and query representations $K_h^{(j)}$, $V_h^{(j)}$ and $Q_h^{(j)}$ of dimensions $T \times d_k$, $T \times d_q$, and $T \times d_v$, respectively. We can then multiply $Q_h^{(j)}$ by $K_h^{(j)}$ to obtain a $T \times T$ matrix of attention weights $A_h^{(j)}$ between each pair of tokens in the sentence. Following Vaswani et al. (2017) we perform scaled dot-product attention: We scale the weights by the inverse square root of their embedding dimension

---

[2] All linear projections include bias terms, which we omit in this exposition for the sake of clarity.

and normalize with the softmax function to produce a distinct distribution for each token over all the tokens in the sentence:

$$A_h^{(j)} = \text{softmax}(d_k^{-0.5} Q_h^{(j)} {K_h^{(j)}}^T) \qquad (2)$$

These attention weights are then multiplied by $V_h^{(j)}$ for each token to obtain the self-attended token representations $M_h^{(j)}$:

$$M_h^{(j)} = A_h^{(j)} V_h^{(j)} \qquad (3)$$

Row t of $M_h^{(j)}$, the self-attended representation for token t at layer j, is thus the weighted sum with respect to t (with weights given by $A_h^{(j)}$) over the token representations in $V_h^{(j)}$.

The outputs of all attention heads for each token are concatenated, and this representation is passed to the feed-forward layer, which consists of two linear projections each followed by leaky ReLU activations (Maas et al., 2013). We add the output of the feed-forward to the initial representation and apply layer normalization to give the final output of self-attention layer j, as in Eqn. 1.

2.2 Syntactically-informed self-attention

Typically, neural attention mechanisms are left on their own to learn to attend to relevant inputs. Instead, we propose training the self-attention to attend to specific tokens corresponding to the syntactic structure of the sentence as a mechanism for passing linguistic knowledge to later layers.

Specifically, we replace one attention head with the deep bi-affine model of Dozat and Manning (2017), trained to predict syntactic dependencies. Let A_{parse} be the parse attention weights, at layer i. Its input is the matrix of token representations $S^{(i-1)}$. As with the other attention heads, we project $S^{(i-1)}$ into key, value and query representations, denoted K_{parse}, Q_{parse}, V_{parse}. Here the key and query projections correspond to $parent$ and $dependent$ representations of the tokens, and we allow their dimensions to differ from the rest of the attention heads to more closely follow the implementation of Dozat and Manning (2017). Unlike the other attention heads which use a dot product to score key-query pairs, we score the compatibility between K_{parse} and Q_{parse} using a bi-affine operator U_{heads} to obtain attention weights:

$$A_{parse} = \text{softmax}(Q_{parse} U_{heads} K_{parse}^T) \qquad (4)$$

These attention weights are used to compose a weighted average of the value representations V_{parse} as in the other attention heads.

We apply auxiliary supervision at this attention head to encourage it to attend to each token's parent in a syntactic dependency tree, and to encode information about the token's dependency label. Denoting the attention weight from token t to a candidate head q as $A_{parse}[t, q]$, we model the probability of token t having parent q as:

$$P(q = \text{head}(t) \mid \mathcal{X}) = A_{parse}[t, q] \qquad (5)$$

using the attention weights $A_{parse}[t]$ as the distribution over possible heads for token t. We define the root token as having a self-loop. This attention head thus emits a directed graph[3] where each token's parent is the token to which the attention A_{parse} assigns the highest weight.

We also predict dependency labels using per-class bi-affine operations between parent and dependent representations Q_{parse} and K_{parse} to produce per-label scores, with locally normalized probabilities over dependency labels y_t^{dep} given by the softmax function. We refer the reader to Dozat and Manning (2017) for more details.

This attention head now becomes an oracle for syntax, denoted $\mathcal{P}$, providing a dependency parse to downstream layers. This model not only predicts its own dependency arcs, but allows for the injection of auxiliary parse information at test time by simply setting A_{parse} to the parse parents produced by e.g. a state-of-the-art parser. In this way, our model can benefit from improved, external parsing models without re-training. Unlike typical multi-task models, ours maintains the ability to leverage external syntactic information.

2.3 Multi-task learning

We also share the parameters of lower layers in our model to predict POS tags and predicates. Following He et al. (2017), we focus on the end-to-end setting, where predicates must be predicted on-the-fly. Since we also train our model to predict syntactic dependencies, it is beneficial to give the model knowledge of POS information. While much previous work employs a pipelined approach to both POS tagging for dependency parsing and predicate detection for SRL, we take a multi-task learning (MTL) approach (Caruana,

---

[3] Usually the head emits a tree, but we do not enforce it here.

1993), sharing the parameters of earlier layers in our SRL model with a joint POS and predicate detection objective. Since POS is a strong predictor of predicates[4] and the complexity of training a multi-task model increases with the number of tasks, we combine POS tagging and predicate detection into a joint label space: For each POS tag TAG which is observed co-occurring with a predicate, we add a label of the form TAG:PREDICATE.

Specifically, we feed the representation $s_t^{(r)}$ from a layer r preceding the syntactically-informed layer p to a linear classifier to produce per-class scores r_t for token t. We compute locally-normalized probabilities using the softmax function: $P(y_t^{prp} \mid \mathcal{X}) \propto \exp(r_t)$, where y_t^{prp} is a label in the joint space.

2.4 Predicting semantic roles

Our final goal is to predict semantic roles for each predicate in the sequence. We score each predicate against each token in the sequence using a bilinear operation, producing per-label scores for each token for each predicate, with predicates and syntax determined by oracles $\mathcal{V}$ and $\mathcal{P}$.

First, we project each token representation $s_t^{(J)}$ to a predicate-specific representation s_t^{pred} and a role-specific representation s_t^{role}. We then provide these representations to a bilinear transformation U for scoring. So, the role label scores s_{ft} for the token at index t with respect to the predicate at index f (i.e. token t and frame f) are given by:

$$s_{ft} = (s_f^{pred})^T U s_t^{role} \tag{6}$$

which can be computed in parallel across all semantic frames in an entire minibatch. We calculate a locally normalized distribution over role labels for token t in frame f using the softmax function: $P(y_{ft}^{role} \mid \mathcal{P}, \mathcal{V}, \mathcal{X}) \propto \exp(s_{ft})$.

At test time, we perform constrained decoding using the Viterbi algorithm to emit valid sequences of BIO tags, using unary scores s_{ft} and the transition probabilities given by the training data.

2.5 Training

We maximize the sum of the likelihoods of the individual tasks. In order to maximize our model's ability to leverage syntax, during training we clamp $\mathcal{P}$ to the gold parse ($\mathcal{P}_G$) and $\mathcal{V}$ to gold predicates $\mathcal{V}_G$ when passing parse and predicate representations to later layers, whereas syntactic head prediction and joint predicate/POS prediction are conditioned only on the input sequence $\mathcal{X}$. The overall objective is thus:

$$\begin{aligned}\frac{1}{T}\sum_{t=1}^{T}\Big[\sum_{f=1}^{F}&\log P(y_{ft}^{role} \mid \mathcal{P}_G, \mathcal{V}_G, \mathcal{X})\\ &+ \log P(y_t^{prp} \mid \mathcal{X})\\ &+ \lambda_1 \log P(\text{head}(t) \mid \mathcal{X})\\ &+ \lambda_2 \log P(y_t^{dep} \mid \mathcal{P}_G, \mathcal{X})\Big]\end{aligned} \tag{7}$$

where λ_1 and λ_2 are penalties on the syntactic attention loss.

We train the model using Nadam (Dozat, 2016) SGD combined with the learning rate schedule in Vaswani et al. (2017). In addition to MTL, we regularize our model using dropout (Srivastava et al., 2014). We use gradient clipping to avoid exploding gradients (Bengio et al., 1994; Pascanu et al., 2013). Additional details on optimization and hyperparameters are included in Appendix A.

3 Related work

Early approaches to SRL (Pradhan et al., 2005; Surdeanu et al., 2007; Johansson and Nugues, 2008; Toutanova et al., 2008) focused on developing rich sets of linguistic features as input to a linear model, often combined with complex constrained inference e.g. with an ILP (Punyakanok et al., 2008). Täckström et al. (2015) showed that constraints could be enforced more efficiently using a clever dynamic program for exact inference. Sutton and McCallum (2005) modeled syntactic parsing and SRL jointly, and Lewis et al. (2015) jointly modeled SRL and CCG parsing.

Collobert et al. (2011) were among the first to use a neural network model for SRL, a CNN over word embeddings which failed to out-perform non-neural models. FitzGerald et al. (2015) successfully employed neural networks by embedding lexicalized features and providing them as factors in the model of Täckström et al. (2015).

More recent neural models are syntax-free. Zhou and Xu (2015), Marcheggiani et al. (2017) and He et al. (2017) all use variants of deep LSTMs with constrained decoding, while Tan et al. (2018) apply self-attention to obtain state-of-the-art SRL with gold predicates. Like this work, He et al. (2017) present end-to-end experiments, predicting predicates using an LSTM, and He et al.

---

[4] All predicates in CoNLL-2005 are verbs; CoNLL-2012 includes some nominal predicates.

(2018) jointly predict SRL spans and predicates in a model based on that of Lee et al. (2017), obtaining state-of-the-art predicted predicate SRL. Concurrent to this work, Peters et al. (2018) and He et al. (2018) report significant gains on PropBank SRL by training a wide LSTM language model and using a task-specific transformation of its hidden representations (ELMo) as a deep, and computationally expensive, alternative to typical word embeddings. We find that LISA obtains further accuracy increases when provided with ELMo word representations, especially on out-of-domain data.

Some work has incorporated syntax into neural models for SRL. Roth and Lapata (2016) incorporate syntax by embedding dependency paths, and similarly Marcheggiani and Titov (2017) encode syntax using a graph CNN over a predicted syntax tree, out-performing models without syntax on CoNLL-2009. These works are limited to incorporating partial dependency paths between tokens whereas our technique incorporates the entire parse. Additionally, Marcheggiani and Titov (2017) report that their model does not out-perform syntax-free models on out-of-domain data, a setting in which our technique excels.

MTL (Caruana, 1993) is popular in NLP, and others have proposed MTL models which incorporate subsets of the tasks we do (Collobert et al., 2011; Zhang and Weiss, 2016; Hashimoto et al., 2017; Peng et al., 2017; Swayamdipta et al., 2017), and we build off work that investigates where and when to combine different tasks to achieve the best results (Søgaard and Goldberg, 2016; Bingel and Søgaard, 2017; Alonso and Plank, 2017). Our specific method of incorporating supervision into self-attention is most similar to the concurrent work of Liu and Lapata (2018), who use edge marginals produced by the matrix-tree algorithm as attention weights for document classification and natural language inference.

The question of training on gold versus predicted labels is closely related to learning to search (Daumé III et al., 2009; Ross et al., 2011; Chang et al., 2015) and scheduled sampling (Bengio et al., 2015), with applications in NLP to sequence labeling and transition-based parsing (Choi and Palmer, 2011; Goldberg and Nivre, 2012; Ballesteros et al., 2016). Our approach may be interpreted as an extension of teacher forcing (Williams and Zipser, 1989) to MTL. We leave exploration of more advanced scheduled sampling techniques to future work.

4 Experimental results

We present results on the CoNLL-2005 shared task (Carreras and Màrquez, 2005) and the CoNLL-2012 English subset of OntoNotes 5.0 (Pradhan et al., 2006), achieving state-of-the-art results for a single model with predicted predicates on both corpora. We experiment with both standard pre-trained GloVe word embeddings (Pennington et al., 2014) and pre-trained ELMo representations with fine-tuned task-specific parameters (Peters et al., 2018) in order to best compare to prior work. Hyperparameters that resulted in the best performance on the validation set were selected via a small grid search, and models were trained for a maximum of 4 days on one TitanX GPU using early stopping on the validation set. We convert constituencies to dependencies using the Stanford head rules v3.5 (de Marneffe and Manning, 2008). A detailed description of hyperparameter settings and data pre-processing can be found in Appendix A.

We compare our **LISA** models to four strong baselines: For experiments using predicted predicates, we compare to He et al. (2018) and the ensemble model (**PoE**) from He et al. (2017), as well as a version of our own self-attention model which does not incorporate syntactic information (**SA**). To compare to more prior work, we present additional results on CoNLL-2005 with models given gold predicates at test time. In these experiments we also compare to Tan et al. (2018), the previous state-of-the art SRL model using gold predicates and standard embeddings.

We demonstrate that our models benefit from injecting state-of-the-art predicted parses at test time (**+D&M**) by fixing the attention to parses predicted by Dozat and Manning (2017), the winner of the 2017 CoNLL shared task (Zeman et al., 2017) which we re-train using ELMo embeddings. In all cases, using these parses at test time improves performance.

We also evaluate our model using the gold syntactic parse at test time (**+Gold**), to provide an upper bound for the benefit that syntax could have for SRL using LISA. These experiments show that despite LISA's strong performance, there remains substantial room for improvement. In §4.3 we perform further analysis comparing SRL models using gold and predicted parses.

Table 2: Precision, recall and F1 on CoNLL-2005 with gold predicates.

4.1 Semantic role labeling

Table 1 lists precision, recall and F1 on the CoNLL-2005 development and test sets using predicted predicates. For models using GloVe embeddings, our syntax-free SA model already achieves a new state-of-the-art by jointly predicting predicates, POS and SRL. LISA with its own parses performs comparably to SA, but when supplied with D&M parses LISA out-performs the previous state-of-the-art by 2.5 F1 points. On the out-of-domain Brown test set, LISA also performs comparably to its syntax-free counterpart with its own parses, but with D&M parses LISA performs exceptionally well, more than 3.5 F1 points higher than He et al. (2018). Incorporating ELMo embeddings improves all scores. The gap in SRL F1 between models using LISA and D&M parses is smaller due to LISA's improved parsing accuracy (see §4.2), but LISA with D&M parses still achieves the highest F1: nearly 1.0 absolute F1 higher than the previous state-of-the art on WSJ, and more than 2.0 F1 higher on Brown. In both settings LISA leverages domain-agnostic syntactic information rather than over-fitting to the newswire training data which leads to high performance even on out-of-domain text.

To compare to more prior work we also evaluate our models in the artificial setting where gold predicates are provided at test time. For fair comparison we use GloVe embeddings, provide predicate indicator embeddings on the input and re-encode the sequence relative to each gold predicate. Here LISA still excels: with D&M parses, LISA out-performs the previous state-of-the-art by more than 2 F1 on both WSJ and Brown.

Table 3 reports precision, recall and F1 on the CoNLL-2012 test set. We observe performance similar to that observed on ConLL-2005: Using GloVe embeddings our SA baseline already out-performs He et al. (2018) by nearly 1.5 F1. With its own parses, LISA slightly under-performs our syntax-free model, but when provided with stronger D&M parses LISA out-performs the state-of-the-art by more than 2.5 F1. Like CoNLL-2005, ELMo representations improve all models and close the F1 gap between models supplied with LISA and D&M parses. On this dataset ELMo also substantially narrows the

difference between models with- and without syntactic information. This suggests that for this challenging dataset, ELMo already encodes much of the information available in the D&M parses. Yet, higher accuracy parses could still yield improvements since providing gold parses increases F1 by 4 points even with ELMo embeddings.

4.2 Parsing, POS and predicate detection

Data	Model	POS	UAS	LAS

CoNLL-12	LISA	99.8	94.7	97.2

Table 5: Predicate detection precision, recall and F1 on CoNLL-2005 and CoNLL-2012 test sets.

We first report the labeled and unlabeled attachment scores (LAS, UAS) of our parsing models on the CoNLL-2005 and 2012 test sets (Table 4) with GloVe (G) and ELMo (E) embeddings. D&M achieves the best scores. Still, LISA's GloVe UAS is comparable to popular off-the-shelf dependency parsers such as spaCy,[5] and with ELMo embeddings comparable to the standalone D&M parser. The difference in parse accuracy between LISA$_G$ and D&M likely explains the large increase in SRL performance we see from decoding with D&M parses in that setting.

In Table 5 we present predicate detection precision, recall and F1 on the CoNLL-2005 and 2012 test sets. SA and LISA with and without ELMo attain comparable scores so we report only LISA+GloVe. We compare to He et al. (2017) on CoNLL-2005, the only cited work reporting comparable predicate detection F1. LISA attains high predicate detection scores, above 97 F1, on both in-domain datasets, and out-performs He et al. (2017) by 1.5-2 F1 points even on the out-of-domain Brown test set, suggesting that multi-task learning works well for SRL predicate detection.

4.3 Analysis

First we assess SRL F1 on sentences divided by parse accuracy. Table 6 lists average SRL F1 (across sentences) for the four conditions of LISA and D&M parses being correct or not (**L**±, **D**±). Both parsers are correct on 26% of sentences.

---

[5] spaCy reports 94.48 UAS on WSJ using Stanford dependencies v3.3: `https://spacy.io/usage/facts-figures`

	L+/D+	L–/D+	L+/D–	L–/D–
Proportion	26%	12%	4%	56%
SA	79.29	75.14	75.97	75.08
LISA	79.51	74.33	79.69	75.00
+D&M	79.03	76.96	77.73	76.52
+*Gold*	*79.61*	*78.38*	*81.41*	*80.47*

Table 6: Average SRL F1 on CoNLL-2005 for sentences where LISA (L) and D&M (D) parses were completely correct (+) or incorrect (–).

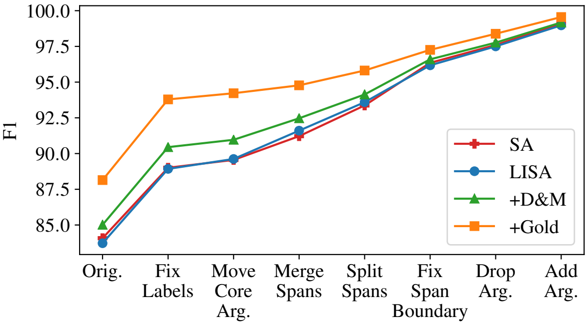

Figure 3: Performance of CoNLL-2005 models after performing corrections from He et al. (2017).

Here there is little difference between any of the models, with LISA models tending to perform slightly better than SA. Both parsers make mistakes on the majority of sentences (57%), difficult sentences where SA also performs the worst. These examples are likely where gold and D&M parses improve the most over other models in overall F1: Though both parsers fail to correctly parse the entire sentence, the D&M parser is less wrong (87.5 vs. 85.7 average LAS), leading to higher SRL F1 by about 1.5 average F1.

Following He et al. (2017), we next apply a series of corrections to model predictions in order to understand which error types the gold parse resolves: e.g. *Fix Labels* fixes labels on spans matching gold boundaries, and *Merge Spans* merges adjacent predicted spans into a gold span.[6]

In Figure 3 we see that much of the performance gap between the gold and predicted parses is due to span boundary errors (*Merge Spans*, *Split Spans* and *Fix Span Boundary*), which supports the hypothesis proposed by He et al. (2017) that incorporating syntax could be particularly helpful for resolving these errors. He et al. (2017) also point out that these errors are due mainly to prepositional phrase (PP) attachment mistakes. We also find this to be the case: Figure 4 shows a breakdown of split/merge corrections by phrase type. Though the number of corrections decreases substantially across phrase types, the proportion of corrections attributed to PPs remains the same (approx. 50%) even after providing the correct PP attachment to the model, indicating that PP span boundary mistakes are a fundamental difficulty for SRL.

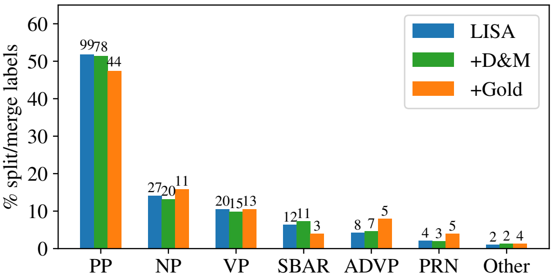

Figure 4: Percent and count of split/merge corrections performed in Figure 3, by phrase type.

5 Conclusion

We present linguistically-informed self-attention: a multi-task neural network model that effectively incorporates rich linguistic information for semantic role labeling. LISA out-performs the state-of-the-art on two benchmark SRL datasets, including out-of-domain. Future work will explore improving LISA's parsing accuracy, developing better training techniques and adapting to more tasks.

Acknowledgments

We are grateful to Luheng He for helpful discussions and code, Timothy Dozat for sharing his code, and to the NLP reading groups at Google and UMass and the anonymous reviewers for feedback on drafts of this work. This work was supported in part by an IBM PhD Fellowship Award to E.S., in part by the Center for Intelligent Information Retrieval, and in part by the National Science Foundation under Grant Nos. Abstract

Machine translation systems achieve near human-level performance on some languages, yet their effectiveness strongly relies on the availability of large amounts of parallel sentences, which hinders their applicability to the majority of language pairs. This work investigates how to learn to translate when having access to only large monolingual corpora in each language. We propose two model variants, a neural and a phrase-based model. Both versions leverage a careful initialization of the parameters, the denoising effect of language models and automatic generation of parallel data by iterative back-translation. These models are significantly better than methods from the literature, while being simpler and having fewer hyper-parameters. On the widely used WMT'14 English-French and WMT'16 German-English benchmarks, our models respectively obtain 28.1 and 25.2 BLEU points without using a single parallel sentence, outperforming the state of the art by more than 11 BLEU points. On low-resource languages like English-Urdu and English-Romanian, our methods achieve even better results than semi-supervised and supervised approaches leveraging the paucity of available bitexts. Our code for NMT and PBSMT is publicly available.[1]

1 Introduction

Machine Translation (MT) is a flagship of the recent successes and advances in the field of natural language processing. Its practical applications and use as a testbed for sequence transduction algorithms have spurred renewed interest in this topic.

While recent advances have reported near human-level performance on several language pairs using neural approaches (Wu et al., 2016; Hassan et al., 2018), other studies have highlighted several open challenges (Koehn and Knowles, 2017; Isabelle et al., 2017; Sennrich, 2017). A major challenge is the reliance of current learning algorithms on large parallel corpora. Unfortunately, the vast majority of language pairs have very little, if any, parallel data: learning algorithms need to better leverage monolingual data in order to make MT more widely applicable.

While a large body of literature has studied the use of monolingual data to boost translation performance when limited supervision is available, two recent approaches have explored the fully unsupervised setting (Lample et al., 2018; Artetxe et al., 2018), relying only on monolingual corpora in each language, as in the pioneering work by Ravi and Knight (2011). While there are subtle technical differences between these two recent works, we identify several common principles underlying their success.

First, they carefully initialize the MT system with an inferred bilingual dictionary. Second, they leverage strong language models, via training the sequence-to-sequence system (Sutskever et al., 2014; Bahdanau et al., 2015) as a denoising autoencoder (Vincent et al., 2008). Third, they turn the unsupervised problem into a supervised one by automatic generation of sentence pairs via *back-translation* (Sennrich et al., 2015a), i.e., the source-to-target model is applied to source sentences to generate inputs for training the target-to-source model, and vice versa. Finally, they constrain the latent representations produced by the encoder to be shared across the two languages. Empirically, these methods achieve remarkable results considering the fully unsupervised setting; for instance, about 15 BLEU points on the WMT'14 English-French benchmark.

The first contribution of this paper is a model

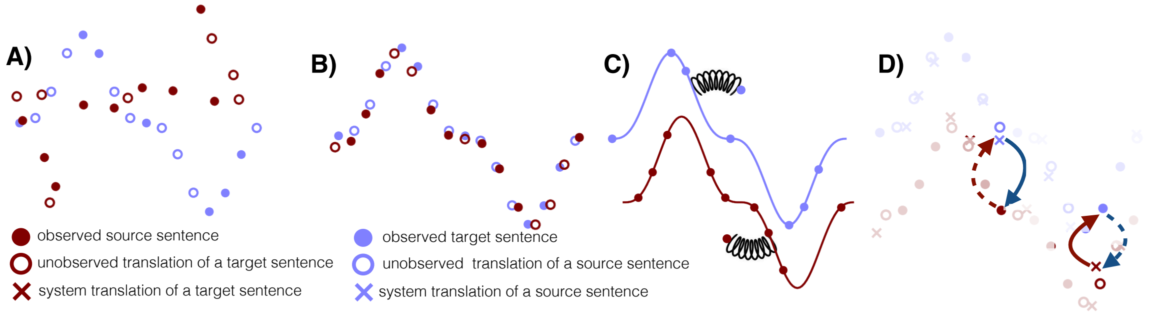

Figure 1: Toy illustration of the three principles of unsupervised MT. **A)** There are two monolingual datasets. Markers correspond to sentences (see legend for details). **B)** First principle: **Initialization**. The two distributions are roughly aligned, e.g. by performing word-by-word translation with an inferred bilingual dictionary. **C)** Second principle: **Language modeling**. A language model is learned independently in each domain to infer the structure in the data (underlying continuous curve); it acts as a data-driven prior to denoise/correct sentences (illustrated by the spring pulling a sentence outside the manifold back in). **D)** Third principle: **Back-translation**. Starting from an observed source sentence (filled red circle) we use the current source → target model to translate (dashed arrow), yielding a potentially incorrect translation (blue cross near the empty circle). Starting from this (back) translation, we use the target → source model (continuous arrow) to reconstruct the sentence in the original language. The discrepancy between the reconstruction and the initial sentence provides error signal to train the target → source model parameters. The same procedure is applied in the opposite direction to train the source → target model.

that combines these two previous neural approaches, simplifying the architecture and loss function while still following the above mentioned principles. The resulting model outperforms previous approaches and is both easier to train and tune. Then, we apply the same ideas and methodology to a traditional phrase-based statistical machine translation (PBSMT) system (Koehn et al., 2003). PBSMT models are well-known to outperform neural models when labeled data is scarce because they merely count occurrences, whereas neural models typically fit hundred of millions of parameters to learn distributed representations, which may generalize better when data is abundant but is prone to overfit when data is scarce. Our PBSMT model is simple, easy to interpret, fast to train and often achieves similar or better results than its NMT counterpart. We report gains of up to +10 BLEU points on widely used benchmarks when using our NMT model, and up to +12 points with our PBSMT model. Furthermore, we apply these methods to distant and low-resource languages, like English-Russian, English-Romanian and English-Urdu, and report competitive performance against both semi-supervised and supervised baselines.

2 Principles of Unsupervised MT

Learning to translate with only monolingual data is an ill-posed task, since there are potentially many ways to associate target with source sentences. Nevertheless, there has been exciting progress towards this goal in recent years, as discussed in the related work of Section 5. In this section, we abstract away from the specific assumptions made by each prior work and instead focus on identifying the common principles underlying unsupervised MT.

We claim that unsupervised MT can be accomplished by leveraging the three components illustrated in Figure 1: (i) suitable initialization of the translation models, (ii) language modeling and (iii) iterative back-translation. In the following, we describe each of these components and later discuss how they can be better instantiated in both a neural model and phrase-based model.

Initialization: Given the ill-posed nature of the task, model initialization expresses a natural prior over the space of solutions we expect to reach, jump-starting the process by leveraging approximate translations of words, short phrases or even sub-word units (Sennrich et al., 2015b). For instance, Klementiev et al. (2012) used a provided bilingual dictionary, while Lample et al. (2018) and Artetxe et al. (2018) used dictionaries inferred in an unsupervised way (Conneau et al., 2018; Artetxe et al., 2017). The motivating intuition is that while such initial “word-by-word” translation may be poor if languages or corpora are not closely related, it still preserves some of the original semantics.

Language Modeling: Given large amounts of monolingual data, we can train language models on both source and target languages. These models express a data-driven prior about how sentences should read in each language, and they improve the quality of the translation models by per-

Algorithm 1: Unsupervised MT

```
Language models: Learn language models $P_s$ and $P_t$ over source and target languages;
Initial translation models: Leveraging $P_s$ and $P_t$, learn two initial translation models, one in each direction: $P^{(0)}_{s\to t}$ and $P^{(0)}_{t\to s}$;
for k=1 to N do
    Back-translation: Generate source and target sentences using the current translation models, $P^{(k-1)}_{t\to s}$ and $P^{(k-1)}_{s\to t}$, factoring in language models, $P_s$ and $P_t$;
    Train new translation models $P^{(k)}_{s\to t}$ and $P^{(k)}_{t\to s}$ using the generated sentences and leveraging $P_s$ and $P_t$;
end
```

forming local substitutions and word reorderings.

Iterative Back-translation: The third principle is back-translation (Sennrich et al., 2015a), which is perhaps the most effective way to leverage monolingual data in a semi-supervised setting. Its application in the unsupervised setting is to couple the source-to-target translation system with a backward model translating from the target to source language. The goal of this model is to generate a source sentence for each target sentence in the monolingual corpus. This turns the daunting unsupervised problem into a supervised learning task, albeit with noisy source sentences. As the original model gets better at translating, we use the current model to improve the back-translation model, resulting in a coupled system trained with an iterative algorithm (He et al., 2016).

3 Unsupervised MT systems

Equipped with the three principles detailed in Section 2, we now discuss how to effectively combine them in the context of a NMT model (Section 3.1) and PBSMT model (Section 3.2).

In the reminder of the paper, we denote the space of source and target sentences by $\mathcal{S}$ and $\mathcal{T}$, respectively, and the language models trained on source and target monolingual datasets by P_s and P_t, respectively. Finally, we denote by $P_{s\to t}$ and $P_{t\to s}$ the translation models from source to target and vice versa. An overview of our approach is given in Algorithm 1.

3.1 Unsupervised NMT

We now introduce a new unsupervised NMT method, which is derived from earlier work by Artetxe et al. (2018) and Lample et al. (2018). We first discuss how the previously mentioned three key principles are instantiated in our work, and then introduce an additional property of the system, the sharing of internal representations across languages, which is specific and critical to NMT. From now on, we assume that a NMT model consists of an encoder and a decoder. Section 4 gives the specific details of this architecture.

Initialization: While prior work relied on bilingual dictionaries, here we propose a more effective and simpler approach which is particularly suitable for related languages.[2] First, instead of considering words, we consider byte-pair encodings (BPE) (Sennrich et al., 2015b), which have two major advantages: they reduce the vocabulary size and they eliminate the presence of unknown words in the output translation. Second, instead of learning an explicit mapping between BPEs in the source and target languages, we define BPE tokens by *jointly* processing both monolingual corpora. If languages are related, they will naturally share a good fraction of BPE tokens, which eliminates the need to infer a bilingual dictionary. In practice, we i) join the monolingual corpora, ii) apply BPE tokenization on the resulting corpus, and iii) learn token embeddings (Mikolov et al., 2013) on the same corpus, which are then used to initialize the lookup tables in the encoder and decoder.

Language Modeling: In NMT, language modeling is accomplished via denoising autoencoding, by minimizing:

$$\begin{aligned}\mathcal{L}^{lm} = \ & \mathbb{E}_{x\sim\mathcal{S}}[-\log P_{s\to s}(x|C(x))] + \\ & \mathbb{E}_{y\sim\mathcal{T}}[-\log P_{t\to t}(y|C(y))] \qquad (1)\end{aligned}$$

where C is a noise model with some words dropped and swapped as in Lample et al. (2018). $P_{s\to s}$ and $P_{t\to t}$ are the composition of encoder and decoder both operating on the source and target sides, respectively.

Back-translation: Let us denote by $u^*(y)$ the sentence in the source language inferred from $y \in \mathcal{T}$ such that $u^*(y) = \arg\max P_{t\to s}(u|y)$. Similarly, let us denote by $v^*(x)$ the sentence in the target language inferred from $x \in \mathcal{S}$ such that $v^*(x) = \arg\max P_{s\to t}(v|x)$. The pairs $(u^*(y), y)$ and $(x, v^*(x)))$ constitute automatically-generated parallel sentences which, following the back-translation principle, can be

---

[2] For unrelated languages, we need to infer a dictionary to properly initialize the embeddings (Conneau et al., 2018).

used to train the two MT models by minimizing the following loss:

$$\begin{aligned}\mathcal{L}^{back} &= \mathbb{E}_{y\sim\mathcal{T}}[-\log P_{s\to t}(y|u^*(y))] + \\ &\quad \mathbb{E}_{x\sim\mathcal{S}}[-\log P_{t\to s}(x|v^*(x))]. \quad (2)\end{aligned}$$

Note that when minimizing this objective function we do not back-prop through the reverse model which generated the data, both for the sake of simplicity and because we did not observe improvements when doing so. The objective function minimized at every iteration of stochastic gradient descent, is simply the sum of $\mathcal{L}^{lm}$ in Eq. 1 and $\mathcal{L}^{back}$ in Eq. 2. To prevent the model from cheating by using different subspaces for the language modeling and translation tasks, we add an additional constraint which we discuss next.

Sharing Latent Representations: A shared encoder representation acts like an interlingua, which is translated in the decoder target language regardless of the input source language. This ensures that the benefits of language modeling, implemented via the denoising autoencoder objective, nicely transfer to translation from noisy sources and eventually help the NMT model to translate more fluently. In order to share the encoder representations, we share all encoder parameters (including the embedding matrices since we perform joint tokenization) across the two languages to ensure that the latent representation of the source sentence is robust to the source language. Similarly, we share the decoder parameters across the two languages. While sharing the encoder is critical to get the model to work, sharing the decoder simply induces useful regularization. Unlike prior work (Johnson et al., 2016), the first token of the decoder specifies the language the module is operating with, while the encoder does not have any language identifier.

3.2 Unsupervised PBSMT

In this section, we discuss how to perform unsupervised machine translation using a Phrase-Based Statistical Machine Translation (PBSMT) system (Koehn et al., 2003) as the underlying backbone model. Note that PBSMT models are known to perform well on low-resource language pairs, and are therefore a potentially good alternative to neural models in the unsupervised setting.

When translating from x to y, a PBSMT system scores y according to: $\arg\max_y P(y|x) = \arg\max_y P(x|y)P(y)$, where $P(x|y)$ is derived from so called "phrase tables", and $P(y)$ is the score assigned by a language model.

Given a dataset of bitexts, PBSMT first infers an alignment between source and target phrases. It then populates phrase tables, whose entries store the probability that a certain n-gram in the source/target language is mapped to another n-gram in the target/source language.

In the unsupervised setting, we can easily train a language model on monolingual data, but it is less clear how to populate the phrase tables, which are a necessary component for good translation. Fortunately, similar to the neural case, the principles of Section 2 are effective to solve this problem.

Initialization: We populate the initial phrase tables (from source to target and from target to source) using an inferred bilingual dictionary built from monolingual corpora using the method proposed by Conneau et al. (2018). In the following, we will refer to phrases as single words, but the very same arguments trivially apply to longer n-grams. Phrase tables are populated with the scores of the translation of a source word to:

$$p(t_j|s_i) = \frac{e^{\frac{1}{T}\cos(e(t_j),We(s_i))}}{\sum_k e^{\frac{1}{T}\cos(e(t_k),We(s_i))}}, \quad (3)$$

where t_j is the j-th word in the target vocabulary and s_i is the i-th word in the source vocabulary, T is a hyper-parameter used to tune the peakiness of the distribution[3], W is the rotation matrix mapping the source embeddings into the target embeddings (Conneau et al., 2018), and $e(x)$ is the embedding of x.

Language Modeling: Both in the source and target domains we learn smoothed n-gram language models using KenLM (Heafield, 2011), although neural models could also be considered. These remain fixed throughout training iterations.

Iterative Back-Translation: To jump-start the iterative process, we use the unsupervised phrase tables and the language model on the target side to construct a seed PBSMT. We then use this model to translate the source monolingual corpus into the target language (back-translation step). Once the data has been generated, we train a PBSMT in supervised mode to map the generated data back to the original source sentences. Next, we perform

---

[3] We set $T = 30$ in all our experiments, following the setting of Smith et al. (2017).

both generation and training process but in the reverse direction. We repeat these steps as many times as desired (see Algorithm 2 in Section A).

Intuitively, many entries in the phrase tables are not correct because the input to the PBSMT at any given point during training is noisy. Despite that, the language model may be able to fix some of these mistakes at generation time. As long as that happens, the translation improves, and with that also the phrase tables at the next round. There will be more entries that correspond to correct phrases, which makes the PBSMT model stronger because it has bigger tables and it enables phrase swaps over longer spans.

4 Experiments

We first describe the datasets and experimental protocol we used. Then, we compare the two proposed unsupervised approaches to earlier attempts, to semi-supervised methods and to the very same models but trained with varying amounts of labeled data. We conclude with an ablation study to understand the relative importance of the three principles introduced in Section 2.

4.1 Datasets and Methodology

We consider five language pairs: English-French, English-German, English-Romanian, English-Russian and English-Urdu. The first two pairs are used to compare to recent work on unsupervised MT (Artetxe et al., 2018; Lample et al., 2018). The last three pairs are instead used to test our PBSMT unsupervised method on truly low-resource pairs (Gu et al., 2018) or unrelated languages that do not even share the same alphabet.

For English, French, German and Russian, we use all available sentences from the WMT monolingual News Crawl datasets from years 2007 through 2017. For Romanian, the News Crawl dataset is only composed of 2.2 million sentences, so we augment it with the monolingual data from WMT'16, resulting in 2.9 million sentences. In Urdu, we use the dataset of Jawaid et al. (2014), composed of about 5.5 million monolingual sentences. We report results on *newstest* 2014 for $en-fr$, and *newstest* 2016 for $en-de$, $en-ro$ and $en-ru$. For Urdu, we use the LDC2010T21 and LDC2010T23 corpora each with about 1800 sentences as validation and test sets, respectively.

We use Moses scripts (Koehn et al., 2007) for tokenization. NMT is trained with 60,000 BPE codes. PBSMT is trained with true-casing, and by removing diacritics from Romanian on the source side to deal with their inconsistent use across the monolingual dataset (Sennrich et al., 2016).

4.2 Initialization

Both the NMT and PBSMT approaches require either cross-lingual BPE embeddings (to initialize the shared lookup tables) or n-gram embeddings (to initialize the phrase table). We generate embeddings using fastText (Bojanowski et al., 2017) with an embedding dimension of 512, a context window of size 5 and 10 negative samples. For NMT, fastText is applied on the concatenation of source and target corpora, which results in cross-lingual BPE embeddings.

For PBSMT, we generate n-gram embeddings on the source and target corpora independently, and align them using the MUSE library (Conneau et al., 2018). Since learning unique embeddings of every possible phrase would be intractable, we consider the most frequent 300,000 source phrases, and align each of them to its 200 nearest neighbors in the target space, resulting in a phrase table of 60 million phrase pairs which we score using the formula in Eq. 3.

In practice, we observe a small but significant difference of about 1 BLEU point using a phrase table of bigrams compared to a phrase table of unigrams, but did not observe any improvement using longer phrases. Table 1 shows an extract of a French-English unsupervised phrase table, where we can see that unigrams are correctly aligned to bigrams, and vice versa.

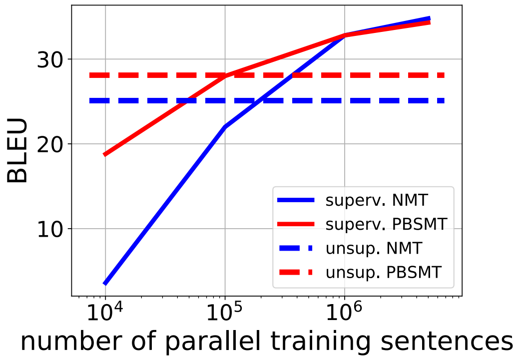

Figure 2: Comparison between supervised and unsupervised approaches on WMT'14 En-Fr, as we vary the number of parallel sentences for the supervised methods.

Model	en-fr	fr-en	en-de	de-en
(Artetxe et al., 2018)	15.1	15.6	-	-
(Lample et al., 2018)	15.0	14.3	9.6	13.3
(Yang et al., 2018)	17.0	15.6	10.9	14.6
NMT (LSTM)	24.5	23.7	14.7	19.6
NMT (Transformer)	25.1	24.2	17.2	21.0
PBSMT (Iter. 0)	16.2	17.5	11.0	15.6
PBSMT (Iter. n)	**28.1**	27.2	17.9	22.9
NMT + PBSMT	27.1	26.3	17.5	22.1
PBSMT + NMT	27.6	**27.7**	**20.2**	**25.2**

Table 2: **Comparison with previous approaches.** BLEU score for different models on the $en - fr$ and $en - de$ language pairs. Just using the unsupervised phrase table, and without back-translation (PBSMT (Iter. 0)), the PBSMT outperforms previous approaches. Combining PBSMT with NMT gives the best results.

4.3 Training

The next subsections provide details about the architecture and training procedure of our models.

4.3.1 NMT

In this study, we use NMT models built upon LSTM (Hochreiter and Schmidhuber, 1997) and Transformer (Vaswani et al., 2017) cells. For the LSTM model we use the same architecture as in Lample et al. (2018). For the Transformer, we use 4 layers both in the encoder and in the decoder. Following Press and Wolf (2016), we share all lookup tables between the encoder and the decoder, and between the source and the target languages. The dimensionality of the embeddings and of the hidden layers is set to 512. We used the Adam optimizer (Kingma and Ba, 2014) with a learning rate of 10^{-4}, $\beta_1 = 0.5$, and a batch size of 32. At decoding time, we generate greedily.

4.3.2 PBSMT

The PBSMT uses Moses' default smoothed n-gram language model with phrase reordering disabled during the very first generation. PBSMT is trained in a iterative manner using Algorithm 2. At each iteration, we translate 5 million sentences randomly sampled from the monolingual dataset in the source language. Except for initialization, we use phrase tables with phrases up to length 4.

4.4 Model selection

Moses' implementation of PBSMT has 15 hyper-parameters, such as relative weighting of each scoring function, word penalty, etc. In this work, we consider two methods to set these hyper-parameters. We either set them to their default values in the toolbox, or we set them using a small validation set of parallel sentences. It turns out that with only 100 labeled sentences in the validation set, PBSMT would overfit to the validation set. For instance, on $en \rightarrow fr$, PBSMT tuned on 100 parallel sentences obtains a BLEU score of 26.42 on *newstest* 2014, compared to 27.09 with default hyper-parameters, and 28.02 when tuned on the 3000 parallel sentences of *newstest* 2013. Therefore, unless otherwise specified, all PBSMT models considered in the paper use default hyper-parameter values, and do not use any parallel resource whatsoever.

For the NMT, we also consider two model selection procedures: an *unsupervised criterion* based on the BLEU score of a "round-trip" translation (source → target → source and target → source → target) as in Lample et al. (2018), and cross-validation using a small validation set with 100 parallel sentences. In our experiments, we found the unsupervised criterion to be highly correlated with the test metric when using the Transformer model, but not always for the LSTM. Therefore, unless otherwise specified, we select the best LSTM models using a small validation set of 100 parallel sentences, and the best Transformer models with the unsupervised criterion.

4.5 Results

The results reported in Table 2 show that our unsupervised NMT and PBSMT systems largely outperform previous unsupervised baselines. We report large gains on all language pairs and directions. For instance, on the $en \rightarrow fr$ task, our unsupervised PBSMT obtains a BLEU score of 28.1, outperforming the previous best result by more than 11 BLEU points. Even on a more complex task like $en \rightarrow de$, both PBSMT and NMT surpass the baseline score by more than 10 BLEU

	en → fr	fr→ en	en→ de	de→ en	en→ ro	ro→ en	en→ ru	ru→ en

Table 3: **Fully unsupervised results.** We report the BLEU score for PBSMT, NMT, and their combinations on 8 directed language pairs. Results are obtained on *newstest* 2014 for $en - fr$ and *newstest* 2016 for every other pair.

points. Even before iterative back-translation, the PBSMT model significantly outperforms previous approaches, and can be trained in a few minutes.

Table 3 illustrates the quality of the PBSMT model during the iterative training process. For instance, the $fr \rightarrow en$ model obtains a BLEU score of 17.5 at iteration 0 – i.e. after the unsupervised phrase table construction – while it achieves a score of 27.2 at iteration 4. This highlights the importance of multiple back-translation iterations. The last rows of Table 3 also show that we get additional gains by further tuning the NMT model on the data generated by PBSMT (PBSMT + NMT). We simply add the data generated by the unsupervised PBSMT system to the back-translated data produced by the NMT model. By combining PBSMT and NMT, we achieve BLEU scores of 20.2 and 25.2 on the challenging $en \rightarrow de$ and $de \rightarrow en$ translation tasks. While we also tried bootstraping the PBSMT model with back-translated data generated by a NMT model (NMT + PBSMT), this did not improve over PBSMT alone.

Next, we compare to fully supervised models. Figure 2 shows the performance of the same architectures trained in a fully supervised way using parallel training sets of varying size. The unsupervised PBSMT model achieves the same performance as its supervised counterpart trained on more than 100,000 parallel sentences.

This is confirmed on low-resource languages. In particular, on $ro \rightarrow en$, our unsupervised PBSMT model obtains a BLEU score of 23.9, outperforming Gu et al. (2018)'s method by 1 point, despite its use of 6,000 parallel sentences, a seed dictionary, and a multi-NMT system combining parallel resources from 5 different languages.

On Russian, our unsupervised PBSMT model obtains a BLEU score of 16.6 on $ru \rightarrow en$, showing that this approach works reasonably well on distant languages. Finally we train on $ur \rightarrow en$, which is both low resource and distant. In a supervised mode, PBSMT using the noisy and out-of-domain 800,000 parallel sentences from Tiedemann (2012) achieves a BLEU score of 9.8. Instead, our unsupervised PBSMT system achieves 12.3 BLEU using only a validation set of 1800 sentences to tune Moses hyper-parameters.

4.6 Ablation Study

In Figure 3 we report results from an ablation study, to better understand the importance of the three principles when training PBSMT. This study shows that more iterations only partially compensate for lower quality phrase table initialization (Left), language models trained over less data (Middle) or less monolingual data (Right). Moreover, the influence of the quality of the language model becomes more prominent as we iterate. These findings suggests that better initialization methods and more powerful language models may further improve our results.

We perform a similar ablation study for the NMT system (see Appendix). We find that back-translation and auto-encoding are critical components, without which the system fails to learn. We also find that initialization of embeddings is very important, and we gain 7 BLEU points compared to prior work (Artetxe et al., 2018; Lample et al., 2018) by learning BPE embeddings over the concatenated monolingual corpora.

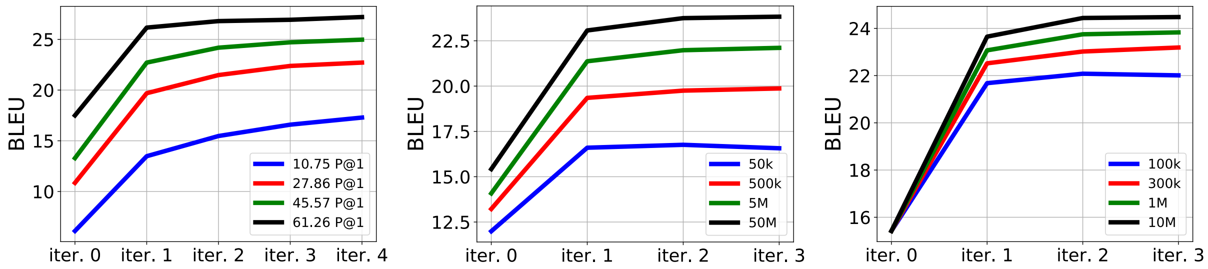

Figure 3: Results with PBSMT on the $fr \rightarrow en$ pair at different iterations. We vary: Left) the quality of the initial alignment between the source and target embeddings (measured in P@1 on the word translation task), Middle) the number of sentences used to train the language models, Right) the number of sentences used for back-translation.

5 Related Work

A large body of literature has studied using monolingual data to boost translation performance when limited supervision is available. This limited supervision is typically provided as a small set of parallel sentences (Sennrich et al., 2015a; Gulcehre et al., 2015; He et al., 2016; Gu et al., 2018; Wang et al., 2018); large sets of parallel sentences in related languages (Firat et al., 2016; Johnson et al., 2016; Chen et al., 2017; Zheng et al., 2017); cross-lingual dictionaries (Klementiev et al., 2012; Irvine and Callison-Burch, 2014, 2016); or comparable corpora (Munteanu et al., 2004; Irvine and Callison-Burch, 2013).

Learning to translate *without* any form of supervision has also attracted interest, but is challenging. In their seminal work, Ravi and Knight (2011) leverage linguistic prior knowledge to reframe the unsupervised MT task as deciphering and demonstrate the feasibility on short sentences with limited vocabulary. Earlier work by Carbonell et al. (2006) also aimed at unsupervised MT, but leveraged a bilingual dictionary to seed the translation. Both works rely on a language model on the target side to correct for translation fluency.

Subsequent work (Klementiev et al., 2012; Irvine and Callison-Burch, 2014, 2016) relied on bilingual dictionaries, small parallel corpora of several thousand sentences, and linguistically motivated features to prune the search space. Irvine and Callison-Burch (2014) use monolingual data to expand phrase tables learned in a supervised setting. In our work we also expand phrase tables, but we initialize them with an inferred bilingual n-gram dictionary, following work from the connectionist community aimed at improving PBSMT with neural models (Schwenk, 2012; Kalchbrenner and Blunsom, 2013; Cho et al., 2014).

In recent years back-translation has become a popular method of augmenting training sets with monolingual data on the target side (Sennrich et al., 2015a), and has been integrated in the “dual learning” framework of He et al. (2016) and subsequent extensions (Wang et al., 2018). Our approach is similar to the dual learning framework, except that in their model gradients are backpropagated through the reverse model and they pretrain using a relatively large amount of labeled data, whereas our approach is fully unsupervised.

Finally, our work can be seen as an extension of recent studies (Lample et al., 2018; Artetxe et al., 2018; Yang et al., 2018) on *fully unsupervised* MT with two major contributions. First, we propose a much simpler and more effective initialization method for related languages. Second, we abstract away three principles of unsupervised MT and apply them to a PBSMT, which even outperforms the original NMT. Moreover, our results show that the combination of PBSMT and NMT achieves even better performance.

6 Conclusions and Future Work

In this work, we identify three principles underlying recent successes in fully unsupervised MT and show how to apply these principles to PBSMT and NMT systems. We find that PBSMT systems often outperform NMT systems in the fully unsupervised setting, and that by combining these systems we can greatly outperform previous approaches from the literature. We apply our approach to several popular benchmark language pairs, obtaining state of the art results, and to several low-resource and under-explored language pairs.

It’s an open question whether there are more effective instantiations of these principles or other principles altogether, and under what conditions our iterative process is guaranteed to converge. Future work may also extend to the semi-supervised setting.
