In order to overcome these difficulties of discourse relation parsing in social media, we simplify and minimize the use of syntactic parsing results and capture relations between discourse arguments, and investigate the use of a recursive neural network model (RNN). Recent work has shown that RNNs are effective for utilizing discourse structures for their downstream tasks (Ji and Smith, 2017; Bhatia et al., 2015; Wieting et al., 2015; Paulus et al., 2014), but they have yet to be directly used for discourse relation prediction in social media. We evaluated our model by comparing it to off-the-shelf end-to-end discourse relation parsers and traditional models. We found that the SVM and random forest classifiers work better than the LSTM classifier for the causality detection, while the LSTM classifier outperforms other models for identifying causal explanation.

The contributions of this work include: (1) the proposal of models for both (a) causality prediction and (b) causal explanation identification, (2) the extensive evaluation of a variety of models from social media classification models and discourse relation parsers to RNN-based application models, demonstrating that feature-based models work best for causality prediction while RNNs are superior for the more difficult task of causal explanation identification, (3) performance analysis on architectural differences of the pipeline and the classifier structures, (4) exploration of the applications of causal explanation to downstream tasks, and (5) release of a novel, anonymized causality Facebook dataset along with our causality prediction and causal explanation identification models.

2 Related Work

Identifying causal explanations in documents can be viewed as discourse relation parsing. The Penn Discourse Treebank (PDTB) (Prasad et al., 2007) has a 'Cause' and 'Pragmatic Cause' discourse type under a general 'Contingency' class and Rhetorical Structure Theory (RST) (Mann and Thompson, 1987) has a 'Relations of Cause'. In most cases, the development of discourse parsers has taken place *in-domain*, where researchers have used the existing annotations of discourse arguments in newswire text (e.g. Wall Street Journal) from the discourse treebank and focused on exploring different features and optimizing various types of models for predicting relations (Pitler et al., 2009; Park and Cardie, 2012; Zhou et al., 2010). In order to further develop automated systems, researchers have proposed end-to-end discourse relation parsers, building models which are trained and evaluated on the annotated PDTB and RST Discourse Treebank (RST DT). These corpora consist of documents from Wall Street Journal (WSJ) which are much more well-organized and grammatical than social media texts (Biran and McKeown, 2015; Lin et al., 2014; Ji and Eisenstein, 2014; Feng and Hirst, 2014).

Only a few works have attempted to parse discourse relations for out-of-domain problems such as text categorizations on social media texts; Ji and Bhatia used models which are pretrained with RST DT for building discourse structures from movie reviews, and Son adapted the PDTB discourse re-

---

[1] Off-the-shelf Penn Discourse Treebank (PDTB) end-to-end parsers perform poorly on our Facebook causal prediction dataset (see Table 3)

[2] Each discourse relation theory uses a different term for minimal discourse text spans: 'Elementary Discourse Unit (EDU)' in RST and 'Discourse Argument' in PDTB. We will call it 'Discourse Argument' in this paper, since we adapted the PDTB text segmentation method.

lation parsing approach for capturing counterfactual conditionals from tweets (Bhatia et al., 2015; Ji and Smith, 2017; Son et al., 2017). These works had substantial differences to what propose in this paper. First, Ji and Bhatia used a pretrained model (not fully optimal for some parts of the given task) in their pipeline; Ji's model performed worse than the baseline on the categorization of legislative bills, which is thought to be due to legislative discourse structures differing from those of the training set (WSJ corpus). Bhatia also used a pretrained model finding that utilizing discourse relation features did not boost accuracy (Bhatia et al., 2015; Ji and Smith, 2017). Both Bhatia and Son used manual schemes which may limit the coverage of certain types of positive samples–Bhatia used a hand-crafted schema for weighting discourse structures for the neural network model and Son manually developed seven surface forms of counterfactual thinking for the rule-based system (Bhatia et al., 2015; Son et al., 2017). We use social-media-specific features from pretrained models which are directly trained on tweets and we avoid any hand-crafted rules except for those included in the existing discourse argument extraction techniques.

The automated systems for discourse relation parsing involve multiple subtasks from segmenting the whole text into discourse arguments to classifying discourse relations between the arguments. Past research has found that different types of models and features yield varying performance for each subtask. Some have optimized models for discourse relation classification (i.e. given a document indicating if the relation existing) without discourse argument parsing using models such as Naive-Bayes or SVMs, achieve relatively stronger accuracies but a simpler task than that associated with discourse arguments (Park and Cardie, 2012; Zhou et al., 2010; Pitler et al., 2009). Researchers who, instead, tried to build the end-to-end parsing pipelines considered a wider range of approaches including sequence models and RNNs (Biran and McKeown, 2015; Feng and Hirst, 2014; Ji and Eisenstein, 2014; Li et al., 2014). Particularly, when they tried to utilize the discourse structures for out-domain applications, they used RNN-based models and found that those models are advantageous for their downstream tasks (Bhatia et al., 2015; Ji and Smith, 2017).

In our case, for identifying causal explanations from social media using discourse structure, we build an RNN-based model for its structural effectiveness in this task (see details in section 3.2). However, we also note that simpler models such as SVMs and logistic regression obtained the state-of-the-art performances for text categorization tasks in social media (Lynn et al., 2017; Mohammad et al., 2013), so we build relatively simple models with different properties for each stage of the full pipeline of our parser.

3 Methods

We build our model based on PDTB-style discourse relation parsing since PDTB has a relatively simpler text segmentation method;[3] for explicit discourse relations, it finds the presence of discourse connectives within a document and extracts discourse arguments which parametrize the connective while for implicit relations, it considers all adjacent sentences as candidate discourse arguments.

3.1 Dataset

We created our own causal explanation dataset by collecting 3,268 random Facebook status update messages. Three well-trained annotators manually labeled whether or not each message contains the causal explanation and obtained 1,600 causality messages with substantial agreement ($\kappa = 0.61$). We used the majority vote for our gold standard. Then, on each causality message, annotators identified which text spans are causal explanations.

For each task, we used 80% of the dataset for training our model and 10% for tuning the hyperparameters of our models. Finally, we evaluated all of our models on the remaining 10% (Table 1 and Table 2). For causal explanation detection task, we extracted discourse arguments using our parser and selected discourse arguments which most cover the annotated causal explanation text span as our gold standard.

3.2 Model

We build two types of models. First, we develop feature-based models which utilize features of the successful models in social media analysis and causal relation discourse parsing. Then, we

---

[3] RST parsing builds fully hierarchical discourse tree structures out of the whole span of target text which highly depends on syntactic parsing and exact matching of elementary discourse units which are extremely hard to obtain from social media texts

Dataset	Causality	Non-Causal	Total
Training	1,284	1,330	2,614
Validation	150	177	327
Test	164	163	327
Total	1,598	1,670	3,268

Table 1: Number of messages containing causality or not in our dataset.

Causality messages	CE DA	Total DA
Training	1,278	5,606
Validation	160	652
Test	160	757
Total	1,598	7,015

Table 2: The number of discourse arguments in causality messages. Across 1,598 total causality messages, we found 7,015 discourse arguments (Total DA) and the one which covers annotated causal explanation are used as causal explanation discourse arguments (CE DA)

build a recursive neural network model which uses distributed representation of discourse arguments as this approach can even capture latent properties of causal relations which may exist between distant discourse arguments. We specifically selected bidirectional LSTM since the model with the discourse distributional structure built in this form outperformed the traditional models in similar NLP downstream tasks (Ji and Smith, 2017).

Discourse Argument Extraction As the first step of our pipeline, we use Tweebo parser (Kong et al., 2014) to extract syntactic features from messages. Then, we demarcate sentences using punctuation (',') tag and periods. Among those sentences, we find discourse connectives defined in PDTB annotation along with a Tweet POS tag for conjunction words which can also be a discourse marker. In order to decide whether these connectives are really discourse connectives (e.g., I went home, **but** he stayed) as opposed to simple connections of two words (I like apple **and** banana) we see if verb phrases [4] exist before and after the connective by using dependency parsing results. Although discourse connective disambiguation is a complicated task which can be much improved by syntactic features (Pitler and Nenkova, 2009), we try to minimize effects of syntactic parsing and simplify it since it is highly error-prone in social media. Finally, according to visual inspection, emojis ('E' tag) are crucial for discourse relation in social media so we take them as separate discourse arguments (e.g.,in "My test result... :(" the sad feeling is caused by the test result, but it cannot be captured by plain word tokens).

Feature Based Models We trained a linear SVM, an rbf SVM, and a random forest with N-gram, charater N-gram, and tweet POS tags, sentiment tags, average word lengths and word counts from each message as they have a pivotal role in the models for many NLP downstream tasks in social media (Mohammad et al., 2013; Lynn et al., 2017). In addition to these features, we also extracted *First-Last, First3* features and *Word Pairs* from every adjacent pair of discourse arguments since these features were most helpful for causal relation prediction (Pitler et al., 2009). *First-Last, First3* features are first and last word and first three words of two discourse arguments of the relation, and *Word Pairs* are the cross product of words of those discourse arguments. These two features enable our model to capture interaction between two discourse arguments. (Pitler et al., 2009) reported that these two features along with verbs, modality, context, and polarity (which can be captured by N-grams, sentiment tags and POS tags in our previous features) obtained the best performance for predicting Contingency class to which causality belongs.

Recursive Neural Network Model We load the GLOVE word embedding (Pennington et al., 2014) trained in Twitter [5] for each token of extracted discourse arguments from messages. For the distributional representation of discourse arguments, we run a Word-level LSTM on the words' embeddings within each discourse argument and concatenate last hidden state vectors of forward LSTM ($\overrightarrow{h}$) and backward LSTM ($\overleftarrow{h}$) which is suggested by (Ji and Smith, 2017) ($DA = [\overrightarrow{h}; \overleftarrow{h}]$). Then, we feed the sequence of the vector representation of discourse arguments to the Discourse-argument-level LSTM (DA-level LSTM) to make a final prediction with log softmax function. With this structure, the model can learn the representation of interaction of tokens inside each discourse argument, then capture discourse relations across all of the discourse argu-

---

[4] minimal discourse unit is verb phrases with very few exceptions (Prasad et al., 2007)

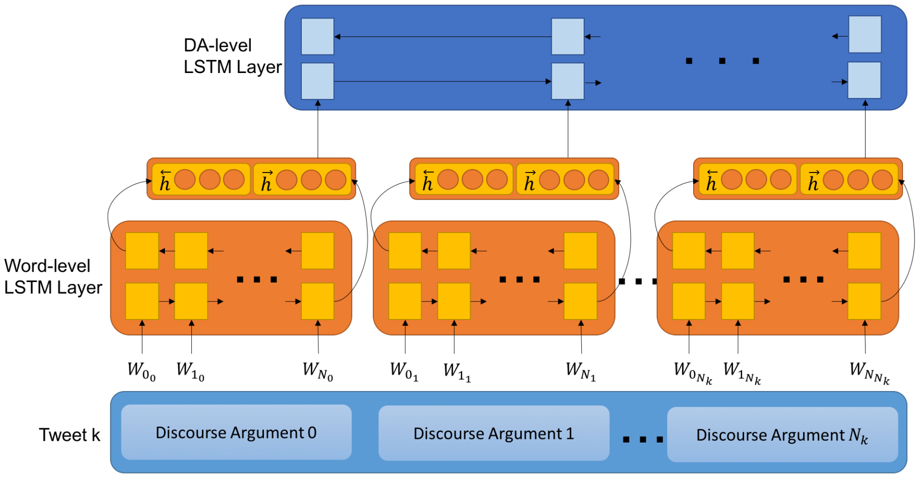

Figure 2: LSTM classifier for causality detection and explanation identification

ments in each message (Figure 2). In order to prevent the overfitting, we added a dropout layer between the Word-level LSTM and the DA-level LSTM layer.

Architectural Variants We also explore subsets of the full RNN architecture, specifically with one of the two LSTM layers removed. In the first model variant, we directly input all word embeddings of a whole message to a BiLSTM layer and make prediction (**Word LSTM**) without the help of the distributional vector representations of discourse arguments. In the second model variant, we take the average of all word embeddings of each discourse argument ($DA_k = \frac{1}{N_k}\sum_{i=1}^{N_k} W_i$), and use them as inputs to a BiLSTM layer (**DA AVG LSTM**) as the average vector of embeddings were quite effective for representing the whole sequence (Ji and Smith, 2017; Wieting et al., 2015). As with the full architectures, for CP both of these variants ends with a many-to-one classification per message, while the CEI model ends with a sequence of classifications.

3.3 Experiment

Feature Based Model We explored three types of models (RBF SVM, Linear SVM, and Random Forest Classifier) which have previously been shown empirically useful for the language analysis in social media. We filtered out low frequency **Word Pairs** features as they tend to be noisy and sparse (Pitler et al., 2009). Then, we conducted univariate feature selection to restrict all remaining features to those showing at least a small relationship with the outcome. Specifically, we keep all features passing a family-wise error rate of $\alpha = 60$ with the given outcome. After comparing the performance of the optimized version of each model, we also conducted a feature ablation test on the best model in order to see how much each feature contributes to the causality prediction.

Neural Network Model We used bidirectional LSTMs for causality classification and causal explanation identification since the discourse arguments for causal explanation can show up either before and after the effected events or results and we want our model to be optimized for both cases. However, there is a risk of overfitting due to the dataset which is relatively small for the high complexity of the model, so we added a dropout layer (p=0.3) between the Word-level LSTM and the DA-level LSTM.

For tuning our model, we explore the dimensionality of word vector and LSTM hidden state vectors of discourse arguments of 25, 50, 100, and 200 as pretrained GLOVE vectors were trained in this setting. For optimization, we used Stochastic Gradient Descent (SGD) and Adam (Kingma and Ba, 2014) with learning rates 0.01 and 0.001.

We ignore missing word embeddings because our dataset is quite small for retraining new word embeddings. However, if embeddings are extracted as separate discourse arguments, we used the average of all vectors of all discourse arguments in that message. Average embeddings have performed well for representing text sequences in other tasks (Wieting et al., 2015).

Model	F1
(Biran and McKeown, 2015)	0.434

- POS tags	0.734
- (Char + Word) N-grams	0.769
- Sentiment tags	0.791

Table 4: Feature ablation test of Linear SVM for causality prediction

Model Evaluation We first use state-of-the-art PDTB taggers for our baseline (Lin et al., 2014; Biran and McKeown, 2015) for the evaluation of the causality prediction of our models ((Biran and McKeown, 2015) requires sentences extracted from the text as its input, so we used our parser to extract sentences from the message). Then, we compare how models work for each task and disassembled them to inspect how each part of the models can affect their final prediction performances. We conducted McNemar's test to determine whether the performance differences are statistically significant at $p < .05$.

4 Results

We investigated various models for both causality detection and explanation identification. Based on their performances on the task, we analyzed the relationships between the types of models and the tasks, and scrutinized further for the best performing models. For performance analysis, we reported weighted F1 of classes.

4.1 Causality Prediction

In order to classify whether a message contains causal relation, we compared off-the-shelf PDTB parsers, linear SVM, RBF SVM, Random forest and LSTM classifiers. The off-the-shelf parsers achieved the lowest accuracies ((Biran and McKeown, 2015) and (Lin et al., 2014) in Table 3). This result can be expected since 1) these models were trained with news articles and 2) they are trained for all possible discourse relations in addition to causal relations (e.g., contrast, condition, etc). Among our suggested models, SVM and random forest classifier performed better than LSTM and, in the general trend, the more complex the models were, the worse they performed. This suggests that the models with more direct and simpler learning methods with features might classify the causality messages better than the ones more optimized for capturing distributional information or non-linear relationships of features.

Model	Prec	Rec	F1
Linear SVM	0.773	0.727	0.743
RBF SVM	0.773	0.727	0.743
Random Forest	0.747	0.790	0.746
LSTM	**0.851**	**0.858**	**0.853**

Table 5: Causal explanation identification performance. Bold indicates significant imrpovement over next best model ($p < .05$)

Causality Classifier Analysis Table 4 shows the results of a feature ablation test to see how each feature contributes to causality classification performance of the linear SVM classifier. POS tags caused the largest drop in F1. We suspect POS tags played a unique role because discourse connectives can have various surface forms (e.g., because, cuz, bcuz, etc) but still the same POS tag 'P'. Also POS tags can capture the occurrences of modal verbs, a feature previously found to be very useful for detecting similar discourse relations (Pitler et al., 2009). N-gram features caused 0.022 F1 drop while sentiment tags did not affect the model when removed. Unlike the previous work where *First-Last, First3* and *Word pairs* tended to gain a large F1 increase for multiclass discourse relation prediction, in our case, they did not affect the prediction performance compared to other feature types such as POS tags or N-grams.

4.2 Causal Explanation Identification

In this task, the model identifies causal explanations given the discourse arguments of the causality message. We explored over the same models as those we used for causality (sans the output layer), and found the almost opposite trend of performances (see Table 5). The Linear SVM ob-

Model	CP (F1)	CEI (F1)
Full LSTM	0.758	0.853
DA AVG LSTM	0.685	0.818
Word LSTM	0.694	0.792

Table 6: The effect of Word-level LSTM (Word LSTM) and discourse argument LSTM (DA AVG LSTM) for causality prediction (CP) and causal explanation identification (CEI). Note that, as described in methods, there are architectural differences for CP and CEI models with the same names, most notably that the output layer is always a single classification for CP and a sequence of classifications for CEI.

tained lowest F1 while the LSTM model made the best identification performance. As opposed to the simple binary classification of the causality messages, in order to detect causal explanation, it is more beneficial to consider the relation across discourse arguments of the whole message and implicit distributional representation due to the implicit causal relations between two distant arguments.

4.3 Architectural Variants

For causality prediction, we experimented with only word tokens in the whole message without help of Word-level LSTM layer (**Word LSTM**), and F1 dropped by 0.064 (CP in Table 6). Also, when we used the average of the sequence of word embeddings of each discourse argument as an input to the DA-level LSTM and it caused F1 drop of 0.073. This suggests that the information gained from both the interaction of words in and in between discourse arguments help when the model utilizes the distributional representation of the texts.

For causal explanation identification, in order to test how the LSTM classifier works without its capability of capturing the relations between discourse arguments, we removed DA-level LSTM layer and ran the LSTM directly on the word embedding sequence for each discourse argument for classifying whether the argument is causal explanation, and the model had 0.061 F1 drop (**Word LSTM** in CEI in Table 6). Also, when we ran DA-level LSTM on the average vectors of the word sequences of each discourse argument of messages, F1 decreased to 0.818. This follows the similar pattern observed from other types of models performances (i.e., SVMs and Random Forest classifiers) that the models with higher complexity for capturing the interaction of discourse arguments tend to identify causal explanation with the higher accuracies.

For CEI task, we found that when the model ran on the sequence representation of discourse argument (**DA AVG LSTM**), its performance was higher than the plain sequence of word embeddings (**Word LSTM**). Finally, in both subtasks, when the models ran on both Word-level and DA-Level (**Full LSTM**), they obtained the highest performance.

Model	Prec	Rec	F1
CP + CEI$_{causal}$	**0.864**	**0.877**	**0.868**
CP + CEI$_{all}$	0.842	0.864	0.848
CEI$_{causal}$ Only	0.847	0.788	0.810
CEI$_{all}$ Only	0.836	0.848	0.842

Table 7: The effect of Linear SVM Cauality model (CP) within our pipeline. CEI$_{all}$: LSTM CEI models trained on all messages; CEI$_{causal}$: LSTM CEI models trained only on causality messages (CEI$_{causal}$); CP + CEI$_{all|causal}$: the combination of Linear SVM and each LSTM model. Bold: significant ($p < .05$) increase in F1 over the next best model, suggesting the two-step approach worked best.

4.4 Complete Pipeline

Evaluations thus far zeroed-in on each subtask of causal explanation analysis (i.e. CEI only focused on data already identified to contain causal explanations). Here, we seek to evaluate the complete pipeline of CP and CEI, starting from all of test data (those or without causality) and evaluating the final accuracy of CEI predictions. This is intended to evaluate CEI performance under an applied setting where one does not already know whether a document has a causal explanation.

There are several approaches we could take to perform CEI starting from unannotated data. We could simply run CEI prediction by itself (**CEI Only**) or the pipeline of CP first and then only run CEI on documents predicted as causal (**CP + CEI**). Further, the CEI model could be trained only on those documents annotated causal (as was done in the previous experiments) or on all training documents including many that are not causal.

Table 7 show results varying the pipeline and how CEI was trained. Though all setups performed decent ($F1 > 0.81$) we see that the pipelined approach, first predicting causality (with the linear SVM) and then predicting causal explanations only for those with marked causal (CP + CEI$_{causal}$) yielded the strongest results. This also utilized the CEI model only trained on those annotated causal. Besides performance, an added benefit from this two step approach is that the CP step is less computational intensive of the CEI step and approximately 2/3 of documents will never need the CEI step applied.

Limitations. We had an inevitable limitation on the size of our dataset, since there is no other causality dataset over social media and the annotation required an intensive iterative process. This might have limited performances of more complex models, but considering the processing time and the computation load, the combination of the linear model and the RNN-based model of our pipeline obtained both the high performance and efficiency for the practical applications to downstream tasks. In other words, it's possible the linear model will not perform as well if the training size is increased substantially. However, a linear model could still be used to do a first-pass, computationally efficient labeling, in order to shortlist social media posts for further labeling from an LSTM or more complex model.

5 Exploration

Here, we explore the use of causal explanation analysis for downstream tasks. First we look at the relationship between use of causal explanation and one's demographics: age and gender. Then, we consider their use in sentiment analysis for extracting the causes of polarity ratings. Research involving human subjects was approved by the University of Pennsylvania Institutional Review Board.

Demographic differences. We first explored variance in number of causality posts by demographics. To do this, we used self-authored posts from a random 300 consenting-users of the MyPersonality dataset (Kosinski et al., 2013). For each user we calculate a cp_ratio, defined as the number of causality predicted posts divided by their total number of posts, indicating the percentage of their posts which include a causal explanation. We then correlated this ratio with real-valued age using Pearson correlation and looked the differences by dichotomous gender using Cohen's d (the difference in standardized means; only binary gender was available). We found significant ($p < .05$) moderate-sized associations for both, indicating both older individuals and females were likely to use more causal explanations.

	CE Top Ngrams	**Non-CE** Top Ngrams
1	worst	not
2	was	no
3	not	”

5	horrible	she
6	rude	told
7	bad	said
8	overpriced	minutes
9	over	?
10	slow	me

Table 8: Top words most associated with negative reviews from within causal explanations (CE) and outside of causal explanation (Non-CE).

Causality in Sentiment Analysis We explored the application of causality explanation identification for sentiment analysis using the Yelp polarity dataset (Zhang et al., 2015). We randomly selected 10,000 of both positive and negative reviews and ran our complete pipeline on them to extract the causal explanations from the reviews. We then analyzed the ngrams from (a) causal explanation and (b) all other discourse arguments testing for associations with polarity. We used the a Bayesian interpretation of the log odds ratio using an informative dirichlet prior defined by Monroe et al. (2008). We found difference in the top ngrams depending on whether the argument the ngram originated from was a causal explanation or not (see Table 8). Top ngrams for causal explanations included more content words (e.g. 'rude', 'overpriced', 'slow') suggesting analyzing causal explanations within reviews can better target the *reasons* for the negative review.

6 Conclusion

We developed a pipeline for causal explanation analysis over social media text, including both causality prediction and causal explanation identification. We examined a variety of model types and RNN architectures for each part of the pipeline, finding an SVM best for causality prediction and a hierarchy of BiLSTMs for causal explanation identification, suggesting the later task relies more heavily on sequential information. In fact, we found replacing either layer of the hierarchical LSTM architecture (the word-level or the DA-level) with a an equivalent "bag of features" approach resulted in reduced accuracy. Results of our whole pipeline of causal explanation analysis were found quite strong, achieving an $F1 = 0.868$ at identifying discourse arguments that are causal explanations.

Finally, we demonstrated use of our models in applications, finding associations between demographics and rate of mentioning causal explanations, as well as showing differences in the top words predictive of negative ratings in Yelp reviews. Utilization of discourse structure in social media analysis has been a largely untapped area of exploration, perhaps due to its perceived difficulty. We hope the strong results of causal explanation identification here leads to the integration of more syntax and deeper semantics into social media analyses and ultimately enables new applications beyond the current state of the art.

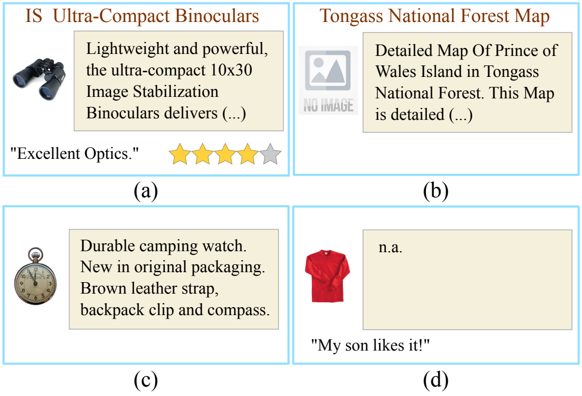
Abstract

Multimodal learning has shown promising performance in content-based recommendation due to the auxiliary user and item information of multiple modalities such as text and images. However, the problem of incomplete and missing modality is rarely explored and most existing methods fail in learning a recommendation model with missing or corrupted modalities. In this paper, we propose LRMM, a novel framework that mitigates not only the problem of missing modalities but also more generally the cold-start problem of recommender systems. We propose modality dropout (*m*-drop) and a multimodal sequential autoencoder (*m*-auto) to learn multimodal representations for complementing and imputing missing modalities. Extensive experiments on real-world Amazon data show that LRMM achieves state-of-the-art performance on rating prediction tasks. More importantly, LRMM is more robust to previous methods in alleviating data-sparsity and the cold-start problem.

1 Introduction

Recommender systems (RS) are useful filtering tools which aid customers in a personalized way to make better purchasing decisions and whose recommendations are based on the customer's preferences and purchasing histories. Recommender systems can be roughly divided into collaborative filtering (CF) (Koren et al., 2009) or content-based filtering (CBF) (Pazzani and Billsus, 2007) methods. CF-based methods predict the product preference of users based on their previous purchasing and reviewing behavior by computing latent representations of users and products. Standard matrix factorization (MF) and its variants are widely used in CF approaches (Koren et al., 2009). While CF-based approaches were demonstrated to perform well in many application domains (Ricci et al., 2015), these methods are based solely on the sparse user-item rating matrix and, therefore, suffer from the so-called *cold-start* problem (Schein et al., 2002; Huang and Lin, 2016; Wang et al., 2017) as shown in Figure 1(b)+(c). For new users without a rating history and newly added products with few or no ratings, the systems fail to generate high-quality personalized recommendations.



(a) (b) (c) (d)

Figure 1: Examples of typical multimodal product data from online retailers: image, title, description, reviews, star ratings. The cold-start problem is present in cases (b) and (c) where neither review text nor ratings are available.

Alternatively, CBF approaches incorporate auxiliary modalities/information such as product descriptions, images, and user reviews to alleviate the cold-start problem by leveraging the correlations between multiple data modalities. Unfortunately, a pure CBF method often suffers difficulties in generating a recommendation on incomplete and missing data (Sedhain et al., 2015; Wang et al., 2016b; Volkovs et al., 2017; García-Durán et al., 2018).

In this work, a multimodal imputation framework (LRMM) is proposed to make RS robust to incomplete and missing modalities. First, LRMM learns multimodal correlations (Ngiam et al., 2011; Srivastava and Salakhutdinov, 2012;

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3360–3370
Brussels, Belgium, October 31 - November 4, 2018.

Wang et al., 2016a, 2018) from product images, product metadata (title+description), and product reviews. We propose modality dropout (*m*-drop) which randomly drops representations of some data modalities. In combination with the modality dropout approach, a sequential autoencoder (*m*-auto) for multi-modal data is trained to reconstruct missing modalities and, at test time, is used to impute missing modalities through its learned reconstruction function.

Multimodal imputation for recommender systems is a non-trivial issue. (1) Existing RS methods usually assume that all data modalities are available during training and inference. In practice, however, incomplete and missing data modalities are very common. (2) At its core it addresses the cold-start problem. In the context of missing modalities, cold-start can be viewed as missing user or item preference information.

With this paper we make the following contributions:

- For the first time, we introduce multimodal imputation in the context of recommender systems.
- We reformulate the data-sparsity and cold-start problem when data modalities are missing.
- We show that the proposed method achieves state-of-the-art results and is competitive with or outperforms existing methods on multiple data sets.
- We conduct additional extensive experiments to empirically verify that our approach alleviates the missing data modalities problem.

The rest of paper is structured as follows: Section 2 introduces our proposed methods. Section 3 describes the experiments and reports on the empirical results. In section 4 we discuss the method and its advantages and disadvantages, and in section 5 we discuss related work. Section 6 concludes this work.

2 Proposed Methods

The general framework of LRMM is depicted in Figure 2. There are two objectives for LRMM: (1) learning multimodal embeddings that capture inter-modal correlations, complementing missing modalities (Sec. 2.1); (2) learning intra-modal distributions where missing modalities are reconstructed via a missing modality imputation mechanism (sec. 2.2 and 2.3).

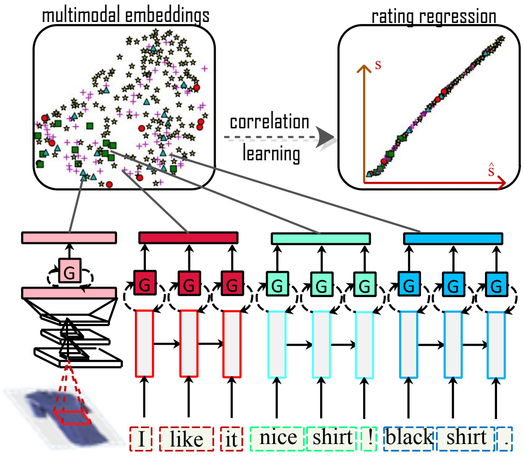

Figure 2: Overview of LRMM. It adopts CNN for visual embeddings (pink part) and three LSTMs for textual embeddings of user review text (red part), item review text (green part) and item metadata (blue part), respectively. The generative (autoencoder) model is used to reconstruct modality-specific embeddings and impute missing modality. Missing user and item review text lead to user- and item-based cold-start respectively.

2.1 Learning Multimodal Embeddings

We denote a user $\mathbf{u}$ having k review texts as $\mathbf{r}^u{=}(r^u_{o_1}, r^u_{o_2}, ..., r^u_{o_k})$ where $r^u_{o_i}$ represents review text written by $\mathbf{u}$ for item o_i. An item $\mathbf{o}$ is denoted as $\mathbf{r}^o{=}(r^o_{u_1}, r^o_{u_2}, ..., r^o_{u_p})$ where $r^o_{u_j}$ represents the review text written by user $\mathbf{u}_j$ for item $\mathbf{o}$. Following Zheng et al. (2017), to represent each user and item, the reviews of $\mathbf{u}$ and $\mathbf{o}$ are concatenated into one review history document:

$$\mathbf{D}^u = r^u_{o_1} \oplus r^u_{o_2} \oplus, ..., \oplus r^u_{o_k} \tag{1}$$

$$\mathbf{D}^o = r^o_{u_1} \oplus r^o_{u_2} \oplus, ..., \oplus r^o_{u_p} \tag{2}$$

where $\oplus$ is the concatenation operator. Similarly, the metadata of each item $\mathbf{o}$ can be represented as $\mathbf{D}^m$. For readability, we use u, o, m, v to denote user, item, metadata, and the image modality, respectively.

For text-based representation learning for user and item, unlike Zheng et al. (2017) in which CNNs (Convolutional Neural Networks) with Word2Vec (Mikolov et al., 2013) are employed, our method treats text as sequential data and learns embeddings over word sequences by maximizing the following probabilities:

$$p(\mathbf{x}_1^g, ..., \mathbf{x}_T^g) = \prod\nolimits_{t=1}^{T^g} p(\mathbf{x}_t^g | \mathbf{x}_1^g, ..., \mathbf{x}_{t-1}^g) \quad (3)$$

$$p(\mathbf{x}_t^g | \mathbf{x}_1^g, ..., \mathbf{x}_{t-1}^g) = p(\mathbf{x}_t^g | \mathbf{e}_t^g) \quad (4)$$

$$\mathbf{e}_t^g = \mathcal{M}^g(\mathbf{e}_{t-1}^g, \mathbf{x}_t^g; \mathbf{\Theta}^g) \quad (5)$$

where $\mathcal{M}^g$, $g \in \{u, o, m\}$ is a recurrent model and $(\mathbf{x}_1^g, ..., \mathbf{x}_T^g)$ is the word sequence of either review or metadata text, each $\mathbf{x}_t^g \in \mathcal{V}$ and $\mathcal{V}$ is a vocabulary set. T^g is the length of input and output sequence and $\mathbf{e}_t^g$ is the hidden state computed from the corresponding LSTM (Long Short Term Memory) (Hochreiter and Schmidhuber, 1997) by:

$$\begin{pmatrix} \mathbf{i}_t \\ \mathbf{f}_t \\ \mathbf{o}_t \\ \mathbf{g}_t \end{pmatrix} = \begin{pmatrix} \text{sigm} \\ \text{sigm} \\ \text{sigm} \\ \text{tanh} \end{pmatrix} \mathbf{W} \begin{pmatrix} \mathbf{x}_t \\ \mathbf{h}_{t-1} \end{pmatrix} \quad (6)$$

$$\mathbf{c}_t = \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \mathbf{g}_t \quad (7)$$

$$\mathbf{h}_t = \mathbf{o}_t \odot \tanh(\mathbf{c}_t) \quad (8)$$

where $\mathbf{i}_t$, $\mathbf{f}_t$ and $\mathbf{o}_t$ are input, forget and output gate respectively, $\mathbf{c}_t$ is memory cell, $\mathbf{h}_t$ is the hidden output that we used for computing user or item embedding $\mathbf{e}^g$, $g \in \{u, o, m\}$.

As we treat each text document $\mathbf{D}^g$ as a word sequence of length T^g, we adopt average pooling on word embeddings for each modality to obtain document-level representations:

$$\mathbf{e}^g = \frac{\sum_{t \in T^g,\, g \in \{u,o,m\}} \mathbf{e}_t^g}{T^g} \quad (9)$$

Visual embeddings $\mathbf{e}^v$ are extracted with a pretrained CNN and transformed by a function f

$$\mathbf{e}^v = f(\text{CNN}(I, \mathbf{\Theta}_c); \mathbf{\Theta}_f), \quad (10)$$

where $\mathbf{\Theta}_f \in \mathbb{R}^{4096 \times d}$ to ensure $\mathbf{e}^v$ has same dimension as the user $\mathbf{e}^u$, item $\mathbf{e}^o$, and metadata embedding $\mathbf{e}^m$. The multimodal joint embedding then can be learned by a shared layer and used for making a prediction:

$$\hat{\mathbf{s}} = f_s(\mathbf{W}_s(\mathbf{e}^u \oplus \mathbf{e}^o \oplus \mathbf{e}^m \oplus \mathbf{e}^v) + \mathbf{b}_s) \quad (11)$$

where $f_s : \mathbb{R}^{4 \times d} \to \mathbb{R}^1$, parameterized with $\mathbf{W}_s$ and $\mathbf{b}_s$, is a scoring function to map the multimodal joint embedding to a rating score.

2.2 Modality Dropout

Modality dropout (*m*-drop) is designed to remove a data modality during training according to some parametric distribution. This is motivated by dropout (Srivastava et al., 2014) which randomly masks hidden layer activations to zero to increase the generalization capability of the underlying model. More formally, *m*-drop changes the original feed-forward equation:

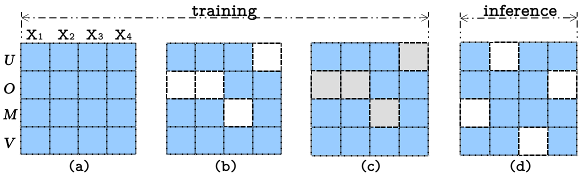

Figure 3: Missing modality imputation. (a) Full training data, (b) *m*-drop randomly drops modalities, (c) *m*-auto learns to reconstruct missing data based on existing data. (d) Inference with missing modalities. Dropping user and item view is equivalent to learning models being able to address cold-start problem.

$$\mathbf{Z}^{(L+1)} = \varphi(\mathbf{W}^{(L+1))}\mathbf{X}^{(L)} + \mathbf{b}^{(L+1)}) \quad (12)$$

being able to randomly drop modality by:

$$r^{(L)} \sim \text{Bernoulli}\ (p_m) \quad (13)$$

$$k^{(L)} \sim \text{Bernoulli}\ (1 - 1/n_m) \quad (14)$$

$$\widetilde{\mathbf{X}}^{(L)} = (\mathbf{X}^{(L)} \odot \mathbf{r}^{(L)}) \odot \mathbf{k}^{(L)} \quad (15)$$

$$\mathbf{Z}^{(L+1)} = \varphi(\mathbf{W}^{(L+1))}\widetilde{\mathbf{X}}^{(L)} + \mathbf{b}^{(L+1)}) \quad (16)$$

where each sample $\mathbf{X}_1 = x_1, ..., x_{n_m}$ and n_m is the number of modalities. $\mathbf{r}^{(L)}$ is a vector of independent Bernoulli random variables each of which has probability p_m of being 1. $\mathbf{k}^{(L)}$ is a vector of independent variables which indicate the dropout on modality with a given probability. $\varphi(\cdot)$ is an activation function.

Figure 3 (a-b) shows how *m*-drop works. Note the differences between modality dropout (*m*-drop) and original dropout: (1) *m*-drop targets specifically the multimodal scenario where some modalities are completely missing; and (2) *m*-drop is performed on the input layer ($L \equiv 0$).

2.3 Mutlimodal Sequential Autoencoder

The autoencoder has been used in prior work (Sedhain et al., 2015; Strub et al., 2016) to reconstruct missing elements (mostly ratings) in recommender systems. This is equivalent to the case of missing at random (MAR). For MAR, it is rare to have a continuous large block of missing entries (Tran et al., 2017). Differently, in recommending with missing modality, the missing entries typically occur in a *large continuous block*. For instance, an extreme case is the absence of all item reviews and ratings (data sparsity is 100%, leading to the so-called item cold-start problem). Existing methods (Lee and Seung, 2000; Koren, 2008; Marlin, 2003; Wang and Blei, 2011; McAuley and Leskovec, 2013; Li et al., 2017; Zheng et al., 2017) have difficulties when entire data modalities are missing during the *training* and/or *inference* stages.

To address this limitation, we propose a multimodal sequence autoencoder (*m*-auto) to impute textual sequential embeddings and visual embeddings for the missing modalities. Modality-specific autoencoders are placed between the modality-specific encoders (i.e., CNN and LSTMs) and the shared layer (equation 11). The reconstruction layers, therefore, can capture the inter-modal and intra-modal correlations. More formally, for each data modality $g \in \{u, o, m, v\}$, the modality-specific encoder is given as

$$\mathbf{e}^g_{hid} = \text{sigm}(\mathbf{W}^g_{vh}\mathbf{e}^g_{in} + \mathbf{b}^g_{vh}) \tag{17}$$

and the modality-decoder is given as

$$\mathbf{e}^g_{recon} = \frac{1}{T^g}\sum_{t \in T^g} \text{sigm}(\mathbf{W}^g_{hv}\mathbf{e}^g_{hid} + \mathbf{b}^g_{hv}) \tag{18}$$

where $\mathbf{W}_{vh} \in \mathbb{R}^{d \times d_h}$ and $\mathbf{W}_{hv} \in \mathbb{R}^{d_h \times d}$ are weights, $\mathbf{b}_{vh}$, $\mathbf{b}_{hv}$ are biases receptively for visible-to-hidden, and hidden-to-visible layers. $\mathbf{e}^g_{in}$, $\mathbf{e}^g_{hid}$ present the original, hidden word-level embeddings, and $\mathbf{e}^g_{recon}$ is the reconstructed document-level embeddings. The $\mathbf{e}^g$ is a modality-specific embedding.

m-auto is different from previous reconstruction models(Sedhain et al., 2015; Strub et al., 2016) in that its reconstructions are based on inter-modal and intra-modal correlations in the context of multimodal learning.

2.4 Model Optimization

The optimization of the network is formulated as a regression problem by minimizing the mean squared error (MSE) loss $\mathcal{L}_{reg}$:

$$\mathcal{L}_{reg} = \frac{1}{|\mathcal{D}|}\sum_{(u,o,m,v) \in \mathcal{D}} (\hat{\mathbf{s}} - \mathbf{s})^2 + \lambda \parallel \mathbf{\Theta}_r \parallel_2 \tag{19}$$

where $\hat{\mathbf{s}}$ and $\mathbf{s}$ are the predicted and truth rating scores. $|\mathcal{D}|$ is dataset size , λ is weight decay parameter and $\mathbf{\Theta}_r$ is regression model parameters. To constrain the representations to be compact in reconstruction, a penalty term is utilized

$$\mathcal{H} = \sum_{i=1}^{h_n} \log \frac{\rho}{\hat{\rho}_i} + (1-\rho)\log\frac{1-\rho}{1-\hat{\rho}_i} \tag{20}$$

where ρ and $\hat{\rho}$ are sparsity parameters and average activation of hidden unit i, h_n is the number of hidden units. The reconstruction loss for each modality is now

$$\begin{aligned}\mathcal{L}^g_{recon} =& \frac{1}{|\mathcal{D}|}\sum_{g \in \{u,o,m,v\}} \|\mathbf{e}^g_{recon} - \mathbf{e}^g_{in}\|^2 \\ &+ \lambda_\rho \sum_{g \in \{u,o,m,v\}} \mathcal{H}^g\end{aligned} \tag{21}$$

where λ_ρ is a sparsity regularization term. The objective of the entire model is then

$$\mathcal{L} = \alpha\mathcal{L}_{reg} + \beta \sum_{g \in \{u,o,m,v\}} \mathcal{L}^g_{recon} \tag{22}$$

where α and β are learnable parameters. The model is learned in an end-to-end fashion through back-prorogation (LeCun et al., 1989).

3 Experiments

This section evaluates LRMM on rating prediction tasks with real-world datasets. We firstly compare LRMM with recent methods (sec. 3.4), then we empirically show the effectiveness of LRMM in alleviating the cold-start, the incomplete/missing data, and the data sparsity problem (sec. 3.5-3.8).

3.1 Datasets and Evaluation Metrics

We conducted experiments on the Amazon dataset (McAuley et al., 2015; He and McAuley, 2016)[1], which is widely used for the study of recommender systems. It consists of different modalities such as text, image, and numerical data. We used 4 out of 21 categories: Sports and Outdoors (S&O), Health and Personal Care (H&P), Movies and TV, Electronics. Some statistics of the datasets are listed in Table 1. We randomly split each dataset into 80% training, 10% validation, and 10% test data. Each input instance consists of four parts $\mathbf{x}^{(i)} = (\mathbf{x}^{(i)}_u, \mathbf{x}^{(i)}_o, \mathbf{x}^{(i)}_m, \mathbf{x}^{(i)}_v)$, where $\mathbf{x}^{(i)}_u$ and $\mathbf{x}^{(i)}_i$ are the concatenated reviews of users and items in the training data. $\mathcal{V}$ is the vocabulary that was built based on reviews and metadata on the training data. Words with an absolute frequency of at least 20 are included in the vocabulary.

---

[1] `http://jmcauley.ucsd.edu/data/amazon/`

Table 1: Datasets

Dataset	S&O	H&P	Movie	Electronics
Users	35494	38599	111149	192220
Items	16415	17909	27019	59782
Samples	272453	336769	974582	1614105
$\lvert\mathcal{V}\rvert$	42095	47476	160117	198598

To evaluate the proposed models on the task of rating prediction, we employed two metrics, namely, Root Mean Square Error (RMSE)

$$RMSE = \sqrt{\frac{1}{|\mathcal{D}|} \sum_{(u,o,m,v)\in\mathcal{D}} (\hat{\mathbf{s}}_{i,j} - \mathbf{s}_{i,j})^2} \quad (23)$$

and Mean Absolute Error (MAE)

$$MAE = \frac{1}{|\mathcal{D}|} \sum_{(u,o,m,v)\in\mathcal{D}} |\hat{\mathbf{s}}_{i,j} - \mathbf{s}_{i,j}| \quad (24)$$

where $\hat{\mathbf{s}}_{i,j}$ and $\mathbf{s}_{i,j}$ represent the predicted rating score and ground truth rating score that user i gave to item j.

3.2 Baselines and Competing Methods

We compare our models with several baselines[2]. The baselines can be categorized into three groups.

1. Matrix factorization: *NMF* (Lee and Seung, 2000) and *SVD++* (Koren, 2008).
2. Topic model methods: *URP* (Marlin, 2003), *CTR* (Wang and Blei, 2011), *HFT* (McAuley and Leskovec, 2013) and *RMR* (Ling et al., 2014).
3. Deep learning models: *NRT* (Li et al., 2017) and *DeepCoNN* (Zheng et al., 2017), which are current state-of-the-art approaches.

We also include a naive method—*Offset* (McAuley and Leskovec, 2013) which simply takes the average across all training ratings.

3.3 Implementation

We implemented LRMM with Theano[3]. The weights for the non-recurrent layer were initialized by drawing from the interval $\left[-\sqrt{\frac{6}{N_{in}+N_{out}}}, \sqrt{\frac{6}{N_{in}+N_{out}}}\right]$ (N is the number of units) uniformly at random. We used 1024 hidden units for the autoencoder. The LSTMs have 256 hidden units and the internal weights $\mathbf{W}$ are orthogonally initialized (Saxe et al., 2014). We used a batch size of 256, $\lambda = 0.0001$, sparsity parameter $\rho = 0.05$, $\lambda_\rho = 0.01$, an initial learning rate of 0.0001 and a dropout rate of 0.5 after the recurrent layer. The models were optimized with ADADELTA (Zeiler, 2012). The length of the user, item and meta-data document $\mathbf{D}^u$, $\mathbf{D}^o$, and $\mathbf{D}^m_o$ were fixed to $L = 100$. We truncated documents with more than 100 words. The image features are extracted from the first fully-connected layer of CNN on ImageNet (Russakovsky et al., 2015).

We implemented NMF and SVD++ with the SurPrise package[4]. Offset and HFT were implemented by modifying authors' implementation[5]. For DeepCoNN, we adapted the implementation from (Chen et al., 2018)[6]. The numbers of other methods are taken from Li et al. (2017).

3.4 Compare with State-of-the-art

First, we compare LRMM with state-of-the-art methods listed in Sec. 3.2. In this setting, LRMM is trained with all data modalities and tested with different missing modality regimes. Table 2 lists the results on the four datasets. By leveraging multimodal correlations, LRMM significantly outperforms MF-based models (i.e. NMF, SVD++) and topic-based methods (i.e., URP, CTR, RMR, and HFT). LRMM also outperforms recent deep learning models (i.e., NRT, DeepCoNN) with respect to almost all metrics.

LRMM is the only method with a robust performance for the cold-start recommendation problem where user review or item review texts are removed. While the cold-start recommendation is more challenging, LRMM(-U) and LRMM(-O) are still able to achieve a similar performance to the baselines in the standard recommendation setting. For example, RMSE 1.101 (LRMM(-O)) to 1.107 (NRT) on Electronics, MAE 0.680 (LRMM(-O)) to 0.667 (DeepCoNN)on S&O. We conjecture that the cross-modality dependen-

---

[2] To make a fair comparison, implemented baselines are trained with grid search (for NMF and SVD++, regularization [0.0001, 0.0005, 0.001], learning rate [0.0005, 0.001, 0.005, 0.01]. For HFT, regularization [0.0001, 0.001, 0.01, 0.1, 1], lambda [0.1, 0.25, 0.5, 1]). For DeepCoNN, we use the suggested default parameters. The best scores are reported.

LRMM(-V)	0.886	0.624	0.989	0.708	0.991	0.725	1.052	0.766

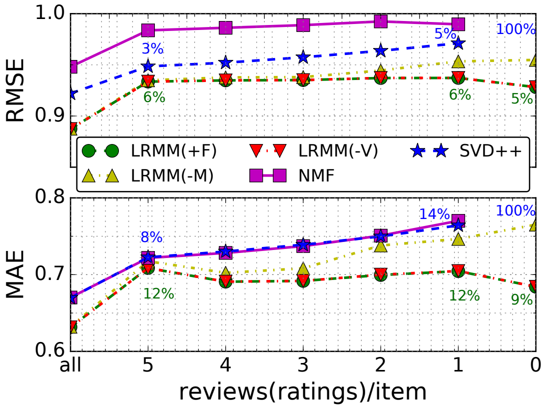

Figure 4: Performance with reduced reviews (ratings) on S&O dataset. (% : performance drops for SVD++ (in blue) and LRMM(+F) (in green))

cies (Srivastava and Salakhutdinov, 2012) make LRMM more robust when modalities are missing. Table 5 lists some randomly selected rating predictions. Similar to Table 2, missing user (-U) and item (-O) preference significantly deteriorates the performance.

3.5 Cold-Start Recommendation

Prior work (McAuley and Leskovec, 2013; Zhang et al., 2017) has considered users (items) with sparse preference information as the cold-start problem (e.g., Figure 1(d)), that is, where there is still some information available. In practice, preference information could be missing in larger quantities or even be entirely absent (e.g., Figure 1(b-c)). In this situation, the aforementioned methods are not applicable as they require some data to work with. In this experiment, we examine how LRMM leverages modality correlations to alleviate the data sparsity problem when training data becomes even sparser. To this end, we train models for the item cold-start problem by reducing the number of reviews (for LRMM) and ratings (for NMF and SVD++) of each item in the training set.

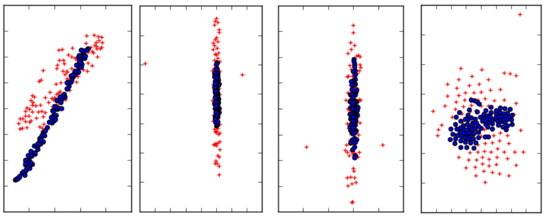
Figure 4 demonstrates the robustness of LRMM when the training data becomes more sparse. Note that NMF and SVD++ fail to train models when there is no ratings data available. In contrast, LRMM is trained by leveraging item images and metadata even if item reviews are completely missing for a product. The average number of reviews per item on this dataset is 16.7. Reducing the number of ratings to 5 severely degrades the performance of NMF, SVD++, and LRMM. However, LRMM remains rather stable in maintaining good performance when considering the performance degradation at 5, 1, and 0 reviews (ratings), respectively. One interesting observation is that, with a reduced number of reviews, the product metadata plays a more and more important role in maintaining the performance: LRMM(-V) is close to LRMM(+F) in Figure 4 while the gap between LRMM(-M) and LRMM(+F) is large.

3.6 Missing Modality Imputation

The proposed *m*-drop and *m*-auto methods allow LRMM to be more robust to missing data modalities. Table 3 lists the results of train-

Table 3: The performance of training with missing modality imputation.

Dataset	S&O		H&P	
Models	RMSE	MAE	RMSE	MAE
LRMM(+F)	0.997	0.790	1.131	0.912
LRMM(-U)	0.998	0.795	1.132	0.914
LRMM(-O)	0.999	0.796	1.133	0.917
LRMM(-M)	0.998	0.797	1.133	0.913
LRMM(-V)	0.997	0.791	1.132	0.913



(a) $\mathbf{e}^v$ (b) $\mathbf{e}^u$ (c) $\mathbf{e}^o$ (d) $\mathbf{e}^m$

Figure 5: Visualization of embeddings (blue) and reconstructed embeddings (red)

ing LRMM with missing data modalities for the modality dropout ratio $p_m = 0.5$ on the S&O and H&P datasets, respectively. Both RMSE and MAE of LRMM deteriorate but are still comparable to the MF-based approaches NMF and SVD++. However, the proposed method LRMM is robust to missing data in both training and inference stages, a problem rarely addressed by existing approaches. In Figure 5, we visualized the modality-specific embeddings and their reconstructed embeddings of 100 randomly selected samples with t-SNE (van der Maaten and Hinton, 2008). The plots suggest that it is more challenging to reconstruct item metadata and image embeddings as compared to the user or item embeddings. One possible explanation is that some selected metadata contains noisy data (e.g., "*ISBN - 9780963235985*", "*size: 24* ×*46*" and "*Dimensions: 15W* × *22H*") for which visual data is more diverse. This would increase the difficulty of incorporating visual data into the embeddings.

3.7 The Effect of Text Length

To alleviate the data sparsity problem, existing work (McAuley and Leskovec, 2013; Zhang et al., 2017) concatenates review texts and utilizes topic modeling (e.g. HFT) or CNNs combined with Word2Vec (e.g. DeepCoNN) to learn user or item embeddings. Differently, LRMM treats the concatenated reviews as sequential data and learns sequence embeddings with RNNs. In this experiment, we show that learning sequential embedding is beneficial on sparse data because it is unnecessary to exploit all reviews so as to reach good performance. Figure 6 shows the performance of LRMM with varied word sequence lengths. In general, sequence embeddings learned with larger length achieve better performance. Note that, by considering a certain amount of words (e.g. L=50), LRMM is able to achieve a result as good as accounting more words (e.g. L=100 or 200). Although this is dataset-dependent to some degree, e.g., LRMM (L=200) improves RMSE and MAE in a certain margin as compared to L=100 on the H&P data, it demonstrates the superiority of sequential user or item embeddings as compared to topic and CNN+Word2Vec embeddings on more sparse data as shown in Table 2.

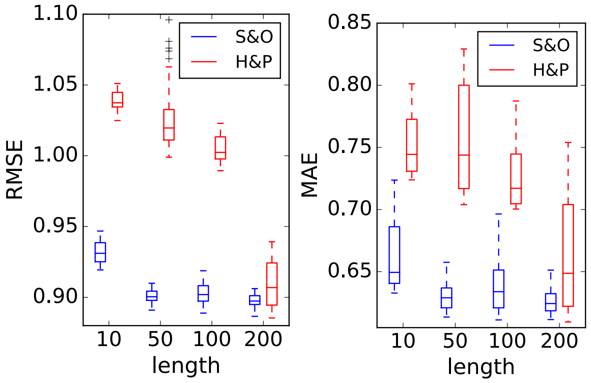


Figure 6: RMSE and MAE with varied text lengths on S&O and H&P datasets.

3.8 Cross-Domain Adaptation

To consider an even more challenging situation we explore cases where the full training set is missing. Inspired by the recent success of domain adaptation (DA) (Csurka, 2017), a special form of transfer learning (Pan and Yang, 2010; Weiss et al., 2016), we perform the recommendation task on the target domain test set $\mathcal{D}^t_{test}$ (e.g., "Sport") but with the model $\mathcal{C}$ trained on a different domain training set $\mathcal{D}^s_{train}$ (e.g. "Movie"). This is achieved by extracting the multimodal embeddings on the source domain and by performing prediction on the target domain. Table 4 shows the performance of LRMM when performing adaptation from larger datasets to smaller datasets. Although the performance is not as good as on $\mathcal{D}^s_{test}$, LRMM is still able to obtain decent results even

Table 4: Cross-Domain Adaptation with LRMM

$\mathcal{D}^s \rightarrow \mathcal{D}^t$	**+F**	**-U**	**-O**	**-M**	**-V**
Movie→S&O	1.061	1.013	1.071	1.061	1.062
Movie→H&P	1.190	1.140	1.170	1.190	1.190
Elect.→S&O	1.072	1.012	1.088	1.073	1.073
Elect.→H&P	1.191	1.137	1.180	1.191	1.192

Table 5: Exemplary rating prediction on S&O datatset. 'T' means true ratings, the best prediction is in blue, the worst prediction is in red.

Item image	T	+F	-U	-O	-M	-V
	3	3.18	**3.97**	3.48	**3.03**	3.28
	3	3.36	**4.07**	3.5	3.33	**3.27**
	5	**4.63**	4.50	**4.36**	4.60	**4.63**
	3	**3.11**	**3.77**	3.49	3.44	3.57
	4	**4.00**	**4.31**	3.87	3.92	4.02

Table 6: Examples on H&P datatset with domain adaptation. The model is trained on Movie dataset.

Item image	T	+F	-U	-O	-M	-V
	4	**4.01**	4.18	**3.70**	4.04	4.05
	2	**2.58**	**3.85**	2.82	2.82	2.76
	3	2.97	**4.33**	2.77	**2.99**	2.96
	4	4.09	**3.68**	4.14	4.09	**4.04**
	5	**4.99**	**4.39**	4.47	4.94	**5.01**

without using training data $\mathcal{D}^t_{train}$. Table 6 shows some example rating predictions on DA for different categories of products. It demonstrates the strong generalization capability of DA from one product category to another.

4 Discussion

Empirically, we have shown that multimodal learning (**+F**) plays an important role in mitigating the problems associated with missing data/modality and, in particular, those associated with the cold-start problem (**-U** and **-O**) of recommender systems. The proposed method LRMM is in line and grounded in recent developments (e.g. DeepCoNN, NRT) to incorporate multimodal data. LRMM distinguishes itself from previous methods: (1) the cold-start problem is reformulated in the context of missing modality; (2) A novel multimodal imputation method which consists of *m*-drop and *m*-auto is proposed to learn models more robust to missing data modalities in both the training and inference stages.

5 Related Work

Collaborative filtering (CF) is the most commonly used approach for recommender systems. CF methods generally utilize the item-user feedback matrix. Matrix factorization (MF) is the most popular CF method (Koren et al., 2009) due to its simplicity, performance, and high accuracy as demonstrated in previous work (Chen et al., 2015). Another strength of MF, making it widely used in recommender systems, is that side information other than existing ratings can easily be integrated into the model to further increase its accuracy. Such information includes social network data (Li et al., 2015; Lagun and Agichtein, 2015; Zhao et al., 2016; Xiao et al., 2017), locations of users and items (Lu et al., 2017) and visual appearance (He and McAuley, 2016; Salakhutdinov and Mnih, 2007) proposed Probabilistic Matrix Factorization (PMF) which extends MF to a probabilistic linear model with Gaussian noise. Following PMF, there are many extensions (Salakhutdinov et al., 2007; Chen et al., 2013; Zheng et al., 2016; Zhang et al., 2016; He et al., 2016b, 2017) aiming to improve its accuracy.

Unfortunately, CF methods suffer from the cold-start problem when dealing with new items or users without rich information. Content based filtering (CBF) (Pazzani and Billsus, 2007), on the other hand, is able to alleviate the cold-start problem by taking auxiliary product and user information (texts, images, videos, etc.) into consideration. Recently, several approaches (Almahairi et al., 2015; Xu et al., 2014; He et al., 2014; Tan et al., 2016) were proposed to consider the information of review text to address the data sparsity problem which leads to the cold-start problem. The topic model (e.g. LDA (Blei et al., 2003)) based approaches including CTR (Wang and Blei, 2011), HFT (McAuley and Leskovec, 2013), RMR (Ling et al., 2014), TriRank (He et al., 2015), and sCVR (Ren et al., 2017) achieve significant improvements compared to previous work on recommender systems.

Inspired by the recent success of deep learning techniques (Krizhevsky et al., 2012; He et al., 2016a), some deep network based recommendation approaches have been introduced (Wang et al., 2015; Sedhain et al., 2015; Wang et al., 2016b; Seo et al., 2017; Xue et al., 2017; Zhang et al., 2017). Deep cooperative neural network (Deep-CoNN) (Zheng et al., 2017) was introduced to learn a joint representation from items and users using two coupled network for rating prediction. It is the first approach to represent users and items in a joint manner with review text. TransNets (Catherine and Cohen, 2017) extends Deep-CoNN by introducing an additional latent layer representing the user-item pair. NRT (Li et al., 2017) is a method for rating prediction and abstractive tips generation (Zhou et al., 2017). A four-layer neural network was used for rating regression model. NRT outperforms the state-of-the-art methods on rating prediction. There is a large body of work for recommender systems and we refer the reader to for surveys of state-of-the-art CF based approaches, CBF methods, and deep learning based methods, respectively (Shi et al., 2014; Lops et al., 2011; Zhang et al., 2017).

Our work differs from previous work in that we simultaneously address various types of missing data together with the data-sparsity and cold-start problems.

6 Conclusion

We presented LRMM, a framework that improves the performance and robustness of recommender systems under missing data. LRMM makes novel contributions in two ways: multimodal imputation and jointly alleviating the missing modality, data sparsity, and cold-start problem for recommender systems. It learns to recommend when entire modalities are missing by leveraging inter- and intra-modal correlations from data through the proposed *m*-drop and *m*-auto methods. LRMM achieves state-of-the-art performance on multiple data sets. Empirically, we analyzed LRMM in different data sparsity regimes and demonstrated the effectiveness of LRMM. We aim to explore a generalized domain adaptation approach for recommender systems with missing data modalities.

Content Explorer: Recommending Novel Entities for a Document Writer

Google AI
zens@google.com

Abstract

Background research is an essential part of document writing. Search engines are great for retrieving information once we know what to look for. However, the bigger challenge is often identifying topics for further research. Automated tools could help significantly in this discovery process and increase the productivity of the writer. In this paper, we formulate the problem of recommending topics to a writer. We consider this as a supervised learning problem and run a user study to validate this approach. We propose an evaluation metric and perform an empirical comparison of state-of-the-art models for extreme multi-label classification on a large data set. We demonstrate how a simple modification of the cross-entropy loss function leads to improved results of the deep learning models.

1 Introduction

An important part of writing about some topic is researching relevant background material, which can be a challenging and tedious task. If the author has a clear idea what to write about, web search engines provide an excellent tool for retrieving information. However, the author often first has to spend time discovering which topics are related, i.e., she needs to conduct *exploratory search* (White and Roth, 2009). This is challenging with traditional keyword-based search engines like *Google*, which are tailored to providing the information that a user is explicitly searching for (Marie, 2014).

Exploratory search poses a challenge in the writing process. It has been shown that the *exploration* phase elicits strong negative feelings in students writing essays (Smith and Campbell, 1999; Kuhlthau, 1990) and that students consider the research activity to be at the cost of other pending commitments (Smith and Campbell, 1999). Moreover, exploratory search is more cognitively demanding than lookup search tasks (Marie, 2014). Automatic tools tailored to exploratory search for new content could significantly alleviate the difficulty the writer faces in the research phase.

Intuitively, the tool should suggest topics for further research which are relevant and interesting. Hence the suggestions need to be related to the document and should not be too obvious. For instance, a student writing about the *monarch butterfly* might benefit from a suggestion *milkweed* as it is both relevant and interesting. On the other hand, *insect* would be a rather poor suggestion as it is too obvious. To summarize, the key challenge we set out to address is: *For a given piece of text, what are the related topics and how important are they?* In Section 3.2 we describe a user study where annotators evaluated usefulness of entities, which we then use to identify characteristics of good suggestions.

It is worth mentioning that systems for providing automatic recommendations of entities to a document writer have recently been introduced by the industry, including Google Explore in Docs[1] and Microsoft Researcher[2]. The systems are proprietary and their design is not published, making the comparison not possible. To the best of our knowledge this is the first documented attempt to address the problem of recommending novel entities to a document writer. We hope this paper will attract the interest of the research community and inspire future work.

The contributions of this paper are:

1. Formulating the problem of recommending future entities to a document writer.

---

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3371–3380
Brussels, Belgium, October 31 - November 4, 2018.

2. Conducting a user study to identify what topic suggestions users find useful.

3. Formulating the problem and defining an automatic evaluation metric, both motivated by the user study.

4. Evaluating state of the art approaches to extreme multi-label classification.

5. Demonstrating how a modified loss function helps improve over state of the art neural network models.

2 Related Work

Recommending topics to a document writer can be viewed in the context of different fields which we discuss below.

Exploratory Search White and Roth (2009) define exploratory search as "information seeking problem context that is open-ended, persistent, and multi-faceted" and "information-seeking processes that are opportunistic, iterative, and multi-tactical". Research on exploratory search focuses on supporting a user in the interactive and iterative process of seeking for information and includes: designing better interfaces, visualization of search results, clustering of results, supporting serendipitous discoveries, supporting different user profiles (Marie, 2014). Instead, in this work we aim to fully automate discovery of *relevant* and *interesting* topics to the document writer. Moreover, the input in our case is an initial portion of a document written by a user rather than a query or a single entity, as is usually the case in the information retrieval setups.

Extreme Multi-label Classification Extreme multi-label classification (XML) is an instance of a multi-label classification problem (i.e., where multiple labels can be assigned to a single example at the same time) under a large label space. There are multiple works investigating XML, including random forest (RF) (Prabhu and Varma, 2014; Jain et al., 2016) and embedding (Bhatia et al., 2015) approaches. These methods rely on bag of words feature representation, ignoring the sequential nature of text. Neural networks (NNs) have been successful in modeling NLP tasks through their ability to learn structure, however have not been widely studied for XML problems. Covington et al. (2016) applied NNs to YouTube video recommendation, and Liu et al. (2017) showed a convolutional neural network architecture to outperform strong baselines on a range of NLP tasks. The importance of label weighting for recommending rare items has not been considered in the NNs for extreme multi-label classification, which is a central problem in our task, as in other tasks with extreme label spaces (Jain et al., 2016). In Section 5 we describe the state of the art RF and NN approaches to XML.

Entity Retrieval and Tagging Assigning entities to an input has been considered, however in different contexts. In tag recommendation, a text is summarized with a set of entities (Song et al., 2011) and in entity search one needs to answer queries about entities against a set of documents and entities (Cheng et al., 2007). These tasks are different as no new content is predicted.

The Related Entity Finding (REF) challenge of the Text Retrieval Conference (TREC) considered a task where given a source entity, a relation and a target type, a target entity needs to be identified satisfying the required relation (Balog et al., 2010). This is a different problem since no specification for relations between the entities is provided in the input document from a user.

The work on semantic relatedness of entities (Milne and Witten, 2008) is different since, as explained in the introduction, good entity recommendations are not necessarily those which are semantically related to entities from the user text. Bordino et al. (2013) considered retrieving entities related to a query in the question answering scenario. The authors did not set the problem in a supervised learning setup and instead find entities closest in terms of similarity of documents containing them. In contrast, in Section 3.2 we justify a supervised learning setup of the task.

The TREC Complex Answer Retrieval Track (CAR)[3] is a challenge where based on a document outline, related text passages and entities are retrieved (Dietz et al., 2017). In this formulation it is assumed that a general outline of what a document author intends to cover is given, thus providing a clear guidance for what is relevant. Instead, our input is an initial part of a document and we seek to find novel entities based on the input.

---

[3] `http://trec-car.cs.unh.edu`

Recommending Rare Items Information retrieval applications emphasized the importance of retrieving rare labels rather than common ones which are likely to be already known to a user. Baeza-Yates and Ribeiro-Neto (1999) defined novelty of a set of recommendations as the proportion of unknown items to the user, a challenging definition to work with when user's knowledge is unknown (Hurley and Zhang, 2011). Bordino et al. (2013) explored the problem of retrieving *serendipitous* results when retrieving answers to queries. The authors built an information retrieval system based on finding entities most often co-occurring with a query entity and employed IDF (inverse document frequency) for filtering out overly generic answers. Also many other works employ IDF for rewarding rare items (Zhou et al., 2010; Vargas and Castells, 2011; Wu et al., 2014; Jain et al., 2016). Here we take a supervised learning approach to the entity recommendation problem, demonstrate the usefulness of IDF scoring in the context of our problem with a user study, and utilize IDF in the evaluation metric.

Hurley and Zhang (2011) define novelty of an item in the context of the set of relevant recommendations using an average dissimilarity from other items in the set. Similarly, the Maximal Marginal Relevance metric evaluates a set of retrieved items in an information retrieval problem by rewarding the diversity of the set (Carbonell and Goldstein, 1998). Note this is a different notion of novelty from that considered in this work.

3 Investigating the Problem

In this section we investigate the problem formulation and what it means for an entity to be a useful suggestion for a user.

3.1 Problem Definition

Let a document d be represented as a sequence of entities $(e^1, \dots, e^{|d|}) = E$. We partition these entities into two sets C_d and F_d: those which occur in the first h sentences (in our case $h = 10$) and those which don't. Hence, $C_d \cap F_d = \emptyset$ and $C_d \cup F_d = E$.

We are not interested in retrieving all entities that could occur in the future, because it is not feasible to provide all such recommendations to a user. Instead, we focus on ranking the target entities, and selecting the most relevant k to suggest, which is a standard practice in retrieval tasks (Jain et al., 2016).

3.2 What Entities are Good Suggestions?

In this section we describe a user study we ran for testing the hypotheses about which entities constitute useful recommendations. In particular, we test whether what a user writes next in a document is actually considered to be a good recommendation by the raters and whether IDF score correlates with how useful an entity is considered.

Human Evaluation Dataset We consider 1000 Wikipedia documents for a human evaluation study. For each document, let E denote the set of all entities that occur in the document and E_p denote entities occurring in the initial passage p. We found 5 most co-occurring entities from $E \setminus E_p$[4] with the entities from E_p across sentences from a large scale web documents corpus (the dataset described later in Section 4). Annotators were then asked to rate entity suggestions against an input passage p in terms of how *useful* they are in the process of continuing to write the document. Each entity was rated by 3 annotators with a score ranging from 1 to 5 and the total number of annotators was 845. To evaluate agreement among raters, we employ the Intraclass Coefficient for consistency[5] (ICC; (McGraw and Wong, 1996)) for two-way random effects model with the effects corresponding to a rater and a rated entity. We found the average score ICC to be equal $\mathrm{ICC}(\mathrm{C}, 3) = 0.69$. We refer the reader to the supplemental material for details about how ICC was applied.

Evaluating the Supervised Setup We found that the mean rating for entities which actually occur in the future is 3.24 ± 0.83, whereas the mean rating for the other entities is 2.59 ± 0.93. Running an independent T-test for comparing means between the two groups yields a p-value $p < 0.001$. This supports the supervised learning setup of entity suggestion, where we split documents from a corpus into two parts, and unseen entities from later parts form labels for the initial parts.

Does IDF Correlate with Usefulness? One of the requirements we set for the entity recommendation is the interestingness of the entities. As

---

[4] I.e., excluding entities occurring in the passage.

[5] Intraclass Coefficient is an approach to evaluate inter-rater reliability when ratings are organized into groups, as in our case, where entities are grouped into passages against which they are scored.

reported in Section 2, one popular approach to recommending rare items in information retrieval tasks is weighting their utility by their IDF score (Bordino et al., 2013; Jain et al., 2016). Let us analyze in the document writing setup how useful users perceive entities which score high in IDF. To this end, we measure how the *ground truth reviewer* (the average rating given by the human annotators to an item) correlates against the baseline rating *B* and how it correlates against the IDF weighted rating *W*. Here, the baseline rating *B* simply rates an entity with 0 if it does not occur in the future of the document and with 1 if it does occur in the future of the document. The IDF weighted rating *W* rates an entity with its IDF score multiplied by the score returned by the reviewer *B*. We employ ICC(A, 1) to find the agreements between pairs of ratings. We find ICC(A, 1) between the *ground truth reviewer* and *B* to be 0.30, and between the *ground truth reviewer* and *W* to be 0.42. This shows that entities with high IDF scores are perceived as more useful. Note the potential space for improvement by finding a metric which would yield even higher correlation against the human rating than IDF.

3.3 Automatic Evaluation

Recall that we aim at rewarding entities which are both *relevant* (i.e., within the target set of entities) and *interesting* (i.e., are not obvious, as the entity *insect* was for the *monarch butterfly* example from Section 1). Since we care only about the k highest ranked recommendations from the system, a potentially useful metric for evaluation is prec@k$=\frac{1}{k}\sum_{j=1}^{k} I_{\{p^j \in F_d\}}$, where p^j are the predictions. Even though prec@k captures relevancy, it fails to distinguish between generic and specific entities. Documents tend to contain many entities in the target set, some of which are generic (e.g. *insect*). Prec@k scores all entities the same and rewards predictions of generic entities occurring across almost all web documents (e.g. *Internet*), which are arguably not interesting.

We propose a metric based on cumulative gain (Järvelin and Kekäläinen, 2002), where we use IDF for scoring the relevance of labels:

$$\text{CG-IDF@k} = \sum_{j=1}^{k} I_{\{p^j \in F_d\}} \text{IDF}(p^j).$$

To facilitate interpretability, we use a normalized version of CG-IDF@k, the normalized cumulative gain (NCG-IDF@k). NCG-IDF@k is obtained by dividing CG-IDF@k by the maximum sum of IDF scores of k entities from the target set.

Why would IDF help make entities more interesting? As shown by the user study in Section 3.2 IDF correlates with how relevant an entity is perceived by a user. Moreover, as reported in Section 2, IDF is widely used for boosting rare, novel items (Bordino et al., 2013; Jain et al., 2016).

4 Dataset

We consider the problem of recommending topics that an author writing a document might be interested in writing about next. In Section 3.2 we used a human evaluation study to support a supervised learning setup for this problem, where what is written later in a document is deemed to be a good recommendation for an initial part. The Web is a rich source of documents which facilitates construction of large datasets. Below we describe details of how we construct the dataset composed of web documents and report basic statistics thereof.

Construction We collected a dataset of 10M web documents with high pagerank (Page et al., 1998) scores across the Web as of November 2017. We ran entity recognition and linking to the Freebase knowledge graph using the Google NLP cloud.[6] Moreover, only the 100K most frequent entities are kept.[7] We randomly select 10K documents for the test set and 10K for the validation set which we use for hyperparameter tuning.

Statistics As shown in Figure 1 the document frequencies for the 100K most frequent entities from the dataset follow a power law distribution, with a small number of very frequent entities and many infrequent ones. The average number of documents per target entity is 4694.95, which is 3 orders of magnitude smaller than the maximum frequency. We found that the average number of future entities per document is 96, and the average number of input entities is 10. In Figure 2 we show the percentage of times a context entity is followed by a particular target entity (row and column, respectively). Notice the matrix is asymmetric. For

---

[6] `http://tinyurl.com/h246dnz`

[7] 100K entities are kept due to the challenges in handling larger output spaces by the models. Scaling to larger output spaces is possible but requires modifications which we leave for future work.

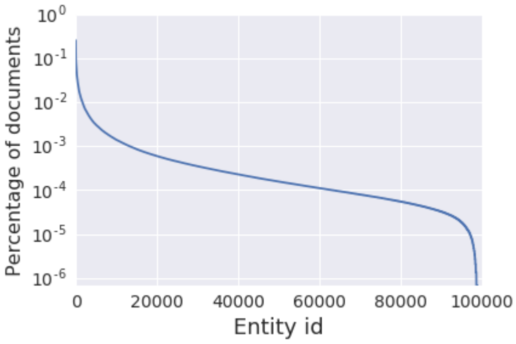

Figure 1: Percentage of documents for which each target entity occurs.

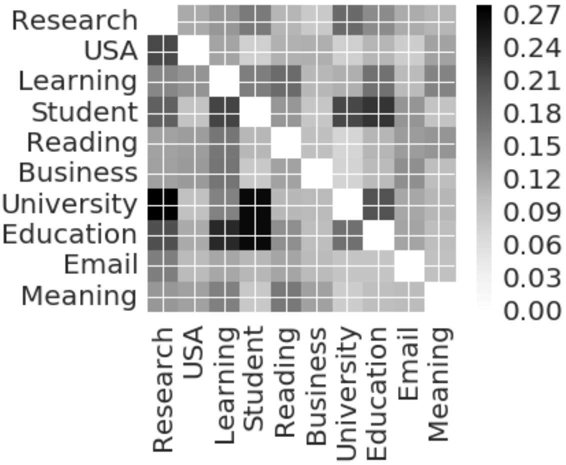

Figure 2: A heatmap showing what percentage of times a context entity (row) is followed by a particular target entity (column).

instance, USA is more likely to be followed by Research than the other way around.

5 Baselines and Models

In this section we describe the models that we applied to the entity recommendation problem.

5.1 Linear Models

Let us represent input entities via n-hot vector representation, i.e., vector entries corresponding to entities present in the input set are set to one, whereas other entries are set to zero. We consider *linear models*, where such an input vector is multiplied by a square weight matrix of size #entities × #entities, and a resulting vector contains scores for predicted entities. There are different possibilities for filling the entries of the weight matrix. We considered multiple options:

1. N(C, F) obtained by putting the raw co-occurrences of the context entity C (corresponding to a row) and the future entity F (corresponding to a column).

2. P$(F|C)$ obtained by normalizing the N(C, F) matrix row-wise.

3. PPMI(C, F) (positive pointwise mutual information) aims to show how much more likely an entity F is to occur for a context C compared to observing them independently (Jurafsky and Martin, 2000). PPMI is a popular preprocessing step on the co-occurrence matrix before applying dimensionality reduction, such as SVD (see Section 5.2) (Herbelot and Vecchi, 2015).

5.2 Matrix Factorization

Matrix factorization methods (MFM) are among the most popular approaches for recommendation systems (Koren et al., 2009). This approach works similar to the *linear model*, except that the resulting matrix is decomposed into a sequence of smaller matrices, the product of which approximates the *linear model*. This approach reduces the number of parameters, which speeds predictions, saves memory, and may improve robustness to overfitting. We employ SVD and reduce the rank of the resulting matrix of the *linear model* to 100. MFM is applied analogously to the *linear model*, namely a vector encoding input entities is mapped into a vector with scores of target entities.

5.3 Random Forests

FastXML FastXML (Prabhu and Varma, 2014) is one of the most popular approaches to extreme multi-label classification. Each tree in this random forest model is grown recursively by splitting each node by a separating hyperplane. The hyperplane weight vector is chosen by optimizing for nDCG score (a non-differentiable loss which poses issues in the NN framework) and is additionally regularized with ℓ_1 norm to induce sparsity. Each leaf node contains a probability distribution over labels. At prediction time, the distributions from reached leaf nodes across the trees are aggregated and a final ranking of entities is created.

PFastreXML PFastreXML (Jain et al., 2016) builds on the FastXML model by introducing two modifications. First, the nDCG loss function is replaced by a propensity weighted nDCG (in our case, the IDF weighted nDCG), resulting in rare items ranked higher. Second, the final ranking is re-ranked using tail label classifiers, which aims at further improvements in how highly rare items are scored.

Experimental Setup The scale of our dataset is bigger than that reported by Jain et al. (2016) and consequently the size of the generated random forests tends to be very large. Therefore, apart from keeping most of the hyperparameters as reported by Jain et al. (2016), in order to limit the size of generated trees, we modify two hyperparameters: the maximum number of labels per leaf node is set to 50 (instead of 10), and the maximum number of training examples per leaf node is set to 50 (instead of 10). Even under such a setup, the size of the generated models is around 150GB.

5.4 Neural models

Recently NN models have been applied to extreme classification. In this section we discuss the YouTube neural model used for recommending YouTube videos (Covington et al., 2016) and next the XML-CNN model which has been demonstrated to achieve competitive results on a few NLP tasks (Liu et al., 2017).

The YouTube Model A NN model (depicted in Figure 3(a)) has been successfully applied for the YouTube recommendation problem (Covington et al., 2016). In the model, the input entities are embedded into a latent dimensionality V. The embeddings are then summed, and the resulting vector is passed through a number of layers, where in each layer an input vector is passed through matrix multiplication and a rectified linear unit (RELU) (Nair and Hinton, 2010). Afterwards, the resulting vector is converted into the space of dimensionality equal to the number of entities via an output layer. This way, scores are obtained over the entity space, which are used to choose the highest scored entities for predictions. The loss function is the cross-entropy (CE) between the soft-maxed activations and a uniform distribution over the target entities.

XML-CNN Convolutional neural networks (CNNs) have been successfully applied to a range of NLP problems (Kim, 2014; Bitvai and Cohn, 2015). Recently Liu et al. (2017) demonstrated how CNNs can be effective for XML problems. We depict their architecture in Figure 3(b). The input sequence is embedded in V dimensions, and passed through a convolutional layer, a fully connected layer and an output layer. After the convolutional layer the authors employ dynamic pooling which helps retain information about where in the input sequence the convolutions got triggered. The loss function is binary cross entropy (BCE), which considers labels individually rather than jointly. BCE is given by the formula $\mathrm{BCE}(\mathbf{p},\mathbf{y}) = \sum_{j=1}^{j=M} y_j \log(\sigma(p_j)) + (1-y_j)\log(1-\sigma(p_j))$, where σ is the sigmoid function. Lastly, a hidden bottleneck layer is used, which is motivated by introducing better generalization. In the experiments we did not find the dynamic max pooling to be beneficial, and instead we found max pooling with a higher number of filters (512 compared to 32 in (Liu et al., 2017)) to be better, keeping the number of parameters.

Modified Loss Function A potential problem with CE and BCE is that they reward all entities equally. However, as demonstrated in Section 3.2, some entities are more valuable than others. Since we would like to promote interesting entities over generic ones, we consider an alternative training loss function to BCE and CE which incorporates the IDF scores of target entities. We use CE, but instead of comparing the soft-maxed activations to a uniform distribution over target entities, we compare against normalized IDF scores from the training set. We call this loss function CE-IDF. When using CE-IDF with XML-CNN, we found that adding ℓ_2 norm of the weights and the cross-entropy regularization (Pereyra et al., 2017) helps prevent the model from overfitting. We select the hyperparameters controlling these two regularization terms using a held out validation set. This contribution is analogous to that of PFastreXML over FastXML due to Jain et al. (2016), where weighting the loss function in random forests by label propensity scores helps achieve better propensity weighted results.

Experimental Setup To regularize the networks we use a 50% dropout rate (Srivastava et al., 2014). We set the dimensionality of the embeddings to 1000, and the hidden layer size to 512. The hyperparameters for XML-CNN are set as reported by Liu et al. (2017), except for the ℓ_2 and cross-entropy regularization hyperparameters

which were selected on the validation set. Note we optimize all parameters, including the entity embeddings, on the training data.

6 Experiments

In Table 1 we report results from the experiments on the 10M web documents dataset for prec and NDCG-IDF metrics for $k = 1, 3, 5, 7$, limiting k to small values as is common in the recommendation problems from large sets of items (Jain et al., 2016). The $p(F)$ baseline always predicts entities according to their frequency over the training set. It can be viewed as maximum likelihood estimate (MLE) for the model which is only composed of a bias vector (i.e., input entities are ignored). Notice the relatively high performance when the most popular entities are taken. For example, in 36.76% of cases entity *Research* (the most popular future entity from the corpus) is in the future of the document (as can be also seen from Figure 1, where the entity *Research* corresponds to the leftmost point of the graph). This constitutes a high value, as the vocabulary consists of $100K$ entities.

Among the *linear models*, P$(F|C)$ yields the highest scores, significantly outperforming the baselines. PPMI$(F|C)$ model yields relatively high NCG-IDF scores (although in most cases lower than P$(F|C)$), and very low precision scores. Notice that the SVD methods are consistently worse than the *linear models*. This shows that no additional generalization is gained when lowering the number of parameters of the *linear models*. When experimenting with higher ranks for SVD decomposition we found the performance increases, but does not improve over the *linear models*.

NNs improve over *linear models* according to both NCG-IDF and prec scores. This is especially apparent for NCG-IDF, where the relative improvement is very significant. XML-CNN is in all cases better than the Youtube model, which shows how utilizing more linguistic structure than simply bag of entities is helpful in the NN framework. Both Youtube and XML-CNN models with a modified loss function improve over the basic NN models in terms of the NCG-IDF metrics, showing that a simple adjustment of a loss function in the NN framework can lead to more rare

Table 2: Example inputs and corresponding top 4 entity predictions from the models.

entities being recommended. This comes at the cost of lowering prec@k scores, which however correlates with user judgments to a lesser extent, as we showed in Section 3.2. The Random Forest models turn out to be the most competitive. Notice that no linguistic structure is captured in FastXML models, only the bags of entities. This is in contrast with XML-CNN approach which looks at local contexts of feature entities. FastXML performs particularly well on the precision scores, which however is not necessarily useful, as demonstrated in the examples discussed later.

Last, we inspect the sizes of the different models reported in the rightmost column of Table 1. Model size is an important factor to consider in practical applications, e.g. when deploying a system on the device. PFastreXML model takes 150GB, by far the most of all methods, resulting in its capability in recommending tail entities. The *linear models* take 4.7GB related to the fact that in the full $100K \times 100K$ co-occurrence matrix approximately 11% of entries are non-zero. Applying SVD matrix decomposition helps reduce this size significantly. The NN models take around 2GB, significantly less than the random forests.

Analysis To demonstrate the usefulness of the models, in Table 2 we report top 4 entity predictions from XML-CNN and FastXML models for a few example inputs from the test set. Notice how predictions from XML-CNN base are more generic than from XML-CNN IDF. In particular, for the first input related to Antarctic Ice Sheet gaining ice entities *Earth* and *research* are recommended. The relevance of them is clear, however their usefulness is doubtful due to how obvious to the writer they may be. Due to often making such safe predictions XML-CNN base scores higher in precision than XML-CNN IDF. XML-CNN IDF instead makes more specific recommendations, such as *sea level rise* or *temperature* for the first input. This shows how much more beneficial scoring high in NDCG-IDF compared to precision is. An analogous phenomenon takes place between FastXML and PFastreXML – despite FastXML achieving very high precision scores, the predictions tend to be less interesting.

When comparing PFastreXML results against XML-CNN IDF, the results become even more specific. For the first input the entities such as *glaciology* or *Greenland ice sheet* are recommended. For the third input about econometrics and machine learning, both XML-CNN base and FastXML predict a generic entity *information*, XML-CNN IDF predicts more specific *statistics*, and PFastreXML recommends *R programming language*, a popular statistics toolkit for statisticians and mathematicians with support for machine learning. The usefulness of PFastreXML predictions is particularly profound for the last example about gene biology, where all other approaches back off to very generic entities.

7 Conclusions

In this paper we introduced the problem of entity recommendation for a document writer. Good entity recommendations need to be both relevant and interesting, which we motivated with a user study. In particular, we showed how entities which users write in the document are considered as good recommendations and how IDF score correlates with how useful an entity is considered to be. We corroborated this with example predictions, showing how models scoring higher in metrics weighted by IDF provide more interesting suggestions.

The problem of recommending content to document writers has recently been addressed by industry with tools like Google Explore in Docs and Microsoft Researcher, however the systems are proprietary and the methods have not been published. In particular, this work is the first to formalize the problem and provide insights about it to the research community. We hope that this work will inspire further research on recommending novel content to document writers.

Many avenues for further work can be identified, including: finding a better metric capturing novelty of entities, analyzing the influence of the size of the input passage to quality of predictions, and experimenting with new models. Moreover, recent work has considered incorporating knowledge graph information for better use of entity features (Dalton et al., 2014; Liu et al., 2018). This could also be explored for better feature representation in our problem.

Acknowledgments

We would like to thank Kishore Papineni and Shankar Kumar for inspiring and useful discussions which greatly impacted the shape of this work. We also thank the anonymous reviewers for their insightful suggestions.

Abstract

Likability prediction of books has many uses. Readers, writers, as well as the publishing industry, can all benefit from automatic book likability prediction systems. In order to make reliable decisions, these systems need to assimilate information from different aspects of a book in a sensible way. We propose a novel multimodal neural architecture that incorporates genre supervision to assign weights to individual feature types. Our proposed method is capable of dynamically tailoring weights given to feature types based on the characteristics of each book. Our architecture achieves competitive results and even outperforms state-of-the-art for this task.

1 Introduction

Book likability prediction is an important but challenging task. It can be a valuable resource for supporting buying decisions. The experience of choosing a book can be daunting for readers, considering the overwhelming number of books being published. On the other hand, being able to predict how a book will fare in the market has relevant economic value for the publishing industry in order to increase their revenue. The current process is guided by humans, but this is error-prone, very subjective, and a non-scalable process.

An alternative to the human-guided process is to design a reliable automatic system that predicts the likability of books. Such a system, we argue, must be able to take into account all of the many aspects involved in the eventual success of a book. These include not only the topic of the book and the writing style of the author, but in the case of creative writing, also include elements such as creativity, plot structure, and the flow of sentiments (Hall, 2012; Archer and Jockers, 2016; Maharjan et al., 2018; Kar et al., 2018). Other relevant aspects influencing readers' interest for a book could be the cover and the title of the book.

We believe that in addition to the ability to incorporate the different aspects, it is equally important to have a robust mechanism that gives higher weight to the most relevant aspects, while at the same time disregards the noisy or redundant aspects. Traditionally, this is achieved by searching through multiple feature combination experiments for an optimal combination of different feature types (Yang and Pedersen, 1997; Forman, 2003). The main problem with these methods is that they are time-consuming and too rigid. The resulting feature types are fixed for every document. In some books, the style of the author may contribute more than the specific topic, whereas the reverse may be true for other books. These methods lack the ability to dynamically assign weights to different features based on the characteristics of a particular test instance. Most likely, a more flexible scheme that adjusts feature weights based on the current book, can lead to better results.

This paper attempts to solve this problem by introducing a novel method that is capable of automatically combining information from different aspects and learning to weight them dynamically for each book in order to improve likability prediction. Our method also extends the attention model to incorporate domain specific information like the genre of books. As far as we know, we are the first to use genre supervision while computing attention weights and to use them in the field of feature importance. There are many potentially relevant aspects of books that make them likable by readers. Here we focus on different textual modalities, like the lexical, stylistic, syntactic, and neural representations, along with the visual modality from book covers. Our main contributions in this paper are as follows:

- We propose a novel neural architecture,

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3381–3391
Brussels, Belgium, October 31 - November 4, 2018.

which incorporates genre supervision for computing attention weights to learn the importance of hand-engineered and deep learning features coming from different modalities for predicting the likability of books.

- We show through our results that an adaptive combination of features with the genre-aware attention model performs better than strong baselines and also outperforms state-of-the-art.
- We present visualizations that increase interpretability of our results and also demonstrate the advantages of our model.

Along with these contributions, we also show that book cover images contain sufficient information by themselves to perform likability classification, although their contribution becomes negligible in the presence of strong textual features.

2 Methodology

We propose a model that we call Genre-Aware Attention model (GA), which dynamically weights features coming from different aspects of a book by using genre supervision. We first feed our textual and visual features through a non-linear layer to train higher feature representations. We then use our genre-aware attention model to compute appropriate weights for these feature representations. The motivation to add genre information comes from our previous work showing that adding genre classification as an auxiliary task to success prediction improved results (Maharjan et al., 2017). Moreover, it is also reasonable to expect that different genres should have different sets of features that are more relevant when trying to predict whether readers will like the book. For instance, in *Science Fiction*, the theme may be more relevant than say, in *Drama*, where the characters and their interactions or their struggles might be more relevant for likeability prediction.

2.1 Features

For our features, we build on the work by Maharjan et al. (2017) that provides a comprehensive exploration of different hand-crafted features and neural representations. They showed that a combination of writing density (WR) (distribution of word, character, sentences, and paragraphs), Book2Vec, and recurrent neural network representations (RNN) works well for books. Similar to their work, our textual features consist of word, character, and typed character n-grams (Sapkota et al., 2015), syntactic features, sentiment and sentic concepts and scores (SCS) (Cambria et al., 2014), style-related WR and readability (R), and neural representations learned using Word2Vec (Mikolov et al., 2013), Doc2Vec and RNN. We consider these categories of the textual features as different modalities or sources since they capture different aspects of a book and are generated by different processes. In addition to these features, we also add visual information extracted from the book covers. To extract the visual features, we rely on state-of-the-art visual feature extractor methods like VGG (Simonyan and Zisserman, 2014) and Resnet (He et al., 2016), initialized with the weights trained on the Imagenet dataset.

2.2 Genre-Aware Attention Model

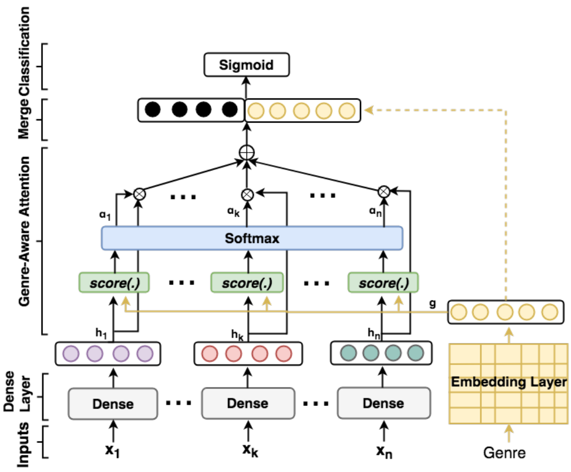

Figure 1: Genre-Aware Attention Model.

Figure 1 shows the overall architecture of our Genre-Aware Attention model. Let X be a collection of books. For a book $x \epsilon X$, let $\mathbf{x_1}, \mathbf{x_2}, \ldots, \mathbf{x_n}$ be the feature representations from the different textual modalities and the visual modality. Since these features have different dimensions, we first pass them through a non-linear layer to project them into a space with the same dimension using Equation 1. This will allow us to perform a weighted average of features from different modalities according to their importance:

$$\mathbf{h_i} = selu(\mathbf{W_h x_i} + \mathbf{b_h}) \tag{1}$$

The source code and data for this paper can be downloaded from `https://github.com/sjmaharjan/genre_aware_attention` where i is the index of the modality whose feature representation is fed into the network, $\mathbf{W_h}$ is the weight matrix, $\mathbf{x_i}$ is the input feature vector for the ith modality, $\mathbf{b_h}$ is the bias, and $selu$ (Klambauer et al., 2017) is the activation function. All of these feature vectors from different modalities may not be equally important to the final representation and in turn to the likability prediction task. We use the genre-aware attention mechanism to learn the importance of each of these features towards our task and aggregate them to get the final representation. The final book representation $\mathbf{r}$ is the weighted sum of $\mathbf{h_i}$ vectors:

$$\mathbf{r} = \sum_i \alpha_i \mathbf{h_i} \tag{2}$$

where α_i are the weights measuring the importance of the different modalities. The GA model combines the genre vector $\mathbf{g} \epsilon \mathbb{R}^{d_g}$ (d_g being the dimension of the genre vector) while computing the α weights. The α_i weights are computed as follows:

$$\alpha_i = \frac{\exp(score(\mathbf{h_i}, \mathbf{g}))}{\sum_{i'} \exp(score(\mathbf{h_{i'}}, \mathbf{g}))} \tag{3}$$

and the $score(.)$ function is defined as:

$$score(\mathbf{h_i}, \mathbf{g}) = \mathbf{v}^T selu(\mathbf{W_a h_i} + \mathbf{W_g g} + \mathbf{b_a}) \tag{4}$$

where, $\mathbf{W_a}$ and $\mathbf{W_g}$ are the weight matrices and $\mathbf{v}$ is the weight vector. The addition of $\mathbf{W_g g}$ incorporates genre supervision. These parameters are shared across all modalities. This will prevent parameter explosion that is likely to occur when the number of modalities is high, which is the case for us. To further investigate the effect of the genre, we also experiment by concatenating the genre vector $\mathbf{g}$ to the final weighted averaged vectors from different modalities $\mathbf{r}$ to obtain $\mathbf{r};\mathbf{g}$. The dotted line from genre vector $\mathbf{g}$ represents this in Figure 1. We then use a non-linear layer with sigmoid activation to project the book representation (either $\mathbf{r}$ or the concatenation $\mathbf{r};\mathbf{g}$) to class probabilities.

$$\hat{p} = \sigma(\mathbf{W_c r} + \mathbf{b_c}) \tag{5}$$

where, $\mathbf{W_c}$ is the weight matrix and $\mathbf{b_c}$ is the bias vector. Finally, we train the network by minimizing the binary cross entropy loss using Adam (Kingma and Ba, 2015).

$$L = -\sum_i p_i \log \hat{p}_i \tag{6}$$

where, p_i and $\hat{p}_i$ are true labels and predictions, respectively.

3 Dataset

We experiment with the dataset collected by Maharjan et al. (2017). The dataset consists of books from eight different genres: *Detective Mystery*, *Drama*, *Fiction*, *Historical Fiction*, *Love Stories*, *Poetry*, *Science Fiction*, and *Short Stories*. These books have been reviewed by at least ten reviewers. Based on the average rating received by the books on Goodreads[1], they labeled the books into two categories: *Successful* and *Unsuccessful*. The collection has a total of 1,003 books. However, the dataset did not include book covers. We augmented this dataset by downloading the covers from Goodreads. Since this dataset only contains publicly available books, all of them were published over 100 years ago. Some of the books only had the title of the book on a plain background as their cover images on Goodreads. We manually searched for these books with Google Image Search and found the actual covers for most of them. However, even after an exhaustive search, we were unable to obtain proper covers for 21 books. We did not remove these books from the dataset for the sake of comparison with Maharjan et al. (2017).

4 Experiments and Results

We used the same train and test folds as used by Maharjan et al. (2017) for all of our experiments. The dataset consists of 349 books belonging to the *Unsuccessful* class and 654 books belonging to the *Successful* class. Since the dataset is imbalanced, they as well as we use weighted F1-score to evaluate the performance.

4.1 Baselines

The most naive baseline will be to predict the majority class for all test instances. This majority class baseline yields a weighted F1-score of 50.6% for the likability classification task. This baseline will help to understand whether our proposed model is actually learning from the data at all. Apart from this, we compare with the results from Maharjan et al. (2017) and we also define several other baselines to validate the superiority of our proposed model. All of the

---

[1] https://www.goodreads.com/

baseline methods are listed below:

Mah'17: The current state-of-the-art for this dataset by Maharjan et al. (2017). They have several results on various combinations of textual features.

Mah'17+Vis: This method is the extension of the Mah'17 method with the addition of visual features. Similar to them, we use the SVM classifier under two settings: Single-task (ST) and Multi-task (MT). In ST, we simply predict the likability of books. In MT, along with predicting likability, we also predict genre simultaneously. This experiment will allow us to make a direct comparison with Mah'17 regarding the effect of adding visual modalities.

Concatenation: Similar to GA, we first feed the features from different modalities through a non-linear layer each having the same number of neurons. We then concatenate them to obtain the final representation for a book. We send this representation to a sigmoid layer for success prediction.

Average Pooling: Instead of concatenation, we take an average of the features after passing them through the non-linear layer. This is also comparable to an attention model assigning equal weights to all modalities.

Attention: We use a multilayer perceptron to learn the appropriate weights for each of the features from different modalities. This method is similar to our proposed method, except that we do not use genre information for computing the attention weights. We compute the $score(.)$ as $\mathbf{v}^T selu(\mathbf{W_a h_i} + \mathbf{b_a})$, without the genre information. This experiment will help us understand the importance of genre in computing weights for the feature types.

Bilinear Model: We combine the non-linear transformed modalities $\mathbf{h_1}, \ldots, \mathbf{h_n}$ using a bilinear form $(\mathbf{h_i}^T \mathbf{W_b h_j} + \mathbf{b_b})$, where $\mathbf{W_b} \epsilon \mathbb{R}^{k \times d_{h_i} \times d_{h_j}}$ is the weight tensor and $\mathbf{b_b}$ is the bias vector (Socher et al., 2013; Laha and Raykar, 2016; Fukui et al., 2016; Gao et al., 2016). This operation gives us a k-dimensional vector. In the case of more than two modalities, we first create $\binom{n}{2}$ pairs of these modalities and combine each of them using a bilinear form. The final book vector is the concatenation of the resulting vectors from each of these pairs. Bilinear models are used in the visual question answering community to fuse visual and textual information (Fukui et al., 2016). This experiment will help us understand how our proposed model compares with other state-of-the-art multimodal approaches.

For all these models as well, we also performed additional experiments by concatenating the genre vector $\mathbf{g}$ with the final representations $\mathbf{r}$ obtained from each of these models to study the significance of including genre explicitly for likability prediction.

4.2 Experimental Settings

For the experiments involving the SVM classifier, we tuned the C hyper-parameter with values {1e-4, ..., 1e4} by performing three-fold grid search over the training data and then used the best hyper-parameters to train the final model. For the neural network experiments, we first separated 20% of the training data as a validation set and tuned dropout rates {0.2, 0.4, 0.5}, different weights initialization schemes {Glorot Uniform (Glorot and Bengio, 2010), LeCun Uniform (LeCun et al., 1998)}, learning rate with Adam {1e-4, ..., 1e-1}, number of hidden neurons in different layers {100, 200}, and batch size {1, 4, 8} with early stopping criteria. We initialized the genre embeddings with orthogonal vectors.

4.3 Results

Table 1 shows and compares our results with different baselines. We experimented with both low performing as well as high performing features and their combinations as found by Maharjan et al. (2017). We obtained the best weighted F1-score of 75.4% with our proposed GA+Genre concatenation model. This is 4.2% and 8.7% above the corresponding results reported by Mah'17 with their MT and ST settings, respectively. We also see a significant* improvement of 6.5% (over MT) and 22.2% (over ST) when using *RNN* features with our proposed method as compared to Mah'17. These results support the superiority of our method in learning high-quality book representations than Mah'17's state-of-the-art methods.

The results also show that it is beneficial to use at least some form of attention over just *Average Pooling*. This suggests that using all available features without regards to their individual contribution towards the task at hand can actually worsen the performance. Our proposed model is capable

Table 1: Weighted F1-scores(%) for different multimodal methods for books' likability classification task (ST=Single Task, MT=Multitask, SCS=Sentic Concepts and Scores, WR=Writing Density, RNN=Recurrent Neural Network Representations, + Genre= genre embedding $\mathbf{g}$ concatenated with the final book vector $\mathbf{r}$). Our baselines and proposed method include visual features as well.

of assigning importance to these features and the results clearly show that this works to our benefit. The results also demonstrate the added advantage of using genre supervision while computing feature weights. There is a considerable improvement in the performance over the *Attention* method after taking the genre information into account using our GA method. We suspect that the genre meta-information is helping to learn more specialized weights based on the genre of the books.

With the neural baseline methods like *Concatenation* and *Average pooling*, we do not always see improvement in performance after combining the genre information with the final book representation. Apart from these two, the combination of genre information does improve the results for other methods. The *Bilinear* and *Attention* methods seem to be able to utilize this information well. However, none of these methods are capable of doing better than our method. GA and GA+Genre concatenation models always achieve the best performance for all experiments. This also illustrates the latent power of our method to better exploit domain information like genre for performance improvement.

Another interesting finding is that with the addition of multiple modalities, the performance of Bilinear methods degrades to the majority class baseline (Table 1, last row). This may be due to parameter explosion with the increase in the number of modalities. However, our method is able to selectively weight the feature sources and discount the effect of redundant and irrelevant features to obtain the best performance, even with a larger number of modalities. In short, we see that our proposed method is able to cope with feature pollution and parameter explosion.

Next, we investigate the addition of visual information with the textual information for the likability prediction of books. Under the ST setting with SVMs, we see that the low performing textual features are benefited significantly by the addition of visual features, sometimes even outperforming the MT setting (Table 1, rows 1-4). However, the visual features are not able to contribute much when combined with strong textual features that were already performing well. On the other hand, for the MT setting, the performance decreases for most of the feature combinations with the addition of the visual modality. We suspect that book covers are not very helpful at predicting genre and thus the MT setting does not do well with additional visual features.

Visual Results: Our next set of experiments considers only the visual information for books' likability prediction. Even though we do believe that this current corpus might not be ideal for using cover features, we believe it is still interesting to explore whether the current book covers have sufficient information to perform likability classification with reasonable accuracy. We used VGG and Resnet to extract features from book cover images. We replaced the top layers by a dense layer of 256 neurons, and a classification layer (eight neurons with softmax for genre classification and one neuron with sigmoid activation for success classification). We also added a dropout layer in between the dense and the classification layer. The layers were initialized with weights trained on the Imagenet dataset.

Resnet + SVM	**59.5**	54.5	**25.9**	19.7

Table 2: Weighted F1-scores(%) for visual features for likability and genre classification of books with Single Task (ST) and Multitask (MT) settings.

Table 2 shows the results with only the visual features for likability and genre classification of books under the ST and MT settings. We obtain the highest weighted F1-score of 61.8% and 25.9% for likability and genre classification tasks, respectively. With the neural experimental setup, we get similar performance under the ST and the MT settings for both tasks. We also experimented with transferring the visual feature vectors to the SVM classifier under the ST and the MT settings. We saw a decrease in performance under the MT settings with both the VGG and Resnet features (Table 2, last two rows). This is the opposite of the Mah'17 results for the textual features as seen in Table 1. The reason behind this may be due to the fact that the textual features are better at both the likability and the genre classification tasks individually, whereas the visual features are not as good as the textual features for the genre classification task. Iwana et al. (2016) also concluded that genre classification with book covers is a difficult task as book covers have images with few visual features or ambiguous features.

These results also empirically verify the decrease in performance for the MT settings with the addition of visual features for likability prediction. Although these results are significantly lower (p<0.001*) than our best results, they are still better than the majority baseline (50.6% and 10.7% for success and genre classification tasks, respectively). These results support our hypothesis that the books' cover images correlate with the likability of books. Also, they dictate for the need of extracting other features that consider different aspects of books.

5 Attention Weights Visualization

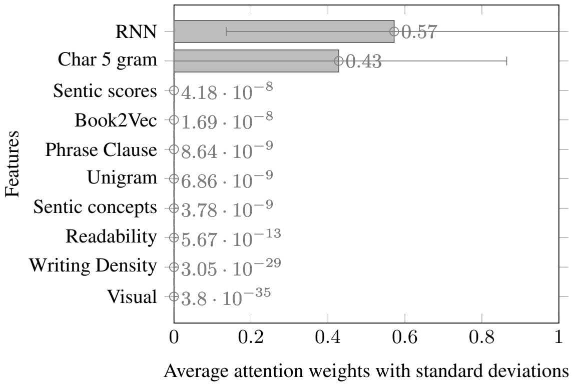

Figure 2: Feature importance for the feature combination: All best handcrafted, RNN, and visual (RNN = Recurrent Neural Networks).

Figure 2 shows the average attention weights given by the best model to the different feature types for the books in the test set. The purpose of this visualization is to understand which aspects of a book are deemed to be more important by the model. The figure shows that most of the weights are assigned to the *Char* 5-*gram* and the *RNN* representations. The results in Table 1 also support that *RNN* features are indeed one of the most important features. The contribution of the visual representations is negligible in the presence of strong textual features. The results in Table 1 also validate this finding. These two textual features also dominate over the other weaker textual features. In the same way, as for the visual features, we see negligible weights assigned to the other textual features as well. Our model seems to have learned that the *Char* 5-*gram* and the *RNN* features can cover the information given by the rest of the features. The *Char* 5-*gram* feature is capable of capturing the content, topic, and style of a text and as such might be able to cover the *Unigram* and *Sentic Concepts* features. Likewise, the *Book2Vec* features may be non-essential in the presence of the *RNN* representations. The model is reducing redundant information that does not aid the classification task and instead might just add noise.

In order to validate that features given the top weights by our model are indeed the best features for the task, we ran an experiment with only the *Char* 5-*gram* and the *RNN* features. We were able to obtain a weighted F1-score of 73.6% with just these two features. This score is close to the best score of 75.4%, showing that these features are indeed good features for the task. Also, note that our model was able to figure out this feature set automatically, while using traditional methods would have entailed performing multiple experiments ($2^n - 1$ experiments, where n is the number of feature types) which is often times not possible to do exhaustively. There is still an extra boost when using the whole feature set rather than using just the *Char* 5-*gram* and the *RNN* features. Since our method tailors the feature weights to each book and its genre as well, the boost likely comes from the presence of other visual and textual features, which at least for some books must be informative.

We just saw that only two out of all feature types are given most of the weights. However, the results in Table 1 show that even without these fea-

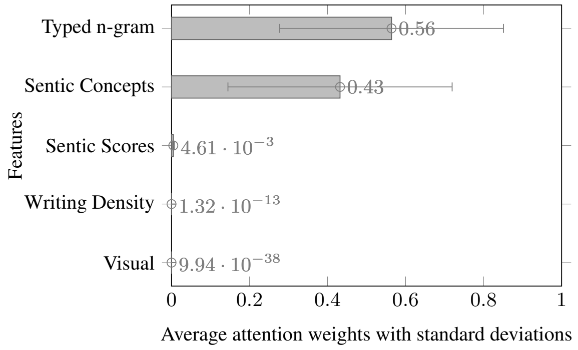

Figure 3: Feature importance for feature combination Sentic Concepts and Scores, Writing Density, Typed n-gram, and Visual.

tures, we are able to get good performances. To understand this, we analyze a model that does well without these two features. Figure 3 plots the average attention weights for a model with *Sentic Concepts and Scores*, *Writing Density*, *Typed* n-*grams*, and *Visual* features' combination. We see that the weights now shift to *Typed* n-*grams*, and *Sentic Concepts and Scores*. The topic and content captured through *Sentic concepts* and the style with *Typed* n-*grams* prove important. These features capture different aspects of books and are not strongly correlated with one another. Our model is capable of figuring out that in the absence of *Char* 5-*gram*, which encompasses all this information, these other features need to be made more prominent. We can also see that the model knows three different feature types to capture the same amount of information as captured by the two best ones from before.

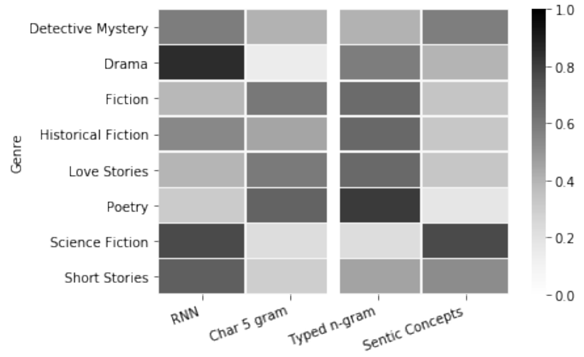

Figure 4: Average attention weights with respect to genre for the best features from two models.

Figure 4 further breaks down the attention weights by genre for *RNN* and *Char* 5-*gram*, and *Typed* n-*grams* and *Sentic Scores and Concepts*. From the figure, it is evident that different genres respond differently to each feature type. Comparing the two models, we see that *Char* 5-*gram* activates similarly to *Typed* n-*gram*, and *RNN* similarly to *Sentic concepts* for different genres.

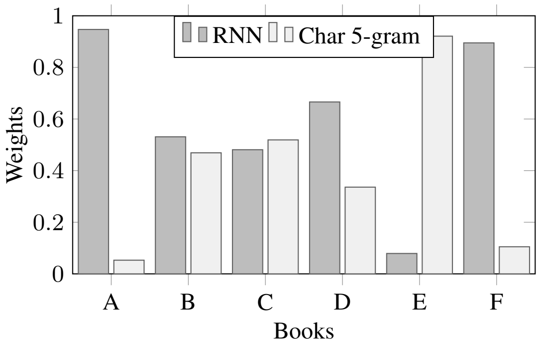

Figure 5: Feature importance as assigned by attention weights for two most important features for six different books: *A=The Count of Monte Cristo, B=The Scouts of the Valley, C=The Daughter of the Commandant, D=The Northern Light , E=The Great Secret, F=House of the Seven Gables.*

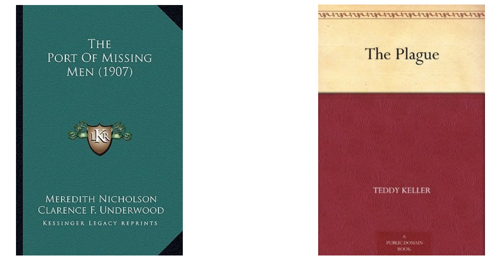
Figure 5 shows the feature importance for the *Char 5-gram* and *RNN* feature types for six different books having different attention weights for the two features. This validates our assumption that the model is able to dynamically learn and assign weights to different modalities, not only according to the genre but also according to the characteristics of each book. The high variance of attention weights for the top features in Figures 2 and 3 also support this claim. This gives an edge to our model and helps it excel over all other methods.

6 Error Analysis



(a) The Port of Missing Men (b) The Plague

Figure 6: Books misclassified by visual features but correctly classified when textual features are added.

We took the books that were misclassified when we used the visual features only but were correctly predicted after the combination with the textual dimensions. As expected, we found that the books without proper covers were misclassified by visual features. But upon addition of other textual

Figure 7: Books misclassified by visual and text features' combination but correctly classified when only visual features are used.

features, they were correctly classified. Figure 6 shows the cover image of two of such books. The fact that the cover has no images with just plain background, and title, leaves little information for the visual modality. Similarly, we also analyzed the books that were correctly classified by visual features only and misclassified when textual features were added. Figure 7 shows two such books. Both the cover image and the title (present in the cover) of these two books seem to be interesting and are very likely to attract a reader's attention.

7 Related Work

Prior works have shown that stylistic traits to be useful features to predict success of books (Ashok et al., 2013; Underwood and Sellers, 2016; Maharjan et al., 2017). Ashok et al. (2013) used stylistic features extracted using the first 1K sentences from books to classify highly successful literature from less successful literature. van Cranenburgh and Bod (2017) used lexical and rich syntactic tree features to distinguish the degrees of high and less literary novels. Louis and Nenkova (2013) defined genre-specific and general features to predict the article quality in science journalism domain. Maharjan et al. (2017) compared their work with Ashok et al. (2013) and presented a new dataset for the book success prediction task. Their multitask approach with the combination of deep representations and hand-crafted features improved the classification results. Maharjan et al. (2018) also showed that modeling sequential flow of emotions across entire books improves likability prediction of books. Iwana et al. (2016) used neural networks to learn relationships between book covers and genre. They showed that book covers tend to have carefully designed color and tone, objects, and text. Our work relies on prior works' hand-engineered and deep learning features but differs in a way how these features are combined to produce a meaningful book representations.

The attention mechanism (Bahdanau et al., 2014) has been successfully applied in enhancing the document representation for several text classification (Zhang et al., 2016; Wang et al., 2016b), sentiment classification (Kar et al., 2017; Nguyen and Shirai, 2015; Wang et al., 2016a), question answering (Tan et al., 2015; Chen et al., 2016a; Hermann et al., 2015), named entity recognition (Bharadwaj et al., 2016; Aguilar et al., 2017), summarization (Rush et al., 2015), image-captioning (Xu et al., 2015) tasks. Zhang et al. (2017) used summary vectors and position vectors while computing the attention weights for the slot filling problem. Chen et al. (2016b) applied user preferences and product characteristics as attentions to words and sentences in reviews to learn the final representation for the sentences and reviews. They used these representation to do the sentiment classification task and showed that adding user information was much more effective in enhancing the document representations than the product information. Similar to their idea, we fuse the genre information while computing attention weights.

8 Conclusions and Future Work

We present a novel method to fuse the information coming from different modalities using a genre-aware attention mechanism to predict the likability of books. We showed that our proposed method outperforms strong baselines and state-of-the-art by learning to distinguish the important features from irrelevant or redundant ones. Other methods either suffered from feature pollution or parameter explosion and yielded low performance. Along with this, our results also showed that the book cover images by themselves also have sufficient information to perform success prediction. However, the difficulty in predicting genre from book covers decreased the performance in multi-task settings with additional visual features. We also used different visualizations to support our findings and improve interpretability of our model. As future work, we will extend the proposed method to include components that learn weights for individual feature elements and not only the entire feature type. This could likely result in higher quality multimodal representations.

Abstract

The task of thread popularity prediction and tracking aims to recommend a few popular comments to subscribed users when a batch of new comments arrive in a discussion thread. This task has been formulated as a reinforcement learning problem, in which the reward of the agent is the sum of positive responses received by the recommended comments. In this work, we propose a novel approach to tackle this problem. First, we propose a deep neural network architecture to model the expected cumulative reward (Q-value) of a recommendation (action). Unlike the state-of-the-art approach, which treats an action as a sequence, our model uses an attention mechanism to integrate information from a set of comments. Thus, the prediction of Q-value is invariant to the permutation of the comments, which leads to a more consistent agent behavior. Second, we employ a greedy procedure to approximate the action that maximizes the predicted Q-value from a combinatorial action space. Different from the state-of-the-art approach, this procedure does not require an additional pre-trained model to generate candidate actions. Experiments on five real-world datasets show that our approach outperforms the state-of-the-art.

1 Introduction

Online discussion forums allow people to join in-depth conversations about different topics in form of threads. Each thread corresponds to one conversation, which is initiated by a post and users respond to it with comments. In addition, a comment can be further replied by another comment, forming a discussion tree. Users who are interested in a particular thread will subscribe to it. After the subscription, users will receive a notification when a new comment arrives in that thread. However, the speed of content generation in a well-known discussion forum is breakneck. For instance, in Reddit[1], there were more than 900 million comments posted in 2017 (Reddit, 2017). Hence, merely pushing every new comment to the subscribers leads to a poor user experience. Motivated by this issue, He et al. (2016c) proposed the task of thread *popularity prediction* and *tracking*. When N new comments arrive in a thread, the system performs one step of recommendation by pushing K comments to the subscribers. We want to maximize the sum of popularities of the recommended comments over all recommendation steps. The popularity of a comment is measured by the number of positive reactions it received, e.g., the rating. With the assumption that a user needs to know the prior context in order to understand a comment, the system can only recommend new comments that are in the subtrees of previously recommended comments. Thus, the selection of comments at the current recommendation step will affect the comments that we can choose in the future recommendation steps.

To incorporate the long-term consequences of recommendations, the task of thread popularity prediction and tracking has been formulated as a reinforcement learning problem, in which an agent selects an action (a set of K comments) according to its current state (previous recommended comments), with the goal of maximizing the cumulative reward (total popularities of the recommended comments over all recommendation steps). The optimal action of the agent at each step is the action that maximizes the Q-function, $Q(s, a)$, which denotes the long-term reward of choosing action a in state s. In practice, we learn this Q-function using a parametric function, $Q(s, a; \theta)$, where θ is the model parameter vector. Thus, the predicted optimal action of the agent is the action

---

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3392–3401
Brussels, Belgium, October 31 - November 4, 2018.

that maximizes $Q(s, a; \theta)$.

This reinforcement learning problem has two main challenges. First, we need to develop a parametric model, $Q(s, a; \theta)$, to approximate the Q-function. Second, finding the action that maximizes $Q(s, a; \theta)$ requires the prediction of all $\binom{N}{K}$ possible actions, which is intractable. Thus, we need a procedure to approximate the predicted optimal action from a combinatorial action space.

To address the first challenge, He et al. (2016c) proposed a neural network model, DRRN-BiLSTM, to approximate the Q-function. In this model, a bi-directional long short-term memory (LSTM) (Graves and Schmidhuber, 2005) is used to encode the set of K comments in an action. To address the second challenge, they proposed the two-stage Q-learning procedure to approximate the predicted optimal action (He et al., 2017). In this procedure, the agent uses a pre-trained and less-sophisticated model to rank all possible actions, then it uses the DRRN-BiLSTM to re-rank the top-M actions and selects the best one. However, this approach has two limitations. First of all, bi-directional LSTM is a sequence model, which treats the set of K comments in an action as a sequence. Although they tried to fix this problem by feeding randomly-permuted comments to the model, a different permutation of the same set of comments leads to a different Q-value prediction. Thus, the agent may not consistently select the predicted optimal action. Secondly, the two-stage Q-learning procedure requires an additional pre-trained model to generate candidate actions.

Our work addresses these two limitations as follows. We propose a novel neural network model, DRRN-Attention, to approximate the Q-function. In our model, we use an attention mechanism (Bahdanau et al., 2014) to integrate the information from a set of comment into an action embedding vector. In a nutshell, the attention mechanism outputs a weighted sum of the comment representations, where the weights are learned by a subnetwork to indicate the importance of each comment. Thus, the action embedding is invariant to the permutation of the comments, which leads to a permutation invariant Q-value prediction. Next, we employ a greedy procedure to approximate the action that maximizes $Q(s, a; \theta)$. This procedure only requires the prediction of $O(NK)$ actions, which is significantly lower than $\binom{N}{K}$. Moreover, it does not require an additional pre-trained model to generate candidate actions.

In our experiments, we evaluate the performance of our DRRN-Attention model and the greedy approximation procedure against the baselines on five real-world datasets. Experimental results demonstrate that our approach beats the baselines on four of the datasets and achieves a competitive performance on one of the datasets. Furthermore, we analyze the performance of our approach across four action sizes ($K = 2, 3, 4, 5$). Our approach consistently achieves a higher cumulative reward than the baselines across all these action sizes.

We summarize our contributions as follow: (1) a new neural network architecture to model the Q-value of the agent which is invariant to the permutation of sub-actions; (2) a greedy procedure for the agent to select an action from the combinatorial action space without an additional pre-trained model; and (3) the new state-of-the-art performances on five real-world datasets.

2 Related Work

2.1 Reinforcement Learning in Text-based Tasks

Reinforcement learning has been widely applied in various text-based tasks. There are several articles in literature studying the tasks of mapping instruction manuals to a sequence of commands, such as game commands (Branavan et al., 2011), software commands (Branavan et al., 2010), and navigation directions (Vogel and Jurafsky, 2010). In the task of text-based game, an agent selects a textual command from a set of feasible commands at every time step. Narasimhan et al. (2016) considered a special case that all the textual commands have a fixed structure, while He et al. (2016b) and Chen et al. (2017) considered another case that all commands are free text.

In the task of thread popularity prediction and tracking, the agent selects a set of K comments from N available comments at every time step, where each comment is a free text. He et al. (2016c) proposed two different approaches to tackle this task. In their first approach, the agent uses the Deep Reinforcement Relevance Network (DRRN) (He et al., 2016b) to model the Q-function of selecting a comment. In their second approach, the agent uses the DRRN-BiLSTM (He et al., 2016c) to model the Q-function of an action. To due with the combinatorial action space, the agent uses uniform sampling to generate a set of M candidate actions. To improve this random sampling scheme, they proposed the two-stage Q-learning procedure in their later work (He et al., 2017), which used a pre-trained model to generate M candidate actions. Their experimental results showed that using DRRN-BiLSTM with two-stage Q-learning procedure outperforms all other existing methods. The difference between our model and DRRN-BiLSTM is that we use attention to encode a set of comments rather than using a bi-directional LSTM. Besides, the greedy procedure in our approach does not require any extra pre-trained model. He et al. (2017) also considered a special case that the agent can access an external knowledge source to augment the state representation. This setting is orthogonal to this work since we focus on the action encoding and the approximation of predicted optimal action.

One line of research focused on the integration of sequence-to-sequence (SEQ2SEQ) model (Sutskever et al., 2014) and reinforcement learning framework, examples including dialogue generation (Dhingra et al., 2017; Li et al., 2016; Su et al., 2016), question answering system (Buck et al., 2017), and machine translation (He et al., 2016a). In these tasks, the agent selects an action by generating a free text using a SEQ2SEQ model.

2.2 Deep Learning on Sets

Most of the deep learning models on sets employed attention to integrate information from a set of input. This idea was first introduced in the read-process-and-write network (Vinyals et al., 2016), which uses a process module to perform multiple steps of attention over a set of vectors to obtain a permutation-invariant embedding. Our work adapts this idea to aggregate a set of comment embedding vectors. In the domain of graph learning, several models (Sukhbaatar et al., 2015; Zhang et al., 2017) learn an embedding of a node by attending over its neighboring nodes. All of the above models can be interpreted as a special case of memory network (Weston et al., 2015; Sukhbaatar et al., 2015; Zhang et al., 2017), if we view the set of feature vectors as external memory. Max-pooling is another promising technique for the problem of learning on sets. Qi et al. (2017) used max-pooling to aggregate the feature vectors of a set of 3D geometry points. Recently, Zaheer et al. (2017) derived the necessary and sufficient conditions for a neural network layer to be permutation invariant.

2.3 Popularity Prediction

Another related line of research is popularity prediction problem in a supervised learning setting. Yano and Smith (2010) used the LDA topic model (Blei et al., 2003) to predict the number of comments of a blog post in a political blog. There are also several studies focused on the task of predicting the number of reshares on Facebook (Cheng et al., 2014) and the number of retweets in tweeter based on the text content (Tan et al., 2014; Hong et al., 2011). Recently, Cheng et al. (2017) proposed a neural network model to learn comment embeddings for the task of community endorsement prediction in a supervised learning setting.

3 Preliminary

3.1 Discussion Tree

A discussion thread in an online forum can be represented as a tree. Each node in the tree stores a free text. The root node represents the post of the thread and each non-root node represents a comment of the thread. There is a directed edge from node u to node v if and only if a comment (or post) u is replied by comment v. This tree keeps growing as new comments are submitted to the thread.

3.2 Problem Definition

The task of thread popularity prediction and tracking is formally defined as a reinforcement learning problem. We use M_t to denote the set of comments that are being tracked at time t. Given a discussion thread, we start an episode as follows. First, we initialize M_1 to be the post of a thread. Then, at each time step t the agent performs the following operations:

- Read the current state s_t, which is all the previously tracked comments $\{M_1, \ldots, M_t\}$.
- Read N new comments, $c_t = \{c_{t,1}, \ldots, c_{t,N}\}$, in the subtree of M_t.
- Select a set of K comments from c_t to recommend, $a_t = \{c_t^1, \ldots, c_t^K\}$, where $c_t^i \in c_t$ for $i = 1, \ldots, K$ and $c_t^i \neq c_t^j$ for $i \neq j$.

- Receive a reward, $r_{t+1} = \sum_{i=1}^{K} \eta_{c_t^i}$, where $\eta_{c_t^i}$ is the number of positive reactions received by comment c_t^i.
- Track the set of recommended comments in the next time step, $M_{t+1} = a_t$.

The episode terminates when no more new comments appear in the subtree of M_t. The goal of the agent is to maximize the cumulative reward.

3.3 Q-function

The state-action value function (or Q-function), $Q(s, a)$, is defined as the expected cumulative reward starting from state s and taking action a. More formally, $Q(s, a) = \mathbb{E}[\sum_{l=0}^{+\infty} \gamma^l r_{t+1+l} | s_t = s, a_t = a]$, where $\gamma \in (0, 1]$ is a discount factor for future rewards. Since the goal of the agent is to maximize the cumulative reward, the optimal action for each state is the action that achieves the highest Q-value. Thus, the Q-function is associated with an optimal policy: in every state, the agent selects the action that maximizes the Q-function, i.e., $a_t = \operatorname{argmax}_a Q(s_t, a)$, $\forall t$. Since this Q-function is unknown to the agent, we approximate the Q-function using a parametric model, $Q(s, a; \theta)$, and update the parameters θ using received rewards.

3.4 Exploration-Exploitation Trade-off

The agent needs to balance the exploration-exploitation trade-off when selecting an action. On one hand, the agent can choose the action with the highest estimated Q-value to exploit its current knowledge of the Q-function. On the other hand, the agent can choose a non-greedy action to get more information about the Q-value of other actions. The balance between exploration and exploitation can be achieved by using the ϵ-greedy policy, in which the agent selects a random action with probability ϵ, and selects a greedy action with probability $1 - \epsilon$. Note that the term "greedy" in the ϵ-greedy policy means that the agent selects the action that is predicted to be optimal, i.e., select $a_t = \operatorname{argmax}_a Q(s_t, a; \theta)$. It does not refer to the greedy procedure, which is used to approximate the predicted optimal action in a combinatorial action space.

4 DRRN-Attention Model

In this work, we propose a new deep neural network model, named DRRN-Attention, to approximate the Q-function for the task of thread popularity prediction and tracking. The input to our model is a state, s_t, and an action, $a_t = \{c_t^1, \ldots, c_t^K\}$, as defined in Section 3.2. The output is the prediction of Q-value, i.e., $Q(s_t, a_t; \theta) \in \mathbb{R}$. Figure 1 illustrates the overall architecture of DRRN-Attention. We divide our model into three modules as follows.

4.1 Text Representation Module

The text representation module reads s_t and $a_t = \{c_t^1, \ldots, c_t^K\}$. We first convert $s_t, c_t^1, \ldots, c_t^K$ into bag-of-words (BOW) representations, $b_{s_t}, b_{c_t^1}, \ldots, b_{c_t^K}$. Then, we use a 2-layer feedforward neural network to embed b_{s_t} into a d-dimensional state embedding vector, $m_{s_t} \in \mathbb{R}^d$. After that, we use another 2-layer feedforward neural network to embed $b_{c_t^i}$ into a d-dimensional comment embedding vector, $m_{c_t^i} \in \mathbb{R}^d$, for $i = 1, \ldots, K$. This module outputs m_{s_t} and $\{m_{c_t^1}, \ldots, m_{c_t^K}\}$.

4.2 Set Embedding Module

The input to this module is a set of d-dimensional comment embeddings, $\{m_{c_t^1}, \ldots, m_{c_t^K}\}$. The output is an action embedding vector, $m_{a_t} \in \mathbb{R}^{h+d}$, which is invariant to the ordering of comment embeddings. The module consists of a single-layer LSTM with a hidden size of h, and a shared attention mechanism, $f : \mathbb{R}^h \times \mathbb{R}^d \to \mathbb{R}$. The initial hidden state, $q_0 \in \mathbb{R}^h$, of the LSTM is a trainable vector. Inspired by (Vinyals et al., 2016), we perform L steps of computations over the comment embedding vectors. More specifically, at each step of computation $l = 0, 1, \ldots, L - 1$:

- The query vector, $q_l \in \mathbb{R}^h$, is the current hidden state of the LSTM.
- Apply the attention mechanism to compute an attention coefficient, $e_{i,l}$, between the query, q_l, and a comment embedding, $m_{c_t^i}$, for $i = 1, \ldots, K$. In general, this framework is agnostic to the underlying attention mechanism. In this work, we closely follow the attentional setup in (Bahdanau et al., 2014), as shown in the following equation.

$$e_{i,l} = v^T \tanh(\mathbf{W_e} m_{c_t^i} + \mathbf{U_e} q_l), \qquad (1)$$

where $v \in \mathbb{R}^{h'}$, $\mathbf{W}_e \in \mathbb{R}^{h' \times d}$, and $\mathbf{U}_e \in \mathbb{R}^{h' \times h}$.

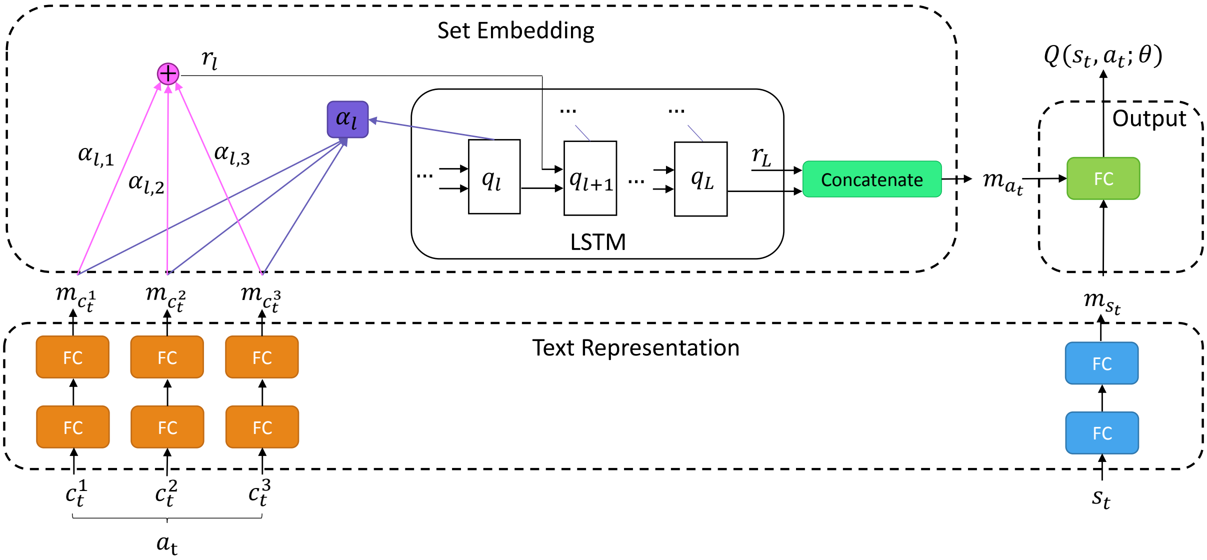

Figure 1: Architecture of DRRN-Attention model. The text representation module first converts state s_t and each comment c_t^i in action a_t into embedding vectors. Then, the comment embedding vectors are passed to the set embedding module to learn an action embedding vector. Finally, the state embedding and the action embedding are passed to the output module to output a prediction of Q-value.

- Apply softmax function to normalize the attention coefficients,

$$\alpha_{i,l} = \frac{\exp(e_{i,l})}{\sum_{j=1}^{K} \exp(e_{j,l})}. \tag{2}$$

- Use the normalized attention coefficients to compute a weighted sum of the comment embedding vectors, as the readout in this computation step,

$$r_l = \sum_{i=1}^{K} \alpha_{i,l} m_{c_t^i}. \tag{3}$$

- The LSTM takes q_l and r_l as input and computes the next hidden state, q_{l+1},

$$q_{l+1} = \text{LSTM}([q_l, r_l]). \tag{4}$$

Note that swapping any two comment embedding vectors, $m_{c_t^i}$ and $m_{c_t^j}$, will not affect the query vector q_l as well as the attention readout r_l. After L steps of computation, this module concatenates q_L and r_L to yield the final output action embedding, $m_{a_t} = [q_L, r_L] \in \mathbb{R}^{h+d}$.

4.3 Output Module

The input to this module is a state embedding vector, $m_{s_t} \in \mathbb{R}^d$, and an action embedding vector, $m_{a_t} \in \mathbb{R}^{h+d}$. We simply concatenate m_{s_t} and m_{a_t} and pass them through a fully-connected layer. The output is $Q(s_t, a_t; \theta) \in \mathbb{R}$, which is the prediction of $Q(s_t, a_t)$.

Algorithm 1 Greedy$(s_t, c_t, Q(\cdot, \cdot; \theta), K)$

```
$a = \emptyset$
for $i = 1 \to K$ do
    $c^* = \text{argmax}_{c \in c_t \setminus a} Q(s_t, a \cup c; \theta)$
    $a = a \cup c^*$
return $a$
```

5 Greedy Procedure

The next challenge that we need to address is to approximate the predicted optimal action in a combinatorial action space. Finding the predicted optimal action, $\text{argmax}_a Q(s_t, a; \theta)$, is intractable since it requires the prediction of all $\binom{N}{K}$ actions. In this work, we use a greedy procedure to compute an approximation. The complete procedure is shown in Algorithm 1. We start from an empty action, $a_t = \emptyset$, and then iteratively adds into a_t the comments that leads to the largest increase in $Q(s_t, a_t; \theta)$, until $|a_t| = K$. The procedure consists of K iterations. In each iteration i, we need to predict the Q-value for $n - i$ actions. In total, it only requires the prediction of $O(NK)$ actions, which is tractable. The advantage of this procedure over existing methods is that it does not require another pre-trained model to generate candidate actions.

6 Parameter Learning

We use the deep Q-learning algorithm (Mnih et al., 2015), which is a variant of the traditional Q-learning algorithm (Watkins and Dayan, 1992), to learn the model parameters of $Q(s, a; \theta)$ from the received rewards. The complete training procedure is shown in Algorithm 2 in the Appendix. The network parameters θ are first initialized arbitrarily. At each time step t, the agent selects an action a_t according to the ϵ-greedy policy, receives a reward r_{t+1}, and transits to the next state s_{t+1}. Thus, it yields a transition tuple, $\zeta_t = (s_t, a_t, r_{t+1}, s_{t+1})$. Instead of using the current transition tuple, ζ_t, to update the parameters, we first store ζ_t into an experience memory, D. This experience memory has a limited capacity, $|D|$, and the stored transition tuples are rewritten in a first-in-first-out manner. Then, we sample mini-batches of transition tuples (s, a, r, s') from D uniformly at random. Using the sampled transition tuples, we perform a step of stochastic gradient descent to minimize the following loss function,

$$L(\theta) = \mathbb{E}_{(s,a,r,s')\sim U(D)}[(y - Q(s, a; \theta))^2], \quad (5)$$

where $y = r + \gamma \max_{a'} Q(s', a'; \theta^-)$ is the Q-learning target, θ^- are the network parameters of the Q-learning target. We update θ^- to match the network parameters, θ, after every F time steps, where F is a hyperparameter.

7 Experimental Setup

In the experiments, we analyze the performances of different neural network models and different approximation procedures. First, their performances are evaluated on five real-world datasets, with a fix action size K. Then, we evaluate their performances with different action sizes, on one dataset. For each experiment setting, we do the following comparative analysis:

- Compare the performance of our DRRN-Attention model with the baseline models using different approximation procedures.
- Compare the performance of the greedy procedure with the baseline approximation procedures using different neural network models.
- Find the approach (combination of neural network model and approximation procedure) that achieves the best performance.

Finally, we conduct a case study to better illustrate the difference between our DRRN-Attention model and the DRRN-BiLSTM baseline.

Subreddit	**# Posts**	**# Comments**
askscience	0.94k	0.15M
askmen	4.45k	0.94M
todayilearned	9.44k	4.65M
worldnews	8.00k	4.28M
nfl	11.73k	5.72M

Table 1: Basic statics of discussion threads data from five subreddits.

7.1 Datasets

All the experiments are conducted on discussion thread data from the Reddit discussion forum. In Reddit, threads are grouped into different categories, called subreddits, according to different discussion themes. Registered users are allowed to give up-votes or down-votes to a comment, these votes are then aggregated to compute a *karma score* for the comment. We use it as the reward for recommending that comment. Using the post IDs provided by He et al. (2016c), we crawl five datasets from five different subreddits respectively, including askscience, askmen, todayilearned, worldnews, and nfl. These subreddits cover a wide range of discussion topics and language styles. The basic statistics of the datasets are presented in Table 1. Since some of the posts and comments were deleted by Reddit, we remove all the deleted posts and comments from the datasets. Thus, the statistics of our datasets are different from that in He et al. (2016c). For each dataset, we use the simulator provided by He et al. (2016c) to partition 90% of the data as a training set, and 10% of the data as a testing set.

7.2 Evaluation

The evaluation metric is the cumulative reward per episode averaged over 1,000 episodes (He et al., 2016c). For each setting, we evaluate an agent as follows. First, we train the agent on the training set using Algorithm 2 in the Appendix for 3,500 episodes. Then, we test the agent using the testing set for 1,000 episodes and choose every action according to the ϵ-greedy policy, but the agent cannot use the received rewards to update the model parameters. We repeat the testing for five repetitions and report the mean and the standard deviation of the evaluation metric. Throughout the training and testing, we fix $\epsilon = 0.1$.

Table 2: Comparison of average episodic reward on different datasets.

7.3 Baselines

Our DRRN-Attention model is compared with two baselines. The first one is DRRN-BiLSTM, which is the current state-of-the-art model to approximate the Q-value for this task (He et al., 2016c). We modify the DRRN-BiLSTM model by replacing the Bi-directional LSTM with a mean operator and call this new model DRRN-Mean. This DRRN-mean is used as the second baseline model. In addition, we compare the greedy procedure with two baseline approximation procedures. The first is random sampling procedure in (He et al., 2016c). The second is the two-stage Q-learning procedure in (He et al., 2017), which is the state-of-the-art approximation procedure for this task.

7.4 Implementation Details

In preprocessing, we remove all punctuations and lowercase all alphabetic characters. To construct the bag-of-words representations, we use the dictionary provided by He et al. (2016c). This dictionary contains the most frequent 5,000 words in the data. All model parameters are initialized by a uniform distribution within the interval $[-0.1, 0.1]$. In our DRRN-Attention model, we set the comment embedding size d to 16, the hidden size of the LSTM h to 16, the hidden size of the attention mechanism h' to 16, and the steps of attention L to 2. In the text embedding module of DRRN-Attention, each fully-connected layer has a hidden size of 16. In the baseline models, we set the hidden size of the bidirectional LSTM to 20, the comment embedding size to 20. The text embedding module of the baselines has two layers and each layer has a hidden size of 20. For the deep Q-learning algorithm, we set $F = 1000$. We update the model parameters using stochastic gradient descent with RMSprop (Tieleman and Hinton, 2012). We set different initial learning rates for different datasets (askscience: 0.00001; askmen: 0.00008; todayilearned, worldnews, and nfl: 0.00002). The mini batch size is 100. All the above hyperparameters are tuned by five-fold cross-validation. We also found that the model performances tuned by five-fold cross-validation are similar to that tuned by the testing set. We set the remaining hyperparameters according to (He et al., 2017). The memory size $|D|$ is set to 10000. The discount factor γ is set to 0.9. The candidate size m of the baseline approximation procedures is set to 10.

8 Experimental Results

8.1 Agent Performances on Various Datasets

In this section, the performances of different neural network models and approximation procedures are evaluated on five datasets with $N = 10$, $K = 3$. The results are shown in Table 2. We analyze the performances of our DRRN-Attention model in each approximation procedure. With the random sampling procedure, our model achieves a higher cumulative reward than the baseline models across all datasets. When using the two-stage Q-learning procedure, or the greedy procedure, our model outperforms the baselines on four of the datasets; its performance is competitive to the baselines in the remaining dataset. Next, we analyze the performances of the greedy procedure in each neural network model. When using the DRRN-BiLSTM model or the DRRN-Mean model to parameterize the Q-function, the greedy procedure achieves a higher cumulative reward than other two baseline procedures across all datasets. When using the DRRN-Attention model, the greedy procedure outperforms the baseline procedures in four of the datasets. In sum up, us-

Models	Procedure	K=2	K=3	K=4	K=5
DRRN-BiLSTM	Random	431.6±18.8	546.9±21.8	743.7±15.9	899.5±53.9
	Two-stage	484.3±10.6	643.2±28.2	765.7±32.8	928.6±20.5
	Greedy	467.8±24.5	672.2±22.2	772.9±28.2	929.2±18.6
Our model	Random	482.7±18.1	648.6±19.6	806.0±13.5	941.2±7.3
	Two-stage	537.5±26.1	685.6±24.6	772.8±22.8	903.5±22.4
	Greedy	**545.2±27.3**	**757.4±10.9**	**820.1±24.2**	**944.1±29.6**

Table 3: Comparison of average episodic reward with different action sizes on askscience dataset.

ing DRRN-Attention model with the greedy procedure outperforms all the baselines in four of the datasets.

8.2 Agent Performances on Various Action Sizes

We evaluate all the neural network models and approximation procedures across various action sizes with $K = 2, 3, 4, 5$ and fix $N = 10$ on the askscience dataset. The results are presented in Table 3. Our DRRN-Attention model outperforms the baselines across all the action sizes form $K = 2$ to $K = 5$ with the random sampling procedure or the greedy procedure. With the two-stage Q-learning procedure, our model achieves a higher cumulative reward than the baseline models when $K = 2, 3, 4$. Then, we analyze the performance of the greedy procedure in each neural network model. When using the DRRN-BiLSTM to parameterize the Q-function, the greedy procedure outperforms the baseline procedures when $K = 3, 4, 5$. When using our DRRN-Attention, the greedy procedure achieves a higher cumulative reward than the baselines when $K = 2, 3, 5$. Overall, using the DRRN-Attention model with the greedy procedure achieves the best performances across all the action sizes form $K = 2$ to $K = 5$.

8.3 Case Study

Table 4 presents an example of Q-value prediction of a state and three sub-actions on the askscience dataset. In this study, we enumerate every permutation of these three sub-actions, e.g., (1, 3, 2) denotes a permutation of comments that we place comment (1) in the first position, comment (3) in the second position, and comment (2) in the third position. Then, we use a trained DRRN-BiLSTM model and a trained DRRN-Attention model to predict the Q-value of each permutation of comments. When we use the DRRN-BiLSTM model, a different permutation of comments yields a different Q-value prediction. The Q-value prediction of the permutation (1, 3, 2) almost triples that of the permutation (2, 3, 1). On the other hand, any permutation of the comments does not change the Q-value prediction when we use our DRRN-Attention model. This example demonstrates that the ordering of the comments can significantly affect the predicted Q-value when we use the DRRN-BiLSTM model.

State
Is the heat I feel when I face a bonfire transmitted to me mostly by infrared radiation or by heated air?
Sub-actions (comments)
(1) Should it also be taken into consideration, that electromagnetic radiation is received differently depending on it's wavelength? (2) Are the light from the fire and it's heat one in the same? Because when I'm sitting at a campfire and it starts making my face feel hot... (3) The infrared radiation of a hot object is proportional to the fourth power of T, where T is the centigrade temperature + 273, ...

8.4 Discussions

As mentioned in Section 7.1, the datasets that we use have a fewer number of comments than the datasets used by previous work. Table 5 com-

Subreddit	**# Cmts (their)**	**# Cmts (our)**
askscience	0.32M	0.15M
askmen	1.06M	0.94M
todayilearned	5.11M	4.65M
worldnews	5.99M	4.28M
nfl	6.12M	5.72M

Table 5: The number of comments in the datasets used by He et al. (2016c) and us.

Subreddit	**Reward (their)**	**Reward (our)**
askscience	833.9	643.2
askmen	148.0	184.3
todayilearned	697.9	659.0

Table 6: The cumulative reward achieved by the DRRN-BiLSTM + two-stage Q-learning baseline reported by He et al. (2017) and us.

pares the number of comments in the datasets used by (He et al., 2016c) and us. The experiments in (He et al., 2017) used three of the datasets (askscience, askmen, and todayilearned) from (He et al., 2016c). We compare our results and the results reported in (He et al., 2017) of the DRRN-BiLSTM + two-stage Q-learning baseline on these three datasets in Table 6. On the askscience and todayilearned datasets, the results of our implementation are worse than the results reported by them. Since the number of comments in our askscience dataset is only half of that in (He et al., 2017), the results of our implementation on the askscience dataset are significantly worse than the results reported by them. On the askmen dataset, the number of comments that we use is slightly less than the askmen dataset used by them. However, the results of our implementation on askmen are better than the results reported by them. We suspect that the deleted comments may have low karma scores, which cause the agent to achieve a higher cumulative reward.

9 Conclusion

In this work, we propose a new approach to the task of thread popularity prediction and tracking. In our approach, we propose a new neural network architecture, DRRN-Attention, to approximate the Q-function, which well respect the permutation invariance of the comments in an action. Moreover, our approach employs the greedy procedure to approximate the predicted optimal action, which does not require an additional pre-trained model to generate candidate actions. Empirical studies on real data demonstrate that our approach beats the current state-of-the-art in most of the experimental settings.

Abstract

Sentiment analysis has immense implications in modern businesses through user-feedback mining. Large product-based enterprises like Samsung and Apple make crucial business decisions based on the large quantity of user reviews and suggestions available in different e-commerce websites and social media platforms like Amazon and Facebook. Sentiment analysis caters to these needs by summarizing user sentiment behind a particular object. In this paper, we present a novel approach of incorporating the neighboring aspects related information into the sentiment classification of the target aspect using memory networks. Our method outperforms the state of the art by 1.6% on average in two distinct domains.

1 Introduction

Sentiment analysis plays a huge role in user-feedback extraction from different popular e-commerce websites like Amazon, eBay, etc. Large enterprises are not only interested in the overall user sentiment about a given product, but the sentiment behind the finer aspects of a product is also very important to them. Companies allocate their resources to research, development, and marketing based on these factors. Aspect-based sentiment analysis (ABSA) caters to these needs.

Users tend to express their opinion on different aspects of a given product. For example, the sentence "*Everything is so easy to use, Mac software is just so much simpler than Microsoft software.*" expresses sentiment behind three aspects: "*use*", "*Mac software*", and "*Microsoft software*" to be positive, positive, and negative respectively. This leads to two tasks to be solved: aspect extraction (Shu et al., 2017) and aspect sentiment polarity detection (Wang et al., 2016). In this paper, we tackle the latter problem by modeling the relation among different aspects in a sentence.

Recent works on ABSA does not consider the neighboring aspects in a sentence during classification. For instance, in the sentence "*The menu is very limited - I think we counted 4 or 5 entries.*", the sub-sentence "*I think ... entries*" does not reflect the true sentiment behind containing aspect "*entries*", unless the other aspect "*menu*" is considered. Here, the negative sentiment of "*menu*" induces "*entries*" to have the same sentiment. We hypothesize that our architecture iteratively models the influence from the other aspects to generate accurate target aspect representation.

In sentences containing multiple aspects, the main challenge an Aspect-Based-Sentiment-Analysis (ABSA) classifier faces is to correctly connect an aspect to the corresponding sentiment-bearing phrase (typically adjective). Let us consider this sentence "*Coffee is a better deal than overpriced cosi sandwiches*". Here, we find two aspects: *"coffee"* and *"cosi sandwiches"*. It is clear in this sentence that the sentiment of *"coffee"* is expressed by the sentimentally charged word *"better"*; on the other hand, *"overpriced"* carries the sentiment of *"cosi sandwiches"*. The aim of the ABSA classifier is to learn these connections between the aspects and their sentiment bearing phrases.

In this work, we argue that during sentiment prediction of an aspect (say *"coffee"* in this case), the knowledge of the existence and representation of the other aspects (*"cosi sandwiches"*) in the sentence is beneficial. The sentiment of an aspect in a sentence can influence the succeeding aspects due to the presence of conjunctions. In particular, for sentences containing conjunctions like *and, not only, also, but, however, though,* etc., aspects tend

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3402–3411
Brussels, Belgium, October 31 - November 4, 2018.

to share their sentiments. In the sentence *“Food is usually very good, though I wonder about freshness of raw vegetables”*, the aspect *“raw vegetables”* does not have any trivial sentiment marker linked to it. However, the positive sentiment of *“food”*, due to the word “”*good*”, and presence of conjunction “*though*” determines the sentiment of *“raw vegetables”* to be negative. Thus, aspects when arranged as a sequence, reveal high correlation and interplay of sentiments.

To model these scenarios, firstly, following Wang et al. (2016), we independently generate aspect-aware sentence representations for all the aspects using gated recurrent unit (GRU) (Chung et al., 2014) and attention mechanism (Luong et al., 2015). Then, we employ memory networks (Sukhbaatar et al., 2015) to repeatedly match the target aspect representation with the other aspects to generate more accurate representation of the target aspect. This refined representation is fed to a softmax classifier for final classification. We empirically show below that our method outperforms the current state of the art (Ma et al., 2017) by 1.6% on average in two distinct domains: restaurant and laptop.

The rest of the paper structured as follows: Section 2 discusses previous works; Section 3 delves into the method we present; Section 4 mentions the dataset, baselines, and experimental settings; Section 5 presents and analyzes the results; finally, Section 6 concludes this paper.

2 Related Works

Sentiment analysis is becoming increasingly important due to the rise of the need to process textual data in wikis, micro-blogs, and other social media platforms. Sentiment analysis requires solving several related NLP problems, like aspect extraction (Poria et al., 2016). Aspect based sentiment analysis (ABSA) is a key task of sentiment analysis which focuses on classifying sentiment of each aspect in the sentences.

In this paper, we focus on ABSA, which is a key task of sentiment analysis that aims to classify sentiment of each aspect individually in a sentence. In recent days, thanks to the increasing progress of deep neural network research (Young et al., 2018), novel frameworks have been proposed, achieving notable performance improvement in aspect-based sentiment analysis.

The common way of doing ABSA is feeding the aspect-aware sentence representation to the neural network for classification. This was first proposed by Wang et al. (2016) where they appended aspect embeddings with the each word embeddings of the sentence to generate aspect-aware sentence representation. This representation was further fed to an attention layer followed by softmax for final classification.

More recently, Ma et al. (2017) proposed a model where both context and aspect representations interact with each other’s attention mechanism to generate the overall representation. Tay et al. (2017) proposed word-aspect associations using circular correlation as an improvement over Wang et al. (2016)’s work. Also, Li et al. (2018) used transformer networks for target-oriented sentiment classification.

ABSA has also been researched from a question-answering perspective where deep memory networks have played a major role (Tang et al., 2016b; Li et al., 2017). However, unlike our proposed method, none of these methods have tried to model the inter-aspect relations.

3 Method

In this section, we formalize the task and present our method.

3.1 Problem Definition

Input We are given a sentence $S = [w_1, w_2, \dots, w_L]$, where w_i are the words and L is the maximum number of words in a sentence. Also, the given aspect-terms for sentence S are $A_1, A_2, \dots, A_M$, where $A_i = [w_k, \dots, w_{k+m-1}]$, $1 \leq k \leq L$, $0 < m \leq L - k + 1$, and M is the maximum number of aspects in a sentence.

Output Sentiment polarity (1 for positive, 0 for negative, and 2 for neutral) for each aspect-term A_i.

3.2 Model

The primary distinction between our model and the literature is the consideration of the neighboring aspects in a sentence with the target aspect. We assume that our inter-aspect relation modeling (IARM) architecture[1] models the relation between the target aspect and surrounding aspects, while filtering out irrelevant information. Fig. 1 depicts our model.

---

[1] Implementation available on `http://github.com/senticnet/IARM`

3.2.1 Overview

Our IARM model can be summarized with the following steps:

Input Representation We replace the words in the input sentences and aspect-terms with pre-trained Glove word embeddings (Pennington et al., 2014). For multi-worded aspect-terms, we take the mean of constituent word embeddings as aspect representation.

Aspect-Aware Sentence Representation Following Wang et al. (2016), all the words in a sentence are concatenated with the given aspect representation. These modified sequence of words are fed to a gated recurrent unit (GRU)[2] for context propagation, followed by an attention layer to obtain the aspect-aware sentence representation; we obtain for all the aspects in a sentence.

Inter-Aspect Dependency Modeling We employ memory network (Sukhbaatar et al., 2015) to model the dependency of the target aspect with the other aspects in the sentence. This is achieved through matching target-aspect-aware sentence representation with aspect-aware sentence representation of the other aspects. After a certain number of iterations of the memory network, we obtain a refined representation of the sentence that is relevant to the sentiment classification of the target aspect. Further, this representation is passed to a softmax layer for final classification. The following subsections discuss these steps in details.

3.2.2 Input Representation

The words (w_i) in the sentences are represented with 300 (D) dimensional Glove word embeddings (Pennington et al., 2014), resulting sentence $S \in \mathbb{R}^{L \times D}$.

Similarly, aspect terms are represented with word embeddings. Multi-worded aspect terms are averaged over the constituent words. This results aspect representation $a_i \in \mathbb{R}^D$ for i^{th} aspect term.

3.2.3 Aspect-Aware Sentence Representation

It would be fair to assume that not all the words in a sentence carry sentimental information of a particular aspect (e.g., stop words have no impact). This warrants a sentence representation that reflects the sentiment of the given aspect. To achieve this, we first concatenate aspect a_i to all the words in the sentence S:

$$S_{a_i} = [w_1 \oplus a_i, w_2 \oplus a_i, \dots, w_L \oplus a_i] \in \mathbb{R}^{L \times 2D}. \quad (1)$$

In order to propagate the context information within the sentence, we feed S_{a_i} to a Gated Recurrent Unit (GRU) with output size D_s (kindly refer to Table 1 for the value). We denote this GRU as GRU_s. $GRU_{\cdot}$ is described as follows:

$$z = \sigma(x_t U_{\cdot}^{z} + s_{t-1} W_{\cdot}^{z}), \quad (2)$$

$$r = \sigma(x_t U_{\cdot}^{r} + s_{t-1} W_{\cdot}^{r}), \quad (3)$$

$$h_t = \tanh(x_t U_{\cdot}^{h} + (s_{t-1} * r) W_{\cdot}^{h}), \quad (4)$$

$$s_t = (1 - z) * h_t + z * s_{t-1}, \quad (5)$$

where h_t and s_t are the hidden outputs and the cell states respectively at time t. We obtain $R_{a_i} = GRU_s(S_{a_i})$, where $R_{a_i} \in \mathbb{R}^{L \times D_s}$ and the GRU_s has the following parameters: $U_s^z \in \mathbb{R}^{2D \times D_s}$, $W_s^z \in \mathbb{R}^{D_s \times D_s}$, $U_s^r \in \mathbb{R}^{2D \times D_s}$, $W_s^r \in \mathbb{R}^{D_s \times D_s}$, $U_s^h \in \mathbb{R}^{2D \times D_s}$, $W_s^h \in \mathbb{R}^{D_s \times D_s}$.

To amplify the sentimentally relevant words to aspect a_i, we employ an attention layer to obtain the aspect-aware sentence representation (it is effectively a refined aspect representation) r_{a_i}:

$$z = R_{a_i} W_s + b_s, \quad (6)$$

$$\alpha = \text{softmax}(z), \quad (7)$$

$$r_{a_i} = \alpha^T R_{a_i}, \quad (8)$$

where $z = [z_1, z_2, \dots, z_L] \in \mathbb{R}^{L \times 1}$, $\text{softmax}(x) = [e^{x_1}/\sum_j e^{x_j}, e^{x_2}/\sum_j e^{x_j}, \dots]$, $\alpha = [\alpha_1, \alpha_2, \dots, \alpha_L] \in \mathbb{R}^{L \times 1}$, $r_{a_i} \in \mathbb{R}^{D_s}$, $W_s \in \mathbb{R}^{D_s \times 1}$, and b_s is a scalar.

3.2.4 Inter-Aspect Dependency Modeling

We feed $R = [r_{a_1}, r_{a_2}, \dots, r_{a_M}] \in \mathbb{R}^{M \times D_s}$ to a GRU (GRU_a) of size D_o (kindly refer to Table 1 for the value) to propagate aspect information among the aspect-aware sentence representations and obtain $Q = GRU_a(R)$, where $Q \in \mathbb{R}^{M \times D_o}$ and GRU_a has the following parameters: $U_a^z \in \mathbb{R}^{D_s \times D_o}$, $W_a^z \in \mathbb{R}^{D_o \times D_o}$, $U_a^r \in \mathbb{R}^{D_s \times D_o}$, $W_a^r \in \mathbb{R}^{D_o \times D_o}$, $U_a^h \in \mathbb{R}^{D_s \times D_o}$, $W_a^h \in \mathbb{R}^{D_o \times D_o}$. This partially helps to model the dependency among aspects in a sentence.

After this, in order to further inter-aspect dependency modeling, we employ memory networks (Sukhbaatar et al., 2015), where the target-aspect representation (target-aspect-aware sentiment representation) r_{a_t} is supplied as the query.

---

[2] LSTM (Hochreiter and Schmidhuber, 1997) yields similar performance, but requires training more parameters

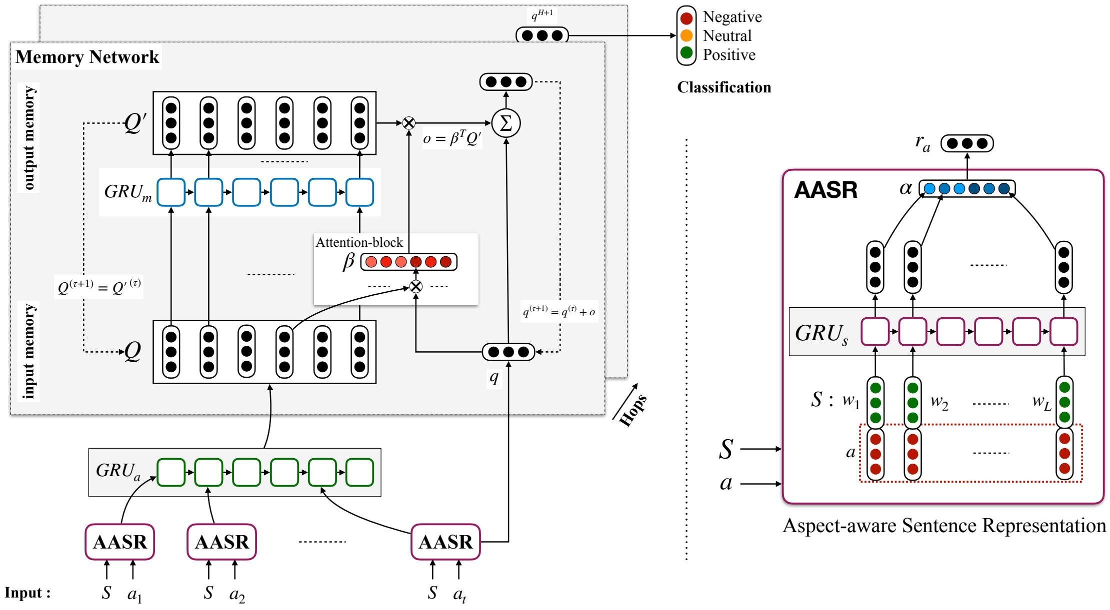

Figure 1: The proposed IARM architecture; AASR stands for *Aspect-Aware Sentence Representation*.

r_{a_t} is transformed into internal query state (q) with a fully connected layer as

$$q = \tanh(r_{a_t} W_T + b_T), \quad (9)$$

where $q \in \mathbb{R}^{D_o}$, $W_T \in \mathbb{R}^{D_s \times D_o}$, and $b_T \in \mathbb{R}^{D_o}$.

Input Memory Representation All the aspects in the sentence are stored in memory. Each aspect is represented by their corresponding aspect-aware sentence representation in Q. An attention mechanism is used to read these memories from Q (Weston et al., 2014). We compute the match between the query q and the memory slots in Q with inner product:

$$z = qQ^T, \quad (10)$$

$$\beta = softmax(z), \quad (11)$$

where $z = [z_1, z_2, \dots, z_M] \in \mathbb{R}^{M \times 1}$, $\beta = [\beta_1, \beta_2, \dots, \beta_M] \in \mathbb{R}^{M \times 1}$. Here, β_i is the measure of relatedness between target aspect and aspect i i.e., the attention score.

Output Memory Representation We choose the output memory vectors (Q') to be a refined version of the input memory vectors (Q), obtained by applying a GRU of size D_o (named GRU_m) on Q. Hence,

$$Q' = GRU_m(Q), \quad (12)$$

where GRU_m has the following parameters: $U_m^z \in \mathbb{R}^{D_o \times D_o}$, $W_m^z \in \mathbb{R}^{D_o \times D_o}$, $U_m^r \in \mathbb{R}^{D_o \times D_o}$, $W_m^r \in \mathbb{R}^{D_o \times D_o}$, $U_m^h \in \mathbb{R}^{D_o \times D_o}$, $W_m^h \in \mathbb{R}^{D_o \times D_o}$.

The response vector o is obtained by summing output vectors in Q', weighted by the relatedness measures in β:

$$o = \beta^T Q', \quad (13)$$

where $o \in \mathbb{R}^{D_o}$.

Final Classification (Single Hop) In the case of single hop, target aspect representation q is added with memory output o to generate refined target aspect representative. This sum is passed to a softmax classifier of size C ($C = 3$ due to the classes of sentiment polarity):

$$\mathcal{P} = \text{softmax}((q + o)W_{smax} + b_{smax}), \quad (14)$$

$$\hat{y} = \underset{i}{\text{argmax}}(\mathcal{P}[i]), \quad (15)$$

where $W_{smax} \in \mathbb{R}^{D_o \times C}$, $b_{smax} \in \mathbb{R}^C$, and $\hat{y}$ is the estimated sentiment polarity (0 for negative, 1 for positive, and 2 for neutral).

Multiple Hops We use total H (kindly refer to Table 1 for the value) number of hops in our model. Each hop generates a finer aspect representation q. Hence, we formulate the hops in the following way:

- Query (q) at the end of hop τ is updated as

$$q^{(\tau+1)} = q^{(\tau)} + o. \tag{16}$$

- Output memory vectors of hop τ, $Q'^{(\tau)}$, is updated as the input memory vectors of hop $\tau + 1$:

$$Q^{(\tau+1)} = Q'^{(\tau)}. \tag{17}$$

After H hops, $q^{(H)}$ becomes the target-aspect-aware sentence representation vector for the final classification:

$$\mathcal{P} = \text{softmax}(q^{(H+1)} W_{smax} + b_{smax}), \tag{18}$$

$$\hat{y} = \underset{i}{\text{argmax}}(\mathcal{P}[i]), \tag{19}$$

where $W_{smax} \in \mathbb{R}^{D_o \times C}$, $b_{smax} \in \mathbb{R}^C$, and $\hat{y}$ is the estimated sentiment polarity (0 for negative, 1 for positive, and 2 for neutral). The whole algorithm is summarized in Algorithm 1.

3.3 Training

We train the network for 30 epochs using categorical cross entropy with L2-regularizer as loss function (L):

$$L = -\frac{1}{N} \sum_{i=1}^{N} \sum_{k=0}^{C-1} y_{ik} \log \mathcal{P}[k] + \lambda \left\|\theta\right\|_2, \tag{20}$$

where N is the number of samples, i is the sample index, k is the class value, λ is the regularization weight (we set it to 10^{-4}),

$$y_{ik} = \begin{cases} 1, & \text{if expected class value of sample } i \text{ is } k, \\ 0, & \text{otherwise,} \end{cases} \tag{21}$$

and θ is the set of parameters to be trained, where

$$\theta = \{U^z_{\{s,a,m\}}, W^z_{\{s,a,m\}}, U^r_{\{s,a,m\}}, W^r_{\{s,a,m\}}, U^h_{\{s,a,m\}}, W^h_{\{s,a,m\}}, W_s, b_s, W_T, b_T, W_{smax}, b_{smax}\}.$$

As optimization algorithm, Stochastic Gradient Descent (SGD)-based ADAM algorithm (Kingma and Ba, 2014) is used with learning-rate 0.001 due to its parameter-wise adaptive learning scheme.

Hyper-Parameters We employed grid-search to obtain the best hyper-parameter values. Table 1 shows the best choice of these values.

Algorithm 1 IARM algorithm

```
procedure TRAINANDTESTMODEL($U$, $V$)    ▷ $U$ = train set, $V$ = test set
    Aspect-aware sentence representation extraction:
    for i:[1,$M$] do    ▷ generate for all the aspects in the sentence
        $r_{a_i} \leftarrow AspectAwareSentRep(S, a_i)$

    Query generation:
    $q \leftarrow FCLayer(r_{a_t})$    ▷ Transform the target-aspect-aware sentence representation to the query of memory network

    Memory networks:
    $Q \leftarrow GRU_a([r_{a_1}, r_{a_2}, \ldots, r_{a_M}])$    ▷ initial input memory
    $Q' \leftarrow GRU_m(Q)$    ▷ initial output memory

    for i:[1,$H$] do    ▷ memory network hops
        $z \leftarrow qQ^T$    ▷ match with target aspect
        $\beta \leftarrow softmax(z)$
        $o \leftarrow \beta^T Q'$    ▷ response vector
        $Q \leftarrow Q'$    ▷ input memory for the next hop
        $q \leftarrow q + o$    ▷ update target-aspect-aware sentence representation (query)

    Classification:
    $\hat{y} = \underset{j}{\text{argmax}}(softmax(q)[j])$    ▷ softmax classification
    $TestModel(V)$

procedure ASPECTAWARESENTREP(S,a)    ▷ generation of aspect-aware sentence representation
    $R_a \leftarrow GRU_s([w_1 \oplus a, w_2 \oplus a, \ldots, w_L \oplus a])$    ▷ $S = [w_1, w_2, \ldots, w_L]$
    $z \leftarrow FCLayer(R_a)$
    $\alpha \leftarrow softmax(z)$
    $r_a \leftarrow \alpha^T R_a$
    return $r_a$

procedure TESTMODEL($V$)
    Similar to the training phase, $V$ is passed through the learnt models to get the classification outputs. Section 3.3 mentions the trainable parameters ($\theta$).
```

4 Experiments

In this section, we discuss the dataset used and different experimental settings devised for the evaluation of our model.

4.1 Dataset Details

We evaluate our model with SemEval-2014 ABSA dataset[3]. It contains samples from two different domains: Restaurant and Laptop. Table 2 shows the distribution of these samples by class labels. Also, Table 3 shows the count of the samples with single aspect sentence and multi-aspect sentence.

---

[3] http://alt.qcri.org/semeval2014/task4

4.2 Baseline Methods

We compare our method against the following baseline methods:

LSTM Following Wang et al. (2016), the sentence is fed to a long short-term memory (LSTM) network to propagate context among the constituent words. The mean of all the hidden outputs from the LSTM is taken as the sentence representation, which is fed to a softmax classifier. Aspect-terms have no participation in the classification process.

TD-LSTM Following Tang et al. (2016a), sequence of words preceding (left context) and succeeding (right context) target aspect term are fed to two different LSTMs. Mean of the hidden outputs of the LSTMs are concatenated and fed to softmax classifier.

AE-LSTM Following Wang et al. (2016), the sentence is fed to an LSTM for context propagation. Then, the hidden outputs are concatenated with target-aspect representation, from which attention scores are calculated. Hidden outputs are pooled based on the attention scores to generate intermediate aspect representation. Final representation is generated as the sum of the affine transformations of intermediate representation and final LSTM hidden output. This representation is fed to softmax classifier.

ATAE-LSTM Following Wang et al. (2016), ATAE-LSTM is identical to AE-LSTM, except the LSTM is fed with the concatenation of aspect-term representation and word representation.

IAN Following Ma et al. (2017), target-aspect and its context are sent to two distinct LSTMs and the means of the hidden outputs are taken as intermediate aspect representation and context representation respectively. Attention scores are generated from the hidden outputs of both LSTMs which is used to generate final aspect and context representation. The concatenation of these two vectors are sent to a softmax classifier for final classification.

4.3 Experimental Settings

In order to draw a comprehensive comparison between our IARM model and the baseline methods, we performed the following experiments:

Overall Comparison IARM is compared with the baseline methods for both of the domains.

Single Aspect and Multi Aspect Scenarios In this setup, samples with single aspect and multi aspect sentences are tested independently on the trained model. For IAN, we ran our own experiments for this scenario.

Cross-Domain Evaluation Here, the model trained for restaurant domain is tested with the test set for laptop domain and vice versa. For IAN, we ran our own experiments for this scenario.

5 Results and Discussion

We discuss the results of different experiments below:

Overall Comparison We present the overall performance of our model against the baseline methods in Table 4.

It is evident from the results that our IARM model outperforms all the baseline models, including the state of the art, in both of the domains. We obtained bigger improvement in laptop domain, of 1.7%, compared to restaurant domain, of 1.4%. This shows that the inclusion of the neighboring aspect information and memory network has an overall positive impact on the classification process.

Single Aspect and Multi-Aspect Scenarios Following Table 5, our IARM model beats the

Domain	Train		Test	
	SA	MA	SA	MA
Restaurant	1007	2595	285	835
Laptop	917	1396	259	379

Table 3: Distribution of the samples by single aspect/multi aspect sentence criteria in SemEval 2014 (SA: Single Aspect, MA: Multi Aspect).

Model	Domain	
	Restaurant	Laptop
Majority Voting	53.4	65.0
LSTM	74.3	66.5
TD-LSTM	75.6	68.1
AE-LSTM	76.2	68.9
ATAE-LSTM	77.2	68.7
IAN (SoA)	78.6	72.1
IARM	**80.0**	**73.8**

Table 4: Domain-wise accuracy (%) of the discussed models. Best accuracy for each domain is marked with bold font.

state of the art in both single aspect and multi-aspect scenarios in both of the domains. It is interesting that both model perform better in multi-aspect scenario for restaurant domain. However, for laptop domain IAN performs better in single aspect scenario, even though there are more multi-aspect samples than single aspect samples (shown in Table 3). This indicates the failure of IAN model to learn multi-aspect scenario, where IARM model performs significantly better.

Model	Restaurant		Laptop	
	SA	MA	SA	MA
IAN (SoA)	75.4	77.7	72.5	71.6
IARM	**78.6**	**80.48**	**73.4**	**74.1**

Table 5: Accuracy of the models for single aspect and multi aspect scenario; SA: Single Aspect, MA: Multi Aspect.

Cross-Domain Evaluation Following Table 6, IARM outperforms the state of the art IAN by 2% in both cross-domain scenarios. This indicates the ability of IARM in learning general domain-independent semantic structures from the training data.

Model	Rest → Lap	Lap → Rest
IAN (SoA)	64.6	72.0
IARM	**66.7**	**74.0**

Table 6: Accuracy for cross-domain evaluation; Rest: Restaurant domain, Lap: Laptop domain; A → B signifies train-set is the train-set of domain A and test-set is the test-set of domain B.

5.1 Case Study

We analyze and compare IARM and IAN with single aspect and multi-aspect samples from the SemEval 2014 dataset.

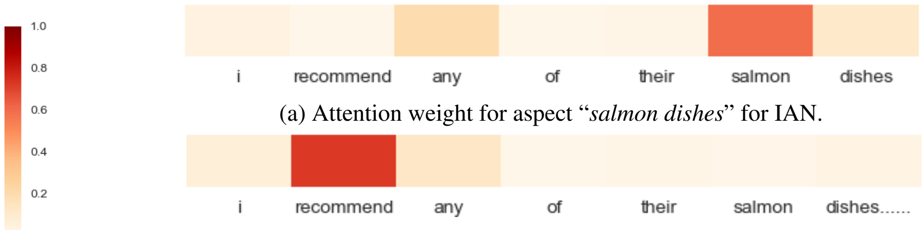
Single Aspect Case It is evident from Table 5, that IARM outperforms IAN in single-aspect scenario. For example, the sentence "*I recommend any of their salmon dishes......*" having aspect "*salmon dishes*", with positive sentiment, fails to be correctly classified by IAN as the attention network focuses on the incorrect word "*salmon*", as shown in Fig. 2a. Since, "*salmon*" does not carry any sentimental charge, the network generates a ineffective aspect-aware sentiment representation, which leads to misclassification.

On the other hand, IARM succeeds in this case, because the word-level attention network generates correct attention value as α in Eq. (7). α for this case is depicted in Fig. 2b, where it is clear that the network emphasizes the correct sentiment-bearing word "*recommended*". This leads to effective aspect-aware sentence representation by the network, making correct final classification.

Multi-Aspect Case IARM also outperforms IAN in multi-aspect scenario, which can be observed in Table 5. We suspect that the presence of multiple aspects in sentence makes IAN network perplexed as to the connection between aspect and the corresponding sentiment-bearing word in the sentence. For example, the sentence "*Coffee is a better deal than overpriced cosi sandwiches*" contains two aspects: "*coffee*" and "*better*". Clearly, the sentiment behind aspect "*coffee*" comes from the word "*better*" and the same for aspect "*cosi sandwiches*" comes from "*overpriced*". However, IAN fails to make this association for the aspect "*cosi sandwiches*", evident from the attention weights of IAN shown in Fig. 3a where the emphasis is on "*better*". This leads to imperfect aspect-aware sentence representation generation, resulting misclassification of the target aspect to be positive.

However, IARM resolves this issue with the combination of word-level aspect aware attention (α) and the memory network. Since, the memory network compares the target-aspect-aware sentence representation with the sentence representations for the other aspects repeatedly, eventually the correct representation for the target aspect emerges from the memory network.

Also, the consideration of surrounding aspects forces the network to better distinguish the sentiment-bearing words for a particular aspect. These points are reflected in the α attention weights of the aspects "*coffee*" and "*cosi sand-*



(a) Attention weight for aspect "*salmon dishes*" for IAN.

(b) Attention weight for aspect "*salmon dishes*" for IARM.

Figure 2: Attention weights for IAN and IARM for "*I recommend any of their salmon dishes*".

(a) Attention weights for aspect "*cosi sandwiches*" for IAN.

(b) Attention weights for aspect "*cosi sandwiches*" for IARM.

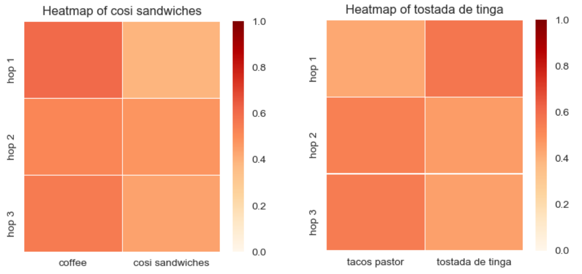
(c) Attention weights for aspect "*coffee*" for IARM.

Figure 3: Attention weights for IAN and IARM for the sentence "*Coffee is a better deal than overpriced cosi sandwiches*".

wiches", shown in Fig. 3b and Fig. 3c respectively, where the network emphasizes the correct sentiment-bearing words for each aspect, "*better*" and "*overpriced*", respectively. Again, the memory network compares the target aspect-aware sentence representation for "*cosi sandwiches*" with the same for "*coffee*" and incorporates relevant information into the target-aspect representation q in Eq. (16) along several hops.

This phenomenon is indicated in Fig. 4a, where the degree of incorporation of the aspect terms is measured by the attention weights β in Eq. (11). Here, the network is incorporating information from aspect "*coffee*" into aspect "*cosi sandwiches*" over three hops. We surmise that this information is related to the sentiment-bearing word "*better*" of the aspect "*coffee*", because a comparison using the word "*better*" implies the presence of a good ("*coffee*") and a bad ("*cosi sandwiches*") object. However, this semantics is misconstrued by IAN, which leads to aspect misclassification.

IARM performs considerably well when conjunction plays a vital role in understanding the sentence structure and meaning for sentiment analysis. For example, "*my favs here are the tacos pastor and the tostada de tinga*" where the aspects *"tacos pastor"* and *"tostada de tinga"* are connected using conjunction *"and"* and both rely on the sentiment bearing word *favs*. Such complex relation between the aspects and the corresponding sentiment-bearing word is grasped by IARM as shown in Fig. 4b. Another example where the inter-aspect relation is necessary for the correct classification is shown in Fig. 5, where the aspects *"atmosphere"* and *"service"* both rely on the sentiment bearing word *"good"*, due to the conjunction *"and"*.



(a) Memory network attention weights for the sentence "*Coffee is a better deal than overpriced cosi sandwiches.*".

(b) Memory network attention weights for the sentence "*my favs here are the tacos pastor and the tostada de tinga.*".

Figure 4: Memory network attention weights for IARM.

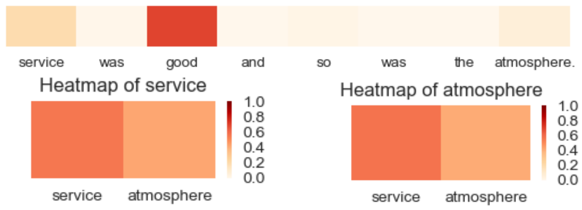


Figure 5: Memory network attention weights for IARM for the sentence "*service was good and so was the atmosphere.*" The word importance heatmap is for the aspect *"atmosphere"*.

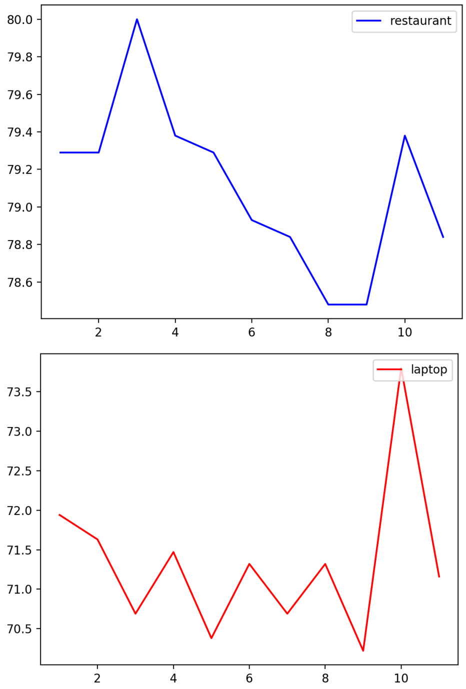

Figure 6: Hop-Accuracy plot for both domains.

5.2 Error Analysis

IARM also fails to correctly classify in some cases, e.g., in the sentence "*They bring a sauce cart up to your table and offer you 7 or 8 choices of sauces for your steak (I tried them ALL).*", the aspect "*choices of sauces*" is misclassified by our network as neutral. This happened due to the IARM's inability to correctly interpret the positive sentiment behind "*7 or 8 choices of sauces*" .

Again, the IARM could not correctly classify aspect the "*breads*" to be positive in the sentence "*Try the homemade breads.*". This happened, because the word "*try*" itself is not sentimentally charged, but can carry sentimental meaning given the right context. This context was not recognized by IARM, which led to misclassification.

5.3 Hop-Performance Relation

In our experiments, we tried different hop counts of the memory network. We observed that the network performs best with three hops for restaurant domain and ten hops for laptop domain, which is shown in the hop count - performance plot in Figure Fig. 6. It can be observed that the plot for restaurant domain is smoother than the plot for laptop domain. We assume that this is due to the restaurant domain having higher number of samples than laptop domain, as shown in Table 2.

Also, the plot for restaurant domain shows a downward trend over the increasing number of hops, with spikes in hop 3, hop 10. This suggests a irregular cyclic nature of the memory network where those certain hop counts yields higher quality representations than their neighbor. The same cannot be said for laptop domain as the plot presents a zig-zag pattern.

6 Conclusion

In this paper, we presented a new framework, termed IARM, for aspect-based sentiment analysis. IARM leverages recurrent memory networks with multihop attention mechanism. We empirically illustrate that an aspect in a sentence is influenced by its neighboring aspects. We exploit this property to obtain state-of-the-art performance in aspect-based sentiment analysis in two distinct domains: restaurant and laptop. However, there remains plenty of room for improvement in the memory network, e.g., for generation of better aspect-aware representations.

Abstract

We propose Limbic, an unsupervised probabilistic model that addresses the problem of discovering aspects and sentiments and associating them with authors of opinionated texts. Limbic combines three ideas, incorporating authors, discourse relations, and word embeddings. For discourse relations, Limbic adopts a generative process regularized by a Markov Random Field. To promote words with high semantic similarity into the same topic, Limbic captures semantic regularities from word embeddings via a generalized Pólya Urn process. We demonstrate that Limbic (1) discovers aspects associated with sentiments with high lexical diversity; (2) outperforms state-of-the-art models by a substantial margin in topic cohesion and sentiment classification.

1 Introduction

How can we understand opinionated texts, e.g., social media postings, expressing sentiments about various entities? Three phenomena are key. First, even for similar entities, authors may differ both on aspects and sentiments about those aspects. For example, when reviewing a hotel, Alice may consider aspects such as *Concierge* and *Room*, whereas Bob may consider aspects such as *Nearby* and *Room*. Capturing similarities and differences among authors can help produce recommendations for services that are better aligned with a user's expectations (Wang et al., 2013). Second, reviews exhibit discourse structure, i.e., relations between propositions, which carries valuable information about sentiment. Third, crucial relationships between rare words are lost because each review may be short and use distinct rare words.

Probabilistic topic models (Hofmann, 1999; Blei et al., 2003) provide an unsupervised means to learn latent constructs from texts. Author-specific topic discovery associates texts with their authors (Rosen-Zvi et al., 2004; Kim et al., 2012; Diao and Jiang, 2013) but ignores sentiments. Sentiment analysis methods jointly model aspects and sentiments but exclude either authors (Lazaridou et al., 2013), discourse relations (Mukherjee et al., 2014; Poddar et al., 2017), or both (Jo and Oh, 2011; Lin et al., 2012; Kim et al., 2013).

Word co-occurrence sparsity plagues existing approaches, which model documents as distributions over latent topics and estimate them from word co-occurrence. Since word frequency follows a power law, most words are rare and representative words of a topic rarely co-occur, especially in short opinionated texts, despite semantic proximity. For example, a reviewer would not use both *spotless* and *immaculate* to express a positive sentiment toward the cleanliness of a hotel room. Losing information about word relatedness impedes learning effectiveness, producing topics that are not semantically cohesive.

We contribute Limbic, an unsupervised probabilistic model for discovering author-based aspects and sentiments from opinionated texts that incorporates discourse-level topic modeling and semantic cohesion. (1) It associates authors and sentiment-aspect pairs by generating a mixture over sentiments and aspects for each author. (2) It captures discourse relations by applying a Markov Random Field over Sentiment Expression Units (SEUs), i.e., text elements describing sentiment-aspect pairs. (3) It promotes words with high semantic similarity into the same topic by incorporating semantic regularities from word embeddings using a generalized Pólya Urn process.

We empirically compare Limbic with state-of-the-art models using datasets from two domains. Qualitatively, Limbic discovers aspect-sentiment pairs with higher lexical diversity. Quantitatively, Limbic obtains substantial improvements in topic cohesion and sentiment classification.

Brussels, Belgium, October 31 - November 4, 2018.

2 Model and Inference in Limbic

We now introduce our proposed model.

2.1 Sentiment Expression Unit (SEU)

Existing topic models represent documents as bags of words or as sentences. Bag-of-words models, e.g., LDA (Blei et al., 2003), AT (Rosen-Zvi et al., 2004), JST (Lin et al., 2012), JAST (Mukherjee et al., 2014), and AATS (Poddar et al., 2017), rely on word co-occurrence at the document level, which is problematic when applied to opinionated texts. Sentence-based models, e.g., ASUM (Jo and Oh, 2011), assume that words appearing in a sentence belong to the same aspect and sentiment, which often fails to hold in real text. For instance, the TripAdvisor review sentence *Service was good and friendly, location is good and my room was spacious but oldish*, exhibits three aspects, *Service*, *Location*, and *Room*, and two sentiments. Zhang and Singh's (2014) segmentation algorithm leverages transition cues to convert sentences into segments. Although transition cues are good indicators for capturing sentiment change, their algorithm disregards syntactic information in sentences, which also helps reveal changes of aspects and sentiments.

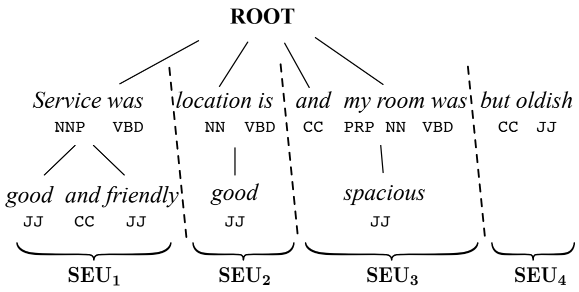

Figure 1: Generate SEUs from a sentence.

We propose a concept of sentiment expression unit (SEU). Each SEU contains either a sentiment, or an aspect, or both. We extract SEUs by incorporating both discourse and syntactic information. We first split sentences in reviews into snippets based on contradiction transition cues, such as *but*. Then we apply a grammar parser on each snippet. We extract phrases from snippets by using two syntactic patterns commonly observed in opinionated texts including (1) existential (EX) with verb (VB) and adjective (JJ) and (2) noun (NN) with verb (VB) and adjective (JJ). If a phrase matches a pattern, we identify it as an SEU. Otherwise, the phrase joins its following phrases iteratively until the combination matches a pattern. Figure 1 demonstrates the process of generating SEUs from the above hotel review sentence.

2.2 Discourse Relation

Markov Random Field (MRF) is a probabilistic framework to model statistical dependencies between variables. Limbic applies an MRF to capture the discourse relations between SEUs. Given a document containing N SEUs, let a_i and s_i be the aspect and sentiment assignments of SEU$_\mathrm{i}$, respectively. Limbic creates an undirected edge $\langle s_i, s_j \rangle$ between the sentiment assignments of this SEU and its preceding SEU. Let r be the discourse relation between SEUs, Limbic imposes a binary potential on the edge.

Limbic focuses on two discourse relations frequently observed in opinionated texts: *Comparison* and *Expansion*. Comparison highlights prominent differences between two SEUs and often signals a change of sentiment regardless of the change of aspect. For example, in SEU$_1$: {The location was great} and SEU$_2$: {but it was just too noisy}, we see that *but* indicates a sentiment difference. Other transition cues for Comparison include *however*, *in contrast*, and such.

Expansion extends the discourse and indicates a continuation of sentiment across SEUs. For example, in SEU$_3$: {There are no safes here which is unfortunate} and SEU$_4$: {And speaking of unfortunate, the breakfast is hardly impressive}, we see that *and* and *unfortunate* indicate the negative sentiment in SEU$_3$ continues toward aspect *Breakfast* in SEU$_4$. Other transition cues for Expansion include *also*, *moreover*, and such.

Formally, $\mathcal{R}_{r,i,j}$ asserts discourse relation r between SEU$_i$ and SEU$_j$. For Comparison, $\mathcal{R}_{c,i,j}$ holds if $s_i \neq s_j$, SEU$_j$ contains Comparison cues, and (1) SEU$_j$ contains syntactic patterns described in Section 2.1 and $a_i \neq a_j$ or (2) SEU$_j$ contains incomplete syntactic patterns and $a_i = a_j$.

For Expansion, $\mathcal{R}_{e,i,j}$ holds if $s_i = s_j$, SEU$_j$ contains Expansion cues, and (1) SEU$_j$ contains syntactic patterns and $a_i = a_j$ or (2) SEU$_j$ contains incomplete syntactic patterns and $a_i \neq a_j$.

Given document d, the joint probability of its sentiment assignments is:

$$p(\boldsymbol{s}|\theta_d) = \prod_i p(s_i|\theta_d) \exp\{\lambda \sum_{r=1}^{R}(I(\mathcal{R}_{r,i-1,i}))\}, \tag{1}$$

where R is the number of discourse relation types; θ_d is the sentiment distribution of d; I is an identity function that returns 1 if its argument is true; λ controls reinforcing the effects of discourse relations.

Take the expansion relation, for example. During the sampling process, Equation 1 generates a large value if two SEUs share an expansion relation and have the same sentiments and yields a small value if the two SEUs have different sentiments. Therefore, SEUs in an expansion relation have a high probability to be associated with the same sentiment.

2.3 Generative Process

Figure 2 shows Limbic's model. With $Dir(\cdot)$ and $Mul(\cdot)$ as Dirichlet and multinomial distributions, hyperparameter α is the Dirichlet prior of the word distribution ϕ, β is the Dirichlet prior of the sentiment distribution θ, and γ is the Dirichlet prior of the aspect distribution ψ. Given a set of reviews D written by a set of authors U with regards to a set of aspects T and a set of sentiments S, the generative process in Limbic is as follows.

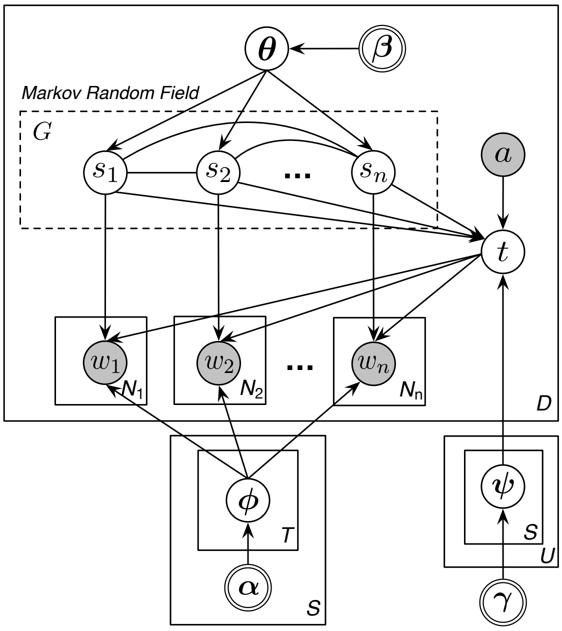

Figure 2: Generative process of Limbic.

First, for each pair of aspect t and sentiment s, draw a word distribution $\phi_{t,s} \sim Dir(\alpha)$. Second, for each author a and each sentiment s, draw an aspect distribution $\psi_{s,a} \sim Dir(\gamma)$. Third, given a review d written by a, draw a sentiment distribution $\theta_d \sim Dir(\beta)$, and for each SEU in d, (a) choose a sentiment s using Equation 1; (b) given s, choose an aspect $t \sim Mul(\psi_{s,a})$; (c) given t and s, sample word $w \sim Mul(\phi_{t,s})$.

2.4 Model Inference

Limbic estimates $p(\boldsymbol{s},\boldsymbol{t}|\boldsymbol{w},a)$, the posterior distribution of latent variables, sentiments $\boldsymbol{s}$ and aspects $\boldsymbol{t}$, given all words used in reviews written by author a. We factor the joint probability of the assignments of sentiments, aspects, and words for a:

$$p(\boldsymbol{s},\boldsymbol{t},\boldsymbol{w}|a,\boldsymbol{\alpha},\boldsymbol{\beta},\boldsymbol{\gamma}) = p(\boldsymbol{w}|\boldsymbol{s},\boldsymbol{t},\boldsymbol{\alpha})p(\boldsymbol{t}|\boldsymbol{s},a,\boldsymbol{\gamma})p(\boldsymbol{s}|\boldsymbol{\beta}). \tag{2}$$

By integrating over $\Phi = \{\boldsymbol{\phi_i}\}_{i=1}^{S\times T}$, we calculate the first term of Equation 2 as follows.

$$p(\boldsymbol{w}|\boldsymbol{s},\boldsymbol{t},\boldsymbol{\alpha}) = \int p(\boldsymbol{w}|\boldsymbol{s},\boldsymbol{t},\Phi)p(\Phi|\boldsymbol{\alpha})\mathrm{d}\Phi = \left(\frac{\Gamma(\sum_{w=1}^{W}\alpha_w)}{\prod_{w=1}^{W}\Gamma(\alpha_w)}\right)^{S\times T} \times \prod_{s=1}^{S}\prod_{t=1}^{T}\frac{\prod_{w=1}^{W}\Gamma(n_{s,t}^{w}+\alpha_w)}{\Gamma[\sum_{w=1}^{W}(n_{s,t}^{w}+\alpha_w)]}, \tag{3}$$

where W is the size of the vocabulary; $n_{s,t}^{w}$ equals the number of occurrences of the word w that are assigned to sentiment s and aspect t; and $\Gamma(\cdot)$ is the Gamma function.

Next, by integrating over $\Psi_a = \{\boldsymbol{\psi_i}\}_{i=1}^{S}$, we calculate the second term in Equation 2 as follows.

$$p(\boldsymbol{t}|\boldsymbol{s},\boldsymbol{\gamma},a) = \int p(\boldsymbol{t}|\boldsymbol{s},\Psi_a,a)p(\Psi_a|\boldsymbol{\gamma})\mathrm{d}\Psi_a = \left(\frac{\Gamma(\sum_{t=1}^{T}\gamma_t)}{\prod_{t=1}^{T}\Gamma(\gamma_t)}\right)^{S} \times \prod_{s=1}^{S}\frac{\prod_{t=1}^{T}\Gamma(n_{s,a}^{t}+\gamma_t)}{\Gamma[\sum_{t=1}^{T}(n_{s,a}^{t}+\gamma_t)]}, \tag{4}$$

where $n_{s,a}^{t}$ equals the number of SEUs in author a's reviews associated with sentiment s and aspect t.

Similarly, for the third term in Equation 2, by integrating over $\Theta = \{\boldsymbol{\theta_i}\}_{i=1}^{D}$, we obtain

$$p(\boldsymbol{s}|\boldsymbol{\beta}) = \int p(\boldsymbol{s}|\Theta)p(\Theta|\boldsymbol{\beta})\mathrm{d}\Theta = \left(\frac{\Gamma(\sum_{s=1}^{S}\beta_s)}{\prod_{s=1}^{S}\Gamma(\beta_s)}\right)^{D} \times \prod_{d=1}^{D}\frac{\prod_{s=1}^{S}\Gamma(n_{d}^{s}+\beta_s)}{\Gamma[\sum_{s=1}^{S}(n_{d}^{s}+\beta_s)]} \tag{5}$$
$$\times \prod_{l=1}^{L}\exp\{\lambda\sum_{r=1}^{R}(I(\mathcal{R}_{r,i-1,i}))\},$$

where D is the number of reviews; n_d^s is the number of times that an SEU from review d is associated with sentiment s; and n_d is the number of SEUs in review d; L is the number of SEUs.

We obtain the conditional probability for a via Gibbs sampling (Liu, 1994)

$$\begin{aligned}
&p(s_i = s, t_i = t | \boldsymbol{s_{-i}}, \boldsymbol{t_{-i}}, \boldsymbol{w}, a) \\
&\quad \propto \frac{n_{s,a,-i}^t + \gamma_t}{\sum_{t=1}^T (n_{s,a,-i}^t + \gamma_t)} \\
&\quad \times \frac{n_{d,-i}^s + \beta_s}{\sum_{s=1}^S (n_{d,-i}^s + \beta_s)} \\
&\quad \times \frac{\prod_v \prod_{c=0}^{C_v^i - 1} (n_{t,s,-i}^v + \alpha_v + c)}{\prod_{c=0}^{C_i - 1} (n_{t,s,-i} + \sum_{w=1}^W \alpha_w + c)} \\
&\quad \times \exp\{\lambda \sum_{r=1}^{R} (I(\mathcal{R}_{r,i-1,i}))\}
\end{aligned} \tag{6}$$

where $n_{s,a}^t$, as in Equation 4, is the number of SEUs associated with sentiment s and aspect t from reviews written by author a; n_d^s is the number of SEUs from review d associated with sentiment s; C_i is the number of words in SEU$_i$; C_v^i is the number of words v in SEU$_i$; $n_{t,s}^v$ is the number of words v assigned sentiment s and aspect t; $n_{t,s}$ is the number of words assigned sentiment s and aspect t in all reviews; an index of $-i$ means we exclude SEU$_i$ from the count; R, I, and $\mathcal{R}$ are as in Equation 1.

Equations 7, 8, and 9, respectively, approximate the probabilities of word w occurring given sentiment s and aspect t; of aspect t of an SEU occurring given sentiment s and author a; of sentiment s occurring given document d.

$$\phi_{s,t,w} = \frac{n_{s,t}^w + \alpha_w}{\sum_{w=1}^W (n_{s,t}^w + \alpha_w)}. \tag{7}$$

$$\psi_{s,t,a} = \frac{n_{s,a}^t + \gamma_t}{\sum_{t=1}^T (n_{s,a}^t + \gamma_t)}. \tag{8}$$

$$\theta_{d,s} = \frac{n_d^s + \beta_s}{\sum_{s=1}^S (n_d^s + \beta_s)}. \tag{9}$$

Incorporating Word Embeddings. Word embedding approaches (Mikolov et al., 2013; Pennington et al., 2014) leverage local contextual information surrounding words to map the words into continuous vector representations. Word embeddings are known to effectively capture semantic and syntactic regularities among words. Based on word embeddings trained using Word2Vec on a hotel review dataset, we observe that the generated word embeddings correctly link opinionated words that are semantically correlated even though they do not co-occur frequently. For example, the three closest words of *spotless* are *immaculate*, *clean*, and *well appointed*.

A Generalized Pólya Urn Process. To promote words with high semantic similarity into the same topic, Limbic incorporates semantic regularities from word embeddings using a generalized Pólya Urn process (Mimno et al., 2011). Start with an urn containing colored balls. At each time step, randomly choose a ball from the urn, observe its color, and return it to the urn with one replicated ball of the same color. A Pólya Urn model describes a random sampling process with reinforcement. In a generalized Pólya Urn process, given a sampled ball with a color, we put back that ball along with a certain number of balls of similar colors. When applied to document generation, balls of different colors represent distinct words. The similarity of colors represents semantic similarity of the words.

Given words v and w in vocabulary W, we compute their semantic similarity $sim(v, w)$ based on the cosine similarity between their word embeddings. For word v, we create its similarity word set $\mathbb{S}_v$ by adding all words $w \in W$ for which $sim(v, w)$ is higher than a predefined threshold ϵ. During sampling, if word v is drawn, we reinforce $w \in \mathbb{S}_v$ via a predefined weight ρ which controls the reinforcement of semantically similar words.

Sentiment Alignment. Widely used Word embedding approaches, such as Word2Vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), and fastText (Bojanowski et al., 2017), are semantically oriented and do not explicitly encode sentiment information in the generated word-vector representations. Hence, semantically related words with opposite polarity may have close vectors. For example, *smell* and *aroma* are synonyms but *smell* often expresses a negative sentiment toward aspect *Cleanliness* whereas *aroma* is often positive. Simply promoting all words may adversely affect the generated topics. Therefore, we calculate the sentiment alignment of each word in a vocabulary based on its average cosine similarity to the words in a general sentiment word list. In the sampling process, we promote words only if their sentiments align with sampled sentiments.

3 Evaluation

To assess Limbic's effectiveness, we prepare online review datasets from two domains. TripUser is a collection of hotel reviews from TripAdvisor. It contains 28,165 reviews posted by 202 randomly selected reviewers, each of whom contributes at least 100 hotel reviews. YelpUser is a set of restaurant reviews from Yelp Dataset Challenge (2017). It contains 23,873 restaurant reviews posted by 144 users, each of whom contributes at least 100 reviews. Table 1 reports statistics on the datasets.

Table 1: Summary of the evaluation datasets.

Statistic	TripUser	YelpUser
Number of reviews	28,165	23,873
Number of SEUs	484,805	359,191
Average SEUs / review	17	15
Average words / SEU	7	6

We remove stop words and HTML tags, expand typical abbreviations, and mark special named entities using a rule-based algorithm (e.g., replace a monetary amount by #MONEY#) and the Stanford Named Entity Recognizer (Finkel et al., 2005). To handle negation, we employ the Stanford Dependency Parser to detect negations. For any word in a negation relation, we add the negated term as a prefix of the word, e.g., *not_work*. Finally, we split each review into SEUs. Datasets and source code are publicly available for research purposes (Limbic, 2018).

3.1 Parameter Settings

Limbic includes three hand-tuned hyperparameters that influence its sampling via a smoothing effect on the associated multinomial distribution. It uses a short list of sentiment words shown in Table 2 as prior knowledge to set asymmetric priors.

Table 2: Sentiment words used as prior knowledge.

Positive
good, nice, excellent, positive, fortunate, correct, free, love attractive, awesome, perfect, comfortable, enjoy, amazing fun, glad, great, happy, impressive, superior, thank, best satisfied, worth, not_bad, recommend, fantastic, favorite
Negative
bad, nasty, poor, negative, unfortunate, wrong, inferior slow, junk, mess, not_good, not_like, not_recommend unacceptable, upset, waste, small, worthless, problem complain, terrible, trouble, regret, annoying, not_worth sorry, disappointed, worst, hate

Consider hyperparameter α, the Dirichlet prior of the word distribution. For any word in the positive list, $\alpha = 0$ if the word appears in an SEU assigned a negative sentiment, and $\alpha = 5$ if the word appears in an SEU assigned a positive sentiment, and conversely for words in the negative list. For all remaining words, we set $\alpha = 0.05$. And, hyperparameter $\beta = 5$ for both sentiments is the Dirichlet prior of the sentiment distribution. Using T as the number of aspects, hyperparameter $\gamma = \frac{50}{T}$ is the Dirichlet prior of the aspect distribution. We set the number of sentiments, S, to two (positive and negative), although our approach generalizes to additional sentiment categories.

For each fold in cross validation, we pretrain two sets of Word2Vec (Mikolov et al., 2013) word embeddings with 300 dimensions and a window size of five using the training split in TripUser (hotels) and YelpUser (restaurants). We exclude words with frequency lower than three. We set the reinforcement weight ρ to 0.3 and 0.1 for hotel and restaurant reviews, respectively, and set the similarity threshold ϵ to 0.6. For all models, we perform 1,000 Gibbs iterations with a burn-in phase of 200 and a sampling gap of 50 iterations.

3.2 Sentiment Aspect Discovery

Our first experiment shows how Limbic discovers sentiment-aspect pairs. We apply Limbic and all baseline models (AT, JST, ASUM, and AATS) to TripUser and YelpUser with the number of aspects set to 30. We manually assign an aspect for each cluster of words. ASUM generates the best results among baseline models. For brevity, we show only some aspects identified by Limbic and ASUM.

Table 3 (top) shows the results on hotel reviews. We see that Limbic discovers word clusters with higher lexical diversity than ASUM. For example, for aspect *Decoration*, in addition to words, *decor*, *modern* and *design*, Limbic discovers words *contemporary*, *minimalist*, *chic*, and so on. For aspect *Service*, comparing with ASUM, Limbic extracts an expanded list of sentiment words including *competent*, *knowledgeable*, and so on.

Limbic discovers finer and more distinctive word clusters than ASUM. For example, for aspect *Cleanliness*, ASUM generates a word cluster that includes negative sentiment words toward multiple entities, such as *carpet* and *hallway*. Limbic generates two distinctive word clusters for aspect

Table 3: Top words discovered from hotel (top section) and restaurant (bottom section) reviews.

table	**knowledgeable**	look	inside	inch	generous	flour	tempura

Cleanliness. One cluster contains words, such as *smoke* and *reek*, which describe bad odor in room and hallway. The other cluster contains words such as, *worn* and *stain*, describes negative sentiments toward carpets. By capturing word semantic relatedness, Limbic discovers highly diverse aspects, including those that arise rarely in reviews, such as *peaceful*, *relaxing*, and *lush*, as positive words describing aspect *Environment*.

Limbic yields promising results for restaurant reviews. In Table 3 (bottom), we see that Limbic yields more specific sentiment words than ASUM. Aspect *Service* in Limbic contains additional positive words, *efficient*, *prompt*, *knowledgeable*, and so on. For aspect *Decoration*, Limbic produces *sleek*, *ambiance*, and so on. By incorporating constraints from discourse relations, Limbic yields aspects that are more sentiment coherent. For example, we see that positive aspect *Portion* in ASUM contains the negative word *small* whereas words in aspect *Portion* in Limbic are all positive.

We observe that restaurants associate more complex aspects than hotels—presumably, because of the large variety of cuisines and thus, on average, smaller data relevant to a cuisine. Titov and McDonald's (2008b) Multi-Grain LDA (MG-LDA) model performs well for hotel reviews but discovers only few ratable aspects from restaurant reviews, which they ascribe to the relatively small occurrences of words describing aspects for specific cuisines (e.g., *Italian*) and general categories (e.g., *Meat*), compared with the words describing major aspects, such as *Service*. In contrast, Limbic discovers words describing specific cuisines, such as *Mexican* and *Seafood*.

3.3 Quantitative Evaluation

Whether topics (word clusters) are semantically cohesive is an important factor in assessing topic modeling approaches. Normalized Pointwise Mutual Information (NPMI) (Lau et al., 2014) has strong correlation with human-judged topic coherence ratings and is widely used for accessing topic modeling approaches (Nguyen et al., 2015a,b;

Table 4: Topic coherence: Hotel reviews.

NPMI	T=10	T=20	T=30	T=40	T=50	T=60

Yang et al., 2017). More recently, O'Callaghan et al. (2015) propose a topic coherence measure, W2V, based on word embeddings. For completeness, we adopt both metrics. Topics with higher scores of NPMI and W2V are semantically more coherent. We compare Limbic with four baselines: AT, JST, ASUM, and AATS, using both TripUser and YelpUser based on the top 15 words in each sentiment-aspect pair. For each number of aspects, we perform five-fold cross-validation. We perform the two-tailed exact permutation test (Good, 2005) on the improvement of Limbic over the best performing baseline. (Throughout, $*$ and $\dagger$ indicate significance at 0.05 and 0.001, respectively.)

Table 4 shows average NPMI and W2V scores of each model on hotel reviews for different numbers of aspects. We observe that Limbic statistically outperforms the other models for both metrics in all settings. Limbic yields substantial improvements, with average gains over the second best models of 6.00 and 0.18 in NPMI and W2V, respectively, which validates that the incorporation of semantic regularities helps Limbic promote semantically equivalent and related words into the same aspect-sentiment pair. Of the baseline models, AT yields the lowest topic coherence. AATS outperforms AT but does not perform well when the number of aspects is small, possibly due to the undesirable mixture of words with different aspects, topics, and sentiments in individual sentences. ASUM, and JST yield comparable results that are consistently better than AATS. Table 5 shows similar conclusions for restaurant reviews.

3.4 Sentiment Classification

We now evaluate Limbic for document-level sentiment classification vis à vis JST, ASUM, and AATS. For comparison purposes, we add a supervised baseline, BiLSTM, using the bidirectional LSTM model (Schuster and Paliwal, 1997). BiLSTM uses 100 as hidden state size and 0.2 as both the recurrent dropout rate and the dropout rate in the last layer. For training, we run 20 epochs with a minibatch size of 1,000. We use two datasets, TripUser and YelpUser. To collect ground-truth labels, we use integer ratings (three and above as positive and rest as negative). Note that our review datasets are imbalanced. Our results are based on five-fold cross-validation (80% of each author's reviews for training and 20% for testing) with the two-tailed exact permutation test. As our principal evaluation metrics, we adopt accuracy; the receiver operating characteristic (ROC) curve; and area under the curve (AUC). ROC and AUC are standard metrics used for evaluating classifiers on data with class imbalance (Bradley, 1997; Hoens and Chawla, 2013).

Tables 6 and 7 report accuracy and AUC on hotel and restaurant reviews. AATS yields high accuracy but low AUC due to a strong bias toward the majority class. Compared with AATS, JST yields higher AUC for both datasets but lower accuracy for TripUser. ASUM outperforms JST, indicating that sentences are more effective as units of sentiment analysis than bags of words. Limbic significantly outperforms ASUM in all settings. For hotel reviews, Limbic attains average gains of 4.0% and 2.3% in accuracy and AUC, respectively. For restaurant reviews, Limbic yields average gains of 5.1% and 3.0% in accuracy and AUC, respectively. In Figure 3 and 4, we compare the ROC curves of Limbic with baselines. The ROC curves show how the true positive rate (TPR) (vertical axis) varies with the false positive rate (FPR) (horizontal axis) by moving the decision boundary. We see that for all FPRs, Limbic yields the highest TPRs. Its ROC curves dominate other models' curves. The results demonstrate that, among all models, Lim-

bic achieves the best tradeoff between positive and negative sentiment classes.

3.5 Model Analysis

To understand the contributions of incorporating authors, discourse relations, and word embeddings, we evaluate variants of Limbic for SEU-level sentiment classification on two datasets: tSEU and tSEU(D). We create tSEU by randomly selecting 200 hotel reviews by seven authors. We manually annotate the sentiments of each SEU, obtaining 2,692 SEUs. We create tSEU(D) by selecting reviews in tSEU containing at least one Comparison or Expansion. We define three variants of Limbic (L): L_A with just authors, no discourse relations or word embeddings; L_{AD} with authors and discourse relations but no word embeddings; L_{AW} with authors and word embeddings but no discourse relations. Table 8 compares Limbic with L_A L_{AD}, and L_{AW}. We observe that for both datasets, incorporating discourse relations improves accuracy. By incorporating word embeddings, L_{AW} yields better accuracy than L_{AD}, showing that word embeddings add more value to Limbic than discourse relations do.

Table 8 (lower part) reports p-values (two-tailed test using a χ^2 distribution) from McNemar's Test on pairwise comparisons (Alpaydin, 2010, p. 501). We see that Limbic is significantly different from each variant, including L_A (omitted for space).

3.6 Related Work

Sentiment and aspect discovery are often based on Latent Dirichlet Allocation (LDA) (Blei et al., 2003). LDA represents a document (for us, a review) as a mixture of topics, each topic being a multinomial distribution over words. The learning process approximates the topic and word distributions based on their co-occurrence in documents. Titov and McDonald's (2008b) model handles global and local topics involved in documents, and their (2008a) framework discovers topics using aspect ratings provided by reviewers. JST (Lin et al., 2012) and ASUM (Jo and Oh, 2011) model a review via multinomial distributions of topics and sentiments and use them to condition the probability of generating words. Kim et al. (2013) extend ASUM by allowing its probabilistic model to discover a hierarchical structure of aspect-based sentiments. Lazaridou et al. (2013) introduce discourse transitions into the document generating process as aspect and sentiment shifters. Although the above models produce good results, they omit author information, which is an intrinsic attribute of opinionated texts.

Table 8: SEU sentiment classification accuracy.

Accuracy	L_A	L_{AD}	L_{AW}	L	
tSEU	0.702	0.723	0.733	**0.750**	
tSEU(D)	0.692	0.715	0.716	**0.735**	
p value	L_{AD}:L_A	L_{AW}:L_A	L_{AD}:L_{AW}	L:L_{AD}	L:L_{AW}
tSEU	0.015	0.003	0.331	0.005	0.002
tSEU(D)	0.017	0.042	0.934	0.055	0.003

Rosen-Zvi et al.'s Author Topic model (AT) (2004) captures authorship by building a topic distribution for each author. When generating a word

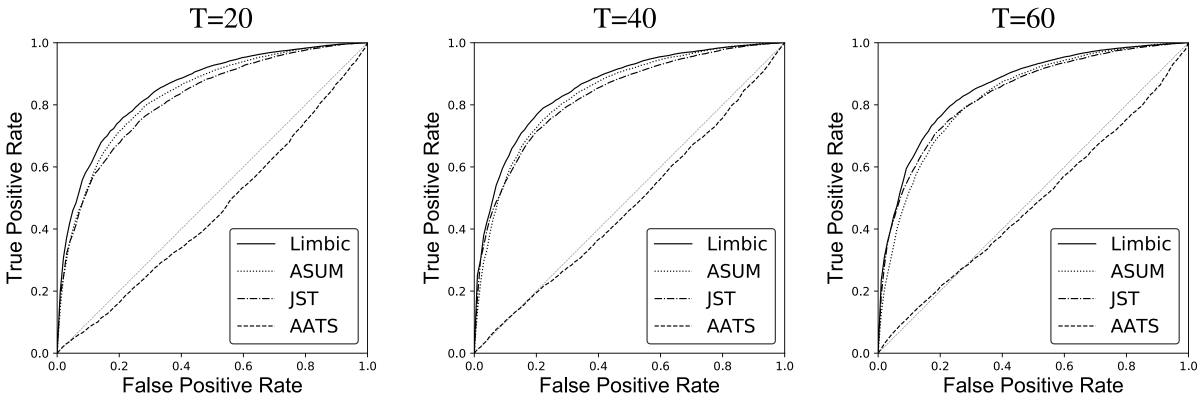

Figure 3: ROC curves comparing the performance of three models on hotel reviews.

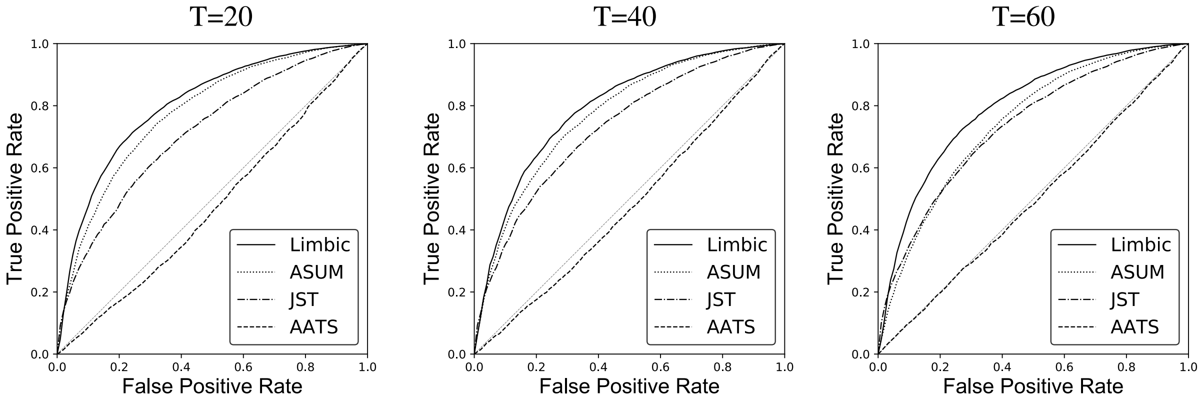

Figure 4: ROC curves comparing the performance of three models on restaurant reviews.

in a document, AT conditions the probability of the topic assignment on the author of the document. Kim et al.'s (2012) topic model captures entities mentioned in documents and models the probability of generating a word as conditioned on both entity and topic. Diao and Jiang's (2013) jointly model topics, events, and users on Twitter. Although these models capture the author associated with a text, they do not handle sentiments.

Mukherjee et al.'s (2014) JAST model jointly considers authors, sentiments, topics, and ratings. JAST does not consider discourse relations and word semantic similarity in its generative process. Poddar et al. (2017) propose a model that jointly considers author, aspect, sentiment, and the non-repetitive generation of aspect sequences. The model uses a Bernoulli process to capture the non-repetitive nature of aspect sequences. This mechanism does not consider discourse relations or syntactic information.

4 Conclusion and Discussion

Limbic provides an unsupervised method to discover aspects and sentiments from opinionated texts. By incorporating authors as a factor, Limbic allows for reviews written by the same or similar authors to exhibit an idiosyncratic preference toward certain aspects and sentiments. It assigns aspects of SEUs by sampling author-specific aspect distributions. This makes the model more suitable for opinionated texts in which aspects and sentiments are tightly bound to authors who follow their specific criteria and preferences when writing reviews. By incorporating a Markov Random Field and word embeddings into its sampling process, Limbic imposes constraints associated with discourse relations, effectively captures word semantic relatedness, and generates word clusters with high topic cohesion and lexical diversity. In future work, we plan to extend Limbic to capture long-distance discourse relations and the influence decay of discourse relations between SEUs as their distance increases.

An Interpretable Neural Network with Topical Information for Relevant Emotion Ranking

Abstract

Text might express or evoke multiple emotions with varying intensities. As such, it is crucial to predict and rank multiple relevant emotions by their intensities. Moreover, as emotions might be evoked by hidden topics, it is important to unveil and incorporate such topical information to understand how the emotions are evoked. We proposed a novel interpretable neural network approach for relevant emotion ranking. Specifically, motivated by transfer learning, the neural network is initialized to make the hidden layer approximate the behavior of topic models. Moreover, a novel error function is defined to optimize the whole neural network for relevant emotion ranking. Experimental results on three real-world corpora show that the proposed approach performs remarkably better than the state-of-the-art emotion detection approaches and multi-label learning methods. Moreover, the extracted emotion-associated topic words indeed represent emotion-evoking events and are in line with our common-sense knowledge.

1 Introduction

With the growth of social web, people tend to share their opinions, feelings and attitudes on the social platforms such as online news sites and blogs. Emotion detection can enhance the understanding of users' emotional states, which is useful in many downstream applications such as human-computer interaction and personalized recommendation. Therefore, it is crucial to predict emotions from texts accurately (Picard and Picard, 1997).

Research on emotion detection can be roughly categorized into two types: generative model based and discriminative model based. Generative model based approaches (Bao et al., 2012; Rao et al., 2014a) usually build on topic models and assume texts are generated from emotions and hidden topics. While these models can extract emotion-associated topics, they perform less satisfactorily in emotion classification since they are not optimized directly to minimize the misclassification rate. Discriminative model based approaches consider each emotion category as a class label and typically cast emotion detection as a classification problem. Approaches to the prediction of both multiple emotions and their intensities include (Zhou et al., 2018, 2016; Wang and Pal, 2015). Those approaches usually assumed word-level representations and ignored the latent topical information behind words, therefore failed to effectively distinguish different emotions carried by the same word in different topical contexts.

In this paper, we focus on relevant emotion ranking (RER) by differentiating relevant emotions from irrelevant ones and only learning the rankings of relevant emotions while ignoring the irrelevant ones. A neural network with a novel loss function is proposed to tackle the RER problem. A topic representing a real-world event, an abstract entity, or an object could indicate the subject or context of the emotion. Different topics might contain or invoke different emotions (Stoyanov and Cardie, 2008). Incorporating such latent topics is essential for discovering topic-associated emotions. Motivated by transfer learning, we incorporate hidden topics and the topic distributions generated from a topic model into a neural network for RER. The main contributions of the paper are summarized below:

- A novel Interpretable Neural Network for Relevant Emotion Ranking (INN-RER) is proposed. A novel error function is employed to optimize the whole network for parameter estimation. To the best of our knowledge, it is the first neural network based approach for RER.

Brussels, Belgium, October 31 - November 4, 2018.

- To understand how the emotions are evoked, the neural network is initialized to make its hidden layer approximate the behavior of topic models so that the topical information is unveiled and incorporated.

- Experimental results on three different real-world corpora show that the proposed method can effectively deal with the emotion detection problem and perform better than the state-of-the-art emotion detection methods and multi-label learning methods. Moreover, emotion-association topic words extracted by INN-RER indeed represent emotion-evoking events.

2 Related Work

In general, approaches for emotion detection can be divided into two categories: generative model based and discriminative model based. Generative model based approaches typically built on topic models. For example, the emotion-topic model (Bao et al., 2012) was proposed by adding an extra emotion layer into traditional topic models to capture the generation of both emotions and topics from text at the same time. Other topic model based approaches such as affective topic model (Rao et al., 2014a), multi-label supervised topic model and sentiment latent topic model (Rao et al., 2014b) also modeled the emotions and topics simultaneously. Contextual sentiment topic model (Rao, 2016) assumed each word is either drawn from a background theme, a contextual theme or a topic and explicitly distinguished between context-dependent and context-independent topics.

For discriminative model based methods, emotion detection is often casted as a classification problem by considering each emotion category as a class label. If only choosing the strongest emotion as the label for a given text, emotion detection is essentially a single-label classification problem. Lin et al. (2008) studied the classification of news articles into different categories based on readers' emotions with various combinations of feature sets. Strapparava and Mihalcea (2008) proposed several knowledge-based and corpus-based methods for emotion classification. Quan et al. (2015) proposed a logistic regression model with emotion dependency for emotion detection. Latent variables were introduced to model the latent structure of input text. Li et al. (2016) combined bi-term topic model and conventional neural network to detect single social emotion from short texts. To predict multiple emotions simultaneously, emotion detection can be solved using multi-label classification. Bhowmick (2009) presented a method for classifying news sentences into multiple emotion categories using an ensemble based multi-label classification technique. Wang and Pal (2015) output multiple emotions with intensities using non-negative matrix factorization with several novel constraints such as topic correlation and emotion bindings. To predict multiple emotions with different intensities in a single sentence, Zhou et al. (2016) proposed a novel approach based on emotion distribution learning. Following this way, a relevant label ranking framework for emotion detection was proposed for predict multiple relevant emotions as well as the ranking of emotions based on their intensities (Zhou et al., 2018).

Our work is partly inspired by (Zhou et al., 2018) for relevant emotion ranking, but with the following differences: (1) our model takes into account latent topics in texts for emotion detection, which was ignored in the model proposed in (Zhou et al., 2018); (2) our model is built upon topic models and neural networks with a novel objective function defined to consider the interplay between topics and emotions, while the model in (Zhou et al., 2018) was developed based on a ranking framework with a linear objective function which was not able to describe complex relations between the input texts and their emotions.

3 The Proposed Approach

Assuming a set of T emotions $L = \{e_1, e_2, ...e_T\}$ and a set of n text instances $X = \{x_1, x_2, x_3, ..., x_n\}$, each instance $x_i \in \mathbb{R}^d$ is associated with a ranked list of its relevant emotions $R_i \subseteq L$ and also a list of irrelevant emotions $\overline{R_i} = L - R_i$. Relevant emotion ranking aims to learn a score function $\mathbf{g}(x_i) = [g_1(x_i), ..., g_T(x_i)]$ which assigns a score $g_j(x_i)$ to each emotion $e_j, (j \in \{1, ..., T\})$. In order to differentiate relevant emotions from irrelevant ones, we need to define a threshold Θ which could be simply set to a fixed value or learned from data (Fürnkranz et al., 2008). Those emotions with scores lower than the threshold will be considered as irrelevant and hence discarded. The identification of relevant emotions and their ranking can be obtained simultaneously according to their scores assigned by the learned ranking function **g**. As mentioned before, it is unnecessary to consider the rankings of irrelevant emotions since they might introduce errors into the model during the learning process.

We propose an Interpretable Neural Network for Relevant Emotion Ranking (INN-RER) built upon a multi-layer feed-forward neural network. Instead of using the simple sum-of-squares error function, a novel loss function is designed and employed. Accordingly, a new learning algorithm is proposed to minimize the new loss function. Furthermore, motivated by transfer learning, topical information generated from a topic model is transferred into the neural network by making its hidden layer approximate the behavior of topic models.

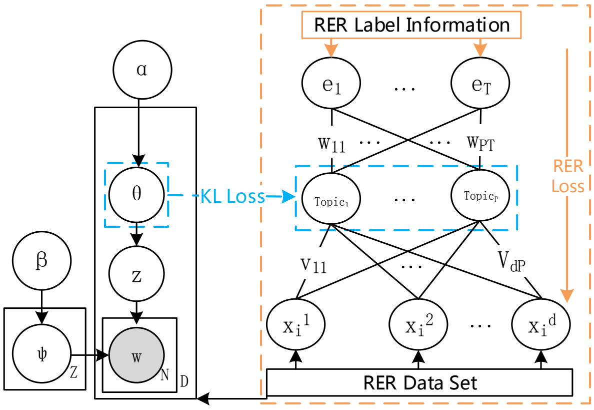

Figure 1: The overall framework of Interpretable Neural Network for Relevant Emotion Ranking (INN-RER).

The overall framework of INN-RER is shown in Figure 1. The left part is a typical topic model (Blei et al., 2003). It is designed for discovering the main topics that pervade a large unstructured collection of documents. A document is allowed to contain a mixture of topics with different weights. As such, a document d can be represented by its topic distribution θ_d. The right part is a three-layer neural network. It has d input units corresponding to the d-dimensional feature vector of each training sample x_i, T output units corresponding to all possible emotion labels, and one hidden layer with P hidden units corresponding to the hidden topics. The input layer is fully connected to the hidden layer with weights $V = [v_{qh}](1 \leq q \leq d, 1 \leq h \leq P)$ and the hidden layer is fully connected to the output layer with weights $W = [w_{hj}](1 \leq h \leq P, 1 \leq j \leq T)$. The bias parameters $\alpha_h(1 \leq h \leq P)$ of the hidden units are considered as weights from an extra input unit with a fixed value of 1. Similarly, the bias parameters $\beta_j(1 \leq j \leq T)$ of the output units are considered as weights from an extra hidden unit, with a fixed value of 1.

The learning process of INN-RER consists of two main steps. Firstly, the first two layers of the network are initialized based on the output of the topic model. The feature transformation in neural network is conducted by minimizing the Kullback-Leibler (KL) divergence between the topic distribution θ produced by the topic model and the approximated distribution $[Topic_1, Topic_2, ..., Topic_P]$ learned by the first two layers of the neural network, which is denoted by the blue rectangular dash line boxes in Figure 1. Then, the whole network is learnt and fine-tuned based on the novel loss function, which is denoted as the orange rectangular dash line boxes. Each step will be described in details in the following subsections.

3.1 INN-RER Initialization

As the number of hidden neurons and its semantic meaning is usually treated as a black box in conventional neural networks, the generated topics from the topic model are employed for guiding the construction of the hidden layer in the proposed neural network. By doing that, semantic topic information is incorporated to enhance the interpretability and accuracy of the proposed neural network. For a particular text sample x_i in training set G, the input layer takes its term-frequency representation x_i^q as the input and feeds it to the hidden layer. Assuming the total number of topics is fixed as P, then the hidden layer would contain P neurons. The topic mixture θ_{x_i} generated from the topic model is approximated by the weights connecting the input and the hidden layers. Mathematically, the initialization procedure learns a function $f(x_i^q|v_{qh}, \alpha_h)$ so that the output of $f(x_i^q|v_{qh}, \alpha_h)$ is as close to θ_{x_i} as possible, where x_i^q, v_{qh}, α_h and θ_{x_i} denote the input, weight vector, bias of the first two layers of the network and the topic distribution of text x_i generated from the topic model, respectively. A softmax function is applied to the output of the hidden layer, i.e., $f(x_i^q|v_{qh}, \alpha_h)$, and the Kullback-Leibler divergence (Leahy, 2006) is employed as follows:

$$L(\theta, f) = \theta \log \frac{\theta}{f} + (1-\theta) \log \frac{1-\theta}{1-f} \qquad (1)$$

where θ denotes a topic distribution derived from the topic model, and f denotes the output of the hidden layer. The KL divergence is a measure of the difference between two distributions. It is always non-negative and equals to zero when the two distributions are the same. As shown in Equation 1, the KL divergence can describe the difference between the topic distribution generated from topic models and the approximate distributions learned in the initialization procedure. Note that the topic distribution for a document generated by the topic model is used as the supervision information for initializing INN-RER. Thus, maximizing the log-likelihood is equivalent to minimizing the KL divergence according to Equation 1, and its gradients are as follows:

$$\frac{\partial L(\theta, f)}{\partial v_{qh}} = -(\theta_{x_i,h} - f_h(x_i^q | v_{qh}, \alpha_h)) \cdot x_i^q \qquad (2)$$

$$\frac{\partial L(\theta, f)}{\partial \alpha_h} = -(\theta_{x_i,h} - f_h(x_i^q | v_{qh}, \alpha_h)) \qquad (3)$$

According to the gradient descent method, the first two layers can be initialized iteratively by Equation 2 and 3. The initialization procedure for INN-RER is shown in Algorithm 1. η_{init} with the subscript $init$ represents the learning rate during the initialization procedure and λ is the penalty term. Note that the first two layer should be learnt from topic model as much as possible in order to incorporate topic information, thus the learning rate term η_{init} should be larger than the learning rate during training procedure.

3.2 INN-RER Learning

This step aims to optimize the three-layer neural network to tackle the relevant emotion ranking problem. It can adjust the neural network initialized at previous step at the same time. An intuitive way is to define the global error function for the network on the training set. However, some important characteristics of relevant emotion ranking, such as ranking, not considering irrelevant emotions, are not considered in the classical back propagation algorithm (Rumelhart et al., 1988).

Algorithm 1 Algorithm of INN-RER Initialization.

```
Input: $x_i^q$: Term frequency of text $x_i$; $\theta_{x_i}$: Topic distribution of text $x_i$
Output: $\Delta v, \Delta\alpha$: gradient approximation of initialization procedure
Initialize $\Delta v, \Delta\alpha$ as random values
for each iteration do
    for each text $x_i \in G$ do
        for $q = 1, ..., d, h = 1, ..., P$ do
            $\Delta v_{qh} \leftarrow \Delta v_{qh} + \eta_{init} \cdot (\theta_{x_i,h} - f_h(x_i^q | v_{qh}, \alpha_h)) \cdot x_i^q + \lambda \cdot \Delta v_{qh}$
        end for
        for $h = 1, ..., P$ do
            $\Delta\alpha_h \leftarrow \Delta\alpha_h + \eta_{init} \cdot (\theta_{x_i,h} - f_h(x_i^q | v_{qh}, \alpha_h)) + \lambda \cdot \Delta\alpha_h$
        end for
    end for
end for
```

The error function defined in traditional neural network such as mean-square error only focuses on individual label discrimination, i.e. whether a predicted label is correct or not. It does not consider the correlations between different labels of a training instance, e.g., relevant emotions should be ranked higher than irrelevant ones and there is a ranking for relevant emotions according to their intensities. Therefore, to fulfil the requirements of relevant emotion ranking, a novel global error function is defined as follows:

$$\begin{aligned} E = \sum_{i=1}^{n} \sum_{e_t \in R_i} \sum_{e_s \in \prec(e_t)} & \frac{1}{norm_{t,s}} \\ & [\, \exp(-(g_t(x_i) - g_s(x_i))) + \\ & \quad \omega_{ts}(g_t(x_i) - g_s(x_i))^2 \,] \end{aligned} \qquad (4)$$

Here, emotion e_t and emotion e_s are two emotion labels and e_s is less relevant than emotion e_t, represented by $e_s \in \prec (e_t)$. The normalization term $norm_{t,s}$ is used to balance emotion pairs (e_t, e_s) to avoid dominated terms by their set sizes. The term $g_t(x_i) - g_s(x_i)$ measures the difference between two emotion outputs, e_t and e_s, of a given input text x_i. We want the difference as larger as possible. Furthermore, the negation of this difference is fed to the exponential function in order to severely penalize the i-th error term if emotion e_t is much smaller than e_s. As the relationships among different emotions can provide important clues for emotion detection, we further incorporate the information into the loss function as constraints. Here, ω_{ts} is the relationship between emotion e_t and e_s which is calculated by Pearson correlation coefficient (Nicewander, 1988).

The minimization of the global relevant emotion ranking loss function defined in Equation 4 is carried out by gradient descent combined with the back propagation (Rumelhart et al., 1988). For training instance x_i and its label set L_i, the actual output of the j-th output neuron is(omitting the superscript i without loss of generality):

$$g_j = f(netg_j + \beta_j) \tag{5}$$

where β_j is the bias of the j-th output neuron which is a "tanh" function:

$netg_j$ is the input to the j-th output neuron:

$$netg_j = \sum_{h=1}^{P} b_h w_{hj} \tag{6}$$

where w_{hj} is the weight which connects the h-th hidden neuron and the j-th output neuron, and P is the number of hidden neurons, i.e., the topics. b_h is the output of the h-th hidden neuron:

$$b_h = f(netb_h + \alpha_h) \tag{7}$$

where α_h is the bias of the h-th hidden neuron, $f()$ is also a "tanh" function. $netb_h$ is the input to the h-th hidden neuron:

$$netb_h = \sum_{q=1}^{d} x^q v_{qh} \tag{8}$$

where x^q is the q-th dimension of instance x. v_{qh} is the weight which connects the q-th input neuron and the h-th hidden neuron.

"tanh" function is differentiable, the error of the j-th output neuron can be defined as:

$$d_j = \begin{cases} [\frac{1}{norm}exp(-(g_j - g_s)) + 2\omega_{js}(g_j - g_s)] \\ (1+g_j)(1-g_j), if e_j \in R_i \& e_s \in \prec (e_j) \\ [-\frac{1}{norm}exp(-(g_t - g_j)) - 2\omega_{tj}(g_t - g_j)] \\ (1+g_j)(1-g_j), \\ if(e_j \in R_i \& e_j \in \prec (e_t)) or \\ (e_j \in \overline{R_i} \& e_j \in \prec (e_t)) \end{cases} \tag{9}$$

Similarly, the error of the h-th hidden neuron can be defined as:

$$e_h = \left(\sum_{j=1}^{T} g_j w_{hj} \right) (1+b_h)(1-b_h) \tag{10}$$

In order to reduce the error of the neural network INN-RER, we can use gradient descent strategy:

$$\begin{aligned} \Delta w_{hj} &= -\eta \frac{\partial E_i}{\partial w_{hj}} = -\eta \frac{\partial E_i}{\partial netg_j} \frac{\partial netg_j}{\partial w_{hj}} \\ &= \eta d_j \left[\frac{\partial [\sum_{h=1}^{P} b_h w_{hj}]}{\partial w_{hj}} \right] = \eta d_j b_h \end{aligned} \tag{11}$$

$$\begin{aligned} \Delta v_{qh} &= -\eta \frac{\partial E_i}{\partial v_{qh}} = -\eta \frac{\partial E_i}{\partial netb_h} \frac{\partial netb_h}{\partial v_{qh}} \\ &= \eta e_h \left[\frac{\partial [\sum_{q=1}^{d} x^q v_{qh}]}{\partial v_{qh}} \right] = \eta e_h x^q \end{aligned} \tag{12}$$

the biases are updated as follows:

$$\Delta \beta_j = \eta d_j ; \Delta \alpha_h = \eta e_h \tag{13}$$

where η is the learning rate.

The training process of the neural network is presented in Algorithm 2.

Algorithm 2 Algorithm of INN-RER Learning.

Input: x_i^q: Term frequency of text x_i; $\Delta v, \Delta \alpha$: Parameters after initialization; L: emotion labels

Output: A predictable neural network INN-RER.

```
Initialize INN-RER network parameters from Algorithm 1
for each iteration do
    for each text $x_i \in G$ do
        Forward compute output of INN-RER's score function g given $x_i$.
        Backward compute the gradient according to g and $L$ based on the relevant emotion ranking loss function with learning rate of $\eta_{learn}$ and penalty term $\lambda$.
    end for
end for
```

4 Experiments

We evaluate the proposed approach on the following three corpora:

Sina Social News (News) was collected from the Sina news *Society* channel where readers can choose one of the six emotions such as *Amusement*, *Touching*, *Anger*, *Sadness*, *Curiosity*, and *Shock* after reading a news article. As Sina is one of the largest online news sites in China, it is sensible to carry out experiments to explore the readers' emotion (social emotion). News articles with less than 20 votes were discarded since few votes can not be considered as proper representation of social emotion. In total, 5,586 news articles published from January 2014 to July 2016 were kept, together with the readers' emotion votes.

Ren-CECps corpus (Blogs) (Quan and Ren, 2010) contains 1,487 blogs in Chinese. Each document is annotated with eight basic emotions from writer's perspective, including *anger*, *anxiety*, *expect*, *hate*, *joy*, *love*, *sorrow* and *surprise*, together with their emotion scores indicating the level of emotion intensity in the range of $[0, 1]$. Higher scores represent higher emotion intensity.

SemEval (Strapparava and Mihalcea, 2007) is an English data set containing 1,250 news headlines extracted from Google news, CNN, and many other portals. The news headlines are typically short. Each headline was manually scored in a fine-grained valence scale of 0 to 100 across 6 emotions (i.e., *anger*, *disgust*, *fear*, *joy*, *sad* and *surprise*). After pruning 4 items with the total scores equal to 0, 1246 headlines are got for the experiments.

News		Blogs		SemEval	
Category	#Votes	Category	#Scores	Category	#Scores
Touching	694,006	Joy	349.2	anger	12042
Shock	572,651	Hate	174.2	disgust	7634
Amusement	869,464	Love	610.6	fear	20306
Sadness	837,431	Sorrow	408.4	joy	23613
Curiosity	212,559	Anxiety	422.6	sad	24039
Anger	1,109,315	Surprise	59.2	surprise	21495
		Anger	116.4		
		Expect	385.5		
All	4,295,426	All	2526.1	All	109,129

Table 1: Statistics for the three corpora used in our experiments.

The statistics of the three corpora are shown in Table 1. The first two corpora were preprocessed by using the python jieba segmenter[1] for word segmentation and filtering. The third corpus SemEval is in English and can be tokenized by white spaces. Stop words and words appeared only once or in less than two documents were removed to alleviate data sparsity. Next, TF-IDF (term frequency-inverse document frequency) was used to extract the features from text. TF-IDF is a numerical statistic method that is designed to reflect how important a word is to a document in a corpus. In our experiments, we set the dimension of each text representation to 2,000 according to the ranking of the TF-IDF weights with each dimension of term-frequency(TF) features. After that, the text representations are fed into the proposed INN-RER method.

η_{init}, η_{learn}, λ, the number of iterations and the number of topics are set to 0.9, 0.1, 0.001, 100 and 60 respectively. The parameters were chosen by 10-fold cross-validation. The topic distribution used in INN-RER are derived in different ways. For long text such as News and Blogs, Latent Dirichlet Allocation (LDA) (Blei et al., 2003) is employed for generating topic distributions. For short texts in Semeval, bi-term topic model (BTM) (Cheng et al., 2014) was used, since short text typically contains a few words which results in sparse word co-occurrence patterns. BTM is a variant of LDA which effectively infers the latent topic distribution of short text by modeling the generation of bi-terms in the whole corpus and it alleviates the problem of sparsity at the document level. For each method, 10-fold cross validation is conducted using the same feature construction method to get the final performance.

Evaluation metrics typically used in multi-label learning and label ranking are employed which are different from those of classical single-label learning systems (Sebastiani, 2001). The detailed explanation of evaluation metrics are presented in Table 2. Note that metrics from PRO Loss to $F1_{exam}$ work by evaluating performance on each test example separately and returning the mean value across test set. MicroF1 and MacroF1 work by evaluating performance on each emotion category separately and returning the macro/micro-averaged value across all emotion categories.

4.1 Experimental Results

There are several approaches addressing multiple emotions detection from texts. Three generative model based baselines and three discriminative model based baselines are chosen.

- **Emotion Distribution Learning (EDL)** (Zhou et al., 2016) learns a mapping

Table 3: Experimental results of the proposed approach and the baselines. 'PL' represent Pro Loss, 'HL' represents Hamming Loss, 'RL' represents ranking loss, 'OE' represents one error, 'AP' represent average precision, 'Cov' represent coverage, 'F1' represents $F1_{exam}$, MiF1' represents MicroF1, 'MaF1' represents MacroF1. "↓" indicates "the smaller the better", while "↑" indicates "the larger the better". The best performance on each evaluation measure is highlighted by boldface.

Name	**Definition**
PRO Loss	$\frac{1}{n}\sum_{i=1}^{n}\sum_{e_t\in R_i\cup\{\Theta\}}\sum_{e_s\in\prec(e_t)}\frac{1}{norm_{t,s}}l_{t,s}$ $l_{t,s}$ is a modified 0-1 error;$norm_{t,s}$is the set size of label pair(e_t,e_s)
Hamming Loss	$\frac{1}{nT}\sum_{i=1}^{n}\lvert\hat{R}_i\triangle R_i\rvert$ The predicted relevant emotions: $\hat{R}_i$.
Ranking Loss	$\frac{1}{n}\sum_{i=1}^{n}(\sum_{(e_t,e_s)\in R_i\times\overline{R_i}}\delta[g_t(x_i)<g_s(x_i)])/(\lvert R_i\rvert\times\lvert\overline{R_i}\rvert)$ where δ is the indicator function.
One Error	$\frac{1}{n}\sum_{i=1}^{n}\delta[\underset{\mathbf{e_t}}{\text{argmax}}\, g_t(x_i)\notin R_i]$
Average Precision	$\frac{1}{n}\sum_{i=1}^{n}\frac{1}{\lvert R_i\rvert}\times$ $(\sum_{t:e_t\in R_i}\lvert\{e_s\in R_i\vert g_s(x_i)>g_t(x_i)\}\rvert)/(\lvert\{e_s\vert g_s(x_i)>g_t(x_i)\}\rvert)$
Coverage	$\frac{1}{n}\sum_{i=1}^{n}\max_{t:e_t\in R_i}\lvert\{e_s\vert g_s(x_i)>g_t(x_i)\}\rvert$
$F1_{exam}$	$\frac{1}{n}\sum_{i=1}^{n}2\lvert R_i\cap\hat{R}_i\rvert/(\lvert R_i\rvert+\lvert\hat{R}_i\rvert)$
MicroF1	$F1(\sum_{t=1}^{T}TP_t,\sum_{t=1}^{T}FP_t,\sum_{t=1}^{T}TN_t,\sum_{t=1}^{T}FN_t)$
MacroF1	$\frac{1}{T}\sum_{t=1}^{T}F1(TP_t,FP_t,TN_t,FN_t)$

Table 2: Evaluation criteria for the Multi-Label Learning (MLL) methods. TP_t, FP_t, TN_t, FN_t represent the number of true positive, false positive, true negative, and false negative test examples with respect to emotion t respectively. $F1(TP_t, FP_t, TN_t, FN_t)$ represent specific binary classification metric F1 (Manning et al., 2008).

function from texts to their emotion distributions based on label distribution learning.

- **EmoDetect** (Wang and Pal, 2015) outputs the emotion distribution based on a dimensionality reduction method using non-negative matrix factorization which combines several constraints such as emotions bindings and topic correlations.

- **RER** (Zhou et al., 2018) predicts multiple emotions and their rankings from text based on relevant emotion ranking using support vector machines.

- **Multi-label supervised topic model (MSTM) and Sentiment latent topic model (SLTM)** (Rao et al., 2014b): As the variants of supervised topic models, MSTM and SLTM connect latent topics with evoked emotions of

Touching		Anger		Amusement

Figure 2: The top topic words under each emotion category from the News corpus.

texts. MSTM first generates a set of topics from words, and then samples emotions from each topic. SLTM generates topics directly from emotions.

- **Affective topic model (ATM)** (Rao et al., 2014a) employs the exponential distribution to generate ratings for each emotion.

We also evaluated INN-RER with random initialization instead of the proposed initialization procedure, which is denoted as INN-RER(-t).

Experimental results on the three corpora are summarized in Table 3. It can be observed from the table that: (1) INN-RER outperforms the baselines on almost all evaluation metrics across all the data sets; (2) INN-RER achieves better performance on almost all the evaluation metrics than INN-RER(-t), which further verifies the effectiveness of incorporating the topic information; (3) Both INN-RER and INN-RER(-t) perform remarkably better than RER which is based on linear models. It verifies the effectiveness of using the neural networks for RER task, which are able to learn dynamic and complex functions.

4.2 INN-RER Interpretation

In addition to comparing the performance of the proposed model with several baselines, we also present the experimental results from the perspective of result interpretation to fully understand INN-RER. The topic words of each emotion in three corpora are extracted according to the ranking of weights learned by INN-RER, i.e., the probabilities of topics conditioned on emotions (weights between the hidden layer and the output layer) and words conditioned on topics (weights between the input layer and the hidden layer). Results are shown in Figure 2, 3, 4 respectively. It can be observed that the extracted topics words under each emotion category correspond to a certain event, which evokes the emotion. It is in ac-

Table 4: Comparison with Multi-Label Learning (MLL) Methods. The evaluation criteria are same as in Table 3.

cord with what has been observed in social psychology (Stoyanov and Cardie, 2008). For example, in the Sina corpus, Topic 1 under the emotion *touching* is about **“heroic rescue”**; Topic 1 under the emotion *anger* is about **“sexual molestation of a child”** and Topic 2 under the emotion *sadness* is about an **“car accident”**. In the SemEval and the Blog corpora, we can also find that topic words listed under each emotion category are related to some social events. For example, in the SemEval corpus, the *Joy* topic is about **“home entertainment”** and the *Anger* topic is about **”terrorist attack”**. In the Blog corpus, the *sorrow* topic is about **”earthquake and the lost of their loved ones”**. The extracted emotion-associated topic words unveil how the corresponding emotion is evoked. By incorporating topical information into neural network learning, we are able to obtain more interpretable results from INN-RER.

4.3 Comparison with Multi-Label Methods

Since relevant emotion ranking can be seen as an extension of multi-label learning, the proposed INN-RER is also compared with three widely used well-established multi-label learning methods such as LIFT (Zhang, 2011), Rank-SVM (Zhang and Zhou, 2014) and BP-MLL (Zhang and Zhou, 2006). In our experiments, LIFT used linear kernel and Rank-SVM uses the RBF kernel with the width σ set to 1 using the threshold Θ which is initialized as 0.15 after normalization.

The results of INN-RER in comparison with MLL baselines are presented in Table 4. It can be observed that INN-RER outperforms all the baselines across all the datasets on all evaluation measures most of the time. This further verifies the effectiveness of our proposed INN-RER for multi-label emotion detection due to its consideration of rankings of the relevant emotions and the incorporation of topic models.

5 Conclusion

In this paper, we have proposed a novel interpretable neural network for relevant emotion ranking. Specifically, motivated by transfer learning, the neural network is initialized to make its hidden layer approximate the behavior of a topic model. Moreover, a novel error function is defined to optimize the whole neural network for relevant emotion ranking. Experimental results on three real-world corpora show that the proposed approach performs remarkably better than the state-of-the-art emotion detection approaches and multi-label learning methods. Moreover, the extracted emotion-associated topic words indeed represent emotion-evoking events which are in line with our common-sense knowledge. In the future, we will explore the possibility of learning a topic model and an emotion ranking function simultaneously in a unified framework.

Abstract

We propose a novel multi-grained attention network (MGAN) model for aspect level sentiment classification. Existing approaches mostly adopt coarse-grained attention mechanism, which may bring information loss if the aspect has multiple words or larger context. We propose a fine-grained attention mechanism, which can capture the word-level interaction between aspect and context. And then we leverage the fine-grained and coarse-grained attention mechanisms to compose the MGAN framework. Moreover, unlike previous works which train each aspect with its context separately, we design an aspect alignment loss to depict the aspect-level interactions among the aspects that have the same context. We evaluate the proposed approach on three datasets: laptop and restaurant are from SemEval 2014, and the last one is a twitter dataset. Experimental results show that the multi-grained attention network consistently outperforms the state-of-the-art methods on all three datasets. We also conduct experiments to evaluate the effectiveness of aspect alignment loss, which indicates the aspect-level interactions can bring extra useful information and further improve the performance.

1 Introduction

Aspect level sentiment classification is a fundamental task in sentiment analysis (Pang et al., 2008; Liu, 2012), which aims to infer the sentiment polarity (e.g. positive, neutral, negative) of sentence with respect to the aspects. For example, in sentence "*I like coming back to Mac OS but this laptop is lacking in speaker quality compared to my $400 old HP laptop*", the polarity of the sentence towards the aspect "*Mac OS*" is positive while the polarity is negative in terms of aspect "*speaker quality*".

Many statistical methods, such as support vector machine (SVM) (Wagner et al., 2014; Kiritchenko et al., 2014), are employed with well-designed handcrafted features. In recent years, neural network models (Socher et al., 2011; Dong et al., 2014; Nguyen and Shirai, 2015) are studied to automatically learn low-dimensional representations for aspects and their context. Attention mechanism (Wang et al., 2016; Li et al., 2017; Ma et al., 2017) is also be studied to characterize the effect of aspect on enforcing the model to pay more attention on the important words of the context. Previous works (Tang et al., 2016b; Chen et al., 2017) mainly employed the simple averaged aspect vector to learn the attention weights on the context words. Ma et al. [2017] further proposed the bidirectional attention mechanism, which interactively learns the attention weights on context/aspect words, with respect to the averaged vector of aspect/context, respectively.

These above attention methods are all at the coarse-grained level, which simply averages the aspect/context vector to guide learning the attention weights on the context/aspect words. The simple average pooling mechanism might cause information loss, especially for the aspect with multiple words or larger context. For example, in sentence "*I like coming back to Mac OS but this laptop is lacking in speaker quality compared to my $400 old HP laptop*", the simple averaged vector of long context might lose information when steering the attention weights on aspect words. Similarly, the simple averaged vector of aspect (i.e. *"speaker quality"*) may deviate from the intuitive core meaning (*i.e. "quality"*) when enforcing the model to pay varying attentions on the context words. From another perspective, previous works all regard the aspect and its context words as one instance, and train each instance separately. However, they do not consider the relationship among

---

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3433–3442
Brussels, Belgium, October 31 - November 4, 2018.

the instances that have the same context words. The aspect-level interactions among the instances with same context might bring extra useful information. Considering the above example, intuitively, the aspect *"speaker quality"* should pay more attention on *"lacking"* and less attention on *"like"*, compared with aspect *"Mac OS"*, since they have different sentiment polarities.

In this paper, we propose a multi-grained attention network to address the above two issues in aspect level sentiment classification. Specifically, we propose a fine-grained attention mechanism (*i.e. F-Aspect2Context* and *F-Context2Aspect*), which is employed to characterize the word-level interactions between aspect and context words, and relieve the information loss occurred in coarse-grained attention mechanism. In addition, we utilize the bidirectional coarse-grained attention (*i.e. C-Aspect2Context* and *C-Context2Aspect*) and combine them with fine-grained attention vectors to compose the multi-grained attention network for the final sentiment polarity prediction, which can leverage the advantages of them. More importantly, in order to make use of the valuable aspect-level interaction information, we design an aspect alignment loss in the objective function to enhance the difference of the attention weights towards the aspects which have the same context and different sentiment polarities. As far as we know, we are the first to explore the interactions among the aspects with the same context.

To evaluate the proposed approach, we conduct experiments on three datasets: laptop and restaurant are from the SemEval 2014 Task 4 and the third one is a tweet collection. Experimental results show that our method achieves the best performance on all three datasets.

2 Related Work

Aspect-level sentiment analysis is a branch of sentiment classification, which requires considering both the sentence and aspect information.

Traditional approaches (Jiang et al., 2011; Kiritchenko et al., 2014; Vo and Zhang, 2015) regard this task as the text classification problem and design effective features, which are utilized in statistical learning algorithms for training a classifier. Kiritchenko et al. [2014] proposed to use SVM based on n-gram features, parse features and lexicon features, which achieved the best performance in SemEval 2014. Vo and Zhang [2015] designed sentiment-specific word embedding and sentiment lexicons as rich features for prediction. These methods highly depend on the effectiveness of the laborious feature engineering work and easily reach the performance bottleneck.

In recent works, there are growing studies on neural network based methods due to their capability of encoding original features as continuous and low-dimensional vectors without feature engineering. Recursive Neural Network (Socher et al., 2011; Dong et al., 2014; Nguyen and Shirai, 2015) are studied to conduct semantic compositions on tree structures, and generate representations for prediction. Methods on LSTM (Hochreiter and Schmidhuber, 1997) were proposed to model the context information and use an aggregated vector for prediction. TD-LSTM (Tang et al., 2016a) adopted LSTM to model the left context and right context of the aspect, and concatenate them as the representation for prediction. However, these works only focused on modeling the contexts without considering the aspects, which performed an important role in estimate the sentiment polarity.

Attention mechanisms (Wang et al., 2016; Lei et al., 2016; Li et al., 2017) are studied to enhance the influence of aspects on the final representation for prediction. Many approaches (Tang et al., 2016b; Chen et al., 2017) adopted the averaged aspect vector to learn the attention weights on the hidden vectors of context words. Ma et al. [2017] further proposed bidirectional attention mechanism, which also learns the attention weights on aspect words towards the averaged vector of context words. These attention methods only consider the coarse-grained level attention, through using the simple averaged aspect/context vector to steer the attention weights learning on the context/aspect words, which might cause some information loss on the long aspect or context case.

In contrast, motivated by the bidirectional attention flow approaches (Seo et al., 2017; Pan et al., 2017) in machine comprehension, we propose a fine-grained attention mechanism which is responsible for linking and fusing information from the aspect and the context words. Furthermore, we leverage both the coarse-grained and fine-grained attentions to compose the multi-grained attention network (MGAN). In addition, existing works train each instance separately. However, we observe that the interactions among the aspects, which have the same context words, could bring extra useful information. Thus we design the aspect alignment loss in the objective function to depict such kind of relationship, which is the first work to explore the aspect-level interactions.

3 Our Approach

3.1 Task Definition

Given a sentence $s = \{w_1, w_2, \cdots, w_N\}$ consisting of N words, and an aspect list $A = \{a_1, \cdots, a_k\}$, where the aspect list size is k and each aspect $a_i = \{w_{i_1}, \cdots, w_{i_M}\}$ is a subsequence of sentence s, which contains $M \in [1, N)$ words. Aspect-level sentiment classification evaluates sentiment polarity of the sentence s with respect to each aspect a_i.

We present the overall architecture of the proposed Multi-grained Attention Network (MGAN) model in Figure 1. It consists of the Input Embedding layer, the Contextual Layer, the Multi-grained Attention Layer and the Output Layer.

3.2 Input Embedding Layer

Input Embedding Layer maps each word to a high dimensional vector space. We employ the pre-trained word vector, GloVe (Pennington et al., 2014), to obtain the fixed word embedding of each word. Specifically, we denote the embedding lookup matrix as $\mathbb{L} \in \mathbb{R}^{d_v \times |V|}$, where d_v is the word vector dimension and $|V|$ is the vocabulary size.

3.3 Contextual Layer

We employ a bidirectional Long Short-Term Memory Network (BiLSTM) on top of the embedding layer to capture the temporal interactions among words. Specifically, at time step t, given the input word embedding x, the update process of forward LSTM network can be formalized as follows:

$$i_t = \sigma(\overrightarrow{W}_i \cdot [\overrightarrow{h}_{t-1}, \overrightarrow{x}_t] + \overrightarrow{b}_i) \tag{1}$$

$$f_t = \sigma(\overrightarrow{W}_f \cdot [\overrightarrow{h}_{t-1}, \overrightarrow{x}_t] + \overrightarrow{b}_f) \tag{2}$$

$$o_t = \sigma(\overrightarrow{W}_o \cdot [\overrightarrow{h}_{t-1}, \overrightarrow{x}_t] + \overrightarrow{b}_o) \tag{3}$$

$$g_t = tanh(\overrightarrow{W}_g \cdot [\overrightarrow{h}_{t-1}, \overrightarrow{x}_t] + \overrightarrow{b}_g) \tag{4}$$

$$\overrightarrow{c}_t = f_t * \overrightarrow{c}_{t-1} + i_t * g_t \tag{5}$$

$$\overrightarrow{h}_t = o_t * tanh(\overrightarrow{c}_t) \tag{6}$$

Where σ is the sigmoid activation function, i_t, f_t, o_t are the input gate, forget gate and output gate, respectively. $\overrightarrow{W}_i, \overrightarrow{W}_f, \overrightarrow{W}_o, \overrightarrow{W}_g \in \mathbb{R}^{d*(d+d_v)}$, $\overrightarrow{b}_i$, $\overrightarrow{b}_f$, $\overrightarrow{b}_o$, $\overrightarrow{b}_g \in \mathbb{R}^d$, and d is the hidden dimension size. The backward LSTM does the similar process and we can get the concatenated output $h_t = [\overrightarrow{h}_t, \overleftarrow{h}_t] \in \mathbb{R}^{2d}$. Given the word embeddings of a context sentence s and a corresponding aspect a_j, we will employ the BiLSTM separately and get the sentence contextual output $H \in \mathbb{R}^{2d*N}$ and aspect contextual output $Q \in \mathbb{R}^{2d*M}$.

In addition, considering that the context words with closer distance to an aspect may have higher influence to the aspect, we utilize the position encoding mechanism to simulate the observation. Formally, the weight for a context word w_j, which has l word-level distance from the aspect (here we treat the aspect phrase as a single unit), is defined as follows:

$$w_t = 1 - \frac{l}{N - M + 1} \tag{7}$$

Specifically, we treat the weights of words within the aspect as 0 in order to focus on the context words in the sentence. Then we can obtain the final contextual outputs of context words $H = [H_1 * w_1, \cdots, H_N * w_N]$.

3.4 Multi-grained Attention Layer

Attention mechanism is a common way to capture the interactions between the aspect and context words. Previous methods (Tang et al., 2016b; Ma et al., 2017; Chen et al., 2017) only adopt coarse-grained attentions, which simply use the averaged aspect/context vector as the guide to learn the attention weights on context/aspect. However, the simple average pooling in generating the guide vector might bring some information loss, especially for the aspect with multiple words or larger context. We propose the fine-grained attention mechanism, which is responsible for linking and fusing information from the aspect and context words. This mechanism is designed to capture the word-level interactions which estimate how each aspect/context word affect each context/aspect word. In addition, we concatenate both the fine-grained and coarse-grained attention vectors to obtain the final representation. From other perspective, we observe the relationship among aspects can introduce extra valuable information. Hence, we propose an aspect alignment loss, which is designed to strengthen the at-

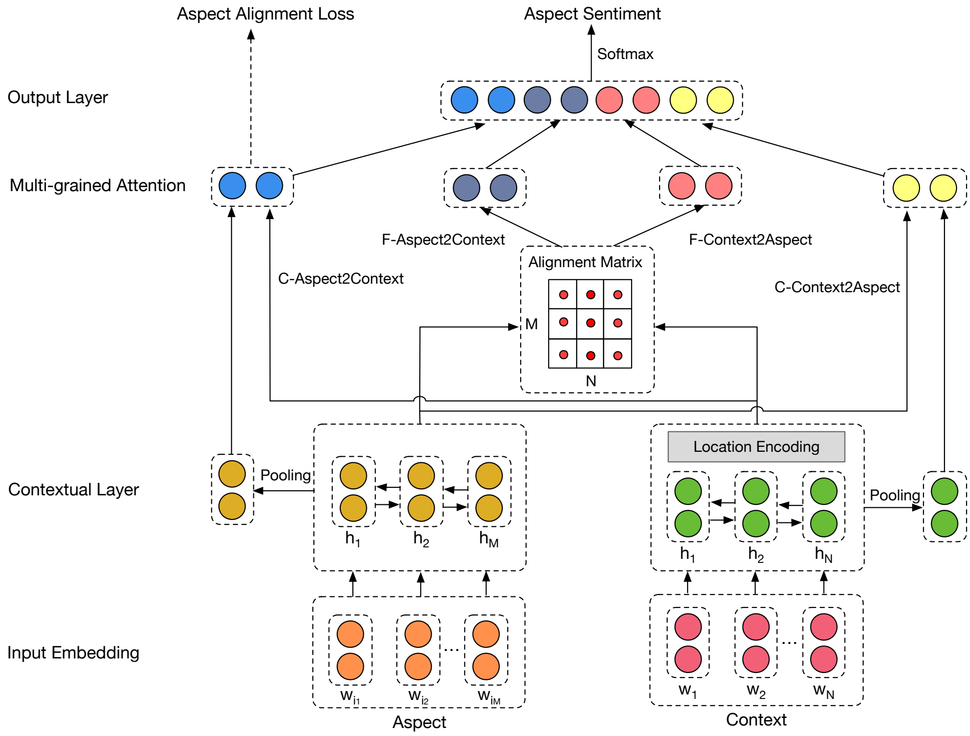

Figure 1: The architecture of the proposed multi-grained attention network.

tention difference among aspects with same context and different sentiment polarities.

Coarse-grained Attention

Coarse-grained attention is a widely used mechanism to capture the interactions between aspect and context, which utilizes an averaged aspect vector to steer the attention weights on the context words. Follow the work in (Ma et al., 2017), we employ the bidirectional attention mechanism, namely *C-Aspect2Context* and *C-Context2Aspect*.

(1) C-Aspect2Context learns to assign attention scores to the context words with respect to the averaged aspect vector. Here we employ an average pooling layer above aspect contextual output Q to generate the averaged aspect vector $Q_{avg} \in \mathbb{R}^{2d}$. For each word vector H_i in context, we can compute the attention score a_i^{ca} as follows:

$$s_{ca}(Q_{avg}, H_i) = Q_{avg} * W_{ca} * H_i \tag{8}$$

$$a_i^{ca} = \frac{exp(s_{ca}(Q_{avg}, H_i))}{\sum_{k=1}^{N} exp(s_{ca}(Q_{avg}, H_k))} \tag{9}$$

Where the score function s_{ca} computes the weight which indicates the importance of a context word towards aspect sentiment. $W_{ca} \in \mathbb{R}^{2d*2d}$ is the attention weight matrix. Then the weighted combination of the context output $m^{ca} \in \mathbb{R}^{2d}$ is calculated as follows:

$$m^{ca} = \sum_{i=1}^{N} a_i^{ca} \cdot H_i \tag{10}$$

(2) C-Context2Aspect learns to assign attention weights on aspects words, which follows the similar learning process with *C-Aspect2Context*. We utilize the average pooling mechanism to obtain the averaged context vector H_{avg}, and compute the weights for each word w_i in the aspect phrase. We compute the final weighted combination of aspect vector $m^{cc} \in \mathbb{R}^{2d}$ as follows:

$$s_{cc}(H_{avg}, Q_i) = H_{avg} * W_{cc} * Q_i \tag{11}$$

$$a_i^{cc} = \frac{exp(s_{cc}(H_{avg}, Q_i))}{\sum_{k=1}^{M} exp(s_{cc}(H_{avg}, Q_k))} \tag{12}$$

$$m^{cc} = \sum_{i=1}^{M} a_i^{cc} \cdot Q_i \tag{13}$$

where $W^{cc} \in \mathbb{R}^{2d*2d}$ is the attention weight matrix.

Fine-grained Attention

As introduced above, we propose a fine-grained attention mechanism to characterize the word-level interactions and evaluate how each aspect/context word affect each context/aspect word. Considering the previous example "*I like coming back to Mac OS but this laptop is lacking in speaker quality compared to my \$400 old HP laptop*", the word *"quality"* in aspect *"speaker quality"* should have more effect on the context words compared with word *"speaker"*. Accordingly, the context words should pay more attention on *"quality"* instead of *"speaker"*.

Formally, we define an alignment matrix $U \in \mathbb{R}^{N*M}$, between the contextual output of and the context H and the aspect Q, where U_{ij} indicates the similarity between i-th context word and j-th aspect word. The similarity matrix U is computed by

$$U_{ij} = W_u([H_i; Q_j; H_i * Q_j]) \tag{14}$$

Where $W_u \in \mathbb{R}^{1*6d}$ is the weight matrix, $[;]$ is the vector concatenation across row, $*$ is the elementwise multiplication. Then we use U to calculate the attention vectors in both directions.

(1) F-Aspect2Context estimates which context word has the closest similarity to one of the aspect word and are hence critical for determining the sentiment. We can compute the attention weights a^{fa} on context words by

$$s_i^{fa} = max(U_{i,:}) \tag{15}$$

$$a_i^{fa} = \frac{exp(s_i^{fa})}{\sum_{k=1}^{N} exp(s_k^{fa})} \tag{16}$$

where s_i^{fa} obtains the maximum similarity across column. And then we can get the attended vector $m^{fa} \in \mathbb{R}^{2d}$ as follows:

$$m^{fa} = \sum_{i=1}^{N} a_i^{fa} \cdot H_i \tag{17}$$

(2) F-Context2Aspect measures which aspect words are most relevant to each context word. Let $a_i^{fc} \in \mathbb{R}^M$ be the attention weights on aspect contextual output Q with respect to the i-th context word vector H_i. The attended aspect vector $q^{fc} \in \mathbb{R}^{2d*N}$ is defined as follows:

$$a_{ij}^{fc} = \frac{exp(U_{ij})}{\sum_{k=1}^{M} exp(U_{ik})} \tag{18}$$

$$q_i^{fc} = \sum_{j=1}^{M} a_{ij}^{fc} \cdot Q_j \tag{19}$$

Then we use an average pooling layer on q^{fc} to get the attended vector $m^{fc} \in \mathbb{R}^{2d}$:

$$m^{fc} = Pooling([q_1^{fc}, \cdots, q_N^{fc}]) \tag{20}$$

3.5 Output Layer

At last, we concatenate both the coarse-grained and fine-grained attention vectors as the final representation $m \in \mathbb{R}^{8d}$, which will be fed to a softmax layer for determining the aspect sentiment polarity.

$$m = [m^{ca}; m^{cc}; m^{fa}; m^{fc}] \tag{21}$$

$$p = softmax(W_p * m + b_p) \tag{22}$$

where $p \in \mathbb{R}^C$ is the probability distribution for the polarity of aspect sentiment, $W_p \in \mathbb{R}^{C*8d}$ and $b_p \in \mathbb{R}^C$ are the weight matrix and bias, respectively. Here we set $C = 3$, which is the number of aspect sentiment classes.

3.6 Model Training

Aspect Alignment Loss

Existing approaches train each aspect with its context separately, without considering the relationship among the aspects. However, we observe the aspect-level interactions can bring extra valuable information. In order to enhance the attention differences of aspects, which have the same context and different sentiment polarities, we design the aspect alignment loss on the C-Aspect2Context attention weights. C-Aspect2Context is employed to find the important context words in terms of a specific aspect. With the constraint of aspect alignment loss, each aspect will pay more attention on the important words through the comparisons with other related aspects. In terms of the previous example, the aspect *"speaker quality"* should pay more attention on *"lacking"* and less attention on *"like"*, compared with aspect *"Mac OS"* due to their different sentiment polarities.

Specifically, for each aspect pair a_i and a_j in aspect list A, we compute the square loss on the coarse-grained attention vector a_i^{ca} and a_j^{ca}, and also estimate the distance $d_{ij} \in [0, 1]$ between a_i and a_j as the loss weight.

$$d_{ij} = \sigma(W_d([Q_i; Q_j; Q_i * Q_j]) \tag{23}$$

$$\mathcal{L}_{align} = -\sum_{i=1}^{M-1} \sum_{j=i+1, y_i \neq y_j}^{M} \sum_{k=1}^{N} d_{ij} \cdot (a_{ik}^{ca} - a_{jk}^{ca})^2 \tag{24}$$

Where σ is the sigmoid function, $W_d \in \mathbb{R}^{1*6d}$ is weight matrix for computing the distance, y_i and y_j are the true labels of the aspect a_i and a_j, a_{ik}^{ca} and a_{jk}^{ca} are the attention weights on k-th context word towards aspect a_i and a_j, respectively.

For training the multi-grained attention network (MGAN), we should optimize all the parameters Θ from the LSTM networks: $[W_i, W_o, W_f, W_g, b_i, b_o, b_f, b_g]$, the attention and alignment loss parameters: $[W_{ca}, W_{cc}, W_u, W_d]$ and softmax parameters: $[W_p, b_p]$. The final loss function is consisting of the cross-entropy loss, aspect alignment loss and regularization item as follows:

$$\mathcal{L} = -\sum_{i=1}^{C} y_i log(p_i) + \beta \mathcal{L}_{align} + \lambda \|\Theta\|^2 \tag{25}$$

Where $\beta \geq 0$ and $\lambda \geq 0$ controls the influence of the aspect alignment loss and the L_2 regularization item, respectively. We employ the stochastic gradient descent (SGD) optimizer to compute and update the training parameters. In addition, we utilize dropout strategy to avoid overfitting.

4 Experiments

In this section, we conduct experiments to evaluate our two hypotheses: (1) whether the word-level interaction between aspect and context can help relieve the information loss and improve the performance. (2) whether the relationship among the aspects, which have the same context and different sentiment polarities, can bring extra useful information.

4.1 Experiment Setting

We conduct experiments on three datasets, as shown in Table 1. The first two are from the SemEval 2014 Task 4[1] (Pontiki et al., 2014), which contains the reviews in laptop and restaurants, respectively. The third one is a tweet collection, which are gathered by (Dong et al., 2014). Each aspect with the context is labeled by three sentiment polarities, namely *Positive*, *Neutral* and *Negative*. In addition, we adopt *Accuracy* and *Macro-F1* as the metrics to evaluate the performance of aspect-level sentiment classification, which is widely used in previous works (Tang et al., 2016b; Ma et al., 2017; Chen et al., 2017; Wang et al., 2016).

In our experiments, word embeddings for both context and aspect words are initialized by Glove (Pennington et al., 2014). The dimension of word embedding d_v and hidden state d are set to 300. The weight matrix and bias are initialized by sampling from a uniform distribution $U(0.01, 0.01)$. The coefficient λ of L_2 regularization item is 10^{-5}, the parameter β of aspect alignment loss and drop out rate are set to 0.5.

Dataset	Positive		Neutral		Negative	
	Train	Test	Train	Test	Train	Test
Laptop	994	341	870	128	464	169
Restaurant	2164	728	807	196	637	196
Twitter	1561	173	3127	346	1560	173

Table 1: The statistics of the datasets.

4.2 Compared Methods

To evaluate the performance of proposed approach, we compared with the following methods:

Majority is the basic baseline, which chooses the largest sentiment polarity in the training set to each instance in the test set.

Feature+SVM (Kiritchenko et al., 2014) uses n-gram features, parse features and lexicon features based on SVM, which achieves the state-of-the-art performance in SemEval 2014.

LSTM (Wang et al., 2016) utilizes one LSTM network to learn the hidden states and obtain the averaged vector to predict the sentiment polarity.

ATAE-LSTM (Wang et al., 2016) learns attention embeddings and combine them with the LSTM hidden states to predict the polarity.

TD-LSTM (Tang et al., 2016a) employs two directional LSTM networks, which estimate the left context and right context of the target aspect, respectively. Finally it takes the last hidden states of LSTM networks for prediction.

MemNet (Tang et al., 2016b) applys multi-hop attentions on the word embeddings, learns the attention weights on context word vectors with respect to the averaged query vector.

IAN (Ma et al., 2017) interactively learns the coarse-grained attentions between the context and aspect, and concatenate the vectors for prediction.

BILSTM-ATT-G (Liu and Zhang, 2017) models left and right context with two attention-based LSTMs and utilizes gates to control the importance of left context, right context and the entire sentence for prediction.

RAM(Chen et al., 2017) learns multi-hop attentions on the hidden states of bidirectional LSTM networks for context words, and proposes to use GRU network to get the aggregated vector from the attentions. Similar with **MemNet**, the atten-

---

[1] The detailed task introduction can be found in http://alt.qcri.org/semeval2014/task4/.

tion weights on context words are steered by the simple averaged aspect vector.

We also list the variants of MGAN model, which are used to analyze the effects of coarse-grained attention, fine-grained attention and aspect alignment loss, respectively.

MGAN-C only employs the coarse-grained attentions for prediction, which is similar with **IAN**.

MGAN-F only utilizes the proposed fine-grained attentions for prediction.

MGAN-CF adopts both the coarse-grained and fine-grained attentions, while without applying the aspect alignment loss.

MGAN is the complete multi-grained attention network model.

4.3 Overall Performance Comparison

Table 2 shows the performance comparison results of MGAN with other baseline methods. We can have the following observations.

(1) **Majority** performs worst since it only utilizes the data distribution information. **Feature+SVM** can achieve much better performance on all the datasets, with the well-designed feature engineering. Our method **MGAN** outperforms **Majority** and **Feature+SVM** since **MGAN** could learn the high quality representation for prediction.

(2) **ATAE-LSTM** is better than **LSTM** since it employs attention mechanism on the hidden states and combines with attention embedding to generate the final representation. **TD-LSTM** performs slightly better than **ATAE-LSTM**, and it employs two LSTM networks to capture the left and right context of the aspect. **TD-LSTM** performs worse than our method **MGAN** since it could not properly pay more attentions on the important parts of the context.

(3) **IAN** achieves slightly better results with the previous LSTM-based methods, which interactively learns the attended aspect and context vector as final representation. Our method consistently performs better than **IAN** since we utilize the fine-grained attention vectors to relieve the information loss in **IAN**. **MemNet** continuously learns the attended vector on the context word embedding memory, and updates the query vector at each hop. **BILSTM-ATT-G** models left context and right context using attention-based LSTMs, which achieves better performance than **MemNet**. **RAM** performs better than other baselines. It employs bidirectional LSTM network to generate contextual memory, and learns the multiple attended vector on the memory. Similar with **MemNet**, it utilizes the averaged aspect vector to learn the attention weights on context words.

Our proposed **MGAN** consistently performs better than **MemNet**, **BILSTM-ATT-G** and **RAM** on all three datasets. On one hand, they only consider to learn the attention weights on context towards the aspect, and do not consider to learn the weights on aspect words towards the context. On the other hand, they just use the averaged aspect vector to guide the attention, which will lose some information, especially on the aspects with multiple words. From another perspective, our method employs the aspect alignment loss, which can bring extra useful information from the aspect-level interactions.

4.4 Analysis of MGAN model

Table 3 shows the performance comparison among the variants of MGAN model. We can have the following observations.

(1) the proposed fine-grained attention mechanism **MGAN-F**, which is responsible for linking and fusing the information between the context and aspect word, achieves competitive performance compared with **MGAN-C**, especially on laptop dataset. To investigate this case, we collect the percentage of aspects with different word lengths in Table 4. We can find that laptop dataset has the highest percentage on the aspects with more than two words, and the second-highest percentage on two words. It demonstrates **MGAN-F** has better performance on aspects with more words, and make use of the word-level interactions to relieve the information loss occurred in coarse-grained attention mechanism.

(2) **MGAN-CF** is better than both **MGAN-C** and **MGAN-F**, which demonstrates the coarse-grained attentions and fine-grained attentions could improve the performance from different perspectives. Compared with **MGAN-CF**, the complete **MGAN** model gains further improvement by bringing the aspect alignment loss, which is designed to capture the aspect level interactions. Specifically, we collect the statistics of sentence-level with different aspect amounts, which is shown in Table 5. We can observe that both laptop and restaurant datasets have relatively high percentage on the sentences with multiple aspects.

Method	Laptop		Restaurant		Twitter	
	Acc	Macro-F1	Acc	Macro-F1	Acc	Macro-F1
Majority	0.5350	0.3333	0.6500	0.3333	0.5000	0.3333
Feature-SVM	0.7049	-	0.8016	-	0.6340	0.6330
ATAE-LSTM	0.6870	-	0.7720	-	-	-
TD-LSTM	0.7183	0.6843	0.7800	0.6673	0.6662	0.6401
IAN	0.7210	-	0.7860	-	-	-
MemNet	0.7237	-	0.8032	-	0.6850	0.6691
BILSTM-ATT-G	0.7312	0.6980	0.7973	0.6925	0.7038	0.6837
RAM	0.7449	0.7135	0.8023	0.7080	0.6936	0.6730
MGAN	**0.7539**	**0.7247**	**0.8125**	**0.7194**	**0.7254**	**0.7081**

Table 2: The performance comparisons of different methods on the three datasets, where the results of baseline methods are retrieved from published papers. The best performances are marked in bold.

Method	Laptop		Restaurant		Twitter	
	Acc	Macro-F1	Acc	Macro-F1	Acc	Macro-F1
MGAN-C	0.7273	0.6933	0.8054	0.7099	0.7153	0.6952
MGAN-F	0.7398	0.7082	0.8000	0.7092	0.7110	0.6918
MGAN-CF	0.7445	0.7121	0.8089	0.7135	0.7254*	0.7081*
MGAN	**0.7539**	**0.7247**	**0.8125**	**0.7194**	**0.7254**	**0.7081**

Table 3: The performance comparisons of MGAN variants. $*$ means MGAN-CF and MGAN can be regarded as the same method on twitter dataset.

Dataset	#words=1	#words=2	#words>2
Laptop	61.60%	29.16%	9.24%
Restaurant	74.47%	17.32%	8.21%
Twitter	29.99%	69.91%	0.10%

Table 4: The percentage of aspects with different word length on three datasets. Here we give the overall statistic of each dataset.

The improved performance on the two datasets shows the importance of capturing the aspect-level interactions. In terms of twitter dataset, almost all of the sentences only has one aspect. In this case, the method **MGAN** can be regarded as **MGAN-CF**.

Dataset	#aspects=1	#aspects=2	#aspects>2
Laptop	63.94%	23.32%	12.74%
Restaurant	50.89%	28.60%	20.51%
Twitter	99.91%	0.09%	0.00%

Table 5: The percentage of sentences with different aspect numbers on three datasets. Aspects with the same context are regarded as the same sentence.

4.5 Case Study

In order to demonstrate the effect of aspect alignment loss, we visualize the attention weights of the C-Aspect2Context mechanism. Figure 2 shows the attention weights of two aspects “resolution” and “fonts”, whose sentiment polarities are positive and negative, respectively. From the above two bars, we can observe that the C-Aspect2Context can enforce the model to pay more attentions on the important words with respect to the aspect. For example, in terms of the aspect“resolution”, the words “has”, “higher” and “but” have higher attention weights compared with other words. In contrast, aspect “fonts” pays more attentions on words “but”, “fonts” and “small”. In addition, we evaluate the effect of aspect alignment loss, which enhances the attention difference between the aspect “resolution” and “fonts”. For the two bars at bottom, we can find that aspect “fonts” has more attention on “small” and less attention on “higher”, compared with the aspect “resolution”. This phenomenon shows that with the constraint of aspect alignment loss, C-Aspect2Context can not only learn the important context words for each aspect, but also can make the attention gaps on the important words be as large as possible for aspects with different polarities.

5 Conclusion

In this paper, we propose a multi-grained attention network (MGAN) for aspect-level sentiment classification. Specifically, we propose a fine-grained attention mechanism, which is responsible for linking and fusing the words from the aspect and context, to capture the word-level interaction. And we combine it with the coarse-grained atten-

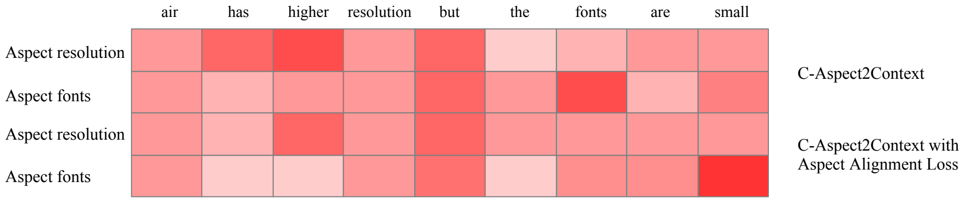

Figure 2: The attention visualizations on aspect "resolution" and "fonts". The above two bars are from the C-Aspect2Context attention mechanism, and the two bars at bottom are from the C-Aspect2Context attention mechanism with the constraint of aspect alignment loss.

tion mechanism to compose the MGAN model. In addition, we design an aspect alignment loss to characterize the aspect-level interactions among aspects, which have the same context and different sentiment polarities, to explore extra valuable information. Experimental results demonstrate the effectiveness of our approach on three public datasets.

Abstract

This paper proposes a new neural architecture that exploits readily available sentiment lexicon resources. The key idea is that that incorporating a word-level prior can aid in the representation learning process, eventually improving model performance. To this end, our model employs two distinctly unique components, i.e., (1) we introduce a lexicon-driven contextual attention mechanism to imbue lexicon words with long-range contextual information and (2), we introduce a contrastive co-attention mechanism that models contrasting polarities between all positive and negative words in a sentence. Via extensive experiments, we show that our approach outperforms many other neural baselines on sentiment classification tasks on multiple benchmark datasets.

1 Introduction

Across the rich history of sentiment analysis research (Kim and Hovy, 2004; Liu, 2012; Pang et al., 2008), sentiment lexicons have been extensively used as features for sentiment classification tasks. Lexicons, either handcrafted or algorithmically generated, consist of words and their associated polarity score. For instance, lexicons assign a high positive score for the word '*excellent*' but a negative score for the word '*terrible*'. Traditionally, the summation of lexicon scores has been treated as a reasonable heuristic estimate (or feature) that is capable of supporting opinion mining applications. Throughout the years, plenty of lexicon lists have been built for various specific domains or general purposes (Hu and Liu, 2004; Mohammad et al., 2013; Wilson et al., 2005). They are indeed valuable resources that should be exploited.

However, sentiment lexicons are in reality hardly useful without context. After all, the complexity and ambiguity of natural language pose great challenges for the crude bag-of-words generalization of lexicons. Firstly, the concept of semantic compositionality is non-existent in simple lexicon approaches which raises problems when handling flipping negation (*not happy*), content word negation (*ameliorates pain*) or unbounded dependencies (*no body passed the exam*). Secondly, lexicons also do not handle word sense, e.g., not being able to differentiate the meaning of *hot* in the phrases *'a hot, attractive person'* and a *'a scorching hot day'*. Thirdly, simple summation over lexicon scores cannot deal with sentences with double contrasting polarities, e.g., the lexicon polarity score of *'Thanks for making this uncomfortable situation more comfortable'* becomes negative because *uncomfortable* has a higher negative lexicon score over the positive score of the word *comfortable*. Lastly, strongly positive or negative words may occur in neutral context which forces an inclination of predictions towards a non-neutral polarity. As such, the exploitation of readily available lexicon lists is an inherently challenging task.

Deep learning has demonstrated incredibly competitive performance in many NLP tasks (Liu et al., 2015; Bradbury et al., 2016; Tai et al., 2015). With no exception, the task of sentiment analysis is recently also dominated by neural architectures. It has been proven from the fact that the top systems from SemEval Sentiment analysis challenges (e.g., notably 2016 and 2017) have mainly leveraged the effectiveness of deep learning models. The main advantage of deep learning approach is that it is effective in exploring both linguistic and semantic relations between words, thus can overcomes the problems of lexicon-based approach. However, current deep learning approach

[*] Denotes equal contribution.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3443–3453
Brussels, Belgium, October 31 - November 4, 2018.

for sentiment analysis usually faces with the major shortcoming, i.e., being limited by the quantity of high quality labeled data. Manual labeling of data, however, is costly and require domain expert knowledge which is not always available in practice.

Given the pros and cons of previous two previous approaches, we aim to combine the best of both worlds - the traditional sentiment lexicon and modern deep learning architectures. To the best of our knowledge, the only work that combines the two paradigms within *end-to-end* neural networks is the Lexicon RNN model (Teng et al., 2016). In their approach, sentiment lexicons are extracted from the hidden states of a recurrent neural network and passed through a simple feed-forward neural network to produce a new polarity weight. This approach, however, has some limitations which will be illustrated using the following example:

"Thanks for making this horrible situation at work more bearable."

Firstly, the Lexicon RNN does not consider the interactions between positive or negative lexicon words, which makes it susceptible to misleading strong lexicon priors. In the above example, the word '*horrible*' is a strongly negative word in most lexicons. As a result, the Lexicon RNN (and many other lexicon based approaches in general) will assign a negative polarity to the sentence. Clearly, modeling similarity between two contrasting polarity words ('*horrible*' and '*bearable*') can help the model resolve this confusion. Secondly, the RNN encoder in the Lexicon RNN is restricted by the sequential nature of the recurrent model, resulting in a limited global view of the entire sentence. For example, the word pairs ('*horrible*', '*bearable*') and ('*thanks*', '*bearable*') are useful for detecting the polarity of the sentence but do not have any explicit interaction even with a sequential RNN encoder. Moreover, the word pair ('*thanks*', '*bearable*') is very far apart in the above example sentence, making it challenging for RNN encoders to capture interactions between them. Finally, the Lexicon RNN faces difficulty dealing with more than two classes due to its design, i.e., linear combination of two scalar scores. In order to cope with this weakness, the authors define hardcoded *dataset specific* thresholds for 5-way classification. Adapting this to 3-way (positive, negative and neutral) is cumbersome as thresholds have to be found by either maximizing over the development set or defined heuristically.

In this paper, we introduce a new end to end paradigm that integrates lexicon information into neural network for the task of sentiment analysis. More specifically, instead of learning a lexicon-based score, we propose to learn an auxiliary embedding by exploiting lexicon information. The key motivation behind the auxiliary representation is that compositional learning with prior/global knowledge of positive and negative inclined words can lead to improved representations. Next, a gating mechanism controls the additive blend between this lexicon-based representation and a standard attention-based recurrent model. In essence, this supporting network aims to learn a *'lexicon-based'* view of the sentence and can be interpreted as *'learning to compose'* by exploiting lexicon information. Finally, instead of the combination of two scalar values (the base lexicon score and sentence bias score) as in the Lexicon RNN model, we propose to use the k-class softmax function at the final layer. Intuitively, it is a more natural solution for fine-grained sentiment classification over the cumbersome tuning of ad-hoc threshold values. Our contributions can be summarized as follows:

- We propose to learn an auxiliary embedding by exploiting lexicon information rather than learning a lexicon-based score. Its design is a more natural and flexible solution for k-class sentiment classification.
- We propose a *contextual attention* (CA) mechanism that learns to attend to lexicon words based on the context. Unlike Lexicon RNN which extracts the hidden representations from the recurrent model, contextual attention allows a wider, global and more complete view of the context (sentence) by matching against every single word in the sentence. In addition to semantic *compositionality*, our model also benefits from semantic *similarity*.
- We propose to model the interaction between the positive and negative lexicon words inside the neural network. Positive and negative lexicon words are modeled seperately and subsequently compared using *contrasive co-attention* (CC) which learns the relative importance of positive lexicons with respect

to negative lexicons (and vice versa). Modeling such intricacies between positive and negative words allows our model to deal with scenarios such as contrasting polarities, neutrality and also sarcasm. We also discover that our CC mechanism produces a neutralizing effect which negates misleading attention on words with intense polarity even though the context is neutral.

Overall, we propose AGLR (*Attentive Gated Lexicon Reader*), a new attention-based neural architecture that exploits sentiment lexicons for learning to compose an auxiliary sentence embedding. Our model achieves state-of-the-art performance on several benchmark datasets. Finally, our AGLR, a *single neural model*, also achieves competitive performance with respect to top teams in SemEval runs which are mostly comprised of extensively engineered ensembles.

2 Related Work

Sentiment lexicons have a rich traditional in sentiment analysis research and have been exploited in many statistical methods across the years (Hu and Liu, 2004; Kim and Hovy, 2004; Agarwal et al., 2011; Mohammad et al., 2013; Tang et al., 2014b,a; Teng et al., 2016). It is easy to see how sentiment lexicons are able to benefit opinion mining applications. More specifically, sentiment lexicons form an integral role in the winning solutions of SemEval 2013 (Mohammad et al., 2013) and 2014 (Miura et al., 2014). In many of these these approaches, standard machine learning classifiers (such as Support Vector Machines) are trained on discrete features partly derived from resources such as sentiment lexicon.

In recent years, we see a shift of the state-of-the-art from discrete models to neural models (Socher et al., 2013; Kim, 2014; Dong et al., 2014; Tang et al., 2016; Tai et al., 2015; Ren et al., 2016; Zhang et al., 2016; Teng and Zhang, 2016). This ranges from learning sentiment-specific word embeddings (Tang et al., 2014b; Faruqui et al., 2015) to end-to-end neural architectures (Teng et al., 2016; Angelidis and Lapata, 2017). The winning solution of SemEval 2016 (Deriu et al., 2016) utilized ensembles of convolutional neural networks (CNN). Recurrent-based models such as the bidirectional long short-term memory (BiLSTM) (Hochreiter and Schmidhuber, 1997; Graves et al., 2013) are popular and standard strong baselines for many opinion mining tasks including sentiment analysis (Tay et al., 2017) and sarcasm detection (Tay et al., 2018c). These neural models such as the BiLSTM are capable of modeling semantic compositionality and produce a feature vector which can be used for classification.

To integrate the information of lexicon inside Lexicon RNN model, Teng et al. (2016) proposed to use the hidden representations from a BiLSTM to influence the lexicon score, i.e., learning context-sensitive lexicon features. However, our method can be considered as a vastly different paradigm and instead learns a d-dimensional embedding using neural attention (Bahdanau et al., 2014; Luong et al., 2015) instead of a lexicon score. The key idea of neural attention is that it allows neural networks to look (or attend) to certain words in a sequence. This concept has indeed profoundly impacted the fields of NLP, giving rise to many variant architectures including end-to-end memory networks (Sukhbaatar et al., 2015; Li et al., 2017).

Our approach draws inspiration from memory networks and co-attentive models for machine comprehension (Xiong et al., 2016; Seo et al., 2016). In fact, the auxiliary network can be interpreted as a form of *multi-layered attention* which draws connection to vanilla memory networks. Attending over two sequences (or bidirectional attention) are intuitive approaches for NLP tasks such as information retrieval (Tay et al., 2018b) and generic text matching (Tay et al., 2018a). In our work, we adapt this to model the similarities between (1) lexicon-context and (2) contrasting polarities which borrows inspiration from (Riloff et al., 2013). Since our matching problem is derived from the same sequence (identified by a lexicon prior), this work can be interpreted as a form of self-attention (Vaswani et al., 2017) which draws relations to the intra-attentive model for sarcasm detection (Tay et al., 2018c).

3 Attentive Gated Lexicon Reader

In this section, we describe our proposed deep learning model for sentiment classification. The key idea of our model is to generate two representations, i.e., a lexicon-based auxiliary embedding of the sentence and also a generic compositional representation of the sentence. The former is generated via a supporting network that consists of contextual attention and contrastive co-attention layers. The latter is generated by a vanilla attention-based BiLSTM model. A gating mechanism then combines them for prediction.

3.1 Embedding Layer

Firstly, we extract all lexicon words from the input sequence and then separately[1] denote them as positive or negative words. Overall, our model accepts three sequences as an input. (1) the original sentence, (2) a list of positive lexicon words found in the sentence and (3) a list of negative lexicon words found in the sentence. The three sequences are indexed into a word embedding layer $W \in \mathbb{R}^{|V| \times d}$ which outputs three matrices $S \in \mathbb{R}^{d \times L_s}$ (sentence embeddings), $P \in \mathbb{R}^{d \times G_p}$ (positive lexicon embeddings) and $N \in \mathbb{R}^{d \times G_n}$ (negative lexicon embeddings). d is the dimensionality of the word embeddings and L_s, G_p and G_n are the maximum sequence lengths of sentence, positive lexicon and negative lexicon respectively.

3.2 Learning Sentence Representation

To learn sentence representations of the input sequence, we pass $S = (w_1, w_2 \cdots w_{L_s})$ into a Bidirectional Long Short-Term Memory (LSTM) layer. As such, the output of the BiLSTM is described as follows:

$$h_t = BiLSTM(h_{t-1}, w_t) \tag{1}$$

where h_t is the hidden representation at step t. Given a sequence of inputs $w_1, w_2 \cdots w_L$, the output of the BiLSTM layer is a sequence of hidden states $h_1, h_2 \cdots h_L$. Note that since we use a bidirectional LSTM, then $h_t \in \mathbb{R}^{2r}$ where r is the dimensionality of the BiLSTM layer. In our case r is set to $\frac{d}{2}$ such that the output vector has dimensionality d.

Sentence Attention To learn a final sentence representation of the sentence, we adopt an attention mechanism. The attention mechanism is defined by the following equations:

$$\mathbf{Y} = \tanh(\mathbf{W}_y \, H) \tag{2}$$

$$a_c = softmax(w_y^T \, \mathbf{Y}) \text{ and } s = H \, a_c^T \tag{3}$$

where $s \in \mathbb{R}^d$ is the output sentence representation, $\mathbf{W}_y \in \mathbb{R}^{d \times d}$ and $w_y \in \mathbb{R}^d$ are parameters of the attention layer. Intuitively, the attention layer learns to pay attention to important segments of the sentence, producing a weighted representation of the hidden states of the BiLSTM layer.

3.3 Learning Auxiliary Lexicon Embedding

This layer aims to learn a single d-dimensional lexicon-based representation of the sentence. In order to learn the lexicon embedding, our model adopts a two layer attention mechanism, namely the contextual attention (CA) and contrastive co-attention (CC).

Contextual Attention (CA) We utilize an attention mechanism to learn the relative importance of each lexicon word based on the sentence representation. This layer is applied to and is functionally identical for both P and N. As such, for notational convenience, we use Q to represent either positive (P) or negative (N), and G to represent the maximum number of lexicon words. Let $Q \in \mathbb{R}^{G \times d}$ be a sequence of lexicon words and $H \in \mathbb{R}^{L_s \times d}$ be the intermediate hidden representations obtained from the contextual BiLSTM layer:

$$M = tanh(Q \, \mathbf{U} \, H^T) \tag{4}$$

where $\mathbf{U} \in \mathbb{R}^{d \times d}$ are the parameters of this layer. Next, we apply a column-wise max pooling of M. The key idea is to generate an attention vector:

$$a = sm(\max_{col}(M)) \; ; \; c_i = a_i * q_i \tag{5}$$

where $a \in \mathbb{R}^G$. The softmax function normalizes the values of the vector $\max_{col}(M)$ into a probability distribution. To learn the context-sensitive weight importance of each lexicon word, we then apply the attention vector on Q. $C = \{c_1, c_2 \cdots c_G\}$ is the context-sensitive lexicon representation of Q. Intuitively, the CA mechanism attends to each lexicon word based on its *maximum* influence on each word of the main sentence. There are several advantages to our context attention mechanism. Unlike Lexicon RNN which simply extracts the hidden representation (generated from BiLSTM) of the lexicon word, our approach has a global view of the entire sentence which allows each lexicon word to benefit from wider contextual knowledge as opposed to being limited to the temporal compositionality provided by the BiLSTM layer. Overall, the outputs of this layer are two matrices (positive and negative lexicon embeddings) which are context-sensitive.

---

[1] For our experiments, we mainly use ST140 lexicon and therefore use $score > 0$ to separate positive and negative words. Notably, about $\approx 85\%$ of all words in the sentence has a lexicon assignment.

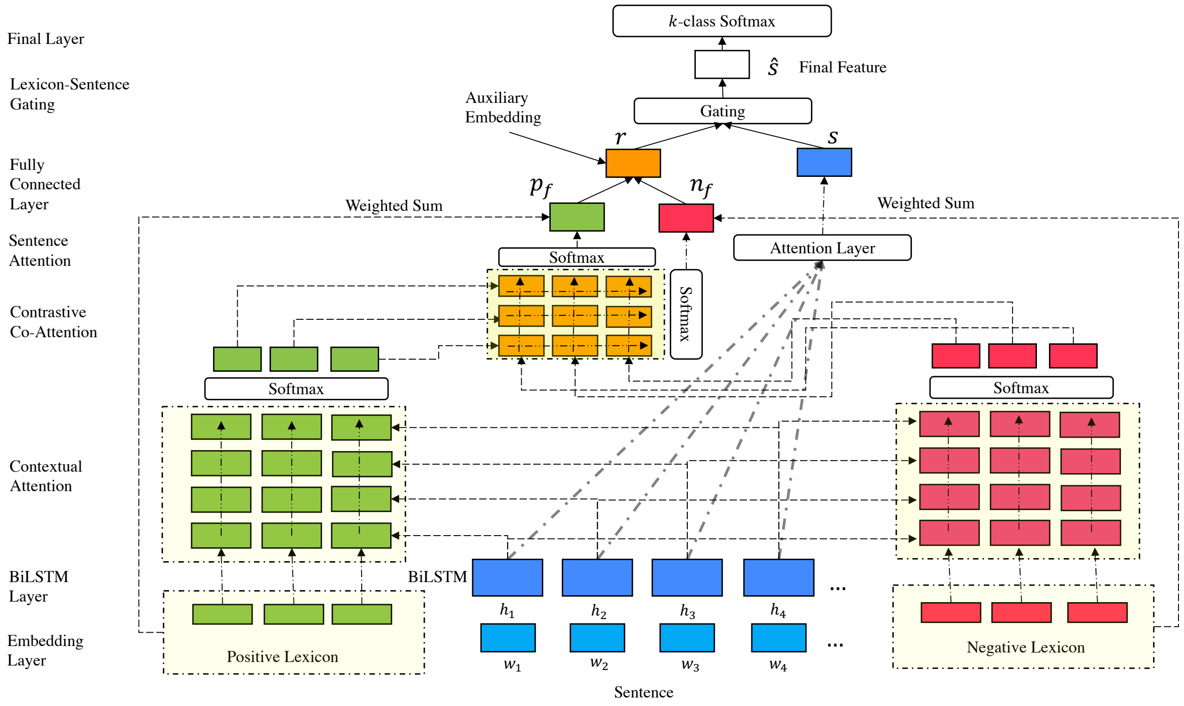

Figure 1: Illustration of our proposed Attentive Gated Lexicon Reader model (*best viewed in color*).

Note that these lexicon embeddings retain their dimensionality passing through this layer.

Contrastive Co-Attention (CC) This layer aims to model the contrast between polarities. Intuitively, this layer helps to model sentences with double or conflicting polarities. It also aims to negate strongly positive or negative words in the case of a neutral context. In order to do so, we employ a contrastive co-attention model that learns to weight the relative importance of each positive lexicon word based on the negative lexicon (and vice versa). We accept the contextualized positive and negative lexicon embeddings from the previous layer as an input. Let $\hat{P} \in \mathbb{R}^{G \times d}$ be the contextualized positive lexicons and $\hat{N} \in \mathbb{R}^{G \times d}$ be the contextualized negative lexicons, our co-attention layer learns a soft attention alignment between positive and negative lexicon embeddings. Similar to our contextual attention layer, we first learn an affinity matrix Z that models the relationship between positive and negative lexicon embeddings:

$$Z = tanh(P\,\mathbf{A}\,N^T) \tag{6}$$

Next, we apply both column-wise and row-wise max-pooling on the affinity matrix Z to obtain two attention vectors. The two attention vectors are then normalized with the softmax function (denoted as sm).

$$a_p = sm(\max_{col}(Z))\ ;\ a_n = sm(\max_{row}(Z)) \tag{7}$$

a_p is the attention vector for the positive lexicon embeddings and a_n is the attention vector for the negative lexicon embeddings. The final vector representations are therefore:

$$p_f = P\,a_p^\top\ ;\ n_f = N\,a_n^\top \tag{8}$$

where $p_f \in \mathbb{R}^d$ and $n_f \in \mathbb{R}^d$ are the vector representations for positive lexicon and negative lexicon respectively. Note that this layer, unlike the contextual attention layer, is named 'co-attention' because both P and N are both 'attended over' concurrently. It is also good to note that attentions are applied over the original embeddings P, N and not the *contextualized* embeddings $\hat{P}, \hat{N}$.

Fully-Connected Layer Next, we pass the concatenation of p and n through a fully-connected layer to learn the final representation for the auxiliary lexicon embedding, i.e., $r = tanh(\mathbf{W}_h\ ([p; n]) + b_h)$ where $\mathbf{W}_h \in \mathbb{R}^{2d \times d}$ are the parameters of the hidden layer and b_h is the bias value. The output $r \in \mathbb{R}^d$ is the final auxiliary lexicon-based embedding.

Learning Final Representations To combine the lexicon-based representation with the sentence representation, we adopt a gating mechanism.

$$\hat{s} = \sigma(w_g \odot r) \odot r + (1 - \sigma(w_g \odot r)) \odot s \quad (9)$$

where $w_g \in \mathbb{R}^d$ are the parameters of this layer, σ is the sigmoid function. $\hat{s}$ is the overall final representation.

3.4 Final Layer and Optimization

Finally, we pass $\hat{s}$ the overall final representation into a softmax layer.

$$y = softmax(\mathbf{W}_f \, \hat{s} + b_f) \quad (10)$$

where $y \in \mathbb{R}^k$, where k is the number of classes (2 for positive and negative and 3 including neutral). $\mathbf{W}_f$ and b_f are standard parameters of a linear regression layer. For optimization, we adopt the standard cross entropy loss function with L2 regularization.

$$L = -\sum_{i=1}^{N} [y_i \log o_i + (1 - y_i) \log(1 - o_i)] + R \quad (11)$$

where o is the output of the softmax layer and $R = \lambda \, \|\psi\|_2^2$ is the L2 regularization.

4 Empirical Evaluation

This section describes our empirical experiments.

4.1 Evaluation Procedure

In this section, we describe the datasets used, evaluation metric and implementation details.

Datasets We conduct our experiments[2] on subsets of sentiment analysis benchmarks from SemEval 2013 (Nakov et al., 2013), SemEval 2014 (Rosenthal et al., 2014) and SemEval 2016 (Nakov et al., 2016). More specifically, we focus on the sentence level of sentiment analysis and evaluate on the datasets of SemEval 2013 task 2, SemEval 2014 task 9 and SemEval 2016 task 4, which we will name as *SemEval13*, *SemEval14* and *SemEval16* respectively in this section. For fair comparison, we use the same setting of training, development and testing as in SemEval competitions. To further evaluate the performance of methods when data is limited, for *SemEval16*, we experiment on two different training settings. The first, TRAIN, uses only the 2016 training set while the other, TRAIN-ALL, appends the 2013 training set to the 2016 training set, following the official setting of SemEval 2016 while TRAIN explores the setting where training data is limited.

Evaluation Metrics We evaluate on two settings, i.e., 3-way (positive, negative and neutral) and also binary (positive and negative) classification. We report the accuracy and macro-averaged F1 score for all settings.

Compared Baselines In this section, we list the neural baselines we use for comparisons.

- **NBOW-MLP** (Neural Bag-of-Words + Multi-layered Perceptron) is a simple sum of all word embeddings which is connected to a 2-layer MLP of 100 dimensions.
- **CNN** (Convolutional Neural Network) is another popular neural encoder for learning sentence representations. We use a filter size of 3 and 150 filters.
- **BiLSTM** (Bidirectional Long Short-Term Memory) is a standard strong neural baseline for many NLP tasks. The size of the LSTM is set to 150.
- **AT-BiLSTM** (Attention-based BiLSTM) is an extension of the BiLSTM model with neural attention.
- **Lexicon RNN** (Lexicon Recurrent Neural Network) is the model of (Teng et al., 2016). The first neural model that incorporates sentiment lexicon. The size of the BiLSTM in this model is also set to 150.

All models except Lexicon RNN optimize the softmax cross entropy loss. The authors use Lexicon RNN for binary and 5-way classification. In order to adapt Lexicon RNN to 3-way classification (positive, negative, neutral), we adapt the 5-way formulation that minimizes the MSE (mean square error) loss to 3-way. The output is scaled[3] to $s \in [-1, 1]$ where $s > 0.25$ is treated as positive, $s < -0.25$ is treated as negative and everything in between is neutral.

---

[2] SemEval 2015 was omitted due to space in favor of SemEval 2016 since testing sets are significantly larger in the latter.

[3] We experimented with other thresholds but found 0.25 to work the best.

Implementation Details Text are lowercased, tokenized using NLTK's tweet tokenizer and padded to the maximum sequence length of the dataset. For Lexicon RNN and AGLR, we use[4] the ST140 (Sentiment140) lexicon which was created by distant supervision (Mohammad et al., 2013). The maximum numbers of positive lexicons and negative lexicons extracted per sample are tuned amongst $\{5, 8, 10\}$. Models are trained for a maximum of 30 epochs with early stopping if the performance on the development set does not improve after 5 epochs. Results reported are the test scores from the model that performed best on the development set. The batch size is tuned amongst $\{50, 100, 300\}$. L2 Regularization tuned amongst $\{10^{-6}, 10^{-7}, 10^{-8}\}$. Dropout is set to 0.5. We optimized all networks with the RMSprop optimizer and with initial learning rate tuned amongst $\{0.01, 0.005, 0.001\}$. Word embeddings are initialized with Glove 27B (Pennington et al., 2014) ($d = 200$) trained on tweets and are trainable parameters. The size of the BiLSTM is $d = 100$.

4.2 Experimental Results

Table 1 and Table 2 report the results of our experiments. The results on TRAIN-ALL are higher than TRAIN for *SemEval16* in lieu of the larger dataset. Firstly, we observe that our proposed AGLR outperforms all neural baselines on 3-way classification. The overall performance of AGLR achieves state-of-the-art performance. On average, AGLR outperforms Lexicon RNN and AT-BiLSTM by $1\% - 3\%$ in terms of F1 score. We also observe that AGLR always improves AT-BiLSTM which ascertains the effectiveness of learning auxiliary lexicon embeddings. The key idea here is that the auxiliary lexicon embeddings provide a *different view* of the sentence which supports the network in making predictions.

We also observe that Lexicon RNN does not handle 3-way classification well. Even though it has achieved good performance on binary classification, the performance on 3-way classification is lackluster (the performance of AGLR outperforms Lexicon RNN by up to 8% on *SemEval16* TRAIN). This could also be attributed to the MSE based loss function. Conversely, by learning an auxiliary embedding (instead of a scalar score), our model becomes more flexible at the final layer and can be adapted to using a k softmax function. Finally, we observe that BiLSTM and AT-BiLSTM outperform Lexicon RNN on average with Lexicon RNN being slightly better on binary classification.

---

[4] We also used Bing Liu's opinion lexicon but found it to perform slightly worse.

Comparisons against Top SemEval Systems Table 3 reports the results of our proposed approach against the top team of each SemEval run, i.e., *NRC-Canada* (Mohammad et al., 2013) for 2013 Task 2, *Team-X* (Miura et al., 2014) for 2014 Task 9, *SwissCheese* (Deriu et al., 2016) for 2016 Task 4. We follow the exact training datasets allowed for each SemEval run. Following the competition setting, with the exception of accuracy for SemEval 2016, all metrics reported are the macro averaged F1 score of positive and negative classes.

		Top System	Ours
SemEval13	Tweets	69.02	**70.10**
SemEval14	Tweets	70.96	**71.11**
	Sarcasm	56.50	**58.87**
	LiveJournal	69.44	**72.52**
SemEval16	Tweets	**63.30**	61.90
	Tweets (Acc)	64.60	**66.60**

Table 3: Comparisons against top SemEval systems. Results reported are the F^{PN} metric scores used in the SemEval tasks.

We observe that AGLR achieves competitive performance relative to the top runs in SemEval 2013, 2014 and 2016. It is good to note that SemEval approaches are often heavily engineered containing ensembles and many handcrafted features which include extensive use of sentiment lexicons, POS tags and negation detectors. Recent SemEval runs gravitate towards neural ensembles. For instance, the winning approach for *SwissCheese* (SemEval 2016) uses an ensemble of 6 CNN models along with a meta-classifier (random forest classifier). On the other hand, our proposed model is *a single neural model*. In addition, SwissCheese also uses emoticon-based distant supervision which exploits a huge corpus of sentences (millions) for training. Conversely, our approach only uses the 2013 and 2016 training sets which are significantly smaller. Given these conditions, we find it remarkable that our single model is able to achieve competitive performance relative to the extensively engineered approach of SwissCheese. Moreover, we actually outperform significantly in terms of pure accuracy. AGLR performs competitively on SemEval 2013 and 2014 as well. The good performance on the *sarcasm* dataset could be attributed to our contrastive attention mechanism.

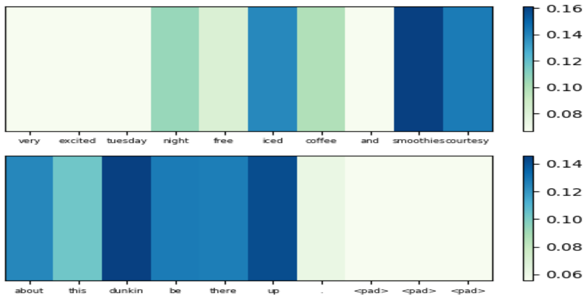
Ablation Study In this section, we study the impacts and contribution of the different components of our model. Specifically, we tested 3 settings. The first, we removed CC only. In this case, positive and negative lexicons are *summed* instead of a *weighted summed* using attention. In the next setting, we removed CA only. Similarly, embeddings are summed instead of attentively summed. Finally, we removed both CA and CC. In this case, all lexicons are considered neural bag-of-words (NBOW) and passed to the MLP layer. Table 4 shows the results of this ablation study on *SemEval16* using the TRAIN-ALL setting.

Model	Acc	F1
AT-BiLSTM only	64.20 (-2.42)	61.64 (-2.96)
AGLR (*-CA and -CC*)	62.42 (-4.20)	59.48 (-4.88)
AGLR (*-CA*)	65.81 (-0.81)	60.47 (-3.89)
AGLR (*-CC*)	64.38 (-2.24)	61.26 (-3.10)
AGLR	66.62	64.36

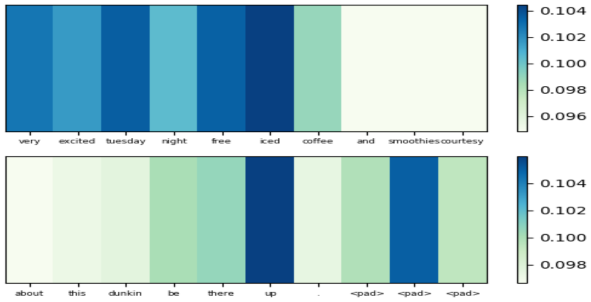
Table 4: Ablation study on *SemEval16* (TRAIN-ALL)

It is clear that both CC and CA are critical to the performance of AGLR. Removing either or both can cause performance to degrade. In particular, we also observe that CA seems to be less important than CC, i.e., performance drops more as compared to removing CA. We also note that removing both and a simple NBOW for lexicons can degrade performance since the base AT-BiLSTM is better than using NBOW lexicons as an auxiliary support. As such, the design of the auxiliary embeddings must be treated with care.

Qualitative Analysis In order to study what are the specific roles of the contextual and contrastive attention mechanism, we inspect the attention maps over the positive and negative lexicons. We use the following example in which the ground truth label is *positive*: *"Very excited about Tuesday night @user free iced coffee and smoothies courtesy of Dunkin Donuts will be set up."*. Figure 2a shows the attention maps for contextual attention. We observe that contextual attention focuses more on the context, i.e., focusing on words such as 'night', 'iced coffee' and 'smoothies'. On the other hand, Figure 2b shows the attention maps after contrastive attention. We observe that contrastive attention learns more polarity specific attentions, i.e., shifting some focus to *'very excited'*. We also observe that the contrastive attention tends to shift its attention weights to less meaningful words for the negative lexicon if the ground truth label is positive (and vice versa). We believe that this indicates that there is an absence of negative sentiment.



(a) Attention over positive and negative lexicons for contextual attention.



(b) Attention over positive and negative lexicons for contrastive attention.

Figure 2: Visualization of Contextual Attention and Contrastive Co-Attention.

5 Conclusion

We proposed a novel method of incorporating lexicons into neural models for the task of sentiment analysis. More specifically, we learn an auxiliary lexicon embedding using neural attention. Our proposed model AGLR achieves an overall state-of-the-art performance on multiple benchmark datasets outperforming strong neural baselines such as AT-BiLSTM and Lexicon RNN. The performance of AGLR is also competitive relative to top SemEval systems which utilized neural ensembles or very extensive feature engineering.

Abstract

Multi-modal sentiment analysis offers various challenges, one being the effective combination of different input modalities, namely *text*, *visual* and *acoustic*. In this paper, we propose a recurrent neural network based multi-modal attention framework that leverages the contextual information for utterance-level sentiment prediction. The proposed approach applies attention on multi-modal multi-utterance representations and tries to learn the contributing features amongst them. We evaluate our proposed approach on two multi-modal sentiment analysis benchmark datasets, *viz.* CMU Multi-modal Opinion-level Sentiment Intensity (CMU-MOSI) corpus and the recently released CMU Multi-modal Opinion Sentiment and Emotion Intensity (CMU-MOSEI) corpus. Evaluation results show the effectiveness of our proposed approach with the accuracies of 82.31% and 79.80% for the MOSI and MOSEI datasets, respectively. These are approximately 2 and 1 points performance improvement over the state-of-the-art models for the datasets.

1 Introduction

Traditionally, sentiment analysis (Pang and Lee, 2005, 2008) has been applied to a wide variety of texts (Hu and Liu, 2004; Liu, 2012; Turney, 2002; Akhtar et al., 2016, 2017; Mohammad et al., 2013). In contrast, multi-modal sentiment analysis has recently gained attention due to the tremendous growth of many social media platforms such as YouTube, Instagram, Twitter, Facebook (Chen et al., 2017; Poria et al., 2016, 2017d,b; Zadeh et al., 2017, 2016) etc. It depends on the information that can be obtained from more than one modality (e.g. *text*, *visual* and *acoustic*) for the analysis. The motivation is to leverage the varieties of (often distinct) information from multiple sources for building an efficient system. For example, it is a non-trivial task to detect the sentiment of a sarcastic sentence "*My neighbours are home!! it is good to wake up at 3am in the morning.*" as *negative* considering only the textual information. However, if the system has access to some other sources of information, e.g. *visual*, it can easily detect the unpleasant gestures of the speaker and would classify it with the *negative* sentiment polarity. Similarly, for some instances acoustic features such as *intensity*, *pitch*, *pause* etc. have important roles to play in the correctness of the system. However, combining these information in an effective manner is a non-trivial task that researchers often have to face (Zadeh et al., 2017; Chen et al., 2017).

A video provides a good source for extracting multi-modal information. In addition to the *visual frames*, it also provides information such as *acoustic* and *textual* representation of *spoken language*. Additionally, a speaker can utter multiple utterances in a single video and these utterances can have different sentiments. The sentiment information of an utterance often has inter-dependence on other contextual utterances. Classifying such an utterance in an independent manner poses many challenges to the underlying algorithm.

In this paper, we propose a novel method that employs a recurrent neural network based multi-modal multi-utterance attention framework for sentiment prediction.We hypothesize that applying attention to contributing neighboring utterances and/or multi-modal representations may assist the network to learn in a better way. The main challenge in multi-modal sentiment analysis lies in the proper utilization of the information extracted from multiple modalities. Although it is often argued that incorporation of all the available modalities is always beneficial for enhanced performance, it must be noted that not all the modalities play equal role. Another concern in multi-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3454–3466
Brussels, Belgium, October 31 - November 4, 2018.

modal framework is that the presence of noise in one modality can affect the overall performance. To better address these concerns we propose a novel fusion method by focusing on inter-modality relations computed between the target utterance and its context. We argue that in multi-modal sentiment classification, not only the relation among two modalities of the same utterance is important, but also relatedness with the modalities across its context are important.

Think of an utterance U_t that constitutes of three modalities, say A_t (i.e. audio), V_t (i.e. visual) and T_t (i.e. text). Let us also assume U_k being a member of the contextual utterances consisting of the modalities - A_k, V_k and T_k. In this case, our model computes the relatedness among the modalities (for e.g., V_t and T_k) of U_t and U_k in order to produce a richer multi-modal representation for final classification. The attention mechanism is then used to attend to the important contextual utterances having higher relatedness or similarity (computed using inter-modality correlations) with the target utterance.

Unlike previous approaches that simply apply attentions over the contextual utterance for classification, we attend over the contextual utterances by computing correlations among the modalities of the target utterance and the context utterances. This explicitly helps us to distinguish which modalities of the relevant contextual utterances are more important for sentiment prediction of the target utterance. The model facilitates this modality selection by attending over the contextual utterances and thus generates better multi-modal feature representation when these modalities from the context are combined with the modalities of the target utterance. We evaluate our proposed approach on two recent benchmark datasets, i.e. CMU-MOSI (Zadeh et al., 2016) and CMU-MOSEI (Zadeh et al., 2018c), with one being the largest (CMU-MOSEI) available dataset for multi-modal sentiment analysis (c.f. Section 4.1). Evaluation shows that the proposed attention framework attains better performance than the state-of-the-art systems for various combinations of input modalities (i.e. *text*, *visual* & *acoustic*).

The main contributions of our proposed work are three-fold: **a)** we propose a novel technique for multi-modal sentiment analysis; **b)** we propose an effective attention framework that leverages contributing features across multiple modalities and neighboring utterances for sentiment analysis; and **c)** we present the state-of-the-art systems for sentiment analysis in two different benchmark datasets.

2 Related Work

A survey of the literature suggests that multi-modal sentiment prediction is relatively a new area as compared to textual based sentiment prediction (Morency et al., 2011; Mihalcea, 2012; Poria et al., 2016, 2017b; Zadeh et al., 2018a). A good review covering the literature from uni-modal analysis to multi-modal analysis is presented in (Poria et al., 2017a). An application of multi-kernel learning based fusion technique was proposed in (Poria et al., 2016), where they employed deep convolutional neural networks for extracting the textual features and fused it with other (*visual* & *acoustic*) modalities for prediction.

Zadeh et al. (2016) introduced the multi-modal dictionary to better understand the interaction between facial gestures and spoken words when expressing the sentiment. Authors introduced the MOSI dataset, the first of its kind to enable the studies of multi-modal sentiment intensity analysis. Zadeh et al. (2017) proposed a Tensor Fusion Network (TFN) model to learn the intra-modality and inter-modality dynamics of the three modalities (i.e. text, visual and acoustic). They reported the improved accuracy using multi-modality on the CMU-MOSI dataset. An application to leverage on the gated multi-modal embedded Long Short Term Memory (LSTM) with temporal attention (GME-LSTM(A)) for the word-level fusion of multi-modality inputs is proposed in (Chen et al., 2017). The Gated Multi-modal Embedding (GME) alleviates the difficulties of fusion while the LSTM with Temporal Attention (LSTM(A)) performs word-level fusion.

The works mentioned above did not take contextual information into account. Poria et al. (2017b) proposed a LSTM based framework that leverages the contextual information to capture the inter-dependencies between the utterances. In another work, Poria et al. (2017d) proposed an user opinion based framework to combine the three modality inputs (i.e. *text, visual & acoustic*) by applying a multi-kernel learning based method. Zadeh et al. (2018a) proposed multi-attention blocks (MAB) to capture information across three modalities (*text, visual & acoustic*). They reported improved accuracies in the range of

2-3% over the state-of-the-art models for the different datasets.

The fundamental difference between our proposed method and the existing works is that our framework applies focus on the neighboring utterances to leverage contextual information for utterance-level sentiment prediction. To the best of our knowledge, our current work is the very first of its kind that attempts to employ multi-modal attention block (exploiting neighboring utterances) for sentiment prediction. We use *multi-modal attention* framework that leverages contributing features across *multiple modalities* and the *neighboring utterances* for sentiment analysis.

3 Proposed Methodology

In our proposed framework, we aim to leverage the multi-modal and contextual information for predicting the sentiment of an utterance. Utterances of a particular speaker in a video represent the time series information and it is logical that the sentiment of a particular utterance would affect the sentiments of the other neighboring utterances. To model the relationship with the neighboring utterances and multi-modality, we propose a recurrent neural network based multi-modal attention framework. The proposed framework takes multi-modal information (i.e. *text*, *visual* & *acoustic*) for a sequence of utterances and feeds it into three separate bi-directional Gated Recurrent Unit (GRU) (Cho et al., 2014). This is followed by a dense (fully-connected) operation which is shared across the time-steps or utterances (one each for text, visual & acoustic). We then apply multi-modal attention on the outputs of the dense layers. The objective is to learn the joint-association between the multiple modalities & utterances, and to emphasize on the contributing features by putting more attention to these. In particular, we employ bi-modal attention framework, where an attention function is applied to the representations of *pairwise* modalities i.e. *visual-text*, *text-acoustic* and *acoustic-visual*. Finally, the outputs of pairwise attentions along with the representations are concatenated and passed to the *softmax* layer for classification. We call our proposed architecture ***Multi-Modal Multi-Utterance - Bi-Modal Attention (MMMU-BA)*** framework. An overall architecture of the proposed *MMMU-BA* framework is illustrated in Figure 1. Please refer to Figure 3 in appendix for illustration of attention computation.

For comparison, we also experiment with two other variants of the proposed *MMMU-BA* framework i.e. a). *Multi-Modal Uni-Utterance-Self Attention (MMUU-SA)* framework and b). *Multi-Utterance-Self Attention (MU-SA)* framework. The architecture of these variants differ with respect to the attention computation module and the naming conventions "*MMMU*", "*MMUU*" or "*MU*" signify the information that participates in the attention computation. For example, in *MMMU-BA*, we compute attention over the multi-modal and multi-utterance inputs, whereas in *MMUU-SA*, the attention is computed over the mutli-modal but uni-utterance inputs. In contrast, we compute attention over only multi-utterance inputs in *MU-SA*. Rest of the components for all the three variants remain same.

3.1 Multi-modal Multi-utterance - Bi-modal Attention (*MMMU-BA*) Framework

Assuming a particular video has '*u*' utterances, the raw *utterance level* multi-modal features are represented as $T_R \in \mathbb{R}^{u\times 300}$ (*raw text*), $V_R \in \mathbb{R}^{u\times 35}$ (*raw visual*) and $A_R \in \mathbb{R}^{u\times 74}$ (*raw acoustic*). Three separate Bi-GRU layers with forward & backward state concatenation are first applied on the raw data followed by the fully-connected dense layers, resulting in $T \in \mathbb{R}^{u\times d}$ (*text*), $V \in \mathbb{R}^{u\times d}$ (*visual*) and $A \in \mathbb{R}^{u\times d}$ (*acoustic*), where '*d*' is the number of neurons in the dense layer. Finally, *pairwise-attentions* are computed on various combinations of three modalities- (*V*, *T*), (*T*, *A*) & (*A*, *V*). In particular the attention between *V* and *T* is computed as follows:

- ***Bi-modal Attention:*** Modality representations of *V* & *T* are obtained from the Bi-GRU network, and hence contain the contextual information of the utterances for each modality. At first, we compute a pair of matching matrices $M_1, M_2 \in \mathbb{R}^{u\times u}$ over two representations that account for the cross-modality information.

$$M_1 = V.T^T \quad \& \quad M_2 = T.V^T$$

- ***Multi-Utterance Attention:*** As mentioned earlier, in the proposed model we aim to leverage the contextual information of each utterance for the prediction. We compute the probability distribution scores ($N_1 \in \mathbb{R}^{u\times u}$ & $N_2 \in \mathbb{R}^{u\times u}$) over each utterance of bi-modal attention matrices M_1 & M_2 using a softmax function. This essentially computes the attention weights for the contextual

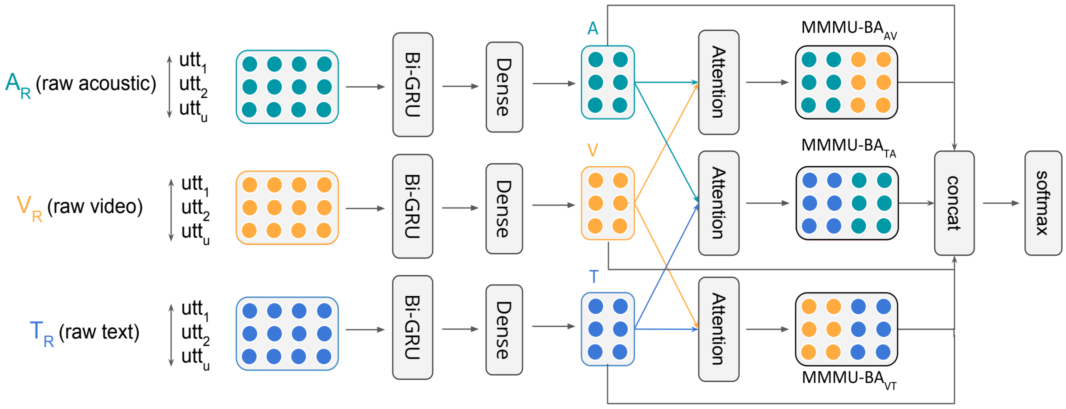

Figure 1: Overall architecture of the proposed MMMU-BA framework.

utterances. Finally, soft attention is applied over the multi-modal multi-utterance attention matrices to compute the modality-wise attentive representations (i.e. O_1 & O_2).

$$N_1(i,j) = \frac{e^{M_1(i,j)}}{\sum_{k=1}^{u} e^{M_1(i,k)}} \quad \text{for} \quad i,j = 1,..,u$$
$$N_2(i,j) = \frac{e^{M_2(i,j)}}{\sum_{k=1}^{u} e^{M_2(i,k)}} \quad \text{for} \quad i,j = 1,..,u.$$
$$O_1 = N_1.T \quad \& \quad O_2 = N_2.V$$

- ***Multiplicative Gating & Concatenation:*** Finally, a multiplicative gating function following (Dhingra et al., 2016) is computed between the multi-modal utterance specific representations of each individual modality and the other modalities. This element-wise matrix multiplication assists in attending to the important components of multiple modalities and utterances.

$$A_1 = O_1 \odot V \quad \& \quad A_2 = O_2 \odot T$$

Attention matrices A_1 & A_2 are then concatenated to obtain the *MMMU-BA$_{VT}$* $\in \mathbb{R}^{u\times 2d}$ between V and T.

$$\textit{MMMU-BA}_{VT} = concat[A_1, A_2]$$

***MMMU-BA$_{AV}$* & *MMMU-BA$_{TA}$* computations:** Similar to *MMMU-BA$_{VT}$*, we follow the same procedure to compute *MMMU-BA$_{AV}$* & *MMMU-BA$_{TA}$*. For a data source comprising of raw visual (V_R), acoustic (A_R) & text (T_R) modalities, at first, we compute the bi-modal attention pairs for each combination i.e. *MMMU-BA$_{VT}$*, *MMMU-BA$_{AV}$* & *MMMU-BA$_{TA}$*. Finally, motivated by the residual skip connection network (He et al., 2016), we concatenate the bi-modal attention pairs with individual modalities (i.e. *V*, *A* & *T*) to boost the gradient flow to the lower layers. This concatenated feature is then used for final classification.

3.2 Multi-Modal Uni-Utterance - Self Attention (*MMUU-SA*) Framework

MMUU-SA framework does not account for information from the other utterances at the attention level, rather it utilizes multi-modal information of single utterance for predicting the sentiment. For a video having *'q'* utterances, *'q'* separate attention blocks are needed, where each block computes the self-attention over multi-modal information of a single utterance. Let $X_{u_p} \in \mathbb{R}^{3\times d}$ is the information matrix of the p^{th} utterance where the three *'d'* dimensional rows are the outputs of the dense layers for the three modalities.

The attention matrix $A_{u_p} \in \mathbb{R}^{3\times d}$ is computed separately for, p = 1^{st}, 2^{nd}, ... q^{th} utterances. Finally, for each utterance p, A_{u_p} and X_{u_p} are concatenated and passed to the output layer for classification. Please refer to the appendix for more details.

3.3 Multi-Utterance - Self Attention (*MU-SA*) Framework

In *MU-SA* framework, we apply self attention on the utterances of each modality separately, and use these for classification. In contrast to *MMUU-SA* framework, *MU-SA* utilizes the contextual information of the utterances at the attention level. Let, $T \in \mathbb{R}^{u\times d}$ (*text*), $V \in \mathbb{R}^{u\times d}$ (*visual*) and $A \in \mathbb{R}^{u\times d}$ (*acoustic*) are the outputs of the dense layers. For the three modalities, three separate attention blocks are required, where each block takes multi-utterance information of a single modality and computes the self attention matrix. Attention matrices A_t, A_v and A_a are computed for text, visual and acoustic, respectively. Finally A_v, A_t, A_a, V, T & A are concatenated and passed to the output layer for classification.

4 Datasets, Experiments and Analysis

In this section we describe the datasets used for our experiments and report the results along with the necessary analysis.

4.1 Datasets

We evaluate our proposed approach on two benchmark datasets, namely CMU Multi-modal Opinion-level Sentiment Intensity (CMU-MOSI) corpus (Zadeh et al., 2016) and the recently published CMU Multi-modal Opinion Sentiment and Emotion Intensity (CMU-MOSEI) dataset (Zadeh et al., 2018c). CMU-MOSI dataset consists of 93 videos spanning over 2199 utterances. Each utterance has a sentiment label associated with it. It has 52, 10 & 31 videos in training, validation & test set accounting for 1151, 296 & 752 utterances.

CMU-MOSEI has 3229 videos with 22676 utterances from more than 1000 online YouTube speakers. The training, validation & test set comprise of 16216, 1835 & 4625 utterances, respectively. More details about these datasets are presented in the appendix.

Each utterance in CMU-MOSI dataset has been annotated as either positive or negative, whereas in CMU-MOSEI dataset labels are in the continuous range of -3 to +3. However, in this work we project the instances of CMU-MOSEI in a *two-class classification* setup with $values \geq 0$ signify positive sentiments and $values < 0$ signify negative sentiments. We adopt such a strategy to be consistent with the previous published works on CMU-MOSI datasets (Poria et al., 2017b; Chen et al., 2017).

4.2 Feature extraction

We use the CMU-Multi-modal Data SDK[1] (Zadeh et al., 2018a) for feature extraction. For MOSEI dataset, *word-level* features were provided where *text* features were extracted by *GloVe embeddings*, *visual* features by *Facets*[2] & *acoustic* features by *CovaRep* (Degottex et al., 2014). Thereafter, we compute the average of *word-level* features in an utterance to obtain the *utterance-level* features. For each word, the dimension of the feature vector is set to 300 (*text*), 35 (*visual*) & 74 (*acoustic*).

In contrast, for MOSI dataset we use *utterance-level* features[3] provided in (Poria et al., 2017b). These *utterance-level* features represent the outputs of a convolutional neural network (Karpathy et al., 2014), 3D convolutional neural network (Ji et al., 2013) & openSMILE (Eyben et al., 2010) for *text*, *visual* & *acoustic* modalities, respectively. Dimensions of *utterance-level* features are 100, 100 & 73 for *text*, *visual* & *acoustic*, respectively.

4.3 Experiments

We evaluate our proposed approach for CMU-MOSI (test data) & CMU-MOSEI (dev data) [4]. Accuracy score is used as the evaluation metric.

We use Bi-directional GRUs having 300 neurons, each followed by a dense layer consisting of 100 neurons. Utilizing the dense layer, we project the input features of all the three modalities to the same dimensions. We set *dropout=0.5 (MOSI) & 0.3 (MOSEI)* as a measure of regularization. In addition, we also use *dropout=0.4 (MOSI) & 0.3 (MOSEI)* for the Bi-GRU layers. We employ *ReLu* activation function in the dense layers, and *softmax* activation in the final classification layer. For training the network we set the batch size=32, use *Adam* optimizer with *cross-entropy* loss function and train for 50 epochs. We report the average result of 5 runs for all our experiments.

We experiment with all the valid combinations of *uni-modal* (where only one modality is taken at a time), *bi-modal* (any two modalities are taken at a time) and *tri-modal* (all three modalities are taken at a time) inputs for *text*, *visual* and *acoustic*. In multi-modal attention frameworks i.e. *MMMU-BA* & *MMUU-SA*, the attention is computed over at least two modalities, hence, these two frameworks are not-applicable (*NA*) for *uni-modal* experiments in Table 1).

For MOSEI dataset, we obtain better performance with *text*. Subsequently, we take two modalities at a time for constructing bi-modal inputs and feed it to the network. For *text-acoustic* input pairs, we obtain the highest accuracies with 79.74%, 79.60% and 79.32% for *MMMU-BA*,

[4] Gold annotation of CMU-MOSEI test data wasn't released at the time of paper submission.

Modality	T	V	A	CMU-MOSEI *MMMU-BA*	 *MMUU-SA*	 *MU-SA*	CMU-MOSI *MMMU-BA*	 *MMUU-SA*	 *MU-SA*
Uni-modal	✓	-	-	*NA*	*NA*	78.23	*NA*	*NA*	80.18
	-	✓	-	*NA*	*NA*	74.84	*NA*	*NA*	63.70
	-	-	✓	*NA*	*NA*	75.88	*NA*	*NA*	62.10
Bi-modal	✓	✓	-	**79.40**	79.02	79.26	**81.51**	80.85	80.45
	✓	-	✓	**79.74**	79.60	79.32	**80.58**	80.31	79.78
	-	✓	✓	**76.66**	76.46	76.43	**65.16**	64.22	63.22
Tri-modal	✓	✓	✓	**79.80**	79.76	79.63	**82.31**	79.52	80.58

Table 1: Experimental results on CMU-MOSEI and CMU-MOSI datasets. *MMMU-BA* & *MMUU-SA* frameworks require atleast two modalities to compute the attentions, hence, these two frameworks are *not-applicable (NA)* for *uni-modal* inputs. All results are average of 5 runs with different random seeds. **T:** *Text*, **V:** *Visual*, **A:** *Acoustic*. Results are reported in accuracy.

MMUU-SA and *MU-SA* frameworks, respectively. The results that we obtain from the bi-modal combinations suggest that the *text-acoustic* combination is a better choice than the others as it improves the overall performance. Finally, we experiment with tri-modal inputs and observe an improved performance of 79.80%, 79.76% and 79.63% for *MMMU-BA*, *MMUU-SA* and *MU-SA* frameworks, respectively. This improvement entails that combination of all the three modalities is a better choice. The performance improvement was also found to be statistically significant (*T-test*) than the bi-modality and uni-modality inputs. Further, we observe that the *MMMU-BA* framework reports the best accuracy of 79.80% for the MOSEI dataset, thus supporting our claim that multi-modal attention framework (i.e. *MMMU-BA*) captures more information than the self-attention frameworks (i.e. *MMUU-SA* & *MU-SA*).

4.4 Analysis of Attention Mechanism

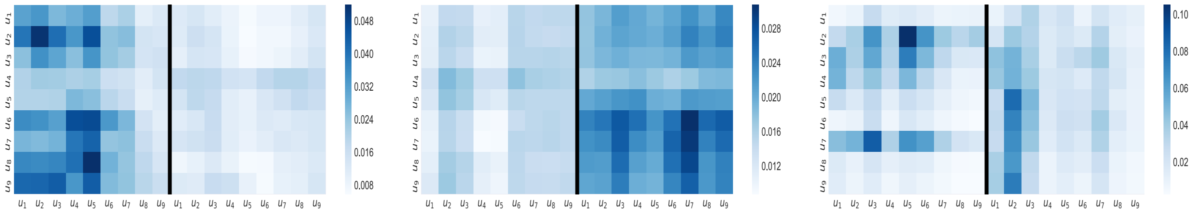
We analyze the attention values to understand the learning behavior of the proposed architecture. To illustrate, we take an example video from the CMU-MOSI test dataset. The transcript of the utterances for this particular video are presented in Table 2. The gold sentiments are positive for all the utterances except u_3 & u_4. We found that the proposed tri-modal *MMMU-BA* model predicts the labels of all the nine instances correctly, whereas other models make at least one misclassification. For the proposed tri-modal *MMMU-BA* model, the heatmaps of the pair-wise *MMMU-BA* softmax attention weights N_1 & N_2 of *visual-text*, *acoustic-visual* & *text-acoustic* are illustrated in Figure 2a, Figure 2b & Figure 2c, respectively. N_1 & N_2 are the softmax attention weights obtained from the pairwise matching matrices M_1 & M_2. Elements of the rows of N_1 & N_2 matrices signify different weights across multiple utterances. From the attention heatmaps, it is evident that by applying different weights across contextual utterances and modalities the model is able to predict labels of all the utterances correctly. All the heatmaps justify that the model learns to incorporate multi-modal & multi-utterance information and thus is able to correctly predict the labels of all the utterances. For example, heatmap of *MMMU-BA*$_{VT}$ (Figure 2a) signifies that elements of N_1 are weighted higher than N_2, and thus the model puts more attention on the *textual* part and relatively lesser on the *visual* part (as N_1 is multiplied with T & N_2 is multiplied with V). Also it can be concluded that textual features of the first few utterances are the most helpful compared to the rest of the textual features and visual features.

The softmax attention weights of *text* (N_t), *visual* (N_v) & *acoustic* (N_a) in tri-modal *MU-SA* model are illustrated in Figure 2d, Figure 2e & Figure 2f, respectively. The attention matrices are 9*9 dimensional. This model wrongly predicts the label of the utterance u_5. On the other hand, softmax attention weights in tri-modal *MMUU-SA* model are illustrated in Figure 2g. Nine separate attention weights (N_{u_1}, N_{u_2}, .., N_{u_9}) are computed for the nine utterances. This model wrongly predicts the labels of the utterances u_4 & u_5.

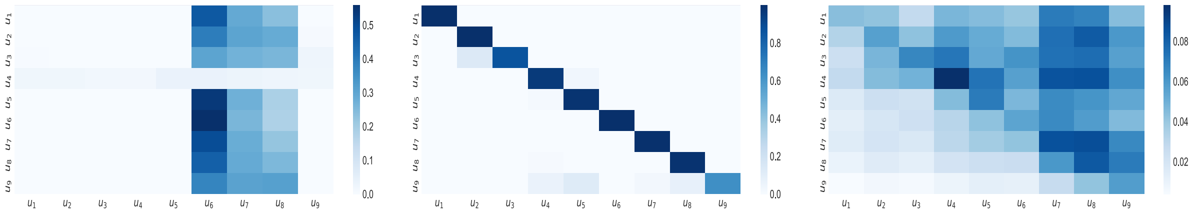
We further analyze our proposed architecture (i.e. *MMMU-BA*) *with* and *without* attention. In MOSI for tri-modal inputs, the *MMMU-BA* architecture reports a reduced accuracy of 80.89% without attention framework as compared to 82.31% with attention. We observe similar performance in the MOSEI dataset, where we obtain 79.02%

	Transcript	**Gold Label**	**Predicted**		
			MMMU-BA	***MMUU-SA***	***MU-SA***
u_1	*well he plays that well so he's good villain*	Positive	Positive	Positive	Positive
u_2	*he also has some really cool guns so that its like a desert eagle but it has to barrels to it*	Positive	Positive	Positive	Positive
u_3	*it's pretty pretty scary looking*	Negative	Negative	Negative	Negative
u_4	*i wouldn't want that pointed at me*	**Negative**	**Negative**	***Positive***	**Negative**
u_5	*and i who would i mean*	**Positive**	**Positive**	***Negative***	***Negative***
u_6	*um like i said i thought the movie was great*	Positive	Positive	Positive	Positive
u_7	*the action they do have is really well done*	Positive	Positive	Positive	Positive
u_8	*um they did a good job with car*	Positive	Positive	Positive	Positive
u_9	*they did a good job with fight scenes*	Positive	Positive	Positive	Positive

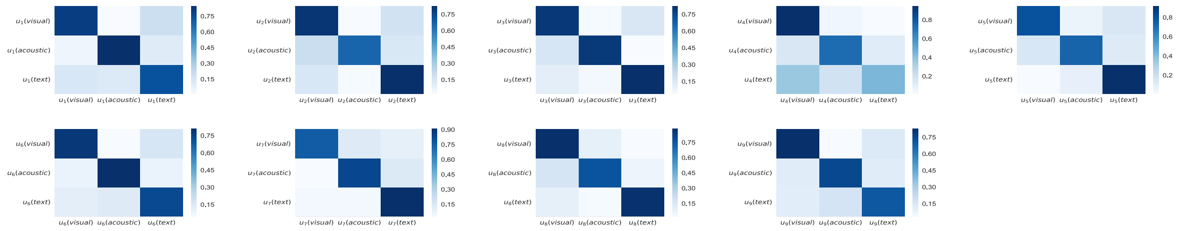
Table 2: Transcript, gold labels and predicted labels of a video in CMU-MOSI dataset having nine utterances. 7 utterances are labeled positive whereas 2 utterances are labeled negative. Predicted labels are for our different tri-modal models. Bolded labels are misclassified by at least one model.



(a) *Softmax attention weights* N_1 *&* N_2 *for MMMU- BA*$_{VT}$.
(b) *Softmax attention weights* N_1 *&* N_2 *for MMMU- BA*$_{AV}$.
(c) *Softmax attention weights* N_1 *&* N_2 *for MMMU- BA*$_{TA}$.



(d) *MU-SA*$_{text}$ matrix.
(e) *MU-SA*$_{visual}$ matrix.
(f) *MU-SA*$_{acoustic}$ matrix.



(g) Softmax attention weights (N_{u_1}, N_{u_2}, .., N_{u_9}) for *MMUU-SA* model.

Figure 2: (a), (b) & (c): Pair-wise softmax attention weights N_1 & N_2 of *visual-text*, *acoustic-visual* & *text-acoustic* in Tri-modal *MMMU-BA* model. Solid line at the center represents boundary of N_1 & N_2. The heatmaps represent attention weights of a particular utterance with respect to other utterances in N_1 & N_2. (d), (e) & (f) Softmax attention weights of *text* (N_t), *visual* (N_v) and *acoustic* (N_a) in Tri-modal MU-SA model. This model wrongly predicts the label of utterance u_5. (g) Softmax attention weights of the 9 utterances (N_{U_1}, N_{U_2}, .., N_{U_9}) in Tri-modal MMUU-SA model. This model wrongly predicts the label of utterance u_4 & u_5. The Tri-modal MMMU-BA model predicts all 9 instances correctly, whereas, the other two models makes at least one misclassification. Heatmap signifies that the model is able to predict labels of all the utterances correctly by incorporating multi-modal & multi-utterance information.

Table 3: Analysis of attention mechanism in *MMMU-BA* architecture. *w/ attention* → with multi-modal multi utterance attention mechanism and *w/o attention* → without attention mechanism.

accuracy without attention framework against 79.80% accuracy with attention framework. Statistical *T-test* shows these improvements to be significant. We also observed the similar trends for bi-modal inputs in both the datasets. All these experiments (c.f. Table 3) suggest that the attention framework is an important component in our proposed architecture, and in absence of this the network finds it more difficult for learning in all the cases (i.e. bi-modal & tri-modal input setups).

We successfully show that attention computation on pairwise combination of modalities (i.e. bi-modal attention framework) is more effective than the combination of self-attention on single modality. Further for the completeness of the proposed approach, we also experiment with tri-modal attention framework (attention is computed on three modalities at a time). Though the results that we obtain are convincing, it does not improve the performance over the bi-modal attention framework. We obtain the accuracies of 79.58% & 81.25% on MOSEI and MOSI, respectively, for the tri-modal attention framework.

4.5 Comparative Analysis

For MOSI datasets we compare the performance of our proposed approach with the the following state-of-the-art systems: i). Poria et al. (2017b)-LSTM-based sequence model to capture the contextual information of the utterances; ii). Poria et al. (2017c)- Tensor level fusion technique for combining all the three modalities; iii). Chen et al. (2017)-A gated multi-modal embedded LSTM with temporal attention (GME-LSTM(A)) for word-level fusion of multi-modality inputs. and iv). Zadeh et al. (2018a)- Multiple attention blocks for capturing the information across the three modalities.

In Table 4 we present the comparative performance between our proposed model and other state-of-the-art systems. In MOSI dataset, Poria et al. (2017b; 2017c) reported the accuracies of 80.3% & 81.3 %, respectively, utilizing tri-modal inputs. Zadeh et al. (2018a) obtained an accuracy of & 77.4%. Chen et al. (2017) reported accuracies of 75.7% (LSTM(A)) & 76.5% (GME-LSTM(A)) for two variants of their model. In contrast to the state-of-the-art systems, our proposed model attains an improved accuracy of 82.31% when we utilize all the three modalities, i.e. *text*, *visual* & *acoustic*. Our proposed system also obtains better performance as compared to the state-of-the-arts for bi-modal inputs.

For MOSEI dataset, we evaluate against the following systems: i) Poria et al. (2017b), ii) Zadeh et al. (2018a), and iii) Zadeh et al. (2018b), where authors proposed a memory fusion network for multi-view sequential learning. We evaluate the system of Poria et al. (2017b) on MOSEI dataset and obtain 77.64% accuracy with the tri-modal inputs. Authors in (Zadeh et al., 2018a) & (Zadeh et al., 2018b) reported the accuracy 76.0% and 76.4%, respectively, with the tri-modal inputs. In comparison, our proposed approach yields an accuracy of 79.80%. As reported in Table 4 the proposed approach also attains better performance for all the bi-modal and uni-modal input combinations when compared to Poria et al. (2017b).

As reported in Table 4, we observe that the performance achieved in our proposed approach is significantly better in comparison to the state-of-the-art systems with p-value< 0.05 (obtained using T-test). For further analysis, we also report results for *three-class classification* (positive, neutral & negative classes) problem setup for MOSEI dataset in Table 7. Note that this setup is not feasible in MOSI as labels are only positive or negative.

4.6 Error Analysis

We perform error analysis on the predictions of our proposed *MMMU-BA* model with all the three input sources. Confusion matrices for both the datasets are demonstrated in Table 5. For MOSEI dataset we observe that the precision and recall for positive class (84% *precision* & 88% *recall*; are quite encouraging. However, the same are comparatively on the lower side for the negative class (68% *precision* & 58% *recall*. In contrast, for the MOSI dataset - which is relatively balanced - we obtain quite similar performance for both the classes i.e. positive (86% *precision* & 85% *recall*) and negative (77% *precision* & 75% *recall*). We further analyze our outputs qualitatively and list a few frequently occurring error categories with examples in Table 6.

5 Conclusion

In this paper, we have proposed a recurrent neural network based multi-modal attention framework that leverages the contextual information for utterance-level sentiment prediction. The network learns on top of three modalities, *viz.* text, visual and acoustic, considering sequence of utterances in a video. Through evaluation results on two benchmark datasets (one being the popular & commonly used (MOSI) and other being the most recent & largest (MOSEI) dataset for multi-modal sentiment analysis), we successfully showed that the proposed attention based framework performs better than various state-of-the-art systems.

In future, we would like to investigate new techniques, and explore the ways to handle implicit sentiment and sarcasm. Future direction of work also include adding more dimensions, e.g. emotion analysis & intensity prediction.

7 Appendix

7.1 Multi-Modal Uni-Utterance - Self Attention (*MMUU-SA*) Framework

Let $X_p \in \mathbb{R}^{3\times d}$ is the information matrix of the p^{th} utterance where the three *'d'* dimensional rows are the outputs of the time-distributed dense layer for the three modalities. Computation in the p^{th} attention block proceeds as follows:

$$\begin{aligned} M_{u_p} &= X_{u_p}.X_{u_p}^T \\ N_{u_p}(i,j) &= \frac{e^{M_{u_p}(i,j)}}{\sum_{k=1}^{3} e^{M_{u_p}(i,k)}} \quad \text{for} \quad i,j = 1,2,3; \\ O_{u_p} &= N_{u_p}.X_{u_p} \\ A_{u_p} &= O_{u_p} \odot X_{u_p} \end{aligned}$$

The attention matrix $A_{u_p} \in \mathbb{R}^{3\times d}$ is computed separately for, p = 1^{st}, 2^{nd}, ... q^{th} utterances. Finally, for each utterance p, A_{u_p} and X_{u_p} are concatenated and passed to the output layer for classification.

7.2 Multi-Utterance - Self Attention (*MU-SA*) Framework

In *MU-SA* framework, we apply self attention on the utterances of each modality separately, and use these for classification. In contrast to *MMUU-SA* framework, *MU-SA* utilizes the contextual information of the utterances at the attention level. Let, $T \in \mathbb{R}^{u\times d}$ (*text*), $V \in \mathbb{R}^{u\times d}$ (*visual*) and $A \in \mathbb{R}^{u\times d}$ (*acoustic*) are the outputs of the dense layers. For the three modalities, three separate attention blocks are required, where each block takes multi-utterance information of a single modality and computes the self attention matrix. Specifically, the *MU-SA* attention (A_v) on V (visual) will be computed as follows,

$$\begin{aligned} M_v &= V.V^T \\ N_v(i,j) &= \frac{e^{M_v(i,j)}}{\sum_{k=1}^{u} e^{M_v(i,k)}} \quad \text{for} \quad i,j = 1,..,u \\ O_v &= N_v.V \\ A_v &= O_v \odot V \end{aligned}$$

The attention matrix $A_p \in \mathbb{R}^{3\times d}$ is computed for $p = 1^{st}, 2^{nd}, ...u^{th}$ utterances. Finally, for each utterance u, A_p and X_p are concatenated and passed to the output layer with softmax activation for classification.

Abstract

We consider the cross-domain sentiment classification problem, where a sentiment classifier is to be learned from a source domain and to be generalized to a target domain. Our approach explicitly minimizes the distance between the source and the target instances in an embedded feature space. With the difference between source and target minimized, we then exploit additional information from the target domain by consolidating the idea of semi-supervised learning, for which, we jointly employ two regularizations – entropy minimization and self-ensemble bootstrapping – to incorporate the unlabeled target data for classifier refinement. Our experimental results demonstrate that the proposed approach can better leverage unlabeled data from the target domain and achieve substantial improvements over baseline methods in various experimental settings.

1 Introduction

In practice, it is often difficult and costly to annotate sufficient training data for diverse application domains on-the-fly. We may have sufficient labeled data in an existing domain (called the source domain), but very few or no labeled data in a new domain (called the target domain). This issue has motivated research on cross-domain sentiment classification, where knowledge in the source domain is transferred to the target domain in order to alleviate the required labeling effort.

One key challenge of domain adaptation is that data in the source and target domains are drawn from different distributions. Thus, adaptation performance will decline with an increase in distribution difference. Specifically, in sentiment analysis, reviews of different products have different vocabulary. For instance, restaurants reviews would contain opinion words such as “tender”, “tasty”, or “undercooked” and movie reviews would contain “thrilling”, “horrific”, or “hilarious”. The intersection between these two sets of opinion words could be small which makes domain adaptation difficult.

Several techniques have been proposed for addressing the problem of domain shifting. The aim is to bridge the source and target domains by learning domain-invariant feature representations so that a classifier trained on a source domain can be adapted to another target domain. In cross-domain sentiment classification, many works (Blitzer et al., 2007; Pan et al., 2010; Zhou et al., 2015; Wu and Huang, 2016; Yu and Jiang, 2016) utilize a key intuition that domain-specific features could be aligned with the help of domain-invariant features (pivot features). For instance, “hilarious” and “tasty” could be aligned as both of them are relevant to “good”.

Despite their promising results, these works share two major limitations. First, they highly depend on the heuristic selection of pivot features, which may be sensitive to different applications. Thus the learned new representations may not effectively reduce the domain difference. Furthermore, these works only utilize the unlabeled target data for representation learning while the sentiment classifier was solely trained on the source domain. There have not been many studies on exploiting unlabeled target data for refining the classifier, even though it may contain beneficial information. How to effectively leverage unlabeled target data still remains an important challenge for domain adaptation.

In this work, we argue that the information from unlabeled target data is beneficial for domain adaptation and we propose a novel **D**omain **A**daptive **S**emi-supervised learning framework (DAS) to better exploit it. Our main intuition is to treat the problem as a semi-supervised learning task by considering target instances as unla-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3467–3476
Brussels, Belgium, October 31 - November 4, 2018.

beled data, assuming the domain distance can be effectively reduced through domain-invariant representation learning. Specifically, the proposed approach jointly performs feature adaptation and semi-supervised learning in a multi-task learning setting. For feature adaptation, it explicitly minimizes the distance between the encoded representations of the two domains. On this basis, two semi-supervised regularizations – entropy minimization and self-ensemble bootstrapping – are jointly employed to exploit unlabeled target data for classifier refinement.

We evaluate our method rigorously under multiple experimental settings by taking label distribution and corpus size into consideration. The results show that our model is able to obtain significant improvements over strong baselines. We also demonstrate through a series of analysis that the proposed method benefits greatly from incorporating unlabeled target data via semi-supervised learning, which is consistent with our motivation. Our datasets and source code can be obtained from `https://github.com/ruidan/DAS`.

2 Related Work

Domain Adaptation: The majority of feature adaptation methods for sentiment analysis rely on a key intuition that even though certain opinion words are completely distinct for each domain, they can be aligned if they have high correlation with some domain-invariant opinion words (pivot words) such as "excellent" or "terrible". Blitzer et al. (2007) proposed a method based on structural correspondence learning (SCL), which uses pivot feature prediction to induce a projected feature space that works well for both the source and the target domains. The pivot words are selected in a way to cover common domain-invariant opinion words. Subsequent research aims to better align the domain-specific words (Pan et al., 2010; He et al., 2011; Wu and Huang, 2016) such that the domain discrepancy could be reduced. More recently, Yu and Jiang (2016) borrow the idea of pivot feature prediction from SCL and extend it to a neural network-based solution with auxiliary tasks. In their experiment, substantial improvement over SCL has been observed due to the use of real-valued word embeddings. Unsupervised representation learning with deep neural networks (DNN) such as denoising autoencoders has also been explored for feature adaptation (Glorot et al., 2011; Chen et al., 2012; Yang and Eisenstein, 2014). It has been shown that DNNs could learn transferable representations that disentangle the underlying factors of variation behind data samples.

Although the aforementioned methods aim to reduce the domain discrepancy, they do not explicitly minimize the distance between distributions, and some of them highly rely on the selection of pivot features. In our method, we formally construct an objective for this purpose. Similar ideas have been explored in many computer vision problems, where the representations of the underlying domains are encouraged to be similar through explicit objectives (Tzeng et al., 2014; Ganin and Lempitsky, 2015; Long et al., 2015; Zhuang et al., 2015; Long et al., 2017) such as maximum mean discrepancy (MMD) (Gretton et al., 2012). In NLP tasks, Li et al. (2017) and Chen et al. (2017) both proposed using adversarial training framework for reducing domain difference. In their model, a sub-network is added as a domain discriminator while deep features are learned to confuse the discriminator. The feature adaptation component in our model shares similar intuition with MMD and adversary training. We will show a detailed comparison with them in our experiments.

Semi-supervised Learning: We attempt to treat domain adaptation as a semi-supervised learning task by considering the target instances as unlabeled data. Some efforts have been initiated on transfer learning from unlabeled data (Dai et al., 2007; Jiang and Zhai, 2007; Wu et al., 2009). In our model, we reduce the domain discrepancy by feature adaptation, and thereafter adopt semi-supervised learning techniques to learn from unlabeled data. Primarily motivated by (Grandvalet and Bengio, 2004) and (Laine and Aila, 2017), we employed entropy minimization and self-ensemble bootstrapping as regularizations to incorporate unlabeled data. Our experimental results show that both methods are effective when jointly trained with the feature adaptation objective, which confirms to our motivation.

3 Model Description

3.1 Notations and Model Overview

We conduct most of our experiments under an unsupervised domain adaptation setting, where we have no labeled data from the target domain. Consider two sets D_s and D_t. $D_s = \{\mathbf{x}_i^{(s)}, \mathbf{y}_i^{(s)}\}|_{i=1}^{n_s}$ is from the source domain with n_s labeled examples, where $\mathbf{y}_i \in \mathbb{R}^C$ is a one-hot vector representation of sentiment label and C denotes the number of classes. $D_t = \{\mathbf{x}_i^{(t)}\}|_{i=1}^{n_t}$ is from the target domain with n_t unlabeled examples. $N = n_s + n_t$ denotes the total number of training documents including both labeled and unlabeled[1]. We aim to learn a sentiment classifier from D_s and D_t such that the classifier would work well on the target domain. We also present some results under a setting where we assume that a small number of labeled target examples are available (see Figure 3).

For the proposed model, we denote G parameterized by θ_g as a neural-based feature encoder that maps documents from both domains to a shared feature space, and $\mathcal{F}$ parameterized by θ_f as a fully connected layer with softmax activation serving as the sentiment classifier. We aim to learn feature representations that are domain-invariant and at the same time discriminative on both domains, thus we simultaneously consider three factors in our objective: (1) minimize the classification error on the labeled source examples; (2) minimize the domain discrepancy; and (3) leverage unlabeled data via semi-supervised learning.

Suppose we already have the encoded features of documents $\{\boldsymbol{\xi}_i^{(s,t)} = G(\mathbf{x}_i^{(s,t)}; \theta_g)\}|_{i=1}^{N}$ (see Section 4.1), the objective function for purpose (1) is thus the cross entropy loss on the labeled source examples

$$L = -\frac{1}{n_s} \sum_{i=1}^{n_s} \sum_{j=1}^{C} \mathbf{y}_i^{(s)}(j) \log \tilde{\mathbf{y}}_i^{(s)}(j) \qquad (1)$$

where $\tilde{\mathbf{y}}_i^{(s)} = \mathcal{F}(\boldsymbol{\xi}_i^{(s)}; \theta_f)$ denotes the predicted label distribution. In the following subsections, we will explain how to perform feature adaptation and domain adaptive semi-supervised learning in details for purpose (2) and (3) respectively.

3.2 Feature Adaptation

Unlike prior works (Blitzer et al., 2007; Yu and Jiang, 2016), our method does not attempt to align domain-specific words through pivot words. In our preliminary experiments, we found that word embeddings pre-trained on a large corpus are able to adequately capture this information. As we will later show in our experiments, even without adaptation, a naive neural network classifier with pre-trained word embeddings can already achieve reasonably good results.

We attempt to explicitly minimize the distance between the source and target feature representations ($\{\boldsymbol{\xi}_i^{(s)}\}|_{i=1}^{n_s}$ and $\{\boldsymbol{\xi}_i^{(t)}\}_{i=1}^{n_t}$). A few methods from literature can be applied such as Maximum Mean Discrepancy (MMD) (Gretton et al., 2012) or adversary training (Li et al., 2017; Chen et al., 2017). The main idea of MMD is to estimate the distance between two distributions as the distance between sample means of the projected embeddings in Hilbert space. MMD is implicitly computed through a characteristic kernel, which is used to ensure that the sample mean is injective, leading to the MMD being zero if and only if the distributions are identical. In our implementation, we skip the mapping procedure induced by a characteristic kernel for simplifying the computation and learning. We simply estimate the distribution distance as the distance between the sample means in the current embedding space. Although this approximation cannot preserve all statistical features of the underlying distributions, we find it performs comparably to MMD on our problem. The following equations formally describe the feature adaptation loss $\mathcal{J}$:

$$\mathcal{J} = KL(\mathbf{g}_s||\mathbf{g}_t) + KL(\mathbf{g}_t||\mathbf{g}_s) \qquad (2)$$

$$\mathbf{g}'_s = \frac{1}{n_s}\sum_{i=1}^{n_s} \boldsymbol{\xi}_i^{(s)}, \qquad \mathbf{g}_s = \frac{\mathbf{g}'_s}{\|\mathbf{g}'_s\|_1} \qquad (3)$$

$$\mathbf{g}'_t = \frac{1}{n_t}\sum_{i=1}^{n_t} \boldsymbol{\xi}_i^{(t)}, \qquad \mathbf{g}_t = \frac{\mathbf{g}'_t}{\|\mathbf{g}'_t\|_1} \qquad (4)$$

L_1 normalization is applied on the mean representations $\mathbf{g}'_s$ and $\mathbf{g}'_t$, rescaling the vectors such that all entries sum to 1. We adopt a symmetric version of KL divergence (Zhuang et al., 2015) as the distance function. Given two distribution vectors $P, Q \in \mathbb{R}^k$, $KL(P||Q) = \sum_{i=1}^{k} P(i) \log(\frac{P(i)}{Q(i)})$.

3.3 Domain Adaptive Semi-supervised Learning (DAS)

We attempt to exploit the information in target data through semi-supervised learning objectives, which are jointly trained with L and $\mathcal{J}$. Normally, to incorporate target data, we can minimize the cross entropy loss between the true label distributions $\mathbf{y}_i^{(t)}$ and the predicted label distributions

---

[1] Note that unlabeled source examples can also be included for training. In that case, $N = n_s + n_t + n_{s'}$ where $n_{s'}$ denotes the number of unlabeled source examples. This corresponds to our experimental setting 2. For simplicity, we only consider n_s and n_t in our description.

$\tilde{\mathbf{y}}_i^{(t)} = \mathcal{F}(\boldsymbol{\xi}_i^{(t)}; \theta_f)$ over target samples. The challenge here is that $\mathbf{y}_i^{(t)}$ is unknown, and thus we attempt to estimate it via semi-supervised learning. We use entropy minimization and bootstrapping for this purpose. We will later show in our experiments that both methods are effective, and jointly employing them overall yields the best results.

Entropy Minimization: In this method, $\mathbf{y}_i^{(t)}$ is estimated as the predicted label distribution $\tilde{\mathbf{y}}_i^{(t)}$, which is a function of θ_g and θ_f. The loss can thus be written as

$$\Gamma = -\frac{1}{n_t} \sum_{i=1}^{n_t} \sum_{j=1}^{C} \tilde{\mathbf{y}}_i^{(t)}(j) \log \tilde{\mathbf{y}}_i^{(t)}(j) \qquad (5)$$

Assume the domain discrepancy can be effectively reduced through feature adaptation, by minimizing the entropy penalty, training of the classifier is influenced by the unlabeled target data and will generally maximize the margins between the target examples and the decision boundaries, increasing the prediction confidence on the target domain.

Self-ensemble Bootstrapping: Another way to estimate $\mathbf{y}_i^{(t)}$ corresponds to bootstrapping. The idea is to estimate the unknown labels as the predictions of the model learned from the previous round of training. Bootstrapping has been explored for domain adaptation in previous works (Jiang and Zhai, 2007; Wu et al., 2009). However, in their methods, domain discrepancy was not explicitly minimized via feature adaptation. Applying bootstrapping or other semi-supervised learning techniques in this case may worsen the results as the classifier can perform quite bad on the target data.

Inspired by the ensembling method proposed in (Laine and Aila, 2017), we estimate $\mathbf{y}_i^{(t)}$ by forming ensemble predictions of labels during training, using the outputs on different training epochs. The loss is formulated as follows:

$$\Omega = -\frac{1}{N} \sum_{i=1}^{N} \sum_{j=1}^{C} \tilde{\mathbf{z}}_i^{(s,t)}(j) \log \tilde{\mathbf{y}}_i^{(s,t)}(j) \qquad (6)$$

where $\tilde{\mathbf{z}}$ denotes the estimated labels computed on the ensemble predictions from different epochs. The loss is applied on all documents. It serves for bootstrapping on the unlabeled target data, and it also serves as a regularization that encourages the network predictions to be consistent in different training epochs. Ω is jointly trained with L, $\mathcal{J}$, and Γ. Algorithm 1 illustrates the overall training process of the proposed domain adaptive semi-supervised learning (DAS) framework.

Algorithm 1 Pseudocode for training DAS

    $\tilde{\mathbf{z}} \leftarrow \textit{one-hot-vectors}(\mathbf{Z})$
  end for
```

In Algorithm 1, λ_1, λ_2, and $w(t)$ are weights to balance the effects of $\mathcal{J}$, Γ, and Ω respectively. λ_1 and λ_2 are constant hyper-parameters. We set $w(t) = \exp[-5(1 - \frac{t}{\textit{max-epochs}})^2]\lambda_3$ as a Gaussian curve to ramp up the weight from 0 to λ_3. This is to ensure the ramp-up of the bootstrapping loss component is slow enough in the beginning of the training. After each training epoch, we compute $\mathbf{Z}'_i$ which denotes the predictions made by the network in current epoch, and then the ensemble prediction $\mathbf{Z}_i$ is updated as a weighted average of the outputs from previous epochs and the current epoch, with recent epochs having larger weight. For generating estimated labels $\tilde{\mathbf{z}}_i$, $\mathbf{Z}_i$ is converted to a one-hot vector where the entry with the maximum value is set to one and other entries are set to zeros. The self-ensemble bootstrapping is a generalized version of bootstrappings that only use the outputs from the previous round of training (Jiang and Zhai, 2007; Wu et al., 2009). The ensemble prediction is likely to be closer to the correct, unknown labels of the target data.

4 Experiments

4.1 CNN Encoder Implementation

We have left the feature encoder G unspecified, for which, a few options can be considered. In our implementation, we adopt a one-layer CNN structure from previous works (Kim, 2014; Yu and Jiang, 2016), as it has been demonstrated to work well for sentiment classification tasks. Given a review document $\mathbf{x} = (x_1, x_2, ..., x_n)$ consisting of n words, we begin by associating each word with a continuous word embedding (Mikolov et al., 2013) $\mathbf{e}_x$ from an embedding matrix $\mathbf{E} \in \mathbb{R}^{V \times d}$, where V is the vocabulary size and d is the embedding dimension. E is jointly updated with other network parameters during training. Given a window of dense word embeddings $\mathbf{e}_{x_1}, \mathbf{e}_{x_2}, ..., \mathbf{e}_{x_l}$, the convolution layer first concatenates these vectors to form a vector $\hat{\mathbf{x}}$ of length ld and then the output vector is computed by Equation (7):

$$Conv(\hat{\mathbf{x}}) = f(\mathbf{W} \cdot \hat{\mathbf{x}} + \mathbf{b}) \tag{7}$$

$\theta_g = \{\mathbf{W}, \mathbf{b}\}$ is the parameter set of the encoder G and is shared across all windows of the sequence. f is an element-wise non-linear activation function. The convolution operation can capture local contextual dependencies of the input sequence and the extracted feature vectors are similar to n-grams. After the convolution operation is applied to the whole sequence, we obtain a list of hidden vectors $\mathbf{H} = (\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_n)$. A max-over-time pooling layer is applied to obtain the final vector representation $\boldsymbol{\xi}$ of the input document.

4.2 Datasets and Experimental Settings

Existing benchmark datasets such as the Amazon benchmark (Blitzer et al., 2007) typically remove reviews with neutral labels in both domains. This is problematic as the label information of the target domain is not accessible in an unsupervised domain adaptation setting. Furthermore, removing neutral instances may bias the dataset favorably for max-margin-based algorithms like ours, since the resulting dataset has all uncertain labels removed, leaving only high confidence examples. Therefore, we construct new datasets by ourselves. The results on the original Amazon benchmark is qualitatively similar, and we present them in Appendix A for completeness since most of previous works reported results on it.

Small-scale datasets: Our new dataset was derived from the large-scale Amazon datasets[2] released by McAuley et al. (2015). It contains four domains[3]: Book (BK), Electronics (E), Beauty (BT), and Music (M). Each domain contains two datasets. Set 1 contains 6000 instances with exactly balanced class labels, and set 2 contains 6000 instances that are randomly sampled from the large dataset, preserving the original label distribution, which we believe better reflects the label distribution in real life. The examples in these two sets do not overlap. Detailed statistics of the generated datasets are given in Table 1a.

In all our experiments on the small-scale datasets, we use set 1 of the source domain as the only source with sentiment label information during training, and we evaluate the trained model on set 1 of the target domain. Since we cannot control the label distribution of unlabeled data during training, we consider two different settings:

Setting (1): Only set 1 of the target domain is used as the unlabeled set. This tells us how the method performs in a condition when the target domain has a close-to-balanced label distribution. As we also evaluate on set 1 of the target domain, this is also considered as a transductive setting.

Setting (2): Set 2 from both the source and target domains are used as unlabeled sets. Since set 2 is directly sampled from millions of reviews, it better reflects real-life sentiment distribution.

Large-scale datasets: We further conduct experiments on four much larger datasets: IMDB[4]

---

[2] http://jmcauley.ucsd.edu/data/amazon/

[3] The original reviews were rated on a 5-point scale. We label them with rating < 3, > 3, and $= 3$ as negative, positive, and neutral respectively.

[4] IMDB is rated on a 10-point scale, and we label reviews with rating < 5, > 6, and $= 5/6$ as negative, positive, and neutral respectively.

(I), Yelp2014 (Y), Cell Phone (C), and Baby (B). IMDB and Yelp2014 were previously used in (Tang et al., 2015; Yang et al., 2017). Cell phone and Baby are from the large-scale Amazon dataset (McAuley et al., 2015; He and McAuley, 2016). Detailed statistics are summarized in Table 1b. We keep all reviews in the original datasets and consider a transductive setting where all target examples are used for both training (without label information) and evaluation. We perform sampling to balance the classes of labeled source data in each minibatch $B^{(s)}$ during training.

4.3 Selection of Development Set

Ideally, the development set should be drawn from the same distribution as the test set. However, under the unsupervised domain adaptation setting, we do not have any labeled target data at training phase which could be used as development set. In all of our experiments, for each pair of domains, we instead sample 1000 examples from the training set of the source domain as development set. We train the network for a fixed number of epochs, and the model with the minimum classification error on this development set is saved for evaluation. This approach works well on most of the problems since the target domain is supposed to behave like the source domain if the domain difference is effectively reduced.

Another problem is how to select the values for hyper-parameters. If we tune λ_1 and λ_2 directly on the development set from the source domain, most likely both of them will be set to 0, as unlabeled target data is not helpful for improving in-domain accuracy of the source domain. Other neural network models also have the same problem for hyper-parameter tuning. Therefore, our strategy is to use the development set from the target domain to optimize λ_1 and λ_2 for one problem (e.g., we only do this on E→BK), and fix their values on the other problems. This setting assumes that we have at least two labeled domains such that we can optimize the hyper-parameters, and then we fix them for other new unlabeled domains to transfer to.

4.4 Training Details and Hyper-parameters

We initialize word embeddings using the 300-dimension GloVe vectors supplied by Pennington et al., (2014), which were trained on 840 billion tokens from the Common Crawl. For each pair of domains, the vocabulary consists of the top 10000 most frequent words. For words in the vocabulary but not present in the pre-trained embeddings, we randomly initialize them.

We set hyper-parameters of the CNN encoder following previous works (Kim, 2014; Yu and Jiang, 2016) without specific tuning on our datasets. The window size is set to 3 and the size of the hidden layer is set to 300. The nonlinear activation function is Relu. For regularization, we also follow their settings and employ dropout with probability set to 0.5 on $\boldsymbol{\xi}_i$ before feeding it to the output layer $\mathcal{F}$, and constrain the l_2-norm of the weight vector θ_f, setting its max norm to 3.

On the small-scale datasets and the Aamzon benchmark, λ_1 and λ_2 are set to 200 and 1, respectively, tuned on the development set of task E→BK under setting 1. On the large-scale datasets, λ_1 and λ_2 are set to 500 and 0.2, respectively, tuned on I→Y. We use a Gaussian curve $w(t) = \exp[-5(1 - \frac{t}{t_{max}})^2]\lambda_3$ to ramp up the weight of the bootstrapping loss Ω from 0 to λ_3, where t_{max} denotes the maximum number of training epochs. We train 30 epochs for all experiments. We set λ_3 to 3 and α to 0.5 for all experiments.

The batch size is set to 50 on the small-scale datasets and the Amazon benchmark. We increase the batch size to 250 on the large-scale datasets to reduce the number of iterations. RMSProp optimizer with learning rate set to 0.0005 is used for all experiments.

4.5 Models for Comparison

We compare with the following baselines:

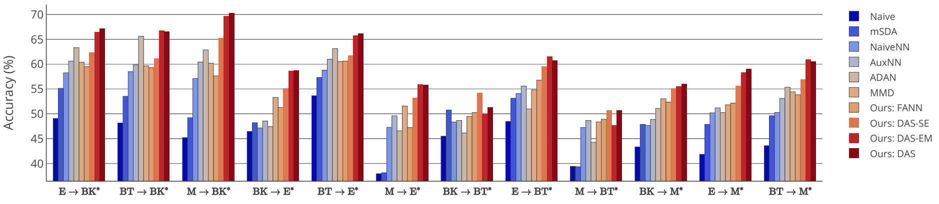
(1) **Naive**: A non-domain-adaptive baseline with bag-of-words representations and SVM classifier trained on the source domain.

(2) **mSDA** (Chen et al., 2012): This is the state-of-the-art method based on discrete input features. Top 1000 bag-of-words features are kept as pivot features. We set the number of stacked layers to 3 and the corruption probability to 0.5.

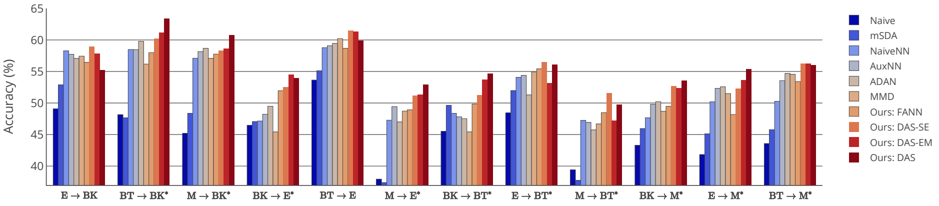
(3) **NaiveNN**: This is a non-domain-adaptive CNN trained on source domain, which is a variant of our model by setting λ_1, λ_2, and λ_3 to zeros.

(4) **AuxNN** (Yu and Jiang, 2016): This is a neural model that exploits auxiliary tasks, which has achieved state-of-the-art results on cross-domain sentiment classification. The sentence encoder used in this model is the same as ours.

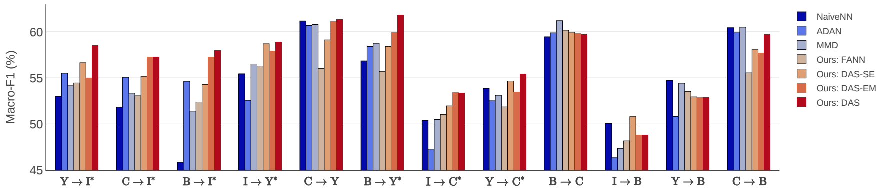
(5) **ADAN** (Chen et al., 2017): This method exploits adversarial training to reduce representa-



(a) Accuracy on the small-scale dataset under setting 1.



(b) Accuracy on the small-scale dataset under setting 2.



(c) Macro-F1 on the large-scale dataset.

Figure 1: Performance comparison. Average results over 5 runs with random initializations are reported for each neural method. * indicates that the proposed method (either of DAS, DAS-EM, DAS-SE) is significantly better than other baselines (baseline 1-6) with $p < 0.05$ based on one-tailed unpaired t-test.

tion difference between domains. The original paper uses a simple feedforward network as encoder. For fair comparison, we replace it with our CNN-based encoder. We train 5 iterations on the discriminator per iteration on the encoder and sentiment classifier as suggested in their paper.

(6) **MMD**: MMD has been widely used for minimizing domain discrepancy on images. In those works (Tzeng et al., 2014; Long et al., 2017), variants of deep CNNs are used for encoding images and the MMDs of multiple layers are jointly minimized. In NLP, adding more layers of CNNs may not be very helpful and thus those models from image-related tasks can not be directly applied to our problem. To compare with MMD-based method, we train a model that jointly minimize the classification loss L on the source domain and MMD between $\{\boldsymbol{\xi}_i^{(s)}|_{i=1}^{n_s}\}$ and $\{\boldsymbol{\xi}_i^{(t)}|_{i=1}^{n_t}\}$. For computing MMD, we use a Gaussian RBF which is a common choice for characteristic kernel.

In addition to the above baselines, we also show results of different variants of our model. **DAS** as shown in Algorithm 1 denotes our full model. **DAS-EM** denotes the model with only entropy minimization for semi-supervised learning (set $\lambda_3 = 0$). **DAS-SE** denotes the model with only self-ensemble bootstrapping for semi-supervised learning (set $\lambda_2 = 0$). **FANN** (feature-adaptation neural network) denotes the model without semi-supervised learning performed (set both λ_2 and λ_3 to zeros).

4.6 Main Results

Figure 1[5] shows the comparison of adaptation results (see Appendix B for the exact numerical numbers). We report classification accuracy on the small-scale dataset. For the large-scale dataset, macro-F1 is instead used since the label distribution in the test set is extremely unbalanced. Key observations are summarized as follows. (1) Both DAS-EM and DAS-SE perform better in most cases compared with ADAN, MDD, and FANN, in which only feature adaptation is performed. This demonstrates the effectiveness of the pro-

---

[5] We exclude results of Naive, mSDA and AuxNN on the large-scale dataset. Both Naive and mSDA have difficulties to scale up to the large dataset. AuxNN relies on manually selecting positive and negative pivots before training.

posed domain adaptive semi-supervised learning framework. DAS-EM is more effective than DAS-SE in most cases, and the full model DAS with both techniques jointly employed overall has the best performance. (2) When comparing the two settings on the small-scale dataset, all domain-adaptive methods[6] generally perform better under setting 1. In setting 1, the target examples are balanced in classes, which can provide more diverse opinion-related features. However, when considering unsupervised domain adaptation, we should not presume the label distribution of the unlabeled data. Thus, it is necessary to conduct experiments using datasets that reflect real-life sentiment distribution as what we did on setting2 and the large-scale dataset. Unfortunately, this is ignored by most of previous works. (3) Word-embeddings are very helpful, as we can see even NaiveNN can substantially outperform mSDA on most tasks.

To see the effect of semi-supervised learning alone, we also conduct experiments by setting $\lambda_1 = 0$ to eliminate the effect of feature adaptation. Both entropy minimization and bootstrapping perform very badly in this setting. Entropy minimization gives almost random predictions with accuracy below 0.4, and the results of bootstrapping are also much lower compared to NaiveNN. This suggests that the feature adaptation component is essential. Without it, the learned target representations are less meaningful and discriminative. Applying semi-supervised learning in this case is likely to worsen the results.

4.7 Further Analysis

In Figure 2, we show the change of accuracy with respect to the percentage of unlabeled data used for training on three particular problems under setting 1. The value at $x = 0$ denotes the accuracies of NaiveNN which does not utilize any target data. For DAS, we observe a nonlinear increasing trend where the accuracy quickly improves at the beginning, and then gradually stabilizes. For other methods, this trend is less obvious, and adding more unlabeled data sometimes even worsen the results. This finding again suggests that the proposed approach can better exploit the information from unlabeled data.

We also conduct experiments under a setting with a small number of labeled target examples available. Figure 3 shows the change of accuracy with respect to the number of labeled target examples added for training. We can observe that DAS is still more effective under this setting, while the performance differences to other methods gradually decrease with the increasing number of labeled target examples.

4.8 CNN Filter Analysis

In this subsection, we aim to better understand DAS by analyzing sentiment-related CNN filters. To do that, 1) we first select a list of the most related CNN filters for predicting each sentiment label (positive, negative neutral). Those filters can be identified according to the learned weights θ_f

---

(c) DAS

Table 2: Comparison of the top trigrams (each column) from the target domain (beauty) captured by the 5 most positive-sentiment-related CNN filters learned on E→BT. $*$ denotes a padding.

of the output layer $\mathcal{F}$. Higher weight indicates stronger relatedness. 2) Recall that in our implementation, each CNN filter has a window size of 3 with Relu activation. We can thus represent each selected filter as a ranked list of trigrams with highest activation values.

We analyze the CNN filters learned by NaiveNN, FANN and DAS respectively on task E→BT under setting 1. We focus on E→BT for study because electronics and beauty are very different domains and each of them has a diverse set of domain-specific sentiment expressions. For each method, we identify the top 10 most related filters for each sentiment label, and extract the top trigrams of each selected filter on both source and target domains. Since labeled source examples are used for training, we find the filters learned by the three methods capture similar expressions on the source domain, containing both domain-invariant and domain-specific trigrams. On the target domain, DAS captures more target-specific expressions compared to the other two methods. Due to space limitation, we only present a small subset of positive-sentiment-related filters in Table 2. The complete results are provided in Appendix C. From Table 2, we can observe that the filters learned by NaiveNN are almost unable to capture target-specific sentiment expressions, while FANN is able to capture limited target-specific words such as "clean" and "scent". The filters learned by DAS are more domain-adaptive, capturing diverse sentiment expressions in the target domain.

5 Conclusion

In this work, we propose DAS, a novel framework that jointly performs feature adaptation and semi-supervised learning. We have demonstrated through multiple experiments that DAS can better leverage unlabeled data, and achieve substantial improvements over baseline methods. We have also shown that feature adaptation is an essential component, without which, semi-supervised learning is not able to function properly. The proposed framework could be potentially adapted to other domain adaptation tasks, which is the focus of our future studies.

Abstract

Many existing systems for analyzing and summarizing customer reviews about products or service are based on a number of prominent review aspects. Conventionally, the *prominent review aspects* of a product type are determined manually. This costly approach cannot scale to large and cross-domain services such as Amazon.com, Taobao.com or Yelp.com where there are a large number of product types and new products emerge almost everyday. In this paper, we propose a novel framework, for extracting the most prominent aspects of a given product type from textual reviews. The proposed framework, ExtRA, extracts K most prominent aspect terms or phrases which do not overlap semantically automatically without supervision. Extensive experiments show that ExtRA is effective and achieves the state-of-the-art performance on a dataset consisting of different product types.

1 Introduction

Online user review is an essential part of e-commerce. Popular e-commerce websites feature an enormous amount of text reviews, especially for popular products and services. To improve the user experience and expedite the shopping process, many websites provide qualitative and quantitative analysis and summary of user reviews, which is typically organized by different *prominent review aspects*. For instance, Figure 1 shows a short review passage from a customer on TripAdvisor.com, and the customer is also asked to give scores on several specific aspects of the hotel, such as *location* and *cleanness*. With aspect-based reviews summary, potential customers can assess a product from various essential aspects very efficiently and directly. Also, aspect-based review summary offers an effective way to group products by their prominent aspects and hence enables quick comparison.

"Miami Vacation"
●●●○○ Reviewed 5 days ago

Pool is small and only 4 ft but refreshing. Hot tub also there. Staff were super friendly each day. Room was nothing special but clean and comfy. Lots of restaurants and bars nearby. Breakfast was great and despite being a busy weekend there was always a big selection available.

Stayed June 2016, traveled with family

●●○○○ Value	●●●○○ Rooms
●●●●● Location	●●●●○ Cleanliness
●●●○○ Sleep Quality	●●●●○ Service

Figure 1: An example user review about a hotel on TripAdvisor. The grades are organized by different prominent review aspects: *value*, *rooms*, etc.

Existing approaches for producing such prominent aspect terms have been largely manual work (Poria et al., 2014; Qiu et al., 2011). This is feasible for web services that only sell (or review) a small number of product types of the same domain. For example, TripAdvisor.com only features travel-related products, and Cars.com only reviews automobiles, so that human annotators can provide appropriate aspect terms for customers based on their domain knowledge. While it is true that the human knowledge is useful in characterizing a product type, such manual approach does not scale well for general-purpose e-commerce platforms, such as Amazon, eBay, or Yelp, which feature too many product types, not to mention that new product and service types are emerging everyday. In these cases, manually selecting and pre-defining aspect terms for each type is too costly and even impractical.

Moreover, the key aspects of a product type may also change over time. For example, in the past, people care more about the screen size and signal intensity when reviewing cell phones. These aspects are not so much of an issue in present days. People instead focus on battery life and processing speed, etc. Therefore, there is a growing need to automatically extract prominent aspects from user

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3477–3486
Brussels, Belgium, October 31 - November 4, 2018.

reviews.

A related but different task is *aspect-based opinion mining* (Su et al., 2008; Zeng and Li, 2013). Here techniques have been developed to automatically mine product-specific "opinion phrases" such as those shown in Figure 2. In this example, the most frequently mentioned opinion phrases about a phone model along with the mention frequency are displayed. Their goal is to get the *fine-grained* opinion summary on possibly overlapping aspects of a particular product. For example, "good looks" and "beautiful screen" both comments on the "appearance" aspect of the phone. However, these aspects are implicit and can't be used in aspect-based review summarization directly. The main disadvantage of these opinion phrases is that their aspects differ from product to product, making it difficult to compare the product side by side.

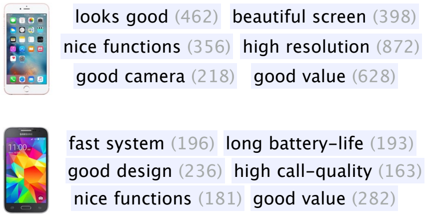

Figure 2: Automatic review summarization for two mobile phones on an e-commerce website

The goal of this paper is to develop an unsupervised framework for automatically extracting K most prominent, non-overlapping review aspects for a given type of product from user review texts. Developing such an unsupervised framework is challenging for the following reasons:

- The extracted prominent aspects not only need to cover as many customer concerns as possible but also have little semantic overlap.
- The expression of user opinions is highly versatile: aspect terms can be expressed either explicitly or implicitly. For example, the mention of "pocket" implies the aspect "size".
- Product reviews are information rich. A short piece of comments may target multiple aspects, so topics transit quickly from sentence to sentence.

Most previous unsupervised approaches for the prominent aspect extraction task are variants of topic modeling techniques (Lakkaraju et al., 2011; Lin and He, 2009; Wang et al., 2011a). The main problem of such approaches is that they typically use only word frequency and co-occurrence information, and thus degrade when extracting aspects from sentences that appear different on the surface but actually discuss similar aspects.

Given all review text about a certain product type, our framework, ExtRA, extracts most prominent aspect terms in four main steps: first it extracts potential aspect terms from text corpus by lexico-syntactic analysis; then it associates the terms to synsets in WordNet and induce a sub-graph that connect these terms together; after that it ranks the aspect terms by a personalized page rank algorithm on the sub-graph; and finally picks the top K non-overlapping terms using the subsumption relation in the subgraph.

The main contributions in this paper are as follows:

1. We propose a novel framework for extracting prominent aspects from customer review corpora (Section 2), and provide an evaluation dataset for future work in this research area.
2. Extensive experiments show that our unsupervised framework is effective and outperforms the state-of-the-art methods by a substantial margin (Section 3).

2 Framework

In this section, we first state the *review aspect extraction problem*, then present the workflow of our method, shown in Figure 3.

2.1 Problem Statement

The review aspect extraction problem is given all the text reviews about one type of product or service, extract K words (or phrases), each of which represents a prominent and distinct review aspect.

For instance, if the given product type is *hotel*, we expect a successful extraction framework to extract $K = 5$ aspect terms as follows: *room, location, staff, breakfast, pool*.

2.2 Aspect Candidates Extraction

Following the observation of Liu (2004; 2015), we assume that aspect terms are nouns and noun phrases. First, we design a set of effective syntactic rules, which can be applied across domains, to collect the aspect candidates from review texts.

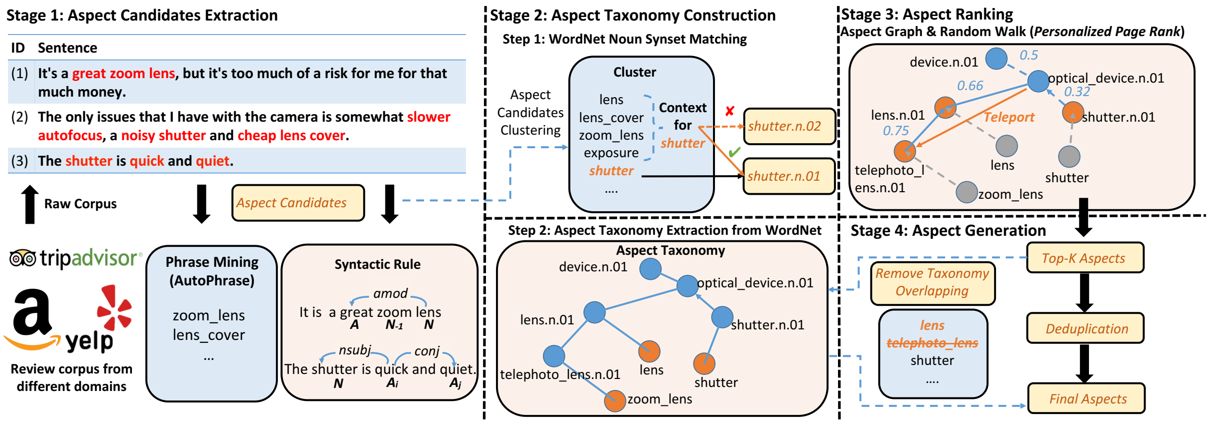

Figure 3: Overall framework.

We mainly use the adjectival modifier dependency relation (*amod*) and the nominal subject relation (*nsubj*) to extract the aspect-opinion pairs $\langle N, A\rangle$. In addition, we leverage the conjunction relation (*conj*) between adjectives to complement the extracted pairs. Formally, the extraction rules can be specified as follows:

Rule 1. If $amod(N, A)$, then extract $\langle N, A\rangle$.

Rule 2. If $nsubj(A, N)$, then extract $\langle N, A\rangle$.

Rule 3. If $\langle N, A_i\rangle$ and $conj(A_i, A_j)$, then extract $\langle N, A_j\rangle$.

In this case, N indicates a noun, and A (e.g. A_i, A_j) is an adjective. The dependencies (e.g. $amod(N, A)$) are expressed as *rel(head, dependent)*, where *rel* is the dependency relation which holds between *head* and *dependent*. Note that many aspects are expressed by phrases, thus, we extend the phrases as aspect candidates by introducing the extension rules as follows:

Rule E1. If $\langle N, A\rangle$ and $N_{-1}\_N \in P$, then use $\langle N_{-1}\_N, A\rangle$ to replace $\langle N, A\rangle$.

Rule E2. If $\langle N, A\rangle$ and $N\_N_{+1} \in P$, then use $\langle N\_N_{+1}, A\rangle$ to replace $\langle N, A\rangle$.

where N_{-1} and N_{+1} denotes the noun word, and the subscript represents displacement to N in the sentence. We use AutoPhrase (Liu et al., 2017) to extract a set of phrases P with high coherence. Then we use P to filter out the incoherent phrases so as to obtain the high-quality phrases as aspect candidates. The example in Figure 3 (Stage 1) demonstrates the extraction process. For example, we extract the pair ⟨ *great*, *zoom_lens* ⟩ from sentence (1) by applying *Rule 1* and *Rule E1*. Similarly, the extraction rules match ⟨ *slower*, *autofocus* ⟩, ⟨ *noisy*, *shutter* ⟩, ⟨ *cheap*, *lens_cover* ⟩ in sentence (2) and ⟨ *quick*, *shutter* ⟩, ⟨ *quiet*, *shutter* ⟩ in sentence (3) as potential aspect-opinion pairs. After extracting such pairs from the text reviews, we sort them by the number of occurrences, and extract the nouns and noun phrases in the top pairs as aspect candidates, assuming that the most prominent aspects are subsumed by those candidates terms.

2.3 Aspect Taxonomy Construction

The aspect candidates extracted in the last stage come with the counts modified by adjectives. We can directly use such raw counts to rank the aspect candidates. This is one of the baseline models in our experiments. However, such ranking usually suffers from the aspect overlapping problem which obviously violates the principle of pursuing both coverage and distinctiveness of prominent aspects. For example, given the number of prominent aspects K as 5, we can extract both of ‘location‘ and ‘place‘ aspects from the hotel reviews. In order to solve this problem, we construct an aspect taxonomy to obtain such overlapping information between aspect candidates by leveraging the WordNet ontology.

2.3.1 WordNet Synset Matching

First, we need to match our aspect candidates onto WordNet synsets. The accuracy of synset matching is very important for our aspect taxonomy construction. This is actually a classical word sense disambiguation (WSD) problem. Our initial attempt is to use a Python WSD tool (Tan, 2014). For each aspect candidate, we take it as the target and randomly sample a bunch of sentences that contain this target. We use the extended word sense disambiguation algorithm (Banerjee and Pedersen, 2003) in this tool. We count the total occurrences for each noun sense (synset) of the candidate and match the candidate to the most frequent synset. However, such a method is not good enough for our problem, as shown in the results later. It only considers the local context information within the review sentence. Whats more, the review sentences are usually very short and colloquial, which makes it more difficult to match properly by a common WSD algorithm. Therefore, it is critical to construct more reliable contexts for aspect candidate matching.

To achieve this goal, we cluster the aspect candidates with similar semantics together. Then, for each aspect candidate, we take the other candidates within the same cluster as its context for later disambiguation. As shown in the first step of stage 2 in Figure 3, the semantic similar aspect candidates such as *lens, lens_cover, zoom_lens, exposure and shutter* are clustered together. For example, we can disambiguate the sense of *shutter* by leveraging *lens, lens_cover, zoom_lens, and exposure*. We observed that our aspect candidates can be fine-grain clustered with a two-stage k-means clustering method,[1] which generates the better context for the aspect candidates. More specifically, for a particular aspect candidate a_t from the cluster $C = \{a_1, a_2, ..., a_t, ..., a_n\}$, we calculate the context vector of a_t as:

$$c(a_t) = \sum_{i=1, i \neq t}^{n} E(a_i), \quad (1)$$

where $c(a_t)$ denotes the context vector of a_t, and $E(a_i)$ represents the embedding of a_i. The set of candidate synsets $S(a_t) = \{s_1^t, s_2^t, ..., s_m^t\}$ consists of the noun senses (e.g. s_i^t) of a_t from WordNet. Each sense s_i^t is associated with a *gloss* g_i^t (i.e. a brief definition of s_i^t) which covers the semantics of the sense. Therefore, we encode s_i^t as the summation of the word vectors in g_i^t:

$$v(s_i^t) = \sum_{j=1}^{q} E(w_j^{t,i}), \quad (2)$$

$W(g_i^t)$ is the sequence of words in g_i^t, i.e., $W(g_i^t) = [w_1^{t,i}, w_2^{t,i}, ..., w_q^{t,i}]$. For each candidate sense s_i^t of the aspect candidate a_t, we calculate the cosine semantic similarity between $v(s_i^t)$ and $c(a_t)$, and match a_t to the most similar s_i^t.

2.3.2 Aspect Taxonomy Extraction from WordNet

In order to construct the aspect taxonomy from WordNet, we first extract the hypernym paths for every matched synsets in the previous step. By definition, a hypernym path p of synset s is the is-a relation path from s to the root synset (i.e. entity.n.01 for nouns). We extract the hypernym paths for each matched synset s_i in the WordNet ontology. Next, we scan over all the collected paths once to construct the aspect taxonomy which is a directed acyclic graph (DAG). In p, s_1 is the synset matched from our potential aspects, and s_{i+1} is the hypernym of s_i. As shown in step 2 of Stage 2 in Figure 3, we match the aspect candidate *shutter* to *shutter.n.01*. The only one hypernym path of *shutter.n.01* is *[shutter.n.01, optical_device.n.01, device.n.01, ..., entity.n.01]*.

However, the matched synset usually has multiple hypernym paths in WordNet. We use the following strategy to compact and minimize the aspect taxonomy:

- Among all the paths from an aspect candidate s_1, we will keep those paths that contain more than 1 aspect candidates, unless there's only one path from s_1. If all paths contain only 1 aspect candidate s_1 each, we will keep all of them.
- To further optimize the taxonomy structure, we induce a minimum subgraph from the original taxonomy using a heuristic algorithm (Kou et al., 1981). Such a subgraph satisfies the following conditions: 1) it contains all the nodes matched from aspect candidates; 2) the total number of nodes in the graph is minimal. Consequently, the induced graph is a weakly connected DAG.

After acquiring the aspect taxonomy for the given product or service, we can now tell if two aspects are semantically overlapped or not.

2.4 Aspect Ranking

In this section, we propose a novel method based on personalized page rank to compute the overall rank values for the potential aspects by leveraging the aspect taxonomy.

---

[1] The implementation details are in Section 3.2.

Let the aspect taxonomy be a graph $G = (V, E)$. Each node $v \in V$ is a synset in the aspect taxonomy and encoded as a vector by instantiating E as Glove embeddings in (2) . Each edge $e = \langle u, v \rangle$ carries a weight which is the semantic similarity between the nodes u and v, computed using cosine similarity.

Next, we perform the random walks on our constructed aspect taxonomy. The propagation starts from candidate aspect nodes in the aspect taxonomy, which are called *seeds* here. The rank values (aspect importance) of all nodes are:

$$x_t = (1 - \alpha) * Ax_{t-1} + \alpha * E, \qquad (3)$$

where t is the time step in random walk process. In the initial state E(i.e. x_0), the aspect importance only distributes on the seeds ($v \in V_b$). E_i is the i-th dimension of E, indicating the portion of aspect importance on node s_i at time step 0. E is calculated as follows:

$$E_i = \begin{cases} \frac{f(le(s_i))}{\sum_{j=1}^{n} f(le(s_j))} & \text{, if } s_i \text{ is a seed} \\ 0 & \text{, otherwise,} \end{cases} \qquad (4)$$

where n is the number of nodes in the graph, s_i is the synset node, $le(s_i)$ denotes the lemma form of s_i, and $f(le(s_i))$ represents the frequency that $le(s_i)$ is modified by adjectives.

The aspect importance is updated using the transition probabilities matrix A which are the normalized weights on the edges of the taxonomy. α is the teleport probability, which is the probability of returning to the initial distribution at each time step. α determines the distance of propagation of the taxonomy.

2.5 Aspect Generation

Finally, we generate the prominent aspects using the rank values of the aspects as well as the is-a relations in the aspect taxonomy.

We sort $le(s_i)$ in decreasing order by their rank values. We essentially take the top aspects from the sorted list. However there might be two types of overlapping that we need to avoid: i) duplicate: different synset nodes may map to the same aspects, i.e., $le(s_i) = le(s_j), s_i \neq s_j$ (aspects); ii) taxonomy overlap: the later aspect in the list is the hypernym or hyponym of the one of previous aspects. To this end, we just skip overlapped aspect, and move along the list until we generate K non-overlapping prominent aspects from the list.

3 Experiments

We compare the ExtRA framework with multiple strong baselines on extracting aspect terms from user reviews. We first introduce the dataset and the competing models, then show the quantitative evaluation as well as qualitative analysis for different models.

3.1 Dataset

We use the customer review corpora of 6 kinds of product and service [2] collected from popular websites, including Amazon, TripAdvisor and Yelp. The number of hotel reviews (Wang et al., 2011b) in the original corpus is huge. Therefore, we randomly sample 20% of the reviews to perform our experiments. The statistics of the corpora are shown in Table 1.

Table 1: Dataset statistics.

Product type	Source	#Reviews
hotel	TripAdvisor	3,155,765
mobile phone	Amazon	185,980
mp3 player	Amazon	30,996
laptop	Amazon	40,744
cameras	Amazon	471,113
restaurant	Yelp	269,000

Existing published aspect extraction datasets (Hu and Liu, 2004; Popescu and Etzioni, 2007; Pavlopoulos and Androutsopoulos, 2014; Ding et al., 2008) include only fine-grained aspects from reviews, which are not suitable for evaluating the performance of prominent aspects extraction. Therefore, we build a new evaluation dataset particularly for this task. Following the previous work (Ganu et al., 2009; Brody and Elhadad, 2010; Zhao et al., 2010; Wang et al., 2015) as well as the popular commercial websites (e.g. TripAdvisor), which most manually labeled 3-6 prominent aspects for rating, we set K as five. Therefore, we ask each annotator who are familiar with the domain to give 5 aspect terms which they think are most important for each category. We have five annotators in total. [3] One prominent aspect can be expressed by different terms. Thus, it is difficult to achieve a satisfied inner-agreement. We propose two evaluation methods, especially the soft accuracy in Section 3.3.1 to compensate

---

[2] The data is available from http://times.cs.uiuc.edu/~wang296/Data/ and https://www.yelp.com/dataset

[3] The complete labeled set of ExtRA is released at http://adapt.seiee.sjtu.edu.cn/extra/.

this problem. To acquire a relatively higher inner-agreement, we educate the annotators with top 100 frequent aspect candidates as hints. Though, they are not required to pick up labels from the candidates. The inter-annotator agreement of each product type shown in Table 3 is computed as the average jaccard similarity between every two annotators.

3.2 Baselines and ExtRA

We introduce three topic modeling based baselines for the task. These are **LDA** (Blei et al., 2003), **BTM** (Cheng et al., 2014) and **MG-LDA** (Titov and McDonald, 2008). MG-LDA is a strong baseline which attempts to capture multi-grain topics (i.e. global & local), where the local topics correspond to the rateable prominent aspects. We treat each review as a document and perform those models to extract K topics. Then, we select most probable words in each topic as our extracted aspect terms. To prevent extracting the same aspects (w) from different topics, we only keep w for the topic t with the highest probability $p(w|t)$ value, then re-select aspects for the other topics until we get K different aspects. For fair comparison among different models, the number of target aspects K is set as 5. The hyper-parameter of MG-LDA (global topics) is set to 30 with fine-tuning.

Another syntactic rule-based baseline model **AmodExt** is from the first stage of our framework. After extracting the aspect candidates using *amod-rule* in Section 2.2, we sort the aspect candidates by their counts of extracted occurrences. Then select the top K candidates as the prominent aspects.

ABAE (He et al., 2017) is a neural based model that can to infer K aspect types. Each *aspect type* is a ranked list of representative words. To generate K prominent aspects, we first infer K aspect types using *ABAE*, then select the most representative word from each aspect type.

For **ExtRA**, in the taxonomy construction stage, we use a two-stage K-means clustering method for synset matching task, and the cluster number is auto-tuned using silhouette score (Rousseeuw, 1987). We use SkipGram (Mikolov et al., 2013) model to train the embeddings on review texts for k-means clustering. We set the dimension of the embeddings as 100 and run 64 epochs for each product corpora. In the aspect ranking stage, we empirically set the teleport probability α as 0.5 which indicates that the expected walk-length from the seeds is $\frac{1}{\alpha} = 2$.

3.3 Evaluation

In this section, we compare ExtRA with five baseline models both quantitatively and qualitatively.

3.3.1 Quantitative Evaluation

First, we perform two experiments to justify our aspect taxonomy construction stage:

- To justify the synset matching step, we compare our proposed cluster method with classical WSD algorithm (Lesk) on matching accuracy. We manually label 100 sampled synset nodes for each category. The synset matching accuracies are shown in Table 2. We can see that our clustering method is effective for the synset matching task.

- We induce the aspect taxonomy using a heuristic algorithm to obtain more compact and aspect-oriented subgraph. We show the size of aspect taxonomy induced before and after taxonomy minimization in Figure 4.

Next, we evaluate our model as well as above baselines on the evaluation dataset described above. We did not remove the duplicate aspect labels for the qualitative evaluation, since the repeated aspects are assume to be better. For a given category, we first calculate the percentage of the 25 labels that exactly match one of the 5 aspect terms generated by the model as the *hard accuracy* of the model. Formally, $Aspects(m) = [a_1, a_2, a_3, a_4, a_5]$ denotes the five prominent aspects generated from model m for the given category. $L = [l_1, l_2, ..., l_{25}]$ are the 25 golden aspect terms, where $L^{(h)} = [l_{5h-4}, ..., l_{5h}]$ are from the h-th human annotator. The hard accuracy is defined as:

$$hacc(m) = \frac{\sum_{i=1}^{25} hit(Aspects(m), l_i)}{25} \quad (5)$$

$$hit(Aspects(m), l_i) = \begin{cases} 1, & l_i \in Aspects(m) \\ 0, & \text{otherwise,} \end{cases} \quad (6)$$

However, counting the number of exact matches makes the accuracy score discrete and coarse. Besides, it penalizes aspect terms that don't match the label but actually have similar meanings. To

Table 2: WordNet Synset matching accuracies

	hotel	mp3	cameras	mobile phone	laptop	restaurant

Table 4: Comparison of *hard* (upper row) & *soft* (lower row) accuracies using different models for aspect extraction.

	LDA	BTM	MG-LDA	ABAE	AmodExt	ExtRA
hotel	0.16	0.16	0.16	0.16	0.44	**0.56**
	0.50	0.49	0.67	0.35	0.65	**0.70**
mp3	0.0	0.08	0.08	0.0	0.35	**0.44**
	0.47	0.49	0.47	0.32	0.58	**0.60**
camera	0.24	**0.40**	0.28	0.04	0.04	0.32
	0.56	**0.69**	0.54	0.29	0.41	0.55
mobile phone	0.16	0.0	0.28	0.0	0.52	**0.60**
	0.58	0.33	0.58	0.31	**0.73**	0.71
laptop	0.08	0.24	0.24	0.0	0.24	**0.28**
	0.40	0.50	0.50	0.22	0.51	**0.53**
restaurant	0.20	0.0	0.0	0.0	**0.56**	**0.56**
	0.49	0.38	0.42	0.29	**0.77**	0.72

remedy this, we propose the *soft accuracy* evaluation measure. For each set of five golden labels from h-th annotator, we first align each generated aspect $a_k \in Aspects(m)$ with one golden aspect $l_j \in L^{(h)}$ (i.e. $align^{(h)}(a_k) = l_j$). We align the exact match terms together, and then choose the optimal alignment for the others by permuting all possible alignments. The optimal alignment $align^{(h)}(a_k)$ acheives maximum soft accuracy. Then we calculate the soft matching score between $Aspects(m)$ and $L^{(h)}$ as $\sum_{k=1}^{K} sim(a_k, align^{(h)}(a_k))$, where sim is the cosine similarity computed by Glove (2014) [4]. We then compute the soft accuracy measure as follows:

$$sacc(m) = \frac{1}{5} * \sum_{h=1}^{5} \sum_{k=1}^{K} sim(a_k, align^{(h)}(a_k)), \tag{7}$$

where $K = 5$ in this case. The comparison results are shown in Table 4.

Our model (ExtRA) outperforms all the other baselines in all categories except cameras using the hard accuracy measure. Besides, ExtRA is the best model on four out of six products under the soft accuracy measure. As shown in Table 2, the accuracy for synset matching is relatively low for cameras and restaurant, resulting in the lower accuracy in overall aspect extraction.

3.3.2 Qualitative Analysis

To qualitatively evaluate different models, we present the extracted 5 aspect terms by each model from each domain in Table 5. Our model (ExtRA) has significant advantage over other baselines for that we can do better aspect extraction with reasonable results, and extract not only words but also phrases as prominent aspects, *e.g. sound quality, image quality*. The proposed model avoid the overlapping aspects appeared in our strong baseline (AmodExt) by deduplication using generated aspect taxonomy information. The overlapping aspects are marked in italics. For example, both *lo-*

	BTM	battery, picture, function, lens, good
	MGLDA	battery, picture, good, mpcture, mode
	ABAE	toy, picture, mailed, ultrazoom, sharpness
	AmodExt	*picture, photo*, quality, feature, shot
	ExtRA	**image_quality, photograph, feature, shot, lens**
mobile phone	LDA	battery, buy, good, apps, work
	BTM	core, good, work, para, apps
	MGLDA	work, battery, screen, good, card
	ABAE	cracked, amazing, continuously, archive, bought
	AmodExt	feature, screen, price, camera, quality
	ExtRA	**feature, price, screen, quality, service**
laptop	LDA	screen, good, buy, drive, chromebook
	BTM	windows, screen, work, drive, good
	MGLDA	windows, battery, screen, good, year
	ABAE	salign, returned, affordable, downloads, position
	AmodExt	drive, machine, price, screen, life
	ExtRA	**drive, price, screen, deal, performance**
restaurant	LDA	food, good, room, time, great
	BTM	good, room, pour, time, order
	MGLDA	great, good, place, time, make
	ABAE	jones, polite, told, chickpea, place
	AmodExt	food, service, place, experience, price
	ExtRA	**service, food, experience, company, price**

cation and *place* are extracted as top aspects, but they mean nearly the same concept. The results from other baseline methods, inevitably contain some sentiment words and opinions, like *good, nice, great, etc.* Our model resolves such drawback by extracting aspect candidates from only nouns and using syntactic rules to find words that are frequently modified by adjectives.

4 Related Work

Existing research on *aspect-based review analysis* has focused on mining opinion based on given aspects (Su et al., 2008; Zeng and Li, 2013) or jointly extracting the aspects and sentiment (Lin and He, 2009; Zhao et al., 2010; Qiu et al., 2011; Wang et al., 2015; Liu et al., 2016). They are mostly interested in detecting aspect words in a given sentence, whereas our goal is to extract the most prominent aspects of a type of product from a large number of reviews about that product type. We divide the existing work on review aspect extraction into three types:

- *rule-based* methods, most of which utilize handcrafted rules to extract candidate aspects and then perform clustering algorithm on them.
- *topic modeling based* methods, which directly model topics from texts and then extract aspects from the topics.
- *neural network based* methods, which takes advantage of the recent deep neural network models.

4.1 Rule-based Methods

These methods leverage word statistical and syntactic features to manually design rules, recognizing aspect candidates from texts. Poria et al. (2014) use manually crafted mining rules. Qiu et al. (2011) also used rules, plus the Double Propagation method to better relate sentiment to aspects. Gindl et al. (2013) cooperate the Double Propagation with anaphora resolution for identifying co-references to improve the accuracy. Su et al. (2008) used a clustering method to map the implicit aspect candidates (which were assumed to be the noun form of adjectives in the paper) to explicit aspects. Zeng et al. (2013) mapped implicit features to explicit features using a set of sentiment words and by clustering explicit feature-sentiment pairs. Rana et al. (2017) propose a two-fold rules-based model, using rules defined by sequential patterns. Their first fold extracts aspects associated with domain independent opinions and the second fold extracts aspects associated with domain dependent opinions.

However, such rule-based models are designed for extracting product features which can not easily adapt to our K most prominent aspect extraction problem. Besides, most of them require human efforts to collect lexicons and to carefully design complex rules and thus do not scale very well.

4.2 Topic Modeling Based Methods

Most work in this domain are based on two basic models, pLSA(Hofmann, 1999) and LDA(Blei et al., 2003). The variants of these models consider two special features of review texts: 1) topics shift quickly between sentences, 2) sentiment plays an important role and there is a strong correlation between sentiments and aspects. The approach of Lin et al. (2011) models are parallel aspects and sentiments per review. Lin et al. (2009) models the dependency between the latent aspects and ratings. Wang et al. (2011a) proposed a generative model which incorporates topic modeling technique into the latent rating regression model (Wang et al., 2010). Moghaddam et al. (2012) made a nice summarization of some basic variations of LDA for opinion mining. In stead of using topics, our method relies on word embeddings to capture the latent semantics of words and phrases and achieves better results. *MG-LDA* (Titov and McDonald, 2008) is a variant of LDA that can also model topics at different granularities, which are based on extensions to standard topic modeling methods such as LDA and PLSA to induce multigrain topics. *D-PLDA* (Moghaddam and Ester, 2012), is a variant of LDA models, which is designed specifically for modeling topics from user reviews. D-PLDA only considers opinion-related terms and phrases, and nouns and phrases are controlled by two separate hidden parameters. Thus, the model needs aspects, ratings, and phrases as input, which are all very expensive.

4.3 Neural Network Based Methods

He et al. (2017) propose a neural attention model for identifying aspect terms. Their goal is similar to ours but instead of directly comparing their extracted terms with the gold standard, they ask human judges to map the extracted terms to one of the prominent gold aspects manually before computing the precision/recall. This evaluation methodology mixed machine results with human judgment and is problematic in our opinion. Our experiments showed that their output aspects are too fine-grained and can not be used as prominent aspects.

5 Conclusion

In this paper, we propose an unsupervised framework ExtRA for extracting the most prominent aspect terms about a type of product or service from user reviews, which benefits both qualitative and quantitative aspect-based review summarization. Using WordNet as a backbone, and by running personalized page rank on the network, we can produce aspect terms that are both important and non-overlapping. Results show that this approach is more effective than a number of other strong baselines.

Cross-Lingual Cross-Platform Rumor Verification Pivoting on Multimedia Content

Weiming Wen[1], **Songwen Su**[1], **Zhou Yu**[1]

[1]University of California, Davis
`wmwen@ucdavis.edu`

Abstract

With the increasing popularity of smart devices, rumors with multimedia content become more and more common on social networks. The multimedia information usually makes rumors look more convincing. Therefore, finding an automatic approach to verify rumors with multimedia content is a pressing task. Previous rumor verification research only utilizes multimedia as input features. We propose not to use the multimedia content but to find external information in other news platforms pivoting on it. We introduce a new features set, cross-lingual cross-platform features that leverage the semantic similarity between the rumors and the external information. When implemented, machine learning methods utilizing such features achieved the state-of-the-art rumor verification results.

1 Introduction

Social network's unmoderated nature leads to the spread and emergence of information with questionable sources. With the increasing popularity of the social media, we are exposed to a plethora of rumors. Here we borrow the rumor definition from DiFonzo and Bordia (2007) as unverified information. Unmoderated rumors have not only caused financial losses to trading companies but also panic for the public (Matthews, 2013). Especially if rumors contain multimedia content, the public generally accepts the multimedia information as a "proof of occurrence" of the event (Sencar and Memon, 2009). Readers usually don't have time to look through similar events across different platforms to make an informed judgment. Therefore, even if a credible platform, such as CNN, has debunked a rumor, it can still go viral on other social media platforms.

Intuitively, people believe fake rumors would contain fabricated multimedia content. Boididou et al. (2015b) used forensics features for detecting multimedia fabrication to verify rumors. However, these features did not lead to noticeable improvement. We suspect that this is because un-tampered multimedia content can still convey false information when paired with fake news from a separate event. For example, Figure 1 shows one fake post on MH 370 that used a real video about US Airways Flight 1549. Inspired by the fact that readers tend to search related information covered by different media outlets to garner an objective view, we propose to verify rumors pivoting on multimedia content to tackle such problems. Compared to keywords, searching information pivoting on the visual content is more effective and accurate.

In order to access information from different platforms easily, we created a new rumor verification dataset by expanding a Twitter rumor dataset to include webpages from different social media platforms using search engines. Previous rumor verification datasets are mainly monolingual, such as English (Derczynski et al., 2017) or Chinese (Wu et al., 2015). However, textual information in the native language where the rumor happened can be more helpful when it comes to ver-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3487–3496
Brussels, Belgium, October 31 - November 4, 2018.

ifying worldwide rumors. Therefore, we not only indexed English webpages by searching Google with images but also included Chinese webpages via Baidu.

We next introduced our cross-lingual cross-platform features which capture the similarity and agreement among rumors with posts from different social media. We built an automatic verification model using the proposed features and achieved the state-of-the-art performance on the MediaEval 2015's Verifying Multimedia Use (VMU 2015) dataset (Boididou et al., 2015a) utilizing information from Google.

Collecting and annotating rumors in foreign languages is difficult and time-consuming, especially for languages with low rumor verification labeling. Finding out an automatic way to verify those rumors in an unsupervised way is also meaningful. Since our cross-lingual cross-platform features are adaptable to rumors in different languages, we demonstrated that these features could transfer learned knowledge by training on one language and testing on another. Such cross-lingual adaptation ability is especially useful for predicting rumors that have low annotation resource with available annotated rumors in languages such as English.

We published our code and dataset on GitHub[1].

2 Related work

Previous research has utilized multimedia information for rumor verification in various ways. Zampoglou et al. (2015); Jin et al. (2015); Boididou et al. (2015b) verified rumors by leveraging forensic features which are extracted to ensure the digital images are not tempered (Sencar and Memon, 2009). However, none of these studies found such information useful for rumor verification on a Twitter-based multimedia dataset. Jin et al. (2017) incorporated image features using a pre-trained deep convolutional neural network (Krizhevsky et al., 2012) on the extended Twitter-based multimedia dataset. Although the image features improve their results, their framework cannot outperform methods other than multimodal fusing networks. One possible reason is that the multimedia content in fake rumors is borrowed from another real event and usually their content corresponds to the text of the rumors. In this case, the image itself is real but not real in the context of the fake news. We thus propose to leverage the multimedia information by finding the agreement and disagreement among posts that are from different social media platforms but share similar visual contents.

The agreement between rumors and their comments is used heavily in automatic verification. Mendoza et al. (2010) declared that fake rumors tended to have more people question their validity. Later, Qazvinian et al. (2011) first annotated comments on tweets as supporting, denying or querying, and then used such stance information in the classification to leverage the "wisdom of crowds". Recently, the best performing system (Enayet and El-Beltagy, 2017) in RumourEval shared task at SemEval 2017 (Derczynski et al., 2017) also used such information. However, the crowd is not always wise. For example, Starbird et al. (2014) suspected the correctness of public opinions in rumors, pointing out some certain fake news received more support than questions. In our work, instead of using the "wisdom of crowds", we used the knowledge from different news platforms to assist rumor verification.

Computational journalism (Cohen et al., 2011) exploits external knowledge widely. Diakopoulos et al. (2012) first leveraged information from reliable sources in the context of journalism. They developed a tool for journalists to search for and assess sources in social media around breaking news events. Ciampaglia et al. (2015) utilized factual knowledge bases, such as Wikipedia, to assess the truth of simple statements. Shao et al. (2016) designed a system for tracking rumors on different platforms, which is probably the closest work to ours. However, they did not utilize cross-platform information for rumor verification. Our proposed method is able to leverage information on any platform to verify rumors as long as it has both textual and multimedia information.

3 CCMR dataset

We created a cross-lingual cross-platform multimedia rumor verification dataset (CCMR) to study how to leverage information from different media platforms and different languages to verify rumor automatically. CCMR consists of three sub-datasets: CCMR Twitter, CCMR Google, and CCMR Baidu.

CCMR Twitter is borrowed from VMU 2015 dataset (Boididou et al., 2015a). There are 17

events containing fake and real posts with images or videos shared on Twitter. We created CCMR Google and CCMR Baidu by searching Google and Baidu indexed webpages that share similar multimodal content with CCMR Twitter. The upper part of Figure 2 shows the collection process. We searched Google with every image (URL for video) in CCMR Twitter to get English webpages. Then we indexed those webpages to form CCMR Google. Similarly, we searched Baidu to get Chinese webpages and created CCMR Baidu. Two human annotators manually annotated both datasets. The annotation is for better analysis and dataset quality control. None of it is utilized during our feature extraction process. Annotators were asked to label collected webpages based on their title and multimedia content. If they are not enough to tell fake news from real news, the webpage is labeled as "others". The Cohen's kappa coefficient for two annotators is 0.8891 in CCMR Google and 0.7907 in CCMR Baidu. CCMR has 15,629 tweets indexed by CCMR Twitter (Twitter), 4,625 webpages indexed by CCMR Google (Google) and 2,506 webages indexed by CCMR Baidu (Baidu) related to 17 events. The webpages from Google and Baidu are in English and Chinese respectively. The statistics of the CCMR dataset with respect to each event is listed in Table 1.

3.1 Observation in Annotation

We observe that 15.7% of webpages are fake in CCMR Google while 20.3% in CCMR Baidu. We speculate that this is because all events in CCMR dataset took place outside China. Chinese webpages searched via Baidu are thus more likely to mistake the information. In the manual annotation process, we found that many images are actually borrowed from other events, which confirms our assumption. Another interesting observation is that webpages indexed by Baidu tend to have more exaggerating or misleading titles to attract click rates. We labeled such webpages as fake if they also convey false information through their multimedia content.

We also found that news in different languages has different distributions concerning the subtopics of the event. For example, in the Boston marathon bombing, Baidu indexed Chinese reports generally put more emphasis on a Chinese student who is one of the victims, while Google indexed English reports cover a wider range of subtopics of the event, such as the possible bomber. This phenomenon is understandable as social media from a specific country usually focus more on information related to their readers.

4 Framework Overview

Figure 2 describes the overview of our framework. After collecting CCMR dataset in Section 3, we first performed Twitter rumor verification leveraging Google in Section 6 as shown in the bottom left of the figure. We extracted cross-lingual cross-platform features for tweets in CCMR Twitter leveraging webpages from CCMR Google (TFG). Section 5 discusses the automatic construction of this feature set. We then use the features to verify rumors automatically.

We then performed Twitter rumor verification

Figure 2: The information flow of our proposed pipeline. TFG represents the cross-lingual cross-platform features for tweets leveraging Google information, while TFB is similar but leverages Baidu information instead. BFG means cross-lingual cross-platform features for Baidu leveraging Google information.

leveraging Baidu in Section 7 to test if our method can verify rumors by borrowing information from different languages and platforms. This experiment is meant to demonstrate that our method is language and platform agnostic. Such an advantage also enables our method to use one language information to predict in another language (see the experiment in Section 8). We extracted cross-lingual cross-platform features for tweets leveraging webpages from CCMR Baidu instead (TFB) and used it to verify tweets in Section 6.

In Section 8, we performed Baidu rumor verification via transfer learning to test the cross-lingual adaptation ability of the cross-lingual cross-platform features. We treated Chinese webpages in CCMR Baidu as rumors and empirically verified them via transfer learning. We extracted cross-lingual cross-platform features for Baidu webpages leveraging Google (BFG) in Section 6. Since BFG and TFG are both cross-lingual cross-platform features leveraging Google, we adopted the classifier pre-trained with TFG on CCMR Twitter to verify webpages in CCMR Baidu using BFG, under the assumption that tweets and webpages follow a similar distribution.

Although we labeled webpages in CCMR Google and CCMR Baidu, we did not leverage the annotation here because annotation is time-consuming and using annotation information is not generalizable to other datasets.

5 Cross-lingual Cross-platform Features

We propose a set of cross-lingual cross-platform features to leverage information across different social media platforms. We first embed both the rumor and the titles of the retrieved webpages into 300-dimension vectors with a pre-trained multilingual sentence embedding. It is trained using English-Chinese parallel news and micro-blogs in UM-Corpus (Tian et al., 2014). We encode English-Chinese parallel sentences with the same word dictionary, as they share some tokens such as

URLs and punctuation. We then use a two-layer bidirectional gated recurrent unit (GRU) (Cho et al., 2014) to generate hidden states. We obtain the embedding by averaging the hidden states of the GRU. A pairwise ranking loss is used to force the cosine distance between embeddings of paired sentences to be small and unpaired sentences to be large. We train our multilingual sentence embedding on 453,000 pairs of English-Chinese parallel sentences and evaluated it on another 2000 sentence pairs. Our published code includes the implementation details of the multilingual sentence embedding.

After obtaining the embeddings of the rumor and the titles of the retrieved webpages, we further calculate the distance and agreement features between these embeddings to create a set of cross-lingual cross-platform features. In total, there are 10 features, two for distance features and eight for agreement features.

5.1 Distance Features

We compute the cosine distances between the embeddings of the target rumors and the titles of the retrieved webpages. The distance indicates if the rumor has similar meaning with the retrieved webpages that have similar multimedia content. We calculate the mean and variance of the distance.

The mean of the distance indicates the average similarity between a rumor and its corresponding webpages from other platforms. A high value in mean suggests that the rumor is very different from the retrieved information from other platforms. We suspect that rumors with this property have a higher probability of being fake. Because the rumor might have borrowed the image from another event that was covered in the retrieved information. Meanwhile, the variance indicates how much these retrieved webpages are different from each other. A high variance indicates that the multimedia information is used by different events or is described in different statements. So the event or the statement the rumor covers could be fake.

5.2 Agreement Features

We first pre-train an agreement classifier on a stance detection dataset provided by the Fake News Challenge[2]. This dataset provides pairs of English sentences with their agreement annotations in “agree”, “disagree”, “discuss” and “unrelated”. Figure 3 shows four example body texts of a headline corresponding to each type of annotation in the dataset. During the training process, we embed the sentences in the Fake News Challenge dataset using our pre-trained multilingual sentence embedding. We then concatenate the embeddings of the sentence pair as the input. We use a multi-layer perceptron to pre-train our agreement classifier. We randomly select a balanced development set containing 250 pairs for each label (1000 in total) and train our agreement classifier on the rest of 74,385 pairs. The agreement classifier achieves 0.652 in the macro-averaged F1-score on the development set. Our published code also includes the details.

EXAMPLE HEADLINE

“Robert Plant Ripped up $800M Led Zeppelin Reunion Contract”

EXAMPLE BODY TEXTS

“Led Zeppelin’s Robert Plant turned down £500 MILLION to reform supergroup.”

CORRECT ANNOTATION: **AGREE**

“No, Robert Plant did not rip up an $800 million deal to get Led Zeppelin back together.”

CORRECT ANNOTATION: **DISAGREE**

“Robert Plant reportedly tore up an $800 million Led Zeppelin reunion deal.”

CORRECT ANNOTATION: **DISCUSSES**

“Richard Branson’s Virgin Galactic is set to launch SpaceShipTwo today.”

CORRECT ANNOTATION: **UNRELATED**

Figure 3: An example headline and its body texts of the Fake News Challenge dataset.

We calculate the agreement features using the mean and variance of the prediction probability between the rumor and all the retrieved webpages. There are in total four agreement labels. Therefore, we have eight agreement features in total. Agreement features capture information about if the rumor’s statement agrees with the corresponding information in other platforms. Besides being able to gain similar benefits as distance features, our agreement features also capture the case that the information stance is portrayed differently by different resource rumors. Conflicting information will also be an indicator of fake news.

6 Rumor Verification Leveraging Cross-platform Information

We extracted cross-lingual cross-platform features for tweets in CCMR Twitter leveraging Google (TFG) and evaluated the effectiveness of TFG on rumor verification tasks.

We proposed a simple multi-layer perceptron classifier (MLP) to leverage the extracted features. MLP has two fully-connected hidden layers of 20 neurons with ReLU as the activation function. Each layer is followed by a dropout of 0.5. We evaluated TFG in two settings: *task* and *event*. 1) The *task* setting used event 1-11 for training and event 12-17 for testing according to (Boididou et al., 2015a). 2) The *event* setting evaluated the model performance on a leave-one-event-out cross-validation fashion. F1-score is used for evaluation metric. Since both collecting source rumors from Google and doing feature extraction for a given tweet can be done automatically, it is fair to compare the performance of our model with baselines described below.

6.1 Baselines

We adopted three best performing models in the VMU 2015 task as our baselines:

UoS-ITI (UoS) (Middleton, 2015) uses a natural language processing pipeline to verify tweets. It is a rule-based regular expression pattern matching method. It ranks evidence from Twitter according to the most trusted and credible sources.

MCG-ICT (MCG) (Jin et al., 2015) is an approach including two levels of classification. It treats each image or video in the dataset as a topic and uses the credibility of these topics as a new feature for the tweets. They used the tweet-based and user-based features (Base), such as the number of hashtags in the tweet or the number of friends of the user who posted the tweet.

CERTH-UNITN (CER) (Boididou et al., 2015b) uses an agreement-based retraining scheme. It takes advantage of its own predictions to combine two classifiers built from tweet-based and user-based features (Base). Besides features provided by the task, it included some additional features such as the number of nouns in tweets and trust scores of URLs in tweets obtained from third-party APIs.

Method	F1-Task	F1-Event
UoS-ITI	0.830	0.224
MCG-ICT	**0.942**	0.756
CERTH-UNITN	0.911	0.693
TFG	0.908	**0.822**
BFG	0.810	0.739
Combo	0.899	0.816

Table 2: The *task* and *event* settings performance.

ID	UoS	MCG	CER	TFG	TFB
01	0.658	0.594	**0.718**	0.715	0.704
02	0.007	0.494	**0.745**	0.557	0.448
03	0.057	0.882	0.595	**0.956**	0.822
04	0.538	0.826	0.717	**0.856**	0.678
05	0.000	**0.988**	0.947	0.969	0.956
06	0.555	0.949	0.916	0.912	**1.000**
07	0.000	**1.000**	0.475	0.989	0.989
08	0.000	0.870	**1.000**	0.960	**1.000**
09	0.000	0.772	0.996	**1.000**	0.996
10	0.000	0.615	0.821	**0.875**	-
11	0.000	**0.963**	0.000	**0.963**	0.667
12	0.000	0.655	**0.754**	0.677	0.656
13	0.000	0.954	0.795	**0.998**	0.850
14	0.000	0.330	0.419	0.409	**0.430**
15	0.000	0.130	**0.156**	0.145	0.154
16	**1.000**	0.990	0.999	0.996	-
17	**1.000**	0.827	**1.000**	0.992	-
Avg	0.224	0.756	0.693	**0.822**	0.739

Table 3: F1-scores for each event.

6.2 Results

We describe the *task* setting results in Table 2, and detailed per-event results in Table 3. Although TFG does not achieve the highest F1-score in the *task* setting, it is mainly due to the split of the dataset. More than half of the tweets in the test set do not have images. Thus we can only leverage cross-platform information by searching videos' URLs, which results in less accurate cross-lingual cross-platform features. In the *event* setting, which has a more fair comparison, TFG outperformed other methods with a big margin ($p<0.001$). It is surprising to see that only 10 features extracted from external resources indexed by search engines leveraged by a simple classifier can bring such a big performance boost.

To further explore the quality of the cross-lingual cross-platform features, we calculated the Pearson correlation coefficient (PCC) between each feature with respect to the tweet's label (fake or real). We evaluated both TFG and features used by baseline models. Table 4 lists the top six features with the highest absolute PCC values. A positive value indicates this feature positively correlates with fake news. We can see four out of the top six features are cross-lingual cross-platform features. The variance of the unrelated probability (unrelated variance) has the highest score, which further validates our design intuition that tweets might convey false information when they have different agreement with all other webpages that shared similar multimedia content. The second feature, "distance var" is also highly correlated with fake news. This result supports our hypothesis that if there is a large information dissimilarity across different platforms, there is a high probability of fake information involved. The only feature from baselines (56 features in total) in the top six features is whether a tweet contains an exclamation mark or not (containsExclaimationMark).

Feature	PCC
unrelated variance	0.306
distance variance	0.286
agree variance	0.280
discuss mean	-0.231
unrelated mean	0.210
containsExclamationMark	0.192

Table 4: Top six features correlated with fake news.

6.3 Analysis

We found that Google webpages usually cover a complete set of different information. There are usually both fake news and real news that debunk these fake ones. As a result, there is a big information variance among all those webpages' titles, which is captured by the cross-lingual cross-platform features. Therefore, TFG performs much better than baselines in a number of events, such as Event 03 (Sochi Olympics). The statistics of the CCMR dataset, described in Table 1, also supports our observation that the labels of posts in CCMR Google are distributed more evenly compared to other media sources.

However, the F1-score of TFG is very low in Event 15 (Garissa Attack). Gunmen stormed the Garissa University College in this event. We analyzed the Google webpages' titles that share the same image in this event. Although some titles are related to the event, more of them are talking about completely unrelated information such as "Daily Graphic News Sun 20th Oct, 2013 — GhHeadlines Total News ...". This webpage's title only shows its published date and the name of the website. Such noise hurt the performance of the cross-lingual cross-platform features. Since we did not perform any manual labeling or filtering, sometimes the crawled webpages can be misleading. To analyze the prevalence of such noise, we randomly picked 100 Google webpages and 100 Baidu webpages from CCMR and counted the number of noisy posts. The ratio of noise is 22% in Google and 18% in Baidu. However, even with such noise, our proposed methods can still outperform current state-of-the-art methods.

7 Rumor Verification Leveraging Cross-lingual Information

We tested if our cross-lingual cross-platform features are able to leverage external information from another language for rumor verification. We simply replaced the Google webpages with Baidu webpages to extract features for tweets (TFB), because we have a pre-trained multilingual sentence embedding that can project Chinese and English to a shared embedding space. We used the same classifier, MLP to evaluate the performance of TFB with both baselines and TFG.

7.1 Results

Experiment results using the *task* setting are shown in Table 2 and the detailed per-event results are listed in Table 3. Similar to the problem in TFG, we can not obtain any Chinese webpages related to events such as Syrian boy, Varoufakis and zdf, which cover most tweets in the test set. Those missing features make TFB perform poorly in the *task* setting. However, TFB performs better than two of the baselines in the *event* setting. If we exclude events without Baidu webpages (event 10, 16 and 17), the average F1-score of UoS, MCG and CER are 0.130, 0.732 and 0.660, which are all lower than TFB's. The performance of TFB proves that our method can be generalized across languages or platforms.

To further test the robustness of our cross-lingual cross-platform features, we also examined if it would still work when leveraging external information that contains different languages. We extracted the cross-lingual cross-platform features for tweets leveraging Google and Baidu webpages together (Combo) and accessed the performance of Combo using MLP similarly. The performance of Combo is also listed in Table 2. Since Combo would contain noise introduced from combining webpages indexed by different search engines, it is not surprising that Combo performs slightly worse than TFG extracted from Google webpages which already cover a wide range of information solely. However, Combo performs much better than TFB which only leverages Baidu webpages. It proves that our cross-lingual cross-platform features are robust enough to utilize combined external information from different languages and platforms.

7.2 Analysis

We checked the actual titles of webpages from CCMR in certain events to analyze the reason for TFB's worse performance exhaustively. We found that those Baidu webpages' titles often talk about subtopics different from the target rumor's on Twitter, while Google webpages are more related. For example, the F1-score of TFB is much lower than TFG's in event 02 (Boston Marathon bombing). This performance corresponds to our observation in Section 3 that Baidu webpages mainly focus on a subtopic related to the Chinese student instead of other things discussed on Twitter.

8 Low-resource Rumor Verification via Transfer Learning

We extracted cross-lingual cross-platform features of webpages in CCMR Baidu leveraging information from Google (BFG). Then we applied Transfer, MLP in Section 6 trained on the whole CCMR Twitter using TFG, to verify those webpages. Because this pre-trained model is for binary classification, only webpages labeled as real or fake in CCMR Baidu are involved.

Since webpages in CCMR Baidu do not share the same features with tweets, such as the number of likes and retweets, we adopted a random selection model as our baseline. It would predict a rumor as real or fake with the same probability. We compared the performance of the Transfer model with this baseline on each event. F1-score is also used for evaluation metric.

8.1 Results

Table 5 lists the detailed results of our transfer learning experiment. We achieved much better performance compared to the baseline with statistical significance ($p<0.001$), which indicates that our cross-lingual cross-platform feature set can be generalized to rumors in different languages. It enables the trained classifier to leverage the information learned from one language to another.

ID	Event	Random	Transfer
01	Hurricane Sandy	0.247	**0.287**
02	Boston Marathon bombing	0.230	**0.284**
03	Sochi Olympics	0.555	**0.752**
04	MH flight 370	0.407	**0.536**
05	Bring Back Our Girls	0.500	**0.923**
06	Columbian Chemicals	0.000	**0.100**
07	Passport hoax	0.000	0.000
08	Rock Elephant	0.000	**0.500**
09	Underwater bedroom	0.577	**0.972**

13	Girl with Samurai boots	0.559	**0.925**
14	Nepal Earthquake	**0.227**	0.211
15	Garissa Attack	**0.125**	0.059
16	Syrian boy	-	-
17	Varoufakis and zdf	-	-
	Avg	0.312	**0.531**

Table 5: Rumor verification performance on the CCMR Baidu, where - indicates there is no webpage in that event.

8.2 Analysis

In event 11 (Pig fish), Transfer achieves much higher performance than the random baseline. Generally, Baidu webpages' titles are semantically different from tweets. However, in this particular event, the textual information of those titles and tweets are semantically close. As a result, models learned from English rumors can easily work on Chinese rumors, which is helpful for our transfer learning. Figure 4 shows three Twitter-Baidu rumor pairs with similar meaning in this event.

Transfer obtains pretty low F1-scores in event 07 (Passport hoax). The annotation conflict caused its weak performance. This event is about a Child drew all over his dads passport and made his dad stuck in South Korea. During the manual annotation process, we found out that it is a real event confirmed by official accounts according to one news article from Chinese social media[3], while CCMR Twitter labeled such tweets as fake. Since Transfer is pre-trained using Twitter dataset, it is not surprising that Transfer achieves 0 in F1-score on this event. The annotation conflict also brings out that rumor verification will benefit from utilizing cross-lingual and cross-platform information.

9 Conclusion

We created a new multimedia rumor verification dataset by extending a multimedia Twitter dataset with external webpages from Google and Baidu that share similar image content. We designed a set of cross-lingual cross-platform features that leverage the similarity and agreement between information across different platforms and languages to verify rumors. The proposed features are compact and generalizable across languages. We also designed a neural network based model that utilizes the cross-lingual cross-platform features and achieved state-of-the-art results in automatic rumor verification.

Extractive Adversarial Networks: High-Recall Explanations for Identifying Personal Attacks in Social Media Posts

Abstract

We introduce an adversarial method for producing high-recall explanations of neural text classifier decisions. Building on an existing architecture for extractive explanations via hard attention, we add an adversarial layer which scans the residual of the attention for remaining predictive signal. Motivated by the important domain of detecting personal attacks in social media comments, we additionally demonstrate the importance of manually setting a semantically appropriate "default" behavior for the model by explicitly manipulating its bias term. We develop a validation set of human-annotated personal attacks to evaluate the impact of these changes.

1 Introduction

The task of explaining classifier decisions has recently attracted increased attention from the research community. It is important for several reasons, including: 1) The increasing performance gap between simple-and-interpretable models and complex-but-opaque models (which demand more sophisticated explanation techniques); 2) The increasing ubiquity of machine learning in business and government and the concomitant need to understand the decisions of models in high-stakes situations; and 3) A rising awareness of the limitations of machine learning and the need for ways to better utilize intrinsically unreliable models (whose weaknesses can potentially be ameliorated by good explanations).

A common way to explain why a model classified an example a certain way is to extract a sparse subset of features that were responsible for the model's decision, sometimes described as a saliency mask or "rationale" in the case of text (Guidotti et al., 2018). This type of local explanation may not completely elucidate why a given example is assigned a given outcome, but it does simplify the relationship by identifying what attributes were considered in the decision.

Existing work on this topic has not explicitly addressed the problem of local feature redundancy. That is, when two features are equally predictive of an outcome, which of them should be included in the saliency mask for that decision? Typical sparsity constraints encourage minimal sufficient masks–unveiling just enough of the example to justify the outcome.

There are domains, however, where it may be important to produce complete explanations rather than minimal explanations. One example is the task of detecting content in online social media that violates a platform's policies. Explanatory models can potentially help human moderators make quicker and more consistent decisions about whether to remove comments (Lakkaraju et al., 2016). However, we propose that truly minimal explanations are liable to give only a partial portrait of why a comment is objectionable, making it harder to render a fair holistic decision. If used to explain to a poster why their post was removed, a minimal explanation can actually be misleading, by implying that some of what was objectionable about their post was benign just because it didn't add marginal signal to the overall classification.

We use an extractive explanatory neural network to identify which social media comments contain personal attacks and which words in those comments are the basis for classifying them as containing personal attacks. We train this model on a large dataset (Wulczyn et al., 2017) of comments labeled for the presence of such attacks, and use the explanatory capacity of the model to identify spans that constitute personal attacks within those comments. We extend the work of (Lei et al., 2016) in using one recurrent neural net (RNN) to produce an explanatory hard-attention rationale

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3497–3507

Figure 1: An example of a highly-attacking comment from the test set, rationalized by the model

and a second RNN to make a prediction, the two models trained in an end-to-end fashion.

To produce complete (i.e high-recall) explanations, we add to this existing architecture a second, adversarial predictive layer whose purpose is to try to make predictions based on what is left out of the rationale. We then add a term to the attention layer objective function which encourages it to fool this secondary predictive layer into making poor predictions by including all predictive signal (i.e personal attacks) in the mask that it generates.

We also show that manipulating the model bias term to set a semantically appropriate "default behavior" or "null hypothesis" for the model significantly improves performance. That is, by explicitly choosing what output a zero-information, empty explanation should correspond to, the model is able to learn explanations that correspond more closely with human-generated data.

To summarize, the contributions of this paper are as follows:

- We articulate explanation as an adversarial problem and introduce an adversarial scheme for extraction of complete (high-recall) explanations for text classifier decisions.

- We demonstrate the value of explicitly setting a default output value in such an explanatory model via bias term manipulation.

- We apply explanatory machine learning for the first time to the task of detecting personal attacks in social media comments, and develop a validation dataset for this purpose.

2 Related work

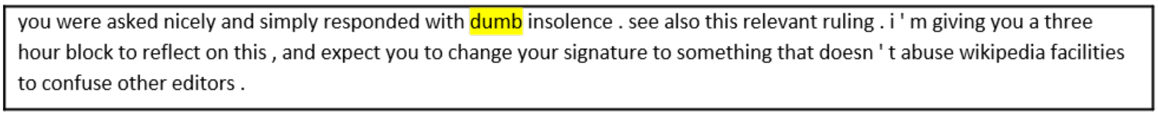
2.1 Online abuse

Online abuse (of which personal attacks are a major dimension) has recently attracted increased attention as a computational problem. Scholarly work has assessed the prevalence and impact of such abuse (Lenhart et al., 2016; Anderson et al., 2014; Pew, 2016; Anderson et al., 2016), while several initiatives have sought to construct datasets for its study (Wulczyn et al., 2017; Abbott et al., 2016; Kennedy et al., 2017; Napoles et al., 2017; Golbeck et al., 2017).

Naturally, much recent work has gone into the use of machine learning to detect online abuse and its perpetrators (Nobata et al., 2016; Pavlopoulos et al., 2017; Cheng et al., 2015), including a workshop at the most recent ACL conference (Association for Computational Linguistics, 2017). However, the idea of fully-automated moderation by machine learning has attracted criticism as being subject to bias, inaccuracy, manipulation and frustration on the user end (Pavlopoulos et al., 2017; Binns et al., 2017; Blackwell et al., 2018; Hosseini et al., 2017; Adams and Dixon, 2017). We propose interpretable models as one potential solution to some of these problems.

2.2 Interpretable machine learning

Major points of division in the interpretability literature include: 1) local vs. global interpretability; 2) post-hoc vs. built-in interpretability; 3) explanation type; 4) input data type; and 5) evaluation metric. Our model is a built-in, feature-based locally interpretable model for text that we evaluate



you were asked nicely and simply responded with dumb insolence . see also this relevant ruling . i ' m giving you a three hour block to reflect on this , and expect you to change your signature to something that doesn ' t abuse wikipedia facilities to confuse other editors .

Figure 2: An example of a not-very-attacking example from the test set, rationalized by the model

relative to a human gold-standard. Guidotti et al. (2018) provides a recent survey of the field.

Recent work on interpretability has focused on local (i.e. instancewise) feature-based explanations. Attention models implicitly produce this type of explanation in the form of attention weights over input features. Lei et al. (2016) utilizes a regularized hard attention mechanism to identify the locally minimum sufficient subset of tokens to make accurate predictions.

Post-hoc methods seek to retroactively probe the behavior of an existing non-explanatory model. These include model-specific gradient-based attribution methods, pioneered by Simonyan et al. (2013) and reviewed recently by Ancona et al. (2017), which have tended to originate in the image classification domain and transfer to other domains such as text (e.g. Arras et al. (2017)). Conversely, LIME (Ribeiro et al., 2016) is a prominent recent model-agnostic work in this space, building local linear approximations of a model and using the coefficients thereof to explain its behavior. Li et al. (2016) trains a hard attention layer to flip the decisions of an existing model.

While feature-based explanations are the most common approach, other forms have been proposed, including: similarity to learned "prototypes" which represent clusters of items from the training data (Li et al., 2017); high-precision feature interaction rules (Ribeiro et al., 2018); reference to predefined human-friendly concepts (Kim et al., 2017); and generated natural language (Ehsan et al., 2017). Likewise, many evaluation criteria have been proposed. These include fully automated evaluation (Arras et al., 2017); comparison to human gold standards (Lei et al., 2016); and human task performance (Nguyen, 2018). Doshi-Velez and Kim (2017) and Gilpin et al. (2018) both present reviews and taxonomies of evaluation types.

2.3 Adversarial learning

Generative Adversarial Networks (Goodfellow et al., 2014) involve the use of a discriminative model to help a generative model match its output to an existing data distribution via an adversarial minimax game. Such models have achieved good results on various generative tasks such as image synthesis (Zhang et al., 2018) and text generation (Yu et al., 2016). Recently, adversarial schemes have begun to be adapted for non-strictly-generative tasks such as fake review detection (Aghakhani et al., 2018), improving the robustness of predictive models to adversarial attacks (Zhao et al., 2017) and image retrieval (Song, 2017).

Ideas similar to the adversarial scheme used in this paper have come not from interpretability but rather from weakly-supervised object localization. Wei et al. (2017) uses a similar scheme to accomplish more complete detection of object shapes in images by iteratively erasing the regions that a predictive model lends the most attention, and forcing it to adjust to the occluded image. Edwards and Storkey (2016) is also similar, using an autoencoder rather than a masking layer to remove identifying information from images.

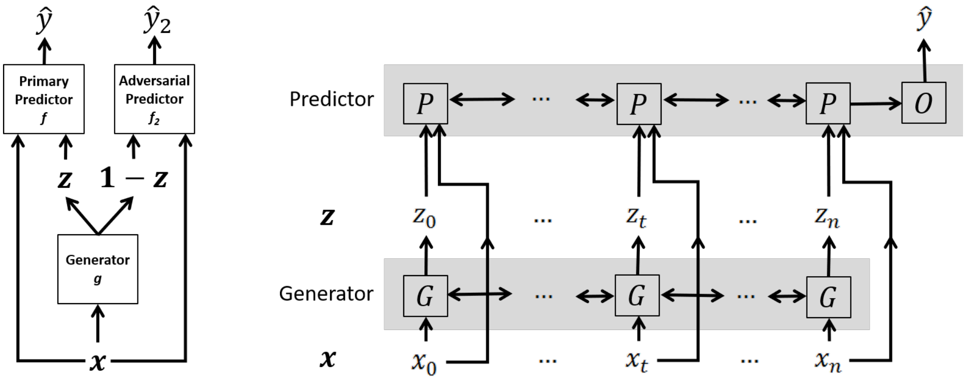
3 Model

The goal of our architecture is to highlight personal attacks in text when such are present, and to highlight little or nothing when there are none, while also performing accurate overall prediction.

These requirements prompt two important edge cases: first, there may be no particular predictive signal in the comment text (i.e. no personal attacks); in a more typical explanatory setting there is always assumed to be some explanation for a decision. Second, there may be redundant signal (i.e. multiple personal attacks), more than is strictly required for accurate prediction, and we assume that it is desirable to identify all of it. We address both of these cases with modifications to the original model architecture.

The model (Figure 3A) is a hard attention architecture which uses one RNN to extract an attention mask of either 0 or 1 for each token, and a different RNN to make a prediction from the attention-masked text (detailed in Figure 3B). Following (Lei et al., 2016), we refer to the mask-producing layer g as the *generator*, but for clarity we call the predictive layer f the *predictor* rather than the encoder. Again following previous work, we refer to the output z of the generator as the *rationale*, in that it rationalizes the prediction of the predictor. We also refer to the inverse rationale, defined as 1-z , as the *antirationale*.

To this basic two-layer scheme, we add a secondary, adversarial predictor f_2, which views the text masked by the antirationale rather than the rationale. The secondary predictor's role is to act as an adversarial discriminator–it tries to make accurate predictions on the antirationale, while the



(A) **(B)**

Figure 3: (A) Overall architecture. Generator and predictors are RNNs; (B) Detail of interaction between generator and one predictor layer. G and P are recurrent units of any kind. O is a sigmoid output layer.

generator tries to prevent it from doing so, which ensures that all predictive signal ends up in the rationale.

3.1 Primary predictor

The primary predictor f is an RNN which views the input text masked by the rationale produced by the generator. Its objective is simply to reduce its own squared loss:

$$cost_f(z, x, y) = \left[f(x, z) - y\right]^2 \tag{1}$$

3.1.1 Default behavior via predictor bias term manipulation

The default behavior of the model is the prediction the predictor makes if the input is entirely masked by the rationale: $f(x, 0)$. When working with a recurrent unit that has no internal bias term, this behavior is entirely determined by the bias term of the final sigmoid output layer, $\sigma(wx + b)$, which with typical random initialization of b results in a default predicted value of roughly 0.5.

However, this 0.5 default value is not always optimal or semantically appropriate to the predictive task. In the personal attack detection task, if no attacks can be detected, the “natural” default target value for a text should be close to 0. We show in the experiments that manually setting the output layer bias term b to $logit(0.05) = -2.94$, so that the default predicted value is 0.05, improves model performance.

3.2 Secondary adversarial predictor

The secondary adversarial predictor is an RNN which views the input text masked by the antirationale, defined as 1 minus the rationale z. Its purpose is to encourage high-recall explanations by trying to make accurate predictions from the antirationale, while the generator tries to prevent it from doing so.

However, if the adversarial predictor’s objective function were simply $\left[f_2(x, 1 - z) - y\right]^2$, it would be able to gain an unfair advantage from the presence of masking in the antirationale. Seeing evidence of ”blanked-out” tokens would tell it that personal attacks were present in that comment, giving it strong hint that the target value is close to 1.0 and vice-versa (see figure 4A).

To take away this advantage, the input to the adversarial predictor has to be permuted such that the mask itself is no longer correlated with the target value, while still allowing it to scan the antirationale for residual predictive signal.

Our solution is to replace the masks of half the items in a training batch with the masks of other items in the batch. We order the batch by target value. If item x_i is selected for replacement, it gets the mask of item x_{N-i} where N is the size of the batch. We call this permutation function c:

$$c(z_i) = c(g(x_i)) = \begin{cases} g(x_i) & \text{if } k_i = 1 \\ g(x_{N-i}) & \text{if } k_i = 0 \end{cases}$$

$$x_i \in \{x_0, ..., x_N\} \qquad k_i \sim Bernoulli(0.5)$$

This ensures that low-target-value items get masks associated with high target values and vice-versa, to maximize the dissociation between masks and target values. Figure 4B demonstrates an example of such permutation. This may slow down the learning, since the adversarial predictor

Figure 4: (A) Fabricated sample batch masked by antirationales. Note the correlation between mask and target; (B) The batch with some antirationales switched with those of other items. The correlation no longer holds.

will sometimes have access to somewhat different features of the input than it will have on the test data, but it should not lead to incorrect learning, since the training data always has the correct label, regardless of the mask.

With $c(1-z)$ as the permuted antirationale resulting from applying this randomization process. The objective for the secondary, adversarial predictor is its predictive accuracy on this permuted antirationale:

$$cost_{f_2}(z,x,y) = \left[f_2(x, c(1-z)) - y\right]^2 \qquad (2)$$

3.3 Generator

Given that the two predictors are trying to minimize error on the rationale and (permuted) antirationale respectively, the objective function for the generator is as follows:

$$\begin{aligned} &cost_g(z,x,y) = && (3)\\ &\quad \left[f(x,z) - y\right]^2 && (3.1)\\ &\quad +\lambda_1 \|z\| && (3.2)\\ &\quad +\lambda_1\lambda_2 \sum_t |z_t - z_{t-1}| && (3.3)\\ &\quad +\lambda_3 \left[f_2(x, 1-z) - f_2(x, 0)\right]^2 && (3.4)\end{aligned}$$

Terms 3.1-3.3 are present in the model of Lei et al. Term 3.1 encourages the generator to allow the primary predictor to make accurate predictions, prevents it from obscuring any tokens that would prevent the predictor from doing so. Term 3.2 encourages the generator to produce minimal rationales; obscuring as many tokens as possible. Term 3.3 encourages rationale coherence by punishing the number of transitions in the rationale; it encourages few contiguous phrases rather than many fragments in the rationale.

In theory, these three terms ensure high precision, selecting the minimal (term 3.2) rationale with sufficient signal for accurate prediction (term 3.1), subject to a coherence constraint (term 3.3).

Term 3.4, which is new, ensures recall by encouraging the adversarial predictor's prediction on the antirationale to be similar to the prediction it would make with no information at all (aka the default value). That is, **the antirationale should contain no predictive signal**. Any personal attacks left out of the rationale would appear in the antirationale, letting the adversarial predictor make a more accurate prediction, which would be penalized by term 3.4.

3.4 Extractive Adversarial Network

In the GAN framework (Goodfellow et al., 2014), a discriminator attempts to accurately classify synthetic examples which a generator is striving to match to the distribution of the true data. In our framework, the adversarial predictor attempts to accurately classify censored examples which the generator is striving to strip of all predictive signal. The discriminator in the GAN framework is trained half on real data, and half on fakes; our adversarial predictor is trained half on correctly-masked items and half on items with permuted masks. Where our framework differs from GAN is instead of generating adversarial examples which are compared to true examples, our architecture extracts a modified example out of an existing example, and so can therefore be described as an Extractive Adversarial Network (EAN).

3.5 Implementation details

For comparability with the original algorithm, we use the same recurrent unit (RCNN) and

REINFORCE-style policy gradient optimization process (Williams, 1992) as Lei et al. (2016) to force the generator outputs to be a discrete 0 or 1. In this framework, the continuous output of the generator on each token is treated as a probability from which the mask is then sampled to produce a discrete value for each token. The gradient across this discontinuity is approximated as:

$$\frac{\partial \mathrm{E}_{z\sim g(x)}[cost_g(z,x,y)]}{\partial\theta_g}$$
$$= \mathrm{E}_{z\sim g(x)}\left[cost_g(z,x,y)\frac{\partial \log p(z|x)}{\partial\theta_g}\right]$$

In theory, one would sample z several times from the generator g to produce a good estimate of the gradient. In practice, we find that a single sample per epoch is sufficient. The predictors f and f_2 are trained as normal, as the error gradient with respect to their parameters is smooth.

We employ a particular hard attention model, but the idea of an adversarial critic is not limited to either hard attention or any particular recurrent unit. In a soft attention setting, our adversarial scheme will actually encourage "harder" attention by encouraging any non-zero attention weight to go to 1.0 (or else the inverse of that weight will leave predictive signal in the anti-explanation).

The attention weights produced by the generator are applied to the predictor at the output rather than the input level. When the recurrent unit P of the predictor operates on a token x_t modified by attention weight z_t, it ingests x_t normally, but depending on z_t it either produces its own output or forwards that of the previous token:

$$P(x_t, z_t) = z_t P_{base}(x_t) \cdot (1 - z_t) P_{base}(x_{t-1})$$

We investigate a similar range of sparsity hyperparameter values as the original model [1]. The weight on the inverse term only matters relative to the model sparsity, as that term cooperates rather than competing with the predictive accuracy term (because it almost never hurts accuracy to add more to the rationale). Therefore we set λ_3 to 1.0 when we want to include the inverse term.

We use Word2Vec (Mikolov et al., 2013) to create input token word vectors and Adam (Kingma and Ba, 2014) for optimization.

4 Data

To train our model of personal attacks, we use the dataset introduced by (Wulczyn et al., 2017), which consists of roughly 100,000 Wikipedia revision comments labeled via crowsourcing for aggression, toxicity and the presence of personal attacks. This dataset includes its own training, development and test set split, which we also use.

To this dataset we add a small validation set of personal attack rationales. 40 undergraduate students used Brat (Stenetorp et al., 2012) to highlight sections of comments that they considered to constitute personal attacks. Comments were sampled in a stratified manner from the development and test sets of the Wulczyn et al. dataset, and each student annotated roughly 150 comments, with each comment viewed by roughly 4 annotators. To calculate gold-standard rationales, we take the majority vote among annotators for each token in each comment. 1089 distinct comments were annotated, split between a development and test set of 549 and 540 examples respectively.

The Krippendorff's alpha on our validation set is 0.53 at the whole-comment level. This value is comparable with that of Wulczyn et al. (2017) (0.45). Agreement at the token level is a lower 0.41, because this includes tokens which are a matter of preference among annotators, such as articles and adverbs, as well as content tokens.

5 Experiments

We show that both modifications to the original algorithm, bias term manipulation and inverse term, increase the tokenwise F1 of the predicted rationales relative to our human-annotated test set. All hyperparameters were tuned to maximize tokenwise F1 on the development set. [2]

5.1 Baselines

We generate six baselines for comparison with our variant of the (Lei et al., 2016) architecture. These include the following:

Sigmoid predictor (logistic regression): Bag-of-words representation with a sigmoid output layer.

RNN predictor: The same sequence model used for the predictor, but with no generator layer.

Mean human performance: The mean tokenwise performance of human annotators measured

Lei2016 + bias + inverse (EAN)	**0.53**	0.48	**0.58**	0.61	0.47	0.87	0.021	0.95	0.77

Table 1: Rationale performance relative to human annotations. Prediction accuracy is based on a binary threshold of 0.5. Performance of both Lei2016 model variants is significantly different from the baseline model (McNemar's test, $p < 0.05$)

against the majority vote for the comments they annotated (with their vote left out).

Sigmoid predictor + feature importance: Bag-of-words representation with sigmoid output layer, with post-hoc feature importance based on model coefficients. Cutoff threshold for features tuned to maximize rationale F1 on development set.

RNN predictor + sigmoid generator: Rationale mask generated by sigmoid layer applied independently to each input token. Prediction layer is same as predictor.

RNN predictor + LIME: Rationale mask generated by applying LIME (Ribeiro et al., 2016) post-hoc to RNN layer predictions. Masking threshold tuned to maximize rationale F1.

5.2 Rationale performance

In the main experiment, we evaluate model rationales relative to rationales created by human annotators. In our validation dataset, human annotators typically chose to annotate personal attacks at the phrase level; hence in the sentence "Get a job, you hippie s***bag", the majority-vote rationale consists of the entire sentence, where it could arguably consist of the last two or even the last word. Therefore, in addition to tokenwise precision, recall and positive F1, we also report a relaxed "phrasewise" version of these metrics where any time we capture part of a contiguous rationale chunk, that is considered a true positive.

We report results for the original model (i.e. terms 3.1-3.3 in the objective function), the original model with its bias term set for a default value of 0.05, and the bias-modified model with the additional inverse term (term 3.4). For every model variant, we optimized hyperparameters for tokenwise F1 on the development set. We also report results for the baselines described above.

Table 1 displays the results. The difference in performance between the three baselines that don't use a RNN generator and the three model variants that do demonstrates the importance of context in recognizing personal attacks within text. The relative performance of the three variants of the Lei et al. model show that both modifications, setting the bias term and the addition of the adversarial predictor, lead to marginal improvements in tokenwise F1. The best-performing model approaches average human performance on this metric.

The phrasewise metric is relaxed. It allows a contiguous personal attack sequence to be considered captured if even a single token from the sequence is captured. The results on this metric show that in an absolute sense, 87% of personal attacks are at least partially captured by the algorithm. The simplest baseline, which produces rationales by thresholding the coefficients of a logistic regression model, does deceptively well on this metric by only identifying attacking words like "jerk" and "a**hole", but its poor tokenwise performance shows that it doesn't mimic human highlighting very well.

5.3 Original model tokenwise recall

A perplexing result of the rationale performance comparison is how good the tokenwise recall of the model is *without* the inverse term. Without it, the model is encouraged to find the minimal rationale which offers good predictive performance. Comments with more than one personal attack

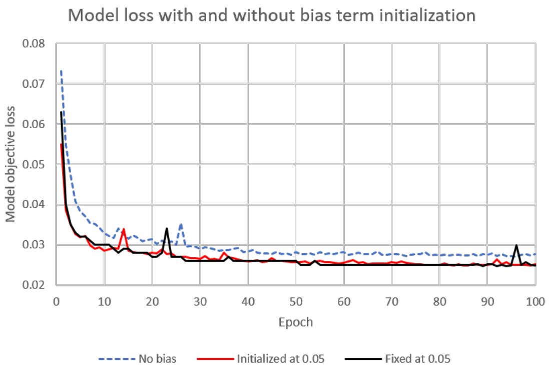

Figure 5: Evolution of model loss over time with and without bias term manipulation

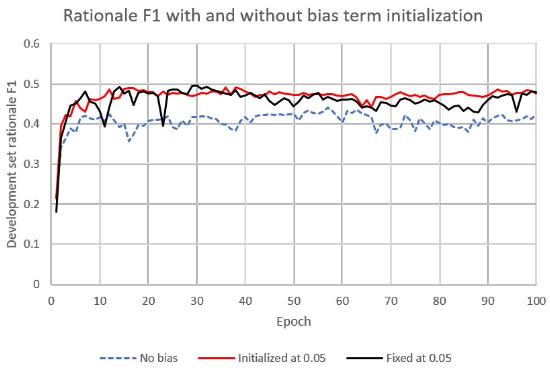

Figure 6: Evolution of development set rationale F1 score over time with and without bias term manipulation

(e.g. Figure 1) constitute 29% of those with at least one attack and 13% of all comments in our validation set. For comments like these, the model should in theory only identify one such attack. However, it tends to find more information than needed, leading to a higher-than-expected recall of .52 in the best overall version of this variant.

To explain this behavior, we run a leave-one-out experiment on the original+bias and original+bias+inverse model variants. For each distinct contiguous rationale chunk predicted by each model (when it generates multi-piece rationales), we try removing this chunk from the predicted rationale, running the prediction layer on the reduced rationale, and seeing whether the result lowers the value of the overall objective function.

For the original+bias model variant, we find that performing this reduction improves the value of the objective function 65% of the time. However, the combined average impact of these reductions on the objective function is to worsen it. What this means is while 65% of distinct phrases discovered by the generator are unnecessary for accurate prediction, the 35% of them that are necessary lead to a major decrease in predictive accuracy.

That is, the generator "hedges its bets" with respect to predictive accuracy by including more information in the rationales than it has to, and experiences a better global optimum as a result. This behavior is less prominent with the inclusion of the inverse term, where the percentage of unnecessary rationale phrases falls to 47%.

5.4 Impact of bias term manipulation

In theory, the model should learn a good bias term for the predictor layer, and therefore the idea of explicitly initializing or fixing the bias term to match the semantics of the task should not impact model performance or represent much of a contribution.

In practice however, as figures 5 and 6 demonstrate, the initialization of the bias term has a big impact on even the long-term learning behavior of the model. Using the best hyperparameters for the original no-bias, no-inverse-term model, figure 5 shows that either initializing or permanently fixing the predictor bias for a default output value of 0.05 leads to improved model loss with respect to its own objective function. Figure 6 shows a similar pattern for tokenwise F1 score.

6 Discussion and future work

One interpretation of the impact of the bias term on model behavior is that an explanation of "why" is really an explanation of "why not"–that is, an explanation is information that distinguishes an item from some alternative hypothesis, and explicitly choosing what this alternative is can improve explanation performance (particularly precision).

Manually setting the model to produce some reasonable default value for an empty rationale makes sense in our setting, but not in domains where there is no default value, such as the beer review dataset of (Lei et al., 2016). A more general approach would be to base explanations on confidence rather than accuracy, where the default value would simply be the mean and variance of the training data, and explanations would consist of tokens that tighten the bounds on the output.

A surprising finding is that the original algorithm often ends up defying its own objective and finds more complete rationales than needed. The leave-one-out experiment described above suggests that the reason for this behavior is that it

Figure 7: Further examples of labeled and rationalized comments. Items E) and G) show that the algorithm struggles with sarcasm.

is how the generator deals with predictive uncertainty, and that it achieves a better global optimum by producing locally suboptimal rationales.

While this "bug" proves useful in our case, it may not generalize. In our setting the adversarial predictor gives a modest improvement in recall; it will produce a larger improvement in settings where the unaltered algorithm is more successful at producing the minimal explanations described by its objective function. Li et al. (2016) finds that a memory network predictor requires less occlusion than an LSTM to flip its predictions, indicating that choice of model can effect completeness of explanations.

In theory, interpretable models can aid human moderaters by pointing them directly at the potentially objectionable content in a comment and giving them a starting point for making their own holistic decision about the comment. However, there are potential pitfalls. Adding explanations as a model output gives the model another way to be wrong–one which humans may be even less able to troubleshoot than simple misclassification. Relatedly, explanations may inspire overconfidence in model predictions. Extensive user testing would clearly be needed before any deployment.

One final concern is the question of whether human-like explanations are really optimal explanations. Are high-recall explanations that mimic human highlighting tendencies really optimal for the types of moderating/self-moderating tasks involved in the domain of personal attacks in online social media? Again, this question can only be answered with human subject experimentation, which we plan to approach in future work.

7 Conclusion

The main contribution of this paper is to frame explanation as an adversarial problem, thereby addressing explanation recall for the first time that we are aware of. We do so by introducing an adversarial framework (an "extractive adversarial network") for ensuring that redundant predictive signal is not omitted from a model's explanations. We also show that choosing a null hypothesis for the model by setting the model bias term improves explanation precision.

Secondarily, we make a domain-specific contribution by applying interpretable machine learning for the first time to the problem of identifying personal attacks in social media comments, with the hope of developing more transparent semi-automated moderation systems. We show that we approach human performance on a dataset we develop for this purpose.

Abstract

Website privacy policies represent the single most important source of information for users to gauge how their personal data are collected, used and shared by companies. However, privacy policies are often vague and people struggle to understand the content. Their opaqueness poses a significant challenge to both users and policy regulators. In this paper, we seek to identify vague content in privacy policies. We construct the first corpus of human-annotated vague words and sentences and present empirical studies on automatic vagueness detection. In particular, we investigate context-aware and context-agnostic models for predicting vague words, and explore auxiliary-classifier generative adversarial networks for characterizing sentence vagueness. Our experimental results demonstrate the effectiveness of proposed approaches. Finally, we provide suggestions for resolving vagueness and improving the usability of privacy policies.

S1	We *may* use the *information* automatically collected from your computer or *other devices* for the following uses... (Vagueness: 3.8)
S2	In addition, in *some* cases the Sites can deliver content based on your current location if you choose to enable that feature. (Vagueness: 2.25)
S3	Our Sites and Services *may*, *from time to time*, provide links to sites operated by *third parties*. (Vagueness: 3.2)
S4	To customize and serve advertising and *other* marketing communications that *may* be visible to you on our Sites and Services or *elsewhere* on the internet. (Vagueness: 4)
S5	This includes your credit card number, income level, or *any other* information that would *normally* be considered confidential. (Vagueness: 3)

Table 1: Example human-annotated vague words and sentences. Vague words are *italicized*. Averaged sentence vagueness is given in the parentheses. Higher score is more vague.

1 Introduction

Website privacy policies are difficult to read and people struggle to understand the content. Recent studies (Sadeh et al., 2013) have raised concerns over their opaqueness, which poses a considerable challenge to both Internet users and policy regulators. Nowadays, consumers supply their personal information to online websites in exchange for personalized services; they are surrounded by smart gadgets such as voice assistants and surveillance cameras, which constantly monitor their activities in the home and work environments. Without clearly specifying how users' information will be collected, used and shared, there is a substantial risk of information misuse, including undesired advertisements and privacy breaches. Especially with recent high-profile cases involving Facebook and Cambridge Analytica, the public is becoming more aware and concerned with how their information is handled.

Privacy policies are binding agreements between companies and users that stipulate how companies collect, use, and share users' personal information. They are lengthy and difficult to read. Bhatia et al. (2016) suggested two possible causes for this. First, privacy policies must be *comprehensive* in order to cover a variety of uses (e.g., in-store and online purchases). Second, the policies have to be *accurate* to all data practices and systems. Clearly, it would be difficult for a company's legal counsel to anticipate all future needs. They need to resort to vague language to describe the content, causing it to be difficult to read and compromising the effectiveness of privacy policies.

In this paper, we present the first study on automatic detection of vague content in website privacy policies. We construct a sizable corpus containing word- and sentence-level human annotations of vagueness for privacy policy documents. The corpus contains a total of 133K words and

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3508–3517
Brussels, Belgium, October 31 - November 4, 2018.

4.5K sentences. Our methods for automatically detecting vague words and sentences are based on deep neural networks, which have demonstrated impressive recent success. Specifically, we investigate context-aware and context-agnostic models for predicting word vagueness, where feature representations of words are built with and without considering their surrounding words. By this, we seek to verify the hypothesis that vagueness is an intrinsic property of words and has little to do with context. To understand sentence vagueness, we explore auxiliary-classifier generative adversarial networks (AC-GAN, Odena et al., 2018). The model has performed strongly on vision tasks (e.g., image synthesis), however, whether it can be adapted to handle text data has not been thoroughly investigated. We train the AC-GAN model to discriminate between real/fake privacy policy sentences while simultaneously classifying sentences exhibiting different levels of vagueness, including "clear," "somewhat clear," "vague," and "extremely vague," thus improving the model's generalization capabilities. The detected vague words and sentences can assist users in browsing privacy policy documents, and privacy regulators in assessing the clarity of privacy policy practices. Our research contributions include the following:

- we present the first study on automatic detection of vague content in privacy policies. Vague content compromises the usability of privacy policies and there is an urgent need to identify and resolve vagueness;
- we construct a sizable text corpus including human annotations for 133K words and 4.5K sentences of privacy policy texts. The data[1] is available publicly to advance research on language vagueness; and
- we investigate both context-aware and context-agnostic methods for predicting vague words. We also explore the auxiliary-classifier generative adversarial networks for characterizing sentence vagueness. This is the first study leveraging deep neural networks for detecting vague content in privacy policies.

2 Related Work

Privacy policies are often verbose, difficult to read, and perceived as ineffective (McDonald and Cranor, 2008). In particular, vague language in these documents hurts understanding. *"A term is regarded as vague if it admits borderline cases, where speakers are reluctant to say either the term definitely applies or definitely does not apply,"* a definition of vagueness quoted from (van Deemter, 2010). Legal scholars and language philosophers strive to understand vagueness from a theoretical perspective (Keefe, 2000; Shapiro, 2006). The "sorites paradox" describes the phenomenon of vagueness (Keefe, 2000). It states that small changes in the object do not affect the applicability of a vague term. For example, a room can remain "bright" even if the light is dimmed little by little until it is entirely extinguished, thus creating a paradox. Hyde (2014) further suggests that vagueness is a feature pertaining to multiple syntactic categories. Nouns, adjectives and adverbs (e.g., "child", "tall", "many") are all susceptible to reasoning. These studies often focus on linguistic case studies but not on developing resources for automatic detection of vagueness.

Recent years have seen a growing interest in using natural language processing techniques to improve the effectiveness of website privacy policies. Sadeh et al. (2013) describe a Usable Privacy Policy Project that seeks to semi-automate the extraction of salient details from privacy policies. Other studies include crowdsourcing privacy policy annotations and categorizing data practices (Ammar et al., 2012; Massey et al., 2013; Wilson et al., 2016b,a), grouping text segments related to certain policy issues (Liu et al., 2014; Ramanath et al., 2014), summarizing terms of services (Braun et al., 2017), identifying user opt-out choices (Sathyendra et al., 2017), and many others. These studies emphasize the "too long to read" issue of privacy policies but leave behind the "difficult to understand" aspect, such as identifying and eliminating vague content.

The work of (Liu et al., 2016) is close to ours. The authors attempt to learn vector representations of words in privacy policies using deep neural networks, where the vectors encode not only semantic/syntactic aspects but also vagueness of words. The model is later fed to an interactive visualization tool (Strobelt et al., 2016) to test its ability to discover related vague terms. While promising, their approach is not fully automatic, and the feasibility of detecting vague words and sentences in an automatic manner is still left untested.

In this work we conduct the first study to auto-

---

matically detect vague content from privacy policies. We ask human annotators to label vague words and sentences and train supervised classifiers to do the same. Classifying vague words is a challenging task, because vagueness is an understudied property and it spans multiple syntactic categories (e.g., "usually," "personal data," "necessary"). Neural network classifiers such as CNN and LSTM have demonstrated prior success on text classification tasks (Zhang and Wallace, 2015), but whether they can be utilized to identify vague terms is not well understood.

For sentence classification, we investigate auxiliary classifier generative adversarial networks (AC-GAN, Odena et al., 2018). GANs have seen growing popularity in recent years (Mirza and Osindero, 2014; Yu et al., 2016; Li et al., 2017; Gu et al., 2018; Cai and Wang, 2018). AC-GAN is a variant of GAN that generates word sequences using class-conditional probabilities. E.g., it generates "fake" privacy policy sentences exhibiting different degrees of vagueness (e.g., "clear," "vague," "extremely vague"). AC-GAN nicely combines real (human-annotated) and fake (synthetic) privacy policy sentences in a discriminative framework to improve the model's generalization capabilities. This can be equated to a semi-supervised learning paradigm through augmentation of the dataset with generated sentences. Data augmentation is particularly valuable for vagueness detection, which generally has small expensive datasets. We perform a full analysis on AC-GAN and compare it to state-of-the-art systems.

3 The Corpus

Annotating vague words and sentences is a non-trivial task. We describe our effort to select privacy policy sentences for annotation, recruit qualified workers, and design annotation guidelines.

We select 100 website privacy policies from the collection gathered by Liu et al. (2014). The documents are quite lengthy, containing on average 2.3K words. More importantly, most content is not vague. To obtain a more balanced corpus, a filtering step is used to select only sentences that have a moderate-to-high chance of containing vague content. Fortunately, Bhatia et al. (2016) provide a list of 40 cue words for vagueness, manually compiled by policy experts. We therefore retain only sentences containing one of the cue words for further annotation. A brief examination shows that most of the sentences removed from the corpus are indeed clear. Even with this bias, the resulting corpus still contains a small portion of clear sentences (See Figure 1). The reason is that a cue word can be used in a way that is not vague. For example, in the sentence "Users *may* post to our website," the word *may* indicates permission but not possibility, and therefore the sentence is not vague.

Table 2: The most frequent vague terms identified by human annotators and their frequencies in our corpus. "pers.," "iden." and "info." are shorthand for "personally," "identifiable" and "information."

Reidenberg et al. (2015) discuss attempts to use crowdsourced workers as a cost-effective alternative to policy experts for annotating privacy policies. In this study, we hire crowd workers from the Amazon Mechanical Turk platform. To recruit quality workers, we require them to reside in the U.S. and be proficient in English; they are skilled workers maintaining a task success rate of 90% or above. We provide example labelled vague terms obtained from the case studies described in Bhatia et al. (2016) to reduce discrepancies among workers. The annotators are then asked to use their best judgment to perform the task.

Given a privacy policy sentence, the annotators are instructed to identify all vague terms[2] and assign a score of vagueness to the sentence. A vague term is limited to be 5 words or less (e.g., "including but not limited to"). We use this rule to prevent annotators from tagging an entire sentence/clause as vague. A slider is provided in the interface to al-

---

[2] We use "term" to denote either a single word or a phrase.

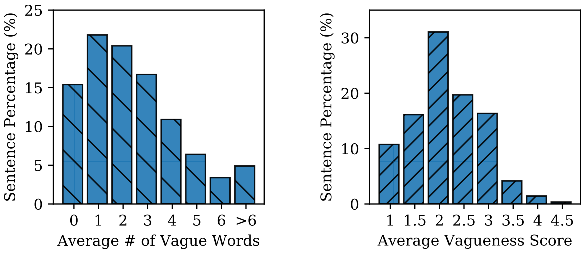

Figure 1: (Left) Percentage of sentences containing different numbers of vague words. (Right) Perc. of sentences with different levels of vagueness. 1 is clear, 5 is extremely vague.

Sent: This includes your credit card number , income level , or any other information that would normally be considered confidential .

Annotator 1: any, other, normally
Annotator 2: any other information
Annotator 3: normally, confidential, any other

Ground Truth Labels: [This]$_0$ [includes]$_0$ [your]$_0$ [credit]$_0$ [card]$_0$ [number]$_0$, [income]$_0$ [level]$_0$, [or]$_0$ ***[any]***$_1$ ***[other]***$_1$ [information]$_0$ [that]$_0$ [would]$_0$ ***[normally]***$_1$ [be]$_0$ [considered]$_0$ [confidential]$_0$.

Table 3: Ground truth labels are obtained by consolidating human-annotated vague terms; "any," "other," "normally" are labelled 1 because they are selected by 2 or more annotators.

low annotators to select a vagueness score for the sentence: 1 is extremely clear and 5 is extremely vague. We design a human intelligence task (HIT) to include 5 privacy policy sentences and a worker is rewarded $0.05 for completing the task. Five human workers are recruited to perform each task.

We obtain annotations for 133K words and 4.5K sentences. The average sentence vagueness score is 2.4±0.9. As of inter-annotator agreement[3], we find that 47.2% of the sentences have their vagueness scores agreed by 3 or more annotators; 12.5% of the sentence vagueness scores are agreed by 4 or more annotators. Furthermore, the annotators are not required to select vague words if they believe the sentences are clear. We remove vague words selected by a single annotator. Among the rest, 46.1% of the words are selected by 3 or more annotators; 18.5% of the words are selected by 4 or more annotators. These results suggest that, although annotating vague terms and sentences is considered challenging, our annotators can reach a reasonable degree of agreement. We present example vague terms in Table 2. Note that we obtain a total of 1,124 unique vague terms, which go well beyond the 40 cue words used for sentence preselection. Figure 1 shows more statistics on sentence vagueness, including (i) the percentages of sentences containing different numbers of vague words, and (ii) the percentages of sentences whose vagueness scores fall in different ranges.

4 Word Vagueness

We seek to test an important hypothesis related to word vagueness. We conjecture that vagueness is an intrinsic property of words; whether a word is vague or not has little to do with its context words. To verify this hypothesis, we build context-aware and context-agnostic models to classify each word in a privacy policy sentence as either vague or non-vague. The ground-truth labels are obtained by consolidating human annotations (see Table 3 for an example). A word is labelled 1 if it is selected by two or more annotators, otherwise 0. We describe details of the two classifiers below.

Context-aware classifier. It builds feature representations of words based on the surrounding context words. Given its strong performance, we construct a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) for this purpose. A word is replaced by its word2vec embedding (Mikolov et al., 2013) before it is fed to the model. For each time step, we concatenate the hidden states obtained from the forward and backward passes and use it as input to a feedforward layer with sigmoid activation to predict if a word is vague or non-vague. Because single words consist of the majority of the human-annotated vague terms, we choose to use binary word labels instead of a BIO scheme (Chiu and Nichols, 2016) for sequence tagging. Figure 2 shows the architecture.

Context-agnostic classifier. It uses intrinsic feature representations of words without considering the context. Specifically, we represent a word using its word2vec embedding, then feed it to a feedforward layer with sigmoid activation to obtain the prediction (Figure 2). We train the classifier using a list of unique words obtained from the training data; a word is considered positive if it has a ground truth label of 1 in any sentence, otherwise negative. Note that the ratio of positive/negative unique words in our corpus is 1068/3176=0.34. At test time, we apply the binary classifier to each word of the test set. A word is assigned the same label regardless of which sentence it appears in. We adopt this setting to ensure the context-aware and context-agnostic results are comparable.

5 Sentence Vagueness

We next investigate how vagueness is manifested in privacy policy sentences. Our goal is to assign a

---

[3] We choose not to calculate a kappa statistic, as labelling vague words/sentences is not a clear-cut classification task.

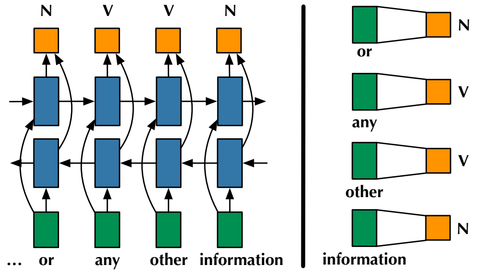

Figure 2: (Left) Context-aware word classifier implemented as a bidirectional LSTM. (Right) Context-agnostic classifier. “V” and “N” are shorthands for “vague” and “non-vague.”

label to each sentence indicating its level of vagueness. We derive ground truth sentence labels by averaging over vagueness scores assigned by human annotators, and further discretizing the scores into four buckets: [1,2), [2,3), [3,4), [4,5], respectively corresponding to “clear,” “somewhat clear,” “vague,” and “extremely vague” categories. The sentences in the four buckets respectively consist of 26.9%, 50.8%, 20.5%, and 1.8% of the total annotated sentences. We choose to predict discrete labels instead of continuous scores because labels are more informative to human readers. E.g., a label of “extremely vague” is more likely to trigger user alerts than a score of 4.2.

5.1 Auxiliary-Classifer GAN

Predicting vague sentences is a nontrivial task due to the complexity and richness of natural language. We propose to tackle this problem by exploring the auxiliary classifier generative adversarial networks (AC-GAN, Odena et al., 2018). We choose GAN because of its ability to combine text generation and classification in a unified framework (Yu et al., 2016; Li et al., 2017; Gu et al., 2018). Privacy policy sentences are particularly suited for text generation because the policy language is restricted and a text generator can effectively learn the patterns. AC-GAN has a great potential to make use of both human-annotated data and “fake” augmented data for classification. The system architecture is presented in Figure 3. The generator learns to generate “fake” privacy policy sentences and sentences exhibiting different levels of vagueness using class conditional probabilities (hence the name auxiliary-classifer GAN). The discriminator learns to discriminate among real/fake sentences as well as sentences of different levels of vagueness. They are jointly trained using a heuristic, non-saturating game loss. In the following we present the model details.

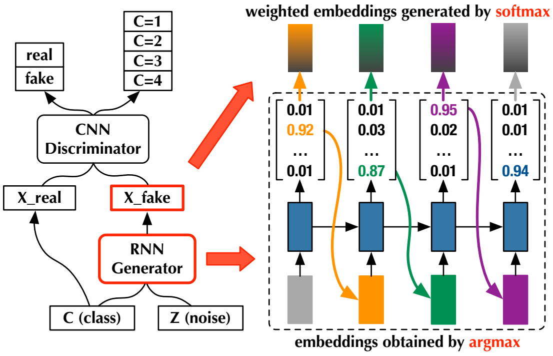

Figure 3: System architecture for AC-GAN. (Left) The Generator generates plausible privacy policy sentences (X_fake). The Discriminator must learn to differentiate between real and fake sentences as well as predicting the vagueness category (C) of the sentences. (Right) RNN-generator. A vocabulary distribution is produced for each step. Gumbel-softmax is applied to the distributions to calculate weighted embeddings to be used by the Discriminator (arrows pointing up). Argmax is applied to the distributions to retrieve embeddings to be passed to the next step (arrows pointing down).

5.2 Sentence Generator

The generator focuses on generating “fake” samples that resemble privacy policy sentences of a given vagueness category. This is denoted by $P(X|C)$, where $X = \{x_t\}_{t=1}^{T}$ is a sequence of words and $C \in \{1,2,3,4\}$ is a vagueness category. A vagueness category is randomly sampled in the generation process, and the generator attempts to generate a sentence of that vagueness level. A typical RNN text generator unrolls the sequence X one word at a time until an end-of-sentence symbol (EOS) is reached. At time step t, it samples a word x_t from a vocabulary-sized vector of probability estimates $P(x_t)$:

$$x_t \sim P(x_t) = \text{softmax}(\mathbf{a}_t), \tag{1}$$

$$\mathbf{a}_t = \mathbf{W}\mathbf{h}_t + \mathbf{b}, \tag{2}$$

$$\mathbf{h}_t = f_{RNN}(\mathbf{h}_{t-1}, x_{t-1}), \tag{3}$$

where $\mathbf{a}_t$ is a vector of activation values and $\mathbf{h}_t$ is the t-th RNN hidden state. We train a neural text generator, implemented as Long Short-Term Memory networks (Hochreiter and Schmidhuber, 1997), on a large collection of privacy policy sentences using cross-entropy loss. While generating natural language sentences is successfully tackled by recurrent neural networks, the generated sentences are not necessarily vague. Training the generator only on vague sentences is impractical because there is a limited number of annotated sentences. In this paper we introduce a new way of defining class conditional probabilities:

$$x_t \sim P(x_t|C) = \text{softmax}(\mathbf{a}_t + \lambda_C \mathbf{v}), \quad (4)$$

where $\mathbf{v}$ is a vocabulary-sized, trainable vector indicating how likely a vocabulary word is vague. λ_C is a coefficient for vagueness category C. The underlying assumption is that a "clear" sentence is less likely to contain vague words (λ_C is negative), whereas an "extremely vague" sentence tends to contain many vague words (λ_C is positive).

Finally, the generated "fake" sentences, together with "real" sentences labelled by human annotators, are fed to the discriminator for training a classifier discriminating between real/fake sentences and sentences of different vagueness levels. Nevertheless, there remains a critical issue with the current system: we cannot backpropagate through discrete samples X. As a result, the generator parameters cannot be properly updated using backpropagation. To circumvent this issue, we attempt the reparameterization trick with Gumbel-Softmax relaxation (Gu et al., 2018).

Straight-Through Gumbel-Softmax. Two competing issues exist in the RNN generator. First, the discriminator requires a continuous form for each generated word to keep the entire model differentiable. Second, the generator requires a discrete choice for each word to generate a sentence, rather than propagating "partial words" through the sequence. To solve this problem, the *softmax* distribution over vocabulary words is sent to the discriminator, while the *argmax* over the distribution is sent to the next step of the generator. This system is referred to as Straight-Through Gumbel.

We explain the process of calculating the softmax distribution to send to the discriminator. To simulate the random-sampling process, the approach applies reparameterization to shift randomness from sampling a discrete variable x_t (Eq. (4)) to sampling a continuous noise vector $\mathbf{z}_t$ following the Gumbel distribution (Eq. (5)). The noise vector is added to the activation $\mathbf{a}_t + \lambda_C \mathbf{v}$ to compute the *argmax* (Eq. (6)). To simulate the argmax operation, a temperature parameter τ is applied to *softmax* (Eq. (7)), where small values of τ greatly skew the distribution, causing it to peak at the largest value, while still remaining differentiable. Similar reparameterization is also used for variational auto-encoders (Kingma and Welling, 2014).

$$\mathbf{z}_t \sim \text{Gumbel}(z) \quad (5)$$

$$x_t = \text{argmax}(\mathbf{a}_t + \mathbf{z}_t + \lambda_C \mathbf{v}) \quad (6)$$

$$P(x_t|C) = \text{softmax}(\frac{\mathbf{a}_t + \mathbf{z}_t + \lambda_C \mathbf{v}}{\tau}) \quad (7)$$

The generator requires a discrete word to propagate to the next time step of the RNN. The word with the maximum activation value is chosen as shown in (Eq. (6)). An illustration of ST Gumbel is presented in Figure 3.

5.3 Sentence Discriminator

A sentence discriminator learns to perform two tasks simultaneously. Given a privacy policy sentence X, it predicts a probability distribution over its sources, denoted by $P(S|X)$, where S = {real, fake}; and a probability distribution over its level of vagueness, denoted by $P(C|X)$, C = {clear, somewhat clear, vague, extremely vague}. The learning objective for the discriminator is to maximize the log-likelihood of making correct predictions on both tasks, denoted by $L_C + L_S$, where L_C and L_S are defined in Eq. (8) and (9).

$$L_C = \mathbb{E}[\log P(C = c|X_{real+fake})] \quad (8)$$

$$\begin{aligned} L_S &= \mathbb{E}[\log P(S = real|X_{real})] \\ &\quad + \mathbb{E}[\log P(S = fake|X_{fake})] \end{aligned} \quad (9)$$

The ground truth vagueness labels C for real sentences are annotated by human annotators. For fake sentences the labels are randomly sampled in the generation process; and conditioned on the sampled vagueness labels, fake sentences are generated using $P(x_t|C)$ (Eq. (7)).

$$L'_C = \mathbb{E}[\log P(C = c|X_{fake})] \quad (10)$$

$$L'_S = \mathbb{E}[\log P(S = real|X_{fake})] \quad (11)$$

The *generator* is trained to maximize $L'_C + L'_S$ as illustrated in Eq. (10-11). Intuitively, the generator is rewarded (or punished) only based on the "fake" samples it produces. It is rewarded by generating sentences correctly exhibiting different levels of vagueness, denoted by (L'_C). It is also rewarded by generating sentences that look "real" and cannot be easily distinguished by the discriminator (L'_S). Eq. (11) corresponds to a heuristic, non-saturating game loss that mitigates gradient saturation (Goodfellow, 2016).

We experiment with two variants of the discriminator, implemented respectively using the convolutional neural networks (CNN) (Zhang and Wallace, 2015) and LSTM (Hochreiter and Schmid-

System	Word-Level		
	P (%)	R (%)	F (%)
Context-Agnostic	11.30	**78.15**	19.71
Context-Aware	**68.39**	53.57	**60.08**

Table 4: Results of detecting vague words in privacy policies using context-aware and context-agnostic classifiers.

huber, 1997). In both cases, the discriminator assigns a source and a vagueness label to each sentence. The CNN discriminator scans through each sentence using using a sliding window and apply a number of filters to each window. A max pooling over the sequence is performed to create a feature map for the sentence. This feature map is treated as the sentence representation. It is fed to two separate dense layers with softmax activation to predict $P(C|X)$ and $P(S|X)$ respectively. In contrast, the LSTM discriminator runs a forward pass through the sentence and uses the last hidden state as the sentence representation. Similarly, this representation is fed to two dense layers used to predict $P(C|X)$ and $P(S|X)$. Both methods produce probability estimations using a shared sentence representation. Given the scarcity of labelled sentences, this multitask setting is expected to improve the model's generalization capabilities.

6 Experiments

We conduct experiments on the annotated corpus using a 5-fold cross validation; 10% of the training data in each fold are reserved for validation. In the following sections we present details of experimental settings and report results on detecting vague words and sentences in privacy policy texts.

6.1 Parameter Settings

The Xavier scheme (Glorot and Bengio, 2010) is used for parameter initialization. For the context-aware word classifier, the bidirectional LSTM has 512 hidden units. For AC-GAN, the CNN discriminator uses convolutional filters of size $\{3, 4, 5\}$ and 128 filters for each size. The LSTM generator and discriminator both have 512 hidden units. The generator is further pretrained on 82K privacy policy sentences using a 10K vocabulary. The coefficient λ_C is set to $\{-1, 0, 1, 2\}$ respectively for 'clear,' 'somewhat clear,' 'vague,' and 'extremely vague' categories. $\mathbf{v}$ is initialized as a binary vector, where an entry is set to 1 if it is one of the 40 cue words for vagueness (Bhatia et al., 2016). Word embeddings are initialized to their word2vec embeddings and are made trainable during the entire training process.

Table 6: The most frequent part-of-speech (POS) tags appeared in false alarms and misses of detected vague words.

6.2 Predicting Vague Words

We compare context-aware with context-agnostic classifiers on detecting vague words in privacy policy text. The goal is to test an important hypothesis: that vagueness is an intrinsic property of words, thus a word being vague has little to do with its context. Results are presented in Table 4.

Interestingly, context-agnostic classifier yields a high recall score (78.15%) despite it ignoring context. This result indicates word vagueness can be encoded in distributed word embeddings. However, the low precision (11.30%) suggests that context is important for fine-grained analysis. While it is possible for experts to create a comprehensive list of vague terms for assessing privacy policies, extra effort is required to verify the tagged vague terms. Using a context-aware classifier produces more balanced results, improving the F-score from 19.71% to 60.08%. Our findings suggest that the context information is necessary for detecting vague words.

In Table 5, we present examples of detected vague words. The nouns have caught our attention. The classifier misses several of these, including "efforts," "information," "services," per-

System	Sentence-Level P (%)	R (%)	F (%)
Baseline (Majority)	25.77	50.77	34.19
LSTM	47.79	50.06	47.88
CNN	49.66	52.51	50.18
AC-GAN (Full Model)	51.00	53.50	50.42
AC-GAN (Vagueness Only)	**52.90**	**54.64**	**52.34**

Table 7: Results on classifying vague sentences.

haps because there is no clear definition for these terminologies. In Table 6, we found nouns consist of 47.64% of all the miss-detected vague words, while adjectives consist of 37.19% of the false alarms. There is also an interesting phenomenon. In S3, "Information" and "those services" are considered more vague by humans than "often depends." However, if those terms are removed from the sentence, yielding "The [..] we obtain from [..] often depends on your settings or their privacy policies." In this case, the vagueness of "often depends" become more prominent and is captured by our system. It suggests that the degree of vagueness may be relative, depending on if other terms in the sentence are more vague.

6.3 Predicting Vague Sentences

In Table 7 we present results on classifying privacy policy sentences into four categories: clear, somewhat clear, vague, and extremely vague. We compare AC-GAN with three baselines: CNN and LSTM trained on human-annotated sentences, and a majority baseline that assigns the most frequent label to all test sentences. We observe that the AC-GAN models (using CNN discriminator) perform strongly, surpassing all baseline approaches. CNN shows strong performance, yielding an F-score of 50.92%. A similar effect has been demonstrated on other sentence classification tasks, where CNN outperforms LSTM and logistic regression classifiers (Kim, 2014; Zhang and Wallace, 2015). We report results of AC-GAN using the CNN discriminator. Comparing "Full Model" with "Vagueness Only," we found that allowing the AC-GAN to only discriminate sentences of different levels of vagueness, but not real/fake sentences, yields better results. We conjecture this is because training GAN models, especially with a multitask learning objective, can be unstable and more effort is required to balance the two objectives (L_S and L_C). Example sentences generated by AC-GAN are presented in Table 9.

% (Freq)	Clear	SomeC	Vague	ExtrV
Clear	**39.4** (477)	59.8 (723)	0.7 (8)	0.2 (2)
SomeC	12.4 (284)	**85.2** (1945)	2.4 (54)	0.0 (1)
Vague	3.4 (31)	89.6 (828)	**7.0** (65)	0.0 (0)
ExtrV	1.2 (1)	88.9 (72)	9.9 (8)	**0.0** (0)

Table 8: Confusion matrix for sentence classification. The decimal values are the percentage of system-identified sentences that were placed in the specified vagueness class. For example: the item in (row 1, col 2) conveys that 59.8% of sentences (absolute count is 723) identified by the system as "clear" were actually "somewhat clear" according to humans.

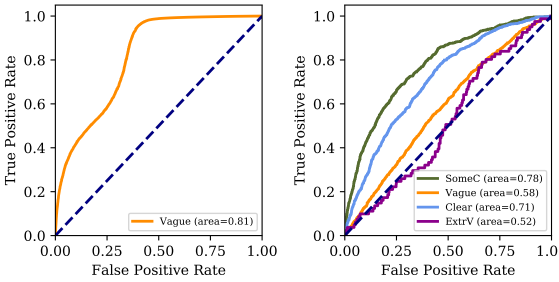

Figure 4: ROC curves for classifying vague words (left) and sentences (right).

Figure 4 shows the ROC curves of the four vagueness classes. Because the dataset is imbalanced, the ROC curves are more informative than F-scores. The "clear" and "somewhat clear" classes yield promising AUC scores of 0.71 and 0.78 respectively. The "vague" and "extremely vague" classes are more challenging. They are also the minority classes, consisting of 20.5% and 1.8% of the annotated data. Confusion matrix in Table 8 reveals that the majority of the sentences are tagged as "somewhat clear," while 7.0% of the vague sentences are tagged as vague. It suggests more annotated data may be helpful to enable the classifier to distinguish "vague" and "extremely vague" sentences. Interestingly, we found there is little correlation between the sentence vagueness score and sentence length (Pearson correlation r=0.18, p <0.001) while there is a relatively strong correlation (r=0.57, p <0.001) between sentence vagueness and the number of vague words in it. This finding verifies our hypothesis that vague words seem to increase the perceived sentence vagueness.

Lessons learned. We summarize some lessons learned from annotating and detecting vague content in privacy policies, useful for policy regulators, users and website operators. In general, privacy policies are suggested to:

- provide clear definitions for key concepts. Lacking definition is a major source of confu-

Clear	Our commitment to travian games uses paid services or send an order online.
	To learn how important anonymization it, we provide a separate medicare.
SomeC	Slate use certain cookies and offers.
	Visitors who apply us an credit card may sign up.
Vague	There may take certain incidents various offerings found on various topics; some or all individual has used.
	You may modify certain edit or otherwise delete certain features or a similar id will no longer.
ExtrV	Also, some apps may offer contests, sweepstakes, games or some community where necessary.
	If necessary, buying or clarify certain links, certain features of our site may place or some or some features may offer stack or unauthorized access some some functionality.

Table 9: Plausible sentences generated by AC-GAN. They exhibit different levels of vagueness. "SomeC" and "ExtrV" are shorthands for "somewhat clear" and "extremely vague."

sion for the unfamiliar reader. Example concepts include personally identifiable information, personal (non-personal) information, third parties, service providers, subsidiaries, etc.

- suppress the use of vague words. There are on average 2.5 vague words per sentence in our corpus. The more vague words, the more likely the sentence is perceived as vague ($r = 0.57$);
- use sentences with simple syntactic structure to ease understanding. A sophisticated sentence with vague terms in it, e.g., "You may request deletion of your personal data by us, but please note that we may be required (by law *or otherwise*) to keep this information and not delete it..." appears especially confusing to readers.

7 Conclusion

In this paper we present the first empirical study on automatic detection of vague content in privacy policies. We create a sizable text corpus including human annotations of vague words and sentences. We further investigate the feasibility of predicting vague words and sentences using deep neural networks. Specifically we investigate context-agnostic and context-aware models for detecting vague words, and AC-GAN for detecting vague sentences. Our results suggest that a supervised paradigm for vagueness detection provides a promising avenue for identifying vague content and improving the usability of privacy policies.

Abstract

A news article's title, content and link structure often reveal its political ideology. However, most existing works on automatic political ideology detection only leverage textual cues. Drawing inspiration from recent advances in neural inference, we propose a novel attention based multi-view model to leverage cues from all of the above views to identify the ideology evinced by a news article. Our model draws on advances in representation learning in natural language processing and network science to capture cues from both textual content and the network structure of news articles. We empirically evaluate our model against a battery of baselines and show that our model outperforms state of the art by 10 percentage points F1 score.

1 Introduction

Many issues covered or discussed by the media and politicians today are so subtle that even word-choice may require one to adopt a particular ideological position (Iyyer et al., 2014). For example, conservatives tend to use the term `tax reform`, while liberals use `tax simplification`. Though objectivity and unbiased reporting remains a cornerstone of professional journalism, several scholars argue that the media displays ideological bias (Gentzkow and Shapiro, 2010; Groseclose and Milyo, 2005; Iyyer et al., 2014). Even if one were to argue that such bias may not be reflective of a lack of objectivity, prior research Dardis et al. (2008); Card et al. (2015) note that framing of topics can significantly influence policy.

Since manual detection of political ideology is challenging at a large scale, there has been extensive work on developing computational models for automatically inferring the political ideology of articles, blogs, statements, and congressional speeches (Gentzkow and Shapiro, 2010; Iyyer et al., 2014; Preoţiuc-Pietro et al., 2017; Sim et al., 2013). In this paper, we consider the detection of ideological bias at the news article level, in contrast to recent work by Iyyer et al. (2014) who focus on the sentence level or the work of (Preoţiuc-Pietro et al., 2017) who focus on inferring ideological bias of social media users. Prior research exists on detecting ideological biases of news articles or documents (Gentzkow and Shapiro, 2010; Gerrish and Blei, 2011; Iyyer et al., 2014). However, all of these works generally only model the text of the news article. However, in the online world, news articles do not just contain text but have a rich structure to them. Such an online setting influences the article in subtle ways: (a) choice of the title since this is what is seen in snippet views online (b) links to other news media and sources in the article and (c) the actual textual content itself. Except for the textual content, prior models ignore the rest of these cues. Figure 1 shows an example from `The New York Times`. Note the presence of hyperlinks in the text, which link to other sources like `The Intercept`(Figure 1a). We hypothesize that such a link structure is reflective of homophily between news sources sharing similar political ideology – homophily which can be exploited to build improved predictive models (see Figure 1b). Building on this insight, we propose a new model **MVDAM**: *Multi-view document attention model* to detect the ideological bias of news articles by leveraging cues from multiple views: the title, the link structure, and the article content. Specifically, our contributions are:

1. We propose a generic framework **MVDAM** to incorporate multiple views of the news article and show that our model outperforms state of the art by 10 percentage points on the F1 score.
2. We propose a method to estimate the ideological proportions of sources and rank them

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3518–3527
Brussels, Belgium, October 31 - November 4, 2018.

by the degree to which they lean towards a particular ideology.

3. Finally, differing from most works, which typically focus on congressional speeches, we conduct ideology detection of news articles by assembling a *large-scale diverse dataset* spanning more than 50 sources.

2 Related Work

Several works study the detection of political ideology through the lens of computational linguistics and natural language processing (Laver et al., 2003; Monroe and Maeda, 2004; Thomas et al., 2006; Lin et al., 2008; Carroll et al., 2009; Ahmed and Xing, 2010; Gentzkow and Shapiro, 2010; Gerrish and Blei, 2011; Sim et al., 2013). Gentzkow and Shapiro (2010) first attempt to rate the ideological leaning of news sources by proposing a measure called "slant index" which captures the degree to which a particular newspaper uses partisan terms or co-allocations. Gerrish and Blei (2011) predict the voting patterns of Congress members based on supervised topic models. Other works use topic models to analyze bias in news articles, blogs, and political speeches (Ahmed and Xing, 2010; Lin et al., 2008). Sim et al. (2013) propose a novel HMM-based model to infer the ideological proportions of the rhetoric used by political candidates in their campaign speeches which relies on a fixed lexicon of bigrams associated with ideologies.

The work that is most closely related to our work is that of Iyyer et al. (2014); Preoţiuc-Pietro et al. (2017). Iyyer et al. (2014) use recurrent neural networks to predict political ideology of congressional debates and articles in the ideological book corpus (IBC) and demonstrate the importance of compositionality in predicting ideology where modifier phrases and punctuality affect the political ideological position. Preoţiuc-Pietro et al. (2017) propose models to infer political ideology of Twitter users based on their everyday language. Most crucially, they also show how to effectively use the relationship between user groups to improve prediction accuracy. Our work draws inspiration from both of these works but differentiates itself from these in the following aspects: We leverage the structure of a news article by noting that an article is just not free-form text, but has a rich structure to it. In particular, we model cues from the title, the inferred network, and the content in a joint generic neural variational inference framework to yield improved models for this task. Furthermore, differing from Iyyer et al. (2014), we also incorporate attention mechanisms in our model which enables us to inspect which sentences (or words) have the most predictive power as captured by our model. Finally, since we work with news articles (which also contain hyperlinks), naturally our setting is different from all other previous works in general (which mostly focus on congressional debates) and in particular from Iyyer et al. (2014) where only textual content is modeled or Preoţiuc-Pietro et al. (2017) which focuses on social media users.

3 Dataset Construction

News Sources We rely on the data released by ALLSIDES.COM[1] to obtain a list of 59 US-based news sources along with their political ideology ratings: LEFT, CENTER or RIGHT which specify our target label space. While we acknowledge that there is no "perfect" measure of political ideology, ALLSIDES.COM is an apt choice for two main reasons. First, and most importantly the ratings are based on a blind survey, where readers are asked to rate news content without knowing the identity of the news source or the author being rated. This is also precisely the setting in which our proposed computational models operate (where the models have access to the content but are agnostic of the source itself) thus seeking to mirror human judgment closely. Second, these are normalized by ALLSIDES to ensure they closely reflect popular opinion and political diversity present in the United States. These ratings also correlate with independent measurements made by the PEW RESEARCH CENTRE. All these observations suggest that these ratings are fairly robust and generally "reflective of the average judgment of the American People"[2].

Content Extraction Given the set of news sources selected above, we extract the article content for these news sources. We control for time by obtaining article content over a fixed time-period for all sources. Specifically, we spider several news sources and perform data cleaning. In particular, the spidering component collates the raw HTML of news sources into a storage engine (MongoDB). We track thousands of US based news outlets including country wide popular news sources as well as many local/state news based outlets like the

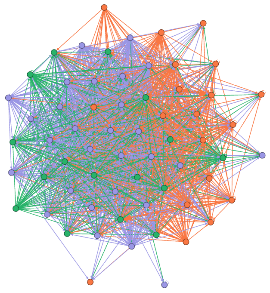
A Run of Good Fortune

Around the same time Mr. Pruitt invested in the house in Oklahoma City, he had finished a big business deal that involved Mr. Kelly, Mr. Wagner and a campaign donor who ran a large staffing company.

A baseball player in college, Mr. Pruitt bought an approximately 25 percent stake in the Oklahoma City RedHawks and became the team's managing partner, making him a highly visible spokesman for the local team. Mr. Wagner also purchased a small stake, and Mr. Kelly's bank provided financing for the deal, as first reported by The Intercept, which also disclosed the bank's loans for one of Mr. Pruitt's suburban Tulsa homes.

(a) A sample news article. Note the presence of hyperlinks to other sources like The Intercept.



(b) Homophily in link structure (viewed in color) of various news sources which can be observed by noting the presence of clusters corresponding to political ideologies. The blue, orange and green clusters correspond to left, right and center leaning sources respectively.

Figure 1: Our proposed framework MVDAM models multiple views of the news article including the content and the link structure. Figure 1a shows a sample article from the New York Times. The presence of such links can provide informative signals for predictive tasks like ideology detection primarily due to homophily (Figure 1b).

Boston Herald[3]. However, in this paper, we consider only the 59 US news sources for which we can derive ground truth labels for political ideology. For each of the news sources considered, we extract the title, the cleaned pre-processed content, and the hyperlinks within the article that reveal the network structure. The label for each article is the label assigned to its source as obtained from ALLSIDES. We choose a random sample of $120,000$ articles and create 3 independent splits for training $(100,000)$, validation $(10,000)$ and test $(10,000)$ with a roughly balanced label distribution. [4]

Data Pre-processing and Cleaning Since the labels were derived from the source, we are careful to remove any systematic features in each article which are trivially reflective of the source, since that would result in over-fitting. In particular we perform the following operations: (a) **Remove source link mentions** When modeling the link structure of an article, we explicitly remove any link to the source itself. Second, we also explicitly remove any systematic link structures in articles that are source specific. In particular, some sources may always have links to other domains (like their own franchisees or social media sites). These links are removed explicitly by noting their high frequency. (b) **Remove headers, footers, advertisements** News sources systematically introduce footers, and advertisements which we remove explicitly. For example, every article of the `The Daily Beast` has the following footer `You can subscribe to the Daily Beast here` which we filter out.

4 Models and Methods

Problem Formulation Given $\boldsymbol{X} = \{\boldsymbol{X_{title}}, \boldsymbol{X}_{net}, \boldsymbol{X_{content}}\}$ which represents a set of multi-modal features of news articles and a label set $\boldsymbol{Y} = \{\text{LEFT}, \text{CENTER}, \text{RIGHT}\}$, we would like to model $\Pr(\boldsymbol{Y}|\boldsymbol{X})$.

Overview of MVDAM We consider a Bayesian approach with stochastic attention units to effectively model textual cues. Bayesian approaches with stochastic attention have been noted to be quite effective at modeling ambiguity as well as avoiding over-fitting scenarios especially in the case of small training data sets (Miao et al., 2016). In particular, we assume a latent representation $\boldsymbol{h}$ learned from the multiple modalities in $\boldsymbol{X}$ which is then mapped to the label space $\boldsymbol{Y}$. In the most general setting, instead of learning a deterministic encoding $\boldsymbol{h}$ given $\boldsymbol{X}$, we posit a latent distribution over the hidden representation $\boldsymbol{h}$, $\Pr(\boldsymbol{h}|\boldsymbol{X})$ to model the overall document where $\Pr(\boldsymbol{h}|\boldsymbol{X})$ is parameterized by a diagonal Gaussian distribution $\mathcal{N}(\boldsymbol{h}|\mu(\boldsymbol{X}), \sigma^2(\boldsymbol{X}))$.

Specifically, consider the distribution $\Pr(\boldsymbol{Y}|\boldsymbol{X})$ which can be written as follows:

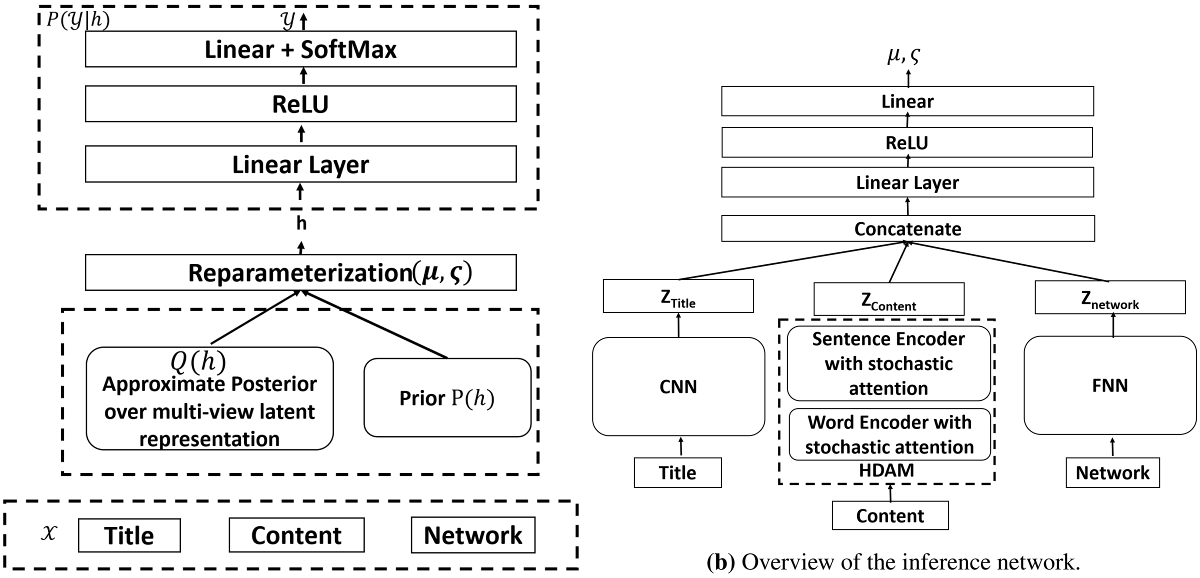
$$\Pr(\boldsymbol{Y}|\boldsymbol{X}) = \sum_{\boldsymbol{h}} \Pr(\boldsymbol{Y}|\boldsymbol{h}) \Pr(\boldsymbol{h}|\boldsymbol{X}) \qquad (1)$$

As noted by Miao et al. (2016), computing the exact posterior is in general intractable. Therefore, we posit a variational distribution $q_\phi(\boldsymbol{h})$ and maximize

---

[3] This is a part of an ongoing project called MediaRank. More details can be found at `http://media-rank.com`

[4] Note that we do not restrict the articles to be strictly political since even articles on other topics like health and sports can be reflective of political ideology (Hoberman, 1977).



(a) Overview of our full model.

(b) Overview of the inference network.

Figure 2: A broad overview of our MVDAM model depicting the three major components:a discriminator, an inference network and a prior and captures cues from multiple views of the news article. As noted by Miao et al. (2016) we use stochastic attention units which are shown to model ambiguity better. We thus train the model end-to-end using neural variational inference.

the evidence lower bound $\mathcal{L} \leq \Pr(\boldsymbol{y}|\boldsymbol{X})$ namely,

$$\mathcal{L} = \mathbb{E}_{q_\phi(\boldsymbol{h})}[p(\boldsymbol{Y}|\boldsymbol{h})] - D_{KL}(q_\phi(\boldsymbol{h})||p(\boldsymbol{h}|\boldsymbol{X})), \tag{2}$$

where $p(\boldsymbol{Y}|\boldsymbol{h})$ denotes a probability distribution over $\boldsymbol{Y}$ given the latent representation $\boldsymbol{h}$, and $p(\boldsymbol{h}|\boldsymbol{X})$ denotes the probability distribution over $\boldsymbol{h}$ conditioned on $\boldsymbol{X}$.

Equation 2 can be interpreted as consisting of three components, each of which can modeled separately: (a) **Discriminator** $p(\boldsymbol{Y}|\boldsymbol{h})$ can be viewed as a discriminator given the hidden representation $\boldsymbol{h}$. Maximizing the first term is thus equivalent to minimizing the cross-entropy loss between the model's prediction and true labels. (b) The second term, the KL Divergence term consists of two components: (1) **Approximate Posterior** The term $q_\phi(\boldsymbol{h})$ also known as the approximate posterior parameterizes the latent distribution which encodes the multi-modal features $\boldsymbol{X}$ of a document. (2) **Prior** The term $p(\boldsymbol{h}|\boldsymbol{X})$ can be viewed as a prior which can be uninformative (a standard Gaussian prior in the most general case, or any other prior model based on other features). We now discuss how we model each of these components in detail.

4.1 Discriminator

We use a simple feed-forward network with a linear layer that accepts as input the latent hidden representation of $\boldsymbol{X}$, followed by a ReLU for non-linearity followed by a linear layer and a final softmax layer to model this component.

4.2 Approximate Posterior

Here we model the approximate posterior $q_\phi(\boldsymbol{h})$ by an inference network shown succinctly in Figure 2b. The inference network takes as input the features $\boldsymbol{X}$ and learns a corresponding hidden representation $\boldsymbol{h}$. More specifically, it outputs two components: $(\mu,\ \varsigma)$ corresponding to the mean and log-variance of the gaussian parametrizing the hidden representation $\boldsymbol{h}$. We model this using a "multi-view" network which incorporates hidden representations learned from multiple modalities into a joint representation. Specifically, given d-dimensional hidden representations corresponding to multiple modalities z_{title}, $z_{network}$, and $z_{content}$ the model first concatenates these representations into a single $3d$-dimensional representation z_{concat} which is then input through a 2-layer feed-forward network to output a d-dimensional mean vector μ and a d-dimensional log-variance vector ς that parameterizes the latent distribution governing $\boldsymbol{h}$. We now discuss the models used for capturing each view.

4.2.1 Modeling the Title

We learn a latent representation of the title of a article by using a convolutional network. Convolutional networks have been shown to be very effective for modeling short sentences like titles of news articles. In particular, we use the same architecture proposed by (Kim, 2014). The input words of the title are mapped to word embeddings and concatenated and passed through convolutional filters of varying window sizes. This is then followed by a max-over-time pooling (Collobert et al., 2011). The outputs of this layer are input to a fully connected layer of dimension d with drop-out which outputs $\boldsymbol{z}_{title}$, the latent representation of the title.

4.2.2 Modeling the Network Structure of articles

Capturing the network structure of article consists of two steps: (a) Learning a network representation of each source based on its social graph G. (b) Using the learned representation of each source to capture the link structure of a particular article.

We use a state-of-the-art network representation learning algorithm to learn representations of nodes in a social network. In particular, we use Node2Vec (Grover and Leskovec, 2016), which learns a d-dimensional representation of each source given the hyperlink structure graph G. Node2Vec seeks to maximize the log likelihood of observing the neighborhood of a node $\mathcal{N}(u)$, given the node u. Let $\boldsymbol{F}$ be a matrix of size (V, d) where $\boldsymbol{F}(u)$ represents the embedding of node u. We then maximize the following likelihood function $\max_{\boldsymbol{F}} \sum_u \log \Pr(\mathcal{N}(u)|u)$. We model the above likelihood similar to the Skip-gram architecture (Mikolov et al., 2013) by assuming that the likelihood of observing a node $v \in \mathcal{N}(u)$ is conditionally independent of any other node in the neighborhood given u. That is $\log \Pr(\mathcal{N}(u)|u) = \sum_{v \in \mathcal{N}(u)} \log \Pr(v|u)$. We then model $\Pr(v|u) = \frac{e^{\boldsymbol{F}(u).\boldsymbol{F}(v)}}{\sum_v e^{\boldsymbol{F}(u).\boldsymbol{F}(v)}}$. Having fully specified the log likelihood function, we can now optimize it using stochastic gradient ascent.

Having learned the embedding matrix $\boldsymbol{F}$ for each source node, we now model the link structure of any given article $\mathcal{A}$ simply by the average of the network embedding representations for each link l referenced in $\mathcal{A}$. In particular, we compute $\boldsymbol{z}_{network}$ as: $\boldsymbol{z}_{network} = \frac{1}{|\mathcal{A}|} \sum_{l \in \mathcal{A}} \boldsymbol{F}(l)$.

4.2.3 Modeling the Content of articles

To model the content of an article, we use a hierarchical approach with attention. In particular, we compute attention at both levels: (a) words and (b) sentences. We closely follow the approach by (Yang et al., 2016) which learns a latent representation of a document d using both word and sentence attention models.

We model the article $\mathcal{A}$ hierarchically, by first representing each sentence i with a hidden representation s_i. We model the fact that not all words contribute equally in the sentence through a word level attention mechanism. We then learn the representation of the article $\mathcal{A}$ by composing these individual sentence level representations with a sentence level attention mechanism.

Learning sentence representations We first map each word to its embedding matrix through a lookup embedding matrix $\boldsymbol{W}$. We then learn a hidden representation of the given sentence h_{it} centered around word w_i by embedding the sentence through a bi-directional GRU as described by (Bahdanau et al., 2014). Since not all words contribute equally to the representation of the sentence, we introduce a word level attention mechanism which attempts to extract relevant words that contribute to the meaning of the sentence. Specifically we learn a word level attention matrix $\boldsymbol{W_w}$ as follows $\alpha_i \propto \exp(\boldsymbol{W_w} h_{it} + b_w), s_i = \sum_t \alpha_i h_{it}$ where s_i is the latent representation of the sentence i.

Composing sentence representations We follow a similar method to learn a latent representation of an article. Given the embedding s_i of each sentence in the article, we learn a hidden representation of the given sentence h_i centered around s_i by embedding the list of sentences through a bi-directional GRU as described by (Bahdanau et al., 2014). Once again, since not all sentences contribute equally to the representation of the article, we introduce a sentence level attention mechanism which attempts to extract relevant sentences that contribute to the meaning of the article. Specifically we learn the weights of a sentence level attention matrix $\boldsymbol{W}_s$ as $\alpha_s \propto \exp(\boldsymbol{W}_s h_s + b_s), \boldsymbol{z}_{content} = \sum_s \alpha_s h_s$, where $\boldsymbol{z}_{content}$ is the latent representation of the article. In this case we let the hidden representation of the sentence be a stochastic representation similar to the work by (Miao et al., 2016) and use the Gaussian re-parameterization trick to enable training via end-to-end gradient based methods [5]. Such techniques have been shown to be useful in

---

[5] Using deterministic sentence representations is a special case.

modeling ambiguity and also generalize well to small training datasets (Miao et al., 2016).

4.3 Prior

The prior models $p(\boldsymbol{h}|\boldsymbol{X})$ in Equation 2. Note that our proposed framework is general and can be used to incorporate a variety of priors. Here, we assume the prior is drawn from a Gaussian distribution with diagonal co-variances. The KL Divergence term in Equation 2 can thus be analytically computed. In particular, the KL Divergence between two K dimensional Gaussian distributions $\boldsymbol{A}, \boldsymbol{B}$ with means μ_A, μ_B and diagonal co-variances κ_A, κ_B is:

$$D_{KL}(\boldsymbol{A}, \boldsymbol{B}) = -\frac{1}{2}\sum_{j=1}^{j=K}(1 + \log\frac{\kappa_{Aj}}{\kappa_{Bj}} - \frac{\kappa_{Aj}}{\kappa_{Bj}} - (\mu_{Aj} - \mu_{Bj})^2/\kappa_{Bj}) \quad (3)$$

Parameter Estimation Having described precisely, the models for each of the components in Equation 2, we can reformulate the maximization of the variational lower bound to the following loss function on the set of all learn-able model parameters θ: $\mathcal{J}(\theta)$ as follows:

$$\mathcal{J}(\theta) = \mathrm{NLL}(\boldsymbol{y}|\boldsymbol{X}) + \lambda \mathrm{D}_{KL}(\boldsymbol{q}(\boldsymbol{h})||\boldsymbol{p}(\boldsymbol{h}|\boldsymbol{X})), \quad (4)$$

where NLL is the negative log likelihood loss computed between the predicted label and the true label, and λ is a hyper-parameter that controls the amount of regularization offered by the KL Divergence term. We use ADADELTA to minimize this loss function.

5 Experiments

We evaluate our model against several competitive baselines which model only a single view to place our model in context:

1. **Chance Baseline** We consider a simple baseline that returns a draw from the label distribution as the prediction.
2. **Logistic Regression LR (Title)** We consider a bag of words classifier using Logistic Regression that can capture linear relationships in the feature space and use the words of the title as the feature set.
3. **CNN (Title)** We consider a convolutional net classifier based on exactly the same architecture as (Kim, 2014) which uses the title of the news article. Convolutional Nets have been shown to be extremely effective at classifying short pieces of text and can capture non-linearities in the feature space(Kim, 2014).
4. **FNN (Network)** We also consider a simple fully-connected feed forward neural network using only the network features to characterize the predictive power of the network alone.
5. **HDAM Model (Content)** We use the state of the art hierarchical document attention model proposed by (Yang et al., 2016) that models the content of the article using both word and sentence level attention mechanisms.

We consider three different flavors of our proposed model which differ in the subset of modalities used (a) **Title and Network** (b) **Title and Content**, and (c) **Full model**: Title, Network, and Content. We train all of our models and the baselines on the training data set choosing all hyper-parameter using the validation set. We report the performance of all models on the held-out test set.

Experimental Settings We set the embedding latent dimension captured by each view to be 128 including the final latent representation obtained by fusing multiple modalities. In case of the CNN's, we consider three convolutional filters of window sizes $3, 4, 5$ each yielding a 100 dimensional feature map followed by max-over time pooling which is then passed through a fully connected layer to yield the output. In all the neural models, we used AdaDelta with an initial learning rate of 1.0 to learn the parameters of the model via back-propagation.

Model	Views	P	R	F1
CHANCE	–	34.53	34.59	34.53
LR	Title	59.53	59.42	59.12
CNN	Title	59.26	59.40	59.24
FNN	Network	68.28	56.54	55.10
HDAM	Content	69.85	68.72	68.92
MVDAM	Title, Network	**69.87**	**69.71**	**69.66**
MVDAM	Title, Content	**70.84**	**70.19**	**69.54**
MVDAM	Title, Network, Content	**80.10**	**79.56**	**79.67**

Table 1: Precision, Recall, and F1 scores of our model MVDAM on the test set compared with several baselines. All flavors of our model significantly outperform baselines and yield state of the art performance.

5.1 Results and Analysis

Quantitative Results Table 1 shows the results of the evaluation. First note that the logistic regression classifier and the CNN model using the Title outperforms the CHANCE classifier significantly

(F1: $\mathbf{59.12}, \mathbf{59.24}$ vs $\mathbf{34.53}$). Second, only modeling the network structure yields a F1 of $\mathbf{55.10}$ but still significantly better than the chance baseline. This confirms our intuition that modeling the network structure can be useful in prediction of ideology. Third, note that modeling the content (HDAM) significantly outperforms all previous baselines (F1:$\mathbf{68.92}$). This suggests that content cues can be very strong indicators of ideology. Finally, all flavors of our model outperform the baselines. Specifically, observe that incorporating the network cues outperforms all uni-modal models that only model either the title, the network, or the content. It is also worth noting that without the network, only the title and the content show only a small improvement over the best performing baseline ($\mathbf{69.54}$ vs $\mathbf{68.92}$) suggesting that the network yields distinctive cues from both the title, and the content. Finally, the best performing model effectively uses all three modalities to yield a F1 score of $\mathbf{79.67}$ outperforming the state of the art baseline by 10 percentage points. Altogether our results suggest the superiority of our model over competitive baselines. In order to obtain deeper insights into our model, we also perform a qualitative analysis of our model's predictions.

Visualizing Attention Scores Figure 3 shows a visualization of sentences based on their attention scores. Note that for a left leaning article (see Figure 3a), the model focuses on sentences involving `gun-control, feminists, and transgender`. In contrast, a visualization of sentence attention scores for an article which the model predicted as "right-leaning" ((see Figure 3b)) reveals a focus on words like `god, religion` etc. These observations qualitatively suggest that the model is able to effectively pick up on content cues present in the article. By examining the distribution over the sentence indices corresponding to the maximum attention scores, we noted that only in about half the instances, the model focuses its greatest attention on the beginning of the article suggesting that the ability to selectively focus on sentences in the news article contributes to the superior performance.

Challenging Cases In Table 2, we highlight some of the challenges of our model. In particular, our model finds it quite challenging to identify the political ideology of the source for articles that are non-political and related to global events, or entertainment. Examples include instances like `Tourist dies hiking in Australia Outback heat` or `Juan Williams makes the 'case for Oprah'`. We also note that articles with "click-baity" titles like `We are all Just Overclocked Chimpanzees` are not necessarily discriminative of the underlying ideology. In summary, while our proposed model significantly advances the state of art, it also suggests scope for further improvement especially in identifying political ideologies of articles in topics like Entertainment or Sports. For example, prior research suggests that engagement in particular sports is correlated with the political leanings (Hoberman, 1977) which suggest that improved models might need to capture deeper linguistic and contextual cues.

Ideological Proportions of News Sources Finally, we compute the expected proportion of an ideology in a given source based on the probability estimates output by our model for the various articles. While one might expect that the expected degree of "left-ness" (or "right-ness") for a given source can easily be computed by taking a simple mean of the prediction probability for the given ideology over all articles belonging to the source, such an approach can be in-accurate because the probability estimates output by the model are not necessarily calibrated and therefore cannot be interpreted as a confidence value. We therefore use isotonic regression to calibrate the probability scores output by the model. Having calibrated the probability scores, we now compute the degree to which a particular news source leans toward an ideology by simply computing the mean output score over all articles corresponding to the source. Table 3 shows the top 10 sources ranked according to their proportions for each ideology. We note that sources like CNN, Buzz Feed, SF Chronicle are considered more left-leaning than the Washington Post. Similarly, we note that NPR and Reuters are considered to be the most center-aligned while Breitbart, Infowars and Blaze are considered to be most right-aligned by our model. These observations are moderately aligned with survey results that place news sources on the ideology spectrum based on the political beliefs of their consumers [6].

Table 3: A Top 10 ranking of Ideological sources as obtained by our model which correlate moderately with external surveys.

6 Conclusion

We proposed a model to leverage cues from multiple views in the predictive task of detecting political ideology of news articles. We show that incorporating cues from the title, the link structure and the content significantly beats state of the art. Finally, using the predicted probabilities of our model, we draw on methods for probability calibration to rank news sources by their ideological proportions which moderately correlates with existing surveys on the ideological placement of news sources. To conclude, our proposed framework effectively leverages cues from multiple views to yield state of the art interpret-able performance and sets the stage for future work which can easily incorporate other modalities like audio, video and images.

Abstract

We present a study on predicting the factuality of reporting and bias of news media. While previous work has focused on studying the veracity of claims or documents, here we are interested in characterizing entire news media. These are under-studied but arguably important research problems, both in their own right and as a prior for fact-checking systems. We experiment with a large list of news websites and with a rich set of features derived from (*i*) a sample of articles from the target news medium, (*ii*) its Wikipedia page, (*iii*) its Twitter account, (*iv*) the structure of its URL, and (*v*) information about the Web traffic it attracts. The experimental results show sizable performance gains over the baselines, and confirm the importance of each feature type.

1 Introduction

The rise of social media has democratized content creation and has made it easy for everybody to share and spread information online. On the positive side, this has given rise to citizen journalism, thus enabling much faster dissemination of information compared to what was possible with newspapers, radio, and TV. On the negative side, stripping traditional media from their gate-keeping role has left the public unprotected against the spread of misinformation, which could now travel at breaking-news speed over the same democratic channel. This has given rise to the proliferation of false information that is typically created either (*a*) to attract network traffic and gain financially from showing online advertisements, e.g., as is the case of *clickbait*, or (*b*) to affect individual people's beliefs, and ultimately to influence major events such as political elections (Vosoughi et al., 2018). There are strong indications that false information was weaponized at an unprecedented scale during the 2016 U.S. presidential campaign.

"Fake news", which can be defined as "fabricated information that mimics news media content in form but not in organizational process or intent" (Lazer et al., 2018), became the word of the year in 2017, according to Collins Dictionary. "Fake news" thrive on social media thanks to the mechanism of sharing, which amplifies effect. Moreover, it has been shown that "fake news" spread faster than real news (Vosoughi et al., 2018). As they reach the same user several times, the effect is that they are perceived as more credible, unlike old-fashioned spam that typically dies the moment it reaches its recipients. Naturally, limiting the sharing of "fake news" is a major focus for social media such as Facebook and Twitter.

Additional efforts to combat "fake news" have been led by fact-checking organizations such as Snopes, FactCheck and Politifact, which manually verify claims. Unfortunately, this is inefficient for several reasons. First, manual fact-checking is slow and debunking false information comes too late to have any significant impact. At the same time, automatic fact-checking lags behind in terms of accuracy, and it is generally not trusted by human users. In fact, even when done by reputable fact-checking organizations, debunking does little to convince those who already believe in false information.

A third, and arguably more promising, way to fight "fake news" is to focus on their source. While "fake news" are spreading primarily on social media, they still need a "home", i.e., a website where they would be posted. Thus, if a website is known to have published non-factual information in the past, it is likely to do so in the future. Verifying the reliability of the source of information is one of the basic tools that journalists in traditional media use to verify information. It is also arguably an important prior for fact-checking systems (Popat et al., 2017; Nguyen et al., 2018).

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3528–3539
Brussels, Belgium, October 31 - November 4, 2018.

Fact-checking organizations have been producing lists of unreliable online news sources, but these are incomplete and get outdated quickly. Therefore, there is a need to predict the factuality of reporting for a given online medium automatically, which is the focus of the present work. We further study the bias of the source (left vs. right), as the two problems are inter-connected, e.g., extreme-left and extreme-right websites tend to score low in terms of factual reporting. Our contributions can be summarized as follows:

- We focus on an under-explored but arguably very important problem: predicting the factuality of reporting of a news medium. We further study bias, which is also under-explored.
- We create a new dataset of news media sources, which has annotations for both tasks, and is 1-2 orders of magnitude larger than what was used in previous work. We release the dataset and our code, which should facilitate future research.[1]
- We use a variety of sources such as (*i*) a sample of articles from the target website, (*ii*) its Wikipedia page, (*iii*) its Twitter account, (*iv*) the structure of its URL, and (*v*) information about the Web traffic it has attracted. This combination, as well as some of the sources, are novel for these problems.
- We further perform an ablation study of the impact of the individual (groups of) features.

The remainder of this paper is organized as follows: Section 2 provides an overview of related work. Section 3 describes our method and features. Section 4 presents the data, the experiments, and the evaluation results. Finally, Section 5 concludes with some directions for future work.

2 Related Work

Journalists, online users, and researchers are well-aware of the proliferation of false information, and thus topics such as credibility and fact-checking are becoming increasingly important. For example, the ACM Transactions on Information Systems journal dedicated, in 2016, a special issue on Trust and Veracity of Information in Social Media (Papadopoulos et al., 2016).

There have also been some related shared tasks such as the SemEval-2017 task 8 on Rumor Detection (Derczynski et al., 2017), the CLEF-2018 lab on Automatic Identification and Verification of Claims in Political Debates (Atanasova et al., 2018; Barrón-Cedeño et al., 2018; Nakov et al., 2018), and the FEVER-2018 task on Fact Extraction and VERification (Thorne et al., 2018).

The interested reader can learn more about "fake news" from the overview by Shu et al. (2017), which adopted a data mining perspective and focused on social media. Another recent survey was run by Thorne and Vlachos (2018), which took a fact-checking perspective on "fake news" and related problems. Yet another survey was performed by Li et al. (2016), covering truth discovery in general. Moreover, there were two recent articles in *Science*: Lazer et al. (2018) offered a general overview and discussion on the science of "fake news", while Vosoughi et al. (2018) focused on the process of proliferation of true and false news online. In particular, they analyzed 126K stories tweeted by 3M people more than 4.5M times, and confirmed that "fake news" spread much wider than true news.

Veracity of information has been studied at different levels: (*i*) claim-level (e.g., *fact-checking*), (*ii*) article-level (e.g., *"fake news" detection*), (*iii*) user-level (e.g., *hunting for trolls*), and (*iv*) medium-level (e.g., *source reliability estimation*). Our primary interest here is in the latter.

2.1 Fact-Checking

At the claim-level, fact-checking and rumor detection have been primarily addressed using information extracted from social media, i.e., based on how users comment on the target claim (Canini et al., 2011; Castillo et al., 2011; Ma et al., 2015, 2016; Zubiaga et al., 2016; Ma et al., 2017; Dungs et al., 2018; Kochkina et al., 2018). The Web has also been used as a source of information (Mukherjee and Weikum, 2015; Popat et al., 2016, 2017; Karadzhov et al., 2017b; Mihaylova et al., 2018; Baly et al., 2018).

In both cases, the most important information sources are *stance* (does a tweet or a news article agree or disagree with the claim?), and *source reliability* (do we trust the user who posted the tweet or the medium that published the news article?). Other important sources are linguistic expression, meta information, and temporal dynamics.

---

[1] The data and the code are at `http://github.mit.edu/CSAIL-SLS/News-Media-Reliability/`

2.2 Stance Detection

Stance detection has been addressed as a task in its own right, where models have been developed based on data from the Fake News Challenge (Riedel et al., 2017; Thorne et al., 2017; Mohtarami et al., 2018; Hanselowski et al., 2018), or from SemEval-2017 Task 8 (Derczynski et al., 2017; Dungs et al., 2018; Zubiaga et al., 2018). It has also been studied for other languages such as Arabic (Darwish et al., 2017b; Baly et al., 2018).

2.3 Source Reliability Estimation

Unlike stance detection, the problem of source reliability remains largely under-explored. In the case of social media, it concerns modeling the user[2] who posted a particular message/tweet, while in the case of the Web, it is about the trustworthiness of the source (the URL domain, the medium). The latter is our focus in this paper.

In previous work, the source reliability of news media has often been estimated automatically based on the general stance of the target medium with respect to known manually fact-checked claims, without access to gold labels about the overall medium-level factuality of reporting (Mukherjee and Weikum, 2015; Popat et al., 2016, 2017, 2018). The assumption is that reliable media agree with true claims and disagree with false ones, while for unreliable media it is mostly the other way around. The trustworthiness of Web sources has also been studied from a Data Analytics perspective. For instance, Dong et al. (2015) proposed that a trustworthy source is one that contains very few false facts. In this paper, we follow a different approach by studying the source reliability as a task in its own right, using manual gold annotations specific for the task.

Note that estimating the reliability of a source is important not only when fact-checking a claim (Popat et al., 2017; Nguyen et al., 2018), but it also gives an important prior when solving article-level tasks such as "fake news" and click-bait detection (Brill, 2001; Finberg et al., 2002; Hardalov et al., 2016; Karadzhov et al., 2017a; De Sarkar et al., 2018; Pan et al., 2018; Pérez-Rosas et al., 2018).

2.4 "Fake News" Detection

Most work on "fake news" detection has relied on medium-level labels, which were then assumed to hold for all articles from that source.

Horne and Adali (2017) analyzed three small datasets ranging from a couple of hundred to a few thousand articles from a couple of dozen sources, comparing (*i*) real news vs. (*ii*) "fake news" vs. (*iii*) satire, and found that the latter two have a lot in common across a number of dimensions. They designed a rich set of features that analyze the text of a news article, modeling its complexity, style, and psychological characteristics. They found that "fake news" pack a lot of information in the title (as the focus is on users who do not read beyond the title), and use shorter, simpler, and repetitive content in the body (as writing fake information takes a lot of effort). Thus, they argued that the title and the body should be analyzed separately.

In follow-up work, Horne et al. (2018b) created a large-scale dataset covering 136K articles from 92 sources from `opensources.co`, which they characterize based on 130 features from seven categories: structural, sentiment, engagement, topic-dependent, complexity, bias, and morality. We use this set of features when analyzing news articles.

In yet another follow-up work, Horne et al. (2018a) trained a classifier to predict whether a given news article is coming from a reliable or from an unreliable ("*fake news*" or *conspiracy*)[3] source. Note that they assumed that all news from a given website would share the same reliability class. Such an assumption is fine for training (distant supervision), but we find it problematic for testing, where we believe manual documents-level labels are needed.

Potthast et al. (2018) used 1,627 articles from nine sources, whose factuality has been manually verified by professional journalists from BuzzFeed. They applied stylometric analysis, which was originally designed for authorship verification, to predict factuality (fake vs. real).

Rashkin et al. (2017) focused on the language used by "fake news" and compared the prevalence of several features in articles coming from trusted sources vs. hoaxes vs. satire vs. propaganda. However, their linguistic analysis and their automatic classification were at the article level and they only covered eight news media sources.

---

[2] User modeling in social media and news community forums has focused on finding malicious users such as opinion manipulation *trolls*, paid (Mihaylov et al., 2015b) or just perceived (Mihaylov et al., 2015a; Mihaylov and Nakov, 2016; Mihaylov et al., 2018; Mihaylova et al., 2018), *sockpuppets* (Maity et al., 2017), *Internet water army* (Chen et al., 2013), and *seminar users* (Darwish et al., 2017a).

[3] We show in parentheses, the labels from `opensources.co` that are used to define a category.

Unlike the above work, (*i*) we perform classification at the news medium level rather than focusing on an individual article. Thus, (*ii*) we use reliable manually-annotated labels as opposed to noisy labels resulting from projecting the category of a news medium to all news articles published by this medium (as most of the work above did).[4] Moreover, (*iii*) we use a much larger set of news sources, namely 1,066, which is 1-2 orders of magnitude larger than what was used in previous work. Furthermore, (*iv*) we use a larger number of features and a wider variety of feature types compared to the above work, including features extracted from knowledge sources that have been largely neglected in the literature so far such as information from Wikipedia and the structure of the medium's URL.

2.5 Media Bias Detection

As we mentioned above, bias was used as a feature for "fake news" detection (Horne et al., 2018b). It has also been the target of classification, e.g., Horne et al. (2018a) predicted whether an article is biased (*political* or *bias*) vs. unbiased. Similarly, Potthast et al. (2018) classified the bias in a target article as (*i*) left vs. right vs. mainstream, or as (*ii*) hyper-partisan vs. mainstream. Finally, Rashkin et al. (2017) studied propaganda, which can be seen as extreme bias. See also a recent position paper (Pitoura et al., 2018) and an overview on bias the Web (Baeza-Yates, 2018).

Unlike the above work, we focus on bias at the medium level rather than at the article level. Moreover, we work with fine-grained labels on an ordinal scale rather then having a binary setup (some work above had three degrees of bias, while we have seven).

3 Method

In order to predict the factuality of reporting and the bias for a given news medium, we collect information from multiple relevant sources, which we use to train a classifier. In particular, we collect a rich set of features derived from (*i*) a sample of articles from the target news medium, (*ii*) its Wikipedia page if it exists, (*iii*) its Twitter account if it exists, (*iv*) the structure of its URL, and (*v*) information about the Web traffic it has attracted. We describe each of these sources below.

Articles We argue that analysis (textual, syntactic and semantic) of the content of the news articles published by a given target medium should be critical for assessing the factuality of its reporting, as well as of its potential bias. Towards this goal, we borrow a set of 141 features that were previously proposed for detecting "fake news" articles (Horne et al., 2018b), as we have described above. These features are used to analyze the following article characteristics:

- **Structure**: POS tags, linguistic features based on the use of specific words (function words, pronouns, etc.), and features for clickbait title classification from (Chakraborty et al., 2016);
- **Sentiment**: sentiment scores using lexicons (Recasens et al., 2013; Mitchell et al., 2013) and full systems (Hutto and Gilbert, 2014);
- **Engagement**: number of shares, reactions, and comments on Facebook;
- **Topic**: lexicon features to differentiate between science topics and personal concerns;
- **Complexity**: type-token ratio, readability, number of cognitive process words (identifying discrepancy, insight, certainty, etc.);
- **Bias**: features modeling bias using lexicons (Recasens et al., 2013; Mukherjee and Weikum, 2015) and subjectivity as calculated using pre-trained classifiers (Horne et al., 2017);
- **Morality**: features based on the Moral Foundation Theory (Graham et al., 2009) and lexicons (Lin et al., 2017)

Further details are available in (Horne et al., 2018b). For each target medium, we retrieve some articles, then we calculate these features separately for the title and for the body of each article, and finally we average the values of the 141 features over the set of retrieved articles.

Wikipedia We further leverage Wikipedia as an additional source of information that can help predict the factuality of reporting and the bias of a target medium. For example, the absence of a Wikipedia page may indicate that a website is not credible. Also, the content of the page might explicitly mention that a certain website is satirical, left-wing, or has some property related to our task.

---

[4] Two notable exceptions are (Potthast et al., 2018) and (Pérez-Rosas et al., 2018), who use news articles whose factuality has been manually checked and annotated.

Accordingly, we extract the following features:

- *Has Page:* indicates whether the target medium has a Wikipedia page;
- Vector representation for each of the following segments of the Wikipedia page, whenever applicable: *Content*, *Infobox*, *Summary*, *Categories*, and *Table of Contents*. We generate these representations by averaging the word embeddings (pretrained word2vec embeddings) of the corresponding words.

Twitter Given the proliferation of social media, most news media have Twitter accounts, which they use to reach out to more users online. The information that can be extracted from a news medium's Twitter profile can be valuable for our tasks. In particular, we use the following features:

- *Has Account:* Whether the medium has a Twitter account. We check this based on the top results for a search against Google, restricting the domain to `twitter.com`. The idea is that media that publish unreliable information might have no Twitter accounts.
- *Verified:* Whether the account is verified by Twitter. The assumption is that "fake news" media would be less likely to have their Twitter account verified. They might be interested in pushing their content to users via Twitter, but they would also be cautious about revealing who they are (which is required by Twitter to get them verified).
- *Created:* The year the account was created. The idea is that accounts that have been active over a longer period of time are more likely to belong to established media.
- *Has Location:* Whether the account provides information about its location. The idea is that established media are likely to have this public, while "fake news" media may want to hide it.
- *URL Match:* Whether the account includes a URL to the medium, and whether it matches the URL we started the search with. Established media are interested in attracting traffic to their website, while fake media might not. Moreover, some fake accounts mimic genuine media, but have a slightly different domain, e.g., `.com.co` instead of `.com`.
- *Counts*: Statistics about the number of friends, statuses, and favorites. Established media might have higher values for these.
- *Description:* A vector representation generated by averaging the *Google News* embeddings (Mikolov et al., 2013) of all words of the profile description paragraph. These short descriptions might contain an open declaration of partisanship, i.e., left or right political ideology (bias). This could also help predict factuality as extreme partisanship often implies low factuality. In contrast, "fake news" media might just leave this description empty, while high-quality media would want to give some information about who they are.

URL We also collect additional information from the website's URL using character-based modeling and hand-crafted features. URL features are commonly used in phishing website detection systems to identify malicious URLs that aim to mislead users (Ma et al., 2009). As we want to predict a website's factuality, using URL features is justified by the fact that low-quality websites sometimes try to mimic popular news media by using a URL that looks similar to the credible source. We use the following URL-related features:

- *Character-based:* Used to model the URL by representing it in the form of a one-hot vector of character n-grams, where $n \in [2, 5]$. Note that these features are not used in the final system as they could not outperform the baseline (when used in isolation).
- *Orthographic:* These features are very effective for detecting phishing websites, as malicious URLs tend to make excessive use of special characters and sections, and ultimately end up being longer. For this work, we use the length of the URL, the number of sections and the excessive use of special characters such as digits, hyphens and dashes. In particular, we identify whether the URL contains digits, dashes or underscores as individual symbols, which were found to be useful as features for detecting phishing URLs (Basnet et al., 2014). We also check whether the URL contains short (less than three symbols) or long sections (more than ten symbols), as a high number of such sections could indicate an irregular URL.

Freedom Outpost	`http://freedomoutpost.com/`	Extreme Right	@FreedomOutpost	N/A

Table 2: Examples of media with various bias scores.

- *Credibility:* Model the website's URL credibility by analyzing whether it (*i*) uses `https://`, (*ii*) resides on a blog-hosting platform such as `blogger.com`, and (*iii*) uses a special top-level domain, e.g., `.gov` is for governmental websites, which are generally credible and unbiased, whereas `.co` is often used to mimic `.com`.

Web Traffic Analyzing the web traffic to the website of the medium might be useful for detecting phishy websites that come and disappear in certain patterns. Here, we only use the reciprocal value of the website's *Alexa Rank*,[5] which is a global ranking for over 30 million websites in terms of the traffic they receive.

We evaluate the above features in Section 4, both individually and as groups, in order to determine which ones are important to predict factuality and bias, and also to identify the ones that are worth further investigation in future work.

4 Experiments and Evaluation

4.1 Data

We use information about news media listed on the Media Bias/Fact Check (MBFC) website,[6] which contains manual annotations and analysis of the factuality of reporting and/or bias for over 2,000 news websites. Our dataset includes 1,066 websites for which *both* bias and factuality labels were explicitly provided, or could be easily inferred (e.g., *satire* is of low factuality).

We model factuality on a 3-point scale (*Low*, *Mixed*, and *High*),[7] and bias on a 7-point scale (*Extreme-Left*, *Left*, *Center-Left*, *Center*, *Center-Right*, *Right*, and *Extreme-Right*).

Some examples from our dataset are presented in Table 1 for factuality of reporting, and in Table 2 for bias. In both tables, we show the names of the media, as well as their corresponding Twitter handles and Wikipedia pages, which we found automatically. Overall, 64% of the websites in our dataset have Wikipedia pages, and 94% have Twitter accounts. In cases of "fake news" sites that try to mimic real ones, e.g., `ABCnews.com.co` is a fake version of `ABCnews.com`, it is possible that our Twitter extractor returns the handle for the real medium. This is where the *URL Match* feature comes handy (see above).

Table 3 provides detailed statistics about the dataset. Note that we have 1-2 orders of magnitude more media sources than what has been used in previous studies, as we already mentioned in Section 2 above.

Factuality		Bias	
Low	256	Extreme-Left	21
Mixed	268	Left	168
High	542	Center-Left	209
		Center	263
		Center-Right	92
		Right	157
		Extreme-Right	156

Table 3: Label distribution (counts) in our dataset.

Table 4: Results for factuality and bias prediction. **Bold** values indicate the best-performing feature type in its family of features, while **underlined** values indicate the best-performing feature type overall.

In order to compute the article-related features, we did the following: (*i*) we crawled 10–100 articles per website (a total of 94,814), (*ii*) we computed a feature vector for each article, and (*iii*) we averaged the feature vectors for the articles from the same website to obtain the final vector of article-related features.

4.2 Experimental Setup

We used the above features in a Support Vector Machine (SVM) classifier, training a separate model for factuality and for bias. We report results for 5-fold cross-validation. We tuned the SVM hyper-parameters, i.e., the cost C, the kernel type, and the kernel width γ, using an internal cross-validation on the training set and optimizing macro-averaged F_1. Generally, the RBF kernel performed better than the linear kernel.

We report accuracy and macro-averaged F_1 score. We also report Mean Average Error (MAE), which is relevant given the ordinal nature of both the factuality and the bias classes, and also MAE^M, which is a variant of MAE that is more robust to class imbalance. See (Baccianella et al., 2009; Rosenthal et al., 2017) for more details about MAE^M vs. MAE.

4.3 Results and Discussion

We present in Table 4 the results of using features from the different sources proposed in Section 3. We start by describing the contribution of each feature type towards factuality and bias.

We can see that the textual features extracted from the ARTICLES yielded the best performance on factuality. They also perform well on bias, being the only type that beats the baseline on MAE. These results indicate the importance of analyzing the contents of the target website. They also show that using the *titles* only is not enough, and that the article *bodies* contain important information that should not be ignored.

Overall, the WIKIPEDIA features are less useful for factuality, and perform reasonably well for bias. The best features from this family are those about the page *content*, which includes a general description of the medium, its history, ideology and other information that can be potentially helpful. Interestingly, the *has page* feature alone yields sizable improvement over the baseline, especially for factuality. This makes sense given that trustworthy websites are more likely to have Wikipedia pages; yet, this feature does not help much for predicting political bias.

Features	Macro-F$_1$	Acc.	MAE	MAE^M
MAJORITY BASELINE	22.47	50.84	0.73	1.00
FULL	59.91	65.48	0.41	0.44

FULL W/O TWITTER	36.88	39.49	1.20	1.38	63.27	69.89	0.38	0.50
FULL W/O URL	36.60	39.68	1.24	1.48	60.93	68.11	0.40	0.53
FULL W/O WIKIPEDIA	34.75	37.62	1.33	1.58	59.92	66.89	0.41	0.54
FULL W/O ARTICLES	29.95	36.96	1.40	1.85	53.67	62.48	0.47	0.62

Table 6: Ablation study for the contribution of each feature type for predicting media bias.

The TWITTER features perform moderately for factuality and poorly for bias. This is not surprising, as we normally may not be able to tell much about the political ideology of a website just by looking at its Twitter profile (not its tweets!) unless something is mentioned in its *description*, which turns out to perform better than the rest of the features from this family. We can see that the *has twitter* feature is less effective than *has wiki* for factuality, which makes sense given that Twitter is less regulated than Wikipedia. Note that the *counts* features yield reasonable performance, indicating that information about activity (e.g., number of statuses) and social connectivity (e.g., number of followers) is useful. Overall, the TWITTER features seem to complement each other, as their union yields the best performance on factuality.

The URL features are better used for factuality rather than bias prediction. This is mainly due to the nature of these features, which are aimed at detecting phishing websites, as we mentioned in Section 3. Overall, this feature family yields slight improvements, suggesting that it can be useful when used together with other features.

Finally, the *Alexa rank* does not improve over the baseline, which suggests that more sophisticated TRAFFIC-related features might be needed.

4.4 Ablation Study

Finally, we performed an ablation study in order to evaluate the impact of removing one family of features at a time, as compared to the FULL system, which uses all the features. We can see in Tables 5 and 6 that the FULL system achieved the best results for factuality, and the best macro-F$_1$ for bias, suggesting that the different types of features are largely complementary and capture different aspects that are all important for making a good classification decision.

For factuality, excluding the WIKIPEDIA features yielded the biggest drop in performance. This suggests that they provide information that may not be available in other sources, including the ARTICLES, which achieved better results alone. On the other hand, excluding the TRAFFIC feature had no effect on the model's performance.

For bias, we experimented with classification on both a 7-point and a 3-point scale.[8] Similarly to factuality, the results in Table 6 indicate that WIKIPEDIA offers complementary information that is critical for bias prediction, while TRAFFIC makes virtually no difference.

---

[8] We performed the following mapping: {*Extreme-Right, Right*}→Right, {*Extreme-Left, Left*}→Left, and {*Center, Right-Center, Left-Center*}→Center

5 Conclusion and Future Work

We have presented a study on predicting factuality of reporting and bias of news media, focusing on characterizing them as a whole. These are under-studied, but arguably important research problems, both in their own right and as a prior for fact-checking systems.

We have created a new dataset of news media sources that has annotations for both tasks and is 1-2 orders of magnitude larger than what was used in previous work. We are releasing the dataset and our code, which should facilitate future research.

We have experimented with a rich set of features derived from the contents of (*i*) a sample of articles from the target news medium, (*ii*) its Wikipedia page, (*iii*) its Twitter account, (*iv*) the structure of its URL, and (*v*) information about the Web traffic it has attracted. This combination, as well as some of the types of features, are novel for this problem.

Our evaluation results have shown that most of these features have a notable impact on performance, with the articles from the target website, its Wikipedia page, and its Twitter account being the most important (in this order). We further performed an ablation study of the impact of the individual types of features for both tasks, which could give general directions for future research.

In future work, we plan to address the task as ordinal regression, and further to model the inter-dependencies between factuality and bias in a joint model. We are also interested in characterizing the factuality of reporting for media in other languages. Finally, we want to go beyond *left vs. right* bias that is typical of the Western world and to model other kinds of biases that are more relevant for other regions, e.g., *islamist vs. secular* is one such example for the Muslim World.

Acknowledgments

This research was carried out in collaboration between the MIT Computer Science and Artificial Intelligence Laboratory (CSAIL) and the Qatar Computing Research Institute (QCRI), HBKU.

We would like to thank Israa Jaradat, Kritika Mishra, Ishita Chopra, Laila El-Beheiry, Tanya Shastri, and Hamdy Mubarak for helping us with the data extraction, cleansing, and preparation.

Finally, we thank the anonymous reviewers for their constructive comments, which have helped us improve this paper.

Abstract

Legal **J**udgment **P**rediction (**LJP**) aims to predict the judgment result based on the facts of a case and becomes a promising application of artificial intelligence techniques in the legal field. In real-world scenarios, legal judgment usually consists of multiple subtasks, such as the decisions of applicable law articles, charges, fines, and the term of penalty. Moreover, there exist topological dependencies among these subtasks. While most existing works only focus on a specific subtask of judgment prediction and ignore the dependencies among subtasks, we formalize the dependencies among subtasks as a Directed Acyclic Graph (DAG) and propose a topological multi-task learning framework, TOPJUDGE, which incorporates multiple subtasks and DAG dependencies into judgment prediction. We conduct experiments on several real-world large-scale datasets of criminal cases in the civil law system. Experimental results show that our model achieves consistent and significant improvements over baselines on all judgment prediction tasks. The source code can be obtained from `https://github.com/thunlp/TopJudge`.

1 Introduction

Legal **J**udgment **P**rediction (**LJP**) aims to predict the judgment results of legal cases according to the fact descriptions. It is a critical technique for the legal assistant system. On the one hand, LJP can provide low-cost but high-quality legal consulting services to the masses who are unfamiliar with legal terminology and the complex judgment procedures. On the other hand, it can serve as the handy reference for professionals (e.g., lawyers and judges) and improve their work efficiency.

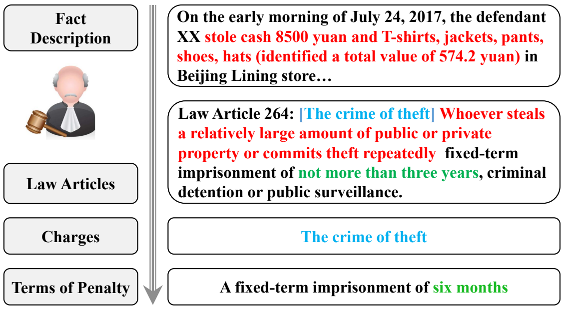

Figure 1: An illustration of the judicial logic of human judges in civil law system.

LJP has been studied for decades (Kort, 1957; Ulmer, 1963; Nagel, 1963; Keown, 1980; Segal, 1984; Lauderdale and Clark, 2012; Ye et al., 2018; Hu et al., 2018), and most existing works formalize LJP as a text classification task. For example, some works (Liu et al., 2004; Liu and Hsieh, 2006) propose to extract shallow textual features (e.g. characters, words, and phrases) for charge prediction. Katz et al. (2017) predict the US Supreme Court's decisions based on efficient features from case profiles. Luo et al. (2017) propose an attention-based neural model for charge prediction by incorporating the relevant law articles.

Despite these efforts in designing efficient features and employing advanced NLP techniques, LJP is still confronted with two major challenges:

Multiple Subtasks in Legal Judgment: Practically, legal judgment usually consists of detailed and complicated subclauses, such as charges, the term of penalty, and fines. Specifically, for those countries with the *civil law system* (e.g., China, France, and Germany), the prediction of relevant articles is also considered to be one of the fundamental subtasks, which will guide the prediction for other subtasks. In other words, all these subtasks compose the complete form of judgment pre-

---

Brussels, Belgium, October 31 - November 4, 2018. ©2018 Association for Computational Linguistics

diction. Nevertheless, existing works on LJP usually focus on one specific subtask of judgments, which does not conform to the real scenarios. Although some methods (Luo et al., 2017) are developed to predict law articles and charges at the same time, their models are designed for a specific set of subtasks which are hard to scale to other subtasks.

Topological Dependencies between Subtasks: For human judges, there exists a strict order among the subtasks of legal judgment. As illustrated in Fig. 1, given the fact description of a specific case, a judge in the civil law system first decides which law articles are relevant to the scenario, and then determines the charges according to the instructions of relevant law articles. Based on these results, the judge further confirms the term of penalty and fines. How to simulate the judicial logic of human judges and model the topological dependencies among legal subtasks will deeply influence the creditability and interpretability of judgment prediction.

As stated above, conventional works cannot handle these two challenges due to both the limitation of specific tasks and neglecting topological dependencies. To address these issues, we propose to model the multiple subtasks in judgment prediction jointly under a novel multi-task learning framework.

We model the topological dependencies among these subtasks with a Directed Acyclic Graph (DAG), which means all subtasks are arranged in topological order. If the judgment of the j-th subtask t_j depends on the output of the i-th subtask t_i, then t_i appears earlier than t_j in such order. It is notable that such formulation provides an explicit explanation of dependency relations among subtasks.

Accordingly, we introduce topological learning for LJP and propose a unified framework, named as TOPJUDGE. Specifically, given the encoded representation of the fact description, TOPJUDGE predicts the outputs of all the subtasks following the topological order, and the output of a specific subtask will be affected by all the subtasks it depends on. In contrast with conventional multi-task learning, our model takes the explicit topological dependencies of LJP subtasks into consideration and is flexible to handle other LJP subtasks. Moreover, the topological order of legal dependencies renders our model interpretable and reliable.

To verify the effectiveness and flexibility of TOPJUDGE, we conduct a series of experiments on several real-world large-scale datasets. Experimental results show that our model achieves significant and consistent improvements over state-of-the-art models on all tasks and datasets. To summarize, we make several noteworthy contributions as follows:

(1) We are the first to explore and formalize the multiple subtasks of legal judgment under a joint learning framework. Moreover, we formulate the dependencies among the subtasks of LJP as a form of DAG and introduce this prior knowledge to enhance judgment prediction.

(2) We propose a novel judgment prediction framework, TOPJUDGE, to unify multiple subtasks and make judgment predictions through topological learning. This model can handle any form of DAG dependent subtasks, which has been verified in the experiments.

(3) We carry out experiments on several large-scale real-world datasets, and our model significantly and consistently outperforms all the baselines on all subtasks.

2 Related Work

2.1 Judgment Prediction

Employing automatic analysis techniques for legal judgment has drawn attention from researchers in the legal field for decades. Early works usually focus on analyzing existing legal cases in specific scenarios with mathematical and statistical algorithms (Kort, 1957; Ulmer, 1963; Nagel, 1963; Keown, 1980; Segal, 1984; Lauderdale and Clark, 2012).

With the development of machine learning and text mining techniques, more researchersformalize this task under text classification frameworks. Most of these studies attempt to extract efficient features from text content (Liu and Hsieh, 2006; Lin et al., 2012; Aletras et al., 2016; Sulea et al., 2017) or case annotations (e.g., dates, terms, locations, and types) (Katz et al., 2017). However, these conventional methods can only utilize shallow textual features and manually designed factors, both require massive human efforts and usually suffer from the generalization issue when applied to other scenarios.

Inspired by the success of neural networks on NLP tasks (Kim, 2014; Baharudin et al., 2010; Tang et al., 2015), researchers began to handle LJP by incorporating neural models with legal knowledge. For example, Luo et al. (2017) present an attention-based neural network that jointly models charge prediction and relevant article extraction. Hu et al. (2018) incorporate 10 discriminative legal attributes to predict few-shot and confusing charges. Nevertheless, these models are designed for specific subtasks and thus non-trivial to be extended to more subtasks of LJP with complex dependencies. Besides, Ye et al. (2018) utilize a Seq2Seq model to generate court views with fact descriptions and predicted charges in Chinese civil law.

2.2 Multi-task Learning

Multi-task learning (MTL) aims to exploit the commonalities and differences across relevant tasks by solving them at the same time. It can transfer useful information among various tasks and has been applied to a wide range of areas, including NLP (Collobert and Weston, 2008), speech recognition (Deng et al., 2013), and computer vision (Girshick, 2015; Mao et al., 2017).

There have been numerous successful usages of MTL in NLP tasks. Most works follow the *hard parameter sharing* setting by sharing representations or some encoding layers among relevant tasks. For example, Collobert and Weston (2008) use shared word embeddings in solving part-of-speech tagging and semantic role labeling tasks. Liu et al. (2015) share the encoding layers of input queries to address query classification and information retrieval. Dong et al. (2015) and Luong et al. (2016) propose to share encoders or decoders to improve one (many) to many neural machine translation. Firat et al. (2016) propose to share attention mechanism in multi-way, multilingual machine translation. Besides *hard parameter sharing*, *soft parameter sharing* is another common approach in MTL. It assumes that each task owns its specific parameters and the distance between parameters in different tasks should be close to each other. For example, Duong et al. (2015) employ L2 distance for regularization, while Yang and Hospedales (2017) use the trace norm. Liu et al. (2016) introduce gates among task-specific RNN layers to control the information flow. Ruder et al. (2017) introduce a model which can decide the amount of sharing between different NLP tasks. There are also some works focusing on increasing tasks (Hashimoto et al., 2017) or handing unlabeled data (Augenstein et al., 2018).

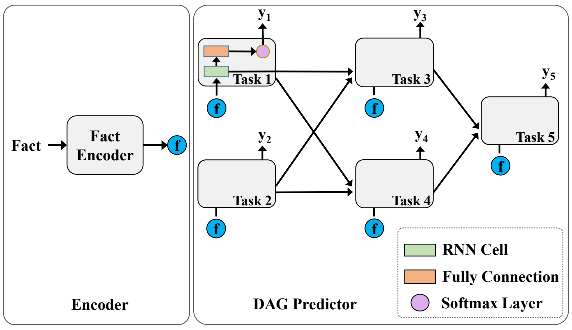

Figure 2: The framework of TopJudge.

In this work, we introduce a topological learning framework TOPJUDGE to handle multiple subtasks in LJP. Different to conventional MTL models which focus on how to share parameters among relevant tasks, TOPJUDGE models the explicit dependencies among these subtasks with scalable DAG forms.

3 Method

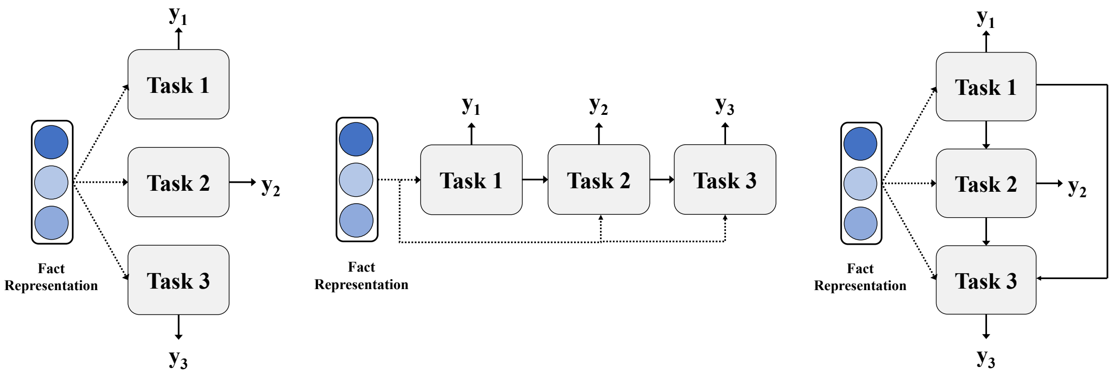
In the following parts, we will first give the essential definitions of LJP task. We then introduce the DAG dependencies of the subtasks in LJP. And finally, we describe the neural encoder for fact representation and the judgment predictor for the subtasks with DAG dependencies. The overall framework of TopJudge has been shown in Fig 2.

3.1 Problem Formulation

We will focus on the LJP tasks in civil law. Suppose the fact description of a case is a word sequence $\mathbf{x} = \{x_1, x_2, \dots, x_n\}$, where n is the length of $\mathbf{x}$ and each word x_i comes from a fixed vocabulary W. Based on the fact description $\mathbf{x}$, the task of LJP T aims to predict judgment results of applicable law articles, charges, term of penalty, fines and so on. Formally, we assume T contains $|T|$ subtasks, i.e., $T = \{t_1, t_2, \dots, t_{|T|}\}$, each of which is a classification task. For the i-th subtask $t_i \in T$, we aim to predict the corresponding result $\mathbf{y}_i \subseteq Y_i$, where Y_i is a subtask-specific label set. Take the subtask of charge prediction for example, the corresponding label set should contain *Theft*, *Traffic Violation*, *Intentional Homicide* and so on.

3.2 DAG Dependencies of Subtasks

We assume that the dependencies among multiple subtasks of LJP form a DAG. As a result, the task list T should satisfy topological constraints. Formally, we use the notation $t_i \lhd t_j$ to denote that



(a) Typical MTL form of DAG (b) Sequential form of DAG (c) General form of DAG

Figure 3: Three typical forms of DAG dependencies.

the j-th subtask depends on the i-th subtask, and $D_j = \{t_i \mid t_i \lhd t_j\}$ to denote the dependency set. The task list T can be ordered to satisfy the following constraint

$$i < j, \quad \forall (i, j) \in \{(i, j) \mid t_i \in D_j\}. \tag{1}$$

We demonstrate the flexibility of our formulation by describing two special cases: (1) As shown in Fig. 3 (a), if no dependencies exist, i.e., $D_j = \emptyset$, it corresponds to the typical MTL setting where we simultaneously make predictions for all subtasks. (2) As shown in Fig. 3 (b), if each task only depends on its previous task, i.e., $D_j = \{t_{j-1}\}$, it forms a sequential learning process.

3.3 Neural Encoder for Fact Descriptions

We employ a fact encoder to generate the fact description's vector representation as the input of TOPJUDGE. In the following part, we briefly introduce an encoder based on Convolutional Neural Networks (CNN) (Kim, 2014).

Taking a word sequence $\mathbf{x}$ as input, the CNN encoder computes the text representation through three layers, i.e., lookup layer, convolution layer and pooling layer.

Lookup We first convert each word x_i in $\mathbf{x}$ into its word embedding $\mathbf{x}_i \in \mathbb{R}^k$, where k is the dimension of word embeddings. The word embedding sequence is then represented as

$$\hat{\mathbf{x}} = \{\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n\}. \tag{2}$$

Convolution A convolution operation involves a convolution matrix $\mathbf{W} \in \mathbb{R}^{m \times (h \times k)}$, which is applied to a sliding window of length h with number of filters m to produce a feature map by

$$\mathbf{c}_i = \mathbf{W} \cdot \mathbf{x}_{i:i+h-1} + \mathbf{b}, \tag{3}$$

where $\mathbf{x}_{i:i+h-1}$ is the concatenation of word embeddings within the i-th window and $\mathbf{b} \in \mathbb{R}^m$ is the bias vector. By applying convolution over each window, we obtain $\mathbf{c} = \{\mathbf{c}_1, \ldots, \mathbf{c}_{n-h+1}\}$.

Pooling We apply per-dimension max-pooling over $\mathbf{c}$ and obtain the final fact representation $\mathbf{d} = [d_1, \ldots, d_m]$ by

$$d_t = \max(\mathbf{c}_{1,t}, \ldots, \mathbf{c}_{n-h+1,t}), \forall t \in [1, m]. \tag{4}$$

3.4 Judgment Predictor over DAG

Based on the DAG assumption, we obtain an ordered task list $T^* = [t_1, t_2, \ldots, t_{|T|}]$. For each task $t_j \in T$, we aim to predict its judgment result $\mathbf{y}_j$ based on the fact representation vector $\mathbf{d}$ and the judgment results of its dependent tasks.

For prediction, we employ a specific LSTM cell for each task and get the output of each task in the topological order. More specifically, for each task $t_j \in T$, we obtain its final judgment result through three steps, i.e., cell initialization, task-specific representation, and prediction.

Cell Initialization As stated above, the prediction result of t_j will be conditioned on the fact representation $\mathbf{d}$ and the outputs of all dependent tasks $\mathbf{y}_k, \forall t_k \in D_j$. Hence, we have

$$\begin{bmatrix} \bar{\mathbf{h}}_j \\ \bar{\mathbf{c}}_j \end{bmatrix} = \sum_{t_i \in D_j} \left(\mathbf{W}_{i,j} \begin{bmatrix} \mathbf{h}_i \\ \mathbf{c}_i \end{bmatrix} \right) + \mathbf{b}_j \tag{5}$$

Here, $\mathbf{h}_i$ and $\mathbf{c}_i$ are the hidden state and memory cell of t_i. $\bar{\mathbf{h}}_j$ and $\bar{\mathbf{c}}_j$ are the initial hidden state and memory cell of t_j. $\mathbf{W}_{i,j}$ and $\mathbf{b}_j$ are transformation matrices and bias vectors specific to t_i and t_j.

Task-Specific Representation Taking the fact representation $\mathbf{d}$, the initial hidden state $\bar{\mathbf{h}}_j$, and the initial memory cell $\bar{\mathbf{c}}_j$ as inputs, we process them with an LSTM cell (Hochreiter and Schmidhuber, 1997).

We regard the final hidden state $\mathbf{h}_j$ as the task-specific representation of task t_j. The last cell state $\mathbf{c}_j$ is used to compose the initial hidden state for the downstream tasks by Eq. 5

Prediction With the representation $\mathbf{h}_j$, we apply an affine transformation followed by softmax and obtain the final prediction as

$$\hat{\mathbf{y}}_j = \text{softmax}\left(\mathbf{W}_j^p \mathbf{h}_j + \mathbf{b}_j^p\right). \tag{6}$$

Here, $\mathbf{W}_j^p$ and $\mathbf{b}_j^p$ are parameters specific to task t_j.

With the prediction result $\hat{\mathbf{y}}_j$, we minimize the cross-entropy between $\hat{\mathbf{y}}_j$ and $\mathbf{y}_j$ as follows:

$$\mathcal{L}_j(\hat{\mathbf{y}}_j, \mathbf{y}_j) = -\sum_{k=1}^{|Y_j|} \mathbf{y}_{j,k} \log(\hat{\mathbf{y}}_{j,k}). \tag{7}$$

3.5 Training

We use cross-entropy loss for each subtask and sum up losses to train TOPJUDGE:

$$\mathcal{L} = \sum_{j=1}^{|T|} \lambda_j \mathcal{L}_j(\hat{\mathbf{y}}_j, \mathbf{y}_j), \tag{8}$$

where λ_j is the weight factor for each subtask t_j. The DAG dependencies of subtasks ensure that our model is differentiable and can be trained in an end-to-end fashion. In practice, we set all weights λ_j to 1, and employ Adam (Kingma and Ba, 2015) for optimization. We also apply dropout (Srivastava et al., 2014) on the fact representation to prevent overfitting.

4 Experiments

To evaluate the proposed TOPJUDGE framework, we conduct a series of experiments on LJP over three large-scale datasets of criminal cases in China. We select three representative judgment prediction subtasks for comparison, including law articles, charges, and the terms of penalty.

4.1 Dataset Construction

As there are no publicly available LJP datasets in previous works, we collect and construct three different LJP datasets, including **CJO**, **PKU**, and **CAIL**. CJO consists of criminal cases published by the Chinese government from China Judgement Online[1]. PKU contains criminal cases published by Peking University Law Online[2]. CAIL (Chinese AI and Law Challenge) is another criminal case dataset for competition released by the Supreme People's Court of China[3]. The details of CAIL can be found in Xiao et al. (2018).

Datasets	CJO	PKU	CAIL
Cases	1,007,744	175,744	113,536
Law Articles	98	68	105
Charges	99	64	122
Term of Penalty	11	11	11

Table 1: The statistics of different datasets.

For all datasets we mentioned above, as the documents are well-structured and human-annotated, we can easily extract *fact descriptions*, *applicable law articles*, *charges* and *the terms of penalty* from each document using regular expressions. We have manually checked a randomly sampled set of cases, and extraction errors are negligible.

In real-world scenarios, there are some cases with multiple defendants and multiple charges, which will increase the complexity of judgment prediction. As our model aims to explore the effectiveness of considering topological dependencies between various subtasks, we filter out these cases and leave them as our future work.

Meanwhile, there are also some infrequent charges and law articles, such as *money laundering*, *smuggling of nuclear materials* and *tax dodge*. We filter out these infrequent charges and law articles and only keep those with frequencies greater than 100. For the term of penalty, we divide the terms into non-overlapping intervals. We list detailed statistics of these datasets in Table 1.

4.2 Baselines

For comparison, we employ the following text classification models and judgment prediction methods as baselines:

TFIDF+SVM: We employ term-frequency inverse document frequency (TFIDF) (Salton and Buckley, 1988) to extract word features and utilize SVM (Suykens and Vandewalle, 1999) for text classification.

CNN: We employ CNN with multiple filter widths (Kim, 2014) for fact encoding and classification.

Hierarchical LSTM (HLSTM): Tang et al. (2015) employs hierarchical neural networks to learn document representations in sentiment clas-

Table 3: Judgment prediction results on PKU.

sification. Based on this work, we employ an LSTM for sentence representations and another one to obtain the representation of complete fact descriptions.

Fact-Law Attention Model: Luo et al. (2017) proposes a neural charge prediction model by capturing the interaction between fact descriptions and applicable laws with attention mechanism.

Pipeline Model (PM): To demonstrate the advantage of TOPJUDGE on modeling subtasks jointly, we also implement a pipelined method for comparison. Here, we train 3 separate CNN classifiers for law articles, charges, and term of penalty. For each subtask, the input is the concatenation of the fact representation and the embeddings for predicted labels of previous subtasks.

Besides, we compare our model with conventional MTL methods that do not consider the dependencies among subtasks as in Fig. 3 (a). These methods are denoted as **CNN-MTL** and **HLSTM-MTL**, where we implement the fact encoder as in Fig. 2 using CNN or HLSTM respectively.

4.3 Experimental Settings

As the case documents are written in Chinese with no space between words, we employ THULAC (Sun et al., 2016) for word segmentation. Afterward, we adopt the Skip-Gram model (Mikolov et al., 2013) to pre-train word embeddings on these case documents, with embedding size set to 200 and frequency threshold set to 25.

For all models, we set the fact representation and task-specific representation size to 256. Meanwhile, we set the maximum sentence length to 128 words and maximum document length to 32 sentences.

For training, the learning rate of Adam optimizer is 10^{-3}, and the dropout probability is 0.5. We also set the batch size to 128 for all models. We train every model for 16 epochs, and evaluate the final model on the testing set.

We employ *accuracy* (Acc.), *macro-precision* (MP), *macro-recall* (MR) and *macro-F_1* (F_1) as evaluation metrics. Here, the macro-precision/recall/F_1 are calculated by averaging the precision/recall/F_1 of each category.

4.4 Results and Analysis

We evaluate the performance on three LJP subtasks, including law articles (denoted as t_1), charges (denoted as t_2), and the terms of penalty (denoted as t_3). Experimental results are shown in Tables 2, 3, and 4. Note that, we implement TOPJUDGE with the dependency relationship in Fig. 3 (c), i.e.,

$$D_1 = \phi, D_2 = \{t_1\}, D_3 = \{t_1, t_2\}. \quad (9)$$

	Tasks	Law Articles				Charges				The Term of Penalty			
	Metrics	Acc.	MP	MR	F_1	Acc.	MP	MR	F_1	Acc.	MP	MR	F_1
Single	TFIDF+SVM	60.1	54.9	45.3	46.3	59.2	53.9	45.0	45.7	28.4	22.9	20.0	18.1
	CNN	81.4	74.4	64.1	65.7	80.7	77.3	65.5	67.2	28.8	34.7	27.8	28.6
	HLSTM	-	-	-	-	-	-	-	-	-	-	-	-
Multi	Fact-Law Att.	70.9	64.8	63.6	59.1	68.7	66.1	65.3	60.1	36.5	29.9	27.6	27.1
	PM	84.7	80.7	68.6	70.8	83.6	81.6	70.0	72.1	**40.0**	**37.4**	32.0	31.6
	CNN-MTL	84.5	80.0	68.1	70.3	83.4	81.6	69.1	71.6	39.5	37.2	32.3	31.3
	HLSTM-MTL	-	-	-	-	-	-	-	-	-	-	-	-
Ours	**TOPJUDGE**	**86.3**	**81.9**	**71.1**	**73.4**	**85.7**	**83.4**	**76.0**	**78.3**	38.3	36.1	**33.1**	**32.1**

Table 4: Judgment prediction results on CAIL. Note that, "-" means the model does not converge within 128 epochs.

This means that the prediction of charges depends on law articles, and the prediction of term of penalty depends on both law articles and charges. Such explicit dependencies conform to the judicial logic of human judges, which will be verified in later sections. These results show that:

(1) The proposed TOPJUDGE model outperforms other baselines significantly on most subtasks and datasets. It demonstrates the effectiveness and robustness of our proposed framework.

(2) Compared with conventional single-task models, e.g., CNN and HLSTM, MTL methods take advantage of the correlation among relevant subtasks and thus achieve promising improvements. It indicates the importance of modeling LJP subtasks jointly.

(3) Moreover, TOPJUDGE significantly outperforms typical MTL models, especially on the prediction of charges and the terms of penalty. It verifies the rationality and importance of modeling dependencies over LJP subtasks with DAG.

4.5 Ablation Analysis

Tasks	t_1		t_2		t_3	
Metrics	Acc.	F_1	Acc.	F_1	Acc.	F_1
TOPJUDGE	**95.4**	**68.4**	**95.6**	**70.9**	**57.8**	**31.8**
$- t_3 \lhd t_1$	95.2	67.7	95.4	70.3	57.4	31.2
$- t_2 \lhd t_1$	94.8	64.7	94.9	60.2	57.0	31.6
ϕ	94.7	64.4	94.9	60.1	57.8	27.6

Table 5: Ablation analysis on PKU.

To further illustrate the significance of legal dependencies and explore how the DAG dependencies influence the performance, we evaluate the performance of TOPJUDGE under various DAG architectures. Using Eq. 9 as the full dependencies, we remove the dependency of $t_3 \lhd t_1$ (law articles and term of penalty, corresponding to the sequential form in Fig. 3), $t_2 \lhd t_1$ (law articles and charges), and all dependencies respectively. Results are summarized in Table 5.

We observe that the performance of TOPJUDGE decreases on all tasks after removing either dependency. More specifically, when we dropped dependencies $t_3 \lhd t_1$ and $t_2 \lhd t_1$ respectively, significant decreases are observed for t_3 and t_2 correspondingly. This demonstrates that incorporating dependencies is beneficial for relevant subtasks, verifying its guiding role in the civil law system.

Meanwhile, we note that there are two main differences between TOPJUDGE and traditional multi-task models, namely the **Cell Initialization** and the **Task-Specific Representation**. We can see that if we eliminate **Cell Initialization** from TOPJUDGE, the dependencies will not be represented in the model and it will become similar to **CNN-MTL**. If we eliminate the **Task-Specific Representation** from TOPJUDGE, TOPJUDGE will become the same as the **Pipeline Model**. In a word, the main improvement of our models comes from the combination.

4.6 Case Study

We give some intuitive examples to demonstrate the significance of TOPJUDGE on LJP subtasks.

As shown in Table 6, case 1 is about negligently causing a fire. The fact description of this case states "The defendant pulled up weeds in the fields and piled them up in haphazard stacks. Afterward, he lighted them up and triggered the forest fires..." TOPJUDGE predicts all judgments correctly, while CNN-MTL fails to predict the charge and term of penalty. Moreover, CNN-MTL obtains conflicting judgments, i.e., "*crime of arson*" and "*1-2 years*", due to its neglecting of dependencies of these subtasks. According to the legal provisions of law article 115, the crime of arson should be sentenced to more than 10 years.

Methods	Law	Charge	Term (months)
CNN-MTL	115	Arson(×)	12-24(×)
TOPJUDGE	115	Negligently Causing a Fire	0-6
CNN-MTL	293	Intentional Damage to Property(×)	12-24(×)
TOPJUDGE	293	Affray	0-6

Table 6: Example cases and their prediction results.

Case 2 in Table 6 is another evidence of the insufficiency of conventional MTL on LJP. This case is about picking quarrels and provoking troubles. Both CNN-MTL and TOPJUDGE succeed to predict the relevant law articles (i.e., law article 293 of the crime of affray). However, CNN-MTL is confused between "*crime of affray*" and "*crime of intentional destruction or damage of properties*", two charges similar to each other. Conversely, TOPJUDGE can utilize the prediction result of law articles and consequently prevent this confusion.

To summarize, modeling the explicit dependencies among various subtasks can remarkably help the LJP model address the issue of predicting conflicting results.

4.7 Error Analysis

Prediction errors induced by our proposed model can be traced down into the following causes.

Data Imbalance. For the subtasks of law articles and charges, our model achieves more than 90% on *accuracy*, while only about 60% for *macro-F1*. This issue is much more severe on the subtask of the term of penalty, which our model yields a poor performance of only 30% *macro-F1*. The bad performance is mainly due to the imbalance of category labels, e.g., there are only a few training instances where the term is "*life imprisonment or death penalty*". Most judgment prediction approaches perform poorly (especially for *Recall*) on these labels as listed in Fig. 4. Instance weighting schemes can be introduced to address this issue in future works.

Incomplete Information. Following existing LJP works, we predict the final judgment according to the fact descriptions, which is incomplete as compared to the whole materials relevant to this case. In Chinese Law, there are certain circumstances under which the sentence can be shortened. For example, minors usually receive a lightened penalty, and those guilty of misdemeanors are allowed for a secured pending trial while paying a security deposit. However, such information is not included in the fact descriptions. The lack of such information also raises difficulties for judgment prediction, especially for the prediction of the term of penalty. In Fig. 4, we can see that the highest error rate comes from the cases with a short term of penalty. Our model fails to distinguish the cases with no penalty and those with 0-6 months term of imprisonment.

	Death or Life Imprisonment	>10 yr	7-10 yr	5-7 yr	3-5 yr	2-3 yr	1-2 yr	9-12 mo	6-9 mo	0-6 mo	No penalty
Death or Life Imprisonment	25	9	10	0	3	1	2	2	1	3	0
>10 yr	22	6	32	2	94	14	13	6	0	4	0
7-10 yr	6	3	41	3	91	35	45	15	3	7	1
5-7 yr	3	1	27	6	171	41	55	8	6	7	0
3-5 yr	3	6	13	2	635	203	152	43	49	43	0
2-3 yr	4	1	11	2	234	1045	363	249	51	166	1
1-2 yr	0	0	18	0	157	408	1203	1239	365	717	3
9-12 mo	2	0	10	2	68	251	957	2541	850	2001	10
6-9 mo	0	0	3	0	35	113	555	1226	1594	2872	5
0-6 mo	0	0	4	1	29	155	473	1266	1173	18675	75
No penalty	0	1	2	0	11	50	58	176	35	1112	71

Figure 4: The confusion matrix in the subtask of predicting the term of penalty on the PKU dataset. The rows denote the ground truth while the columns denote the prediction results.

5 Conclusion

In this paper, we focus on the task of legal judgment prediction (LJP) and address multiple subtasks of judgment predication with a topological learning framework. To be specific, we formalize the explicit dependencies over these subtasks in a DAG form, and propose a novel MTL framework, TOPJUDGE, by integrating the DAG dependencies. Experimental results on three LJP subtasks and three different datasets show that our TOPJUDGE outperforms all single-task baselines and conventional MTL models consistently and significantly.

In the future, we will seek to explore the following directions: (1) We will explore more LJP subtasks and more scenarios of cases such as multiple defendants and charges to investigate the effectiveness of TOPJUDGE. (2) We will explore how to incorporate into LJP the temporal factors, which are not considered in this work.

Hierarchical CVAE for Fine-Grained Hate Speech Classification

Jing Qian, Mai ElSherief, Elizabeth Belding, William Yang Wang

Abstract

Existing work on automated hate speech detection typically focuses on binary classification or on differentiating among a small set of categories. In this paper, we propose a novel method on a fine-grained hate speech classification task, which focuses on differentiating among 40 hate groups of 13 different hate group categories. We first explore the Conditional Variational Autoencoder (CVAE) (Larsen et al., 2016; Sohn et al., 2015) as a discriminative model and then extend it to a hierarchical architecture to utilize the additional hate category information for more accurate prediction. Experimentally, we show that incorporating the hate category information for training can significantly improve the classification performance and our proposed model outperforms commonly-used discriminative models.

1 Introduction

The impact of the vast quantities of user-generated web content can be both positive and negative. While it improves information accessibility, it also can facilitate the propagation of online harassment, such as hate speech. Recently, the Pew Research Center[1] reported that "roughly four-in-ten Americans have personally experienced online harassment, and 63% consider it a major problem. Beyond the personal experience, two-thirds of Americans reported having witnessed abusive or harassing behavior towards others online."

In response to the growth in online hate, there has been a trend of developing automatic hate speech detection models to alleviate online harassment (Warner and Hirschberg, 2012; Waseem and Hovy, 2016). However, a common problem with these methods is that they focus on coarse-grained classifications with only a small set of categories. To the best of our knowledge, the existing work on hate speech detection formulates the task as a classification problem with no more than seven classes. Building a model for more fine-grained multiclass classification is more challenging since it requires the model to capture finer distinctions between each class.

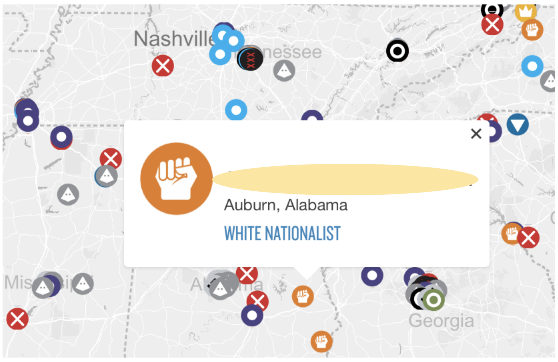

Figure 1: A portion of the hate group map published by the Southern Poverty Law Center (SPLC). Each marker represents a hate group. The markers with the same pattern indicate the corresponding hate groups share the same ideology. The white box shows an example of a hate group in Auburn, Alabama under the category of "White Nationalist". Due to the sensitivity of the data, we mask the name of the group.

Moreover, fine-grained classification is necessary for fine-grained hate speech analysis. Figure 1 is a portion of the hate group map published by the Southern Poverty Law Center (SPLC)[2], where a hate group is defined as "an organization that based on its official statements or principles, the statements of its leaders, or its activities has beliefs or practices that attack or malign an entire class of people, typically for their immutable characteristics." The SPLC divides the 954 hate groups in the United States into 17 categories ac-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3550–3559
Brussels, Belgium, October 31 - November 4, 2018.

cording to their ideologies (e.g. Racist Skinhead, Anti-Immigrant, and others). The SPLC monitors hate groups throughout the United States by a variety of methodologies to determine the activities of groups and individuals: reviewing hate group publications and reports by citizens, law enforcement, field sources and the news media, and conducting their own investigations. Therefore, building automatic classification models to differentiate between the social media posts from different hate groups is both challenging and of practical significance.

In this paper, we propose a fine-grained hate speech classification task that separates tweets posted by 40 hate groups of 13 different hate group categories. Although CVAE is commonly used as a generative model, we find it can achieve competitive results and tends to be more robust when the size of the training dataset decreases, compared to the commonly used discriminative neural network models. Based on this insight, we design a Hierarchical CVAE model (HCVAE) for this task, which leverages the additional hate group category (ideology) information for training. Our contributions are three-fold:

- This is the first paper on fine-grained hate speech classification that attributes hate groups to individual tweets.
- We propose a novel Hierarchical CVAE model for fine-grained tweet hate speech classification.
- Our proposed model improves the Micro-F1 score of up to 10% over the baselines.

In the next section, we outline the related work on hate speech detection, fine-grained text classification, and Variational Autoencoder. In Section 3, we explore the CVAE as a discriminative model, and our proposed method is described in Section 4. Experimental results are presented and discussed in Section 5. Finally, we conclude in Section 6.

2 Related Work

2.1 Hate Speech Detection

An extensive body of work has been dedicated to automatic hate speech detection. Most of the work focuses on binary classification. Warner and Hirschberg (2012) differentiate between anti-semitic or not. Gao et al. (2017), Zhong et al. (2016), and Nobata et al. (2016) differentiate between abusive or not. Waseem and Hovy (2016), Burnap and Williams (2016), and Davidson et al. (2017) focus on three-way classification. Waseem and Hovy (2016) classify each input tweet as racist hate speech, sexist hate speech, or neither. Burnap and Williams (2016) build classifiers for hate speech based on race, sexual orientation or disability, while Davidson et al. (2017) train a model to differentiate among three classes: containing hate speech, only offensive language, or neither. Badjatiya et al. (2017) use the dataset provided by Waseem and Hovy (2016) to do three-way classification. Our work is most closely related to (Van Hee et al., 2015), which focuses on fine-grained cyberbullying classification. However, this study only focuses on seven categories of cyberbullying while our dataset consists of 40 classes. Therefore, our classification task is much more fine-grained and challenging.

2.2 Fine-grained Text Classification

Our work is also related to text classification. Convolutional Neural Networks (CNN) have been successfully applied to the text classification task. Kim (2014) applies CNN at the word level while Zhang et al. (2015) apply CNN at the character level. Johnson and Zhang (2015) exploit the word order of text data with CNN for accurate text categorization. Socher et al. (2013) introduces the Recursive Neural Tensor Network for text classification. Recurrent Neural Networks (RNN) are also commonly used for text classification (Tai et al., 2015; Yogatama et al., 2017). Lai et al. (2015) and Zhou et al. (2015) further combine RNN with CNN. Tang et al. (2015) and Yang et al. (2016) exploit the hierarchical structure for document classification. Tang et al. (2015) generate from the sentence representation to the document representation while Yang et al. (2016) generate from the word-level attention to the sentence-level attention. However, the division of the hierarchies in our HCVAE is according to semantic levels, rather than according to document compositions. We generate from the category-level representations to the group-level representations. Moreover, the most commonly used datasets by these works (Yelp reviews, Yahoo answers, AGNews, IMDB reviews (Diao et al., 2014)) have no more than 10 classes.

2.3 Variational Autoencoder

Variational Autoencoder (VAE) (Kingma and Welling, 2013) has achieved competitive results in

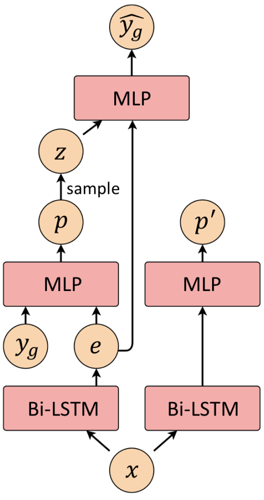

Figure 2: The structure of the baseline CVAE model during training. Bi-LSTM is a bidirectional LSTM layer. MLP is a Multilayer Perceptron. x is the embedded input text. y_g is the ground truth hate group label. $\hat{y_g}$ is the output prediction of the hate group. p is the posterior distribution of the latent variable z while p' is the prior distribution of z. Note that this structure is used for training. During testing, the posterior network is replaced by the prior network to compute $\hat{y_g}$ and thus y_g is not available during testing. Refer to Section 3 for detailed explanation.

many complicated generation tasks, such as handwritten digits (Kingma and Welling, 2013; Salimans et al., 2015), faces (Kingma and Welling, 2013; Rezende et al., 2014), and machine translation (Zhang et al., 2016). CVAE (Larsen et al., 2016; Sohn et al., 2015) is an extension of the original VAE framework that incorporates conditions during generation. In addition to image generation, CVAE has also been successfully applied to several NLP tasks, such as dialog generation (Zhao et al., 2017). Although so far CVAE has always been used as a generative model, we explore the performance of the CVAE as a discriminative model and further propose a hierarchical CVAE model, which exploits the hate group category (ideology) information for training.

3 CVAE Baseline

We formulate our classification task as the following equation:

$$Obj = \sum_{(x,y_g)\in X} \log p(y_g|x) \qquad (1)$$

where x, y_g are the tweet text and hate group label respectively, X is the dataset. Instead of directly parameterizing $p(y_g|x)$, it can be further written as the following equation:

$$p(y_g|x) = \int_z p(y_g|z,x)p(z|x)dz \qquad (2)$$

where z is the latent variable. Since the integration over z is intractable, we instead try to maximize the corresponding evidence lower bound (ELBO):

$$\begin{aligned} ELBO =& E[\log p(y_g|z,x)] - \\ & D_{KL}[q(z|x,y_g)||p(z|x)] \end{aligned} \qquad (3)$$

where D_{KL} is the KullbackLeibler (KL) divergence. $p(y_g|z,x)$ is the likelihood distribution, $q(z|x,y_g)$ is the posterior distribution, and $p(z|x)$ is the prior distribution. These three distributions are parameterized by $p_\varphi(y_g|z,x)$, $q_\alpha(z|x,y_g)$, and $p_\beta(z|x)$. Therefore, the training loss function is:

$$\begin{aligned} \mathcal{L} =& L_{REC} + L_{KL} \\ =& E_{z\sim p_\alpha(z|x,y_g)}[-\log p_\varphi(y_g|z,x)] + \\ & D_{KL}[q_\alpha(z|x,y_g)||p_\beta(z|x)] \end{aligned} \qquad (4)$$

The above loss function consists of two parts. The first part L_{REC} is the reconstruction loss. Optimizing L_{REC} can push the predictions made by the posterior network and the likelihood network closer to the ground truth labels. The second part L_{KL} is the KL divergence loss. Optimizing it can push the output distribution of the prior network and that of the posterior network closer to each other, such that during testing, when the ground truth label y_g is no longer available, the prior network can still output a reasonable probability distribution over z.

Figure 2 illustrates the structure of the CVAE model during training (the structure used for testing is different). The likelihood network $p_\varphi(y_g|z,x)$ is a Multilayer Perceptron (MLP). The structure of both the posterior network $q_\alpha(z|x,y_g)$ and the prior network $p_\beta(z|x)$ is a bidirectional Long Short-Term Memory (Bi-LSTM) (Hochreiter and Schmidhuber, 1997) layer followed by an MLP. The Bi-LSTM is used to encode the tweet text. The only difference between the posterior and the prior network is that for the posterior network the input for the MLP is the encoded text concatenated with the group label while for the prior network only the encoded text is fed forward. During testing, the posterior network will be replaced by the prior network to generate the distribution over the latent variable (i.e. p' will replace

p). Thus during testing, the ground truth labels will not be used to make predictions.

We assume the latent variable z has a multivariate Gaussian distribution: $p = \mathcal{N}(\mu, \Sigma)$ for the posterior network, and $p' = \mathcal{N}(\mu', \Sigma')$ for the prior network. The detailed computation process is as follows:

$$e = f(x) \tag{5}$$

$$\mu, \Sigma = s(y_g \oplus e) \tag{6}$$

$$\mu', \Sigma' = s'(f'(x)) \tag{7}$$

where f is the Bi-LSTM function and e is the output of the Bi-LSTM layer at the last time step. s is the function of the MLP in the posterior network and s' is that of the MLP in the prior network. The notation $\oplus$ means concatenation. The latent variables z and z' are randomly sampled from $\mathcal{N}(\mu, \Sigma)$ and $\mathcal{N}(\mu', \Sigma')$, respectively. During training, the input for the likelihood network is z:

$$\hat{y_g} = w(z) \tag{8}$$

where w is the function of the MLP in the likelihood network. During testing, the prior network will substitute for the posterior network. Thus for testing, the input for the likelihood is z' instead of z:

$$\hat{y_g} = w(z') \tag{9}$$

4 Our Approach

One problem with the above CVAE method is that it utilizes the group label for training, but ignores the available hate group category (ideology) information of the hate speech. As mentioned in Section 1, hate groups can be divided into different categories in terms of ideologies. Each hate group belongs to a specific hate group category. Considering this hierarchical structure, the hate category information can potentially help the model to better capture the subtle differences between the hate speech from different hate groups. Therefore, we extend the baseline CVAE model to incorporate the category information. In this case, the objective function is as follows:

$$\begin{aligned} Obj = & \sum_{(x,y_c,y_g)\in X} \log p(y_c, y_g|x) \\ = & \sum_{(x,y_c,y_g)\in X} \log p(y_c|x) + \log p(y_g|x, y_c) \end{aligned} \tag{10}$$

where y_c is the hate group category label and

$$p(y_c|x) = \int_{z_c} p(y_c|z_c, x)p(z_c|x)dz_c \tag{11}$$

$$p(y_g|x, y_c) = \int_{z_g} p(y_g|z_g, x, y_c)p(z_g|x, y_c)dz_g \tag{12}$$

where z_c and z_g are latent variables. Therefore, the ELBO of our method is the sum of the ELBOs of $\log p(y_c|x)$ and $\log p(y_g|x, y_c)$:

$$\begin{aligned} ELBO = & E[\log p(y_c|z_c, x)] - \\ & D_{KL}[q(z_c|x, y_c)||p(z_c|x)] + \\ & E[\log p(y_g|z_g, x, y_c)] - \\ & D_{KL}[q(z_g|x, y_c, y_g)||p(z_g|x, y_c)] \end{aligned} \tag{13}$$

During testing, the prior networks will substitute the posterior networks and the ground truth labels y_c and y_g are not utilized. Hence the prior $p(z_g|x, y_c)$ in the above equation cannot be parametrized as a network that directly takes the ground truth label y_c and x as inputs. Instead, we parameterize it as shown in the right part of Figure 3. We assume that u' is trained to be a latent representation of y_c, so we use u' and x as inputs for this prior network.

According to the ELBO above, the corresponding loss function $\mathcal{L}$ is the combination of the loss function for the category classification ($\mathcal{L}_c$) and that for the group classification ($\mathcal{L}_g$).

$$\begin{aligned} \mathcal{L} = & \mathcal{L}_c + \mathcal{L}_g, \text{ where} \\ \mathcal{L}_c = & E_{z_c \sim q_\alpha(z_c|x,y_c)}[-\log p_\varphi(y_c|z_c, x)] + \\ & D_{KL}[q_\alpha(z_c|x, y_c)||p_\beta(z_c|x)], \text{ and} \\ \mathcal{L}_g = & E_{z_g \sim q_\eta(z_g|x,y_c,y_g)}[-\log p_\theta(y_g|z_g, x, y_c)] + \\ & D_{KL}[q_\eta(z_g|x, y_c, y_g)||p_\gamma(z_g|x, u)] \end{aligned} \tag{14}$$

Figure 3 shows the structure of our model for training. By assuming the latent variables z_c and z_g have multivariate Gaussian distributions, the actual outputs of the posterior and prior networks are the mean and variance: $p_c = \mathcal{N}(\mu_c, \Sigma_c)$, $p_g = \mathcal{N}(\mu_g, \Sigma_g)$ for the two posterior networks, and $p'_c = \mathcal{N}(\mu'_c, \Sigma'_c)$, $p'_g = \mathcal{N}(\mu'_g, \Sigma'_g)$ for the two prior networks. Note that in addition to these four distributions, there is another distribution $p_x = \mathcal{N}(\mu_x, \sigma_x)$ as shown in Figure 3. This distribution is generated only with the input text x, so it provides the basic distribution (in order to avoid confusion, we call it the basic distribution instead

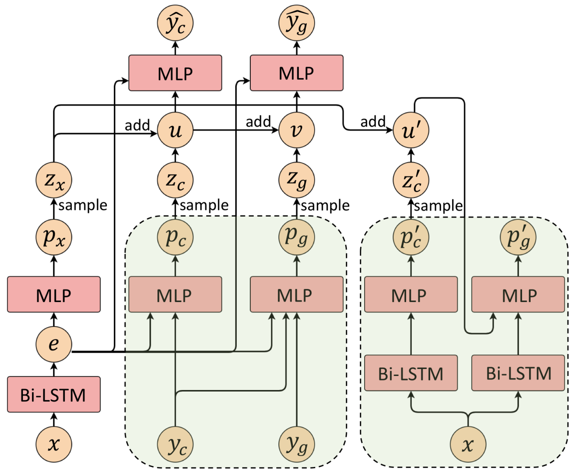

Figure 3: The structure of the HCVAE during training. Bi-LSTM is a bidirectional LSTM layer. MLP is a Multilayer Perceptron. x is the embedded input text. y_c and y_g are the ground truth hate category label and hate group label. $\hat{y_c}$ and $\hat{y_g}$ are the output predictions of the hate category and hate group. z_c, z_g, and z'_c are latent variables. In the left dotted box are two posterior networks. In the right dotted box are two prior networks. Note that this structure is used for training. During testing, the posterior networks will be substituted by the posterior networks (i.e. the left dotted box will be substituted with the right one) to compute $\hat{y_c}$ and $\hat{y_g}$. Thus y_c and y_g are not available during testing. Refer to Section 4 for detailed explanation.

of the prior distribution) for both two posterior networks and two prior networks. With this basic distribution, the two posterior networks only need to capture the additional signals learned from x and labels. Similarly, the prior networks only need to learn the additional signals learned by the posterior networks. The detailed computation process during training is shown as the following equations:

$$e = f(x) \tag{15}$$

$$\mu_x, \Sigma_x = s_x(e) \tag{16}$$

$$\mu_c, \Sigma_c = s_c(y_c \oplus e) \tag{17}$$

$$\mu_g, \Sigma_g = s_g(y_c \oplus y_g \oplus e) \tag{18}$$

$$\mu'_c, \Sigma'_c = s'_c(f'_c(x)) \tag{19}$$

where f is the Bi-LSTM function and e is the output of the Bi-LSTM layer at the last time step. s_x, s_c, s_g, and s'_c are the functions of four different MLPs. f'_c is the Bi-LSTM function in the prior network $p_\beta(z_c|x)$. The latent variables z_x, z_c, z_g, and z'_c are randomly sampled from the Gaussian distributions $\mathcal{N}(\mu_x, \Sigma_x)$, $\mathcal{N}(\mu_c, \Sigma_c)$, $\mathcal{N}(\mu_g, \Sigma_g)$, and $\mathcal{N}(\mu'_c, \Sigma'_c)$ respectively. As mentioned above, p_x is the basic distribution while p_c, p_g, p'_c, and p'_g are trained to capture the additional signals. Therefore, z_x is added to z_c and z'_c, then the results u and u' are further added to z_g and z'_g, respectively, as shown in the following equations:

Algorithm 1 Train & Test Algorithm

        get embeddings $x$;
        compute $e$ with the Bi-LSTM;
        compute $\mu_x$, $\Sigma_x$, $\mu'_c$, $\Sigma'_c$;
        sample $z_x = reparameterize(\mu_x, \Sigma_x)$;
        sample $z'_c = reparameterize(\mu'_c, \Sigma'_c)$;
        $u' = z_x + z'_c$;
        compute $\mu'_g$, $\Sigma'_g$;
        sample $z'_g = reparameterize(\mu'_g, \Sigma'_g)$;
        $v' = u' + z'_g$;
        compute $\hat{y_c}$ and $\hat{y_g}$ according to Eq. 26- 28;
    end for
end function
```

$$u' = z_x + z'_c \tag{20}$$

$$\mu'_g, \Sigma'_g = s'_g(u' \oplus f'_g(x)) \tag{21}$$

$$u = z_x + z_c \tag{22}$$

$$v = u + z_g \tag{23}$$

where f'_g is the Bi-LSTM function and s'_g is the function of the MLP in the prior network $p_\gamma(z_g|x, u)$. $+$ is element-wise addition. During training, u and v are fed into the likelihood networks:

$$\hat{y_c} = w_c(e \oplus u) \tag{24}$$

$$\hat{y_g} = w_g(e \oplus v) \tag{25}$$

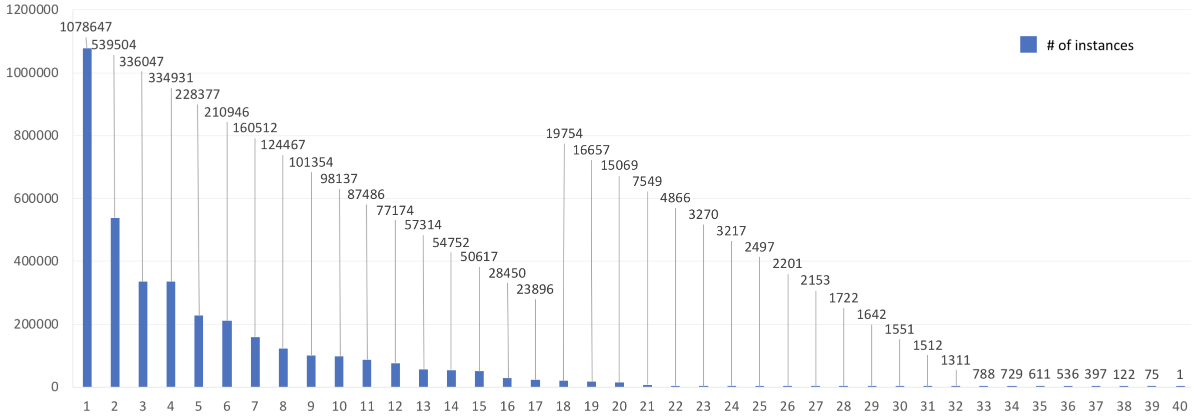

Figure 4: The distribution of the data for 40 hate groups. The X-Axis is each hate group. The Y-Axis is the number of tweets collected for each hate group.

where w_c and w_g are the functions of the MLPs in two likelihood networks. During testing, the prior networks will substitute the posterior networks, so the latent variable z'_g is randomly sampled from the Gaussian distributions $\mathcal{N}(\mu'_g, \Sigma'_g)$, and the last four equations above (Equation 22 - 25) will be replaced by the following ones:

$$\hat{y_c} = w_c(e \oplus u') \tag{26}$$

$$v' = u' + z'_g \tag{27}$$

$$\hat{y_g} = w_g(e \oplus v') \tag{28}$$

Algorithm 1 illustrates the complete training and testing process. BCE refers to the Binary Cross Entropy loss. Note that during training, the ground truth category labels and group labels are fed to the posterior network to generate latent variables. But during testing, the latent variables are generated by the prior network, which only utilizes the texts as inputs.

5 Experiments

5.1 Dataset

We collect the data from 40 hate group Twitter accounts of 13 different hate ideologies, e.g., white nationalist, anti-immigrant, racist skinhead, among others. The detailed themes and core values behind each hate ideology are discussed in the SPLC ideology section.[3] For each hate ideology, we collect a set of Twitter handles based on hate groups identified by the SPLC center.[4] For each hate ideology, we select the top three handles in terms of the number of followers. Due to ties, there are four different groups in several categories of our dataset. The dataset consists of all the content (tweets, retweets, and replies) posted with each account from the group's inception date, as early as 07-2009, until 10-2017. Each instance in the dataset is a tuple of (tweet text, hate category label, hate group label). The complete dataset consists of approximately 3.5 million tweets. Note that due to the sensitive nature of the data, we anonymously reference the Twitter handles for each hate group by using IDs throughout this paper. The distribution of the data is illustrated in Figure 4.

5.2 Experimental Settings

In addition to the discriminative CVAE model described in Section 3, we implement for other baseline methods and an upper bound model as follows.

Support Vector Machine (SVM): We implement an SVM model with linear kernels. We use L2 regularization and the coefficient is 1. The input features are the Term Frequency Inverse Document Frequency (TF-IDF) values of up to 2-grams.

Logistic Regression (LR): We implement the Logistic Regression model with L2 regularization. The penalty parameter C is set to 1. Similar to the SVM model, we use TF-IDF values of up to 2-grams as features.

Character-level Convolutional Neural Network (Char-CNN): We implement the character-level CNN model for text classification as described in (Zhang et al., 2015). It is 9 layers deep with 6 convolutional layers and 3 fully-connected layers.

Table 1: Experimental results. Complete: The performance achieved when 90% of the entire dataset is used for training. Subset: The performance achieved when only 10% of the dataset is used for training. The best results are in bold.

The configurations of the convolutional layers are kept the same as those in (Zhang et al., 2015).
Bi-LSTM: The model consists of a bidirectional LSTM layer followed by a linear layer. The embedded tweet text x is fed into the LSTM layer and the output at the last time step is then fed into the linear layer to predict $\hat{y_g}$.
Upper Bound: The upper bound model also consists of a bidirectional LSTM layer followed by a linear layer. The difference between this model and Bi-LSTM is that it takes the tweet text x along with the ground truth category label y_c as input during both training and testing. The LSTM layer is used to encode x. The encoding result is concatenated with the ground truth category label and then fed into the linear layer to give the prediction of the hate group $\hat{y_g}$. Since it utilizes y_c for prediction during testing, this model sets an upper bound performance for our method.

For the baseline CVAE, Bi-LSTM, the upper bound model, and the HCVAE, we use randomly initialized word embeddings with size 200. All the neural network models are optimized by the Adam optimizer with learning rate 1e-4. The batch size is 20. The hidden size of all the LSTM layers in these models is 64 and all the MLPs are three-layered with non-linear activation function Tanh. For the CVAE and the HCVAE, the size of the latent variables is set to 256.

All the baseline models and our model are evaluated on two datasets. We first use the complete dataset for training and testing. 90% of the instances are used for training and the rest for testing. In order to evaluate the robustness of the baseline models and our model, we also randomly selected a subset (10%) of the original dataset for training while the testing dataset is fixed. Since the upper bound model is used to set an upper bound on performance, we do not evaluate it on the smaller training dataset. We use Macro-F1, Micro-F1, and Weighted-F1 to evaluate the classification results. As shown in Figure 4, the dataset is highly imbalanced, which causes problems for training the above models. In order to alleviate this problem, we use a weighted random sampler to sample instances from the training data. However, the testing dataset is not sampled, so the distribution of the testing dataset remains the same as that of the original dataset. This allows us to evaluate the models' performance on the data with a realistic distribution.

5.3 Experimental Results

The experimental results are shown in Table 1. The testing dataset keeps the imbalanced distribution of the original data, so the Macro-F1 score of each method is significantly lower than the Micro-F1 score and the Weighted-F1 score. Comparing the performance of the Bi-LSTM model and that of the baseline CVAE model shows that although CVAE is traditionally used as a generative model, it can also achieve competitive performance as a discriminative model. All the methods achieve lower F1 scores when using the smaller training dataset. Due to the imbalanced distribution of our dataset, half of the 40 groups has less than 1k tweets in the smaller training dataset, which leads to the sharp decline in the Macro-F1 scores of all the methods. However, the performance of both CVAE-based models degrades less than that of the other two neural network models (the Bi-LSTM model and the Char-CNN model) according to the Micro-F1 Weighted-F1 scores. These two CVAE-based models tend to be more robust when the size of the training dataset is smaller. The difference between the CVAE-based models and the other two models is that both the Bi-LSTM model and the Char-CNN model directly compress the input text into a fixed-length latent

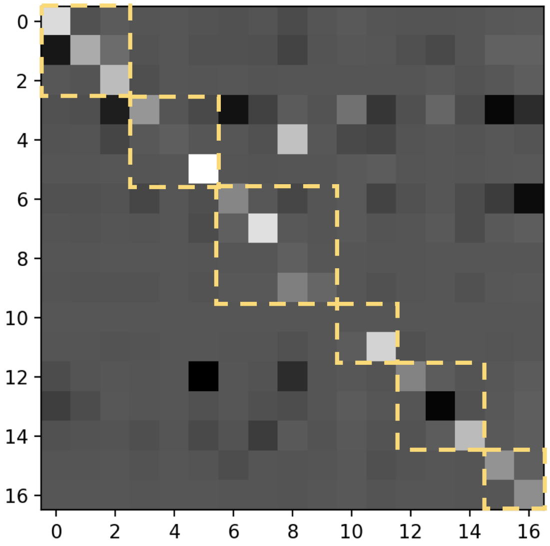

Figure 5: This figure compares a subset (17 hate groups of 6 categories) of the predictions made by the baseline CVAE and the HCVAE. The X and Y axes are the index of each hate group. The hate groups of the same category are grouped together as shown in the dashed squares. The color of the grid (i,j) is mapped from $r_{hcvae}(i,j) - r_{cvae}(i,j)$, where $r(i,j)$ is the fraction of the group i's instances among the instances predicted as the group j. A higher difference value corresponds to a lighter color. A grid darker than the background is mapped from a negative value while a grid lighter than the background is mapped from a positive one.

variable while the CVAE model explicitly models the posterior and likelihood distributions over the latent variable. The result is that, during testing, the inference strategy of the Bi-LSTM model and the Char-CNN model is actually comparing the compressed text to the compressed instances in the training dataset while the strategy of the CVAE-based models is to compare the prior distributions over the latent variable. Compared with the compressed text, prior distributions may capture higher level semantic information and thus enable better generalization.

By further utilizing the hate category label for training, the HCVAE outperforms the baseline CVAE on all three metrics. Figure 5 illustrates the difference between the predictions made by the HCVAE and the CVAE. As shown in the figure, most of the lighter girds are in the dashed squares while most of the darker girds are outside. This indicates that the HCVAE model tends to correct the prediction of the CVAE's misclassified instances to be closer to the ground truth. In most cases, the misclassified instances can be directly corrected to the ground truth (the diagonal). In other cases, they are not corrected to the ground truth but are corrected to the hate groups of the same categories as the ground truth (the dashed squares). This shows that additional ideology information is useful for the model to better capture the subtle differences among tweets posted by different hate groups.

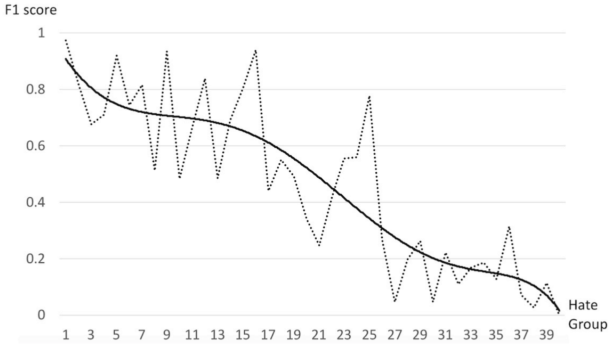

Figure 6: The F1 score achieved by our method on each hate group. The Y-axis is the F1 score. The X-axis is the hate group sorted by the number of instances in the dataset from larger to smaller. The dashed line shows the F1 scores and the solid line is the corresponding trendline.

Although our method outperforms the baseline methods, there is still a gap between its performance and the upper bound performance. We analyze this in the following section.

5.4 Error Analysis

As mentioned above, in some cases our model misclassified the tweet as a group under the same category as the ground truth. Take, for instance, the tweet from *Group1*: *The only good #muslim is a #dead #muslim*. Our HCVAE model predicts it as from *Group2*. But both *Group1* and *Group2* are under the category "neo nazi". One possible reason for this kind of error is that the imbalance of the dataset adversely affects the performance of our method. Figure 6 shows the F1 scores achieved by the HCVAE on each group. The performance of the model tends to be much lower when the number of the group's training instances decreases. Although we use the weighted random sampler to alleviate the problem of the imbalanced dataset, repeating the very limited data instances (less than 3k) of a group during training cannot really help the posterior and prior networks to give a reasonable distribution that can generalize well on unseen inputs. Therefore, when the model comes into the instances in the testing dataset, the performance can be less satisfactory. This is a common problem for all the methods, which is the cause of the significantly lower Macro-F1 scores.

Another type of error is caused by the noisy dataset. Take, for instance, the tweet from *Group3* under the category "ku klux klan": *we must secure the existence of our people and future for the White Children !!* Our model classifies it as from *Group4* under the category "neo nazi", which makes sense but is an error.

6 Conclusion

In this paper, we explore the CVAE as a discriminative model and find that it can achieve competitive results. In addition, the performance of the CVAE-based models tend to be more stable than that of the others when the dataset gets smaller. We further propose an extension of the basic discriminative CVAE model to incorporate the hate group category (ideology) information for training. Our proposed model has a hierarchical structure that mirrors the hierarchical structure of the hate groups and the ideologies. We apply the HCVAE to the task of fine-grained hate speech classification, but this Hierarchical CVAE framework can be easily applied to other tasks where the hierarchical structure of the data can be utilized.

Abstract

Predictive models over social media language have shown promise in capturing community outcomes, but approaches thus far largely neglect the socio-demographic context (e.g. age, education rates, race) of the community from which the language originates. For example, it may be inaccurate to assume people in Mobile, Alabama, where the population is relatively older, will use words the same way as those from San Francisco, where the median age is younger with a higher rate of college education. In this paper, we present *residualized factor adaptation*, a novel approach to community prediction tasks which both (a) effectively integrates community attributes, as well as (b) adapts linguistic features to community attributes (factors). We use eleven demographic and socioeconomic attributes, and evaluate our approach over five different community-level predictive tasks, spanning health (heart disease mortality, percent fair/poor health), psychology (life satisfaction), and economics (percent housing price increase, foreclosure rate). Our evaluation shows that *residualized factor adaptation* significantly improves 4 out of 5 community-level outcome predictions over prior state-of-the-art for incorporating socio-demographic contexts.

1 Introduction

Adapting to human factors has been shown to benefit NLP tasks, especially in tasks that involve predictions over individual social media posts (e.g., sentiment (Hovy, 2015), sarcasm, and stance detection (Lynn et al., 2017)). The main idea behind these approaches is that knowing who wrote a piece of text can help models better understand how to process it. This paper develops methods that apply this idea to community-level prediction tasks, which require making decisions over posts from a community of users. Many community-level outcomes and community-wide language are linked to socio-demographic factors (age, gender, race, education, income levels) with many social scientific studies supporting their predictive value (Cohen et al., 2003), and should therefore affect how a model treats social media-based language features. For example, a high prevalence of the word "bike" in San Francisco, CA might be a signal that exercise is common in the area, while its high prevalence in Mobile, Alabama might indicate greater interest in motor bikes. We present a method for building language-based predictive models which integrate in and adapt to attributes of the communities generating the language.

This work aims to unify two different approaches developed for adapting to human factors and use them for incorporating community attributes in community-level prediction tasks: (1) *residualized controls:* whereby a model is trained in two steps: first over the factors/controls and then fitting the language to the residuals of the control model (Zamani and Schwartz, 2017), and (2) *user-factor adaptation:* whereby linguistic features are adapted, or treated differently, based on the continuous-valued factors of the authors of the features (Lynn et al., 2017).

Combining factor adaptation (FA) and residualized control (RC) into RFA is a non-trivial task. The intent behind both methods are quite different: whereas RC attempts to address the inherent heterogeneity between robust control variables and noisy linguistic variables, FA enables a model to treat linguistic features differently depending on the factors. From a statistical learning perspective, RC separates inference over controls from inference over language (model level integration), while FA brings controls and language together and makes the inference as one single step (data level integration). Additionally, FA has stricter bounds in the number of factors it can accommodate because each new factor has a multiplicative

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3560–3569
Brussels, Belgium, October 31 - November 4, 2018.

effect on the number of learned parameters. On the other hand, each new factor for RC typically only adds one new parameter. Here, we endeavour to develop RFA such that it achieves the benefits of both approaches with little lost to the limitations. RFA inherits the challenges of the FA method with feature explosion. We address this through a systematic exploration of both feature and factor selection.

The main contributions of this work include: (1) the introduction of residualized factor adaptation which effectively combines extra-linguistic and language features, (2) the first empirical evaluation of applying factor adaptation for community-level prediction tasks, (3) analysis of the impact of the size of factors and factor selection in adaptation, and (4) state-of-the-art accuracies for each of the five tasks for which we evaluate RFA.

2 Background

Social media provides easy access to a vast amount of language written by a diverse group of users, making it an increasingly popular resource for measuring community health, psychology, and economics (Coppersmith et al., 2015; Eichstaedt et al., 2015; Weeg et al., 2015; Mowery et al., 2016; Haimson and Hayes, 2017). Coppersmith et al. (2015), for instance, examine trends in language use among Twitter users who self-reported one of ten mental health diagnoses. Eichstaedt et al. (2015) and Weeg et al. (2015) use Twitter to predict the prevalence rates of various health outcomes, such as heart disease mortality and depression, at the county level. Haimson and Hayes (2017) tracked changes in the emotional well-being of transgender communities on Tumblr between 2015 and 2016.

Socio-demographics are often correlated with health outcomes (such as age and heart disease), which is why such variables are often used as controls during analysis (Coppersmith et al., 2015; Dos Reis and Culotta, 2015; Eichstaedt et al., 2015; Weeg et al., 2015). Because of their predictive power, socio-demographics and other extra-linguistic information can additionally be leveraged when building the model itself.

However, a central challenge in integrating community attributes is that they have very different properties than linguistic features and can be lost, in essence, like a needle in a haystack. For example, linguistic features like n-grams are high dimensional, with each dimension having high covariance with other dimensions and likely very little relationship with the outcome. On the other hand community features may be measured more robustly and are relatively low dimensional, often obtained through well-defined measurements. Not surprisingly, Zamani and Schwartz (2017) showed a naive combination that simply concatenates these two sets of features risks losing the effective extra-linguistic features in a sea of weak linguistic features. They go on to show a *residualized control* approach achieves significantly greater accuracy at economic prediction by first learning a model using extra-linguistic features (i.e. controls or community factors) and then train a language model on top of the residual error of the previous model.

It is possible that even when extra-linguistic features are not directly beneficial for prediction, they can still affect people's language. Other related works consider how the meaning of language changes depending on who states it. For instance, when an NLP PhD student says the word 'paper' he/she usually means something different than when a 5^{th} grade student uses the same word (i.e. 'research paper' versus 'piece of paper'). Hu et al. (2017) noted the same words can have different meanings if different people say them. This idea of contextualizing language with extra-linguistic information has been the basis for multiple models: Hovy (2015) learn age- and gender-specific word embeddings, leading to significant improvements for three text classification tasks. Volkova et al. (2013) found that using gender-specific features lead to improvements in sentiment analysis over a gender-agnostic model. Most recently, Lynn et al. (2017) proposed a domain adaptation-inspired method for composing user-level, extra-linguistic information with message-level features, leading to improvements for multiple text classification tasks; we build off of this approach and that of Zamani and Schwartz (2017) in this paper.

While Lynn et al. (2017) injected user-level info into message-level tasks, we are investigating whether same-level adaptation techniques are similarly useful.

We also try to find the circumstances under which each of the adaptation and residualized control approaches are more powerful, and we take on the non-trivial task of exploiting concepts from both the adaptation and the residualized control techniques at the same time, finding that they add even more power when combined with one another.

3 Method

We describe *residualized factor adaptation* (RFA), an approach to text-based prediction utilizing extra-linguistic factors (also called controls – often demographic or socioeconomic information). The key challenge for RFA lies in effectively combining two different types of features. The language-based features, extracted from the tweets, are numerous but are only weak indicators of the outcomes. The socioeconomic and demographic features, on the other hand, are strong indicators but fewer in number. Naively combining both sets of features ignores this crucial difference in their predictive abilities, potentially resulting in important features getting drowned out.

We first describe two methods that effectively combine extra-linguistic factors at two different levels: 1) *Residualized control* is a model-level combination method which builds different models for each type of feature, then combines the results of these models to make the final outcome prediction. 2) *Factor adaptation* is a feature-level combination method that composes the two feature sets with one another to produce a transformed feature space over which a single model may be built. Finally, we present our combined method of *Residualized Factor Adaptation* which takes advantage of both concepts without exploding model parameters.

3.1 Residualized Control Prediction

Language-based features and community-level attributes are qualitatively different modalities. The extra-linguistic variables, while few in number, are mostly unbiased and follow a normal distribution, which can be used to build a strong outcome predictor. However, without special treatment, the signal in extra-linguistic variables can be overwhelmed when combined with a large number of language-based features.

The residualized control approach (Zamani and Schwartz, 2017) avoids this issue by building two models. The first is a prediction model built over the extra-linguistic variables (or *controls*) alone. The error, or *residuals*, produced by this first model represents the information that was unable to be predicted using the extra-linguistic variables alone. The language-based features are therefore brought in to improve upon the initial predictions by using the residuals as training labels for a model based on the linguistic features. In this way, the language-based features are able to account for additional information not captured by the initial extra-linguistic feature-only model. At test time, each instance is fed to both prediction models, and the final outcome is given as a sum of the predictions from both models — the outcome predicted by the extra-linguistic model adjusted for error by the language-based model.

Formally, given extra-linguistic features X_{EL} and language features X_L, the residualized control models are built as follows:

$$\hat{Y} = \alpha \times X_{EL} + \beta \tag{1}$$

$$\epsilon = Y - \hat{Y} \tag{2}$$

$$\epsilon \simeq \gamma \times X_L + \lambda \tag{3}$$

The extra-linguistic control model is parameterized by α weights and the β bias term. ϵ denotes the residual, i.e., the error of the extra-linguistic model. The language-based model aims to predict the ϵ residuals, with γ weights and the λ bias term as parameters.

The motivation for this approach is that extra-linguistic features are more informative and less noisy than the language ones. By exploiting this two-stage learning procedure, the model is biased toward favoring the role of extra-linguistics over language features, which prevents the powerful but rare extra-linguistic features from being lost among thousands of noisy language features.

3.2 Factor Adaptation

Lynn et al. (2017) introduced *user-factor adaptation*, a technique for combining message-level features with user-level information (or *factors*) at the feature level. User-factor adaptation, which is based on the feature augmentation approach for domain adaptation (Daumé III, 2007), uses the extra-linguistic features to transform the language-based features. Each of the language-based features has additional, corresponding features that are a composite of itself and an extra-linguistic factor. In this way, the model is able to capture both factor-specific and factor-general properties of each of the language-based features.

Following the work of Lynn et al. (2017), we use a multiplicative composition function for combining the linguistic and extra-linguistic features.

Instead of using user-level factors, we use extra-linguistic variables obtained at the community level, as described below. More formally, let V_j be a matrix such that:

$$\forall j \in \{0, d\} : V_j = v_j \odot \mathbf{1}^l \tag{4}$$

where d is the number of extra-linguistic factors. With n as the number of data instances, let v_j be a column vector of height n where element $v_{j,i}$ is the score of extra-linguistic feature j for instance i. Having l as the number of language variables, in Eq. 4 for each factor j we make a matrix of size $n \times l$, named V_j, in which every column is equal to v_j, and V_j has the same dimensions as language feature matrix X_L. Now for each factor j we use the Hadamard product to multiply V_j with X_L. In this way each row of X_L will be multiplied by the corresponding row in V_j, which is also equal to the corresponding value in v_j. We therefore can write the factor adaptation as follows:

$$X_A = [V_1 \odot X_L, V_2 \odot X_L, \cdots, V_d \odot X_L] \tag{5}$$

The adapted features together with the original language-based features are used for building a single prediction model:

$$\hat{Y} = \alpha \times [X_L, X_A] + \beta \tag{6}$$

3.3 Residualized Factor Adaptation

Even though both the residualized control and factor adaptation approaches exploit extra-linguistics, they combine these in very different ways. The former does it at the model level by learning different models for different types of features and combining those models together. The latter does it at the data level by first combining both sets of features into a transformed feature set and then learning a single model on the obtained features. In addition, these approaches have different motivations and aim to accomplish different objectives.

These modeling differences suggest that the two approaches could have complementary benefits. Residualized factor adaptation (RFA), our proposed method, inherits the advantages of both the residualized control and adaptation techniques, and is depicted in Fig. 1. There are four main steps:

Step 1: Extra-linguistic control model. We build a regression model solely based on the extra-linguistics, as shown in Equation 1, and then compute the residual error of that model as in Equation 2. This error is ultimately used as the outcome label in the final step of RFA.

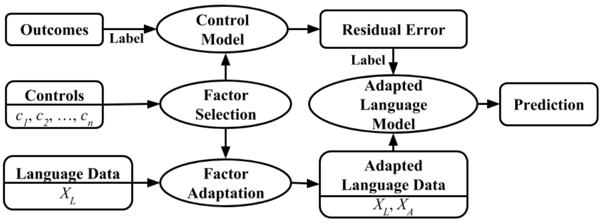

Figure 1: Components of residualized factor adaptation. X_L is language data (topic and n-gram features) and X_A is adapted language data.

Step 2: Factor selection. Adaptation to many factors can increase the model parameters drastically. We explore multiple options for selecting a subset of factors from the available extra-linguistic variables. First, we consider manually selected extra-linguistic factors that are known to influence language use more than others. Second, we use the correlation of the factors with the outcome. Last, we use PCA, an unsupervised method to generate new, lower-dimensional factors from the originals. The purpose of factor selection is to reduce the variance and chance of overfitting.

Step 3: Factor adaptation. We modify the original factor adaptation approach to account for the larger number of factors and features in this task. First, we normalize selected factors by min-max scaling and then multiply the language features by these selected factors as shown in Eq. 5. As we describe later on in Section 4.2, we use n-grams and topics as separate feature sets of language data, so adaptation gives us two corresponding sets of features: adapted n-grams and adapted topics. We then standardize the adapted features using Z-scores and perform feature reduction on each of the four sets of features separately. These reduced features sets are concatenated into a single large set and fed as input to a learning algorithm in the next step.

Step 4: Residual Prediction. The final step, as shown in Eq. 7, is to learn the residual errors of the extra-linguistic control model, using language and adapted language features. Here, we first apply feature selection and reduction on each language feature set: topics, n-grams, adapted-topics and adapted-n-grams. Then we put all of them into a single feature space on which we learn a model to predict the residual error from Step 1.

To produce the final outcome predictions, the predicted error from this model is combined with the predicted outcomes of the extra-linguistic control model from Step 1.

The choice of feature selection is vital for RFA, both due to the fact that it multiplies the number of language features by the number of extra-linguistic features, and because it uses extra-linguistic features at two levels, one separately and one in integration with language features, potentially leading to overfitting. In Section 5.2, we investigate different methods for feature selection to improve RFA's performance.

As Fig. 1 shows, RFA is structured similarly to residualized control. However, residualized control uses language data at its final step, whereas RFA uses both language and adapted language, which is obtained using the factor adaptation technique. This helps RFA to benefit from the advantages of both residualized control and factor adaptation. In other words, RFA combines linguistic and extra-linguistic features on both the feature/data level and the model level. Eq. 7 formulates the RFA method, in which ϵ comes from Eq. 2 and X_A is defined in Eq. 5.

$$\epsilon \simeq \gamma \times [X_L, X_A] + \lambda \tag{7}$$

4 Evaluation Setup

Our task is to predict various community-level outcomes based on publicly available data, including social media and other extra-linguistic data such as socioeconomic and demographic information. We focus on two health-related outcomes: heart disease mortality rate (Eichstaedt et al., 2015) and percent fair/poor health life (Culotta, 2014); one psychology-related outcome: life satisfaction (Schwartz et al., 2013a); and two economy outcomes: Increased real estate price rate and foreclosure rate (Zamani and Schwartz, 2017). Our high-level approach is to train separate regression models for each outcome. For each county, the input is a set of tweets posted by users from that county as well as aggregate values of socioeconomic and demographic variables for the county, including median income, percentage with bachelors degrees and median age. The full list of socioeconomic/demographic variables are given in Section 4.1. The open-source Differential Language Analysis ToolKit was used for the entire analysis pipeline (feature extraction through modeling) (Schwartz et al., 2017)[1].

4.1 Data Set

Our evaluation dataset includes information from three sources: (1) *language data* from Twitter messages, (2) *extra-linguistic data* consisting of 11 socioeconomic and demographic variables, and (3) *outcome data* consisting of 5 county-wise outcomes from 3 categories: Health, Psychology, and Economy.

Our language data can be divided into two groups, (1) for Health and Psychological outcomes and (2) for Economical outcomes. The language data we use for Health- and Psychology-related outcomes was derived from Twitter's 10% random stream collected from July 2009 to February 2015 and includes 1.64 billion tweets (Giorgi et al., 2018)[2]. For Economy outcomes, we used the language data from Zamani and Schwartz (2017). This data was derived from Twitter's 1% random stream collected from 2011 to 2013 and includes 131 million tweets. In both cases, the tweets were mapped to counties based on users' self-reported location strings using the procedure proposed by Schwartz et al. (2013a).

The extra-linguistic data consists of 11 variables used in previous work: 4 *socioeconomic* variables including median income, unemployment rate, percentage of bachelors degrees, and percentage of high school degree, as well as 7 *demographic* variables including median age; percentage: female, black, Hispanic, foreign-born, married; and population density (Census Bureau, 2010). All variables were obtained from the US Census (Census Bureau, 2010), and we henceforth refer to them collectively as *extra-linguistic features*. This dataset is only collected every 10 years, so the 2010 US Census is the most recent dataset for all of the *socioeconomic* and *demographic* variables at the county level.

We consider 5 county-wise measurements as outcomes, 2 health-related (heart disease mortality rate, fair/poor health life), 1 psychological (life satisfaction), and 2 economic (yearly increased real estate price rate, yearly foreclosure rate). Health and psychological data was gathered from the Centers for Disease Control and Prevention (2010b) and contains between 1,630 to 1,749 counties, depending on the outcome. The

economic outcomes, which have been used previously in (Zamani and Schwartz, 2017), were gathered for the year 2013 from Zillow[3]. They contain 427 counties' foreclosure rate and 717 counties' increased real estate price rate.

4.2 Baselines

Our baselines consist of a controls-only prediction model and a language-only prediction model.

Controls-only. The controls-only model is a simple regression model trained over all the 11 extra-linguistic features.

Language-only. Building this baseline consists of three main steps: extracting linguistic features, performing feature reduction, and running ridge-regression (Goeman et al., 2016). Our linguistic features are n-gram features (1-3 grams) and topic features which include mentions of 2,000 LDA (Blei et al., 2003) derived topics previously estimated from social media (Schwartz et al., 2013b).

For language data, we first pruned the sparse n-gram features to only include those that were mentioned in at lease a percentage of the counties, then due to the importance of word count in performance of language predictive models(Zamani et al., 2018) we exploit a word count threshold and drop counties with fewer words. Then we run a correlation threshold to only keep the highest correlated features and finally we perform a randomized principal components analysis (RPCA), an approximate PCA based on stochastic re-sampling (Rokhlin et al., 2009). We apply the correlation threshold and RPCA steps for n-grams and topics independently.

For language data associated with health and psychology outcomes, we pruned the sparse n-gram features to only include those that were mentioned in at least 95% of the counties, and used 20,000 as the word count threshold, resulting in 27,250 n-grams total.

With only 1,749 training instances (one per county), feature selection and dimensionality reduction become necessary for avoiding overfitting. We first limit the features to the top 10,000 n-grams with the highest linear relationships to each outcome. As the topic features are more informa-

---

[3] http://www.zillow.com/research/data/

tive than a single n-gram, we choose to retain all 2,000 topics at this step. Then after performing RPCA we only keep 100 features for each group of ngrams and topcs.

For the language data associated with economy outcomes, we pruned the n-gram features to only include those that were mentioned in at least 10% of the counties, and used 10,000 as the word-count threshold, resulting in 8,897 n-grams across 717 training instances. We use the top 8,000 n-grams and the top 1,500 topic features with the highest linear relationships to each outcome. at the end by applying RPCA we limit the dimension of each feature set to 100.

We compare performances of residualized control, factor adaptation and residualized factor adaptation (RFA). For all these models, we use the same settings as above to generate language features.

5 Results

5.1 Comparison of RC, FA, and RFA

We first compare factor adaptation (FA), residualized control (RC), and residualized factor adaptation (RFA) using three manually selected factors: age, race (percentage of black population), and education (percentage with bachelor's degree) rates. These three factors are often used as "controls" in prior work (Schwartz et al., 2013a; Culotta, 2014; Eichstaedt et al., 2015; Curtis et al., 2018)[4] and also represent examples of demographic and socioeconomic measurements.

In order to ensure a fair comparison, we use the same extra-linguistic features for all models. As mentioned earlier, a naive method is to directly combine the extra-linguistic features with language ones in a single feature set. Here, we also compare this simple model, which we call *added-controls*, with the other three models. In addition, we consider a linear model solely using extra-linguistics, which we call *controls only*. Evaluation is done using 10-fold cross-validation. R^2, or variance explained, is used to measure accuracy.

Table 1 compares results in terms of variance explained, when using the three hand-picked factors vs. using all 11 extra-linguistic factors (Since past work has also used the Pearson-r metric, Table 2 shows the same results for all factors in terms of Pearson-r). As the table shows, FA outperforms controls only, added-controls, and residualized control. RFA does even better and outperforms FA on both the hand-picked factors and when using the entire set of factors. These results demonstrate the complementary nature of the residualized control and factor adaptation approaches and the benefits of combining them.

	No FS	Separated FS	Combined FS	Early FS
HD	0.656	**0.657**	0.65	0.639
FP	0.678	**0.68**	0.676	0.661
LS	0.364	0.396	0.391	**0.401**
IP	**0.425**	0.402	0.392	0.336
FC	0.187	**0.276**	0.268	0.241
AVG	0.462	**0.482**	0.475	0.456

Table 3: Comparing R^2 using different methods of feature selection. Outcomes are heart disease (HD), fair/poor health (FP), life satisfaction (LS), increased price (IP), and foreclosure rate (FC). FS stands for feature selection. Bold cells have the highest R^2 for each outcome.

Even though adding controls directly, as in the "added-controls" column, works better than language-only and controls-only models, it is worse than any other model that exploits both language and extra-linguistic data. This motivates the need for combining different types of features in both an additive (residualized control) and multiplicative (factor adaptation) style.

Overall, these results show the power of RFA over the other models. RFA's improvement over FA was statistically significant for 4 out of 5 outcomes, and 3 out of 5 for residualized control. Recall that added-controls, residualized control, FA, and RFA all have access to the same set of information. The gains of RFA over FA show that RFA's structure utilizing residualized control is better suited for combining extra-linguistic and language-only features.

5.2 Feature Selection

Here we investigate the impact of feature selection on the overall performance of RFA. We consider three different combination of adaptation and feature selection, as well as adaptation without any feature selection: (1) *SeparatedFS:* apply feature selection separately on language features and adapted language features; (2) *CombinedFS:* combine language features and adapted language features into one feature set and then apply feature selection; (3) *EarlyFS:* apply feature selection on

---

[4] Income has also been used frequently but it has been shown to correlate strongly with education rates.

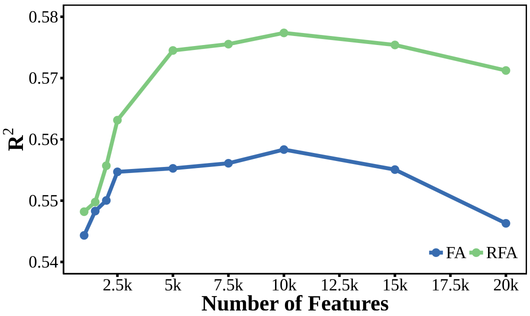

Figure 2: Effect of increasing the number of selected features in univariate feature selection on both factor adaptation (FA) and residualized factor adaptation (RFA) by looking at the average R^2 among health and psychological outcomes. All 11 factors are used in all cases.

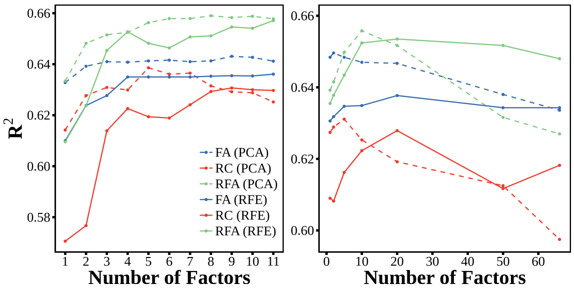

Figure 3: Effect of increasing number of factors on R^2 of residualized factor adaptation (RFA), factor adaptation (FA) and residualized controls (RC) for heart disease outcome. Factors are obtained through Recursive Feature Elimination (RFE) or PCA. Left plot is with original factors, and right plot is with interaction factors (the product from pairing factors).

language features, then apply adaptation on the selected features; and (4) *NoFS:* perform adaptation without any feature selection. Table 3 shows the performance of each method on all 5 outcomes, as well as the the average. SeparatedFS performs better than the others in 3 out of 5 cases, as well as leading the average R^2 across all 5 outcomes. In addition, it produces the most stable results in comparison to the other methods. We therefore use this method for RFA.

We perform another experiment to find the best parameter for the univariate feature selection, that is, the value of k when selecting the k-best n-gram features. Figure 2 shows the results of varying the number of features used for FA and RFA. We report the average R^2 across the 3 health- and psychology-related outcomes. In general, selecting more features leads to better results, though eventually performance does begin to suffer. Recall that our feature selection approach is to first select the k-best n-gram features based on their linear relationship with the outcome, then do a PCA on these k features to obtain a reduced-dimension vector. Even though the feature selection doesn't directly increase the size of our models, it effectively increases the amount of information available to the models, leading to the positive trends we see in Figure 2.

5.3 Increasing Factors and Factor Selection

This experiment has two objectives: first to find out how the number of factors affects performance, and second to find an automated way to select a good subset from the extra-linguistic factors. Here we vary the number of factors from 1 to 11 (i.e. all factors) and compare the effects on RFA, FA, and RC. Factor selection in this experiment is done in two ways, supervised and unsupervised. For the supervised selection we use Recursive Feature Elimination, in which for each k, the least significant factors are recursively dropped until only k factors remain. For unsupervised selection, we use PCA to build k new factors with the highest variance.

The left of Figure 3 shows how the performance of RFA, FA and RC change for heart disease outcome as the number of factors increase, using both PCA and RFE as factor selection methods.

RFA outperforms FA at every factor number, and begins to outperform RC as the number of factors increases. RFA's performance, in general, tends to increase as we add more factors. Using PCA, RFA reaches close to its best performance very quickly, requiring only 5 or 6 factors; adding more factors results in longer runtimes for minimal gain. However, in the case of RFE, using more factors appears to be worthwhile. FA and RC both quickly plateau, or even decline, as more features are added.

Since performance generally improved as more factors were added, we explored adding more factors beyond the 11 that are available to us. To this end we create new factors by multiplying the existing factors with one another. To account for variance in the factor ranges, we first min-max normalize each factor. Then we consider every pair of factors and multiply their normalized values together and re-normalize these new values to create a new factor. This gives a total of 55 new factors in addition to the original 11. We rerun our experiments with this new pool of 66 factors.

The right of Figure 3 shows the results of using this expanded pool of factors. Here, the performance begins to taper off beyond 15 factors for both FA and RFA. Overall, PCA obtains its best performance with only a few factors, but then begins to suffer as more factors are added. RFE, on the other hand, tends to perform worse than PCA initially but remains relatively stable as more factors are added. These newly-created features turned out to be less effective than the original eleven, suggesting that the trade-off in increasing factors via combination is not worthwhile.

Overall, even though reducing the number of factors through PCA-based factor selection could not beat the best accuracy, it is still very competitive. Given the potentially huge number of features obtained through factor adaptation, this slight decrease in performance may be worth potential increases in runtime. RFE-based factor selection, however, helps with neither the runtime nor the performance.

6 Conclusions

Language-based prediction tasks involving communities can benefit from both socio-demographic factors and linguistic features. Because this information comes from different sources and has different distributions, effective mechanisms are needed for combining them. In this paper, we present *residualized factor adaptation*, a method that unites two ways of approaching this problem, one where strong community attributes are augmented (i.e. additive use of factors) with weak but noisy language features, and the other where the contextual differences in language use are mediated via community attributes (i.e. adaptation to community factors). The proposed method effectively combines the complementary benefits of both residualized control and factor adaptation approaches to yield substantial gains over differing community-level prediction tasks across three domains. We see this work as part of a growing need for application-oriented approaches that not only leverage large data effectively by themselves, but do so in the context of other social scientific information that is already available and valuable.

Abstract

Amidst growing concern over media manipulation, NLP attention has focused on overt strategies like censorship and "fake news". Here, we draw on two concepts from the political science literature to explore subtler strategies for government media manipulation: agenda-setting (selecting what topics to cover) and framing (deciding how topics are covered). We analyze 13 years (100K articles) of the Russian newspaper *Izvestia* and identify a strategy of distraction: articles mention the U.S. more frequently in the month directly following an economic downturn in Russia. We introduce embedding-based methods for cross-lingually projecting English frames to Russian, and discover that these articles emphasize U.S. moral failings and threats to the U.S. Our work offers new ways to identify subtle media manipulation strategies at the intersection of agenda-setting and framing.

1 Introduction

Authoritarian countries such as Russia and China have received a great deal of attention for trying to control and distort the spread of information through "fake news" and censorship. However, authoritarian governments might also use subtle tactics of media manipulation that are much harder to detect, like flooding communication channels with irrelevant information or highlighting particular viewpoints of an event to distract public attention (Rozenas and Stukal, Forthcoming; Munger et al., 2018; King et al., 2017). "Fake news" can be identified by fact checkers. Censorship can be detected by checking what content is no longer available. However, we have no systematic way of identifying more subtle forms of media manipulation. To date, research has been limited to occasional leaks to reveal ground truth data (King et al., 2017). This paper proposes techniques—grounded in economics and political science—to automatically identify subtle manipulation at scale, and applies these techniques to study Russian media.

These subtle manipulation strategies can be understood through *agenda-setting*—selecting *what* topics to cover—and *framing*—*how* aspects of those topics are highlighted to promote particular interpretations (Entman, 2007; Ghanem and McCombs, 2001). For example, abortion can be framed in terms of the life of a child or a woman's freedom of choice (Tankard Jr, 2001). Agenda-setting and framing can have a significant influence on public opinion by attending to particular issues at the exclusion of others (McCombs, 2002; Boydstun et al., 2013). Both concepts have been well-studied in English-speaking democratic countries, but understudied in other settings. Here, we apply these concepts to the study of media manipulation in Russia, particularly as strategies of an autocratic regime.

We focus on Russia, because of intense interest in the way Russia is shaping the global information environment (Van Herpen, 2015). Many Russian media outlets are state-owned or heavily influenced by the government. We focus on news coverage from 2003–2016 in one of the most widely-read newspapers in Russia: *Izvestia*. Despite a brief period of autonomy, *Izvestia* has become strongly influenced by the government (Jones, 2002).

Prior work has identified a relationship between negative economic performance in Russia, such as stock market declines, and "selection attribution" in state-controlled media outlets, where negative events are blamed on foreign officials while positive events are credited to domestic officials (Rozenas and Stukal, Forthcoming). We build on these findings and investigate the relationship between economic performance, including that of the Russia Trading System Index (RTSI) and gross

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3570–3580
Brussels, Belgium, October 31 - November 4, 2018.

domestic product (GDP), and news coverage of foreign events. We primarily investigate coverage of the United States because Russia has seen the U.S. as its main rival since the Cold War, and we expect news coverage of foreign events to focus disproportionally on the U.S.

We first establish a strong negative correlation between Russia's economic situation and the proportion of news focused on the U.S. (§2). We then show that the correlation is directed: economic indicators precede (and thereby Granger-cause) the increase in foreign news coverage (§2.2). We consider this a clear case of agenda-setting. We then investigate *how* these news articles *frame* the U.S. We develop a distant supervision method to project English framing annotations onto our Russian corpus (§3), and draw on the projected frames to analyze manipulation strategies in news about the U.S. (§5).

The contributions of this work are manifold: we show how framing and agenda-setting (concepts traditionally applied to policy debates) can be used to understand media manipulation strategies; we use economic metrics to automate the identification of agenda-setting; we devise a novel method for cross-lingual projection of framing annotations; and we use these annotations to show how agenda-setting is realized.

2 Agenda-Setting

All media outlets inevitably use a form of *agenda-setting*: deciding what is "newsworthy" by covering some topics at the exclusion of others. Agenda-setting can powerfully sway the focus of public opinion (McCombs, 2002). We hypothesize that in countries with weak democratic institutions and in particular, with state-controlled media, the government may actively use agenda-setting to shape public opinion. We observe this phenomenon by comparing how much Russian newspapers describe the U.S. and the state of the Russian economy. We then use Granger-causality to show that a decline the Russian stock market is followed by an increase in U.S. news coverage.

Our results are based on a corpus of over 100,000 articles from the newspaper *Izvestia* published in 2003–2016 (see Appendix A for details).

2.1 Correlations

We compared the salience of news focused on the U.S. with indicators that reflect the economic state of Russia to test our hypothesis: that news coverage of the U.S. is used to distract the public from negative economic events. We first performed an initial, simplistic study of this agenda-setting strategy. We define *U.S. coverage* as the ratio of *Izvestia* articles that mention the U.S. at least twice to the total number of articles in any given time slice (in our initial study, a year). We show in Figure 1 the U.S. coverage plotted against Russian GDP, in an annual resolution. We find a strong negative Pearson's correlation (r=-0.83): mentions of the U.S. in *Izvestia* increase as economic indicators deteriorate. The one exception to this trend is 2008, during which there was a high amount of U.S. news coverage and the Russian GDP peaked. This year coincides with both the U.S. financial crisis and the Obama-McCain Presidential election, which would explain a focus on U.S. events regardless of the Russian economic situation.

U.S. coverage, measured by counting mentions of the U.S. in *Izvestia*, is inversely related to the level of the Russian GDP. This negative correlation indicates the possibility of intentional agenda-setting by the Russian government.

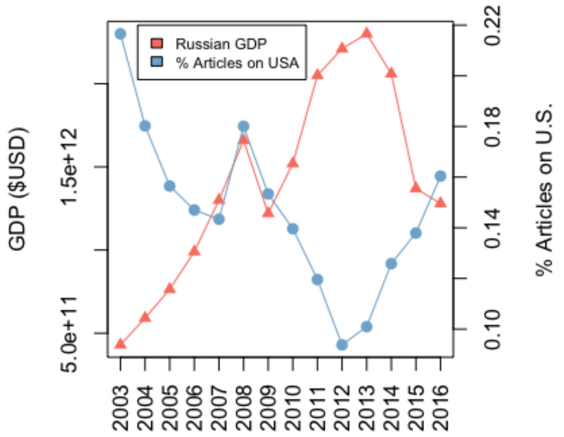

Figure 1: Proportion of articles that mention the U.S. at least twice (blue) and Russian GDP (red), 2003–2016.

We now extend these preliminary results in several ways. First, we refine the definition of *U.S. coverage* by using two metrics: **article level,** the number of articles that mention the U.S. at least twice normalized by the total number of articles in the time slice; and **word level,** the frequency of the occurrences of the U.S., normalized by the total number of words in the time slice. Second, we compare these metrics to *two* economic indicators: GDP (in USD) and the index of the Russian stock market (RTSI), in rubles.[1] Third, we refine the time-resolution and use yearly, quarterly, and monthly time slices.

Table 1 reports the correlations between the two metrics of U.S. coverage and (monthly, quarterly, and yearly) RTSI and GDP values. At all levels, there are strong negative correlations between the proportion of news focused on the U.S. and economic state.

Level:	**Article**	**Word**
RTSI (Monthly, rubles)	-0.54	-0.52
GDP (Quarterly, USD)	-0.69	-0.65
GDP (Yearly, USD)	-0.83	-0.79

Table 1: Pearson's correlation between news coverage of the U.S. and economic indicators.

2.2 Granger Causality

Next, we hypothesize that these correlations are in fact directed: a change in the economy is followed by a change in U.S. news coverage. To investigate this hypothesis we employ Granger causality (Granger, 1988). The key concept behind Granger causality is that cause precedes effect. Thus, a time series X is said to Granger-cause a times series Y if past values x_{t-i} are significant indicators in predicting y_t. First, we computed the article-level (a_t) and word-level (w_t) metrics at a monthly granularity from 2003 to 2016; we also extracted the RTSI monthly close price (in rubles) for the same time period (r_t). We then calculated the percentage change of these series as: $C(w_t) = \frac{w_t}{w_{t-1}} - 1$, and equivalently calculated $C(a_t)$ and $C(r_t)$. By taking the percent change of both series, we control for long term trends (e.g., stock markets tend to trend upwards over time), and instead focus on short-term relations: does a change in the economy directly precede a change in news coverage?

We computed Granger causality between $C(w_t)$ and $C(r_t)$ by fitting a linear regression model:

$$C(w_t) = \sum_{i=1}^{m} \alpha_i(C(w_{t-i})) + \sum_{j=1}^{n} \beta_j(C(r_{t-j}))$$

where m and n denote how far back in time we look (denoted as m-lag or n-lag). We can say that r_t Granger-causes w_t if we find that β is significantly different from zero.

Tables 2 and 3 report the results. A p-value ≤ 0.05 indicates significance; thus we find 1-lag RTSI values Granger-cause coverage of U.S. news by both the word-level and article-level metrics. Importantly, the r_{t-1} coefficient is negative, which indicates that a decline in the stock market is followed by an increase in U.S. news coverage. In the 2-lag analysis, the r_{t-2} values are not significant, which suggests that the changes in news coverage follow changes in the stock market within one month.[2] For completeness, we also computed Granger causality in the reverse direction: i.e., does a change in U.S. news coverage Granger-cause a change in the stock market? As expected, we found no significant results.

	1-Lag		**2-Lag**	
	$\alpha; \beta$	**p-Value**	$\alpha; \beta$	**p-Value**

3 Framing Analysis

We hypothesize that *framing* can further our understanding of why Russian media focuses on the U.S. during economic downturns. By identifying common frames in news coverage of the U.S., we see how the concepts of agenda-setting and framing work together to manipulate public attention. In this section, we first define the concept of framing and demonstrate why existing methods are insufficient for analysis of the *Izvestia* corpus. We then present a new method for analyzing frames and evaluate it quantitatively through hand-annotations and qualitatively through a series

---

[1] Stock market values were obtained from the Moscow exchange website. GDP values were obtained from OECD.

[2] We computed Granger causality at a quarterly and yearly level and found no significant causal relationship. This result is unsurprising; the monthly analysis suggests trends in news coverage are largely driven by the previous month, so we would not expect causality at a quarterly or yearly level.

of examples. Finally, we use this method to contextualize strategies of media manipulation in the *Izvestia* corpus.

3.1 Background on Framing Analyses

While agenda-setting broadly refers to what topics a text covers, framing refers to which *attributes* of those topics are highlighted. Several aspects of framing make the concept difficult to analyze. First, just defining framing has been "notoriously slippery" (Boydstun et al., 2013). Frames can occur as stock phrases, i.e. "death tax" vs. "estate tax", but they can also occur as broader associations or sub-topics (Tsur et al., 2015; McCombs, 2002). Frames also need to be distinguished from similar concepts, like sentiment and stance. For example, the same frame can be used to take different stances on an issue: one politician might argue that immigrants boost the economy by starting new companies that create jobs, while another might argue that immigrants hurt the economy by taking jobs away from U.S. citizens (Baumer et al., 2015; Gamson and Modigliani, 1989). Finally, unlike classification tasks where each article is assigned to a single category, most articles employ a variety of frames (Ghanem and McCombs, 2001).

Recent work has attempted to address these conceptual challenges by defining broad framing categories. The Policy Frames Codebook defines a set of 15 frames (one of which is "Other") commonly used in media for a broad range of issues (Boydstun et al., 2013). In a follow-up work, the authors use these frames to build The Media Frames Corpus (MFC), which consists of articles related to 3 issues: immigration, tobacco, and same-sex marriage (Card et al., 2015). About 11,900 articles are hand-annotated with frames: annotators highlight spans of text related to each frame in the codebook and assign a single "primary frame" to each document. However, the MFC, like other prior framing analyses, relies heavily on labor-intensive manual annotations.

The primary automated methods have relied on probabilistic topic models (Tsur et al., 2015; Boydstun et al., 2013; Nguyen et al., 2013; Roberts et al., 2013). Although topic models can show researchers what themes are salient in a corpus, they have two main drawbacks: they tend to be corpus-specific and hard to interpret. Topics discovered in one corpus are likely not relevant to a different corpus, and it is difficult to compare the outputs of topic models run on different corpora. Other automated framing analyses have used the annotations of the Media Frame Corpus to predict the primary frame of articles (Card et al., 2016; Ji and Smith, 2017), or used classifiers to identify language specifically related to framing (Baumer et al., 2015). Importantly, all of these methods focus exclusively on English data sets. While unsupervised methods like topic models can be applied to other languages, any supervised method requires annotated data, which does not exist in other languages.

3.2 Framing Analysis Methodology

Our goal is to develop a method that is easy to interpret and applicable across-languages. In order to ensure our analysis is interpretable, we ground our method using the annotations of the Media Frames Corpus. However, because the MFC is entirely in English and our test corpora is in Russian, we cannot use a fully supervised method. Instead, we use the MFC annotations to derive lexicons for each frame, which we then translate into Russian. We use query-expansion to reduce the noisiness of machine translation and make the lexicons specific to the *Izvestia* corpus, rather than specific to the MFC. We evaluate the derived lexicons in English and in Russian. Finally, we use these lexicons to analyze frames in *Izvestia* and identify strategies of media manipulation. Our method allows for in-depth analysis by identifying primary and secondary frames in a document and specific words that signify frames.

Generating framing lexicons Although our primary test corpus is in Russian, we also use English test corpora for evaluation; thus, we describe our method as applicable to either language. First, we use the MFC annotations to derive a lexicon of English words related to each frame in the Policy Frames Codebook. For a given frame F we measure pointwise mutual information (Church and Hanks, 1990) for each word in the corpus as:

$$I(F, w) = log\frac{P(F, w)}{P(F)P(w)} = log\frac{P(w \mid F)}{P(w)}$$

We estimate $P(w|F)$ by taking all text segments annotated with frame F, and computing $\frac{Count(w)}{Count(allwords)}$. We similarly compute $P(w)$ from the entire corpus. We then use the 250 words with the highest $I(w, F)$ as the base framing lexicon for frame F, denoted F_{base}. We discard all words that occur in fewer than 0.5% of documents or in more than 98% of documents.

Translation and extension of framing lexicons Next, we use query-expansion to alter F_{base}, with the goal of generalizing the lexicon. Without this step, our lexicons are biased towards words common in English news articles, particularly words specific to the 3 policy issues in the MFC.

When our test corpus is in a different language (i.e. Russian), we use Google Translate to translate F_{base} into the new language. We restrict our vocabulary to the 50,000 most frequent words in the test corpus.

Then, to perform the query-expansion, we train 200-dimensional word embeddings on a large background corpus in the test language, using CBOW with a 5-word context window (Mikolov et al., 2013). We compute the center of each lexicon, c, by summing the embeddings for all words in the lexicon. We then identify up to the K nearest neighbors to this center, determined by the cosine distance from c, as long as the cosine distance is not greater than a manually-chosen threshold (t).[3] We again filtered the final set by removing all words that occur in fewer than 0.5% of documents or in more than 98% of documents.

The final lexicons contain between 100 and 300 words per frame. Table 4 depicts a few examples of lexicon words extracted from the MFC, and words in our final lexicons. We can observe that words in F_{rus} are closely related to words in F_{base}, but also specific to Russian culture and politics.

We consider a document to employ a frame F if the document contains at least 3 instances of a word from F's lexicon. We assign the primary frame of a document to be its most common frame, determined by the number of words from each framing lexicon in the document .[4]

F_{base}	F_{rus}
Political	
republican-controlled	bills
filibuster	conservative
gubernatorial	parlimentary
Economic	
cents	deductions
holdings	tax
profitable	fines
Public Sentiment	
gallup	activism
demonstrators	facsim
rallied	vote

Table 4: Example lexicons extracted from the MFC and transfered to the *Izvestia* corpus.

4 Evaluation of Framing Lexicons

We can evaluate the English lexicons using annotated data from the MFC. For the Russian lexicons, since we do not have annotated Russian data, we instead conduct an annotation task. These evaluation metrics determine how well our method captures which frames are present in a text. Finally, we also qualitatively compare our method to existing methods for framing analysis, specifically topic models.

English Evaluations We first evaluate our lexicons on two tasks using the MFC annotations: primary frame identification and identification of all frames in a document.

Primary frame identification is a 15-class classification problem. Two prior studies evaluate models on this task: Card et al. (2016) and Ji and Smith (2017). Following these studies, we evaluate our model using 10-fold cross-validation on only the "Immigration" subset of the MFC. We use 9 folds to generate framing lexicons and the 10th fold to evaluate. To train word embeddings, we use the entire MFC corpus combined with over 1 million New York Times articles from 1986 - 2016 (Fast and Horvitz, 2017). Table 5 shows the accuracy of our model. Our results outperform Card et al. (2016) and are comparable to Ji and Smith (2017). Furthermore, unlike prior methods, our method is able to transfer to different domains and languages without needing further annotated data.

Ji and Smith (2017)	58.4
Card et al. (2016)	56.8
Our model	57.3

Table 5: Accuracy of primary frame classification.

However, our main interest is in measuring the salience of frames in general, not merely focusing on the primary frame. Thus, we also use our

---

[3] When the test corpus is in English, we set t to 0.4 and K to 500 and we add the identified neighbors to F_{base}. When our test corpus is in Russian, we choose to discard our base lexicon, to prevent the final lexicons from being too U.S.-specific. Instead, we set t to 0.3 and K to 1000, which increases the number of neighbors identified, and we keep only these neighbors in the final lexicon.

[4] We do not generate a lexicon for the "Other" frame, and instead assign a document's primary frame as "Other" only if it does not contain at least 3 words from any framing lexicon. Throughout this process, we use small subsets of the "tobacco" articles for parameter tuning.

lexicons to identify the presence of any frames in a document. As the MFC has multiple annotators, we define a frame to be present in a document if any annotator identified the frame, and use this as gold standard test data. In evaluating our lexicons, we consider a frame to be present in a document if the document contains at least 3 tokens from the frame's lexicon.

To the best of our knowledge, identifying all frames in a document is a new task that was not attempted in prior work. Thus, we use a logistic regression model with bag-of-word features as a standard baseline. As above, we evaluate using 10-fold cross validation on the "Immigration" subset of the MFC. Table 6 shows that our method outperforms the baseline, with the exception of 2 frames, even though the baseline is fully supervised, whereas our method is distantly supervised. We note that the poorest performing frames, "External Regulation and Reputation" and "Morality" are the frames which are least common in this subset of the data – each frame occurs in fewer than 500 articles. When we run the same 10-fold cross validation evaluation on the "Samesex" subsection of the MFC, where the "Morality" frame occurs in over 1000 articles, we achieve a higher F1 score (0.65).

	Ours	**Baseline**
Capacity & Resources	**0.53**	0.48
Crime & Punishment	**0.78**	0.76
Cultural Identity	0.57	**0.62**
Economic	**0.69**	0.67
External Regulation	0.25	**0.47**
Fairness & Equality	**0.50**	0.44
Health & Safety	**0.58**	0.53
Legality & Constitutionality	**0.80**	0.76
Morality	**0.31**	0.25
Policy Prescription	**0.72**	0.69
Political	**0.80**	0.77
Public Sentiment	**0.54**	0.47
Quality of Life	**0.65**	0.63
Security & Defense	0.63	0.63

Table 6: F1 Scores for identification of all frames in a document.

Russian Evaluations Next, we evaluate the quality of our method on the Russian data set. Unlike in English, we do not have frame-annotated data in Russian. We instead performed the intruder detection task, an established method for evaluating topic models (Chang et al., 2009). For each frame F we randomly sampled 5 words from the framing lexicon F_{rus} and 1 word from the lexicon of a different frame, which has no overlap with F_{rus}. We then presented two (native Russian speaking) annotators with the frame heading and the set of 6 words, and asked them to choose which word did not belong in the set. We evaluated 15 sets or 75 words per frame.

Framing can be subjective, and we do not necessarily expect annotators to interpret frames in the same way. We calculate two forms of accuracy: "soft", whether *any* annotator correctly identified the intruder; and "hard", whether both did. We also report average precision as defined in (Chang et al., 2009), i.e. the average number of annotators that correctly identified the intruder, averaged across all sets.

We briefly summarize results here and report them fully in Appendix B. All accuracies are significantly better than random guessing, and no soft accuracy falls below 60%. Only two frames have an average accuracy $\leq 60\%$, "Fairness and Equality" and "Morality", both very abstract concepts. In these frames, we also see a larger difference between hard and soft accuracies, which reflects the subjectivity of framing. The MFC annotators sometimes disagreed on the correct annotations, even after discussing their disagreements (Boydstun et al., 2013). Thus, we can attribute some of the differences between hard and soft accuracies to this subjectivity.

Qualitative Comparison to Structured Topic Models We also qualitatively compared the information our framing lexicons provide with information provided by a Structured Topic Model (STM) (Roberts et al., 2013). We find that our approach is better able to capture frames the way a reader might conceptualize them, whereas topic models are useful for finding fine-grained corpus-specific topics.

Topic models are a common way to analyze frames in a text (Nguyen et al., 2013); the STM specifically allows correlation between topics and covariates. We trained an STM with 10, 15, 20, 25, and 50 topics on U.S.-focused articles in the *Izvestia* corpus, including publication date (month and year) as a covariate. We selected the 20 topic model as having the most coherent topics. Throughout this section, we refer to topics using their most representative words as determined by the "Lift" metric (Roberts et al., 2013).

We randomly selected a sample document for each primary frame to investigate. The framing lexicons are able to connect corpus-specific vocabulary to higher-level concepts. For example, an article describing movies about the U.S. prison facility at Guantanamo Bay has two main STM topics: [laden, sentence, prison] and [author, viewer, filming]. Similarly, the framing lexicons identify ‘Cultural Identity” as the primary frame. However, a secondary frame in the document is “Morality”, captured by words: writer, form, Christ, art. While both the STM and the framing lexicons capture major details of the article, the framing lexicons additionally tie the article to morality, because words like “art” in this corpus are often signs of a moral framework.

Nevertheless, when the STM identifies a topic similar to a frame, we find correlations with the related lexicon, i.e. there is a 0.75 correlation between the frequency of words in the Legality, Constitutionality, Jurisdiction lexicon and the monthly average proportion of each document assigned to the topic [yukos, bill, legislation].

Additionally, the framing lexicons tend to have higher precision in identifying relevant articles than the STM. Topics are commonly identified by their most probably words, which may not occur at all in documents associated with the topic. For example, the STM assigns an article about smoking policies in the U.S. to 3 main topics: [laden, sentence, prison], [kosovo, falcons, because], [author, viewer, filming], none of which are closely related to the article. In contrast, because assignments to the framing lexicons are made directly from words in the lexicon, we can be confident that articles assigned to each frame have words from the actual lexicon, and are very likely related to the frame. The framing lexicons assign the primary frame as “Policy” for this article, which is a good fit. Neither method captures that the article is also related to health.

Finally, the STM is useful for finding fine-grained topics, beyond the Policy Frames Codebook. For example, we find a “sports” topic: [match, nhl, team]. These topics tend to be corpus-specific and more concrete than the framing lexicons: no STM topic captures “Quality of Life”.

5 Identifying Media Manipulation

We first use the generated framing lexicons to determine which frames are frequently associated with the U.S. We then break the frames into finer-categories and manually look at sample articles to determine why associating these frames with the U.S. constitutes a media manipulation strategy. We find that as the stock market declines, not only is news focused more on the U.S., but also emphasizes threats to the U.S.

5.1 Salient frames

To estimate which frames are associated with the U.S. we compute *normalized pointwise-mutual information* (nPMI) between the U.S. and each frame F[5] by mapping the mutual information score onto a [-1,1] scale. A value of 1 represents complete co-occurrence; a value of 0 represents complete independence. By using nPMI, we measure which frames are *overrepresented* in U.S.-focused news, as compared to other news.

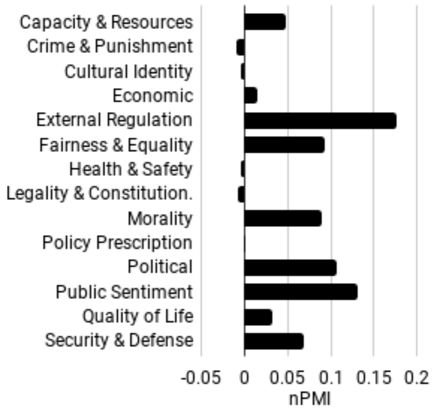

Figure 2: nPMI between U.S. and each frame.

Figure 2 shows the nPMI score between the U.S. and each frame for all articles in our corpus. As any news article about the U.S. is by definition externally focused, the frame with the strongest association is unsurprisingly “External Regulation and Reputation”. Other frames with strong associations include “Morality”, “Political”, “Public Sentiment”, and “Security and Defense”. These frames demonstrate what type of news events in the U.S are reported in Russia. As an example, we look at an article that uses a combination of these frames. The article describes cooling relations between Russia and the U.S. It explains that anti-Russian sentiment will be prevalent in the U.S. during upcoming elections, when politicians on both sides will play the “Russia card”. It ultimately attributes the cooling relations

---

[5] As above, we consider an article to be U.S.-focused if it mentions the U.S. at least 2 times, and we consider an article to employ frame F if it uses at least 3 words from F’s lexicon.

to a mismatch of values and ideology between the two nations. The framing lexicons well-capture the numerous themes in this article. Specifically, the frames identified and the related framing lexicon words are:

Political: electorate, election, former, pre-election, political scientists, congress, president, post, bush

Public Sentiment: elections, campaign, pre-election, democrats, republicans

External Regulation and Reputation: west, war, former, washington, politics, summit, exacerbation, west, decision, bush, president

Morality: peace, sins, ideals, love, values

Fairness and Equality: politics, love, values

This article uses several strategies to promote unity in Russia and actively separate Russia from Western culture, including criticizing American politics and emphasizing a difference of values. Russian articles use a combination of frames to describe the U.S., which demonstrates the importance of looking at all frames in a document, rather than just the primary frame. In the following sections, we provide additional examples demonstrating how combinations of frames can generate anti-U.S. sentiment.

5.2 Salient words within frames

We expect different aspects of frames to be foregrounded during economic upturns than in downturns. To investigate these differences, we define a set of months M_t^+, as the 10% of months where RTSI showed the greatest growth, and a corresponding set M_t^- where RTSI showed the greatest decline. We then take M_{t+1}^+ as the month directly following every month in M_t^+, and we similarly define M_{t+1}^-. From the analysis in §2.2, we expect media manipulation strategies to decline from M_t^+ to M_{t+1}^+, and increase from M_t^- to M_{t+1}^-. For each frame, we take the subset of U.S.-focused articles that use the frame. Then, we use log odds with a Dirichlet prior (Jurafsky et al., 2014; Monroe et al., 2008) to identify words that are overrepresented or underrepresented from M_t^+ to M_{t+1}^+ and from M_t^- to M_{t+1}^-.[6] Thus, for each frame, we identify words which become more common after a stock market downturn and become less common after a stock market upturn. We refer to these words as AgendaLex.

We found the Security and Defense AgendaLex and the Crime and Punishment AgendaLex to be surprisingly coherent, both containing words related to terrorism and countries enemy to the U.S., including bombs, missiles, Guantanamo, North Korea, Iraq, etc. We found a correlation of -0.49 between the frequency of words from the Security and Defense AgendaLexin U.S.-focused articles and the RSTI (-0.49). A 1-lag Granger causality test (to what extent does a change in RTSI Granger-cause a change in the prevalence of the Security and Defense AgendaLex?) has a p-value of 0.0051. As the stock market declines, not only does the news focus more on the U.S., the news focuses specifically on terrorists and other enemies to the U.S. In the next section, we refine this conclusion by looking at sample articles.

5.3 Examples of framing during downturns

By reading sample articles from months just after stock market downturns that used words from the Security and Defense lexicon and AgendaLex, we identified three common strategies for distracting Russian citizens from negative economic events: villainizing the U.S., describing threats to the U.S., and promoting the Russian military over the U.S. military.

First, some articles focus on immoral actions of the U.S. military, describing U.S. troops as "Nazi", or U.S. campaigns in Iraq as "barbaric" or causing "horror and outrage throughout the world". Others discuss Guantanamo Bay, employing the "Morality" or "Legality, Constitutionality, Jurisdiction" frames. By portraying the U.S. government negatively, actions of the Russian government appear positively by comparison. Promoting unity by presenting an external enemy is a well-studied political strategy.

Second, many articles, often in passing, described threats to the U.S. An article about terror attacks in Paris mentions U.S. involvement with words from the Crime and Punishment and Security and Defense lexicons: terrorist, terrorists, special services. An article about the conflict between Israel and Palestine describes increased security in the U.S. An article about a U.S. military operation refers more directly to threats to the U.S. by claiming the killed terrorist will simply be replaced "and everything will start afresh - explosions, chases, roundups...unlucky businessmen, successful terrorists". The articles

---

[6] We take the 500 words with the largest increase in salience from M_t^- to M_{t+1}^- intersected with the 500 words with the largest decrease in salience from M_t^+ to M_{t+1}^+.

portray the U.S. as an unsafe place to live, making Russia seem like a preferable home.

A third type of article also presents Russia as safe by downplaying U.S. military threat: “the missile defense system of the USA does not pose a real threat to Russia’s strategic nuclear forces.” or describing the growth of Russian technology compared to ‘impotent’ American counterparts.

6 Related Work

Most studies on Russian media manipulation focus on state-owned television networks, such as *Channel 1* and *RT*. Strategies identified in these outlets include spreading confusion (Paul and Matthews, 2016) and “selection attribution”, in which negative economic events are attributed to foreign entities and positive events are attributed to Russian officials (Rozenas and Stukal, Forthcoming). Similar strategies have been identified in social media in China and in Venezuela: these regimes flood communication channels with irrelevant information or general “cheerleading”, presumably to distract the public from current events (King et al., 2017; Munger et al., 2018). We expand on these analyses as we study manipulation strategies in a more automated way, through Granger-causality and framing lexicons. We further draw parallels between these strategies and theories of agenda-setting and framing.

Furthermore, our method for analyzing frames contributes to the growing body of work on automated-framing analysis (Nguyen et al., 2013; Boydstun et al., 2013; Card et al., 2016; Baumer et al., 2015). While past work uses fully-supervised methods, which are not applicable to languages lacking training data, or unsupervised topic models, which can be difficult to interpret, we take a semi-supervised approach: using statistical metrics and word embeddings to generate corpus-specific lexicons based on common frameworks.

We additionally integrate our framing and agenda-setting analysis with economic indicators through the concept of Granger causality. While the concept of Granger causality is not new in economics, it is less common in NLP and social sciences. Moreover, modeling relationships between news and economic indicators is a relatively recent area. Most research has focused on using text to predict economic indicators using a variety of features, from frequencies of keywords to sentiment of social media posts (Nardo et al., 2016). Kang et al. (2017) combine text and Granger causality for a different task: automatically explaining causes of time series events. Our study differs from past work in that we reverse the direction: rather than using news articles to model changes in economic data, we use economic data to show changes in news articles.

7 Conclusions

We show that natural language technology, in addition to its ability to address overt manipulation strategies like “fake news” and censorship, has the potential to shed light on more subtle political manipulation strategies, specifically distraction. We offer a way to define these strategies by drawing on social science theories of agenda-setting and framing, combining them with a novel methodology for cross-lingual projection of framing annotations. We investigate how the resulting frames are used in the Russian newspaper *Izvestia*, and show that it reports on negative events in the U.S. as a way of distracting from economic downturns in the Russian economy.

Our approach and our findings serve as a starting point for further research on automating the identification and analysis of media manipulation strategies. These include identification of more nuanced framing strategies, such as mitigation, projections of power among entities mentioned in news, identification of over- and under-represented events, and in general, detection of biases in news articles as a means for understanding trustworthiness in media reports.

Abstract

Vlogs provide a rich public source of data in a novel setting. This paper examined the continuous sentiment styles employed in 27,333 vlogs using a dynamic intra-textual approach to sentiment analysis. Using unsupervised clustering, we identified seven distinct continuous sentiment trajectories characterized by fluctuations of sentiment throughout a vlog's narrative time. We provide a taxonomy of these seven continuous sentiment styles and found that vlogs whose sentiment builds up towards a positive ending are the most prevalent in our sample. Gender was associated with preferences for different continuous sentiment trajectories. This paper discusses the findings with respect to previous work and concludes with an outlook towards possible uses of the corpus, method and findings of this paper for related areas of research.

1 Introduction

Vlogging or video-blogging has become one of the most popular video formats on social media platforms like YouTube. Vlogs have been referred to as 'conversational video-blogs' (Biel and Gatica-Perez, 2010) or 'monologue-like' videos (Aran et al., 2014), and are officially defined in the Cambridge dictionary of English as "a record of your thoughts, opinions or experiences that you film and publish on the internet"[1]. The vast amount of vlogs on YouTube comprises a rich body of visual and textual data, usually covering a vlogger's daily life. The transcripts of vlogs provide researchers with ample opportunity to examine natural language in this young field of communication. Nevertheless, little attention has thus far been paid to investigating the language used in YouTube vlogs.

Much of the literature concerning Youtube vlogs focuses on the visual modality (Aran et al., 2014) or meta-indicators such as views and subscriber counts (Borghol et al., 2012). With the current study, we aim to address this gap in the literature by automatically analyzing the linguistic styles used by YouTube's vloggers. Building on a novel approach to examining the continuous sentiment structure, we seek to shed light on the different temporal trajectories used by vloggers, and, by doing so, we expect to gain a deeper understanding of language use in vlogs.

1.1 Previous research on vlogs

Research on YouTube vlogs has thus far mainly focused on metadata indicators and how they impact video popularity. For example, a pronounced "rich-get-richer" effect regarding video popularity is often found. When controlling for the content, previous views are the best predictor of later video popularity (Borghol et al., 2012). In addition, video age also predicts popularity: when the content is similar, early uploaders have an advantage over later uploaders in terms of popularity (Borghol et al., 2012). Furthermore, related video recommendations shown during or after a playing video also serve as an important indicator of the view count for YouTube videos (Zhou et al., 2010).

Another strand of research has examined the visual content of vlogs. Across 2,268 single-person YouTube videos, four clusters of user activity level

---

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3581–3590
Brussels, Belgium, October 31 - November 4, 2018.

(e.g., stationary or in motion), editing choices, and video quality were identified (Aran et al., 2014). Videos from a cluster with highly edited, active vlogs received more views than simple conversational videos in which the vlogger is stationary in front of the camera. Concerning audio data, videos in which the vlogger is "talking more, faster, and using few pauses" receive more views on average (Biel and Gatica-Perez, 2010). Similarly, the distance of the vlogger to the camera, looking time, and 'looking-while-speaking' were also found to significantly correlate with view count. It has been suggested that these nonverbal characteristics might be related to specific personality traits that promote effective communication and video popularity (Biel and Gatica-Perez, 2010). Lastly, a smaller line of research examines the linguistic content of YouTube vlogs. For example, a manual inspection of a random sample of 100 vlogs suggests that female vloggers are more likely than male vloggers to vlog about personal matters (Molyneaux et al., 2008). In contrast, male YouTubers focused more on entertainment and technology. Research on the linguistic content of vlogs is scarce, which is why the present paper presents a novel methodology and corpus for examining the text modality. In the next section, the proposed method is explained in conjunction with previous research utilizing intra-textual sentiment analysis.

1.2 Continuous sentiment trajectories

With increasing amounts of textual data available online, diverse methods for examining natural language and its linguistic style and content are applied on a large scale. Applications range from the automated detection of fake reviews (Ott et al., 2013), fake news (Thorne et al., 2018; Pérez-Rosas et al., 2018) and lies and truths (Mihalcea and Strapparava, 2009; Kleinberg et al., 2018) to detecting political sentiments (Cambria, 2016).

One important strand of computational linguistics examines the sentiment of texts (i.e., how positive or negative the emotional valence of the content is). Typically, a sentiment score is reported for a piece or section of text (e.g., a sentence or a whole text). However, a recently emerged literature examines shifts in emotional valence throughout a text (hence intra-textual) to assess sentiment over time. This focus on the temporal dimension resembles work on storyline extraction, where the timeline of events is considered, including events that give rise to a 'climax' of a story (Caselli and Vossen, 2016). With intra-textual sentiment analysis, it is also possible to visualize language use leading to a climax in (positive or negative) sentiment. This method has thus far been applied to extract the intra-textual sentiment dynamics in novels (Gao et al., 2016) and was used to identify key narrative moments. Within this same context, Jockers (2015a) analyzed the intra-textual sentiments of over 40.000 novels using hierarchical clustering and observed six shapes, each representing a common sentiment structure in novels (e.g., a 'man-in-hole' structure showcasing a positive-negative-positive sentiment).

A few studies have further examined emotional plot shapes in different bodies of text. Six common emotional arcs were found to underlie 1,327 fictional stories, termed the 'rags to riches' (i.e., a rise in sentiment), 'tragedy' or 'riches to rags' (i.e., a fall in sentiment), 'man in hole' (i.e., fall-rise), 'Icarus' (i.e., rise-fall), 'Cinderella' (i.e., rise-fall-rise), and 'Oedipus' styles (i.e., fall-rise-fall; see Reagan et al., 2016). Comparing these emotional arcs to the number of downloads for each of the fiction titles, the authors suggest that 'Icarus', 'Oedipus', and 'Man in a hole' are the most successful plot shapes.

In a different study IBM's Watson Tone Analyzer was used to examine the continuous trajectories (i.e., in terms of emotion: e.g., joy; language: e.g., analytical language, and personality: e.g., extraversion) in public speaking (Tanveer et al., 2018). The authors investigated the audience's perception of linguistic structures of 2,007 publicly available TED talks. After identifying clusters and comparing these to ratings on the TED website, they found that 'flat' (i.e., less diverse) plot shapes are more likely to be rated as 'long-winded', emphasizing the importance of narrative variety for speech success. Furthermore, the majority of speeches showed a positive ending. While specific linguistic (or visual) characteristics of a video may not be accessible prior to watching a video, its style and structure may play a role in capturing and holding on to the attention of a viewer. Since video streaming services tend to only consider "quality views" (i.e., longer than X amount of time, (YouTube.com, 2018), examining the continuous sentiment styles over narrative time may be a worthwhile endeavor.

1.3 The current study

This investigation aims to use intra-textual sentiment analysis to examine the continuous sentiment styles used in YouTube vlogs. Specifically, we primarily aim to identify distinct trajectories of continuous sentiment. In addition, we explore the sentiment styles' relationship to gender and their overall prevalence on YouTube. Besides these aims, we introduce a novel method of extracting sentiment that is sensitive to valence shifters but can be used on non-punctuated data (e.g., YouTube vlogs). We also present a publicly available corpus of YouTube vlog transcripts.

2 Data

The data and code used to produce the analysis and data in this paper are publicly available.[2] [3]

2.1 Vlog selection

Vlogs were selected by choosing vlog channels (i.e., where YouTubers post their videos) from a list of the top 250 YouTube channels (ranked by subscriber count) in the 'People & Blogs' category (retrieved from www.socialblade.com on 29 March 2018). Channels were selected for inclusion if the videos on the channel were in English and the channel solely focused on vlogs – excluding channels with gaming, music and prank videos. The aim was to select a sample of 20 female and 20 male vloggers from the list of 250 YouTube channels. However, the majority of channels in this list were male or family vloggers, resulting in a somewhat unbalanced sample. After inspecting all 250 channels in the list, 37 channels that satisfied the aforementioned criteria remained.

2.2 Scraping vlog transcripts

To obtain vlog transcripts, we accessed all videos published on the selected YouTube channels and used www.downsub.com to access video transcripts. That website downloads and returns YouTube transcripts for a specified video URL directly in the browser. We developed a python script that takes video URLs as input and communicates indirectly with YouTube via downsub.com to request and retrieve video transcripts. We did not differentiate between manually-added and automatically-generated transcripts but encountered several cases in which neither was available for a certain video. In this case, we ignored the affected video and proceeded without considering it further in the analysis.

2.3 Preprocessing

The retrieved transcripts were XML-encoded, and the preprocessing included the removal of all XML tags to provide human-readable sequences. Furthermore, each row of the XML transcripts contained the word sequence of the vlog with its corresponding start and end time. Since the YouTube transcripts do not include any punctuation information, we decoded each row by removing the XML tags and merged the resulting human-readable sequences to one continuous string for each vlog.

2.4 Feature extraction

The primary aim of this investigation was to examine the continuous sentiment structures of popular vlogs. Taking inspiration from previous work on the narrative arcs of novels (Gao et al., 2016), we wanted to analyze how the sentiment of the spoken content of a vlog moves dynamically throughout the vlog's narrative time. When conducting sentiment extraction, an important consideration is the treatment of valence shifters that influence the meaning of a sentiment. For example, an utterance such as "this was not a bad day" should be rated as a positive sentiment since the valence of "bad" is shifted through the negator "not". Existing methods of extracting sentiment, however, either ignore valence shifters (Jockers, 2015b) or are sentence-based (i.e., they provide weighted sentiments only per sentence, e.g., the *R*-package *sentimentr*, Rinker, 2018b). Since the scraped transcripts are non-punctuated, but we also wanted to account for valence shifters, we built a "naïve context" sentiment extractor that is sensitive to negators (e.g., not, doesn't), [de-]amplifiers (e.g., really, hardly), and adversative conjunctions (e.g., but, however). The rationale is inspired by the algorithm behind *sentimentr* (Rinker, 2018b) but extends that approach to data that are non-punctuated or very brief.

Specifically, our algorithm identifies each sentiment as matched with the 'Jockers & Rinker Polarity Lookup Table' from the *lexicon* R package

---

[2] Data and code for vlog scraping: `https://github.com/ben-aaron188/narrative_structures`.

[3] Code for feature extraction algorithm: `https://github.com/ben-aaron188/naive_context_sentiment`

(Rinker, 2018a) and then constructs a "naïve context" cluster (i.e., without relying on punctuation or other structure) around that sentiment (here: two words before and after the sentiment). For each context cluster, the raw sentiment is then weighted by the presence of valence shifters. For example, "this was not a bad day in the sun" would result in a cluster around the identified sentiment word "bad" of (not a **bad** day in). The weights assigned to the valence shifters in this study (Negator: -1.00, Amplifier: 1.50, De-amplifier: 0.50, Adversative conjunction: 0.25) are motivated by those in the similar software package *sentimentr*.[4] Lastly, the sentiment word in the cluster is replaced by its sentiment value: (-1, 1, -0.75, 1, 1). We can then calculate the product of all vector elements and retrieve the weighted sentiment of that cluster (e.g., 0.75 for "not a bad day in").

We performed the naïve sentiment extraction on each vlog transcript resulting in a vector consisting of zeros (for words that did not match the sentiment lookup table) and weighted sentiment values. That vector was transformed to a standardized narrative time from 0 to 100 using the discrete cosine transformation from the *syuzhet* R package (Jockers, 2015b). The sentiment values were scaled from -1 (lowest sentiment per vlog transcript) to +1 (highest sentiment per vlog transcript). The transformation yielded a vector of 100 sentiment coordinates for each transcript.

3 Results

3.1 Corpus statistics

The final corpus consisted of the transcripts of 27,333 vlogs from 24 vloggers with a total corpus size of 40,318,924 words and vlogs accounting for more than 24 billion views. These are all vlogs of which we were able to retrieve a transcript of at least ten words. Table 1 shows that female vloggers were underrepresented in the sample. More than half of the vlogs stem from male vloggers and a third from families who vlog. Since view count is highly dependent on the number of days the vlog is online, we corrected the view count for each vlog by dividing it by the number of days it was online. We then excluded 462 vlogs (1.69%) that were considered view count outliers (i.e., more than three standard deviations above the mean). All subsequent analyses were conducted on the final sample with these outliers excluded.

	Overall	**Female**	**Male**
# of vlog channels	24	12.50% (n = 3)	54.17% (n = 13)
# of videos	27,333	7.64% (n = 2,087)	49.02% (n = 13,399)
Videos/channel	1138.88	695.67	949.92
Avg. length (# of words)	1475.10 (746.53)	1480.06 (610.72)	1366.31 (804.68)
Avg. view count	893,932 (2,566,021)	456,603 (718,895)	898,089 (1,900,855)
Avg. view count (after outlier removal)	762,143 (1,479,588)	412,592 (490,792)	817,029 (1,476,804)
Stand. view count	1553.69 (2733.35)	1457.40 (2508.95)	1620.12 (2875.96)

Table 1. Descriptive statistics (mean, SD).

3.2 Identifying continuous sentiment styles

The primary aim of this paper was to examine whether the narrative structure of vlogs can be captured by a few overarching sentiment styles. We used the binned sentiments extracted for each vlog in an unsupervised non-hierarchical *k*-means cluster analysis. Using the within-cluster-sum-of-squares in a scree plot for 1 to 30 clusters, we observed an inflection after seven clusters and therefore decided to build a *k*-means model with *k*=7 (Figure 1 and 2).

The *k*-means model assigned one cluster to each vlog transcript, and we subsequently averaged the continuous sentiment structure of all vlogs

---

[4] Consensus on values for valence shifter weights has yet to emerge in literature. The algorithm is available as an *R*-implementation to modify these values.

Cluster	Description	Label	% of vlogs	Avg. length	Stand. view count
1	Highly positive start, followed by semi-negative section, mildly positive section, negative ending	“Downhill from here”	16.06	1477.41 (741.71)	1524.52 (2738.15)
2	Negative start, followed by positive section, mildly negative section, semi-positive ending	“Mood swings”	11.84	1503.70 (759.19)	1504.72 (2702.29)
3	Negative first half, positive second half	“Rags to riches”	15.92	1454.41 (727.83)	1557.04 (2697.74)
4	Positive first half, negative second half	“Riches to rags”	12.36	1485.32 (769.01)	1477.71 (2615.45)
5	Semi-positive start, followed by a highly negative section, semi-positive end	“Bump in the road”	13.46	1480.21 (729.47)	1507.75 (2650.23)
6	Majority of the narrative is semi-negative, with highly positive end	"End on a high note"	18.39	1507.69 (701.18)	1818.73 (3030.10)
7	Majority of the narrative is positive with two peaks	“Twin peaks”	11.97	1402.86 (788.97)	1368.05 (2511.51)

Table 2. Narrative styles taxonomy and descriptive statistics.

belonging to each cluster. Figure 1 and 2 show the distinct average shapes of the continuous sentiment structures of each cluster. The dotted red lines indicate the upper and lower boundaries of the sentiment shape +/- one standard deviation; the blue lines show the 99% confidence intervals. The seven plot shapes represent the average sentiment of all vlogs in that shape cluster in each bin of standardized narrative time (1-100). For example, for the first shape (Figure 1, second plot), the sentiment starts highly positive in the first quantile of the narrative time and then quickly dips below zero to moderately negative sentiment. Halfway through the narrative time, the sentiment neutralizes and becomes negative again until the last quantile from which it gradually becomes less negative and ends in a nearly neutral sentiment.

Table 2 proposes a taxonomy of these seven continuous sentiment styles of YouTube vlogs and provides descriptive statistics for each. We used a linear mixed effects model to test for an effect of the clusters on the view count and transcript length. To account for dependence in the data (i.e., that we have multiple transcripts per vlogger), we included the vlogger as a random effect in the model. The analysis indicated that there was no significant difference in the corrected view count between the clusters; non-standardized β-coefficient of cluster = 6.78, *se* = 7.40, $t(451.25) = 0.92$, $p = .360$. Nor was there a difference in transcript length; $\beta = -1.23$, *se* = 2.07, $t(114.10) = -0.60$, $p = .552$. Thus, it is not statistically justified to argue that one particular narrative style attracted more views than others. Nor do these results provide support for a relationship between a vlog’s length (as measured by the number of words in its transcript) and a particular sentiment style (e.g., that lengthier vlogs contain more sentiment shifts).

A one-sided Chi-square test revealed that the number of vlogs was not uniform per cluster, $X^2(6) = 720.61$, $p < .001$. The observed frequencies of vlogs in each cluster deviated significantly from the frequency that is expected if the vlogs were distributed uniformly ($n = 3832$, 14.29%). Standardized residuals (z-scores) of the observed relative to the expected frequencies can be used to examine which observations deviated in which direction. There were significantly more vlogs than expected in the “downhill-from-here” cluster ($z = 8.30$), the “rags-to-riches” cluster ($z = 7.64$), and the “end-on-a-high-note” cluster (z = 19.21). The clusters “mood swings” (z = -11.45), “riches-to-rags” (z = -9.02), “bump-in-the-road” (z = -3.86), and “twin peaks” (z = -10.82) were significantly underrepresented. Aside from the considerable overrepresentation of the “end-on-a-high-note” cluster and underrepresentation of the “mood swings” and “twin peaks” clusters, the distribution is rather harmonious.[5]

3.3 Additional analysis: Sentiment styles and gender

We also assess whether there is a relationship between gender and the continuous sentiment style. There was significant association as indicated with a 3 (male, female, family) by 7 (clusters) Chi-square test, $X^2(12) = 134.82$, $p < .001$. Table 3 shows that family vloggers used the “twin peaks” style significantly more often than expected and used the “end-on-a-high-note” style significantly less often than expected (* = significant at $p < .01$). For female vloggers, the most used continuous sentiment style was “riches to rags”, while they used “end-on-a-high-note” less often than expected. Male vloggers preferred the "end-on-a-high-note" style while they used the styles "downhill from here" and "twin peaks" less often. Since we did not ascertain a balanced gender distribution, these findings should be treated cautiously and subjected to replications on datasets more suitable for gender analysis.

Cluster	Family	Female	Male
Downhill from here	2.23	1.26	-2.88*
Mood swings	-2.31	1.96	1.25
Rags to riches	2.13	-1.95	-1.08
Riches to rags	-2.05	4.88*	-0.56
Bump in the road	1.69	-1.12	-1.08
End on a high note	-5.16*	-6.03*	8.32*
Twin peaks	3.83*	2.25	-4.99*

4 Discussion

In this paper, we examined the continuous sentiment structures of a new corpus of YouTube vlog transcripts using intra-textual sentiment analysis. We were able to identify seven distinct continuous sentiment styles. The “rags to riches”, “riches to rags” and the “end-on-a-high-note” styles displayed an alternating pattern with one shift between predominantly positive and negative content. By contrast, the “bump in the road” and “twin peaks” styles show a marked negative middle part of the vlog and an overall positive sentiment with a slightly negative beginning and end, respectively. The most volatile styles were the “downhill from here” and the “mood swings” styles with both showing three shifts in sentiment.

While no continuous sentiment style was related to higher view counts, we observed that the “end-on-a-high-note” style was the most common in our corpus. The pattern of this particular style suggests that vloggers build up their content towards a positive ending following the idea to ‘end strong’, possibly to engage their viewers to keep watching subsequent videos. A similar trajectory was found for TED speeches (Tanveer et al., 2018), suggesting that YouTube vloggers may employ strategies similar to those of prolific public speakers. However, since the “downhill from here” style is second most frequent in our dataset, these findings do not indicate any tendency to a general sentiment development over time. In fact, the “downhill from here” and “end on a high note” styles exhibit a somewhat opposing behavior since the first gradually decreases the sentiment over time whereas the second aims at developing a positive sentiment towards the end of the video. When projecting this observation to the gender-specific findings, one can see that the differences between family, female and male vloggers might account for these contradictory findings. Both family and female vloggers (representing 45.83% of all vloggers) used the “downhill from here” more often than male vloggers, whereas male vloggers used the “end on a high note” style most often.

Gender differences might help further understand vlog style choice: family vloggers used the "twin peaks" style more often than female or male vloggers, with the latter significantly under-using that style. Female vloggers resorted to the "riches to rags" style most often, while male vloggers preferred the "end-on-a-high-note" style.

Vlogs made by females started with a definite positive buildup followed by a marked dip towards clear negative sentiment and a gradual increase towards the positive near the end of the vlog. Family vloggers were the only ones who preferred a style that ended with a sentiment leading toward the negative.

Contrary to the findings of Tanveer et al. (2018), we did not find support for the notion that diverse styles characterized by higher sentiment volatility are more popular: both YouTuber's themselves, as well as the audience, did not show a preference for the most volatile narrative styles. The intra-textual analysis approach helped us to uncover dynamics in the sentiment of vlogs that would otherwise have been blurred by an overall sentiment score. In many cases (e.g., for the "rags to riches" and "riches to rags" styles) the sentiment dynamics would have canceled each other out to a neutral sentiment.

4.1 Limitations

Despite the interesting initial findings using the new corpus of vlog transcripts and the linguistic-temporal analysis, the current study is not without its limitations. First, we partially relied on automated transcription of the vlogs, so the retrieved transcripts consisted of texts generated with YouTube's speech recognition software. Although recent advancements in machine learning research provide promising improvements to speech recognition (LeCun et al., 2015; Zhang et al., 2017b; Zhang et al., 2017a) and contributed to an accuracy increase of fifty percent for YouTube's automatic captions in English (Official YouTube Blog, 2017), the automatic generation of YouTube video captions remains a challenging task (Liao et al., 2013). It could be that potential inaccuracies might have affected our findings and future studies could set out to replicate our results using user-provided high-quality vlog transcripts.

Second, the sample consisted of YouTubers that already are successful concerning subscriber count, and we might, therefore, have painted a skewed picture of the vlogging landscape. For future studies, it would be interesting to look at potential moderating variables such as the vloggers 'vlogging age' or the vlog's topic. Possibly, the use of sentiment (and other linguistic dimensions) might differ between starting YouTubers and those who are more prolific and regularly attract millions of views.

Third, by using vlog transcripts, we resorted solely to the linguistic modality of vlogs and did not look at the use of visual aspects in the vlogs. Using a similar dynamic method, future studies could look at how the use of visual content behaves and interacts with language use over the narrative time.

4.2 Future work

Using the corpus, method, and findings presented here as a starting point, we hope that future research can extend this exploratory work.

- For example, it would be interesting to perform unsupervised clustering analyses on the vlog level to find "vlog-twins" or even "vlogger-twins". Using observations that are similar in a multidimensional feature space could be exploited for semi-experimental studies where the effects of individual variables (e.g., a change in vlogging style) can be isolated towards drawing conclusions of causal nature.

- Moreover, the sentiment is only one dimension of the linguistic aspects of vlogs, and the current analysis might be extended to different constructs. For example, a significant challenge lies in detecting extremist content on social media platforms like YouTube (Burgess, 2017) and the dynamic approach might help uncover extremist parts in videos and enable a more fine-grained inspection of vlogs.

- The temporal aspect of narrative time could be broadened so that the evolution of the narrative style across videos of individual vloggers can be captured. This would be a useful method to identify changes in vlogging strategy.

- Finally, the intra-textual method might help in detecting online misinformation or deception within texts. A major challenge, for example, for linguistic deception detection lies in identifying lies embedded within a mostly truthful statement (Bachenko et al., 2008). Similarly, it would be interesting to examine whether a dynamic linguistic-temporal approach as used here can aid in the detection of misinformation online (e.g., Pérez-Rosas et al., 2018). The method used here and in a few related studies (Jockers, 2015a; Gao et al., 2016) could, therefore, also be of interest to researchers across disciplines.

5 Conclusion

Vlogging is a unique and novel means of communication. We explored the transcripts of vlogs as a source for linguistic analysis, and, by looking at intra-textual sentiment dynamics of each vlog, we identified seven distinct continuous sentiment styles. Vlogs ending on a positive note were the most prevalent, and we observed that gender was associated with different vlogging style preferences. The current paper presented an initial glimpse at the rich data source of vlogs, and a dynamic sentiment analysis approach helped uncover continuous sentiment structures. As such we hope the corpus, method, and findings presented here function as an impetus towards more analyses on this emerging means of online communication.

Abstract

We address the task of native language identification in the context of social media content, where authors are highly-fluent, advanced nonnative speakers (of English). Using both linguistically-motivated features and the characteristics of the social media outlet, we obtain high accuracy on this challenging task. We provide a detailed analysis of the features that sheds light on differences between native and nonnative speakers, and among nonnative speakers with different backgrounds.

1 Introduction

The task of *native language identification* (NLI) aims at determining the native language (L1) of an author given only text in a foreign language (L2). NLI has gained much popularity recently, usually with an eye to educational applications (Tetreault et al., 2013): the errors that learners make when they write English depend on their native language (Swan and Smith, 2001), and understanding the different types of errors is a prerequisite for correcting them (Leacock et al., 2010). Consequently, tutoring applications can use NLI to offer better targeted advice to language learners.

However, the NLI task is not limited to the language of learners; it is relevant also, perhaps even more so, in the (much more challenging) context of highly-fluent, advanced nonnative speakers. While the English language dominates the internet, native English speakers are far outnumbered by speakers of English as a foreign language. Consequently, a vast amount of static and dynamic web content is continuously generated by nonnative writers. Developing methods for identifying the native language of nonnative English authors on social media outlets is therefore an important and pertinent goal.

We address the task of native language identification in the context of user generated content (UGC) in online communities. Specifically, we use a large corpus of English *Reddit* posts in which the L1 of authors had been accurately annotated (Rabinovich et al., 2018). On this dataset, we define three closely-related tasks: (i) distinguishing between native and nonnative authors; (ii) determining to which language family the native language of nonnative authors belongs; (iii) identifying the native language of nonnative authors. Importantly, we employ features that take advantage of both linguistic traits present in the texts and the characteristics of the social media outlet. We obtain excellent results: up to 92% accuracy for distinguishing between natives and nonnatives, and up to 69% for the 23-way NLI classification task.[1]

The contribution of this paper is manifold. First, this is one of the first works to address NLI with highly-advanced nonnatives; it is also among the first to address the task in the context of UGC. Furthermore, we define a plethora of features, some which have been used in earlier works but others that are novel. In particular, we define a set of features that rely on the characteristics of the social media outlet, thereby extending the task somewhat, from linguistic analysis to user profiling. Finally, we provide a detailed analysis of the results, including the specific contribution of various features and feature sets. This analysis will be instrumental for future extensions of our work.

2 Related work

The NLI task was introduced by Koppel et al. (2005), who worked on the International Corpus of Learner English (Granger, 2003), which includes texts written by students from Russia, the

[1] It is important to note that some of our features are specific to the Reddit corpus and will not easily generalize to other datasets.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3591–3601
Brussels, Belgium, October 31 - November 4, 2018.

Czech Republic, Bulgaria, France, and Spain. The same experimental setup was adopted by several other authors (Tsur and Rappoport, 2007; Wong and Dras, 2009, 2011). The task gained popularity with the release of nonnative *TOEFL* essays by the Educational Testing Service (Blanchard et al., 2013); this dataset has been used for the first NLI Shared Task (Tetreault et al., 2013) and also for the 2017 NLI Shared Task (Malmasi et al., 2017).

Our task is closely related to the task of *dialect identification*, in which the goal is to discriminate among similar languages, language varieties and dialects. Classic machine learning classification methods are usually applied for this task, often with SVM models. The best reported features include word and character n-grams, part of speech n-grams and function words (Zampieri et al., 2017; Malmasi and Zampieri, 2017).

The current state of the art in NLI, according to Malmasi and Dras (2017), utilizes some variant of contemporary machine learning classifier with the following types of features: (i) word, lemma and character n-grams, (ii) function words (FW), (iii) part-of-speech (POS) n-grams, (iv) adaptor grammar collocations, (v) Stanford dependencies, (vi) CFG rules, and (vii) Tree Substitution Grammar fragments. The best result under cross-validation on the TOEFL dataset, which includes 11 native languages (with a rather diverse distribution of language families), was 85.2% accuracy. Applying these methods to different datasets (the ASK corpus of learners of Norwegian (Tenfjord et al., 2006) and the Jinan Chinese Learner Corpus (Wang et al., 2015), 10-11 native languages in each) resulted in 76.5% accuracy for the Chinese data and 81.8% for the Norwegian data, with LDA-based classification yielding top results.

Notably, all these works identify the native language of *learners*. Identifying the native language of advanced, fluent speakers is a much harder task. Furthermore, our dataset includes texts by native speakers of 23 languages, more than double the number of languages used in previous works; and our L1s are all European, and often typologically close, which makes the task much harder.

Two recent works address the task of NLI on UGC in social media. Anand et al. (2017) summarized the shared task on Indian NLI: given a corpus of Facebook English comments, the task was to identify which of six Indian languages is the L1 of the author. The best reported result was 48.8%, obtained by an SVM with character and word n-grams as features. These are content based features that are highly domain-dependent and are not likely to generalize across domains. Volkova et al. (2018) explored the contribution of various (lexical, syntactic, and stylistic) signals for predicting the foreign language of non-English speakers based on their English posts on Twitter. This effectively results in a 12-way classification task, with 12 different L1s (data sizes are distributed very unevenly), and the best results are unsurprisingly obtained with word unigrams and bigrams.

In contrast to these two studies, we work with many more L1s (23); we explore various types of features, including features based on social network structures and content-independent features; and we evaluate our classifiers both in and outside of the domain of training.

Several works address social aspects of social networks, and in particular identify "influential" users (Ghosh and Lerman, 2010; Trusov et al., 2010; Afrasiabi Rad and Benyoucef, 2011). Network structure has been shown to be useful in other tasks of user profiling, such as geolocation (Jurgens et al., 2015). Our design of the social network features (Section 3.5.4) are motivated by these works.

Works that aim to distinguish between native and nonnative authors (Bergsma et al., 2012; Rabinovich et al., 2016; Tomokiyo and Jones, 2001) typically rely on lexical and grammatical characteristics that reflect influences of L1 on L2. We used such features, but augmented them by features that can be induced from the network structure of social media outlets (Jurgens et al., 2015). To the best of our knowledge, ours is the first work that extensively exploits social network properties for the task of NLI. Our work is also inspired by research on the (related but different) task of identifying translations (Baroni and Bernardini, 2006; Rabinovich and Wintner, 2015; Volansky et al., 2015) and their source language (Koppel and Ordan, 2011; Rabinovich et al., 2017).

3 Experimental setup

3.1 Dataset

Reddit is an online community consisting of thousands of forums for news aggregation, content rating, and discussions. Content entries are organized by areas of interest called *subreddits*, ranging from main forums that receive much attention to smaller ones that foster discussion on niche areas. Subreddit topics include news, science, arts, and many others. An increasing body of work has used Reddit data for social media analysis (Jurgens et al., 2015; Newell et al., 2016, and many more).

We used the Reddit dataset released by Rabinovich et al. (2018). It includes Reddit posts (both initial submissions and subsequent comments), focusing on subreddits (Europe, AskEurope, EuropeanCulture) whose content is generated by users specifying their country as a *flair* (metadata attribute). We refer to these subreddits as *European*. Following Rabinovich et al. (2018), we view the country information as an accurate, albeit not perfect, proxy for the native language of the author.

Rabinovich et al. (2018) justified their trust in the accuracy of the L1 annotation; we conducted an additional validation of the data.[2] We used a specific Reddit thread in which users were asked to comment in their native language. We collected the comments in this thread of all the users in our dataset. Then, we used the Polyglot language identification tool to determine the language of the comments. We filtered out short comments, comments for which the tool's confidence was low, and comments in English of users from non-English speaking countries. Of the remaining 572 users, 479 (84%) contributed comments in the language that we considered their native. We inspected the remaining users, and for many (albeit not all) we attribute the mismatch to errors in the tool (i.e., comments in Serbian written in the Latin alphabet are wrongly predicted to be in closely-related Slavic languages). We conclude that the accuracy of the L1 annotation is high; finally, we note additionally that any noise in this labeling can only work against us in this work.

We filtered out data from multilingual countries (Belgium, Canada, and Switzerland). Rabinovich et al. (2018) showed that the English of reddit non-native authors is highly advanced, almost at the level of native speakers, making the NLI task particularly demanding.

All the posts in the dataset are associated with a unique user ID. The dataset also contains submissions and comments in other subreddits that were written by the same authors, based on their user ID. This provided us with an out-of-domain test set for evaluating the robustness of our methods. The collected data reflect about 50 (mostly European) countries, and consist of over 230M sentences, or 3.5B tokens, annotated with authors' L1.

3.2 Preprocessing

Each sentence in the dataset is tagged with the author's user ID, the subreddit it appeared in and the author's country. We segmented the dataset into *chunks* of 100 sentences, each chunk containing sentences authored by the same user.[3] The sentences were kept in their original order in the posts; users with fewer than 100 sentences were filtered out. We also left out native languages with fewer than 100 users (after the initial filtering). The resulting dataset includes 23 native languages spanning 29 countries, and consists of 34,511 unique users, almost 200M sentences and over 3B tokens. The countries and languages reflected in the dataset are listed in Table 10 (see Supplementary Materials).

All chunks were annotated for part-of-speech using Spacy. We used Aspell to spell-check the texts; every misspelled word in the original chunk was annotated with the first correction suggested by the spell checker. We also extracted from reddit additional social network properties such as users' *karma* scores, number of comments and submissions, number of comments per submission, as well as the number of months each user was active on Reddit and all the subreddits that each user in our dataset posted in (see Section 3.5.4). The processed dataset will be made publicly available.

3.3 Task

We define three classification tasks: **binary classification,** distinguishing between native and non-native authors; **language family classification** determining the language family (Germanic, BaltoSlavic, Romance, or native English) of the user; and **language identification** whose goal is to identify the native language of the user.

Different countries which have the same official language (e.g., Germany and Austria) were tagged with the same language label. For example, USA, UK, Ireland, New Zealand and Australia were all tagged with the label 'English' for the NLI task.

We then randomly downsampled the data to ensure that each class had the same number of users.

---

[2] We thank an anonymous reviewer for suggesting this.

[3] Similar classification tasks, e.g., the TOEFL task (Tetreault et al., 2013; Malmasi et al., 2017), used single essays as the unit for classification. Tasks aiming to identify translation and its source language typically use chunks of 2000 tokens (Volansky et al., 2015). We plan to experiment also with smaller chunks.

See the precise details in Section A.1 of the Supplementary Materials.

3.4 Methodology

We cast NLI as a supervised classification task and used *logistic regression* (as implemented in Scikit-learn) as a classification model. We defined several features that had been proven useful for similar tasks; some of them are general stylistic features that are presumably content-independent: these include function words, POS n-grams, simplification measures such as sentence length, etc. (Rabinovich and Wintner, 2015; Volansky et al., 2015). Other features are content based; most obviously, token n-grams, but also character n-grams (Avner et al., 2016). We expect content-based features to be highly accurate but also highly domain-dependent, and in the case of our dataset, topic-dependent. Content-independent features are expected to be weaker yet more robust.

In addition, we used features that reflect spelling and grammar errors. We assume that native and nonnative speakers make different kinds of errors in English, and that the errors of nonnatives may reveal traces of their L1 (Kochmar, 2011; Berzak et al., 2015).

Aiming to enhance the quality of classification we exploited properties that can be induced from conversational networks. We hypothesize that native speakers of the same language tend to interact more with each other (than with speakers of other languages). We hypothesize further that native speakers post more than nonnatives, and hence we defined user *centrality* measures that reflect that. We also hypothesize that native speakers' posts tend to be more spontaneous, coherent and clear, thereby drawing more attention. To reflect that, we counted the number of comments, up-votes and down-votes that were submitted to each post. While these and similar properties have been studied in the domain of social networking, to the best of our knowledge this is the first attempt to use an extensive set of features inferred from social networks for the NLI task.

3.5 Features

We designed several features to be used in all three tasks. In this section we describe these features.

3.5.1 Content features

Authors are more likely to write about topics that are related to their country and their culture, hence features that reflect content may help distinguish among authors from different countries (and, therefore, languages). For example, the word *'Paris'* is more likely to occur in texts written by French authors, while the word *'canal'* is more likely to occur in texts of Dutch authors. We defined features that take text content into account. We expect these features to yield high accuracy when testing on the training domain, but much lower accuracy when testing on different domains.

Character tri-grams The top 1000 most frequent character 3-grams in the dataset were used as features. For each chunk the value of a certain character 3-gram feature was the number of its occurrences in the chunk normalized by the total number of character 3-grams in the chunk.

Token uni-grams The top 1000 most frequent tokens in the dataset were used as features. For each chunk the value of a certain token feature was the number of its occurrences in the chunk normalized by the total number of tokens in the chunk.

3.5.2 Spelling and grammar

We used a spell checker (Section 3.1) to discover the (first) closest correction for each word marked as incorrect. Based on this correction, we defined several edit-distance-based features using Python's Python-Levenshtein extension.

Edit distance Assuming that nonnative speakers will make more spelling errors than natives, we used the average Levenshtein distance between the original word and the correction offered by the spell checker, for all words in a chunk, as a feature.

Spelling errors Again, we assume that the spelling errors that nonnatives make may reflect properties of their L1; this has already been shown for learners (Tsvetkov et al., 2013). Using the edit distance between a mis-spelled word w in a text chunk, marked by the spell checker, and its suggested correction c, we extract insertions, deletions and substitutions that yield c from w and use them as features. For each chunk, the value of this feature is the number of occurrences of each substitution (a character pair), insertions, and deletions in the chunk. We only used the top-400 most frequent substitutions.

We initially classified spelling errors as content-independent features, assuming that they would reflect transfer of linguistic phenomena from L1. However, having analyzed this feature type, we observed that many of the mis-spelled words turned out to be non-English words, which apparently are abundant in our dataset even after removing non-English sentences. We therefore view this feature as content dependent.

Grammar errors We hypothesize that grammar errors made by nonnatives may reflect grammatical structures revealing their L1. We therefore used LanguageTool, a rule-based grammar checker, to identify grammatical errors in the text.[4] We defined an indicator binary feature for each of the (over 2000) grammar rules detected by the grammar checker.[5]

3.5.3 Content-independent features

Content-based features may overly depend on the domain of the training data, and consequently be less effective when testing on different domains. Content-independent features are expected to be more robust when they are used out-of-domain.

Function words Function words are highly frequent and as such they are assumed to be selected unconsciously; they are therefore considered to reflect style, rather than content. Function words have been used successfully in a variety of style-based classification tasks (Mosteller and Wallace, 1963; Koppel and Ordan, 2011; Volansky et al., 2015; Rabinovich et al., 2016). We used as features (the frequencies of) about 400 function words, taken from Volansky et al. (2015).

POS tri-grams POS n-grams are assumed to reflect (shallow) grammar. The native language of the author is likely to influence the structure of his or her productions in English, and we assume that this will be reflected in this feature set. We used as features the normalized frequency of the top 300 most frequent POS tri-grams in the data set.[6]

Sentence length Texts of nonnative speakers are assumed to be simpler than those of natives; in particular, we expect them to have shorter sentences. The value of this feature is the average length of the sentences in the chunk.

3.5.4 Social network features

We defined several features that are extracted from the social network data, particularly its structure. First, we defined feature sets that express the *centrality* of users, under the assumption that native speakers would be more central on social networks. Consequently, this set of features is expected to be beneficial mainly for the binary native/nonnative classification.

User centrality in the social network of Reddit can be reflected in various ways:

Karma Reddit assigns a *karma* score to each user. This score "reflects how much good the user has done for the reddit community. The best way to gain karma is to submit links that other people like and vote for".[7] The Karma score is an undisclosed function of two separate scores: *link karma*, which is calculated from the user's posts that contain links, and *comment karma*, which is computed from the user's comments. We extracted both types of karma scores for all users in the dataset and used each of them (specifically, the user's monthly average scores) as a feature.

Average score Reddit calculates a *score* for each submission as the number of up-votes minus the number of down-votes the submission received. We used the user's average score per month as a feature.

Average number of submissions We counted for each user the total number of submissions he or she authored. For each chunk the value of this feature is the user's average number of submissions per month.

Average number of comments Same as the above, but counting user's comments (responses to submissions) instead of submissions.

Most popular subreddits Finally, we assume that native speakers of the same language tend to interact more with each other than with others, and we also assume that they are more likely to be interested in similar topics, influenced by their country and culture; specifically, we hypothesize that the forums in which users post most will be common for users from the same country. Therefore, we extracted for each country in the dataset the most popular subreddits among users from this country. For each country, we sorted subreddits according to the number of users from this country who posted at least once in this subreddit. The 30 most popular subreddits of each country

---

[4] We used the Python wrapper for LanguageTool.

[5] The list of English grammar rules is available online.

[6] We also experimented with POS 5-grams but they did not yield better results.

[7] The Reddit Wiki.

were taken as features. The unique list of popular subreddits contains 141 subreddits. For each chunk the value of a certain subreddit feature was a binary value indicating whether or not the author of this chunk has posted in this subreddit.

3.6 Evaluation

It is well known that similar classification tasks are highly domain-dependent; simply put, the properties of the domain overshadow the much more subtle signal of the author's L1. To test the robustness of various feature sets in the face of domain noise, we defined two evaluation scenarios: *in-domain*, where training and testing is done only on chunks from the European subreddits; and *out-of-domain*, where we train on chunks from the European subreddits and test on chunks from other subreddits, making sure they were authored by different users. Note that the out-of-domain corpus spans tens of thousands of subreddits with a huge number of topics. The precise evaluation scenario is somewhat involved and is detailed in Section A.2 of the Supplementary Materials. We report *accuracy*, defined as the percentage of chunks that were classified correctly out of the total number of chunks.

4 Results

We implemented the features discussed in Section 3.5 and evaluated the accuracy of the three classification tasks mentioned in Section 3.4 under the configurations described in Section 3.6. The trivial baseline for the binary classification task is 50%, for language family classification 25%, and for the language identification task 4.35%.

4.1 Individual feature sets

The accuracy results for each feature set described in Section 3.5 for the in-domain evaluation scenario are presented in Table 1.

Feature Set	Binary	Families	NLI
Char. 3-grams	85.58	78.20	62.06
Token unigrams	86.26	69.36	31.26
Spelling	71.04	52.18	27.74
Grammar errors	66.79	37.96	8.36
FW	80.34	57.80	20.15
POS 3-grams	69.14	50.29	13.30
Sentence length	50.37	26.14	4.79
Social network	57.92	32.39	5.75
Subreddits	87.08	82.56	74.46

Table 1: In-domain accuracy, individual feature sets

Evidently, all feature sets outperform the baseline, although some are far better than others. The feature that yields the best accuracy is *Subreddits*, with 87% accuracy on the binary task, 82% on the language family task and 74% on the NLI task. We elaborate on this feature in Section 4.2 below. As expected, the content based features yield relatively high results when the evaluation is in-domain. POS 3-grams and function words yield reasonable results, but not as good as in other classification setups (e.g., Rabinovich et al. (2016)), where the evaluation was done by shuffling texts of various users. As we evaluate on chunks of single users, the personal style of the user may dominate the subtler signal of his or her native language. Sentence length performs poorly, even on the binary task. Our assumption was that the *social network* feature set will work well only for the binary classification; this seems to be borne out by the results.

4.2 Feature combination

We now set out to investigate different feature combinations in both evaluation scenarios, aiming to define feature types that yield the best in-domain accuracy, as well as those that are most robust and generalize well out-of-domain.

Table 2 depicts the results obtained by combining character trigrams, tokens, and spelling features (Sections 3.5.1, 3.5.2). As expected, these content features yield excellent results in-domain, but the accuracy deteriorates out-of-domain, especially in the most challenging task of NLI.

	Binary	Families	NLI
In-domain	91.07	83.51	70.26
Out-of-domain	81.49	65.37	35.99

Table 2: Results: content features

The content-independent features (Section 3.5.3), whose contribution is depicted in Table 3, indeed fare worse, but are seemingly more robust outside the domain of training.

	Binary	Families	NLI
In-domain	81.89	62.40	22.38
Out-of-domain	74.56	52.35	14.86

Table 3: Results: content-independent features

Table 4 shows the results obtained by combining the spelling features with the grammar features

(Section 3.5.2). Clearly, these two feature types reflect somewhat different phenomena, as the results are better than using any of the two alone.

	Binary	Families	NLI
In-domain	72.93	55.59	26.74
Out-of-domain	70.24	47.23	14.15

Table 4: Results: grammar and spelling features

Table 5 shows the accuracy obtained by all the centrality features (Section 3.5.4), excluding the most popular subreddits. As expected, the contribution of these features is small, and is most evident on the binary task. The signal of the native language reflected by these features is very subtle, but is nonetheless present, as the results are consistently higher than the baseline.

	Binary	Families	NLI
In-domain	57.92	32.39	5.75
Out-of-domain	56.29	30.70	5.60

Table 5: Results: centrality features

Finally, the contribution of the most popular subreddits feature is shown in Table 6. The results for this single feature type are superb, both in- and out-of-domain. However, as this feature is unique to the dataset used for the present work, it is hard to see it generalized to similar tasks that use other datasets, even in the context of UGC.

	Binary	Families	NLI
In-domain	87.08	82.56	74.46
Out-of-domain	85.49	82.17	73.63

Table 6: Results: most popular subreddits

Therefore, we report the results obtained with *all* features, with (Table 7) and without (Table 8) the reddit-specific most popular subreddit feature.

	Binary	Families	NLI
In-domain	93.40	90.41	86.05
Out-of-domain	87.19	83.43	78.99

Table 7: Results: all features

	Binary	Families	NLI
In-domain	92.21	82.51	68.97
Out-of-domain	79.34	66.21	36.16

Table 8: Results: all features except subreddits

Summing up, we have shown that the challenging task of native language identification in the context of user generated content, where English texts are authored by highly competent nonnative speakers with as many as 23 native languages, can be accomplished with very high accuracy, as high as 86% when evaluated in-domain, and almost 79% out-of-domain (Table 7). While these results deteriorate when the specific characteristics of our dataset are not taken advantage of, we still obtain very high accuracy on the binary task of distinguishing native from nonnative speakers, and on the four-way task of identifying the language family of the authors' L1 (Table 8).

4.3 Dialect robustness

To assess the robustness of our results, especially in the context of dialect identification, we repeated the experiments in a special scenario: we trained classifiers on all the data, but removed from the English training set users from Ireland. Then, we tested the classifiers only on users from Ireland. We used all the features listed above, except the subreddit feature.

The results are 59.09% accuracy in-domain, compared with 69.21% in the standard scenario, where users from Ireland are also used for training; and 37.51% out-of-domain, compared with 47.85% in the standard scenario. In both cases, accuracy drops by 10 percent points. We conclude that our method is reasonably robust to dialectal variation, at least in the case of English varieties.

5 Analysis

We now set out to analyze some of the more interesting features, both in terms of their contribution to the accuracy of the classification and in terms of what they reveal about the English of advanced nonnative speakers.

5.1 Social network features

Subreddits This feature set works so well because many of the most popular subreddits in which users post are culturally revealing. Specifically, there is a significant presence in this list to (subreddits focusing on) specific countries. Very likely, most of the active users in those subreddits reside in these countries, thereby revealing their native language. This corroborates our hypothesis that native users of the same language tend to be active in mutual subreddits.

Network structure Table 9 lists the average values of the centrality features, comparing native vs. nonnative authors. The average values are higher for native users than for the nonnative ones in all of the centrality features, as we hypothesized. Evidently, native speakers are more central in social networks than nonnative ones.

	Native		nonnative	
	Avg	std	Avg	std
Score	1349	2383	906	1886
# comments	147	173	92	112
# submissions	5	21	4	13
Comment karma	787	1260	529	837
Link karma	202	1012	141	580

Table 9: Centrality features: average values and standard deviation

5.2 Spelling

Edit Distance As expected, the average word edit distance of native users (0.048) was significantly lower compared to nonnative ones (0.071).

Substitutions Most revealing was the analysis of substitutions suggested by the spell checker, as they shed light on phonetic and orthographic influences of the authors' L1 on their English. We list below some of the most common spelling errors.

Vowels Replacing *'e'* with *'a'* was twice as common among nonnative users than native ones. Examples include *'existance'*, *'independance'*, *'privillages'*, and *'apparantly'*. Similarly, replacing *'y'* with *'i'* was three times more common for nonnatives: *'synonims'*, *'analized'*, etc. Replacing *'o'* with *'a'* was common among nonnatives, especially in the context of diphthongs: *'enaugh'* instead of *'enough'*, or *'cauntry'* for *'country'*.

Voicing Replacing *'f'* with *'v'* was common mostly among German speakers: *'devense'*, *'bevore'*, *'sacrivice'*, etc. Another error that was relatively common in texts written by German speakers is the replacement of *'d'* with *'t'*: *'unterstand'*, *'canditate'*, *'upgradet'*, *'hundret'*, etc. Confusing *'z'* with *'s'* was very common across all L1s, even for natives. Among native users this reflects spelling variations between US and UK English. Thus, the spell-checker marks the following forms, i.a., in New Zealand English: *'Organisation'*, *'Recognise'*, *'Realise'*, *'Criticise'*, etc. Replacing *'s'* with *'z'* was not as common in the dataset, and was present mostly in texts of French users: *'advertize'*, *'tablez'*, and, most frequently, *'surprize'*.

Other substitutions Replacing *'c'* with *'k'* was almost four times more common with nonnatives; it was significantly more common among Germanic and Balto-Slavic speakers, and much less common among Romance speakers. Examples include *'inspektor'*, *'klassik'*, etc. Replacing *'t'* with *'c'* was common in words in which the *'t'* is pronounced [ʃ]: *'negociate'*, *'nacional'*. This error was prevalent in texts of Spanish authors.

Insertions and deletions Insertion of *'o'* was common for all nonnative speakers, often when the word contains one *'o'* but the pronunciation is [u], e.g., *'proove'* instead of 'prove'. Spurious occurrences of *'e'* were also very common among all nonnative users, especially authors whose L1 was French: *'governement'*, *'unemployement'*, *'explicitely'*. Deletions of *'e'* were also very common, especially in the context of words that end with *'ely'*: *'definitly'*, *'completly'*, *'extremly'*, *'absolutly'*, etc. Spurious instances of *'u'* were mostly present in texts of authors with Germanic and Romance L1s, e.g.: *'languague'*, *'percentuage'*.

Wrong insertions of *'l'* were very common, especially at the end of words that end with *'l'*: *'untill'*, *'controll'*, *'usefull'*. Deletion of *'l'* was common for all nonnative users, especially with Balto-Slavic L1s. The most common context for this error is words ending with *'ally'*: *'literaly'*, *'actualy'*, *'basicaly'*, *'illegaly'*, *'totaly'*, *'personaly'*, etc.

The most common deletion among nonnatives was omission of the first *'r'* in *'surprise'*, followed by omitting the first *'n'* in *'government'*.

5.3 Grammar

We list below some of the grammar rules whose violations distinguish well between native and nonnative speakers, using the original grammar checker rule names. Unsurprisingly, several grammar rules were violated much more (twice as frequently) by nonnative users:

adverb_word_order wrong position of adverb, e.g., *'people sometimes will respond'* instead of *'people will sometimes respond'*.

cd_nn agreement error of a numeral followed by a singular count noun, e.g., *'I have 5 book'*.

this_nns using *'this'* instead of *'these'* or vice versa, e.g., *'you don't know what these symbol* *represent'*.

did_baseform using a tensed verb after *'did'* or *'didn't'*: *'the court didn't gave him a fair trial'*.

a_uncountable an indefinite article before noncount nouns: *'smaller places have an access to...'*.

fewer_less confusing *'fewer'* with *'less'*: *'with less possibilities'*.

much_countable using *'much'* instead of *'many'*: *'no matter how much people'*. This error was much more common among nonnative users, although, among native speakers, it was significantly more common in texts written by users from New-Zealand and Ireland than in texts of other English speaking users.

en_a_vs_an confusing *'a'* with *'an'*: *'it provides a organized way to discuss'*. This error was very common among speakers of Germanic and Romance languages, but less common among speakers of Balto-slavic languages (presumably due to the lack of articles in their L1s).

In contrast, some grammar rules were violated more by native speakers:

possessive_apostrophe omitting the apostrophe in possessive *''s'*: *'they had 20% of the worlds remittance'*. This error was more than twice as common in texts of natives.

try_and the verb *'try'* followed by *'and'*; this is common in colloquial speech, but is prescriptively wrong: *'a candidate should try and represent'*. This rule was violated over three times more frequently by native speakers (but rarely in texts of New-Zealand users).

their_is *'there'* and *'their'* are commonly confused; this rule spots such cases by the presence of *'be'*: *'their are a lot of'*.

about_its_nn confusing *'its'* and *'it's'* is common; this rule identifies wrong usage after a preposition: *'lash out regularly towards it's neighbors'*. This error was most common in texts of English speakers from Australia, Ireland and the UK, but not the US.

Summing up, it seems that nonnative speakers make more grammatical errors, while the mistakes of native speakers either stem from sloppy writing style and lack of attention, or reflect style variations and casual style rather than actual errors.

6 Conclusion

We described a system that can accurately identify the native language of highly-advanced, fluent nonnative authors as reflected in the social media Reddit corpus. This is among the first studies to perform NLI in the highly challenging scenario of user generated content, particularly at such a large scale. We showed that while content-dependent features yield more accurate results, features that abstract away from content tend to be more robust when tested out of the domain of training. The in-depth analysis of spelling and grammar errors demonstrates that mistakes made by nonnative speakers reflect traces of their native language. We also illuminated some of the social characteristics of native and nonnative authors on social media outlets.

Our future plans include adaptation of the trained models to additional corpora, e.g., user generated content collected from *Facebook* and *Twitter*. Furthermore, we plan to devise *unsupervised* approaches to the identification of native language with the same dataset. We would also like to test the classifiers defined here in the more challenging scenario of smaller text chunks (e.g., 10–20 sentences rather than the 100-sentence text chunks we used here). Finally, we are currently experimenting with adversarial learning models for this task.

Abstract

Neural machine translation usually adopts autoregressive models and suffers from exposure bias as well as the consequent error propagation problem. Many previous works have discussed the relationship between error propagation and the *accuracy drop* (i.e., the left part of the translated sentence is often better than its right part in left-to-right decoding models) problem. In this paper, we conduct a series of analyses to deeply understand this problem and get several interesting findings. (1) The role of error propagation on accuracy drop is overstated in the literature, although it indeed contributes to the accuracy drop problem. (2) Characteristics of a language play a more important role in causing the accuracy drop: the left part of the translation result in a right-branching language (e.g., English) is more likely to be more accurate than its right part, while the right part is more accurate for a left-branching language (e.g., Japanese). Our discoveries are confirmed on different model structures including Transformer and RNN, and in other sequence generation tasks such as text summarization.

1 Introduction

Neural machine translation (NMT) has attracted much research attention in recent years (Bahdanau et al., 2014; Shen et al., 2018; Song et al., 2018; Xia et al., 2018; He et al., 2016; Wu et al., 2017, 2018). The major approach to the task typically leverages an encoder-decoder framework (Cho et al., 2014; Sutskever et al., 2014) and the decoder usually generates the target tokens one by one from left to right autoregressively, in which the generation of a target token is conditioned on previously generated target tokens.

It has been observed that for an NMT model with left-to-right decoding, the right part words in its translation results are usually worse than the left part words in terms of accuracy (Zhang et al., 2018; Bengio et al., 2015; Ranzato et al., 2015; Hassan et al., 2018; Liu et al., 2016b,a). This phenomenon is referred to as *accuracy drop* in this paper. A straightforward explanation to accuracy drop is *error propagation*: If a word is mistakenly predicted during inference, the error will be propagated and the future words conditioned on this one will be impacted. Different methods have been proposed to address the problem of accuracy drop (Liu et al., 2016a,b; Hassan et al., 2018).

Instead of solving the problem, in this paper, we aim to deeply understand the causes of the problem. In particular, we want to answer the following two questions:

- Is error propagation the main cause of accuracy drop?
- Are there any other causes leading to accuracy drop?

To answer these two questions, we conduct a series of experiments to analyze the problem.

First, we train NMT models separately using left-to-right and right-to-left decoding (Sennrich et al., 2016; Liu et al., 2016b; He et al., 2017; Gao et al., 2018) on several language pairs (i.e., German to English, English to German, and English to Chinese). If error propagation is the main cause of accuracy drop, then the right part words in the translation results generated by right-to-left NMT models should be more accurate than the left part words. However, we observe the opposite phenomenon that the accuracy of the right part words of the translated sentences in both left-to-right and right-to-left models is lower than that of the left part, which contradicts with error propagation. This shows that error propagation alone cannot well explain the accuracy drop and even

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3602–3611
Brussels, Belgium, October 31 - November 4, 2018.

suggests that error propagation may not exist or matter.

Second, to further investigate the influence of error propagation on accuracy drop, we conduct a set of experiments with teacher forcing (Williams and Zipser, 1989) during inference, in which we feed the ground-truth preceding words to predict the next target word. Teacher forcing eliminates exposure bias as well as error propagation in inference. The results verify the existence of error propagation, since the later part (the right part in left-to-right decoding and the left part in right-to-left decoding) of the translation results get more accuracy improvement with teacher forcing, regardless of the decoding direction. Meanwhile, the accuracy of the right part is still lower than that of the left part with teacher forcing, which demonstrates that there must be some other causes apart from error propagation leading to accuracy drop.

Third, inspired by linguistics, we find that the concept of branching (Berg et al., 2011; Payne, 2006) can help to explain the problem. We conduct the third set of experiments to study the correlation between language branching and accuracy drop. We find that if a target language is right branching such as English, the accuracy of the left part words is usually higher than that of the right part words, no matter for left-to-right or right-to-left NMT models, while for a left-branching target language such as Japanese, the accuracy of the left part words is usually lower than that of the right part, no matter for which models. The intuitive explanation is that a right-branching language has a clearer structure pattern (easier to predict) in the left part of sentence than that in the right part, since the main subject of the sentence is usually put in the left part. We calculate two statistics to verify this assumption: n-gram statistics (including n-gram frequency and conditional probabilities) and dependency parsing statistics. For right-branching languages, we found higher n-gram frequency/conditional probabilities as well as more dependencies in the left part compared with that in the right part. The opposite results are also found in left-branching languages.

We summarize our findings as follows.

- Through empirical analyses, we find that the influence of error propagation is overstated in the literature, which may misguide the future research. Error propagation alone cannot fully explain the accuracy drop in the left or right part of sentence.
- We find the branching in linguistics well correlates with accuracy drop in the left or right part of sentence and the corresponding analysis on n-gram and dependency parsing statistics well explain this phenomenon.

Our studies show that linguistics can be very helpful to understand existing machine learning models and build better models for language related tasks. We hope that our work can bring some insights to the research on neural machine translation. We believe that our findings can help us to design better translation models. For example, the finding on language branching suggests us to use left-to-right NMT models for right-branching languages such as English and right-to-right NMT models for left-branching languages such as Japanese.

2 Related Work

2.1 Exposure Bias and Error Propagation

Exposure bias and error propagation are two different concepts but often mentioned together in literature (Bengio et al., 2015; Shen et al., 2016; Ranzato et al., 2015; Liu et al., 2016b,a; Zhang et al., 2018; Hassan et al., 2018). Exposure bias refers to the fact that the sequence generation model is usually trained with teacher-forcing while generates the sequence autoaggressviely during inference. This discrepancy between training and inference can yield errors that accumulate quickly along the generated sequence, which is known as error propagation (Bengio et al., 2015; Shen et al., 2016; Ranzato et al., 2015).

Bengio et al. (2015) propose the scheduled sampling method to eliminate the exposure bias and the resulting error propagation, which achieves promising performance on sequence generation tasks such as image captioning. Shen et al. (2016); Ranzato et al. (2015) improve the basic maximum likelihood estimation (MLE) with reinforcement learning or minimum risk training and aim to address the limitation of MLE training and exposure bias problem.

2.2 Tackling Accuracy Drop

(Liu et al., 2016b,a; Zhang et al., 2018; Hassan et al., 2018) mainly ascribe accuracy drop (the accuracy of right part words is worse than that in the left part in most cases) to error propagation and propose different methods to solve this problem. Liu et al. (2016b,a); Hassan et al. (2018) use agreement regularization between the left-to-right and right-to-left models to achieve better performance. Zhang et al. (2018) and (Hassan et al., 2018) propose to use two-pass decoding to refine the generated sequence to yield better quality.

All these works focus on error propagation and accuracy drop. To our knowledge, there is no deep study about other causes of accuracy drop. In this paper, we aim to conduct such a study. Our study shows that accuracy drop is not only caused by error propagation, but also the characteristics of language itself.

3 Error Propagation and Accuracy Drop

3.1 Error Propagation is Not the Only Cause

A left-to-right NMT model feeds target tokens one by one from left to right in training and generate target tokens one by one from left to right during inference, while a right-to-left NMT model trains and generates token in the reverse direction. Intuitively, if error propagation is the root cause of accuracy drop, then a right-to-left NMT model will generate translations with better right half accuracy than the left half. In this section, we study the results of both left-to-right and right-to-left NMT models to analyze the relationship between error propagation and accuracy drop.

We conduct experiments on three translation tasks with different language pairs, which include: IWSLT 2014 German-English (De-En), WMT 2014 English-German (En-De) and WMT 2017 English-Chinese (En-Zh). We choose the state-of-the-art NMT model Transformer (Vaswani et al., 2017) as the basic model structure and train two separate models with left-to-right and right-to-left decoding on each language pair. More details about the datasets and model descriptions can be found in supplementary materials (section A.1 and A.2). We evenly split each generated sentence into the left half and the right half with same number of words[1]. Then for both the left and right half, we compute their accuracy with respect to the reference target sentence, in terms of BLEU score (Papineni et al., 2002) [2].

	De-En	En-De	En-Zh
left-to-right	31.42	26.93	20.79
right-to-left	30.00	25.35	20.23

Table 1: BLEU scores on the test set of the three translation tasks with both left-to-right and right-to-left decoding.

left-to-right	De-En	En-De	En-Zh
Left	**10.17**	**7.90**	**7.41**
Right	8.39	6.60	5.91
right-to-left	De-En	En-De	En-Zh
Right	7.83	6.45	5.77
Left	**9.41**	**7.11**	**7.01**

Table 2: BLEU scores of the left and right half of left-to-right and right-to-left NMT models. In (Liu et al., 2016a), the authors report the *partial BLEU* score without length penalty, our result is consistent with *partial BLEU* if simply removing length penalty when calculating BLEU.

We first report the BLEU scores of the full translation results (without split) in Table 1. As can be seen, the accuracy of the model is comparable to state-of-the-art results (Vaswani et al., 2017; Wang et al., 2017, 2018). Afterwards we report the BLEU scores of the left half and the right half in Table 2. We have several observations.

- When translating from left-to-right, the BLEU score of the left half is higher than the right half on all the three tasks, which is consistent with previous observation and is able to be explained via error propagation.
- When translating from right-to-left, the accuracy of the left half (in this way it's the later part of the generated sentence) is still higher than the right half. Such an observation is contradictory to the previous analyses between error propagation and accuracy drop, which regard that accumulated error brought by exposure bias will deteriorate the quality in later part of translation (i.e., the left half).

The inconsistent observation above suggests that error propagation is not the only cause of accuracy drop that there are other factors beyond er-

---

[1] 1) For most of the sentences, the last word of the sentence is period which is easy to decode. To make a fair comparison, we simply remove the last period before dividing the translation sentence. 2) For sentence with an odd number of words, we simply remove the word in the middle position to make the left half and right half have the same number of words.

[2] We use the *multi-bleu.perl* script `https://github.com/moses-smt/mosesdecoder/scripts/generic/multi-bleu.perl`. When computing BLEU score of the left or right half, the reference is the full reference sentence.

De-En	**left-to-right**			**right-to-left**		
	0	1	Δ	0	1	Δ
Left	**10.17**	**10.71**	0.54	**9.41**	**10.41**	1.00
Right	8.39	9.25	0.86	7.83	8.45	0.62

En-De	**left-to-right**			**right-to-left**		
	0	1	Δ	0	1	Δ
Left	**7.90**	**9.43**	1.53	**7.11**	**10.71**	3.60
Right	6.60	8.36	1.76	6.45	8.37	1.92

En-Zh	**left-to-right**			**right-to-left**		
	0	1	Δ	0	1	Δ
Left	**7.41**	**9.11**	1.70	**7.01**	**9.83**	2.82
Right	5.91	8.55	2.64	5.77	7.54	1.77

Table 3: BLEU scores. ”0” represents the translation results without teacher forcing during inference, and ”1” represents the translation results with teacher forcing during inference. Δ represents the BLEU score improvement of teacher forcing over normal translation.

ror propagation for accuracy drop. It even challenges the existence of error propagation: does error propagation really exist? In the next section we try to answer this question through teacher forcing experiments.

3.2 The Influence of Error Propagation

Teacher forcing (Williams and Zipser, 1989) in sequence generation means that when training a sequence generation model, we feed the previous ground-truth tokens as inputs to predict the next target word. Here we apply teacher forcing in the inference phase of NMT: to generate the next word $\hat{y}_i$, we input the preceding ground-truth words $y_{<i}$ rather than the previously generated words $\hat{y}_{<i}$, which largely alleviates the effect of error propagation, since there will be no error propagated from the previously generated words.

Same as last section, we evaluate the quality of the left and right half of the translation results generated by both the left-to-right and right-to-left models. The results are summarized in Table 3. For comparison, we also include the BLEU scores of normal translation (without teacher forcing). We have several findings from Table 3 as follows:

- Exposure bias exists. The accuracy of both left and right half tokens in the normal translation is lower than that in teacher forcing, which feeds the ground-truth tokens as inputs. This demonstrates that feeding the previously generated tokens (which might be incorrect) in inference indeed hurts translation accuracy.
- Error propagation does exist. We find the error is accumulated along the sequential generation of the sentence. Taking En-Zh and the left-to-right NMT model as an example, the BLEU score improvement of the right half (the second half of the generation) of teacher forcing over normal translation is 2.64, which is much larger than the accuracy improvement of the left half (the first half of the generation): 1.70. Similarly, for En-Zh with the right-to-left NMT model, the BLEU score improvement of the left half (the second half of the generation) of teacher forcing over normal translation is 2.82, which is much larger than the accuracy improvement of the right half (the first half of the generation): 1.77.
- Other causes exist. Taking En-De translation with the left-to-right model as an example, the accuracy of the left half (9.43) is higher than that of the right half (8.36) when there is no error propagation with teacher forcing. Similar results can be found in other language pairs and models. This suggests that there must be some other causes leading to accuracy drop, which will be studied in the next section.

4 Language Branching Matters

Section 3.1 and 3.2 together show that error propagation has influence on but is not the only cause of accuracy drop. We hypothesize that the language itself, i.e., its characteristics, may explain the phenomenon of accuracy drop.

Watanabe and Sumita (2002) finds that left-to-right decoding performs better for Japanese-English translation while right-to-left decoding performs better for English-Japanese translation. We conduct the same analysis settings as in Section 3.1 and 3.2 on English-Japanese (En-Jp) translation dataset. More details about this dataset and model descriptions can be found in supplementary materials (section A.1 and A.2).

Table 4 shows the BLEU score on the En-Jp test set. It can be observed that regardless of decoding direction (i.e., from left-to-right or from right-to-left) and with or without teacher forcing, the accuracy of the right half is always higher than that in the left half. This observation on Japanese is

	left-to-right		**right-to-left**	
	0	1	0	1
left	7.90	9.91	7.45	8.95
right	**8.70**	**11.52**	**9.24**	**10.59**

Table 4: BLEU scores on En-Jp test set. ”0” represents the normal translation results, and ”1” represents the teacher-forcing translation results.

opposite to English, German and Chinese in Section 3.1 and 3.2, and motivates us to investigate the differences between these languages.

We find that a linguistics concept, the branching, can differentiate Japanese from other languages such as English/German. Branching refers to the shape of the parse trees that represent the structure of sentences (Berg et al., 2011; Payne, 2006). Usually, right-branching sentences are head-initial, which means the main subject of the sentence is described first, and is followed by a sequence of modifiers that provide additional information about the subject. On the contrary, left-branching sentences are head-final that putting such modifiers to the left of the sentence (Payne, 2006).

English is a typical right-branching language, while Japanese is almost fully left-branching (Wikipedia, 2018). The two languages demonstrate the opposite phenomenon of accuracy drop as shown in previous studies. When we say a language is typical left/right-branching, we mean most of the sentences in this language follows the left/right-branching structure. While being predominantly right-branching, German is less conclusively so than English. Chinese features a mixture of head-final and head-initial structures, with the noun phrases are head-final while the strict head/complement ordering sentences are head-initial as right-branching (Wikipedia, 2018), but less conclusively than German.

We believe the language branching is a main cause of accuracy drop. Intuitively, the main subject of a right-branching sentence is described first (in the left part) and is followed by additional modifiers (in the right part) (Berg et al., 2011). Therefore, the left half of a right-branching sentence is more likely to possess a clearer structure pattern and thus lead to higher generation accuracy than in the right part, since the main subject is usually simpler and clearer than the modifiers that providing additional information about the subject. In next section, we will verify this intuition this assumption from a statistical perspective.

5 Correlation between Language Branching and Accuracy Drop

As previous work (Arpit et al., 2017) shows, neural networks are easy to learn and memorize simple patterns but difficult to make a correct prediction on noise examples. In this section, we study different branching languages from two aspects, including the n-gram statistics of a target language, which has been used as a kind of characterization of hardness of learning (Bengio et al., 2009), and the dependency statistics in parse trees. We show that these statistics well correlate with the accuracy drop between the left half and the right half of translation results.

5.1 N-gram Statistics

Intuitively speaking, if a pattern occurs frequently and deterministically, it is easy to be learned by neural networks. By comparing the general statistics on the n-gram frequency and n-gram conditional probability of the left and right half tokens, we link the language branching to accuracy drop.

Denote a bilingual dataset $D = \{(x_i, y_i\}, i = 1, \cdots, M$, where each y_i is a sequence of words $y_i = \{y_i^1, \cdots, y_i^{T_i}\}$, T_i is the length of y_i. $F_{i,n}^l$ and $P_{i,n}^l$ denote the average n-gram frequency and n-gram conditional probability of the left half of y_i [3], i.e.,

$$F_{i,n}^l = \frac{1}{T_i/2 - n + 1} \sum_{j=1}^{T_i/2-n+1} F(y_i^j, ..., y_i^{j+n-1}),$$

$$P_{i,n}^l = \frac{1}{T_i/2 - n + 1} \sum_{j=1}^{T_i/2-n+1} P(y_i^{j+n-1} | y_i^j, ..., y_i^{j+n-2}), \tag{1}$$

where $F(.)$ and $P(.)$ are the n-gram frequency and n-gram conditional probability calculated from the training dataset. Similarly, $F_{i,n}^r$ and $P_{i,n}^r$ denote the n-gram frequency and n-gram conditional probability of the right half.

We calculate the average n-gram frequencies F_n^l and F_n^r of the left half and right half over all the target sentences in the training set. We also calculate the average n-gram conditional probabilities P_n^l and P_n^r over all the training sentences to compare the uncertainty of phrases in the left half and

---

[3] Again, we assume T_i is an even number. If not, we simply remove the middle word of y_i, as done in Section 3.1.

right half.

$$
\begin{aligned}
F_n^l &= \frac{1}{M}\sum_{i=1}^{M} F_{i,n}^l,\ F_n^r = \frac{1}{M}\sum_{i=1}^{M} F_{i,n}^r, \\
P_n^l &= \frac{1}{M}\sum_{i=1}^{M} P_{i,n}^l,\ P_n^r = \frac{1}{M}\sum_{i=1}^{M} P_{i,n}^r.
\end{aligned}
\tag{2}
$$

We also calculate the ratio of the sentences that the frequency/conditional probability of left half is bigger/smaller than that in the right half, denoted as $RF_n^{l>r}$/$RF_n^{l<r}$ and $RP_n^{l>r}$/$RP_n^{l<r}$:

$$
\begin{aligned}
RF_n^{l>r} &= \frac{1}{M}\sum_{i=1}^{M} \mathbb{1}\{F_{i,n}^l > F_{i,n}^r\}, \\
RF_n^{l<r} &= \frac{1}{M}\sum_{i=1}^{M} \mathbb{1}\{F_{i,n}^l < F_{i,n}^r\}, \\
RP_n^{l>r} &= \frac{1}{M}\sum_{i=1}^{M} \mathbb{1}\{P_{i,n}^l > P_{i,n}^r\}, \\
RP_n^{l<r} &= \frac{1}{M}\sum_{i=1}^{M} \mathbb{1}\{P_{i,n}^l < P_{i,n}^r\}.
\end{aligned}
\tag{3}
$$

We choose $n = 2$ and 3 to calculate the metrics in Equation 2 and 3 on different translation datasets. The numbers are listed in Table 5 and 6.

We can see the 2/3-gram frequency as well as the conditional probability of the left half is higher than that of the right half for right-branching languages including English, German and Chinese in De-En, En-De and En-Zh translation datasets. For left-branching language Japanese, the result is opposite. The n-gram frequency and conditional probability statistics are consistent with our observations on accuracy drop in left/right-branching languages and verify our hypothesis: right-branching languages have clearer patterns in left part (with larger n-gram frequency as well as the conditional probability) and consequently leads to higher translation accuracy in the left part than the right part; left-branching languages are opposite.

We further visualize how the accuracy drop (between the left half and right half of the translations) correlates with the gap of n-gram statistics in the left and right part. The accuracy drop (e.g., BLEU score) of left/right half is taken from the teacher-forcing with left-to-right decoding in Table 3, and the n-gram gap is taken from the Δ in the last row of Table 5 and 6. Figure 1 shows strong correlation between accuracy drop and the gap of n-gram statistics: As the gap of n-gram statistics increases from negative values to positive values, the accuracy drop also increases from negative to positive.

	De-En		**En-De**	
	2-gram	**3-gram**	**2-gram**	**3-gram**

	En-Zh		**En-Jp**	
	2-gram	**3-gram**	**2-gram**	**3-gram**
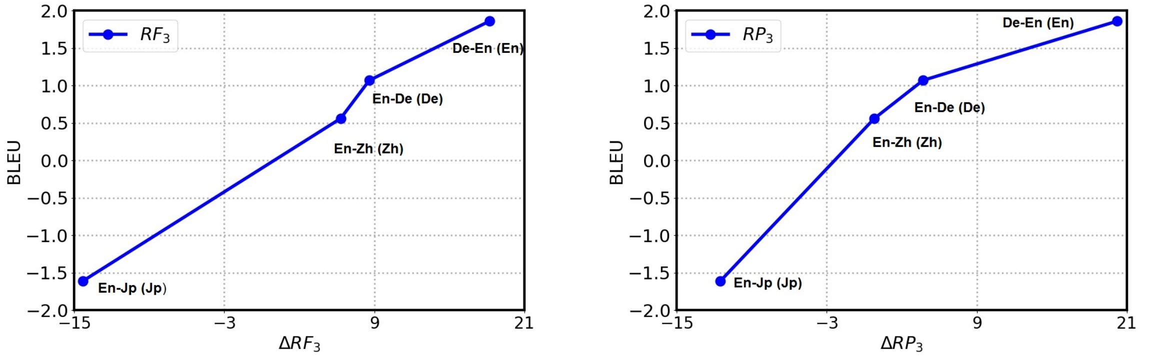
P_n^l	**0.064**	**0.113**	0.082	0.171
P_n^r	0.055	0.108	**0.086**	**0.191**
$RP_n^{l>r}$	**52.1%**	**47.8%**	43.9%	39.4%
$RP_n^{l<r}$	46.6%	47.0%	**49.2%**	**50.9%**
Δ	5.5%	0.8%	-5.3%	-11.5%

Table 6: The n-gram conditional probability statistics on different translation datasets. P_n^l and P_n^r represent the average n-gram conditional probability of left and right half of target sentences. $RP_n^{l>r}$ and $RP_n^{l<r}$ represent the ratio that the n-gram frequency of left half are bigger/smaller than that of the right half. $\Delta = RP_n^{l>r} - RP_n^{l<r}$. Note that the sum of $RP_n^{l>r}$ and $RP_n^{l<r}$ is less than 1 due to two reasons: (1) sentence with less than 4 words does not contribute to the statistics, and (2) we remove the n-gram condition probability with the denominator less than 100 to make probability calculation robust.



(a) Accuracy drop v.s 3-gram frequency gap (%).

(b) Accuracy drop v.s 3-gram conditional probability gap (%).

Figure 1: Accuracy drop (the gap between the left/right BLEU score) with respect to the ΔRF_3 and ΔRP_3 from Table 5 and 6 in the four translation tasks. The x-axis ΔRF_3 and ΔRP_3 represent the gap of between the left and right ratio of the 3-gram frequency/conditional probability defined in Table 5 and 6. The y-axis represents the accuracy drop in terms of BLEU score calculated by the teacher forcing decoding.

5.2 Dependency Statistics

In this subsection, we study language branching from the perspective of dependency structure. We hypothesize that if the left/right half of sentence contains more dependencies between its intra words, this half should be easier to predict, leading to higher accuracy. Here we analyze the English sentence in De-En translation and Japanese sentence in En-Jp translation, since English is fully right-branching and Japanese is fully left-branching as introduced before.

For English parsing, we utilize the well-acknowledged Standford Parser[4] to parse the sentences. After obtaining the parsing results, we split the sentence into left and right half, and separately count the numbers of dependencies in each half[5]. For Japanese, we leverage the open-source toolkit J.DepP[6] to parse the sentence, and then count the number of dependencies of each half.

We provide the results in Table 7. As can be observed, for English sentences, the left-half words depend more on each other than the right-half words, while for the Japanese sentences, the right-half words have more dependencies. This observation is consistent with our observations on accuracy drop, and can well explain the high accuracy of left part in English translation and right part in Japanese translation.

	English	Japanese
Left	**40242**	921735
Right	31509	**1570630**

Table 7: Number of dependencies in left and right half of English (De-En) and Japanese (En-Jp) training corpus. The number varies a lot since the two training corpus have different training sentences.

6 Extended Analyses and Discussions

We have analyzed the accuracy drop problem from the view of error propagation and language itself in previous sections. In this section, we further provide extended analyses and several discussions to give a more clear understanding of the accuracy drop problem.

6.1 More Languages on Left-Branching

The previous analyses are based on four languages, three right-branching (En, De, Zh) and one left-branching language (Jp). To avoid the experimental bias and randomness, we provide one more translation task, English-Turkish (En-Tr) translation[7], as Turkish is a left-branching language. We simply calculate the BLEU score of the left/right half in left-to-right and right-to-left

---

[4] https://nlp.stanford.edu/software/lex-parser.shtml

[5] For simplicity, we just count the number of dependency, without considering dependency types. The detailed parsing formats can be found in the supplementary material (Section A.3).

[6] http://www.tkl.iis.u-tokyo.ac.jp/~ynaga/jdepp/

[7] The detailed dataset and model description can be found in supplementary material (section A.1 and section A.2).

	0	1
Left	**5.83**	7.44
Right	5.27	**7.96**

Table 8: BLEU scores on En-Tr test set with left-to-right generation. Normal translation is denoted as “0”, and teacher-forcing translation is denoted as “1”.

	left-to-right	**right-to-left**
Full	27.63	25.44
Left	**9.17**	**8.37**
Right	7.51	7.25

Table 9: BLEU scores on the left-to-right and right-to-left translation sentences on the De-En test set, with RNN-based model. “Full” means the BLEU score of the whole translation sentence.

decodings, as in Section 3.1 and 3.2.

The result is provided in Table 8. For the left-to-right decoding, the accuracy of the left half is higher than that of the right half in the normal translation. However, the accuracy of the right half becomes higher with teacher forcing translation. This demonstrates that English-Turkish translation performs similar to English-Japanese translation as the accuracy of right half is higher than that of the left half. But different from what we observed in Japanese, Turkish shows the opposite phenomenon: the influence of language branching is weaker than error propagation.

6.2 Other Model Structures

One may wonder whether the results in the paper are biased towards a certain model structure as we use Transformer on all the above analyses. To address such concerns, we conduct an additional experiment on De-En translation task with RNN (GRU)-based model[8]. The results are shown in Table 9 and the observations are consistent with what we observed on Transformer. The accuracy of the left half of the De-En translation sentence is always higher than the right half, in both the left-to-right and right-to-left decodings.

6.3 Other Sequence Generation Tasks

We conduct experimental analysis on abstractive summarization, which is also a sequence generation task. The goal of the task is to recap a long news sentence into a short summary. We use Gigaword dataset which contains $3.8M$ training pairs, $190k$ validation and $2k$ test pairs of English sentence, and train an RNN-based model for sentence summarization. The accuracy is measured by the commonly used metric ROUGE F1 score and are reported in Table 10.

	left-to-right		
	ROUGE-1	**ROUGE-2**	**ROUGE-L**
Full	35.55	16.66	33.01
Left	**24.44**	**9.87**	**23.34**
Right	21.31	8.32	20.38
	right-to-left		
	ROUGE-1	**ROUGE-2**	**ROUGE-L**
Full	35.22	16.55	32.59
Right	21.62	8.41	20.48
Left	**23.60**	**9.54**	**22.52**

Table 10: ROUGE F1 scores for left-to-right and right-to-left generated translation sentences in abstractive summarization task. ROUGE-N stands for N-gram based ROUGE F1 score, ROUGE-L stands for longest common subsequence based ROUGE F1 score. “Full” means the entire translation sentence.

We observe the same phenomenon as in translation tasks. The accuracy of the left half is always better than the right half, no matter in left-to-right or right-to-left decoding, since the target language English is a right-branching language.

7 Conclusion

In this work, we studied the problem of accuracy drop between the left half and the right half of the results generated by neural machine translation models. We found the influence of error propagation is overstated in literature and error propagation alone cannot explain accuracy drop. We showed that language branching well correlates to the accuracy drop problem and the evidences on n-gram statistics as well as the dependency statistics well support this correlation. Our discoveries suggest that left-to-right NMT models fit better for right-branching languages (e.g., English) and right-to-left NMT models fit better for left-branching languages (e.g., Japanese).

For future works, we will study more left/right-branching languages as well as other languages that have no obvious branching characteristics. We will also investigate how language branching influences other natural language tasks, especially for neural networks based models.

---

Abstract

Recent studies have shown that reinforcement learning (RL) is an effective approach for improving the performance of neural machine translation (NMT) system. However, due to its instability, successfully RL training is challenging, especially in real-world systems where deep models and large datasets are leveraged. In this paper, taking several large-scale translation tasks as testbeds, we conduct a systematic study on how to train better NMT models using reinforcement learning. We provide a comprehensive comparison of several important factors (e.g., baseline reward, reward shaping) in RL training. Furthermore, to fill in the gap that it remains unclear whether RL is still beneficial when monolingual data is used, we propose a new method to leverage RL to further boost the performance of NMT systems trained with source/target monolingual data. By integrating all our findings, we obtain competitive results on WMT14 English- German, WMT17 English-Chinese, and WMT17 Chinese-English translation tasks, especially setting a state-of-the-art performance on WMT17 Chinese-English translation task.

1 Introduction

Recently, neural machine translation (NMT) (Bahdanau et al., 2015; Hassan et al., 2018; Wu et al., 2016; He et al., 2017; Xia et al., 2016, 2017; Wu et al., 2018b,a) has become more and more popular given its superior performance without the demand of heavily hand-crafted engineering efforts. It is usually trained to maximize the likelihood of each token in the target sentence, by taking the source sentence and the preceding (ground-truth) target tokens as inputs. Such training approach is referred as maximum likelihood estimation (MLE) (Scholz, 1985). Although easy to implement, the token-level objective function during training is inconsistent with sequence-level evaluation metrics such as BLEU (Papineni et al., 2002).

To address the inconsistency issue, reinforcement learning (RL) methods have been adopted to optimize sequence-level objectives. For example, policy optimization methods such as REINFORCE (Ranzato et al., 2016; Wu et al., 2017b) and actor-critic (Bahdanau et al., 2017) are leveraged for sequence generation tasks including NMT. In machine translation community, a similar method is proposed with the name 'minimum risk training' (Shen et al., 2016). All these works demonstrate the effectiveness of RL techniques for NMT models (Wu et al., 2016).

However, effectively applying RL to real-world NMT systems has not been fulfilled by previous works. First, most of, if not all, previous works verified their methods based on shallow recurrent neural network (RNN) models. However, to obtain state-of-the-art (SOTA) performance, it is essential to leverage recently derived deep models (Gehring et al., 2017; Vaswani et al., 2017), which are much more powerful.

Second, it is not easy to make RL practically effective given quite a few widely acknowledged limitations of RL method (Henderson et al., 2018) such as high variance of gradient estimation (Weaver and Tao, 2001), and objective instability (Mnih et al., 2013). Therefore, several tricks are proposed in previous works. However, it remains unclear, and no agreement is achieved on how to use these tricks in machine translation. For example, baseline reward method (Weaver and Tao, 2001) is suggested in (Ranzato et al., 2016; Nguyen et al., 2017; Wu et al., 2016) but not leveraged in (He and Deng, 2012; Shen et al., 2016).

Third, large-scale datasets, especially monolingual datasets are shown to significantly improve translation quality (Sennrich et al., 2015a; Xia et al.,

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3612–3621
Brussels, Belgium, October 31 - November 4, 2018.

2016) with MLE training, while it remains nearly empty on how to combine RL with monolingual data in NMT.

In this paper, we try to fulfill these gaps and study how to practically apply RL to obtain strong NMT systems with quite competitive, even state-of-the-art performance. Several comprehensive studies are conducted on different aspects of RL training to figure out how to: 1) set efficient rewards; 2) combine MLE and RL objectives with different weights, which aims to stabilize the training procedure; 3) reduce the variance of gradient estimation.

In addition, given the effectiveness of leveraging monolingual data in improving translation quality, we further propose a new method to combine the strength of both RL training and source/target monolingual data. To the best of our knowledge, this is the first work that tries to explore the power of monolingual data when training NMT model with RL method.

We obtain some useful findings through the experiments on WMT17 Chinese-English (Zh-En), WMT17 English-Chinese (En-Zh) and WMT14 English-German (En-De) translation tasks. For instance, multinomial sampling is better than beam search in reward computation, and the combination of RL and monolingual data significantly enhances the NMT model performance. Our main contributions are summarized as follows.

- We provide the first comprehensive study on different aspects of RL training, such as how to setup reward and baseline reward, on top of quite competitive NMT models.
- We propose a new method that effectively leverages large-scale monolingual data, from both the source and target side, when training NMT models with RL.
- Combined with several of our findings and method, we obtain the SOTA translation quality on WMT17 Zh-En translation task, surpassing strong baseline (Transformer big model + back translation) by nearly 1.5 BLEU points. Furthermore, on WMT14 En-De and WMT17 En-Zh translation tasks, we can also obtain strong competitive results.

We hope that our studies and findings will benefit the community to better understand and leverage reinforcement learning for developing strong NMT models, especially in real-world scenarios faced with deep models and large amount of training data (including both parallel and monolingual data). Towards this end, we open source all our codes/dataset at `https://github.com/apeterswu/RL4NMT` to provide a clear recipe for performance reproduction.

2 Background

In this section, we first introduce the attention-based sequence-to-sequence learning framework for neural machine translation (NMT), and then introduce the basis of applying reinforcement learning to training NMT models.

2.1 Neural Machine Translation

Typical NMT models are based on the encoder-decoder framework with attention mechanism. The encoder first maps a source sentence $x = (x_1, x_2, ..., x_n)$ to a set of continuous representations $z = (z_1, z_2, ..., z_n)$. Given z, the decoder then generates a target sentence $y = (y_1, y_2, ..., y_m)$ of word tokens one by one. At each decoding step t of model training, the probability of generating a token y_t is maximized conditioned on x and $y_{<t} = (y_1, ..., y_{t-1})$. Given N training sentence pairs $\{x^i, y^i\}_{i=1}^N$, maximum likelihood estimation (MLE) is usually adopted to optimize the model, and the training objective is defined as:

$$\begin{aligned} L_{mle} &= \sum_{i=1}^{N} \log p(y^i|x^i) \\ &= \sum_{i=1}^{N} \sum_{t=1}^{m} \log p(y_t^i|y_1^i, ..., y_{t-1}^i, x^i), \end{aligned} \tag{1}$$

where m is the length of sentence y^i.

Among all the encoder-decoder models, the recently proposed Transformer (Vaswani et al., 2017) architecture achieves the best translation quality so far. The main difference between Transformer and previous RNNSearch (Bahdanau et al., 2015) or ConvS2S (Gehring et al., 2017) is that Transformer relies entirely on self-attention (Lin et al., 2017) to compute representations of source and target side sentences, without using recurrent or convolutional operations.

2.2 Training NMT with Reinforcement Learning

As aforementioned, reinforcement learning (RL) is leveraged to bridge the gap between training and inference of NMT, by directly optimizing the evaluation measure (e.g., BLEU) at training time. Specifically, NMT model can be viewed as an *agent*, which interacts with the *environment* (the previous words $y_{<t}$ and the context vector z available at each step t). The parameters of the agent define a *policy*, i.e., a conditional probability $p(y_t|x, y_{<t})$. The agent will pick an *action* , i.e., a candidate word out from the vocabulary, according to the policy. A terminal *reward* is observed once the agent generates a complete sequence $\hat{y}$. The reward for machine translation is the BLEU (Papineni et al., 2002) score, denoted as $R(\hat{y}, y)$, which is defined by comparing the generated $\hat{y}$ with the ground-truth sentence y. Note that here the reward $R(\hat{y}, y)$ is the sentence-level reward, i.e., a scalar for each complete sentence $\hat{y}$. The goal of the RL training is to maximize the expected reward:

$$\begin{aligned} L_{rl} &= \sum_{i=1}^{N} E_{\hat{y} \sim p(\hat{y}|x^i)} R(\hat{y}, y^i) \\ &= \sum_{i=1}^{N} \sum_{\hat{y} \in Y} p(\hat{y}|x^i) R(\hat{y}, y^i), \end{aligned} \tag{2}$$

where Y is the space of all candidate translation sentences, which is exponentially large due to the large vocabulary size, making it impossible to exactly maximize L_{rl}. In practice, REINFORCE (Williams, 1992) is usually leveraged to approximate the above expectation via sampling $\hat{y}$ from the policy $p(y|x)$, leading to the objective as maximizing:

$$\hat{L}_{rl} = \sum_{i=1}^{N} R(\hat{y}^i, y^i), \hat{y}^i \sim p(y|x^i), \forall i \in [N]. \tag{3}$$

Throughout the paper we will use REINFORCE as our policy optimization method for RL training.

3 Strategies for RL Training

Although training NMT with RL can fill in the gap between training objectives and evaluation metrics, it is not easy to successfully put RL training into practice. A key challenge is that RL methods are highly unstable and inefficient, due to the noise in gradient estimation and reward computation. To our best knowledge, currently there is no consensus, or even a systematic study on how to configure different setups for RL training to avoid such problems, especially for training deep NMT models on large scale datasets. We therefore aim to shed light on practical applications of RL for NMT training. For this purpose, we provide a comprehensive review of several important methods to stabilize RL training process in this section.

3.1 Reward Computation

It is critical to set up appropriate rewards for RL training, i.e., the $R(\hat{y}, y)$ in Eqn. (3). There are two important aspects to consider in configuring the reward $R(\hat{y}, y)$: how to sample training instance $\hat{y}$ and whether to use reward shaping.

Generate $\hat{y}$ There are two strategies to sample $\hat{y}$ for computing the BLEU reward $R(\hat{y}, y)$. The first one is *beam search* (Sutskever et al., 2014), it is a breadth-first search method that maintains a "beam" of the top-K scoring candidates (prefix hypothesis sentences) at each generation step. Then, for each candidate sentence in the beam, K most likely words are appended, resulting in a pool of $K \times K$ new candidates. Out from this pool, the top-K translations with largest probabilities are selected, and the beam search process continues. The second strategy is *multinomial sampling* (Chatterjee and Cancedda, 2010), which produces each word one by one through multinomial sampling over the model's output distribution. Both sampling strategies terminate the expansion of a candidate sentence when an 'end of sentence' (<EOS>) token is met.

The choice of different sampling strategies reflects the *exploration-exploitation* dilemma. Beam search strategy generates more accurate $\hat{y}$ by exploiting the probabilistic space output via current NMT model, while multinomial sampling pays more attention to explore more diverse candidates.

Whether to Use Reward Shaping From Eqn. (3) we can see that for the entire sequence $\hat{y}$, there is only one terminal reward $R(\hat{y}, y)$ available for model training. Note that the agent needs to take tens of actions (with the number depending on the length of $\hat{y}$) to generate a complete sentence $\hat{y}$, but only one reward is available for all those actions. Consequently, RL training is inefficient due to the sparsity of rewards, and the model updates each token in the training sentence with the same reward value without distinction. Reward shaping (Ng et al., 1999) is a strategy to overcome this shortcoming. In reward shaping, intermediate reward at each decoding step t is imposed and denoted as $r_t(\hat{y}_t, y)$. Bahdanau et al. (2017) sets up the intermediate reward as $r_t(\hat{y}_t, y) = R(\hat{y}_{1...t}, y) - R(\hat{y}_{1...t-1}, y)$, where $R(\hat{y}_{1...t}, y)$ is defined as the BLEU score of $\hat{y}_{1\ldots t}$ with respect to y. Note that we have $R(\hat{y}, y) = \sum_{t=1}^{m} r_t(\hat{y}_t, y)$, where m is the length of $\hat{y}$. During RL training, the cumulative reward $\sum_{\tau=t}^{m} r_\tau(\hat{y}_\tau, y)$ is used to update the policy at time step t. It is verified that using the shaped reward r_t instead of awarding the whole score $R(\hat{y}, y)$ does not change the optimal policy (Ng et al., 1999).

3.2 Variance Reduction of Gradient Estimation

As mentioned before, the REINFORCE algorithm suffers from high variance in gradient estimation, mainly caused by using single sample $\hat{y}$ to estimate the expectation. To reduce the variance, Ranzato et al. (2016) subtracts an average reward from the returned reward at each time step t, and the actual reward used to update the policy is

$$R(\hat{y}, y) - \hat{r}_t, \tag{4}$$

where $\hat{r}_t$ is the estimated average reward at step t, named as *baseline reward* (Weaver and Tao, 2001). Together with reward shaping, the updated reward becomes $\sum_{\tau=t}^{m} r_\tau(\hat{y}_\tau, y) - \hat{r}_t$ at step t.

Intuitively speaking, a baseline reward $\hat{r}_t$ is established, which either encourages a word choice $\hat{y}_t$ if the induced reward R satisfies $R > \hat{r}_t$, or discourages it if $R < \hat{r}_t$. Here R is either the terminal reward $R(\hat{y}, y)$ or the cumulative reward $\sum_{\tau=t}^{m} r_\tau(\hat{y}_\tau, y)$. Such estimated baseline reward $\hat{r}_t$ is designed to decrease the high variance of the gradient estimator.

In practice, the baseline reward $\hat{r}_t$ can be obtained through different approaches. For example, one may sample multiple sentences and use the mean terminal reward for these sentences as baseline reward. In our work, we adopt the function learning approach, using simple network (e.g., multi-layer perceptron) to build the learning function, which is the same as used in (Ranzato et al., 2016; Bahdanau et al., 2017).

3.3 Combine MLE and RL Objectives

The last important strategy we would like to mention is the combination of MLE training objective with RL objective, which is assumed to further stabilize RL training process (Wu et al., 2016; Li et al., 2017; Wu et al., 2017a).

A simple way is to linearly combine the MLE (Eqn. (1)) and RL (Eqn. (3)) objectives as follows:

$$L_{com} = \alpha * L_{mle} + (1 - \alpha) * \hat{L}_{rl}, \tag{5}$$

where α is the hyperparamter controlling the trade-off between MLE and RL objectives. We will empirically evaluate how different values of α impact the final translation accuracy.

4 RL Training with Monolingual Data

Previous works typically conduct RL training with only bilingual data for NMT. Monolingual data has been proved to be able to significantly improve the performance of NMT systems (Sennrich et al., 2015a; Xia et al., 2016; Cheng et al., 2016). It remains an open problem whether it is possible to combine the benefits of RL training and monolingual data such that even more competitive results can be obtained. In this section we provide several solutions for combination and will study them in next section. Note that all the settings discussed in this section are semi-supervised learning, i.e., both bilingual and monolingual data are available.

4.1 With Source-Side Monolingual Data

We first provide a solution to RL training with source-side monolingual data. As shown in Eqn. (3), in RL training we need to calculate the reward signal $R(\hat{y}, y)$ for each generated sentence $\hat{y}$, and therefore the reference sentence y seems to be a must-have, which unfortunately is missing for source-side monolingual data.

We tackle this challenge via generating pseudo target reference y by bootstrapping with the model itself. Apparently, for the source-side monolingual data, the pseudo target reference y should have good translation quality. Therefore, for each source-side monolingual sentence, we use the NMT model trained from the bilingual data to beam search a target sentence and treat it as the pseudo target reference y. Afterwards $\hat{y}$ is obtained via multinomial sampling to calculate the reward. Although multinomial sampling is usually not as good as sampling via beam search, the combination of beam search (to get the pseudo target reference sentence) and the multinomial sampling (to generate the action sequence of the agent) achieves good exploration-exploitation trade-off, since the pseudo target reference exploits the accuracy of current NMT model while $\hat{y}$ achieves better exploration.

4.2 With Target-Side Monolingual Data

For a target-side monolingual sentence, its source sentence x is missing, and consequently $\hat{y}$ is unavailable since it is sampled based on x. We tackle this challenge via back translation (Sennrich et al., 2015a). We first train a reverse NMT model from the target language to the source language with bilingual data. For each target-side monolingual sentence, using the reverse NMT model, we back translate it to get its pseudo source sentence x. We then pair the target monolingual data and its back-translated sentence as a pseudo bilingual sentence pair, which can be used for RL training in the same way as the genuine bilingual sentence pairs.

4.3 With both Source-Side and Target-Side Monolingual Data

A natural extension of previous discussions is to combine both the source-side and target-side monolingual data for RL training. We consider two combinations, the *sequential* method and the *unified* method. The former one sequentially leverages the source-side and target-side monolingual data for RL training. Specifically, we first train an MLE model using the bilingual data and source-side (or target-side) monolingual data; based on this MLE model, we then use REINFORCE for training with target-side (or source-side) monolingual data. For *unified* approach, we pack the paired data out from three domains together: the genuine bilingual data, the source monolingual data with its pseudo target references (introduced in subsection 4.1), and the target monolingual data with its back-translated samples (introduced in subsection 4.2). Then we treat the combined data as normal bilingual data on which the NMT model is trained via MLE or RL principles. Our goal is to investigate the model performance with different training data and find the best recipe of how to use these data in RL training. More details are introduced in next section.

5 Experiments

In this section, we provide a systematic study on aforementioned RL training strategies and the solutions of leveraging monolingual data. The RL training strategies are evaluated on bilingual datasets from three translation tasks, WMT14 English-German (En-De), WMT17 English-Chinese (En-Zh) and WMT17 Chinese-English (Zh-En), and we further conduct the experiments to leverage monolingual data in WMT17 Zh-En translation.

5.1 Experimental Settings

For the bilingual datasets, WMT17 (Bojar et al., 2017) En-Zh [1] and WMT17 Zh-En use the same dataset, which contains about $24M$ sentences pairs, including CWMT Corpus 2017 and UN Parallel Corpus V1.0. The Jieba[2] segmenter is used to perform Chinese word segmentation. We use byte pair encoding (BPE) (Sennrich et al., 2015b) to preprocess the source and target sentences, forming source-side and target-side dictionary with $40,000$ and $37,000$ types, respectively. We use the *newsdev2017* as the dev set and *newstest2017* as the test set. For the WMT14 En-De dataset, it contains about $4.5M$ training pairs, *newstest2012* and *newstest2013* are concatenated as the dev set and *newstest2014* acts as test set. Same as (Vaswani et al., 2017), we also perform BPE to process the En-De dataset, the shared source-target vocabulary contains about $37,000$ tokens.

For the monolingual dataset on Zh-En translation task, similar to (Sennrich et al., 2017), the Chinese monolingual data comes from LDC Chinese Gigaword (4th edition) and the English monolingual data comes from News Crawl 2016 articles. After preprocessing (e.g., language detection and filtering sentences with more than 80 words), we keep $4M$ Chinese sentences and $7M$ English sentences.

We adopt the Transformer model with *transformer_big* setting as defined in (Vaswani et al., 2017) for Zh-En and En-Zh translations, which achieves SOTA translation quality in several other datasets. For En-De translation, we utilize the *transformer_base_v1* setting. These settings are exactly same as used in the original paper, except we set the *layer_prepostprocess_dropout* for Zh-En and En-Zh translation to be 0.05. The optimizer used for MLE training is Adam (Kingma and Ba, 2015) with initial learning rate is 0.1, and we follow the same learning rate schedule in (Vaswani et al., 2017). During training, roughly $4,096$ source tokens and $4,096$ target tokens are paired in one mini batch. Each model is trained using 8 NVIDIA Tesla M40 GPUs. For RL training, the model is initialized with parameters of the MLE model (trained with only bilingual data), and we continue training it with learning rate 0.0001. Same as (Bahdanau et al., 2017), to calculate the BLEU reward, we start all n-gram counts from 1 instead of 0 and

RL (beam + terminal)	27.06	34.25	24.42
RL (multinomial + terminal)	**27.22**	**34.46**	**24.70**
RL (beam + shaping)	27.04	34.28	24.47
RL (multinomial + shaping)	**27.23**	**34.47**	**24.72**

Table 1: Results of different strategies for reward computation. ‘beam’ refers to ‘beam search and ‘multinomial’ to ‘multinomial sampling’. While generating $\hat{y}$ through beam search, we use width 4. ‘shaping’ refers to using reward shaping and ‘terminal’ refers not.

multiply the resulting score by the length of the target reference sentence. For inference, we use beam search with width 6. We run each setting for at least 5 times and report the averaged case sensitive BLEU scores[3] (Papineni et al., 2002) on test set. The test set BLEU is chosen via the best configuration based on the validation set.

5.2 Results of of RL Training Strategies

We first evaluate different strategies for RL training, based only on bilingual datasets from previously introduced three translation tasks.

Reward Computation As reviewed in subsection 3.1, for reward computation, we need to consider how to sample $\hat{y}$ and whether to use reward shaping.

The results are shown in Table 1, where “RL” stands for RL training with the REINFORCE algorithm. We also report the performance of the pre-trained NMT model with the MLE loss. From the table, an interesting finding is that $\hat{y}$ sampled via beam search strategy is worse than that by multinomial sampling, with a gap of roughly 0.2-0.3 BLEU points on the test set (with significant test score $\rho < 0.05$). We therefore conjecture that exploration is more important than exploitation in reward computing: multinomial sampling brings more data diversity to the training of NMT model, while sentences generated by beam search are usually very similar to each other. Furthermore, we find that there is no big difference between the leverage of reward shaping or terminal reward, with only slightly better performance of reward shaping. We therefore use multinomial sampling and reward shaping in later experiments.

Training Strategy	En-De	En-Zh	Zh-En
RL	27.23	34.47	24.72
RL (baseline function)	27.25	34.43	24.73

Table 2: Results of variance reduction of gradient estimation.

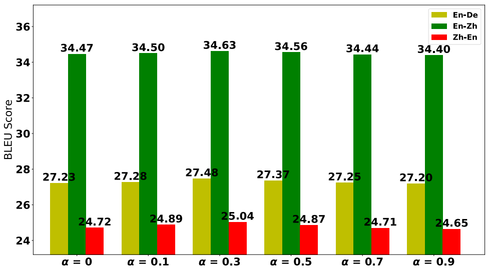

Figure 1: Results of different weights α to combine MLE and RL objectives.

Variance Reduction of Gradient Estimation Next we evaluate the strategies for reducing variance of gradient estimation (see section3.2). We want to know whether the *baseline reward* is necessary. To compute the baseline reward, similar to (Ranzato et al., 2016; Bahdanau et al., 2017), we build a two-layer MLP regressor with Relu (Nair and Hinton, 2010) activation units. The function takes the hidden states from decoder as input, and the parameters of the regressor are trained to minimize the mean squared loss of Eqn. (4). We first pre-train the baseline function for $20k$ steps/mini-batches, and then jointly train NMT model (with RL) and the baseline reward function.

Table 2 shows that the learning of baseline reward does not help RL training. This contradicts with previous observations (Ranzato et al., 2016), and seems to suggest that the variance of gradient estimation in NMT is not as large as we expected. The reason might be that the probability mass on the target-side language space induced by the NMT model is highly concentrated, making the sampled $\hat{y}$ representative enough in terms of estimating the expectation. Therefore, for the economic perspective, it is not necessary to add the additional steps of using baseline reward on RL training for NMT.

Combine MLE and RL Objectives As shown in Eqn. (5), the hyperparameter α controls the trade-off between MLE and RL objectives. For comparison, we set α to be [0, 0.1, 0.3, 0.5, 0.7, 0.9] in our experiments. The results are presented in Figure 1.

---

[3] Calculated by SacréBLEU toolkit, which produces exactly the same evaluation result as that in WMT17 Zh-En campaign. `https://github.com/awslabs/sockeye/tree/master/contrib/sacrebleu`

[Data] (Objective)	Valid	Test
[B] (MLE)	22.32	24.29
[B] (MLE) + [B] (RL)	22.87	25.04
[B] (MLE) + [Ms] (RL)	**23.03**	**25.22**
[B & Ms] (MLE)	24.31	25.31
[B & Ms] (MLE) + [B & Ms] (RL)	24.58	25.60

Table 3: Results with source monolingual data. “B” denotes bilingual data, “Ms” denotes source-side monolingual data, “&” denotes data combination.

The results show that combining the MLE objective with the RL objective achieves better performance (27.48 for En-De, 34.63 for En-Zh and 25.04 for Zh-En with $\alpha = 0.3$). This indicates that MLE objective is helpful to stabilize the training and improve the model performance, as we expected. However, further increasing α does not bring more gain. The best trade-off between MLE and RL objectives in our experiment is $\alpha = 0.3$. Therefore, we set $\alpha = 0.3$ in the following experiments.

5.3 Results of RL Training with Monolingual Data

In this subsection, we report the results on both valid and test set of RL training using bilingual and monolingual data in Zh-En translation. From Table 3 to Table 6, “RL” denotes the model trained with RL using multinomial sampling, reward shaping, no baseline reward, and combined objective, based on the observations in the last subsection. “B” denotes bilingual data, “Ms” denotes source-side monolingual data and “Mt” denotes target-side monolingual data, “&” denotes data combination.

With Source-Side Monolingual Data As discussed before, we use beam search with beam width 4 to sample the pseudo target sentence y for each monolingual sentence x. We consider several settings for RL training: 1) only source-side monolingual data; 2) the combination of bilingual and source-side monolingual data. We first train an MLE model using the augmented dataset combining the genuine bilingual data with the pseudo bilingual data generated from the monolingual data, and then perform RL training on this combined dataset. The results are shown in Table 3.

[Data] (Objective)	Valid	Test
[B] (MLE)	22.32	24.29
[B] (MLE) + [B] (RL)	22.87	25.04
[B] (MLE) + [Mt] (RL)	**22.96**	**25.15**
[B & Mt] (MLE)	24.14	25.24
[B & Mt] (MLE) + [B & Mt] (RL)	24.41	25.58

Table 4: Results with target monolingual data. “B” denotes bilingual data, “Mt” denotes target-side monolingual data, “&” denotes data combination.

[Data] (Objective)	Valid	Test
[B & Ms] (MLE)	24.31	25.31
[B & Ms] (MLE) + [B & Ms] (RL)	24.58	25.60
[B & Ms] (MLE) + [Mt] (RL)	**24.61**	**25.72**
[B & Mt] (MLE)	24.14	25.24
[B & Mt] (MLE) + [B & Mt] (RL)	24.41	25.58
[B & Mt] (MLE) + [Ms] (RL)	**24.75**	**25.92**

Table 5: Results of *sequential* approach for monolingual data. “B” denotes bilingual data, “Ms” denotes source-side monolingual data and “Mt” denotes target-side monolingual data, “&” denotes data combination.

[Data] (Objective)	Valid	Test
[B & Ms & Mt] (MLE)	25.58	26.13
+ [B & Ms & Mt] (RL)	**25.90**	**26.73**

Table 6: Results of *unified* approach for monolingual data. “+” means to initialize the RL model using above MLE model, which is trained on the combination of bilingual data, source-side monolingual data and target-side monolingual data.

With Target-Side Monolingual Data For target-side monolingual data, we first pre-train a translation model from English to Chinese [4], and use it to back translate target-side monolingual sentence y to get pseudo source sentence x. Similarly, we consider several settings for RL training: 1) only target-side monolingual data; 2) the combination of bilingual data and target-side monolingual data. We train an MLE model using both the genuine and the generated pseudo bilingual data, and then perform RL training on this data. The results are presented in Table 4.

From Table 3 and 4, we have several observations. First, monolingual data helps RL training, improving BLEU score from 25.04 to 25.22 ($\rho <$ 0.05) in Table 3. Second, when we only add monolingual data for RL training, the model achieves similar performance compared to MLE training with bilingual and monolingual data (e.g., 25.15 vs. 25.24 ($\rho <$ 0.05) in Table 4).

With both Source-Side and Target-Side Monolingual Data We have two approaches to use both source-side and target-side monolingual data, as described in subsection 4.3. The results are reported in Table 5 and Table 6.

From Table 5, we can observe that the *sequen-*

tial training of monolingual data can benefit the model performance. Taking the last three rows as an example, the BLEU score of the MLE model trained on the combination of bilingual data and target-side monolingual data is 25.24; based on this model, RL training using the source-side monolingual data further improves the model performance by 0.7 ($\rho < 0.01$) BLEU points. From Table 6, we can observe on top of a quite strong MLE baseline (26.13), through the *unified* RL training, we can still improve the test set by 0.6 points to 26.73 ($\rho < 0.01$), which shows the effectiveness of combining source/target monolingual data and reinforcement learning.

5.4 Comparison with Other Models

At last, as a summary of our empirical results, we compare several representataive end-to-end NMT systems to our work in Table 7, which includes the Transformer (Vaswani et al., 2017) model, with/without back-translation (Sennrich et al., 2015a) and the best NMT system in WMT17 Chinese-English translation challenge[5] (SougouKnowing-ensemble). The results clearly show that after combing both source-side and target-side monolingual data with RL training, we obtain the state-of-the-art BLEU score 26.73, even surpassing the best ensemble model in WMT17 Zh-En translation challenge.

6 Related Work

Our work is mainly related with the literature of using reinforcement learning to directly optimize the evaluation measure for neural machine translation. Several representative works are (Ranzato et al., 2016; Shen et al., 2016; Bahdanau et al., 2017). In (Ranzato et al., 2016), the authors propose to train a neural translation model with the objective gradually shifting from maximizing token-level likelihood to optimizing the sentence-level BLEU score. Shen et al. (2016) proposes to adopt minimum risk training (Goel and Byrne, 2000) to minimize the task specific expected loss (i.e., induced by BLEU score) on NMT training data. Instead of the REINFORCE (Williams, 1992) algorithm used in the above two works, Bahdanau et al. (2017) further optimizes the policy by actor-critic algorithm. Wu et al. (2016) introduces a simple RL based method to optimize the stacked LSTM model for NMT, achieving better BLEU scores on English-French translation but not on English-German. Edunov et al. (2017) presents a comparative study of several classical structural prediction losses for NMT model, which also includes sequence-level loss but not exactly the same as RL.

Our work is also related with the research works that leverage monolingual data for improving NMT models (Zhang and Zong, 2016; Sennrich et al., 2015a; Wang et al., 2018; Xia et al., 2016; Cheng et al., 2016). Zhang and Zong (2016) exploits the source-side monolingual data in NMT. Sennrich et al. (2015a) proposes back-translation method to leverage target-side monolingual data for NMT. Xia et al. (2016) formulates the machine translation as a communication game, which leverages the power of two directional translation models and source/target monolingual data. Cheng et al. (2016) proposes a similar semi-supervised approach. However, none of these works have explored the power of monolingual data in the context of training NMT model with reinforcement learning.

7 Conclusion

In this work, we presented a study of how to effectively train NMT models using reinforcement learning. Different RL strategies were evaluated in German-English, English-Chinese and Chinese-English translation tasks on large-scale bilingual datasets. We found that (1) multinomial sampling is better than beam search, (2) several previous tricks such as reward shaping and baseline reward does not make significant difference, and (3) the combination of the MLE and RL objectives is important. In addition, we explored the source/target monolingual data for RL training. By combing the power of RL and monolingual data, we achieve the state-of-the-art BLEU score on WMT17 Chinese-English translation task. We hope that our study and results can benefit the community and bring some insights on how to train deep NMT models with reinforcement learning and big data.

Abstract

In this paper, we propose to extend the recently introduced model-agnostic meta-learning algorithm (MAML, Finn et al., 2017) for low-resource neural machine translation (NMT). We frame low-resource translation as a meta-learning problem, and we learn to adapt to low-resource languages based on multilingual high-resource language tasks. We use the universal lexical representation (Gu et al., 2018b) to overcome the input-output mismatch across different languages. We evaluate the proposed meta-learning strategy using eighteen European languages (Bg, Cs, Da, De, El, Es, Et, Fr, Hu, It, Lt, Nl, Pl, Pt, Sk, Sl, Sv and Ru) as source tasks and five diverse languages (Ro, Lv, Fi, Tr and Ko) as target tasks. We show that the proposed approach significantly outperforms the multilingual, transfer learning based approach (Zoph et al., 2016) and enables us to train a competitive NMT system with only a fraction of training examples. For instance, the proposed approach can achieve as high as 22.04 BLEU on Romanian-English WMT'16 by seeing only 16,000 translated words (~ 600 parallel sentences).

1 Introduction

Despite the massive success brought by neural machine translation (NMT, Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017), it has been noticed that the vanilla NMT often lags behind conventional machine translation systems, such as statistical phrase-based translation systems (PBMT, Koehn et al., 2003), for low-resource language pairs (see, e.g., Koehn and Knowles, 2017). In the past few years, various approaches have been proposed to address this issue. The first attempts at tackling this problem exploited the availability of monolingual corpora (Gulcehre et al., 2015; Sennrich et al., 2015; Zhang and Zong, 2016). It was later followed by approaches based on multilingual translation, in which the goal was to exploit knowledge from high-resource language pairs by training a single NMT system on a mix of high-resource and low-resource language pairs (Firat et al., 2016a,b; Lee et al., 2016; Johnson et al., 2016; Ha et al., 2016b). Its variant, transfer learning, was also proposed by Zoph et al. (2016), in which an NMT system is pretrained on a high-resource language pair before being finetuned on a target low-resource language pair.

In this paper, we follow up on these latest approaches based on multilingual NMT and propose a meta-learning algorithm for low-resource neural machine translation. We start by arguing that the recently proposed model-agnostic meta-learning algorithm (MAML, Finn et al., 2017) could be applied to low-resource machine translation by viewing language pairs as separate tasks. This view enables us to use MAML to find the initialization of model parameters that facilitate fast adaptation for a new language pair with a minimal amount of training examples (§3). Furthermore, the vanilla MAML however cannot handle tasks with mismatched input and output. We overcome this limitation by incorporating the universal lexical representation (Gu et al., 2018b) and adapting it for the meta-learning scenario (§3.3).

We extensively evaluate the effectiveness and generalizing ability of the proposed meta-learning algorithm on low-resource neural machine translation. We utilize 17 languages from Europarl and Russian from WMT as the source tasks and test the meta-learned parameter initialization against five target languages (Ro, Lv, Fi, Tr and Ko), in all cases translating to English. Our experiments using only up to 160k tokens in each of the target task reveal that the proposed meta-learning approach outperforms the multilingual translation

Brussels, Belgium, October 31 - November 4, 2018.

approach across all the target language pairs, and the gap grows as the number of training examples decreases.

2 Background

Neural Machine Translation (NMT) Given a source sentence $X = \{x_1, ..., x_{T'}\}$, a neural machine translation model factors the distribution over possible output sentences $Y = \{y_1, ..., y_T\}$ into a chain of conditional probabilities with a left-to-right causal structure:

$$p(Y|X;\theta) = \prod_{t=1}^{T+1} p(y_t|y_{0:t-1}, x_{1:T'};\theta), \quad (1)$$

where special tokens y_0 ($\langle \mathrm{bos} \rangle$) and y_{T+1} ($\langle \mathrm{eos} \rangle$) are used to represent the beginning and the end of a target sentence. These conditional probabilities are parameterized using a neural network. Typically, an encoder-decoder architecture (Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2015) with a RNN-based decoder is used. More recently, architectures without any recurrent structures (Gehring et al., 2017; Vaswani et al., 2017) have been proposed and shown to speed up training while achieving state-of-the-art performance.

Low Resource Translation NMT is known to easily over-fit and result in an inferior performance when the training data is limited (Koehn and Knowles, 2017). In general, there are two ways for handling the problem of low resource translation: (1) utilizing the resource of unlabeled monolingual data, and (2) sharing the knowledge between low- and high-resource language pairs. Many research efforts have been spent on incorporating the monolingual corpora into machine translation, such as multi-task learning (Gulcehre et al., 2015; Zhang and Zong, 2016), back-translation (Sennrich et al., 2015), dual learning (He et al., 2016) and unsupervised machine translation with monolingual corpora only for both sides (Artetxe et al., 2017b; Lample et al., 2017; Yang et al., 2018).

For the second approach, prior researches have worked on methods to exploit the knowledge of auxiliary translations, or even auxiliary tasks. For instance, Cheng et al. (2016); Chen et al. (2017); Lee et al. (2017); Chen et al. (2018) investigate the use of a pivot to build a translation path between two languages even without any directed resource. The pivot can be a third language or even an image in multimodal domains. When pivots are not easy to obtain, Firat et al. (2016a); Lee et al. (2016); Johnson et al. (2016) have shown that the structure of NMT is suitable for multilingual machine translation. Gu et al. (2018b) also showed that such a multilingual NMT system could improve the performance of low resource translation by using a universal lexical representation to share embedding information across languages.

All the previous work for multilingual NMT assume the joint training of multiple high-resource languages naturally results in a universal space (for both the input representation and the model) which, however, is not necessarily true, especially for very low resource cases.

Meta Learning In the machine learning community, meta-learning, or learning-to-learn, has recently received interests. Meta-learning tries to solve the problem of "fast adaptation on new training data." One of the most successful applications of meta-learning has been on few-shot (or one-shot) learning (Lake et al., 2015), where a neural network is trained to readily learn to classify inputs based on only one or a few training examples. There are two categories of meta-learning:

1. learning a meta-policy for updating model parameters (see, e.g., Andrychowicz et al., 2016; Ha et al., 2016a; Mishra et al., 2017)

2. learning a good parameter initialization for fast adaptation (see, e.g., Finn et al., 2017; Vinyals et al., 2016; Snell et al., 2017).

In this paper, we propose to use a meta-learning algorithm for low-resource neural machine translation based on the second category. More specifically, we extend the idea of model-agnostic meta-learning (MAML, Finn et al., 2017) in the multilingual scenario.

3 Meta Learning for Low-Resource Neural Machine Translation

The underlying idea of MAML is to use a set of source tasks $\{\mathcal{T}^1, \ldots, \mathcal{T}^K\}$ to find the initialization of parameters θ^0 from which learning a target task $\mathcal{T}^0$ would require only a small number of training examples. In the context of machine translation, this amounts to using many high-resource language pairs to find good initial parameters and training a new translation model on a low-resource language starting from the found initial parame-

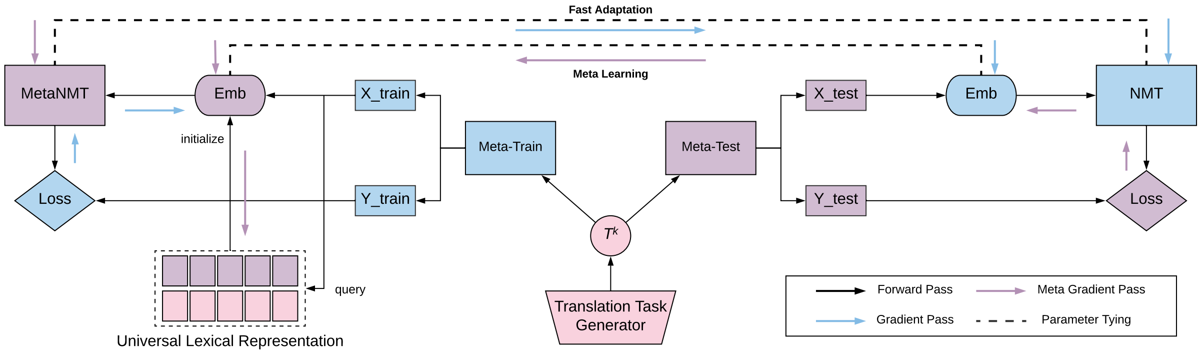

Figure 1: The graphical illustration of the training process of the proposed MetaNMT. For each episode, one task (language pair) is sampled for meta-learning. The boxes and arrows in blue are mainly involved in language-specific learning (§3.1), and those in purple in meta-learning (§3.2).

ters. This process can be understood as

$$\theta^* = \text{Learn}(\mathcal{T}^0; \text{MetaLearn}(\mathcal{T}^1, \ldots, \mathcal{T}^K)).$$

That is, we *meta-learn* the initialization from auxiliary tasks and continue to *learn* the target task. We refer the proposed meta-learning method for NMT to MetaNMT. See Fig. 1 for the overall illustration.

3.1 Learn: language-specific learning

Given any initial parameters θ^0 (which can be either random or meta-learned),

the prior distribution of the parameters of a desired NMT model can be defined as an isotropic Guassian:

$$\theta_i \sim \mathcal{N}(\theta_i^0, 1/\beta),$$

where $1/\beta$ is a variance. With this prior distribution, we formulate the language-specific learning process $\text{Learn}(D_{\mathcal{T}}; \theta^0)$ as maximizing the log-posterior of the model parameters given data $D_{\mathcal{T}}$:

$$\begin{aligned}\text{Learn}(D_{\mathcal{T}}; \theta^0) &= \arg\max_{\theta} \mathcal{L}^{D_{\mathcal{T}}}(\theta) \\ &= \arg\max_{\theta} \sum_{(X,Y)\in D_{\mathcal{T}}} \log p(Y|X,\theta) - \beta\|\theta - \theta^0\|^2,\end{aligned}$$

where we assume $p(X|\theta)$ to be uniform. The first term above corresponds to the maximum likelihood criterion often used for training a usual NMT system. The second term discourages the newly learned model from deviating too much from the initial parameters, alleviating the issue of overfitting when there is not enough training data. In practice, we solve the problem above by maximizing the first term with gradient-based optimization and early-stopping after only a few update steps. Thus, in the low-resource scenario, finding a good initialization θ^0 strongly correlates the final performance of the resulting model.

3.2 MetaLearn

We find the initialization θ^0 by repeatedly simulating low-resource translation scenarios using auxiliary, high-resource language pairs. Following Finn et al. (2017), we achieve this goal by defining the meta-objective function as

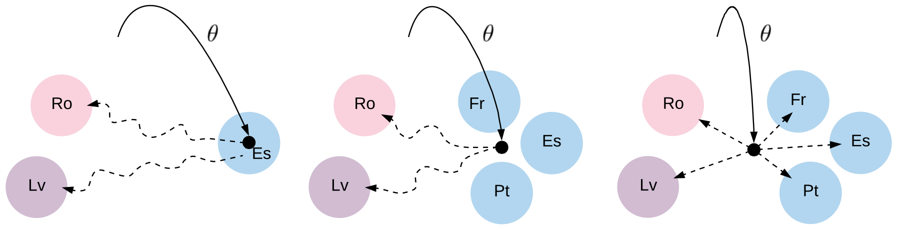
$$\begin{aligned}\mathcal{L}(\theta) =& \mathbb{E}_k \mathbb{E}_{D_{\mathcal{T}^k}, D'_{\mathcal{T}^k}} \\ &\left[\sum_{(X,Y)\in D'_{\mathcal{T}^k}} \log p(Y|X; \text{Learn}(D_{\mathcal{T}^k}; \theta)) \right],\end{aligned} \tag{2}$$

where $k \sim \mathcal{U}(\{1, \ldots, K\})$ refers to one meta-learning episode, and $D_{\mathcal{T}}$, $D'_{\mathcal{T}}$ follow the uniform distribution over $\mathcal{T}$'s data.

We maximize the meta-objective function using stochastic approximation (Robbins and Monro, 1951) with gradient descent. For each episode, we uniformly sample one source task at random, $\mathcal{T}^k$. We then sample two subsets of training examples independently from the chosen task, $D_{\mathcal{T}^k}$ and $D'_{\mathcal{T}^k}$. We use the former to *simulate* language-specific learning and the latter to *evaluate* its outcome. Assuming a single gradient step is taken only the with learning rate η, the simulation is:

$$\theta'_k = \text{Learn}(D_{\mathcal{T}^k}; \theta) = \theta - \eta \nabla_\theta \mathcal{L}^{D_{\mathcal{T}^k}}(\theta).$$

Once the simulation of learning is done, we evaluate the updated parameters θ'_k on $D'_{\mathcal{T}^k}$, The gradient computed from this evaluation, which we refer to as *meta-gradient*, is used to update the



(a) Transfer Learning (b) Multilingual Transfer Learning (c) Meta Learning

Figure 2: An intuitive illustration in which we use solid lines to represent the learning of initialization, and dashed lines to show the path of fine-tuning.

meta model θ. It is possible to aggregate multiple episodes of source tasks before updating θ:

$$\theta \leftarrow \theta - \eta' \sum_k \nabla_\theta \mathcal{L}^{D'_{\mathcal{T}^k}}(\theta'_k),$$

where η' is the meta learning rate.

Unlike a usual learning scenario, the resulting model θ^0 from this meta-learning procedure is not necessarily a good model on its own. It is however a good starting point for training a good model using only a few steps of learning. In the context of machine translation, this procedure can be understood as finding the initialization of a neural machine translation system that could quickly adapt to a new language pair by simulating such a fast adaptation scenario using many high-resource language pairs.

Meta-Gradient We use the following approximation property

$$H(x)v \approx \frac{\nabla(x + \nu v) - \nabla(x)}{\nu}$$

to approximate the meta-gradient:[1]

$$\begin{aligned}
&\nabla_\theta \mathcal{L}^{D'}(\theta') = \nabla_{\theta'} \mathcal{L}^{D'}(\theta') \nabla_\theta (\theta - \eta \nabla_\theta \mathcal{L}^{D}(\theta)) \\
&= \nabla_{\theta'} \mathcal{L}^{D'}(\theta') - \eta \nabla_{\theta'} \mathcal{L}^{D'}(\theta') H_\theta(\mathcal{L}^{D}(\theta)) \\
&\approx \nabla_{\theta'} \mathcal{L}^{D'}(\theta') - \frac{\eta}{\nu} \left[\nabla_\theta \mathcal{L}^{D}(\theta) \Big|_{\hat{\theta}} - \nabla_\theta \mathcal{L}^{D}(\theta) \Big|_{\theta} \right],
\end{aligned}$$

where ν is a small constant and

$$\hat{\theta} = \theta + \nu \nabla_{\theta'} \mathcal{L}^{D'}(\theta').$$

In practice, we find that it is also possible to ignore the second-order term, ending up with the following simplified update rule:

$$\nabla_\theta \mathcal{L}^{D'}(\theta') \approx \nabla_{\theta'} \mathcal{L}^{D'}(\theta'). \tag{3}$$

Related Work: Multilingual Transfer Learning The proposed MetaNMT differs from the existing framework of multilingual translation (Lee et al., 2016; Johnson et al., 2016; Gu et al., 2018b) or transfer learning (Zoph et al., 2016). The latter can be thought of as solving the following problem:

$$\max_\theta \mathcal{L}^{\text{multi}}(\theta) = \mathbb{E}_k \left[\sum_{(X,Y) \in D_k} \log p(Y|X;\theta) \right],$$

where D_k is the training set of the k-th task, or language pair. The target low-resource language pair could either be a part of joint training or be trained separately starting from the solution θ^0 found from solving the above problem.

The major difference between the proposed MetaNMT and these multilingual transfer approaches is that the latter do not consider how learning happens with the target, low-resource language pair. The former explicitly incorporates the learning process within the framework by simulating it repeatedly in Eq. (2). As we will see later in the experiments, this results in a substantial gap in the final performance on the low-resource task.

Illustration In Fig. 2, we contrast transfer learning, multilingual learning and meta-learning using three source language pairs (Fr-En, Es-En and Pt-En) and two target pairs (Ro-En and Lv-En). Transfer learning trains an NMT system specifically for a source language pair (Es-En) and finetunes the system for each target language pair (Ro-En, Lv-En). Multilingual learning often trains a single NMT system that can handle many different language pairs (Fr-En, Pt-En, Es-En), which may or may not include the target pairs (Ro-En, Lv-En). If not, it finetunes the system for each target pair, similarly to transfer learning. Both of these however aim at directly solving the source tasks. On the other hand, meta-learning trains the NMT system to be *useful for fine-tuning* on various tasks including the source and target tasks. This is done by repeatedly simulating the learning process on

---

[1] We omit the subscript k for simplicity.

low-resource languages using many high-resource language pairs (Fr-En, Pt-En, Es-En).

3.3 Unified Lexical Representation

I/O mismatch across language pairs One major challenge that limits applying meta-learning for low resource machine translation is that the approach outlined above assumes the input and output spaces are shared across all the source and target tasks. This, however, does not apply to machine translation in general due to the vocabulary mismatch across different languages. In multilingual translation, this issue has been tackled by using a vocabulary of sub-words (Sennrich et al., 2015) or characters (Lee et al., 2016) shared across multiple languages. This surface-level sharing is however limited, as it cannot be applied to languages exhibiting distinct orthography (e.g., Indo-Euroepan languages vs. Korean.)

Universal Lexical Representation (ULR) We tackle this issue by dynamically building a vocabulary specific to each language using a key-value memory network (Miller et al., 2016; Gulcehre et al., 2018), as was done successfully for low-resource machine translation recently by Gu et al. (2018b). We start with multilingual word embedding matrices $\epsilon^k_{\text{query}} \in \mathbb{R}^{|V_k| \times d}$ pretrained on large monolingual corpora, where V_k is the vocabulary of the k-th language. These embedding vectors can be obtained with small dictionaries of seed word pairs (Artetxe et al., 2017a; Smith et al., 2017) or in a fully unsupervised manner (Zhang et al., 2017; Conneau et al., 2018). We take one of these languages k' to build universal lexical representation consisting of a universal embedding matrix $\epsilon_u \in \mathbb{R}^{M \times d}$ and a corresponding key matrix $\epsilon_{\text{key}} \in \mathbb{R}^{M \times d}$, where $M < |V'_k|$. Both $\epsilon^k_{\text{query}}$ and ϵ_{key} are fixed during meta-learning. We then compute the language-specific embedding of token x from the language k as the convex sum of the universal embedding vectors by

$$\epsilon^0[x] = \sum_{i=1}^{M} \alpha_i \epsilon_u[i],$$

where $\alpha_i \propto \exp\left\{-\frac{1}{\tau}\epsilon_{\text{key}}[i]^\top A \epsilon^k_{\text{query}}[x]\right\}$ and τ is set to 0.05. This approach allows us to handle languages with different vocabularies using a fixed number of shared parameters (ϵ_u, ϵ_{key} and A.)

Learning of ULR It is not desirable to update the universal embedding matrix ϵ_u when fine-tuning on a small corpus which contains a limited set of unique tokens in the target language, as it could adversely influence the other tokens' embedding vectors. We thus estimate the change to each embedding vector induced by language-specific learning by a separate parameter $\Delta\epsilon^k[x]$:

$$\epsilon^k[x] = \epsilon^0[x] + \Delta\epsilon^k[x].$$

During language-specific learning, the ULR $\epsilon^0[x]$ is held constant, while only $\Delta\epsilon^k[x]$ is updated, starting from an all-zero vector. On the other hand, we hold $\Delta\epsilon^k[x]$'s constant while updating ϵ_u and A during the meta-learning stage.

	# of sents.	# of En tokens	Dev	Test
Ro-En	0.61 M	16.66 M	–	31.76
Lv-En	4.46 M	67.24 M	20.24	15.15
Fi-En	2.63 M	64.50 M	17.38	20.20
Tr-En	0.21 M	5.58 M	15.45	13.74
Ko-En	0.09 M	2.33 M	6.88	5.97

Table 1: Statistics of full datasets of the target language pairs. BLEU scores on the dev and test sets are reported from a supervised Transformer model with the same architecture.

4 Experimental Settings

4.1 Dataset

Target Tasks We show the effectiveness of the proposed meta-learning method for low resource NMT with extremely limited training examples on five diverse target languages: Romanian (Ro) from WMT'16,[2] Latvian (Lv), Finnish (Fi), Turkish (Tr) from WMT'17,[3] and Korean (Ko) from Korean Parallel Dataset.[4] We use the officially provided train, dev and test splits for all these languages. The statistics of these languages are presented in Table 1. We simulate the low-resource translation scenarios by randomly sub-sampling the training set with different sizes.

Source Tasks We use the following languages from Europarl[5]: Bulgarian (Bg), Czech (Cs), Danish (Da), German (De), Greek (El), Spanish (Es), Estonian (Et), French (Fr), Hungarian (Hu), Italian (It), Lithuanian (Lt), Dutch (Nl), Polish (Pl), Portuguese (Pt), Slovak (Sk), Slovene (Sl) and

Figure 3: BLEU scores reported on test sets for {Ro, Lv, Fi, Tr} to En, where each model is first learned from 6 source tasks (Es, Fr, It, Pt, De, Ru) and then fine-tuned on randomly sampled training sets with around 16,000 English tokens per run. The error bars show the standard deviation calculated from 5 runs.

Swedish (Sv), in addition to Russian (Ru)[6] to learn the intilization for fine-tuning. In our experiments, different combinations of source tasks are explored to see the effects from the source tasks.

Validation We pick either Ro-En or Lv-En as a validation set for meta-learning and test the generalization capability on the remaining target tasks. This allows us to study the strict form of meta-learning, in which target tasks are unknown during both training and model selection.

Preprocessing and ULR Initialization As described in §3.3, we initialize the query embedding vectors $\epsilon^k_{\text{query}}$ of all the languages. For each language, we use the monolingual corpora built from Wikipedia[7] and the parallel corpus. The concatenated corpus is first tokenized and segmented using byte-pair encoding (BPE, Sennrich et al., 2016), resulting in $40,000$ subwords for each language. We then estimate word vectors using fastText (Bojanowski et al., 2016) and align them across all the languages in an unsupervised way using MUSE (Conneau et al., 2018) to get multilingual word vectors. We use the multilingual word vectors of the 20,000 most frequent words in English to form the universal embedding matrix ϵ_u.

4.2 Model and Learning

Model We utilize the recently proposed Transformer (Vaswani et al., 2017) as an underlying NMT system. We implement Transformer in this paper based on (Gu et al., 2018a)[8] and modify it to use the universal lexical representation from §3.3. We use the default set of hyperparameters ($d_{\text{model}} = d_{\text{hidden}} = 512$, $n_{\text{layer}} = 6$, $n_{\text{head}} = 8$, $n_{\text{batch}} = 4000$, $t_{\text{warmup}} = 16000$) for all the language pairs and across all the experimental settings. We refer the readers to (Vaswani et al., 2017; Gu et al., 2018a) for the details of the model. However, since the proposed meta-learning method is model-agnostic, it can be easily extended to any other NMT architectures, e.g. RNN-based sequence-to-sequence models with attention (Bahdanau et al., 2015).

Table 2: BLEU Scores w.r.t. the source task set for all five target tasks.

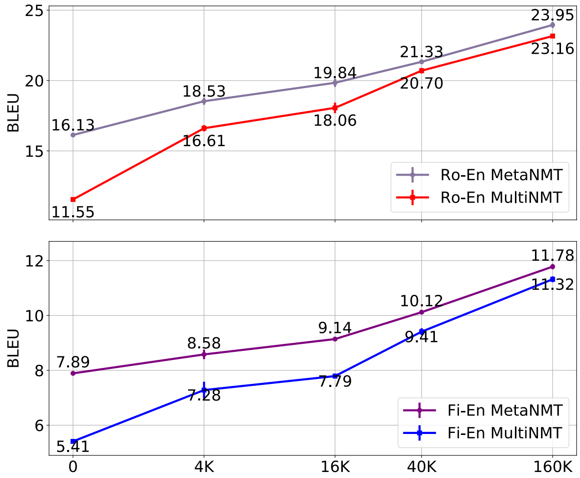

Figure 4: BLEU Scores w.r.t. the size of the target task's training set.

Learning We meta-learn using various sets of source languages to investigate the effect of source task choice. For each episode, by default, we use a single gradient step of language-specific learning with Adam (Kingma and Ba, 2014) per computing the meta-gradient, which is computed by the first-order approximation in Eq. (3).

For each target task, we sample training examples to form a low-resource task. We build tasks of 4k, 16k, 40k and 160k English tokens for each language. We randomly sample the training set five times for each experiment and report the average score and its standard deviation. Each fine-tuning is done on a training set, early-stopped on a validation set and evaluated on a test set. In default without notation, datasets of 16k tokens are used.

Fine-tuning Strategies The transformer consists of three modules; embedding, encoder and decoder. We update all three modules during meta-learning, but during fine-tuning, we can selectively tune only a subset of these modules. Following (Zoph et al., 2016), we consider three fine-tuning strategies; (1) fine-tuning all the modules (all), (2) fine-tuning the embedding and encoder, but freezing the parameters of the decoder (emb+enc) and (3) fine-tuning the embedding only (emb).

5 Results

vs. Multilingual Transfer Learning We meta-learn the initial models on all the source tasks using either Ro-En or Lv-En as a validation task. We also train the initial models to be multilingual translation systems. We fine-tune them using the four target tasks (Ro-En, Lv-En, Fi-En and Tr-En; 16k tokens each) and compare the proposed meta-learning strategy and the multilingual, transfer learning strategy. As presented in Fig. 3, the proposed learning approach significantly outperforms the multilingual, transfer learning strategy across all the target tasks regardless of which target task was used for early stopping. We also notice that the emb+enc strategy is most effective for both meta-learning and transfer learning approaches. With the proposed meta-learning and emb+enc fine-tuning, the final NMT systems trained using only a fraction of all available training examples achieve 2/3 (Ro-En) and 1/2 (Lv-En, Fi-En and Tr-En) of the BLEU score achieved by the models trained with full training sets.

vs. Statistical Machine Translation We also test the same Ro-En datasets with $16,000$ target tokens using the default setting of Phrase-based MT (Moses) with the dev set for adjusting the parameters and the test set for calculating the final performance. We obtain $4.79(\pm 0.234)$ BLEU point, which is higher than the standard NMT performance (0 BLEU). It is however still lower than both the multi-NMT and meta-NMT.

Impact of Validation Tasks Similarly to training any other neural network, meta-learning still requires early-stopping to avoid overfitting to a specific set of source tasks. In doing so, we observe that the choice of a validation task has non-negligible impact on the final performance. For instance, as shown in Fig. 3, Fi-En benefits more when Ro-En is used for validation, while the opposite happens with Tr-En. The relationship between the task similarity and the impact of a validation task must be investigated further in the future.

Training Set Size We vary the size of the target task's training set and compare the proposed meta-learning strategy and multilingual, transfer learning strategy. We use the emb+enc fine-tuning on Ro-En and Fi-En. Fig. 4 demonstrates that the meta-learning approach is more robust to the drop in the size of the target task's training set. The gap between the meta-learning and transfer learning grows as the size shrinks, confirming the effectiveness of the proposed approach on extremely low-resource language pairs.

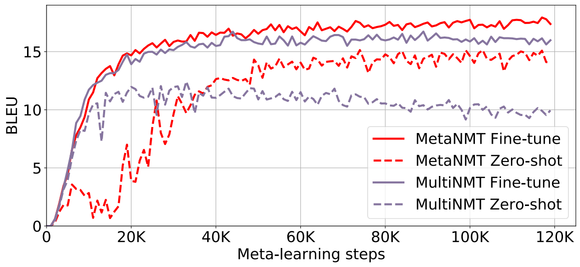

Figure 5: The learning curves of BLEU scores on the validation task (Ro-En).

Impact of Source Tasks In Table 2, we present the results on all five target tasks obtained while varying the source task set. We first see that it is always beneficial to use more source tasks. Although the impact of adding more source tasks varies from one language to another, there is up to 2× improvement going from one source task to 18 source tasks (Lv-En, Fi-En, Tr-En and Ko-En). The same trend can be observed even without any fine-tuning (i.e., unsupervised translation, (Lample et al., 2017; Artetxe et al., 2017b)). In addition, the choice of source languages has different implications for different target languages. For instance, Ro-En benefits more from $\{$Es, Fr, It, Pt$\}$ than from $\{$De, Ru$\}$, while the opposite effect is observed with all the other target tasks.

Training Curves The benefit of meta-learning over multilingual translation is clearly demonstrated when we look at the training curves in Fig. 5. With the multilingual, transfer learning approach, we observe that training rapidly saturates and eventually degrades, as the model overfits to the source tasks. MetaNMT on the other hand continues to improve and never degrades, as the meta-objective ensures that the model is adequate for fine-tuning on target tasks rather than for solving the source tasks.

Sample Translations We present some sample translations from the tested models in Table 3. Inspecting these examples provides the insight into the proposed meta-learning algorithm. For instance, we observe that the meta-learned model without any fine-tuning produces a word-by-word translation in the first example (Tr-En), which is due to the successful use of the universal lexcial representation and the meta-learned initialization. The system however cannot reorder tokens from Turkish to English, as it has not seen any training example of Tr-En. After seeing around 600 sentence pairs (16K English tokens), the model rapidly learns to correctly reorder tokens to form a better translation. A similar phenomenon is observed in the Ko-En example. These cases could be found across different language pairs.

6 Conclusion

In this paper, we proposed a meta-learning algorithm for low-resource neural machine translation that exploits the availability of high-resource languages pairs. We based the proposed algorithm on the recently proposed model-agnostic meta-learning and adapted it to work with multiple languages that do not share a common vocabulary using the technique of universal lexcal representation, resulting in MetaNMT. Our extensive evaluation, using 18 high-resource source tasks and 5 low-resource target tasks, has shown that the proposed MetaNMT significantly outperforms the existing approach of multilingual, transfer learning in low-resource neural machine translation across all the language pairs considered.

The proposed approach opens new opportunities for neural machine translation. First, it is a principled framework for incorporating various extra sources of data, such as source- and target-side monolingual corpora. Second, it is a generic framework that can easily accommodate existing and future neural machine translation systems.

Abstract

While modern machine translation has relied on large parallel corpora, a recent line of work has managed to train Neural Machine Translation (NMT) systems from monolingual corpora only (Artetxe et al., 2018c; Lample et al., 2018). Despite the potential of this approach for low-resource settings, existing systems are far behind their supervised counterparts, limiting their practical interest. In this paper, we propose an alternative approach based on phrase-based Statistical Machine Translation (SMT) that significantly closes the gap with supervised systems. Our method profits from the modular architecture of SMT: we first induce a phrase table from monolingual corpora through cross-lingual embedding mappings, combine it with an n-gram language model, and fine-tune hyperparameters through an unsupervised MERT variant. In addition, iterative backtranslation improves results further, yielding, for instance, 14.08 and 26.22 BLEU points in WMT 2014 English-German and English-French, respectively, an improvement of more than 7-10 BLEU points over previous unsupervised systems, and closing the gap with supervised SMT (Moses trained on Europarl) down to 2-5 BLEU points. Our implementation is available at `https://github.com/artetxem/monoses`.

1 Introduction

Neural Machine Translation (NMT) has recently become the dominant paradigm in machine translation (Vaswani et al., 2017). In contrast to more rigid Statistical Machine Translation (SMT) architectures (Koehn et al., 2003), NMT models are trained end-to-end, exploit continuous representations that mitigate the sparsity problem, and overcome the locality problem by making use of unconstrained contexts. Thanks to this additional flexibility, NMT can more effectively exploit large parallel corpora, although SMT is still superior when the training corpus is not big enough (Koehn and Knowles, 2017).

Somewhat paradoxically, while most machine translation research has focused on resource-rich settings where NMT has indeed superseded SMT, a recent line of work has managed to train an NMT system without any supervision, relying on monolingual corpora alone (Artetxe et al., 2018c; Lample et al., 2018). Given the scarcity of parallel corpora for most language pairs, including less-resourced languages but also many combinations of major languages, this research line opens exciting opportunities to bring effective machine translation to many more scenarios. Nevertheless, existing solutions are still far behind their supervised counterparts, greatly limiting their practical usability. For instance, existing unsupervised NMT systems obtain between 15-16 BLEU points in WMT 2014 English-French translation, whereas a state-of-the-art NMT system obtains around 41 (Artetxe et al., 2018c; Lample et al., 2018; Yang et al., 2018).

In this paper, we explore whether the rigid and modular nature of SMT is more suitable for these unsupervised settings, and propose a novel unsupervised SMT system that can be trained on monolingual corpora alone. For that purpose, we present a natural extension of the skip-gram model (Mikolov et al., 2013b) that simultaneously learns word and phrase embeddings, which are then mapped to a cross-lingual space through self-learning (Artetxe et al., 2018b). We use the resulting cross-lingual phrase embeddings to induce a phrase table, and combine it with a language model and a distance-based distortion model to build a standard phrase-based SMT system. The weights of this model are tuned in an unsupervised manner through an iterative Minimum Error Rate Training (MERT) variant, and the entire system

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3632–3642
Brussels, Belgium, October 31 - November 4, 2018.

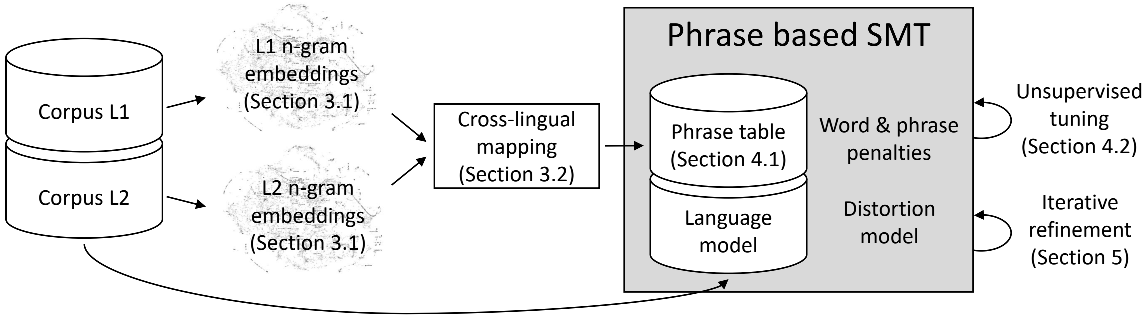

Figure 1: Architecture of our system, with references to sections.

is further improved through iterative backtranslation. The architecture of the system is sketched in Figure 1. Our experiments on WMT German-English and French-English datasets show the effectiveness of our proposal, where we obtain improvements above 7-10 BLEU points over previous unsupervised NMT-based approaches, closing the gap with supervised SMT (Moses trained on Europarl) down to 2-5 points.

The remaining of this paper is structured as follows. Section 2 introduces phrase-based SMT. Section 3 presents our unsupervised approach to learn cross-lingual n-gram embeddings, which are the basis of our proposal. Section 4 describes the proposed unsupervised SMT system itself, while Section 5 discusses its iterative refinement through backtranslation. Section 6 describes the experiments run and the results obtained. Section 7 discusses the related work on the topic, and Section 8 concludes the paper.

2 Background: phrase-based SMT

While originally motivated as a noisy channel model (Brown et al., 1990), phrase-based SMT is now formulated as a log-linear combination of several statistical models that score translation candidates (Koehn et al., 2003). The parameters of these scoring functions are estimated independently based on frequency counts, and their weights are then tuned in a separate validation set. At inference time, a decoder tries to find the translation candidate with the highest score according to the resulting combined model. The specific scoring models found in a standard SMT system are as follows:

- **Phrase table**. The phrase table is a collection of source language n-grams and a list of their possible translations in the target language along with different scores for each of them. So as to translate longer sequences, the decoder combines these partial n-gram translations, and ranks the resulting candidates according to their corresponding scores and the rest of scoring functions. In order to build the phrase table, SMT computes word alignments in both directions from a parallel corpus, symmetrizes these alignments using different heuristics (Och and Ney, 2003), extracts the set of consistent phrase pairs, and scores them based on frequency counts. For that purpose, standard SMT uses 4 scores for each phrase table entry: the direct and inverse lexical weightings, which are derived from word level alignments, and the direct and inverse phrase translation probabilities, which are computed at the phrase level.

- **Language model**. The language model assigns a probability to a word sequence in the target language. Traditional SMT uses n-gram language models for that, which use simple frequency counts over a large monolingual corpus with back-off and smoothing.

- **Reordering model**. The reordering model accounts for different word orders across languages, scoring translation candidates according to the position of each translated phrase in the target language. Standard SMT combines two such models: a distance based distortion model that penalizes deviation from a monotonic order, and a lexical reordering model that incorporates phrase orientation frequencies from a parallel corpus.

- **Word and phrase penalties**. The word and phrase penalties assign a fixed score to every generated word and phrase, and are useful to control the length of the output text and the preference for shorter or longer phrases.

Having trained all these different models, a tuning process is applied to optimize their weights in the resulting log-linear model, which typically maximizes some evaluation metric in a separate validation parallel corpus. A common choice is to optimize the BLEU score through Minimum Error Rate Training (MERT) (Och, 2003).

3 Cross-lingual n-gram embeddings

Section 3.1 presents our proposed extension of skip-gram to learn n-gram embeddings, while Section 3.2 describes how we map them to a shared space to obtain cross-lingual n-gram embeddings.

3.1 Learning n-gram embeddings

Negative sampling skip-gram takes word-context pairs (w, c), and uses logistic regression to predict whether the pair comes from the true distribution as sampled from the training corpus, or it is one of the k draws from a noise distribution (Mikolov et al., 2013b):

$$\log \sigma (w \cdot c) + \sum_{i=1}^{k} \mathbb{E}_{c_N \sim P_D} \left[\log \sigma (-w \cdot c_N) \right]$$

In its basic formulation, both w and c correspond to words that co-occur within a certain window in the training corpus. So as to learn embeddings for non-compositional phrases like *New York Times* or *Toronto Maple Leafs*, Mikolov et al. (2013b) propose to merge them into a single token in a pre-processing step. For that purpose, they use a scoring function based on their co-occurence frequency in the training corpus, with a discounting coefficient δ that penalizes rare words, and iteratively merge those above a threshold:

$$\text{score}(w_i, w_j) = \frac{\text{count}\,(w_i, w_j) - \delta}{\text{count}\,(w_i) \times \text{count}\,(w_j)}$$

However, we also need to learn representations for compositional n-grams in our scenario, as there is not always a 1:1 correspondence for n-grams across languages even for compositional phrases. For instance, the phrase *he will come* would typically be translated as *vendrá* into Spanish, so one would need to represent the entire phrase as a single unit to properly model this relation.

One option would be to merge all n-grams regardless of their score, but this is not straightforward given their overlapping nature, which is further accentuated when considering n-grams of different lengths. While we tried to randomly generate multiple consistent segmentations for each sentence and train the embeddings over the resulting corpus, this worked poorly in our preliminary experiments. We attribute this to the complex interactions arising from the stochastic segmentation (e.g. the co-occurrence distribution changes radically, even for unigrams), severely accentuating the sparsity problem, among other issues.

As an alternative approach, we propose a generalization of skip-gram that learns n-gram embeddings on-the-fly, and has the desirable property of unigram invariance: our proposed model learns the exact same embeddings as the original skip-gram for unigrams, while simultaneously learning additional embeddings for longer n-grams. This way, for each word-context pair (w, c) at distance d within the given window, we update their corresponding embeddings w and c with the usual negative sampling loss. In addition to that, we look at all n-grams p of different lengths that are at the same distance d, and for each pair (p, c), we update the embedding p through negative sampling. In order to enforce unigram invariance, the context c and negative samples c_N, which always correspond to unigrams, are not updated for (p, c). This allows to naturally learn n-gram embeddings according to their co-occurrence patterns as modeled by skip-gram, without introducing subtle interactions that affect its fundamental behavior.

We implemented the above procedure as an extension of *word2vec*, and use it to train monolingual n-gram embeddings with a window size of 5, 300 dimensions, 10 negative samples, 5 iterations and subsampling disabled. So as to keep the model size within a reasonable limit, we restrict the vocabulary to the most frequent 200,000 unigrams, 400,000 bigrams and 400,000 trigrams.

3.2 Cross-lingual mapping

Cross-lingual mapping methods take independently trained word embeddings in two languages, and learn a linear transformation to map them to a shared cross-lingual space (Mikolov et al., 2013a; Artetxe et al., 2018a). Most mapping methods are supervised, and rely on a bilingual dictionary, typically in the range of a few thousand entries, although a recent line of work has managed to achieve comparable results in a fully unsupervised manner based on either self-learning (Artetxe et al., 2017, 2018b) or adversarial training (Zhang et al., 2017a,b; Conneau et al., 2018).

In our case, we use the method of Artetxe et al.

(2018b) to map the n-gram embeddings to a shared cross-lingual space using their open source implementation VecMap[1]. Originally designed for word embeddings, this method builds an initial mapping by connecting the intra-lingual similarity distribution of embeddings in different languages, and iteratively improves this solution through self-learning. The method applies a frequency-based vocabulary cut-off, learning the mapping over the 20,000 most frequent words in each language. We kept this cut-off to learn the mapping over the most frequent 20,000 unigrams, and then apply the resulting mapping to the entire embedding space, including longer n-grams.

4 Unsupervised SMT

As discussed in Section 2, phrase-based SMT follows a modular architecture that combines several scoring functions through a log-linear model. Among the scoring functions found in standard SMT systems, the distortion model and word/phrase penalties are parameterless, while the language model is trained on monolingual corpora, so they can all be directly integrated into our unsupervised system. From the remaining models, typically trained on parallel corpora, we decide to leave the lexical reordering out, as the distortion model already accounts for word reordering. As for the phrase table, we learn cross-lingual n-gram embeddings as discussed in Section 3, and use them to induce and score phrase translation pairs as described next (Section 4.1). Finally, we tune the weights of the resulting log-linear model using an unsupervised procedure based on back-translation (Section 4.2).

Unless otherwise specified, we use Moses[2] with default hyperparameters to implement these different components of our system. We use KenML (Heafield et al., 2013), bundled in Moses by default, to estimate our 5-gram language model with modified Kneser-Ney smoothing, pruning n-grams longer than 3 with a single occurrence.

4.1 Phrase table induction

Given the lack of a parallel corpus from which to **extract phrase translation pairs**, every n-gram in the target language could be taken as a potential translation candidate for each n-gram in the source language. So as to keep the size of the phrase table within a reasonable limit, we train cross-lingual phrase embeddings as described in Section 3, and limit the translation candidates for each source phrase to its 100 nearest neighbors in the target language.

In order to estimate their corresponding **phrase translation probabilities**, we apply the softmax function over the cosine similarities of their respective embeddings. More concretely, given the source language phrase $\bar{e}$ and the translation candidate $\bar{f}$, their direct phrase translation probability is computed as follows[3]:

$$\phi(\bar{f}|\bar{e}) = \frac{\cos(\bar{e}, \bar{f})/\tau}{\sum_{\bar{f}'} \cos(\bar{e}, \bar{f}')/\tau}$$

Note that, in the above formula, $\bar{f}'$ iterates across all target language embeddings, and τ is a constant temperature parameter that controls the confidence of the predictions. In order to tune it, we induce a dictionary over the cross-lingual embeddings themselves with nearest neighbor retrieval, and use maximum likelihood estimation over it. However, inducing the dictionary in the same direction as the probability predictions leads to a degenerated solution (softmax approximates the hard maximum underlying nearest neighbor as τ approaches 0), so we induce the dictionary in the opposite direction and apply maximum likelihood estimation over it:

$$\min_{\tau} \sum_{\bar{f}} \log \phi(\bar{f}|\,\mathrm{NN}_{\bar{e}}(\bar{f})) + \sum_{\bar{e}} \log \phi(\bar{e}|\,\mathrm{NN}_{\bar{f}}(\bar{e}))$$

So as to optimize τ, we use Adam with a learning rate of 0.0003 and a batch size of 200, implemented in PyTorch.

In order to compute the **lexical weightings**, we align each word in the target phrase with the one in the source phrase most likely generating it, and take the product of their respective translation probabilities:

$$\mathrm{lex}(\bar{f}|\bar{e}) = \prod_i \max\left(\epsilon, \max_j w(\bar{f}_i|\bar{e}_j)\right)$$

The constant ϵ guarantees that each target language word will get a minimum probability mass, which is useful to model NULL alignments. In our experiments, we set $\epsilon = 0.001$, which we find to

[3] The inverse phrase translation probability $\phi(\bar{e}|\bar{f})$ is defined analogously.

Algorithm 1 Unsupervised tuning

```
Input: $m_{s \to t}$ (source-to-target models)
Input: $m_{t \to s}$ (target-to-source models)
Input: $c_s$ (source validation corpus)
Input: $c_t$ (target validation corpus)
Output: $w_{s \to t}$ (source-to-target weights)
Output: $w_{t \to s}$ (target-to-source weights)
$w_{t \to s} \leftarrow$ DEFAULT_WEIGHTS
repeat
    $bt_s \leftarrow$ TRANSLATE($m_{t \to s}$, $w_{t \to s}$, $c_t$)
    $w_{s \to t} \leftarrow$ MERT($m_{s \to t}$, $bt_s$, $c_t$)
    $bt_t \leftarrow$ TRANSLATE($m_{s \to t}$, $w_{s \to t}$, $c_s$)
    $w_{t \to s} \leftarrow$ MERT($m_{t \to s}$, $bt_t$, $c_s$)
until convergence
```

work well in practice. Finally, the word translation probabilities $w(\bar{f}_i|\bar{e}_j)$ are computed using the same formula defined for phrase translation probabilities (see above), with the difference that the partition function goes over unigrams only.

4.2 Unsupervised tuning

As discussed in Section 2, standard SMT uses MERT over a small parallel corpus to tune the weights of the different scoring functions combined through its log-linear model. Given that we only have access to monolingual corpora in our scenario, we propose to generate a synthetic parallel corpus through backtranslation (Sennrich et al., 2016) and apply MERT tuning over it, iteratively repeating the process in both directions (see Algorithm 1). For that purpose, we reserve a random subset of 10,000 sentences from each monolingual corpora, and run the proposed algorithm over them for 10 iterations, which we find to be enough for convergence.

5 Iterative refinement

The procedure described in Section 4 suffices to train an SMT system from monolingual corpora which, as shown by our experiments in Section 6, already outperforms previous unsupervised systems. Nevertheless, our proposed method still makes important simplifications that could compromise its potential performance: it does not use any lexical reordering model, its phrase table is limited by the underlying embedding vocabulary (e.g. it does not include phrases longer than trigrams, see Section 3.1), and the phrase translation probabilities and lexical weightings are estimated based on cross-lingual embeddings.

Algorithm 2 Iterative refinement

```
Input: $c_s$ (source language corpus)
Input: $c_t$ (target language corpus)
Input/Output: $m_{t \to s}$ (target-to-source models)
Input/Output: $w_{t \to s}$ (target-to-source weights)
Output: $m_{s \to t}$ (source-to-target models)
Output: $w_{s \to t}$ (source-to-target weights)
$train_s, val_s \leftarrow$ SPLIT($c_s$)
$train_t, val_t \leftarrow$ SPLIT($c_t$)
repeat
    $btt_s \leftarrow$ TRANSLATE($m_{t \to s}$, $w_{t \to s}$, $train_t$)
    $btv_s \leftarrow$ TRANSLATE($m_{t \to s}$, $w_{t \to s}$, $val_t$)
    $m_{s \to t} \leftarrow$ TRAIN($btt_s$, $train_t$)
    $w_{s \to t} \leftarrow$ MERT($m_{s \to t}$, $btv_s$, $val_t$)
    $btt_t \leftarrow$ TRANSLATE($m_{s \to t}$, $w_{s \to t}$, $train_s$)
    $btv_t \leftarrow$ TRANSLATE($m_{s \to t}$, $w_{s \to t}$, $val_s$)
    $m_{t \to s} \leftarrow$ TRAIN($btt_t$, $train_s$)
    $w_{t \to s} \leftarrow$ MERT($m_{t \to s}$, $btv_t$, $val_s$)
until convergence
```

In order to overcome these limitations, we propose an iterative refinement procedure based on backtranslation (Sennrich et al., 2016). More concretely, we generate a synthetic parallel corpus by translating the monolingual corpus in one of the languages with the initial system, and train and tune a standard SMT system over it in the opposite direction. Note that this new system does not have any of the initial restrictions: the phrase table is built and scored using standard word alignment with an unconstrained vocabulary, and a lexical reordering model is also learned. Having done that, we use the resulting system to translate the monolingual corpus in the other language, and train another SMT system over it in the other direction. As detailed in Algorithm 2, this process is repeated iteratively until some convergence criterion is met.

While this procedure would be expected to produce a more accurate model at each iteration, it also happens to be very expensive computationally. In order to accelerate our experiments, we use a random subset of 2 million sentences from each monolingual corpus for training[4], in addition to the 10,000 separate sentences that are held out as a validation set for MERT tuning, and perform a fixed number of 3 iterations of the above algorithm. Moreover, we use FastAlign (Dyer et al., 2013) instead of GIZA++ to make word alignment faster. Other than that, training over the synthetic

---

[4] Note that we reuse the original language model, which is trained in the full corpus.

parallel corpus is done through standard Moses tools with default settings.

6 Experiments and results

In order to make our experiments comparable to previous work, we use the French-English and German-English datasets from the WMT 2014 shared task. As discussed throughout the paper, our system is trained on monolingual corpora alone, so we take the concatenation of all News Crawl monolingual corpora from 2007 to 2013 as our training data, which we tokenize and truecase using standard Moses tools. The resulting corpus has 749 million tokens in French, 1,606 million tokens in German, and 2,109 million tokens in English. Following common practice, the systems are evaluated in newstest2014 using tokenized BLEU scores as computed by the `multi-bleu.perl` script included in Moses. In addition to that, we also report results in German-English newstest2016 (from WMT 2016), as this was used by some previous work in unsupervised NMT (Lample et al., 2018; Yang et al., 2018)[5]. So as to be faithful to our target scenario, we did not use any parallel data in these language pairs, not even for development purposes. Instead, we ran all our preliminary experiments on WMT Spanish-English data, where we made all development decisions.

We present the results of our final system in comparison to other previous work in Section 6.1. Section 6.2 then presents an ablation study of our proposed method, where we analyze the contribution of its different components. Section 6.3 compares the obtained results to those of different supervised systems, analyzing the effect of some of the inherent limitations of our method in a standard phrase-based SMT system. Finally, Section 6.4 presents some translation examples from our system.

6.1 Main results

We report the results obtained by our proposed system in Table 1. As it can be seen, our system obtains the best published results by a large margin, surpassing previous unsupervised NMT systems by around 10 BLEU points in French-English (both directions), and more than 7 BLEU points in German-English (both directions and datasets).

This way, while previous progress in the task has been rather incremental (Yang et al., 2018), our work represents an important step towards high-quality unsupervised machine translation, with improvements over 50% in all cases. This suggests that, in contrast to previous NMT-based approaches, phrase-based SMT may provide a more suitable framework for unsupervised machine translation, which is in line with previous results in low-resource settings (Koehn and Knowles, 2017).

6.2 Ablation analysis

We present ablation results of our proposed system in Table 2. The first row corresponds to the initial system with our induced phrase table (Section 4.1) and default weights as used by Moses, whereas the second row uses our unsupervised MERT procedure to tune these weights (Section 4.2). The remaining rows represent different iterations of our refinement procedure (Section 5), which uses backtranslation to iteratively train a standard SMT system from a synthetic parallel corpus.

The results show that the initial system with default weights (first row) is already better than previous unsupervised NMT systems (Table 1) by a substantial margin (2-6 BLEU points). Our unsupervised tuning procedure further improves results, bringing an improvement of over 1 BLEU

---

[5] Note that we use the same model trained in WMT 2014 for these experiments, so it is likely that our results could be further improved by using the more extensive data from WMT 2016.

point in both French-English directions, although its contribution is somewhat weaker for German-to-English (almost 1 BLEU point in WMT 2014 but only 0.2 in WMT 2016), and does not make any difference for English-to-German.

The proposed iterative refinement method has a much stronger positive effect, with improvements over 2.5 BLEU points in all cases, and up to 5 BLEU points in some. Most gains come in the first iteration, while the second iteration brings weaker improvements and the algorithm seems to converge in the third iteration, with marginal improvements for German-English and a small drop in performance for French-English.

6.3 Comparison with supervised systems

So as to put our results into perspective, Table 3 comprises the results of different supervised methods in the same test sets. More concretely, we report the results of the Transformer (Vaswani et al., 2017), an NMT system based on self-attention that is the current state-of-the-art in machine translation, along with the scores obtained by the best performing system in each WMT shared task at the time, and those of a standard phrase-based SMT system trained on Europarl and tuned on newstest2013 using Moses. We also report the effect of removing lexical reordering from the latter as we do in our initial system (Section 4), restricting the vocabulary to the most frequent unigram, bigram and trigrams as we do when training our embeddings (Section 3), and using our unsupervised tuning procedure over a subset of the monolingual corpus (Section 4.2) instead of using standard MERT tuning over newstest2013.

Quite surprisingly, our proposed system, trained exclusively on monolingual corpora, is relatively close to a comparable phrase-based SMT system trained on Europarl, with differences below 5 BLEU points in all cases and as little as 2.5 in some. Note that both systems use the exact same language model trained on News Crawl, making them fully comparable in terms of the monolingual corpora they have access to. While more of a baseline than the state-of-the-art, note that Moses+Europarl is widely used as a reference system in machine translation. As such, we think that our results are very encouraging, as they show

Table 4: Randomly chosen translation examples from French→English newstest2014.

that our fully unsupervised system is already quite close to this competitive baseline.

In addition to that, the results for the constrained variants of this SMT system justify some of the simplifications required by our approach. In particular, removing lexical reordering and constraining the phrase table to the most frequent n-grams, as we do for our initial system, has a relatively small effect, with a drop of less than 1 BLEU point in all cases, and as little as 0.28 in some. Replacing standard MERT tuning with our unsupervised variant does cause a considerable drop in performance, although it is below 2.5 BLEU points even in the worst case, and our unsupervised tuning method is still better than using default weights as reported in Table 2. This shows the importance of tuning in SMT, suggesting that these results could be further improved if one had access to a small parallel corpus for tuning.

6.4 Qualitative results

Table 4 shows some of the translations produced by the proposed system for French→English. Note that these examples where randomly taken from the test set, so they should be representative of the general behavior of our approach.

While the examples reveal certain adequacy issues (e.g. *The Times of London from Sidney* instead of *Sydney's Sunday Telegraph*), and the produced output is not perfectly grammatical (e.g. *go in Australia*), our translations are overall quite accurate and fluent, and one could get a reasonable understanding of the original text from them. This suggests that unsupervised machine translation can indeed be a usable alternative in low resource settings.

7 Related work

Similar to our approach, statistical decipherment also attempts to build machine translation systems from monolingual corpora. For that purpose, existing methods treat the source language as ciphertext, and model its generation through a noisy channel model involving two steps: the generation of the original English sentence and the probabilistic replacement of the words in it (Ravi and Knight, 2011; Dou and Knight, 2012). The English generative process is modeled using an n-gram language model, and the channel model parameters are estimated using either expectation maximization or Bayesian inference. Subsequent work has attempted to enrich these models with additional information like syntactic knowledge (Dou and Knight, 2013) and word embeddings (Dou et al., 2015). Nevertheless, these systems work in a word-by-word basis and have only been shown to work in limited settings, being often evaluated in word-level translation. In contrast, our method builds a fully featured phrase-based SMT system, and achieves competitive performance in a standard machine translation task.

More recently, Artetxe et al. (2018c) and Lample et al. (2018) have managed to train a standard attentional encoder-decoder NMT system from monolingual corpora alone. For that purpose, they use a shared encoder for both languages with pre-trained cross-lingual embeddings, and train the entire system using a combination of denoising, backtranslation and, in the case of Lample et al. (2018), adversarial training. This method was further improved by Yang et al. (2018), who use a separate encoder for each language, sharing only a subset of their parameters, and incorporate two generative adversarial networks. However, our results in Section 6.1 show that our SMT-based approach obtains substantially better results.

Our method is also connected to some previous approaches to improve machine translation using monolingual corpora. In particular, the generation of a synthetic parallel corpus through backtranslation (Sennrich et al., 2016), which is a key component of our unsupervised tuning and iterative refinement procedures, has been previously used to improve NMT. In addition, there have been several proposals to extend the phrase table of SMT systems by inducing translation candidates and/or scores from monolingual corpora, using either statistical decipherment methods (Dou and Knight, 2012, 2013) or cross-lingual embeddings (Zhao et al., 2015; Wang et al., 2016). While all these methods exploit monolingual corpora to enhance an existing machine translation system previously trained on parallel corpora, our approach learns a fully featured phrase-based SMT system from monolingual corpora alone.

8 Conclusions and future work

In this paper, we propose a novel unsupervised SMT system that can be trained on monolingual corpora alone. For that purpose, we extend the skip-gram model (Mikolov et al., 2013b) to simultaneously learn word and phrase embeddings, and map them to a cross-lingual space adapting previous unsupervised techniques (Artetxe et al., 2018b). The resulting cross-lingual phrase embeddings are used to induce a phrase table, which coupled with an n-gram language model and distance-based distortion yields an unsupervised phrase-based SMT system. We further improve results tuning the weights with our unsupervised MERT variant, and obtain additional improvements re-training the entire system through iterative back-translation. Our implementation is available as an open source project at `https://github.com/artetxem/monoses`.

Our experiments on standard WMT French-English and German-English datasets confirm the effectiveness of our proposal, where we obtain improvements above 10 and 7 BLEU points over previous NMT-based approaches, respectively, closing the gap with supervised SMT (Moses trained on Europarl) down to 2-5 points.

In the future, we would like to extend our approach to semi-supervised scenarios with small parallel corpora, which we expect to be particularly helpful for tuning purposes. Moreover, we would like to try a hybrid approach with NMT, using our unsupervised SMT system to generate a synthetic parallel corpus and training an NMT system over it through iterative backtranslation.

A Visual Attention Grounding Neural Model for Multimodal Machine Translation

Abstract

We introduce a novel multimodal machine translation model that utilizes parallel visual and textual information. Our model jointly optimizes the learning of a shared visual-language embedding and a translator. The model leverages a visual attention grounding mechanism that links the visual semantics with the corresponding textual semantics. Our approach achieves competitive state-of-the-art results on the Multi30K and the Ambiguous COCO datasets. We also collected a new multilingual multimodal product description dataset to simulate a real-world international online shopping scenario. On this dataset, our visual attention grounding model outperforms other methods by a large margin.

1 Introduction

Multimodal machine translation is the problem of translating sentences paired with images into a different target language (Elliott et al., 2016). In this setting, translation is expected to be more accurate compared to purely text-based translation, as the visual context could help resolve ambiguous multi-sense words. Examples of real-world applications of multimodal (vision plus text) translation include translating multimedia news, web product information, and movie subtitles.

Several previous endeavours (Huang et al., 2016; Calixto et al., 2017a; Elliott and Kádár, 2017) have demonstrated improved translation quality when utilizing images. However, how to effectively integrate the visual information still remains a challenging problem. For instance, in the WMT 2017 multimodal machine translation challenge (Elliott et al., 2017), methods that incorporated visual information did not outperform pure text-based approaches with a big margin.

In this paper, we propose a new model called Visual Attention Grounding Neural Machine Translation (VAG-NMT) to leverage visual information more effectively. We train VAG-NMT with a multitask learning mechanism that simultaneously optimizes two objectives: (1) learning a translation model, and (2) constructing a vision-language joint semantic embedding. In this model, we develop a visual attention mechanism to learn an attention vector that values the words that have closer semantic relatedness with the visual context. The attention vector is then projected to the shared embedding space to initialize the translation decoder such that the source sentence words that are more related to the visual semantics have more influence during the decoding stage. When evaluated on the benchmark Multi30K and the Ambiguous COCO datasets, our VAG-NMT model demonstrates competitive performance compared to existing state-of-the-art multimodal machine translation systems.

Another important challenge for multimodal machine translation is the lack of a large-scale, realistic dataset. To our knowledge, the only existing benchmark is Multi30K (Elliott et al., 2016), which is based on an image captioning dataset, Flickr30K (Young et al., 2014) with manual German and French translations. There are roughly 30K parallel sentences, which is relatively small compared to text-only machine translation datasets that have millions of sentences such as WMT14 EN→DE. Therefore, we propose a new multimodal machine translation dataset called IKEA to simulate the real-world problem of translating product descriptions from one language to another. Our IKEA dataset is a collection of parallel English, French, and German product descriptions and images from IKEA's and UNIQLO's websites. We have included a total of 3,600 products so far and will include more in the future.

2 Related Work

In the machine translation literature, there are two major streams for integrating visual information: approaches that (1) employ separate attention for different (text and vision) modalities, and (2) fuse visual information into the NMT model as part of the input. The first line of work learns independent context vectors from a sequence of text encoder hidden states and a set of location-preserving visual features extracted from a pre-trained convnet, and both sets of attentions affect the decoder's translation (Calixto et al., 2017a; Helcl and Libovický, 2017). The second line of work instead extracts a global semantic feature and initializes either the NMT encoder or decoder to fuse the visual context (Calixto et al., 2017b; Ma et al., 2017). While both approaches demonstrate significant improvement over their Text-Only NMT baselines, they still perform worse than the best monomodal machine translation system from the WMT 2017 shared task (Zhang et al., 2017).

The model that performs best in the multimodal machine translation task employed image context in a different way. (Huang et al., 2016) combine region features extracted from a region-proposal network (Ren et al., 2015) with the word sequence feature as the input to the encoder, which leads to significant improvement over their NMT baseline. The best multimodal machine translation system in WMT 2017 (Caglayan et al., 2017) performs element-wise multiplication of the target language embedding with an affine transformation of the convnet image feature vector as the mixed input to the decoder. While this method outperforms all other methods in WMT 2017 shared task workshop, the advantage over the monomodal translation system is still minor.

The proposed visual context grounding process in our model is closely related to the literature on multimodal shared space learning. (Kiros et al., 2014) propose a neural language model to learn a visual-semantic embedding space by optimizing a ranking objective, where the distributed representation helps generate image captions. (Karpathy and Li, 2014) densely align different objects in the image with their corresponding text captions in the shared space, which further improves the quality of the generated caption. In later work, multimodal shared space learning was extended to multimodal multilingual shared space learning. (Calixto et al., 2017c) learn a multi-modal multilingual shared space through optimization of a modified pairwise contrastive function, where the extra multilingual signal in the shared space leads to improvements in image-sentence ranking and semantic textual similarity task. (Gella et al., 2017) extend the work from (Calixto et al., 2017c) by using the image as the pivot point to learn the multilingual multimodal shared space, which does not require large parallel corpora during training. Finally, (Elliott and Kádár, 2017) is the first to integrate the idea of multimodal shared space learning to help multimodal machine translation. Their multi-task architecture called "imagination" shares an encoder between a primary task of the classical encoder-decoder NMT and an auxiliary task of visual feature reconstruction.

Our VAG-NMT mechanism is inspired by (Elliott and Kádár, 2017), but has important differences. First, we modify the auxiliary task as a visual-text shared space learning objective instead of the simple image reconstruction objective. Second, we create a visual-text attention mechanism that captures the words that share a strong semantic meaning with the image, where the grounded visual-context has more impact on the translation. We show that these enhancements lead to improvement in multimodal translation quality over (Elliott and Kádár, 2017).

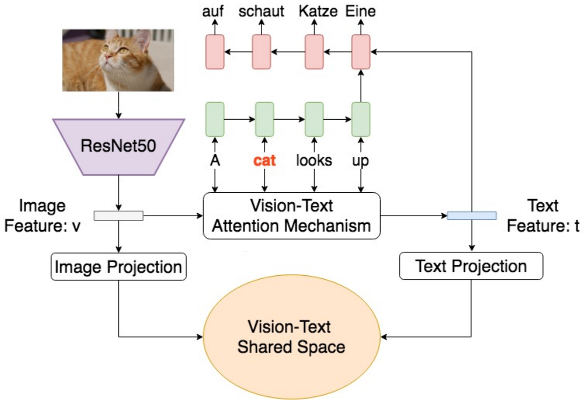

Figure 1: An overview of the VAG-NMT structure

3 Visual Attention Grounding NMT

Given a set of parallel sentences in language X and Y, and a set of corresponding images V paired with each sentence pair, the model aims to translate sentences $\{x_i\}_{i=1}^{N} \in X$ in language X to sentences $\{y_i\}_{i=1}^{N} \in Y$ in language Y with the assistance of images $\{v_i\}_{i=1}^{N} \in V$.

We treat the problem of multimodal machine translation as a joint optimization of two tasks: (1) learning a robust translation model and (2) constructing a visual-language shared embedding that grounds the visual semantics with text. Figure 1 shows an overview of our VAG-NMT model. We adopt a state-of-the-art attention-based sequence-to-sequence structure (Bahdanau et al., 2014) for translation. For the joint embedding, we obtain the text representation using a weighted sum of hidden states from the encoder of the sequence-to-sequence model and we obtain the image representation from a pre-trained convnet. We learn the weights using a visual attention mechanism, which represents the semantic relatedness between the image and each word in the encoded text. We learn the shared space with a ranking loss and the translation model with a cross entropy loss.

The joint objective function is defined as:

$$J(\theta_T, \phi_V) = \alpha J_T(\theta_T) + (1 - \alpha) J_V(\phi_V), \tag{1}$$

where J_T is the objective function for the sequence-to-sequence model, J_V is the objective function for joint embedding learning, θ_T are the parameters in the translation model, and ϕ_V are the parameters for the shared vision-language embedding learning, and α determines the contribution of the machine translation loss versus the visual grounding loss. Both J_T and J_V share the parameters of the encoder from the neural machine translation model. We describe details of the two objective functions in Section 3.2.

3.1 Encoder

We first encode an n-length source sentence $\{x\}$, as a sequence of tokens $x = \{x_1, x_2, \ldots, x_n\}$, with a bidirectional GRU (Schuster and Paliwal, 1997; Cho et al., 2014). Each token is represented by a one-hot vector, which is then mapped into an embedding e_i through a pre-trained embedding matrix. The bidirectional GRU processes the embedding tokens in two directions: left-to-right (forward) and right-to-left (backward). At every time step, the encoder's GRU cell generates two corresponding hidden state vectors: $\overrightarrow{h_i} = \overrightarrow{GRU(h_{i-1}, e_i)}$ and $\overleftarrow{h_i} = \overleftarrow{GRU(h_{i-1}, e_i)}$. The two hidden state vectors are then concatenated together to serve as the encoder hidden state vector of the source token at step i: $h_i = [\overleftarrow{h_i}, \overrightarrow{h_i}]$.

3.2 Shared embedding objective

After encoding the source sentence, we project both the image and text into the shared space to find a good distributed representation that can capture the semantic meaning across the two modalities. Previous work has shown that learning a multimodal representation is effective for grounding knowledge between two modalities (Kiros et al., 2014; Chrupala et al., 2015). Therefore, we expect the shared encoder between the two objectives to facilitate the integration of the two modalities and positively influence translation during decoding.

To project the image and the source sentence to a shared space, we obtain the visual embedding (v) from the pool5 layer of ResNet50 (He et al., 2015a) pre-trained on ImageNet classification (Russakovsky et al., 2015), and the source sentence embedding using the weighted sum of encoder hidden state vectors ($\{h_i\}$) to represent the entire source sentence (t). We project each $\{h_i\}$ to the shared space through an embedding layer. As different words in the source sentence will have different importance, we employ a visual-language attention mechanism—inspired by the attention mechanism applied in sequence-to-sequence models (Bahdanau et al., 2014)—to emphasize words that have the stronger semantic connection with the image. For example, the highlighted word "cat" in the source sentence in Fig. 1 has the more semantic connection with the image.

Specifically, we produce a set of weights $\beta = \{\beta_1, \beta_2, \ldots, \beta_n\}$ with our visual-attention mechanism, where the attention weight β_i for the i'th word is computed as:

$$\beta_i = \frac{\exp(z_i)}{\sum_{l=1}^{N} \exp(z_l)}, \tag{2}$$

and $z_i = \tanh(W_v v) \cdot \tanh(W_h h_i)$ is computed by taking the dot product between the transformed encoder hidden state vector h_i and the transformed image feature vector v, and W_v and W_h are the association transformation parameters.

Then, we can get a weighted sum of the encoder hidden state vectors $t = \sum_{i=1}^{n} \beta_i h_i$ to represent the semantic meaning of the entire source sentence. The next step is to project the source sentence feature vector t and the image feature vector v into the same shared space. The projected vector for text is: $t_{emb} = \tanh(W_{t_{emb}} t + b_{t_{emb}})$ and the projected vector for image is: $v_{emb} = \tanh(W_{v_{emb}} v + b_{v_{emb}})$.

We follow previous work on visual semantic embedding (Kiros et al., 2014) to minimize a pairwise ranking loss to learn the shared space:

$$J_V(\phi_V) = \sum_p \sum_k \max\{0, \gamma - s(v_p, t_p) + s(v_p, t_{k \neq p})\} + \sum_k \sum_p \max\{0, \gamma - s(t_k, v_k) + s(t_k, v_{p \neq k})\}, \tag{3}$$

where γ is a margin, and s is the cosine distance between two vectors in the shared space. k and p are the indexes of the images and text sentences, respectively. $t_{k \neq p}$ and $v_{p \neq k}$ are the contrastive examples with respect to the selected image and the selected source text, respectively. When the loss decreases, the distance between a paired image and sentence will drop while the distance between an unpaired image and sentence will increase.

In addition to grounding the visual context into the shared encoder through the multimodal shared space learning, we also initialize the decoder with the learned attention vector t such that the words that have more relatedness with the visual semantics will have more impact during the decoding (translation) stage. However, we may not want to solely rely on only a few most important words. Thus, to produce the initial hidden state of the decoder, we take a weighted average of the attention vector t and the mean of encoder hidden states:

$$s_0 = \tanh(W_{init}(\lambda t + (1 - \lambda)\frac{1}{N}\sum_i^N h_i)), \tag{4}$$

where λ determines the contribution from each vector. Through our experiments, we find the best value for λ is 0.5.

3.3 Translation objective

During the decoding stage, at each time step j, the decoder generates a decoder hidden state s_j from a conditional GRU cell (Sennrich et al., 2017) whose input is the previously generated translation token y_{j-1}, the previous decoder hidden state s_{j-1}, and the context vector c_j at the current time step:

$$s_j = \text{cGRU}(s_{j-1}, y_{j-1}, c_j) \tag{5}$$

The context vector c_j is a weighted sum of the encoder hidden state vectors, and captures the relevant source words that the decoder should focus on when generating the current translated token y_j. The weight associated with each encoder hidden state is determined by a feed-forward network. From the hidden state s_j we can predict the conditional distribution of the next token y_j with a fully-connected layer W_o given the previous token's language embedding e_{j-1}, the current hidden state d_j and the context vector for current step c_j:

$$p(y_j | y_{j-1}, x) = \text{softmax}(W_o o_t), \tag{6}$$

where $o_t = \tanh(W_e e_{j-1} + W_d d_j + W_c c_j)$. The three inputs are transformed with W_e, W_d, and W_c, respectively and then summed before being fed into the output layer.

We train the translation objective by optimizing a cross entropy loss function:

$$J_T(\theta_T) = -\sum_j \log p(y_j | y_{j-1}, x) \tag{7}$$

By optimizing the objective of the translation and the multimodal shared space learning tasks jointly along with the visual-language attention mechanism, we can simultaneously learn a general mapping between the linguistic signals in two languages and grounding of relevant visual content in the text to improve the translation.

4 IKEA Dataset

Previous available multimodal machine translation models are only tested on image caption datasets, we, therefore, propose a new dataset, IKEA, that has the real-world application of international online shopping. We create the dataset by crawling commercial products' descriptions and images from IKEA and UNIQLO websites. There are 3,600 products and we plan to expand the data in the future. Each sample is composed of the web-crawled English description of a product, an image of the product, and the web-crawled German or French description of the product.

Different than the image caption datasets, the German or French sentences in the IKEA dataset is not an exact parallel translation of its English sentence. Commercial descriptions in different languages can be vastly different in surface form but still keep the core semantic meaning. We think IKEA is a good data set to simulate real-world multimodal translation problems. The sentence in the IKEA dataset contains 60-70 words on average, which is five times longer than the average text length in Multi30K (Elliott et al., 2016). These sentences not only describe the visual appearance of the product, but also the product usage. Therefore, capturing the connection between

visual semantics and the text is more challenging on this dataset. The dataset statistics and an example of the IKEA dataset is in Appendix A.

5 Experiments and Results

5.1 Datasets

We evaluate our proposed model on three datasets: Multi30K (Elliott et al., 2016), Ambiguous COCO (Elliott et al., 2017), and our newly-collected IKEA dataset. The Multi30K dataset is the largest existing human-labeled dataset for multimodal machine translation. It consists of 31,014 images, where each image is annotated with an English caption and manual translations of image captions in German and French. There are 29,000 instances for training, 1,014 instances for validation, and 1,000 for testing. Additionally, we also evaluate our model on the Ambiguous COCO Dataset collected in the WMT2017 multimodal machine translation challenge (Elliott et al., 2017). It contains 461 images from the MSCOCO dataset (Lin et al., 2014), whose captions contain verbs with ambiguous meanings.

5.2 Setting

We pre-process all English, French, and German sentences by normalizing the punctuation, lower casing, and tokenizing with the Moses toolkit. A Byte-Pair-Encoding (BPE) (Sennrich et al., 2015) operation with 10K merge operations is learned from the pre-processed data and then applied to segment words. We restore the original words by concatenating the subwords segmented by BPE in post-processing. During training, we apply early stopping if there is no improvement in BLEU score on validation data for 10 validation steps. We apply beam search decoding to generate translation with beam size equal to 12. We evaluate the performance of all models using BLEU (Papineni et al., 2002) and METEOR (Denkowski and Lavie, 2014). The setting used in IKEA dataset is the same as Multi30K, except that we lower the default batch size from 32 to 12; since IKEA dataset has long sentences and large variance in sentence length, we use smaller batches to make the training more stable. Full details of our hyperparameter choices can be found in Appendix B. We run all models five times with different random seeds and report the mean and standard deviation.

5.3 Results

We compare the performance of our model against the state-of-the-art multimodal machine translation approaches and the text-only baseline. The idea of our model is inspired by the "Imagination" model (Elliott and Kádár, 2017), which unlike our models, simply averages the encoder hidden states for visual grounding learning. As "Imagination" does not report its performance on Multi30K 2017 and Ambiguous COCO in its original paper, we directly use their result reported in the WMT 2017 shared task as a comparison. LIUMCVC is the best multimodal machine translation model in WMT 2017 multimodal machine translation challenge and exploits visual information with several different methods. We always compare our VAG-NMT with the method that has been reported to

	English → German		English → French	
Method	BLEU	METEOR	BLEU	METEOR
LIUMCVC-Multi	59.9 ± 1.9	63.8 ± 0.4	58.4 ± 1.6	64.6 ± 1.8
Text-Only NMT	61.9 ± 0.9	65.6 ± 0.9	65.2 ± 0.7	$\mathbf{69.0 \pm 0.2}$
VAG-NMT	$\mathbf{63.5 \pm 1.2}$	$\mathbf{65.7 \pm 0.1}$	$\mathbf{65.8 \pm 1.2}$	68.9 ± 1.4

Table 3: Translation results on the IKEA dataset

have the best performance on each dataset.

Our VAG-NMT surpasses the results of the “Imagination" model and the LIUMCVC’s model by a noticeable margin in terms of BLEU score on both the Multi30K dataset (Table 1) and the Ambiguous COCO dataset (Table 2). The METEOR score of our VAG-NMT is slightly worse than that of "Imagination" for English -> German on Ambiguous COCO Dataset. This is likely because the “Imagination" result was produced by ensembling the result of multiple runs, which typically leads to 1-2 higher BLEU and METEOR points compared to a single run. Thus, we expect our VAG-NMT to outperform the “Imagination" baseline if we also use an ensemble.

We observe that our multimodal VAG-NMT model has equal or slightly better result compared to the text-only neural machine translation model on the Multi30K dataset. On the Ambiguous COCO dataset, our VAG-NMT demonstrates clearer improvement over this text-only baseline. We suspect this is because Multi30K does not have many cases where images can help improve translation quality, as most of the image captions are short and simple. In contrast, Ambiguous COCO was purposely curated such that the verbs in the captions can have ambiguous meaning. Thus, visual context will play a more important role in Ambiguous COCO; namely, to help clarify the sense of the source text and guide the translation to select the correct word in the target language.

We then evaluate all models on the IKEA dataset. Table 3 shows the results. Our VAG-NMT has a higher value in BLEU and a comparable value in METEOR compared to the Text-only NMT baseline. Our VAG-NMT outperforms LIUMCVC’s multimodal system by a large margin, which shows that the LIUMCVC’s multimodal’s good performance on Multi30K does not generalize to this real-world product dataset. The good performance may come from the visual attention mechanism that learns to focus on text segments that are related to the images. Such attention therefore teaches the decoder to apply the visual context to translate those words. This learned attention is especially useful for datasets with long sentences that have irrelevant text information with respect to the image.

(a) *a cyclist is wearing a helmet*

(b) *a black dog and his favorite toys.*

Figure 2: Top five images retrieved using the given caption. The original corresponding image of the caption is highlighted with a red bounding box.

5.4 Multimodal embedding results

To assess the learned joint embedding, we perform an image retrieval task evaluated using the Recall@K metric (Kiros et al., 2014) on the Multi30K dataset.

We project the image feature vectors $V = \{v_1, v_2, \dots, v_n\}$ and their corresponding captions $S = \{s_1, s_2, \dots, s_n\}$ into a shared space. We follow the experiments conducted by the previous visual semantic embedding work (Kiros et al., 2014), where for each embedded text vector, we find the closest image vectors around it based on the cosine similarity. Then we can compute the recall rate of the paired image in the top K nearest neighbors, which is also known as $R@K$ score. The shared space learned with VAG-NMT achieves 64% R@1, 88.6% R@5, and 93.8% R@10 on Multi30K, which demonstrates the good quality of the learned shared semantics. We also achieved 58.13% R@1, 87.38% R@5 and 93.74% R@10 on IKEA dataset; 41.35% R@1, 85.48% R@5 and 92.56% R@10 on COCO dataset. Besides the quantitative results, we also show several qualitative results in Figure 2. We show the top five images retrieved by the example captions.

a person is skiing or snowboarding down a mountainside .

a mountain climber trekking through the snow with a pick and a blue hat .

the snowboarder is jumping in the snow .

two women are water rafting .

three people in a blue raft on a river of brown water .

people in rafts watch as two men fall out of their own rafts .

Figure 3: Visual-text attention score on sample data from Multi30K. The first and second rows show the three closest images to the caption *a person is skiing or snowboarding down a mountainside* and *two woman are water rafting*, respectively. The original caption is listed under each image. We highlight the three words with highest attention in red.

The images share "cyclist", "helmet", and "dog" mentioned in the caption.

5.5 Human evaluation

We use Facebook to hire raters that speak both German and English to evaluate German translation quality. As Text-Only NMT has the highest BLEU results among all baseline models, we compare the translation quality between the Text-Only and the VAG-NMT on all three datasets. We randomly selected 100 examples for evaluation for each dataset. The raters are informed to focus more on semantic meaning than grammatical correctness when indicating the preference of the two translations. They are also given the option to choose a tie if they cannot decide. We hired two raters and the inter-annotator agreement is 0.82 in Cohen's Kappa.

We summarize the results in Table 4, where we list the number of times that raters prefer one translation over another or think they are the same quality. Our VAG-NMT performs better than Text-Only NMT on MSCOCO and IKEA dataset, which correlates with the automatic evaluation metrics. However, the result of VAG-NMT is slightly worse than the Text-Only NMT on the Multi30K test dataset. This also correlates with the result of automatic evaluation metrics.

Finally, we also compare the translation quality between LIUMCVC multimodal and VAG-NMT on 100 randomly selected examples from the IKEA dataset. VAG-NMT performs better than LIUMCVC multimodal. The raters prefer our VAG-NMT in 91 cases, LIUMCVC multimodal in 68 cases, and cannot tell in 47 cases.

	MSCOCO	Multi30K	IKEA
Text-Only NMT	76	**72**	75
VAG-NMT	**94**	71	**82**
Tie	30	57	43

Table 4: Human evaluation results

6 Discussion

To demonstrate the effectiveness of our visual attention mechanism, we show some qualitative examples in Figure 3. Each row contains three images that share similar semantic meaning, which are retrieved by querying the image caption using our learned shared space. The original caption of each image is shown below each image. We highlight the three words in each caption that have the highest weights assigned by the visual attention mechanism.

In the first row of Figure 3, the attention mechanism assigns high weights to the words “skiing", “snowboarding", and “snow". In the second row, it assigns high attention to “rafting" or “raft" for every caption of the three images. These examples demonstrate evidence that our attention mechanism learns to assign high weights to words that have corresponding visual semantics in the image.

We also find that our visual grounding attention captures the dependency between the words that

	Source Caption:	a tennis player is moving to the side and is gripping his racquet with both hands .
	Text-Only NMT:	ein tennisspieler bewegt sich um die seite und greift mit beiden händen an den boden .
	VAG-NMT:	ein tennisspieler bewegt sich zur seite und greift mit beiden händen den schläger .
	Source Caption:	three skiers skiing on a hill with two going down the hill and one moving up the hill .
	Text-Only NMT:	drei skifahrer fahren auf skiern einen hügel hinunter und eine person fährt den hügel hinunter .
	VAG-NMT:	drei skifahrer auf einem hügel fahren einen hügel hinunter und ein bewegt sich den hügel hinauf .
	Source Caption:	a blue , yellow and green surfboard sticking out of a sandy beach .
	Text-Only NMT:	ein blau , gelb und grünes surfbrett streckt aus einem sandstrand .
	VAG-NMT:	ein blau , gelb und grüner surfbrett springt aus einem sandstrand .

Figure 4: Translations generated by VAG-NMT and Text-Only NMT. VAG-NMT performs better in the first two examples, while Text-Only NMT performs better in the third example. We highlight the words that distinguish the two systems' results in red and blue. Red words are marked for better translation from VAG-NMT and blue words are marked for better translation from Text-Only NMT.

have strong visual semantic relatedness. For example, in Figure 3, words, such as “raft",“river", and “water", with high attention appear in the image together. This shows that the visual dependence information is encoded into the weighted sum of attention vectors which is applied to initialize the translation decoder. When we apply the sequence-to-sequence model to translate a long sentence, the encoded visual dependence information strengthens the connection between the words with visual semantic relatedness. Such connections mitigate the problem of standard sequence-to-sequence models tending to forget distant history. This hypothesis is supported by the fact that our VAG-NMT outperforms all the other methods on the IKEA dataset which has long sentences.

Lastly, in Figure 4 we provide some qualitative comparisons between the translations from VAG-NMT and Text-Only NMT. In the first example, our VAG-NMT properly translates the word "racquet" to “den schläger", while the Text-Only NMT mistranslated it to “den boden" which means “ground" in English. We suspect the attention mechanism and visual shared space capture the visual dependence between the word “tennis" and “racquet". In the second example, our VAG-NMT model correctly translates the preposition “up" to “hinauf" but Text-Only NMT mistranslates it to “hinunter" which means “down" in English. We consistently observe that VAG-NMT translates prepositions better than Text-Only NMT. We think it is because the pre-trained convnet features captured the relative object position that leads to a better preposition choice. Finally, in the third example, we show a failure case where Text-Only NMT generates a better translation. Our VAG-NMT mistranslates the verb phrase “sticking out" to “springt aus" which means “jump out" in German, while Text-Only NMT translates to “streckt aus", which is correct. We find that VAG-NMT often makes mistakes when translating verbs. We think it is because the image vectors are pre-trained on an object classification task, which does not have any human action information.

7 Conclusion and Future Work

We proposed a visual grounding attention structure to take advantage of the visual information to perform machine translation. The visual attention mechanism and visual context grounding module help to integrate the visual content into the sequence-to-sequence model, which leads to better translation quality compared to the model with only text information. We achieved state-of-the-art results on the Multi30K and Ambiguous COCO dataset. We also proposed a new product dataset, IKEA, to simulate a real-world online product description translation challenge.

In the future, we will continue exploring different methods to ground the visual context into the translation model, such as learning a multimodal shared space across image, source language text, as well as target language text. We also want to change the visual pre-training model from an image classification dataset to other datasets that have both objects and actions, to further improve translation performance.

Acknowledge

We would like to thank Daniel Boyla for providing insightful discussions to help with this research. We also want to thank Chunting Zhou and Ozan Caglayan for suggestions on machine translation model implementation. This work was supported in part by NSF CAREER IIS-1751206.

B Hyperparameter Settings

In this Appendix, we share details on the hyperparameter settings for our model and the training process. The word embedding size for both encoder and decoder are 256. The Encoder is a one-layer bidirectional recurrent neural network with Gated Recurrent Unit (GRU), which has a hidden size of 512. The decoder is a recurrent neural network with conditional GRU of the same hidden size. The visual representation is a 2048-dim vector extracted from the `pool5` layer of a pre-trained ResNet-50 network. The dimension of the shared visual-text semantic embedding space is 512. We set the decoder initialization weight value λ to 0.5.

During training, we use Adam (Kingma and Ba, 2014) to optimize our model with a learning rate of $4e-4$ for German Dataset and $1e-3$ for French dataset. The batch size is 32. The total gradient norm is clipped to 1 (Pascanu et al., 2012). Dropout is applied at the embedding layer in the encoder, context vectors extracted from the encoder and the output layer of the decoder. For Multi30K German dataset the dropout probabilities are $(0.3, 0.5, 0.5)$ and for Multi30K French dataset the dropout probabilities are $(0.2, 0.4, 0.4)$. For the Multimodal shared space learning objective function, the margin size γ is set to 0.1. The objective split weight α is set to 0.99. We initialize the weights of all the parameters with the method introduced in (He et al., 2015b).

C Ablation Analysis on Visual-Text Attention

We conducted an ablation test to further evaluate the effectiveness of our visual-text attention mechanism. We created two comparison experiments where we reduced the impact of visual-text attention with different design options. In the first experiment, we remove the visual-attention mechanism in our pipeline and simply use the mean of the encoder hidden states to learn the shared embedding space. In the second experiment, we initialize the decoder with just the mean of encoder hidden states without the weighted sum of encoder states using the learned visual-text attention scores.

We run both experiments on Multi30K German Dataset five times and demonstrate the results in table 5. As can be seen, the performance of the changed translation model is obviously worse than the full VAG-NMT in both experiments. This observation suggests that the visual-attention mechanism is critical in improving the translation performance. The model improvement comes from the attention mechanism influencing the model's objective function and decoder's initialization.

	English → German	
Method	BLEU	METEOR
-attention in shared embedding	30.5 ± 0.6	51.7 ± 0.4
-attention in initialization	30.8 ± 0.8	51.9 ± 0.5
VAG-NMT	$\mathbf{31.6 \pm 0.6}$	$\mathbf{52.2 \pm 0.3}$

Table 5: Ablation analysis on visual-text attention mechanism in the Multi30K German dataset.

Sentiment Classification towards Question-Answering with Hierarchical Matching Network

Abstract

In an e-commerce environment, user-oriented question-answering (QA) text pair could carry rich sentiment information. In this study, we propose a novel task/method to address QA sentiment analysis. In particular, we create a high-quality annotated corpus with specially-designed annotation guidelines for QA-style sentiment classification. On the basis, we propose a three-stage hierarchical matching network to explore deep sentiment information in a QA text pair. First, we segment both the question and answer text into sentences and construct a number of [Q-sentence, A-sentence] units in each QA text pair. Then, by leveraging a QA bidirectional matching layer, the proposed approach can learn the matching vectors of each [Q-sentence, A-sentence] unit. Finally, we characterize the importance of the generated matching vectors via a self-matching attention layer. Experimental results, comparing with a number of state-of-the-art baselines, demonstrate the impressive effectiveness of the proposed approach for QA-style sentiment classification.

1 Introduction

Sentiment analysis, a.k.a. opinion mining, is a task which aims to identify the user sentiment orientation of a product/brand/service by monitoring the online textual data, e.g., reviews and social media messages. It has attracted huge attention in both academic and industrial communities due to its widespread applications, such like recommendation (Zhang et al., 2014) and social media mining (Chambers et al., 2015). As the fundamental component in sentiment analysis, sentiment classification mainly classifies the sentiment polarity as *positive* or *negative*, and has been well-studied from both sentence-level (Kim and Hovy, 2004) and document-level (Xu et al., 2016).

Question 1: *Is the screen clear? How is the battery?*
Answer 1: *It's a nice phone with high-quality screen. But the battery is not durable.*

Question 2: *Summer is coming, I'm afraid of getting darker. Is the sun cream really effective?*
Answer 2: *No, just depending on my own experience.*

Figure 1: Two examples of QA text pairs from "*customer questions & answers*" section in *Amazon*.

Recently, a new QA-style reviewing form, namely "*customer questions & answers*", has become increasingly popular on the giant e-commerce platforms, e.g., *Amazon* and *Taobao*. In this new form, a potential customer asks question(s) about the target product/service while other experienced user(s) can provide answer(s). With the widespread of such QA-style reviews, users find a different channel to efficiently explore rich and useful information, and service providers and scholars are paying more attention to its specific characteristics comparing with traditional reviews (Wachsmuth et al., 2014; Zhou et al., 2015a). Comparing to the traditional reviews, the QA style reviews can be more informative and convincing. More importantly, because answer providers are randomly picked from the users who already purchased the target item, this new form of review can be more reliable and trustful.

Regarding QA-style sentiment analysis, one straightforward method is to directly employ an existing sentiment classification approach that works well on traditional reviews, such as RNN (Nguyen and Shirai, 2015) and LSTM (Chen et al., 2016). However, because of the significant differences between QA-style and classical reviews, existing review mining algorithms, e.g., text-based sentiment analysis/classification, should not be di-

Brussels, Belgium, October 31 - November 4, 2018.

rectly applied to this new kind of QA-style data. More detailed reasons can be found as the followings.

First, in QA-style text, the question and answer text are more likely to be two parallel units rather than a sequence form. On the one hand, for instance, in Figure 1, sentence "*It's a nice phone with high-quality screen.*" in **Answer 1** actually does not follow sentence "*How is the battery?*" in **Question 1** , but corresponds to sentence "*Is the screen clear?*" in **Question 1**. Therefore, when the question text and answer text are presented as two units in a sequence, it is rather difficult to capture the relationship between the question and its corresponding answer due to the possible long distance between them. On the other hand, there often exists both *positive* and *negative* sentiments in answer text according to different parts of question, and this specific case should be categorized as another category named *conflict*. For instance, in Figure 1, **Answer 1** "*It's a nice phone with high-quality screen. But the battery is not durable.*" is a *conflict* answer to **Question 1**. However, when this answer text is considered as a sequence, it is highly possible to be predicted as the category of *positive* or *negative* rather than *conflict*. In order to address these problems, a more appropriate approach is to segment both the question and answer text into some parallel sentences, and then construct the [Q-sentence, A-sentence] units in each QA text pair to detect in-depth sentiment information.

Second, although the main sentiment polarity is usually expressed from the answer text, the question text could also carry important sentiment tips to predict the sentiment polarity of a QA text pair. For instance, in Figure 1, we could hardly estimate the sentiment polarity solely based on **Answer 2**. However, when we take **Question 2**, "*Is the sun cream really effective?*", into consideration, it can be easier to label this QA text pair with a *negative* tag. In this study, we propose an approach to match the sentences inside the question and answer text bidirectionally.

Third, in each QA text pair, the importance degrees of different [Q-sentence, A-sentence] units can be different. For instance, in Figure 1, the [Q-sentence, A-sentence] unit, i.e., sentence "*Summer is coming, I'm afraid of getting darker.*" in **Answer 2** and sentence "*No, just depending on my own experience.*" in **Question 2**, makes tiny contribution to imply the sentiment polarity for the QA text pair. Therefore, a well-behaved network approach should consider the importance degrees of different [Q-sentence, A-sentence] units for predicting the sentiment polarity of a QA text pair.

The contribution of this paper is twofold. First, we propose a novel problem, QA-style sentiment analysis, and build a large-scale annotated corpus tailed for this task. The dataset is released to motivate future investigations for this track of research. Second, we propose a hierarchical matching network model to address the challenges of QA-style sentiment classification. Specifically, we first segment both the question and answer text into sentences and construct the [Q-sentence, A-sentence] units for each QA text pair. Then, by using a QA bidirectional matching layer, we encode each [Q-sentence, A-sentence] unit for exploring sentiment information. Finally, the self-matching attention layer in the model can capture the importance of these [Q-sentence, A-sentence] matching vectors obtained from QA bidirectional matching layer, which could effectively refine the evidence for inferring the sentiment polarity of a QA text pair. Experimental results show that the proposed approach significantly outperforms several strong baselines for QA-style sentiment classification.

2 Related Work

Sentiment classification has become a hot research field in NLP since the pioneering work by Pang et al. (2002). In general, the research on traditional sentiment classification has been carried out in different text levels, such like word-level, document-level and aspect-level.

Word-level sentiment classification has been studied in a long period in the research community of sentiment analysis. Some early studies have devoted their efforts to predicting the sentiment polarity of a word with different learning models and resources. Turney (2002) proposed an approach to predicting the sentiment polarity of words by calculating Pointwise Mutual Information (PMI) values between the seed words and the search hits. Hassan and Radev (2010) and Hassan et al. (2011) applied a Markov random walk model to determine the word polarities with a large word relatedness graph, and the synonyms and hypernyms in WordNet (Miller, 1995). More recently, some studies aim to learn better word embedding of a word rather than its polarity. Tang et al. (2014) developed three neural networks to learn word em-

	Positive	*Negative*	*Conflict*	*Neutral*	*Total*

Table 1: Category distribution of the annotated data in three domains.

bedding by incorporating sentiment polarities of text in loss functions. Zhou et al. (2015b) employed both unsupervised and supervised neural networks to learn bilingual sentiment word embedding.

Document-level sentiment classification has also been studied in a long period in the research community of sentiment analysis. On one hand, many early studies have been devoted their efforts to various of aspects on learning approaches, such as supervised learning (Pang et al., 2002; Riloff et al., 2006), semi-supervised learning (Li et al., 2010; Xia et al., 2015; Li et al., 2015), and domain adaptation (Blitzer et al., 2007; He et al., 2011). On the other hand, many recent studies employ deep learning approaches to enhance the performances in sentiment classification. Tang et al. (2015) proposed a user-product neural network to incorporate both user and product information for sentiment classification. Xu et al. (2016) proposed a Cached Long Short-Term Memory neural networks (CLSTM) to capture the overall semantic information in long texts. More recently, Long et al. (2017) proposed a novel attention model, namely cognition-based attention, for sentiment classification.

Aspect-level sentiment classification is a relatively new research area in the research community of sentiment analysis and it is a fine-grained classification task. Recently, Wang et al. (2016) proposed an attention-based LSTM neural network to aspect-level sentiment classification by exploring the connection between an aspect and the content of a sentence. Tang et al. (2016) proposed a deep memory network with multiple attention-based computational layers to improve the performance. Wang et al. (2018) proposed a hierarchical attention network to explore both word-level and clause-level sentiment information towards a target aspect.

Unlike all the prior studies, this paper focuses on a very different kind of text representation, i.e., QA-style text level, for sentiment classification. To the best of our knowledge, this is the first attempt to perform sentiment classification on this text level.

3 Data Collection and Annotation

We collect QA text pairs from "*Asking All*" in *Taobao* (*Alibaba*)[1], which is the world's biggest e-commerce company. The QA text pairs are mainly from *Beauty*, *Shoe* and *Electronic* domains and each domain contains 10,000 QA text pairs.

We define four sentiment-related categories, i.e., *positive*, *negative*, *conflict* (both *positive* and *negative* sentiment) and *neutral* (neither *positive* nor *negative* sentiment). To guarantee a high annotation agreement, we propose some annotation guidelines after several times of annotation processes on a small size of data. Then, we ask more coders to annotate the whole data set according to these annotation guidelines.

The annotation guidelines contain two main groups. One contains the guidelines which aim to distinguish the categories of *neutral* and *non-neutral*, i.e.,

(a) A QA text pair in which the question and the answer do not match is annotated as a *neutral* sample. In this type of samples, the answer does not reply to the question correctly. **E1** is an example of this type where the question talks about the screen while the answer talks about the battery.

E1: Q: *Is the screen clear?*
A: *The battery life is decent.*

(b) A QA text pair with an unknown or uncertain answer is annotated as a *neutral* sample. **E2** is an example of this type.

E2: Q: *What about these sneakers?*
A: *I don't know, I bought it for my dad.*

(c) A QA text pair with only objective description is annotated as a *neutral* sample. **E3** is an example of this type.

E3: Q: *What's the operation system of the phone?*
A: *Android.*

(d) A QA text pair which compares two different products is annotated as a *neutral* sample. In this type of samples, two products are involved and it

---

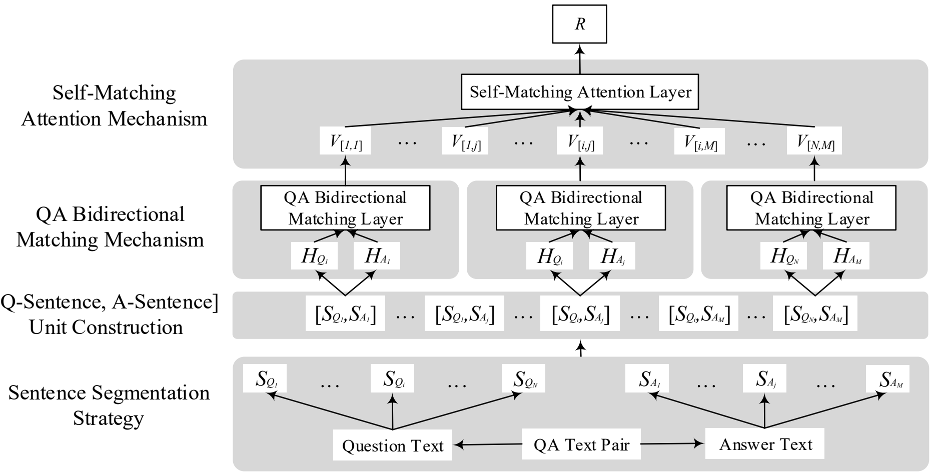

Figure 2: The overview of our approach to QA-style sentiment classification where S_{Q_i} denotes the i-th sentence in question text, S_{A_j} denotes the j-th sentence in answer text, H_{Q_i} and H_{A_j} denote the contextual representations for S_{Q_i} and S_{A_j} respectively, $V_{[i,j]}$ denotes the bidirectional matching vector for $[S_{Q_i}, S_{A_j}]$ unit through QA bidirectional matching layer, and R is the QA text pair representation refined by self-matching attention layer.

is sometimes difficult to tell the sentiment orientation of one product. **E4** is an example of this type.

E4: Q: *How about this phone when compared to iPhone 6s?*
A: *It's up to you, and they're not comparable.*

The other group contains the guidelines which aim to distinguish the categories of *positive* and *negative*, i.e.,
(e) If the answer text contains sentimental expressions to question like "*disappointed*", "*terrible*", and so on, we annotate it as *negative*. **E5** is an example of this type.

E5: Q: *How is the rock climbing shoe?*
A: *I am so disappointed, my feet felt hurt when I wore them.*

(f) If the answer text contains sentimental expressions to question like "*perfect*", "*satisfied*", and so on, we annotate it as *positive*. **E6** is an example of this type.

E6: Q: *How about the fragrance?*
A: *I am so satisfied, it smells distinctive.*

(g) If we cannot confirm the polarity of a QA text pair only depending on answer text, we annotate the polarity according to both the question and answer text. For instance, **E7** is an example with *positive* polarity, while **E8** is an example with *negative* polarity.

E7: Q: *Will the phone get hot when gaming?*
A: *No.*

E8: Q: *Is the sun cream really economic?*
A: *No.*

We assign two annotators to annotate each QA text pair, and the *Kappa* consistency check value of the annotation is 0.84. When annotators cannot reach an agreement, an expert will make the final decision, ensuring the quality of data annotation. Table 1 shows the category distribution of the corpus. To motivate other scholars to investigate this novel but important task, we share the data via Github[2].

4 Methodology

In this section, we introduce the proposed hierarchical matching network approach for QA-style sentiment classification. Figure 2 depicts the overview of the proposed approach.

4.1 QA Bidirectional Matching Mechanism

Word Encoding Layer: After sentence segmentation, the question text in a QA text pair contains N sentences, S_{Q_i} represents the i-th sentence in the question text. Similarly, the answer text in this QA text pair contains M sentences, S_{A_j} represents the j-th sentence in the answer text. We then construct [Q-sentence, A-sentence] units by pairing one sentence in the question text and one sentence in the answer text, and we obtain $N{*}M$ [Q-sentence, A-sentence] units at last.

Given a $[S_{Q_i}, S_{A_j}]$ unit in this QA text pair, i.e., Q-sentence S_{Q_i} with words $w_{i,n}, i \in [1, N], n \in$

---

[2] https://github.com/clshenNLP/QASC/

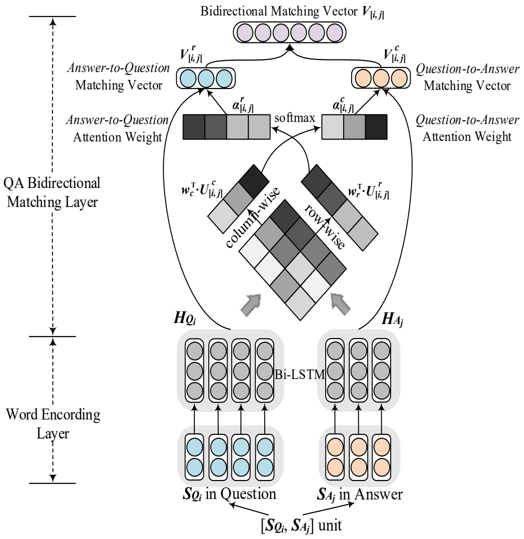

Figure 3: The detail architecture of QA bidirectional matching mechanism.

$[1, N_i]$ and A-sentence S_{A_j} with words $w_{j,m}, j \in [1, M], m \in [1, M_j]$, we first convert the words to their respective word embeddings ($x_{i,n} \in \mathbb{R}^d, i \in [1, N], n \in [1, N_i]$ and $x_{j,m}, j \in [1, M], m \in [1, M_j]$). We then use Bi-directional LSTM (namely Bi-LSTM), which can efficiently make use of past features (via forward states) and future features (via backward states) for a specific time step, to get contextual representations of S_{Q_i} and S_{A_j} individually. The representation of each word is formed by concatenating the forward and backward hidden states. For simplicity, we note contextual representation of S_{Q_i} as H_{Q_i} , and contextual representation of S_{A_j} as H_{A_j} respectively:

$$H_{Q_i} = [h_{i,1}, h_{i,2}, ..., h_{i,n}, ..., h_{i,N_i}] \tag{1}$$

$$H_{A_j} = [h_{j,1}, h_{j,2}, ..., h_{j,m}, ..., h_{j,M_j}] \tag{2}$$

where $h_{i,n} \in \mathbb{R}^{d'}$ denotes the word representation in S_{Q_i} at time step n, $h_{j,m} \in \mathbb{R}^{d'}$ denotes the word representation in S_{A_j} at time step m, and d' is the dimensionality of word representation.

QA Bidirectional Matching Layer: General neural network could not capture sentiment matching information in a $[S_{Q_i}, S_{A_j}]$ unit well. For the sake of solving this problem, we introduce the QA bidirectional matching layer to encapsulate the clues and interactions between S_{Q_i} and S_{A_j} synchronously (Tay et al., 2017; McCann et al., 2017). Figure 3 depicts the detail architecture of QA bidirectional matching mechanism. Specifically, we first calculate the bidirectional pair-wise matching matrix by using the following formula:

$$D_{[i,j]} = (H_{Q_i})^{\top} \cdot (H_{A_j}) \tag{3}$$

where $D_{[i,j]} \in \mathbb{R}^{N_i \times M_j}$ denotes the bidirectional matching matrix for the $[S_{Q_i}, S_{A_j}]$ unit. Each element in $D_{[i,j]}$ is the score that measures how well the word in S_{Q_i} semantically matches the word in S_{A_j} and vice versa.

Given the bidirectional matching matrix $D_{[i,j]}$, we use attention mechanism (Yang et al., 2016; Cui et al., 2017) to mine the sentiment matching information between question and answer from two directions, which could be seen as an *Answer-to-Question* attention and a *Question-to-Answer* attention as follows.

- ***Answer-to-Question*** **Attention:** We employ row-wise operations to compute the attention weight vector $\alpha^r_{[i,j]}$ as follows:

$$U^r_{[i,j]} = \tanh(W_r \cdot D^{\top}_{[i,j]}) \tag{4}$$

$$\alpha^r_{[i,j]} = \text{softmax}(w_r^{\top} \cdot U^r_{[i,j]}) \tag{5}$$

where $\alpha^r_{[i,j]} \in \mathbb{R}^{N_i}$ is the *Answer-to-Question* attention weight vector regarding the importance degrees of all words in Q-sentence S_{Q_i}, $W_r \in \mathbb{R}^{d' \times M_j}$ and $w_r \in \mathbb{R}^{d'}$ are weight matrices. After computing the *Answer-to-Question* attention weight vector, we can get the *Answer-to-Question* matching vector $V^r_{[i,j]} \in \mathbb{R}^{d'}$ as follows:

$$V^r_{[i,j]} = (H_{Q_i}) \cdot \alpha^r_{[i,j]} \tag{6}$$

- ***Question-to-Answer*** **Attention:** Simultaneously, we employ column-wise operations to calculate the attention weight vector $\alpha^c_{[i,j]}$ as follows:

$$U^c_{[i,j]} = \tanh(W_c \cdot D_{[i,j]}) \tag{7}$$

$$\alpha^c_{[i,j]} = \text{softmax}(w_c^{\top} \cdot U^c_{[i,j]}) \tag{8}$$

where $\alpha^c_{[i,j]} \in \mathbb{R}^{M_j}$ is the *Question-to-Answer* attention weight vector regarding the importance degrees of all words in A-sentence S_{A_j}, $W_c \in \mathbb{R}^{d' \times N_i}$ and $w_c \in \mathbb{R}^{d'}$ are weight matrices. After calculating the *Question-to-Answer* attention weight vector, we can get the *Question-to-Answer* matching vector $V^c_{[i,j]} \in \mathbb{R}^{d'}$ as follows:

$$V^c_{[i,j]} = (H_{A_j}) \cdot \alpha^c_{[i,j]} \tag{9}$$

Then, we combine *Answer-to-Question* and *Question-to-Answer* matching vectors to represent the final bidirectional matching vector of the $[S_{Q_i}, S_{A_j}]$ unit:

$$V_{[i,j]} = V^r_{[i,j]} \oplus V^c_{[i,j]} \tag{10}$$

where $\oplus$ denotes the concatenate operator, and $V_{[i,j]}$ denotes the bidirectional matching vector which integrates S_{Q_i} and S_{A_j} with each other.

4.2 Self-Matching Attention Mechanism

Through the QA bidirectional matching layer, informative bidirectional matching vectors are generated to pinpoint the sentiment matching information in each [Q-sentence, A-sentence] unit. Intuitively, each matching vector for [Q-sentence, A-sentence] unit holds different importance to a QA text pair. To better aggregate the evidence from these vectors for inferring the sentiment polarity of the QA text pair, we propose a self-matching attention layer, matching these informative vectors against themselves.

Self-Matching Attention Layer: As aforementioned, we have obtained $N*M$ bidirectional matching vectors through QA bidirectional matching layer, then we calculate the attention weight vector α with these matching vectors by following formulas:

$$V = [V_{[1,1]}, V_{[1,2]}, ..., V_{[i,j]}, ..., V_{[N,M]}] \tag{11}$$

$$U = \tanh(W_h \cdot V) \tag{12}$$

$$\alpha = \mathrm{softmax}(w_h^\top \cdot U) \tag{13}$$

where α is the attention weight vector which measures the importance of these matching vectors, W_h and w_h are the weight matrices.

Finally, we can get the QA text pair representation R as follows:

$$R = V \cdot \alpha \tag{14}$$

4.3 Classification Model

QA text pair representation R is a high level representation which can be used for classification. In our approach, we feed R to a *softmax* classifier:

$$p = \mathrm{softmax}(W_l \cdot R + b_l) \tag{15}$$

where p is a set of predicted distribution of the sentiment categories, i.e., *positive*, *negative*, *neutral*, and *conflict*. W_l is the weight matrix and b_l is the bias.

To learn the whole model, we train an end-to-end model given the training data, and the goal of training is to minimize the cross-entropy loss, i.e.,

$$L(\theta) = -\sum_{s=1}^{S}\sum_{k=1}^{K} y_s^k \cdot \log\hat{y}_s^k + \lambda\|\theta\|_2^2 \tag{16}$$

where S is the number of training data. y_s is the true sentiment label of the s-th sample. $\hat{y}_s$ is the predicted sentiment label of the s-th sample. K is number of all sentiment categories. λ is a L_2-regularization term, θ is the parameter set. In the above equation, the model parameters are optimized by using Adam (Kingma and Ba, 2014).

5 Experimentation

In this section, we evaluate the performances of the proposed approach for QA-style sentiment classification.

5.1 Experimental Settings

- **Data Sets:** As introduced in Section 3, the annotated QA text pairs cover three different domains. In each domain, we randomly split the data into a training set (80% in each category) and a test set (20% in each category). In addition, we set aside 10% from the training set as the development data for parameters tuning.
- **Word Segmentation and Embeddings:** FudanNLP[3] (Qiu et al., 2013) is employed to segment text into Chinese words and word2vec[4] (Mikolov et al., 2013) is employed to pre-train word embeddings. The vector dimensionality is set to be 100.
- **Sentence Segmentation:** CoreNLP[5] (Manning et al., 2014) is employed to segment both the question and answer text into sentences.
- **Hyper-parameters:** In the experiment, all out-of-vocabulary words are initialized by sampling from the uniform distribution $U(-0.01, 0.01)$. All weight matrices are given their initial values by sampling from uniform distribution $U(-0.01, 0.01)$. The LSTM hidden states are set to be 128 and all models are trained by mini-batch of 32 instances. The dropout rate is set to 0.2. The other hyper-parameters are tuned according to the development data.
- **Evaluation Metric:** The performance is evaluated using standard *Accuracy* and *Macro-F1*.

Table 2: Performance of our approaches to QA-style sentiment classification in all domains.

5.2 Experimental Results

The following baseline approaches are employed for comparison. Note that all the approaches share the same word embeddings for fair comparison.

- **SVM:** This baseline employs support vector machine along with word embedding features. The question and answer text in a QA text pair are chained as a sequence.
- **LSTM:** A standard LSTM model utilizes word embeddings and concatenates the question and answer text as a sequence.
- **Bi-LSTM:** A bidirectional LSTM model which concatenates the question and answer text as a sequence.
- **Bidirectional-Match:** This approach employs QA bidirectional matching mechanism, without taking the sentence segmentation strategy and self-matching attention mechanism.
- **AtoQ-Match:** This approach takes the sentence segmentation strategy, and employs QA unidirectional matching mechanism (i.e., only using *Answer-to-Question* attention), but does not employ self-matching attention mechanism. We average the *Answer-to-Question* matching vectors to represent the QA text pair.
- **QtoA-Match:** This approach takes the sentence segmentation strategy, and employs QA unidirectional matching mechanism (i.e., only using *Question-to-Answer* attention), but does not employ self-matching attention mechanism.
- **Bidirectional-Match QA:** This approach takes the sentence segmentation strategy, and employs QA bidirectional matching mechanism, but does not employ self-matching attention mechanism.
- **HMN:** This is our hierarchical matching network model which takes the sentence segmentation strategy and employs both QA bidirectional matching mechanism and self-matching attention mechanism.

Table 2 summarizes the experimental results of all the approaches above, and we can find that:

(1) All LSTM-based approaches are superior to **SVM**, indicating the effectiveness of neural network for this task.

(2) The proposed approaches, with novel QA contextual representation, outperform the other baseline approaches.

(3) When only employing QA bidirectional matching mechanism, **Bidirectional-Match QA**, which takes the sentence segmentation strategy, consistently outperforms **Bidirectional-Match** (without sentence segmentation) in all domains. It confirms our hypothesis that sentence segmentation helps to extract the sentiment matching information between the question and answer.

(4) When comparing to QA unidirectional matching mechanism, **Bidirectional-Match QA**, which employs QA bidirectional matching mechanism, performs better than **AtoQ-Match** and **QtoA-Match**. It confirms our hypothesis that both the question and answer information contribute to sentiment polarity of the QA text pair.

(5) Impressively, the proposed approach **HMN** significantly outperforms all the other approaches in all domains (p-value$<$0.05 via t-test). It verifies the advantages of both QA bidirectional matching mechanism and self-matching attention mechanism for this task.

Besides, we also implement some more recent state-of-the-art approaches for sentiment classification, which are illustrated in Table 3. This result also supports the earlier findings.

- **CNN-Tensor** (Lei et al., 2015)**:** This is a state-of-the-art approach to sentence-level sentiment classification, which models n-gram interactions based on tensor product and evaluates all non-

consecutive *n*-gram vectors as a feature mapping operator for CNNs.

- **Attention-LSTM** (Wang et al., 2016)**:** This is a state-of-the-art approach to aspect-level sentiment classification. In our implementation, we ignore the aspect embedding and directly use the outputs of LSTM to yield the attention.
- **BiMPM** (Wang et al., 2017)**:** This is a state-of-the-art approach to QA matching, which matches the question and answer from multiple perspectives. In our implementation, we use the matching representation to perform QA-style sentiment classification with a *softmax* classifier.
- **HMN:** The proposed hierarchical matching network which employs both QA bidirectional matching mechanism and self-matching attention mechanism, and takes the sentence segmentation strategy.

Table 3 shows the comparison results of these strong baseline approaches and the proposed approach (**HMN**) in all domains. From this table, we can find that: (1) the approaches that take matching strategy, i.e., **BiMPM** and our approach **(HMN)**, outperform other approaches. (2) The proposed approach **(HMN)** significantly outperforms all the other baseline approaches in terms of both *Macro-F1* and *Accuracy* (p-value$<$0.05 via t-test), which confirms the initial hypotheses of this study.

(*The battery is not durable at all. The camera is also not good.*)

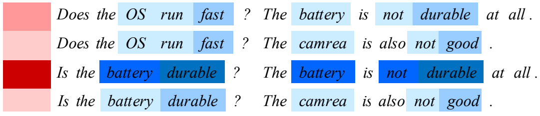

Figure 4: The attention visualizations for a QA text pair.

5.3 Case Study

Table 4 shows some examples, along with the predicted categories via different approaches. We can find that: (1) the approaches based on matching strategy (**BiMPM** and **HMN**) are well-performed, as shown in **E9**, when question and answer carrying different kinds of information. This is a unique challenge for QA-style sentiment mining, and traditional sentiment classification approaches can hardly address this problem. (2) The proposed approach **(HMN)** performs better than other approaches when dealing with *conflict* instances, as shown in **E10**.

5.4 Visualization of Attention

To get a better understanding of our proposed hierarchical matching network for QA-style sentiment classification, we picture the attention weights obtained from Equations (5), (8) and (13). For simplicity, we directly use the English translation of **E11** for illustration and adopt the visualization approach presented by Yang et al. (2016), as shown in Figure 2. Specifically, each line is a [Q-sentence, A-sentence] unit, where the red denotes the [Q-sentence, A-sentence] unit weight, the blue denotes the word weight in each [Q-sentence, A-sentence], and the color depth indicates the importance of attention weights (the darker the more important).

From Figure 4, we can see that the QA bidirectional matching layer always assigns reasonable attention weights to words in each [Q-sentence, A-sentence] unit which makes sentence from question and sentence from answer match correctly. In addition, the self-matching attention layer is able to select informative [Q-sentence, A-sentence] unit for predicting true sentiment polarity of this example.

6 Conclusion

In this paper, we propose a novel but important sentiment analysis task, i.e., QA-style sentiment mining, and we build a large-scale high-quality human annotated corpus for experiment. The dataset is shared to encourage other scholars to investigate this interesting problem. Moreover, we propose a hierarchical matching neural network model to enable QA bidirectional matching mechanism and self-matching attention mechanism for this task. Empirical studies show that the proposed approach significantly outperforms other strong baseline approaches in all the test domains for QA-style sentiment classification.

In the future, we would like to investigate some other network structures to explore deeper information in each QA text pair. Besides, we would like to test the effectiveness of the proposed approach to QA-style sentiment classification in some other languages.

Abstract

Argument mining is a core technology for automating argument search in large document collections. Despite its usefulness for this task, most current approaches are designed for use only with specific text types and fall short when applied to heterogeneous texts. In this paper, we propose a new sentential annotation scheme that is reliably applicable by crowd workers to arbitrary Web texts. We source annotations for over 25,000 instances covering eight controversial topics. We show that integrating topic information into bidirectional long short-term memory networks outperforms vanilla BiLSTMs by more than 3 percentage points in F_1 in two- and three-label cross-topic settings. We also show that these results can be further improved by leveraging additional data for topic relevance using multi-task learning.

1 Introduction

Information retrieval and question answering are by now mature technologies that excel at answering factual queries on noncontroversial topics. However, they provide no specialized support for queries where there is no single canonical answer, as with topics that are controversial or opinion-based. For such queries, the user may need to carefully assess the stance, source, and supportability for each of the answers. These processes can be supported by argument mining (AM), a nascent area of natural language processing concerned with the automatic recognition and interpretation of arguments.

In this paper, we apply AM to the task of *argument search*—that is, searching a large document collection for arguments relevant to a given topic. Searching for and classifying relevant arguments plays an important role in decision making (Svenson, 1979), legal reasoning (Wyner et al., 2010), and the critical reading, writing, and summarization of persuasive texts (Kobayashi, 2009; Wingate, 2012). Automating the argument search process could ease much of the manual effort involved in these tasks, particularly if it can be made to robustly handle arguments from different text types and topics.

But despite its obvious usefulness, this sort of argument search has attracted little attention in the research community. This may be due in part to the limitations of the underlying models and training resources, particularly as they relate to heterogeneous sources. That is, most current approaches to AM are designed for use with particular text types, faring poorly when applied to new data (Daxenberger et al., 2017). Indeed, as Habernal et al. (2014) observe, while there is a great diversity of perspectives on how arguments can be best characterized and modelled, there is no “one-size-fits-all” argumentation theory that applies to the variety of text sources found on the Web.

To approach these challenges, we propose the novel task of topic-based sentential argument mining. Our contributions are as follows: (1) We propose a new argument annotation scheme applicable to the information-seeking perspective of argument search. We show it to be general enough for use on heterogeneous data sources, and simple enough to be applied manually by untrained annotators at a reasonable cost. (2) We introduce a novel corpus of heterogeneous text types annotated with topic-based arguments.[1] The corpus includes over 25,000 instances covering eight controversial topics. This is the first known resource that can be used to evaluate the performance of argument mining methods across topics in heterogeneous sources. (3) We investigate different approaches for incorporating topic information into neural networks and

show that including the topic vector into the ***i***- and ***c***-gates of the LSTM cell outperforms common attention-based approaches in two- and three-label cross-topic experiments. (4) We further improve the performance of the modified LSTM cell by leveraging additional data for topic relevance in a multi-task learning setup. (5) In the more challenging setup of cross-topic experiments, we show that our models yield considerably better performance than common BiLSTM models when little data of the target topic is available.

2 Related work

Most existing approaches treat argument mining at the discourse level, focusing on tasks such as segmenting argumentative discourse units (Ajjour et al., 2017; Goudas et al., 2014), classifying the function of argumentative discourse units (for example, as *claims* or *premises*) (Mochales-Palau and Moens, 2009; Stab and Gurevych, 2014), and recognizing argumentative discourse relations (Eger et al., 2017; Stab and Gurevych, 2017; Nguyen and Litman, 2016). These discourse-level approaches address the identification of argumentative structures within a single document but do not consider relevance to externally defined topics.

To date, there has been little research on the identification of topic-relevant arguments for argument search. Wachsmuth et al. (2017) present a generic argument search framework. However, it relies on already-structured arguments from debate portals and is not yet able to retrieve arguments from arbitrary texts. Levy et al. (2014) investigate the identification of topic-relevant claims, an approach that was later extended with evidence extraction to mine supporting statements for claims (Rinott et al., 2015). However, both approaches are designed to mine arguments from Wikipedia articles; it is unclear whether their annotation scheme is applicable to other text types. It is also uncertain that it can be easily and accurately applied by untrained annotators, since it requires unitizing (i.e., finding the boundaries of argument components at the token level). Hua and Wang (2017) identify sentences in cited documents that have been used by an editor to formulate an argument. By contrast, we do not limit our approach to the identification of sentences related to a given *argument*, but rather focus on the retrieval of any argument relevant to a given *topic*. The fact that we are concerned with retrieval of arguments also sets our work apart from the discourse-agnostic stance detection task of Mohammad et al. (2016), which is concerned with the identification of sentences expressing support or opposition to a given topic, irrespective of whether those sentences contain supporting evidence (as opposed to mere statements of opinion).

Cross-domain AM experiments have so far been conducted only for discourse-level tasks such as claim identification (Daxenberger et al., 2017), argumentative segment identification (Al-Khatib et al., 2016), and argumentative unit segmentation (Ajjour et al., 2017). However, the discourse-level argumentation models these studies employ seem to be highly dependent on the text types for which they were designed; they do not work well when applied to other text types (Daxenberger et al., 2017). The crucial difference between our own work and prior cross-domain experiments is that we investigate AM from heterogeneous texts across different *topics* instead of studying specific discourse-level AM tasks across restricted text types of existing corpora.

3 Corpus creation

There exists a great diversity in models of argumentation, which differ in their perspective, complexity, terminology, and intended applications (Bentahar et al., 2010). For the present study, we propose a model which, though simplistic, is nonetheless well-suited to the argument search scenario. We define an *argument* as a span of text expressing evidence or reasoning that can be used to either support or oppose a given topic. An argument need not be "direct" or self-contained—it may presuppose some common or domain knowledge, or the application of commonsense reasoning—but it must be unambiguous in its orientation to the topic. A *topic*, in turn, is some matter of controversy for which there is an obvious polarity to the possible outcomes—that is, a question of being either *for* or *against* the use or adoption of something, the commitment to some course of action, etc. In some graph-based models of argumentation (Stab, 2017, Ch. 2), what we refer to as a *topic* would be part of a *(major) claim* expressing a positive or negative stance, and our *arguments* would be *premises* with supporting/attacking *consequence relations* to the claim. However, unlike these models, which are typically used to represent (potentially deep or complex) argument structures at the discourse level, ours is a flat model that considers arguments in isolation from their surrounding context. A great

topic	sentence	label
nuclear energy	Nuclear fission is the process that is used in nuclear reactors to produce high amount of energy using element called uranium.	non-argument
nuclear energy	It has been determined that the amount of greenhouse gases have decreased by almost half because of the prevalence in the utilization of nuclear power.	supporting argument
minimum wage	A 2014 study [. . .] found that minimum wage workers are more likely to report poor health, suffer from chronic diseases, and be unable to afford balanced meals.	opposing argument
minimum wage	We should abolish all Federal wage standards and allow states and localities to set their own minimums.	non-argument

Table 1: Example annotations illustrating our annotation scheme.

advantage of this approach is that it allows annotators to classify text spans without having to read large amounts of context and without having to consider relations to other topics or arguments.

In this work, we consider only those topics that can be concisely and implicitly expressed through keywords, and those arguments that consist of individual sentences. Some examples, drawn from our dataset, are shown in Table 1. Note that while the fourth example expresses opposition to the topic, under our definition it is properly classified as a non-argument because it is a mere statement of stance that provides no evidence or reasoning.

Data. For our experiments we gathered a large collection of manually annotated arguments that cover a variety of topics and that come from a variety of text types. We started by randomly selecting eight topics (see Table 2) from online lists of controversial topics.[2] For each topic, we made a Google query for the topic name, removed results not archived by the Wayback Machine,[3] and truncated the list to the top 50 results. This resulted in a set of persistent, topic-relevant, largely polemical Web documents representing a range of genres and text types, including news reports, editorials, blogs, debate forums, and encyclopedia articles. We preprocessed each document with Apache Tika (Mattmann and Zitting, 2011) to remove boilerplate text. We then used the Stanford CoreNLP tools (Manning et al., 2014) to perform tokenization, sentence segmentation, and part-of-speech tagging on the remaining text, and removed all sentences without verbs or with less than three tokens. This left us with a raw dataset of 27,520 sentences (about 2,700 to 4,400 per topic).

Annotators classified the sentences using a browser-based interface that presents a set of instructions, a topic, a list of sentences, and a multiple-choice form for specifying whether each sentence is a supporting argument, an opposing argument, or not an argument with respect to the topic. (In preliminary experiments, we presented annotators with a fourth option for sentences that are ambiguous or incomprehensible. However, we found that these constituted less than 1% of the distribution and so mapped all such answers to the "no argument" class.)

Annotation experiments. We tested the applicability of our annotation scheme by untrained annotators by performing an experiment where we had a group of "expert" annotators and a group of untrained annotators classify the same set of sentences, and then compared the two groups' classifications. The data for this experiment consisted of 200 sentences randomly selected from each of our eight topics. Our expert annotators were two graduate-level language technology researchers who were fully briefed on the nature and purpose of the argument model. Our untrained annotators were anonymous American workers from the Amazon Mechanical Turk (AMT) crowdsourcing platform. Each sentence was independently annotated by the two expert annotators and ten crowd workers.

Inter-annotator agreement for our two experts, as measured by Cohen's κ, was 0.721; this exceeds the commonly used threshold of 0.7 for assuming the results are reliable (Carletta, 1996). We proceeded by having the two experts resolve their disagreements, resulting in a set of "expert" gold-standard annotations. Similar gold standards were produced for the crowd annotations by applying the MACE denoising tool (Hovy et al., 2013); we tested various thresholds (1.0, 0.9, and 0.8) to discard instances that could be confidently assigned a gold label. We then calculated κ between the remaining instances in the expert and crowd gold standards. In order to

determine the relationship between inter-annotator agreement and the number of crowd workers, we performed this procedure with successively lower numbers of crowd workers, going from the original ten annotators per instance down to two. The results are visualized in Fig. 1. We found that using seven annotators and a MACE threshold of 0.9 results in $\kappa = 0.723$; this gives us similar reliability as with the expert annotators without sacrificing much coverage. Table 3 shows the κ and percentage agreement for this setup, as well as the agreement between our expert annotators, broken down by topic.

We proceeded with annotating the remaining instances in our dataset using seven crowd workers each, paying a rate corresponding to the US federal minimum wage of $7.25/hour. Our total expenditure, including AMT processing fees, was $2,774.02. After MACE denoising, we were left with 25,492 gold-standard annotations. Table 2 provides statistics on the size and class distribution of the final corpus. We are releasing the gold-standard annotations for this dataset, and code for retrieving the original sentences from the Wayback Machine, under a Creative Commons licence.

4 Approaches for identifying arguments

We model the identification of arguments as a sentence-level classification task. In particular, given a sentence $\boldsymbol{\varsigma}$ with words $u_1, \ldots, u_{n_\varsigma}$ and a topic $\boldsymbol{\tau}$ of words $v_1, \ldots, v_{n_\tau}$ (e.g., "gun control" or "school uniforms"), we aim to classify $\boldsymbol{\varsigma}$ as a "supporting argument" or "opposing argument" if it includes a relevant reason for supporting or opposing the $\boldsymbol{\tau}$, or as a "non-argument" if it does not include a reason or is not relevant to $\boldsymbol{\tau}$. We also investigate a two-label classification where we combine supporting and opposing arguments into a single category; this allows us to evaluate argument classification independent of stance. We focus on the challenging task of cross-topic experiments, where one topic is withheld from the training data and used for testing. Here, we denote scalars by italic lowercase letters (e.g., t), vector representations by italic bold lowercase letters (e.g., $\boldsymbol{c}$), and matrices as italic bold uppercase letters (e.g., $\boldsymbol{W}$).

4.1 Integrating topic information

Since arguments need to be relevant to the given topic, we posit that providing topic information to the learner results in a more robust prediction capability in cross-topic setups. Below, we present two models that integrate the topic, one that uses an attention mechanism and another that includes the topic vector directly in the LSTM cell.

Outer-attention BiLSTM (outer-att). To let the model learn which parts of the sentence are relevant (or irrelevant) to the given topic, we use an attention-based neural network (Bahdanau et al., 2014) that learns an importance weighting of the input words depending on the given topic. In particular, we adopt an outer-attention mechanism similar to the one proposed by Hermann et al. (2015), which has achieved state-of-the-art results in related tasks such as natural language inference and recognizing textual entailment (Rocktäschel et al., 2015; Wang and Jiang, 2016). We combine the attention mechanism with a common BiLSTM model and, at time step t, determine the importance weighting for each hidden state $\boldsymbol{h}(t)$ as

$$\boldsymbol{m}(t) = \tanh(\boldsymbol{W}_h \boldsymbol{h}(t) + \boldsymbol{W}_p \boldsymbol{p}) \qquad (1)$$

$$f_{attention}(\boldsymbol{h}(t), \boldsymbol{p}) = \frac{\exp(\boldsymbol{w}_m^T \boldsymbol{m}(t))}{\sum_t \exp(\boldsymbol{w}_m^T \boldsymbol{m}(t))} \qquad (2)$$

where $\boldsymbol{W}_h$, $\boldsymbol{W}_p$, and $\boldsymbol{w}_m$ are trainable parameters of the attention mechanism and $\boldsymbol{p}$ is the average of all word embeddings of topic words $v_1, \ldots, v_{n_\tau}$. Using the importance weighting, we determine the final, weighted hidden output state $\boldsymbol{s}$ as

$$\alpha_t \propto f_{attention}(\boldsymbol{h}(t), \boldsymbol{p}) \qquad (3)$$

$$\boldsymbol{s} = \sum_{t=1}^{n} \boldsymbol{h}(t) \alpha_t . \qquad (4)$$

Finally, we feed $\boldsymbol{s}$ into a dense layer with a softmax activation function to get predictions for our two- or three-label setups.

Contextual BiLSTM (biclstm). A more direct approach to integrating an argument's topic is the *contextual LSTM* (CLSTM) architecture (Ghosh et al., 2016), where topic information is added as another term to all four gates of an LSTM cell. We, however, hypothesize that topic information is more relevant at the $\boldsymbol{i}$- and $\boldsymbol{c}$-gates, the former because it has the biggest impact on how a new token is processed and the latter because it is closely linked to how the sequence seen so far is to be interpreted and stored. To this end, we experimented with several modifications to the original CLSTM such as removing peepholes—i.e., removing gates' access to the cell state $\boldsymbol{c}$ (Gers and Schmidhuber, 2000)—and removing topic information from one or more gates. Empirical results on the validation set show that topic integration at the $\boldsymbol{i}$- and $\boldsymbol{c}$-gates only, and removal of all peephole connections, does indeed outperform the original CLSTM on our task by 1 percentage point. Our modified CLSTM (Fig. 2) is defined as

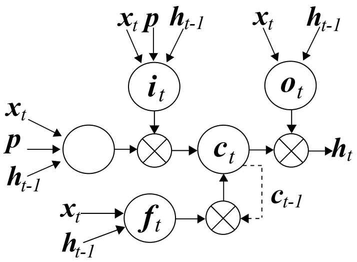

Figure 2: Architecture of a CLSTM cell.

$$\boldsymbol{i}_t = \sigma(\boldsymbol{W}_{x_i} \boldsymbol{x}_t + \boldsymbol{W}_{h_i} \boldsymbol{h}_{t-1} + \boldsymbol{b}_i + \boxed{\boldsymbol{W}_{\boldsymbol{p}_i} \boldsymbol{p}}) \qquad (5)$$

$$\boldsymbol{f}_t = \sigma(\boldsymbol{W}_{x_f} \boldsymbol{x}_t + \boldsymbol{W}_{h_f} \boldsymbol{h}_{t-1} + \boldsymbol{b}_f) \qquad (6)$$

$$\begin{aligned} \boldsymbol{c}_t = \boldsymbol{f}_t \boldsymbol{c}_{t-1} + \boldsymbol{i}_t \sigma_c(&\boldsymbol{W}_{x_c} \boldsymbol{x}_t + \boldsymbol{W}_{h_c} \boldsymbol{h}_{t-1} \\ &+ \boldsymbol{b}_c + \boxed{\boldsymbol{W}_{\boldsymbol{p}_c} \boldsymbol{p}}) \end{aligned} \qquad (7)$$

$$\boldsymbol{o}_t = \sigma(\boldsymbol{W}_{x_o} \boldsymbol{x}_t + \boldsymbol{W}_{h_o} \boldsymbol{h}_{t-1} + \boldsymbol{b}_o) \qquad (8)$$

$$\boldsymbol{h}_t = \boldsymbol{o}_t \sigma_c(\boldsymbol{c}_t). \qquad (9)$$

Here $\boldsymbol{i}$, $\boldsymbol{f}$, and $\boldsymbol{o}$ represent the input, forget, and output gates; $\boldsymbol{c}$ the cell memory; $\boldsymbol{x}_t$ the embedded token of a sentence at timestep t; $\boldsymbol{h}_{t-1}$ the previous hidden state; and $\boldsymbol{b}$ the bias. σ and σ_c are the activation and recurrent activation functions, respectively. The novel terms for topic integration are outlined. We use this model bidirectionally, as we did with our BiLSTM network, and hence refer to it as biclstm.

4.2 Leveraging additional data

As we want to classify arguments related to specific topics, leveraging information that supports the classifier in the decision of topic-relation is crucial. The multi-task learning (mtl) and transfer learning (trl) models are able to make use of auxiliary data that can potentially improve the results on the main task. Thus, we extend our previously described models by integrating them into mtl and trl setups. We also choose to integrate two corpora

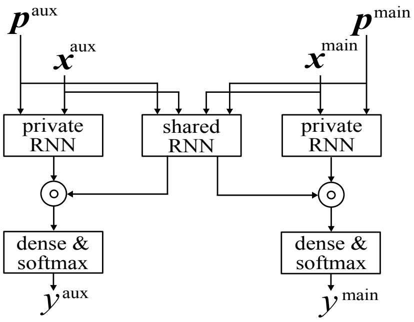

Figure 3: Multi-task learning architecture. The ⊚ symbol denotes the concatenation operator.

from which we expect to learn (a) topic-relevance and (b) the capability to distinguish between supporting and attacking arguments. The first corpus, DIP2016 (Habernal et al., 2016), consists of 49 queries from the educational domain and 100 documents for each query. Each document has its sentences annotated for relevance (true/false) to the query.[4] The second corpus, from SemEval-2016 Task 6 (Mohammad et al., 2016), consists of around 5000 multi-sentence tweets, a corresponding topic (e.g., “atheism”), and the author’s stance on the topic (for/against/neither).

For our mtl and trl approaches, we consider every possible pairing of a model (biclstm, outer-att, and the bilstm baseline we introduce in §5) with an auxiliary corpus (DIP2016, SemEval). We formalize our datasets as $S_k = \{(\boldsymbol{x}_i^k, \boldsymbol{p}_i^k, y_i^k) | i = 0, \ldots, |S_k|\}$, where k can be either our main dataset or an auxiliary dataset, $\boldsymbol{x}_i^k$ denotes a single sentence as a sequence of word embeddings and y_i^k its corresponding label in k, and $\boldsymbol{p}_i^k$ represents the corresponding averaged topic vector.

Transfer learning (trl). For trl, we use the approach of *parameter transfer* (Pan and Yang, 2010)—i.e., we do not modify the model used. Instead, we train the model twice: the first time, we train the model on the chosen auxiliary corpus, and the second time, we keep the trained model’s weights and train it with our own corpus. For the three-label setting, we have to modify the transfer model slightly for the DIP2016 corpus, since it provides only two labels for each training sample. In this case, we simply add a layer with two neurons on top of the layer with three neurons for training with the DIP2016 corpus and remove it afterwards for training with our corpus.

Multi-task learning (mtl). For mtl, we use a shared–private model (Liu et al., 2017), which showed promising results for text classification and word segmentation (Chen et al., 2017). (We also experimented with their adversarial approach to learn topic-invariant features, but abandoned this due to low scores.) The mtl base model consists of a private recurrent neural network (RNN) for both the auxiliary dataset and our dataset, plus a shared RNN that both datasets use (Fig. 3). The last hidden states of the RNNs are concatenated and fed through a dense layer and a softmax activation function. The model is trained in an alternating fashion—i.e., after each epoch the loss for the other dataset is minimized until each dataset has run for the set number of epochs, where the last epoch is always executed on our dataset. At prediction time, only the private RNN trained on our dataset and the shared RNN are used. The core idea is that the shared RNN learns what is relevant for both tasks, while the private ones learn only the task-specific knowledge.

For the cases of mtl+bilstm+*corpus*, mtl+biclstm+*corpus*, and mtl+outer-att+*corpus*, we simply switch the RNN with our bilstm, biclstm, and outer-att, respectively. For mtl+outer-att+*corpus*, we add the outer attention mechanism (see §4.1), modified for use with the mtl model, after each of the private RNNs, while additionally feeding it a second topic vector—the last hidden state of the shared RNN:

$$\boldsymbol{m}(t) = \tanh(\boldsymbol{W}_r \boldsymbol{h}_r(t) + \boldsymbol{W}_s \boldsymbol{h}_s + \boldsymbol{W}_p \boldsymbol{p}) \qquad (10)$$

$$f_{attention}(\boldsymbol{h}_r(t), \boldsymbol{h}_s, \boldsymbol{p}) = \frac{\exp(\boldsymbol{w}_m^T \boldsymbol{m}(t))}{\sum_t \exp(\boldsymbol{w}_m^T \boldsymbol{m}(t))} \qquad (11)$$

$$\alpha_t \propto f_{attention}(\boldsymbol{h}_r(t), \boldsymbol{h}_s, \boldsymbol{p}) \qquad (12)$$

$$\boldsymbol{s} = \sum_{t=1}^{n} \boldsymbol{h}_r(t) \alpha_t \qquad (13)$$

where $\boldsymbol{W}_r$, $\boldsymbol{W}_s$, and $\boldsymbol{W}_p$ are trainable weight matrices, $\boldsymbol{h}_r(t)$ is the hidden state of the private bilstm at timestep t, $\boldsymbol{h}_s$ is the last hidden state of the shared model, and $\boldsymbol{p}$ is the average of all word embeddings of topic words $v_1, \ldots, v_{n_\tau}$.

5 Evaluation

To evaluate the robustness of the models, we conduct cross-topic experiments to evaluate how well the models generalize to an unknown topic. To this end, we combine training (70%) and validation

Table 4: Results for each model on the test sets. Bold numbers indicate the highest score in the column.

data (10%) of seven topics for training and parameter tuning, and use the test data (20%) of the eighth topic for testing. For encoding the words of sentence $\boldsymbol{\varsigma}$ and topic $\boldsymbol{\tau}$, we use 300-dimensional word embeddings trained on the Google News dataset by Mikolov et al. (2013). To handle out-of-vocabulary words, we create separate random word vectors for each.[5]

Since reporting single performance scores is insufficient to compare non-deterministic learning approaches like neural networks (Reimers and Gurevych, 2017), we report all results as averages over ten runs with different random seeds. As evaluation measures, we report the average macro F_1, as well as the precision and the recall for the argument class (P_{arg}, R_{arg}). For the three-label approach, we split the precision and recall for predicting supporting (P_{arg+}, R_{arg+}) and attacking arguments (P_{arg-}, R_{arg-}). As baselines, we use a simple bidirectional LSTM (Hochreiter and Schmidhuber, 1997), as well as a logistic regression model with lowercased unigram features, which has been shown to be a strong baseline for various other AM tasks (Daxenberger et al., 2017; Stab and Gurevych, 2017). We refer to these models as bilstm and lr-uni, respectively. All neural networks are trained using the Adam optimizer (Kingma and Ba, 2015) and cross-entropy loss function. For finding the best model, we run each for ten epochs and take the best model based on the lowest validation loss. In addition to that, we tune the hyperparameters of all neural networks (see Appendix A). To accelerate training, we truncate sentences at 60 words.[6]

5.1 Results

Two-label setup. The results in Table 4 show that all our models outperform the baselines for two-label prediction.[7] F_1 for biclstm improves by 3.5 percentage points over the bilstm baseline and by 5.6 over lr-uni. A main reason for this proves to be the substantial increase in recall for our topic-integrating models—outer-att and especially biclstm—in comparison to our baselines. These results show that knowledge of the argument's topic has a strong impact on argument prediction capability. Further, we observe that integrating biclstm in a multi-task learning setup in order to draw knowledge about topic relevance from the DIP2016 corpus (mtl+biclstm+dip2016) improves F_1 by an additional 2.5 percentage points. It achieves an F_1 of 0.6662, which is 19.48 percentage points less than the human upper bound of 0.861. When using the SemEval corpus, which holds less task-relevant knowledge for our two-label approach, we are able to gain only 1 percentage point when integrating it into mtl+biclstm+*corpus*.

For the transfer learning models that integrate the topic (tr+biclstm+*corpus* and tr+outer-att+*corpus*), the parameter transfer is mostly ineffective. If no topic is provided (tr+bilstm+*corpus*), the transfer learning models are able to improve over the baseline bilstm. This shows that the parameter transfer

---

[5] Each dimension is set to a random number between −0.01 and 0.01. Digits are mapped to the same random word vector.

[6] Only 244 of our sentences (<1%) exceed this length.

[7] Detailed results per topic are given in Appendix B.

itself can be of use, but confuses the model when combined with topic integration.

In general, we observe an overall lower score for trl models that use the DIP2016 corpus compared to those using the SemEval corpus. In contrast to the mtl model, for trl models *all* parameters are transferred to the main task, not just parameters that represent shared knowledge. Thus, we suspect the lower scores of the trl models with DIP2016 are due to overfitting on the vast number of samples which shape the parameters much more than the comparatively small SemEval corpus could.

Three-label setup. For the three-label approach, we observe overall lower scores due to the additional difficulty in distinguishing supporting from opposing arguments. As already observed in the two-label setup, biclstm outperforms both the bilstm and lr-uni baselines; here, the former by 4.5 and the latter by 4.2 percentage points in F_1. Again, this is caused by a substantial increase in recall and shows the impact that the available topic information has on the classifier's predictive power.

For transfer learning, we see similar results as for the two-label approach; both the DIP2016 and SemEval corpora have a generally negative impact when compared to the respective base models. The SemEval corpus does not provide the knowledge required to distinguish supporting from attacking arguments. We conclude that the original purpose of the SemEval task, stance recognition, is too different from our own. But in multi-task learning, where only the shared parameters are taken, we observe slight improvements when using biclstm with DIP2016; this correlates with the same model in the two-label setup.

5.2 Error analysis

To understand the errors of our best model, mtl-biclstm-dip, and the nature of this task, we manually analyzed 100 sentences randomly sampled from the false positive and false negative arguments of the three-label experiments (combining supporting and attacking arguments). Among the false positives, we found 48 off-topic sentences that were wrongly classified as arguments. The 52 on-topic false positives consist of non-argumentative background information or mere opinions without evidence (as with the first and fourth examples of Table 1) and questions about the topic. Among the false negatives, we found 65 arguments that did not explicitly refer to the topic but to related aspects that depend on background knowledge. For instance, the model fails to establish an argumentative link between the topic "gun control" and the Second Amendment to the US Constitution. Lastly, we inspected arguments that are incorrectly classified as supporting and/or opposing a topic. We found several samples in which the term "against" is not correctly interpreted and the argument is classified as supporting a topic. Similarly, for arguments incorrectly classified as attacking, we find various samples where the word "oppose" is used not to oppose the topic but to strengthen a supporting argument, as in "There is reason even for people who oppose the use of marijuana to support its legalization. . . "

5.3 Adapting to new topics

To evaluate the performance of the models in data-scarce scenarios, we gradually add target topic data to the training data and analyze the model performance on the target test set. Figure 4 shows model performance (F_1, P_{arg}, and R_{arg}) on the "marijuana legalization" topic when adding different amounts of randomly sampled topic-specific data to the training data (x-axes).[8] As the results show, the models that integrate the topic achieve higher recall when adding target topic data to the training data. For bilstm, we observe a drastic difference when compared to the other models; the recall for arguments stays at around 30% and rises only when integrating more than 60% target topic data. In strong contrast, topic-integrating models retrieve a much higher number of actual arguments at target topic augmentation levels as low as 20%. Further, and equally important, this does not come at the cost of precision; on the contrary, the precision is mostly steady and slowly rising after around 20% of target topic integration, leading to an overall higher F_1 for these models. Finally, in comparing F_1 between topic-integrating models and bilstm, we conclude that the former need much less target topic data to substantially improve their score, making them more robust in situations of data scarcity.

6 Conclusion

We have presented a new approach for searching a document collection for arguments relevant to a given topic. First, we introduced an annotation scheme suited to the information-seeking perspec-

---

[8] Each data point in the plot is the average score of ten runs with different random samples of target topic data.

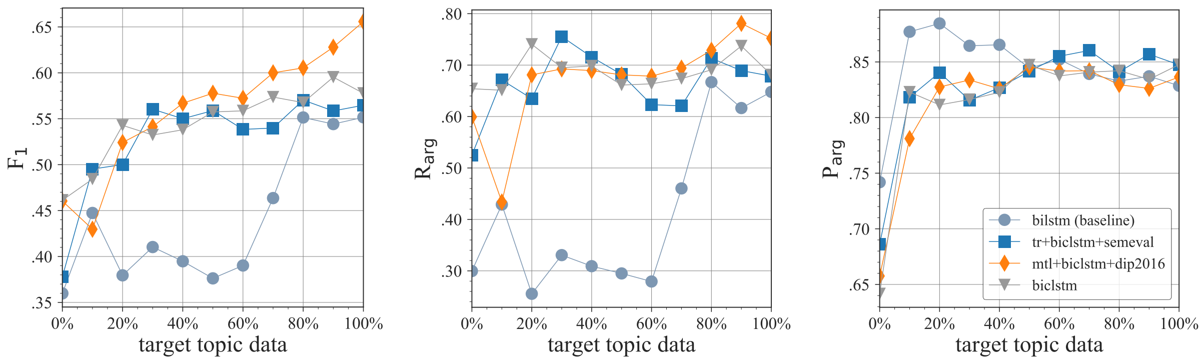

Figure 4: Model performance (y-axes) according to the amount of target topic data in the train sets (x-axes) for the "marijuana legalization" topic in the three-label setup.

tive of argument search and showed that it is cheaply but reliably applicable by untrained annotators to arbitrary Web texts. Second, we presented a new corpus, including over 25,000 instances over eight topics, that allows for cross-topic experiments using heterogeneous text types. Third, we conducted cross-topic experiments and showed that integrating topic information of arguments with our contextual BiLSTM leads to better generalization to unknown topics. Fourth, by leveraging knowledge from similar datasets and integrating our contextual BiLSTM into a multi-task learning setup, we were able to gain an improvement over our strongest baseline of 5.9 percentage points in F_1 in the two-label setup and 4.6 in the three-label setup. Finally, by gradually adding target topic data to our training set, we showed that, when available, even small amounts of target topic data (20%) have a strong positive influence on the recall of arguments.

In a separate, simultaneously written paper (Stab et al., 2018) we evaluate our models in real-world application scenarios by applying them to a large document collection and comparing the results to a manually produced gold standard. An online argument search engine implementing our approach is now available for noncommercial use at `https://www.argumentsearch.com/`. Furthermore, we are experimenting with language adaptation and plan to extend the tool to the German language. Preliminary results are presented in Stahlhut (2018). We also intend to investigate methods for grouping similar arguments.

Summarizing Opinions: Aspect Extraction Meets Sentiment Prediction and They Are Both Weakly Supervised

Stefanos Angelidis and **Mirella Lapata**

Abstract

We present a neural framework for opinion summarization from online product reviews which is knowledge-lean and only requires light supervision (e.g., in the form of product domain labels and user-provided ratings). Our method combines two weakly supervised components to identify salient opinions and form extractive summaries from multiple reviews: an aspect extractor trained under a multi-task objective, and a sentiment predictor based on multiple instance learning. We introduce an opinion summarization dataset that includes a training set of product reviews from six diverse domains and human-annotated development and test sets with gold standard aspect annotations, salience labels, and opinion summaries. Automatic evaluation shows significant improvements over baselines, and a large-scale study indicates that our opinion summaries are preferred by human judges according to multiple criteria.[1]

1 Introduction

Opinion summarization, i.e., the aggregation of user opinions as expressed in online reviews, blogs, internet forums, or social media, has drawn much attention in recent years due to its potential for various information access applications. For example, consumers have to wade through many product reviews in order to make an informed decision. The ability to summarize these reviews succinctly would allow customers to efficiently absorb large amounts of opinionated text and manufacturers to keep track of what customers think about their products (Liu, 2012).

The majority of work on opinion summarization is *entity-centric*, aiming to create summaries from text collections that are relevant to a particular entity of interest, e.g., product, person, company, and so on. A popular decomposition of the problem involves three subtasks (Hu and Liu, 2004, 2006): (1) *aspect extraction* which aims to find specific features pertaining to the entity of interest (e.g., battery life, sound quality, ease of use) and identify expressions that discuss them; (2) *sentiment prediction* which determines the sentiment orientation (positive or negative) on the aspects found in the first step, and (3) *summary generation* which presents the identified opinions to the user (see Figure 1 for an illustration of the task).

A number of techniques have been proposed for aspect discovery using part of speech tagging (Hu and Liu, 2004), syntactic parsing (Lu et al., 2009), clustering (Mei et al., 2007; Titov and McDonald, 2008b), data mining (Ku et al., 2006), and information extraction (Popescu and Etzioni, 2005). Various lexicon and rule-based methods (Hu and Liu, 2004; Ku et al., 2006; Blair-Goldensohn et al., 2008) have been adopted for sentiment prediction together with a few learning approaches (Lu et al., 2009; Pappas and Popescu-Belis, 2017; Angelidis and Lapata, 2018). As for the summaries, a common format involves a list of aspects and the number of positive and negative opinions for each (Hu and Liu, 2004). While this format gives an overall idea of people's opinion, reading the actual text might be necessary to gain a better understanding of specific details. Textual summaries are created following mostly extractive methods (but see Ganesan et al. 2010 for an abstractive approach), and various formats ranging from lists of words (Popescu and Etzioni, 2005), to phrases (Lu et al., 2009), and sentences (Mei et al., 2007; Blair-Goldensohn et al., 2008; Lerman et al., 2009; Wang and Ling, 2016).

In this paper, we present a neural framework for opinion extraction from product reviews. We follow the standard architecture for aspect-based summarization, while taking advantage of the success of neural network models in learning continuous features without recourse to preprocessing tools or linguistic annotations. Central to our system is the ability to accurately identify aspect-

Brussels, Belgium, October 31 - November 4, 2018.

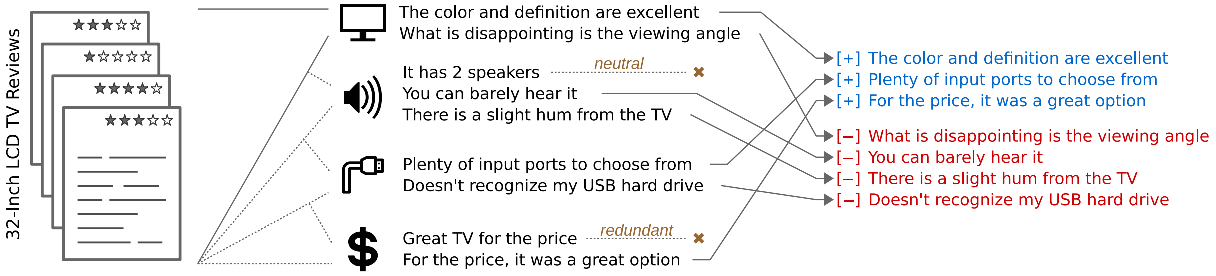

Figure 1: Aspect-based opinion summarization. Opinions on image quality, sound quality, connectivity, and price of an LCD television are extracted from a set of reviews. Their polarities are then used to sort them into positive and negative, while neutral or redundant comments are discarded.

specific opinions by using different sources of information freely available with product reviews (product domain labels, user ratings) and minimal domain knowledge (essentially a few aspect-denoting keywords). We incorporate these ideas into a recently proposed aspect discovery model (He et al., 2017) which we combine with a weakly supervised sentiment predictor (Angelidis and Lapata, 2018) to identify highly salient opinions. Our system outputs extractive summaries using a greedy algorithm to minimize redundancy. Our approach takes advantage of weak supervision signals only, requires minimal human intervention and no gold-standard salience labels or summaries for training.

Our contributions in this work are three-fold: a novel neural framework for the identification and extraction of salient customer opinions that combines aspect and sentiment information and does not require unrealistic amounts of supervision; the introduction of an opinion summarization dataset which consists of Amazon reviews from six product domains, and includes development and test sets with gold standard aspect annotations, salience labels, and multi-document extractive summaries; a large-scale user study on the quality of the final summaries paired with automatic evaluations for each stage in the summarization pipeline (aspects, extraction accuracy, final summaries). Experimental results demonstrate that our approach outperforms strong baselines in terms of opinion extraction accuracy and similarity to gold standard summaries. Human evaluation further shows that our summaries are preferred over comparison systems across multiple criteria.

2 Related Work

It is outside the scope of this paper to provide a detailed treatment of the vast literature on opinion summarization and related tasks. For a comprehensive overview of non-neural methods we refer the interested reader to Kim et al. (2011) and Liu and Zhang (2012). We are not aware of previous studies which propose a neural-based system for end-to-end opinion summarization without direct supervision, although as we discuss below, recent efforts tackle various subtasks independently.

Aspect Extraction Several neural network models have been developed for the identification of aspects (e.g., words or phrases) expressed in opinions. This is commonly viewed as a supervised sequence labeling task; Liu et al. (2015) employ recurrent neural networks, whereas Yin et al. (2016) use dependency-based embeddings as features in a Conditional Random Field (CRF). Wang et al. (2016) combine a recursive neural network with CRFs to jointly model aspect and sentiment terms. He et al. (2017) propose an aspect-based autoencoder to discover fine-grained aspects without supervision, in a process similar to topic modeling. Their model outperforms LDA-style approaches and forms the basis of our aspect extractor.

Sentiment Prediction Fully-supervised approaches based on neural networks have achieved impressive results on fine-grained sentiment classification (Kim, 2014; Socher et al., 2013). More recently, *Multiple Instance Learning* (MIL) models have been proposed that use freely available review ratings to train segment-level predictors. Kotzias et al. (2015) and Pappas and Popescu-Belis (2017) train sentence-level predictors under a MIL objective, while our previous work (Angelidis and Lapata, 2018) introduced MILNET, a hierarchical model that is trained end-to-end on document labels and produces polarity-based opinion summaries of single reviews. Here, we use MILNET to predict the sentiment polarity of individual opinions.

Multi-document Summarization A few extractive neural models have been recently applied to generic multi-document summarization. Cao et al. (2015) train a recursive neural network using a ranking objective to identify salient sentences, while follow-up work (Cao et al., 2017) employs a multi-task objective to improve sentence extraction, an idea we adapted to our task. Yasunaga et al. (2017) propose a graph convolution network to represent sentence relations and estimate sentence salience. Our summarization method is tailored to the opinion extraction task, it identifies aspect-specific and salient units, while minimizing the redundancy of the final summary with a greedy selection algorithm (Cao et al., 2015; Yasunaga et al., 2017). Redundancy is also addressed in Ganesan et al. (2010) who propose a graph-based framework for abstractive summarization. Wang and Ling (2016) introduce an encoder-decoder neural method for extractive opinion summarization. Their approach requires direct supervision via gold-standard extractive summaries for training, in contrast to our weakly supervised formulation.

3 Problem Formulation

Let C denote a corpus of reviews on a set of products $E_{\mathrm{C}} = \{e_i\}_{i=1}^{|E_{\mathrm{C}}|}$ from a domain d_{C}, e.g., televisions or keyboards. For every product e, the corpus contains a set of reviews $R_e = \{r_i\}_{i=1}^{|R_e|}$ expressing customers' opinions. Each review r_i is accompanied by the author's overall rating y_i and is split into segments $(s_1, \ldots, s_m)$, where each segment s_j is in turn viewed as a sequence of words $(w_{j1}, \ldots, w_{jn})$. A segment can be a sentence, a phrase, or in our case an *Elementary Discourse Unit* (EDU; Mann and Thompson 1988) obtained from a *Rhetorical Structure Theory* (RST) parser (Feng and Hirst, 2012). EDUs roughly correspond to clauses and have been shown to facilitate performance in summarization (Li et al., 2016), document-level sentiment analysis (Bhatia et al., 2015), and single-document opinion extraction (Angelidis and Lapata, 2018).

A segment may discuss zero or more *aspects*, i.e., different product attributes. We use $A_{\mathrm{C}} = \{a_i\}_{i=1}^{K}$ to refer to the aspects pertaining to domain d_{C}. For example, *picture quality*, *sound quality*, and *connectivity* are all aspects of televisions. By convention, a *general* aspect is assigned to segments that do not discuss any specific aspects. Let $A_s \subseteq A_{\mathrm{C}}$ denote the set of aspects mentioned in segment s; $pol_s \in [-1, +1]$ marks the *polarity* a segment conveys, where -1 indicates maximally negative and $+1$ maximally positive sentiment. An opinion is represented by tuple $o_s = (s, A_s, pol_s)$, and $O_e = \{o_s\}_{s \in R_e}$ represents the set of all opinions expressed in R_e.

For each product e, our goal is to produce a summary of the most salient opinions expressed in reviews R_e, by selecting a small subset $S_e \subset O_e$. We expect segments that discuss specific product aspects to be better candidates for useful summaries. We hypothesize that *general* comments mostly describe customers' overall experience, which can also be inferred by their rating, whereas aspect-related comments provide specific reasons for their overall opinion. We also assume that segments conveying highly positive or negative sentiment are more likely to present informative opinions compared to neutral ones, a claim supported by previous work (Angelidis and Lapata, 2018).

We describe our novel approach to aspect extraction in Section 4 and detail how we combine aspect, sentiment, and redundancy information to produce opinion summaries in Section 5.

4 Aspect Extraction

Our work builds on the aspect discovery model developed by He et al. (2017), which we extend to facilitate the accurate extraction of aspect-specific review segments in a more realistic setting. In this section, we first describe their approach, point out its shortcomings, and then present the extensions and modifications introduced in our *Multi-Seed Aspect Extractor* (MATE) model.

4.1 Aspect-Based Autoencoder

The *Aspect-Based Autoencoder* (ABAE; He et al. 2017) is an adaptation of the *Relationship Modeling Network* (Iyyer et al., 2016), originally designed to identify attributes of fictional book characters and their relationships. The model learns a segment-level aspect predictor without supervision by attempting to reconstruct the input segment's encoding as a linear combination of aspect embeddings. ABAE starts by pairing each word w with a pre-trained word embedding $\mathbf{v}_w \in \mathbb{R}^d$, thus constructing a word embedding dictionary $\mathbf{L} \in \mathbb{R}^{V \times d}$, where V is the size of the vocabulary. The model also keeps an aspect embedding dictionary $\mathbf{A} \in \mathbb{R}^{K \times d}$, where K is the number of aspects to be identified and i-th row $\mathbf{a}_i \in \mathbb{R}^d$ is a point in the word embedding space. Matrix $\mathbf{A}$ is initialized using the centroids from a

k-means clustering on the vocabulary's word embeddings.

The autoencoder, first produces a vector $\mathbf{v}_s$ for review segment $s = (w_1, \ldots, w_n)$ using an *attention encoder* that learns to attend on aspect words. A segment encoding is computed as the weighted average of word vectors:

$$\mathbf{v}_s = \sum_{i=1}^{n} c_i \mathbf{v}_{w_i} \qquad (1)$$

$$c_i = \frac{exp(u_i)}{\sum_{j=1}^{n} exp(u_j)} \qquad (2)$$

$$u_i = \mathbf{v}_{w_i}^{\mathsf{T}} \cdot \mathbf{M} \cdot \mathbf{v}'_s \,, \qquad (3)$$

where c_i is the i-th word's attention weight, $\mathbf{v}'_s$ is a simple average of the segment's word embeddings and attention matrix $\mathbf{M} \in \mathbb{R}^{d \times d}$ is learned during training.

Vector $\mathbf{v}_s$ is fed into a softmax classifier to predict a probability distribution over K aspects:

$$\mathbf{p}_s^{asp} = \mathrm{softmax}(\mathbf{W}\mathbf{v}_s + \mathbf{b}) \,, \qquad (4)$$

where $\mathbf{W} \in \mathbb{R}^{K \times d}$ and $\mathbf{b} \in \mathbb{R}^{K}$ are the classifier's weight and bias parameters. The segment's vector is then reconstructed as the weighted sum of aspect embeddings:

$$\mathbf{r}_s = \mathbf{A}^{\mathsf{T}} \mathbf{p}_s^{asp} \,. \qquad (5)$$

The model is trained by minimizing a reconstruction loss $J_r(\theta)$ that uses randomly sampled segments $n_1, n_2, \ldots, n_{k_n}$ as negative examples:[2]

$$J_r(\theta) = \sum_{s \in \mathrm{C}} \sum_{i=1}^{k_n} \max(0, 1 - \mathbf{r}_s \mathbf{v}_s + \mathbf{r}_s \mathbf{v}_{n_i}) \quad (6)$$

ABAE is essentially a neural topic model; it discovers topics which will hopefully map to aspects, without any preconceptions about the aspects themselves, a feature shared with most previous LDA-style aspect extraction approaches (Titov and McDonald, 2008a; He et al., 2017; Mukherjee and Liu, 2012). These models will set the number of topics to be discovered to a much larger number (~ 15) than the actual aspects found in the data (~ 5). This requires a many-to-one mapping between discovered topics and genuine aspects which is performed manually.

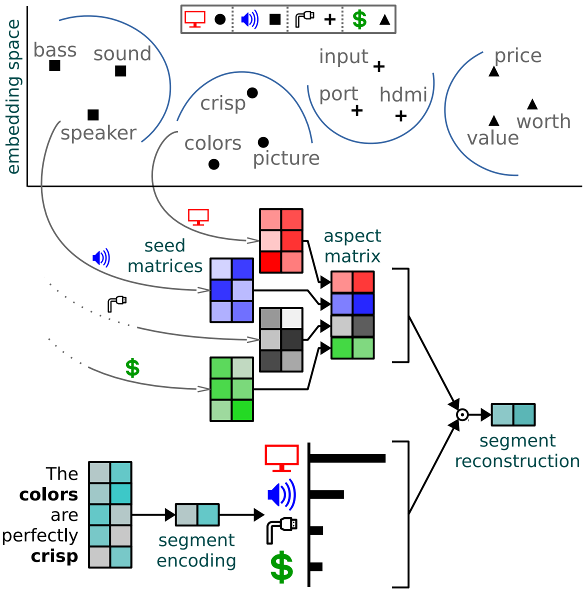

Figure 2: Multi-Seed Aspect Extractor (MATE).

4.2 Multi-Seed Aspect Extractor

Dynamic aspect extraction is advantageous since it assumes nothing more than a set of relevant reviews for a product and may discover unusual and interesting aspects (e.g., whether a plasma television has protective packaging). However, it suffers from the fact that the identified aspects are fine-grained, they have to be interpreted post-hoc, and manually mapped to coarse-grained ones.

We propose a new weakly-supervised set-up for aspect extraction which requires little human involvement. For every aspect $a_i \in A_{\mathrm{C}}$, we assume there exists a small set of seed words $\{sw_j\}_{j=1}^{l}$ which are good descriptors of a_i. We can think of these *seeds* as query terms that someone would use to search for segments discussing a_i. They can be set manually by a domain expert or selected using a small number of aspect-annotated reviews. Figure 2 (top) depicts four television aspects (*image*, *sound*, *connectivity* and *price*) and three of their seeds in word embedding space. MATE replaces ABAE's aspect dictionary with multiple seed matrices $\{\mathbf{A}_1, \mathbf{A}_2, \ldots, \mathbf{A}_K\}$. Every matrix $\mathbf{A}_i \in \mathbb{R}^{l \times d}$, contains one row per seed word and holds the seeds' word embeddings, as illustrated by the set of $[3 \times 2]$ matrices in Figure 2.

MATE still needs to produce an aspect matrix $\mathbf{A} \in \mathbb{R}^{K \times d}$, in order to reconstruct the input segment's embedding. We accomplish this by reducing each seed matrix to a single aspect embedding with the help of seed weight vectors $\mathbf{z}_i \in \mathbb{R}^{l}$ ($\sum_j z_{ij} = 1$), and concatenating the results, illus-

---

[2] ABAE also uses a uniqueness regularization term that is not shown here and is not used in our Multi-Seed Aspect Extractor model.

trated by the $[4 \times 2]$ aspect matrix in Figure 2:

$$\mathbf{a}_i = \mathbf{A}_i^{\mathsf{T}} \mathbf{z}_i \tag{7}$$

$$\mathbf{A} = [\mathbf{a}_1^{\mathsf{T}}; \ldots; \mathbf{a}_K^{\mathsf{T}}] \,. \tag{8}$$

The segment is reconstructed as in Equation (5). Weight vectors $\mathbf{z}_i$ can be uniform (for manually selected seeds), fixed, learned during training, or set dynamically for each input segment, based on the cosine distance of its encoding to each seed embedding. Our experiments showed that fixed weights, selected through a technique described below, result in most stable performance across domains. We only focus on this variant due to space restrictions (but provide more details in the supplementary material).

When a small number of aspect-annotated reviews are available, seeds and their fixed seed weights can be selected automatically. To obtain a ranked list of terms that are most characteristic for each aspect, we use a variant of the *clarity* scoring function which was first introduced in information retrieval (Cronen-Townsend et al., 2002). Clarity measures how much more likely it is to observe word w in the subset of segments that discuss aspect a, compared to the corpus as a whole:

$$\mathrm{score}_a(w) = t_a(w) \log_2 \frac{t_a(w)}{t(w)} \,, \tag{9}$$

where $t_a(w)$ and $t(w)$ are the l_1-normalized *tf-idf* scores of w in the segments annotated with aspect a and in all annotated segments, respectively. Higher scores indicate higher term importance and truncating the ranked list of terms gives a fixed set of seed words, as well as their seed weights by normalizing the scores to add up to one. Table 1 shows the highest ranked terms obtained for every aspect in the *televisions* domain of our corpus (see Section 6 for a detailed description of our data).

4.3 Multi-Task Objective

MATE (and ABAE) relies on the attention encoder to identify and attend to each segment's aspect-signalling words. The reconstruction objective only provides a weak training signal, so we devise a multi-task extension to enhance the encoder's effectiveness without additional annotations.

We assume that aspect-relevant words not only provide a better basis for the model's aspect-based reconstruction, but are also good indicators of the product's domain. For example, the words *colors* and *crisp*, in the segment "*The colors are perfectly crisp*" should be sufficient to infer that the segment comes from a television review, whereas the words *keys* and *type* in the segment "*The keys feel great to type on*" are more representative of the keyboard domain. Additionally, all four words are characteristic of specific aspects.

Aspect	**Top Terms**
Image	picture color quality black bright
Sound	sound speaker quality bass loud
Connectivity	hdmi port computer input component
Price	price value money worth paid
Apps & Interface	netflix user file hulu apps
Ease of Use	easy remote setup user menu
Customer Service	paid support service week replace
Size & Look	size big bigger difference screen
General	tv bought hdtv happy problem

Table 1: Highest ranked words for the television corpus according to Equation (9).

Let $\mathrm{C}_{all} = \mathrm{C}_1 \cup \mathrm{C}_2 \cup \ldots$ denote the union of multiple review corpora, where C_1 is considered *in-domain* and the rest are considered *out-of-domain*. We use $d_s \in \{d_{\mathrm{C}_1}, d_{\mathrm{C}_2}, \ldots\}$ to denote the true domain of segment s and define a classifier that uses the vectors from our segment encoder as inputs:

$$\mathbf{p}_s^{dom} = \mathrm{softmax}(\mathbf{W}_{\mathrm{C}} \mathbf{v}_s + \mathbf{b}_{\mathrm{C}}) \,, \tag{10}$$

where $\mathbf{p}_s^{dom} = \langle p^{(d_{\mathrm{C}_1})}, p^{(d_{\mathrm{C}_2})}, \ldots \rangle$ is a probability distribution over product domains for segment s and $\mathbf{W}_{\mathrm{C}}$ and $\mathbf{b}_{\mathrm{C}}$ are the classifier's weight and bias parameters. We use the negative log likelihood of the domain prediction as the objective function, combined with the reconstruction loss of Equation (5) to obtain a multi-task objective:

$$J_{\mathrm{MT}}(\theta) = J_r(\theta) - \lambda \sum_{s \in \mathrm{C}_{all}} \log p^{(d_s)} \,, \tag{11}$$

where λ controls the influence of the classification loss. Note that the negative log-likelihood is summed over all segments in C_{all}, whereas $J_r(\theta)$ is only summed over the in-domain segments $s \in \mathrm{C}_1$. It is important not to use the out-of-domain segments for segment reconstruction, as they will confuse the aspect extractor due to the aspect mismatch between different domains.

5 Opinion Summarization

We now move on to describe our opinion summarization framework which is based on the aspect extraction component discussed so far, a polarity prediction model, and a segment selection policy which identifies and discards redundant opinions.

Segment	Salience
1. The color and definition are perfect.	[+] 0.89
2. Set up was extremely easy,	[+] 0.79
3. Not worth $ 300.	[−] 0.75
4. The sound on this is horrendous.	[−] 0.52
5. The sound is TERRIBLE.	[−] 0.45
6. Nice and bright with good colors.	[+] 0.44

Table 2: Most salient opinions according to scores from Equation (12) for an LCD TV.

Domain	Products	Reviews	EDUs	Vocab
Laptop Cases	2,040 (10)	42,727 (100)	602K (1,262)	30,443
B/T Headsets	1,471 (10)	80,239 (100)	1.46M (1,344)	51,263
Boots	4,723 (10)	77,593 (100)	987K (1,198)	30,364
Keyboards	983 (10)	33,713 (100)	625K (1,396)	34,095
Televisions	1,894 (10)	56,510 (100)	1.47M (1,483)	59,051
Vacuums	1,184 (10)	68,266 (100)	1.50M (1,492)	46,259

Table 3: The OPOSUM corpus. Numbers in parentheses correspond to the human-annotated subset.

Opinion Polarity Aside from describing a product's aspects, segments also express polarity (i.e., positive or negative sentiment). We identify segment polarity with the recently proposed *Multiple Instance Learning Network* model (MILNET; Angelidis and Lapata 2018). Whilst trained on freely available document-level sentiment labels, i.e., customer ratings on a scale from 1 (negative) to 5 (positive), MILNET learns a segment-level sentiment predictor using a hierarchical, attention-based neural architecture.

Given review r consisting of segments $(s_1, \ldots, s_m)$, MILNET uses a CNN segment encoder to obtain segment vectors $(\mathbf{u}_1, \ldots, \mathbf{u}_m)$, each used as input to a segment-level sentiment classifier. For every vector $\mathbf{u}_i$, the classifier produces a sentiment prediction $\mathbf{p}_i^{stm} = \langle p_i^{(1)}, \ldots, p_i^{(M)} \rangle$, where $p_i^{(1)}$ and $p_i^{(M)}$ are probabilities assigned to the most negative and most positive sentiment class respectively. Resulting segment predictions $(\mathbf{p}_1^{stm}, \ldots, \mathbf{p}_m^{stm})$ are combined via a GRU-based attention mechanism to produce a document-level prediction $\mathbf{p}_r^{stm}$ and the model is trained end-to-end on the reviews' user ratings using negative log-likelihood.

The essential by-product of MILNET are segment-level sentiment predictions $\mathbf{p}_i^{stm}$, which are transformed into polarities pol_{s_i}, by projecting them onto the $[-1, +1]$ range using a uniformly spaced sentiment class weight vector.

Opinion Ranking Aspect predictions $\mathbf{p}_s^{asp} = \langle p_s^{(a_1)}, \ldots, p_s^{(a_K)} \rangle$ and polarities pol_s, form the opinion set $O_e = \{(s, A_s, pol_s)\}_{s \in R_e}$ for every product $e \in E_C$. For simplicity, we set the predicted aspect-set A_s to only include the aspect with the highest probability, although it is straightforward to allow for multiple aspects. We rank every opinion $o_s \in O_e$ according to its salience:

$$sal(o_s) = |pol_s| \cdot (\max_i p_s^{(a_i)} - p_s^{(\mathrm{GEN})}) \,, \quad (12)$$

where the quantity in parentheses is the probability difference between the most probable aspect and the *general* aspect. The salience score will be high for opinions that are very positive or very negative and are also likely to discuss a non-general aspect.

Opinion Selection The final step towards producing summaries is to discard potentially redundant opinions, something that is not taken into account by our salience scoring method. Table 2 shows a partial ranking of the most salient opinions found in the reviews for an LCD television. All segments provide useful information, but it is evident that segments 1 and 6 as well as 4 and 5 are paraphrases of the same opinions.

We follow previous work on multi-document summarization (Cao et al., 2015; Yasunaga et al., 2017) and use a greedy algorithm to eliminate redundancy. We start with the highest ranked opinion, and keep adding opinions to the final summary one by one, unless the cosine similarity between the candidate segment and any segment already included in the summary is lower than 0.5.

6 The OPOSUM Dataset

We created OPOSUM, a new dataset for the training and evaluation of **Opin**ion **Sum**marization models which contains Amazon reviews from six product domains: *Laptop Bags*, *Bluetooth Headsets*, *Boots*, *Keyboards*, *Televisions*, and *Vacuums*. The six training collections were created by downsampling from the *Amazon Product Dataset*[3] introduced in McAuley et al. (2015) and contain reviews and their respective ratings. The reviews were segmented into EDUs using a publicly available RST parser (Feng and Hirst, 2012).

To evaluate our methods and facilitate research, we produced a human-annotated subset of the dataset. For each domain, we uniformly sampled (across ratings) 10 different products with 10 reviews each, amounting to a total of 600 reviews, to be used only for development (300) and testing (300). We obtained EDU-level aspect annotations, salience labels and gold standard opinion

Table 4: Experimental results for the identification of aspect segments (top) and the retrieval of salient segments (bottom) on OpoSum's six product domains and overall (AVG).

summaries, as described below. Statistics are provided in Table 3 and in supplementary material.

Aspects For every domain, we pre-selected nine representative aspects, including the *general* aspect. We presented the EDU-segmented reviews to three annotators and asked them to select the aspects discussed in each segment (multiple aspects were allowed). Final labels were obtained using a majority vote among annotators. Inter-annotator agreement across domains and annotated segments using Cohen's Kappa coefficient was $K = 0.61$ ($N =$ 8,175, $k = 3$).

Opinion Summaries We produced opinion summaries for the 60 products in our benchmark using a two-stage procedure. First, all reviews for a product were shown to three annotators. Each annotator read the reviews one-by-one and selected the subset of segments they thought best captured the most important and useful comments, without taking redundancy into account. This phase produced binary *salience* labels against which we can judge the ability of a system to identify important opinions. Again, using the Kappa coefficient, agreement among annotators was $K = 0.51$ ($N =$ 8,175, $k = 3$).[4] In the second stage, annotators were shown the salient segments they identified (for every product) and asked to create a final extractive summary by choosing opinions based on their popularity, fluency and clarity, while avoiding redundancy and staying under a budget of 100 words. We used ROUGE (Lin and Hovy, 2003) as a proxy to inter-annotator agreement. For every product, we treated one reference summary as system output and computed how it agrees with the rest. ROUGE scores are reported in Table 5 (last row).

7 Experiments

In this section, we discuss implementation details and present our experimental setup and results. We evaluate model performance on three subtasks: aspect identification, salient opinion extraction, and summary generation.

Implementation Details Reviews were lemmatized and stop words were removed. We initialized MATE using 200-dimensional word embeddings trained on each product domain using skip-gram (Mikolov et al., 2013) with default parameters. We used 30 seed words per aspect, obtained via Equation (9). Word embeddings $\mathbf{L}$, seed matrices $\{\mathbf{A}_i\}_{i=1}^{K}$ and seed weight vectors $\{\mathbf{z}_i\}_{i=1}^{K}$ were fixed throughout training. We used the Adam optimizer (Kingma and Ba, 2014) with learning rate 10^{-4} and mini-batch size 50, and trained for 10 epochs. We used 20 negative examples per input for the reconstruction loss and, when used, the multi-tasking coefficient λ was set to 10. Seed words and hyperparameters were selected on the development set and we report results on the test set, averaged over 5 runs.

Aspect Extraction We trained aspect models on the collections of Table 3 and evaluated their predictions against the human-annotated portion of each corpus. Our MATE model and its multi-task counterpart (MATE+MT) were compared against a majority baseline and two ABAE variants: vanilla ABAE, where aspect matrix $\mathbf{A}$ is initialized using k-means centroids and fine-tuned during training; and ABAE$_{init}$, where rows of $\mathbf{A}$

---

[4] While this may seem moderate, Radev et al. (2003) show that inter-annotator agreement for extractive summarization is usually lower ($K < 0.30$).

are fixed to the centroids of respective seed embeddings. This allows us to examine the benefits of our multi-seed aspect representation. Table 4 (top) reports the results using micro-averaged F1. Our models outperform both variants of ABAE across domains. ABAE_{init} improves upon the vanilla model, affirming that informed aspect initialization can facilitate the task. The richer multi-seed representation of MATE, however, helps our model achieve a 3.2% increase in F1. Further improvements are gained by the multi-task model, which boosts performance by 2.7%.

Opinion Salience We are also interested in our system's ability to identify salient opinions in reviews. The first phase of our opinion extraction annotation provides us with binary salience labels, which we use as gold standard to evaluate system opinion rankings. For every product e, we score each segment $s \in R_e$ using Equation (12) and evaluate the obtained rankings via Mean Average Precision (MAP) and Precision at the 5th retrieved segment (P@5).[5] Polarity scores were produced via MilNet; we obtained aspect probabilities from ABAE_{init}, MATE, and MATE+MT. We also experimented with a variant that only uses MilNet's polarities and, additionally, with variants that ignore polarities and only use aspect probabilities.

Results are shown in Table 4 (bottom). The combined use of polarity and aspect information improves the retrieval of salient opinions across domains, as all model variants that use our salience formula of Equation (12) outperform the MilNet- and aspect-only baselines. When comparing between aspect-based alternatives, we observe that the extraction accuracy correlates with the quality of aspect prediction. In particular, ranking using MilNet+MATE+MT gives best results, with a 2.6% increase in MAP against MilNet+MATE and 4.6% against MilNet+ABAE_{init}. The trend persists even when MilNet polarities are ignored, although the quality of rankings is worse in this case.

Opinion Summaries We now turn to the summarization task itself, where we compare our best performing model (MilNet+MATE+MT), with and without a redundancy filter (RD), against the following methods: a baseline that selects segments *randomly*; a *Lead* baseline that only selects the leading segments from each review; *SumBasic*, a generic frequency-based extractive summarizer (Nenkova and Vanderwende, 2005); *LexRank*, a generic graph-based extractive summarizer (Erkan and Radev, 2004); *Opinosis*, a graph-based abstractive summarizer that is designed for opinion summarization (Ganesan et al., 2010). All extractive methods operate on the EDU level with a 100-word budget. For Opinosis, we tested an aspect-agnostic variant that takes every review segment for a product as input, and a variant that uses MATE's groupings of segments to produce and concatenate aspect-specific summaries.

Summarization	ROUGE-1	ROUGE-2	ROUGE-L
Random	35.1	11.3	34.3
Lead	35.5	15.2	34.8
SumBasic	34.0	11.2	32.6
LexRank	37.7	14.1	36.6
Opinosis	36.8	14.3	35.7
Opinosis+MATE+MT	38.7	15.8	37.4
MilNet+MATE+MT	43.5	21.7	42.8
MilNet+MATE+MT+RD	**44.1**	**21.8**	**43.3**
Inter-annotator Agreement	54.7	36.6	53.9

Table 5: Summarization results on OpoSum.

	Inform.	Polarity	Coherence	Redund.
Gold	2.04	**8.70**	**10.93**	**6.11**
This work	**9.26**	3.15	1.11	2.96
Opinosis	-12.78	-10.00	-9.08	-9.45
Lead	1.48	-1.85	-2.96	0.37

Table 6: *Best-Worst Scaling* human evaluation.

Table 5 presents ROUGE-1, ROUGE-2 and ROUGE-L F1 scores, averaged across domains. Our model (MilNet+MATE+MT) significantly outperforms all comparison systems ($p < 0.05$; paired bootstrap resampling; Koehn 2004), whilst using a redundancy filter slightly improves performance. Assisting Opinosis with aspect predictions is beneficial, however, it remains significantly inferior to our model (see the supplementary material for additional results).

We also performed a large-scale user study. For every product in the OpoSum test set, participants were asked to compare summaries produced by: a (randomly selected) human annotator, our best performing model (MilNet+MATE+MT+RD), Opinosis, and the Lead baseline. The study was conducted on the Crowdflower platform using *Best-Worst Scaling* (BWS; Louviere and Woodworth 1991; Louviere et al. 2015), a less labour-intensive alternative to paired comparisons that has been shown to produce more reliable results than rating scales (Kiritchenko and Mohammad, 2017). We arranged every 4-tuple of competing summaries into four triplets. Every triplet was

[5] A system's salience ranking is individually compared against labels from each annotator and we report the average.

Product domain: Televisions
Product name: Sony BRAVIA 46-Inch HDTV

Human	Plenty of ports and settings. Easy hookups to audio and satellite sources. The sound is good and strong. This TV looks very good. and the price is even better. The on-screen menu/options is quite nice. and the internet apps work as expected. The picture is clear and sharp. which is TOO SLOW to stream HD video... The software and apps built into this TV. are difficult to use and setup. Their service is handled off shore making. communication a bit difficult. :(
LexRank	Get a Roku or Netflix box. I watch cable, Netflix, Hulu Plus, YouTube videos and computer movie files on it. Sound is good much better. DO NOT BUY! this SONY Bravia ‘ Smart ’ TV... and avoid the Sony apps at all costs. Because of these two issues, I returned the Sony TV. Also you can change the display and sound settings on each port. However, the streaming speed for netflix is just down right terrible. Most of the time I just quit. Since I do not own the cable box, So, I have the cable.
Opinosis	The picture and not bright at all even compared to my 6-year old sony lcd tv. It will not work with an hdmi. Connection because of a conflict with comcast’s dhcp. Being generous because I usuallly like the design and attention to detail of sony products). I am very disappointed with this tv for two reasons: picture brightness and channel menu. Numbers of options available in the on-line area of the tv are numerous and extremely useful. Wow look at the color, look at the sharpness of the picture, amazing and the amazing.
This work	Plenty of ports and settings and have been extremely happy with it. The sound is good and strong. The picture is beautiful. And the internet apps work as expected. And the price is even better. Unbelieveable picture and the setup is so easy. Wow look at the color, look at the sharpness of the picture. The Yahoo! widgets do not work. And avoid the Sony apps at all costs. Communication a bit difficult. :(

Figure 3: Human and system summaries for a product in the *Televisions* domain.

shown to three crowdworkers, who were asked to decide which summary was *best* and which one was *worst* according to four criteria: *Informativeness* (How much useful information about the product does the summary provide?), *Polarity* (How well does the summary highlight positive and negative opinions?), *Coherence* (How coherent and easy to read is the summary?) *Redundancy* (How successfully does the summary avoid redundant opinions?).

For every criterion, a system’s score is computed as the percentage of times it was selected as best minus the percentage of times it was selected as worst (Orme, 2009). The scores range from -100 (unanimously worst) to +100 (unanimously best) and are shown in Table 6. Participants favored our model over comparison systems across all criteria (all differences are statistically significant at $p < 0.05$ using post-hoc HD Tukey tests). Human summaries are generally preferred over our model, however the difference is significant only in terms of coherence ($p < 0.05$).

Finally, Figure 3 shows example summaries for a product from our televisions domain, produced by one of our annotators and by 3 comparison systems (LexRank, Opinosis and our MILNET+MATE+MT+RD). The human summary is primarily focused on aspect-relevant opinions, a characteristic that is also captured to a large extent by our method. There is substantial overlap between extracted segments, although our redundancy filter fails to identify a few highly similar opinions (e.g., those relating to the picture quality). The LexRank summary is inferior as it only identifies a few useful opinions, and instead selects many general or non-opinionated comments. Lastly, the abstractive summary of Opinosis does a good job of capturing opinions about specific aspects but lacks in fluency, as it produces grammatical errors. For additional system outputs, see supplementary material.

8 Conclusions

We presented a weakly supervised neural framework for aspect-based opinion summarization. Our method combined a seeded aspect extractor that is trained under a multi-task objective without direct supervision, and a multiple instance learning sentiment predictor, to identify and extract useful comments in product reviews. We evaluated our weakly supervised models on a new opinion summarization corpus across three subtasks, namely aspect identification, salient opinion extraction, and summary generation. Our approach delivered significant improvements over strong baselines in each of the subtasks, while a large-scale judgment elicitation study showed that crowdworkers favor our summarizer over competitive extractive and abstractive systems.

In the future, we plan to develop a more integrated approach where aspects and sentiment orientation are jointly identified, and work with additional languages and domains. We would also like to develop methods for abstractive opinion summarization using weak supervision signals.

{ellfae, tobbymailbox, yenhao0218, phejimlin, yishin} @gmail.com

Abstract

Emotions are expressed in nuanced ways, which varies by collective or individual experiences, knowledge, and beliefs. Therefore, to understand emotion, as conveyed through text, a robust mechanism capable of capturing and modeling different linguistic nuances and phenomena is needed. We propose a semi-supervised, graph-based algorithm to produce rich structural descriptors which serve as the building blocks for constructing contextualized affect representations from text. The pattern-based representations are further enriched with word embeddings and evaluated through several emotion recognition tasks. Our experimental results demonstrate that the proposed method outperforms state-of-the-art techniques on emotion recognition tasks.

1 Introduction

Emotions reflect different users' perspectives towards actions and events, therefore they are innately expressed in dynamic linguistic forms. Capturing these linguistic variations is challenging because it involves knowledge of linguistic phenomena such as slang and coded words. Previous methods model these linguistic behaviours through rule-based (Volkova and Bachrach, 2016) and statistics-based approaches (Becker et al., 2017). These methods construct features that rely on hand-crafted resources; thus, they cannot properly capture the *evolving* linguistic variability found in large-scale opinionated content.

Consider the social posts *"Thanks God for everything"* and *"Tnx mom for waaaaking me two hours early. Cant get asleep now"*, a lexicon-based model may not properly represent the emotion-relevant phrases: *"waaaaking me"*, *"Thanks God"*, and *"Tnx mom"*. First, the word *"waaaaking"* doesn't exist in the English vocabulary, hence its referent may vary from its standard form, *"waking"*. Secondly, knowledge of the semantic similarity between the words *"Thanks"* and *"Tnx"* is needed to establish any relationship between the last two phrases. Even if such relationship can be established through knowledge-based techniques, it's difficult to reliably determine the association of these phrases to a group of emotions. This is because traditional methods analyze data at the sentence level, which may be less effective as compared to methods that model the corpus as a complex network (Santos et al., 2017).

We represent an emotion corpus as a graph, which may suffer less from the problems mentioned above. This method efficiently captures the global mutual use of linguistic variations found in textual information. This is particularly important for linguistic behaviour that is socially and culturally influenced, as is common in opinionated content. Other advantages of the graph approach are that minimum domain knowledge and manual effort are required to capture important *contextual* and *latent* information, which are useful to disambiguate meaning in emotional expressions.

As an overview, we first collect an emotion dataset through noisy labels, annotated via *distant supervision* as in (Go et al., 2009). The graph-based mechanism helps to construct contextualized, pattern-based emotion features, which are further enriched with word embeddings in order to preserve semantic relationship between patterns. To evaluate the quality of patterns, emotion detection models are trained using various online classifiers and deep learning models. Our main contributions are as follows: 1) A graph-based algorithm for automatic emotion-relevant feature extraction, 2) a set of emotion-rich feature representations enhanced through word embeddings, 3) and a comprehensive performance analysis of various con-

ventional learning models and deep learning models used for text-based emotion recognition.

The rest of the paper is organized as follows: Section 2 discusses the relevant literature and different aspects of emotion recognition research addressed in this work; then, Section 3 provides details of the proposed methodology for extracting contextualized emotion-relevant representations; next, Section 4 lists the constructed emotion recognition models and comparison models; later, Section 5 discusses the data collection and experimental results; and finally, Section 6 further explains key insights observed from the results.

2 Related Work

Emotion Lexica: Several works use hand-crafted features and statistics-based approaches to train emotion recognition models (Blitzer et al., 2007; Wang et al., 2012; Roberts et al., 2012; Qadir and Riloff, 2013; Volkova et al., 2013; Becker et al., 2017; Saravia et al., 2016a). Some of these studies rely on affect lexicons, such as *LIWC* (Pennebaker et al., 2007) and *WordNet Affect* (Strapparava et al., 2004), to extract emotion features from a text-based corpus. A recent study trained emotion detection systems built on emoticons and hashtag features (Volkova and Bachrach, 2016). Hand-crafted features are useful for emotion recognition but are usually constrained by manually created resources. Our graph-based features are obtained in an semi-supervised manner, requiring minimum domain expertise and no dependency of linguistic resources that quickly become outdated.

Emotion Corpora: There are several affective datasets such as *SemEval-2017 Task 4* (Rosenthal et al., 2017) and *Olympic games* dataset (Sintsova et al., 2013). However, these datasets are limited by quantity. We bootstrap a set of noisy labels to obtain large-scale emotion tweets, and then perform annotation via distant supervision as in (Go et al., 2009; González-Ibánez et al., 2011; Wang et al., 2012; Mohammad and Kiritchenko, 2015; Abdul-Mageed and Ungar, 2017). In emotion recognition studies, Plutchik's wheel of emotions (Plutchik, 2001) or Ekman's six basic emotions (Ekman, 1992), are commonly adopted to define emotion categories (Mohammad, 2012; Suttles and Ide, 2013). Similar to previous works, we rely on hashtags to define our emotion categories.

Feature Representations: Recent emotion recognition systems employ *representation learning* for automatic feature extraction (Poria et al., 2016; Savigny and Purwarianti, 2017; Abdul-Mageed and Ungar, 2017). In general, a combination of word embeddings (Mikolov et al., 2013) and a convolutional neural network (CNN) performs well for sentence classification tasks (Kim, 2014; Zhang et al., 2015). These models learn features which tend to have high coverage, high adaptability, require minimum supervision, and capture contextual information to some extent. We aim to leverage them and combine them with the proposed affect representations. Our graph-based feature extraction algorithm focuses on the underlying interactions between important linguistic components. Graph analysis measurements then help to output the building blocks for constructing pattern-based features. Hence, the patterns can be constructed to capture important contextual and latent emotion-relevant information.

3 Contextualized Affect Representations

In this section, we introduce a graph-based algorithm which helps to output the building blocks used to bootstrap a set of emotion-rich representations. The structural descriptions offered by the graph are particularly efficient at automatically surfacing important information (i.e., contextual and latent information) from a large-scale emotion corpus. Two different measurements are used to surface two families of words, which are in turn used to construct contextualized, pattern-based affect representations. The patterns are further enriched using word embeddings so as to preserve semantic relationship between patterns. After the patterns are constructed, the goal is to assign a weight to each pattern, referred to as a *pattern score*, which denotes how important a pattern p is to an emotion e. In the context of emotion classification, patterns and their weights play the role of features. The graph-based feature extraction algorithm is summarized in the following steps:

Step 1 (Normalization): First, we collected two separate datasets using the Twitter API: subjective tweets S (obtained through hashtags as weak labels) and objective tweets O (obtained from Twitter feeds of news accounts).[1] Both datasets are tokenized by white-spaces and then preprocessed by applying lower case and replacing user mentions and URLs with a <*usermention*> and <*url*>

---

[1] Each dataset contains 2+ million tweets. S was collected using 339 hashtags, similar to the process in Section 5.1.

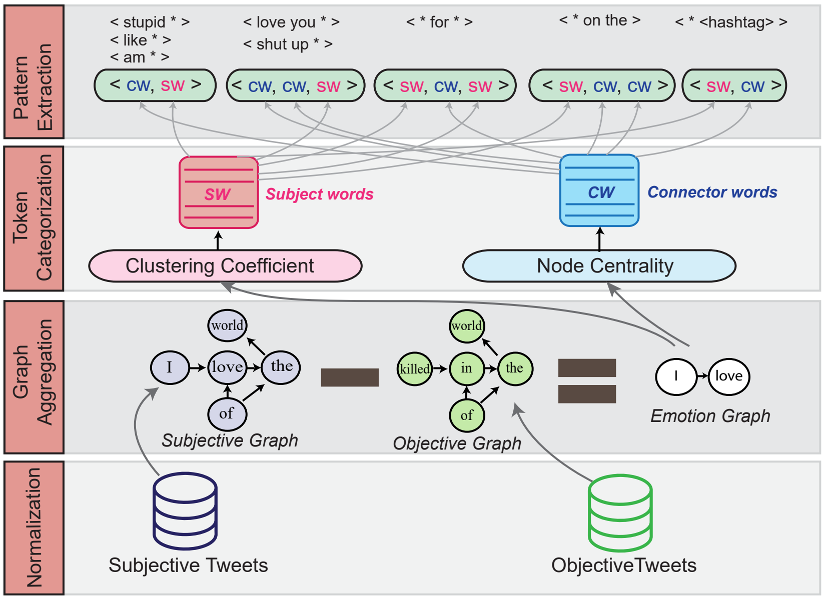

Figure 1: An overview of the important steps used to generate graph-based pattern representations.

placeholder, respectively. Hashtags are used as ground-truth in this work, so to avoid any bias we replace them with a *<hashtag>* placeholder.

Step 2 (Graph Construction): Given the normalized objective tweets O and subjective tweets S, two graphs are constructed: objective graph $G_o(V_o; A_o)$ and subjective graph $G_s(V_s; A_s)$, respectively. Vertices V is a set of nodes which represent the tokens extracted from the corpus. Edges, denoted as A, represent the relationship of words extracted using a window approach. These steps help to preserve the syntactic structure of the data. Given a post *"<usermention> last night's concert was just awesome !!!!! <hashtag>"*, the resulting arcs are: *"<usermention> → last"*, *"last → night"*, ... , *"!!!!! → <hashtag>"*.

Step 3 (Graph Aggregation): In this step we obtain a set of arcs that represent syntactic structures more common in subjective content. By adjusting graph G_s with G_o, we obtain a graph G_e, referred to as the *emotion graph*, which preserves emotion-relevant tokens and is obtained in two steps:

(1). For an arc $a_i \in A$, its normalized weight can be computed as shown in Equation 1.

$$w(a_i) = \frac{freq(a_i)}{\max_{j \in A} freq(a_j)} \tag{1}$$

where $freq(a_i)$ is the frequency of arc a_i.

(2). Subsequently, new weights for arcs $a_i \in G_e$ are assigned based on a pairwise adjustment as shown in Equation 2.

$$w(a_i) = \begin{cases} w(a_{s_i}) - w(a_{o_j}), & \text{if } a_{o_j} = a_{s_i} \in G_o \\ w(a_{s_i}), & \text{otherwise} \end{cases} \tag{2}$$

The resulting weights belonging to graph G_e were adjusted so that the most frequently occurring arcs in objective set G_o are weakened in G_e. As a result, arcs in G_e that have higher weights represent tokens that are more common in subjective content. Furthermore, arcs $a_i \in A_e$ are pruned based on a threshold ϕ_w[2].

Step 4 (Token Categorization): Two different graph measurements are used to extract two family of words from G_e. These will function as the building blocks to build contextualized patterns. We formalize this step as follows: Given an adjacency matrix $\mathbf{M}$, an entry $M_{i,j}$ is computed as:

$$M_{i,j} = \begin{cases} 1 & \text{if node } i \text{ and } j \text{ are linked in } G_e \\ 0 & \text{otherwise} \end{cases} \tag{3}$$

Then, the eigenvector centrality and clustering coefficient of all vertices in V_e are computed and used to categorize tokens into two types:

(1) **Connector Words:** To measure the influence of all nodes in graph G_e, we utilize eigenvec-

---

[2] ϕ_w is an experimentally determined threshold.

tor centrality, which is calculated as:

$$c_i = \frac{1}{\lambda} \sum_{j \in V_e} M_{i,j} c_j \tag{4}$$

where λ denotes a proportionality factor and c_i is the centrality score of node i.

Given λ as the corresponding eigenvalue, Equation 4 can be reformulated in vector notation form as $\mathbf{Mc} = \lambda \mathbf{c}$, where $\mathbf{c}$ is an eigenvector of $\mathbf{M}$. Given a selected eigenvector $\mathbf{c}$ and the eigenvector centrality score of node i, denoted as c_i, the final list of connector words, hereinafter referred to as CW, is obtained by retaining all tokens with $c_i > \phi_{eig}$ [3]. CW correspond to the set of nodes that are very frequent and have high connectivity to high-rank nodes (e.g., *"or"*, *"and"*, and *"my"*).

(2) **Subject Words:** In contrast, subject words or topical words are usually clustered together, i.e., many subject words are interconnected by the same connector words. Therefore, a coefficient is assigned to all nodes in G_e and is computed as:

$$cl_i = \frac{\sum_{j \neq i; k \neq j; k \neq i} M_{i,j} \times M_{i,k} \times M_{j,k}}{\sum_{j \neq i; k \neq j; k \neq i} M_{i,j} \times M_{i,k}} \times \frac{1}{|V_e|} \tag{5}$$

where cl_i denotes the average clustering coefficient of node i which captures the amount of interconnectivity among neighbours of node i. Similar to the connector words, the subject words, hereinafter referred to as SW, are obtained by retaining all the tokens with $cl_i > \phi_{cl}$ [4]. Examples of subjects words obtained are: *"never"* and *"life"*.

The subject words represent psychological oriented words similar to the LIWC affect lexicon (Pennebaker et al., 2007), while connector words reflect the set of most common words in the subjective tweets (e.g., pronouns, auxiliary verbs, and conjunctions). As presented by Chung and Pennebaker (2007), both connector words and subject words are important for conveying emotion. Influenced by their work, we aim to capture intricate relationships – through the graph – between these two families of words. The graph structure helps to preserve syntax and can automatically be used to surface emotion-relevant information.

One of the advantages of using graphs to represent syntactic relationships is that rare and important words are also surfaced. As shown in Table 1, informal words and misspellings, such as *"definetley"*, *"happnd"*, were surfaced. Words containing character repetitions help to express emotion intensity (e.g., *"plzzzzzzz"*, *"aaaaaaah"*, and *"yayyyyy"*). Interestingly, emotion-related coded words are also captured (e.g., *"juju"*, *"sh*t"*, *"4ever"*, and *"baobei"*[5]). All these examples show the benefit of using graph methods to capture emotion-relevant linguistic information.

Subject Words (SW)	Connector Words (CW)
baobei, juju	myy, ??!, urs, congrats
plzzzzzzz, aaaaaaah	bcoz, jus, tsk
happnd, yayyyyy	sh*t, smh, smhh, pfft
definetley, everytin	4ever, stfu, eff

Table 1: Examples of subject words and connector words automatically extracted from the emotion graph G_e.

Step 5 (Pattern Candidates): Given SW and CW, we bootstrap candidate patterns, which are more prevalent in opinionated content, while preserving syntactic structure. We provide the templates used to define the candidate patterns in Table 2. (sw and cw represent arbitrary tokens obtained from the sets SW and CW, respectively). It is important to clarify that sequences of size two and three were used in this work since this setting experimentally produced the best results.

Step 6 (Basic Pattern Extraction): A naive pattern extraction process consists of applying the syntactic templates to a dataset S_p[6] in an exhaustive manner. In addition, the sw component in each pattern is replaced with a "*" placeholder. This operation allows for unknown subject words, not present in our training corpus, to be considered when constructing features. This can enable many useful applications, such as applying the patterns to other domains. We are interested in patterns that are highly associated with subjectivity, so patterns frequently occurring above a threshold are kept and the rest are filtered out. In Table 2, we provide examples of the type of basic patterns extracted along with their corresponding templates.

3.1 Enriched Patterns

As they stand, the patterns constructed in the previous step contain limited information relevant to emotion classification. Therefore, the patterns are enriched using continuous word representations so as to preserve semantic relationship between pat-

---

[3] ϕ_{eig} is an experimentally determined threshold.

[4] ϕ_{cl} is an experimentally defined threshold.

[5] *baobei* is a Chinese word used to show strong affection.

[6] Dataset S_p (size=2+ mil.) is separately collected using similar steps as the subjective dataset S, mainly to avoid bias.

Templates	**Pattern Examples**
$< cw, sw >$	stupid * , like *, am *
$< cw, cw, sw >$	love you *, shut up *
$< sw, cw, sw >$	* for *
$< sw, cw, cw >$	* on the
$< sw, cw >$	* <hashtag>

Table 2: Examples of patterns and templates extracted through the basic pattern extraction mechanism.

terns. The motivation behind this step is to focus on patterns that may be more useful for an emotion classification task. Alternatively, the whole universe of patterns can also be used, but we show in the experiments that the former method significantly improves emotion recognition results.

Pre-trained Word Embeddings: First, we obtain Twitter-based, pre-trained word embeddings from (Deriu et al., 2017) and reweight them via a sentiment corpus through distant supervision (Read, 2005; Go et al., 2009).[7] We trained a fully connected neural network (1 hidden layer) with 10 epochs via backpropagation as in (Deriu et al., 2017). The embeddings size is $d = 52$. Note that term frequency-inverse document frequency (*tf-idf*) was used to reduce the vocabulary of words (from 140K to 20K words).

Word Clusters: We then apply agglomerative clustering to generate clusters of semantically related words through their word embedding information. To determine the quality of the clusters, they are compared with *WordNet-Affect* synsets (Strapparava et al., 2004) and tested for both *homogeneity* and *completeness*. We use *Ward's method* (Ward Jr, 1963) as the linkage criterion and *cosine distance* as the distance metric. The scikit-learn package (Pedregosa et al., 2011) was used to compute a total of $k = 1500$ clusters.

Enriched-Pattern Construction: The purpose of the word clusters is to enrich the patterns by preserving the semantic relationship between them, which is useful for classification purposes. We achieve this by revising the universe of patterns obtained from the *basic pattern extraction* step, and check to see if the words represented by the sw component exist in any of the word embedding clusters. This is done in an exhaustive manner, ensuring that all possible patterns in the dataset S_p are processed to meet the criteria. Furthermore, patterns that appear $<$ 10 times in dataset S_p are filtered out, producing a total of 476,174 patterns.

The resulting *enriched patterns*[8] now contain both the semantic information provided by the word embeddings and the contextual information provided through the graph components, hence the term *contextualized affect representations*.

3.2 Emotion Pattern Weighting

Before using the patterns for classification, they need to be weighted using a weighting mechanism such as *tf-idf* (Leskovec et al., 2014). The weights determine the importance of patterns to each emotion category. The proposed pattern weighting scheme used in this work is a customized version of *tf-idf*, coined as *pattern frequency-inverse emotion frequency* (*pf-ief*), and is defined in two steps. Firstly, we compute for pf as:

$$pf_{p,e} = \log \frac{\left(\sum_{p_i \in P_e} freq(p_i, e) \right) + 1}{freq(p, e) + 1} \tag{6}$$

where $freq(p, e)$ represents the frequency of p in e, and $pf_{p,e}$ denotes the logarithmically scaled frequency of a pattern p in a collection of texts related to emotion e.

Then we compute for ief as:

$$ief_p = \log \frac{freq(p, e) + 1}{\left(\sum_{e_j \in E} freq(p, e_j) \right) + 1} \tag{7}$$

where the inverse emotion frequency ief_p is a measure of the relevance of pattern p across all emotion categories.

Finally, we obtain a pattern score calculated as:

$$ps_{p,e} = pf_{p,e} \times ief_p \tag{8}$$

where $ps_{p,e}$ is the final score that reflects how important a pattern p is to an emotion class e.

4 Models

In this section, we present the emotion recognition models and comparison models used to evaluate the contextualized affect representations. More details are provided in Appendix A.

CARER: The proposed framework combines a multi-layer CNN architecture with a matrix form of the *enriched patterns*. The input $\mathbf{X} \in \mathbb{R}^{n \times m}$ denotes an embedding matrix where entry $X_{i,j}$

---

[7] We collected approximately 10 million tweets via sentiment emoticons (5+ mil. negative and 5+ mil. positive).

[8] Refer to Table 6 for enriched patterns examples.

represents the pattern score of enriched pattern i in emotion j.[9] $\mathbf{X}$ is fed into two 1-D convolutional layers with filters of sizes 3 and 16. The output of this process is passed through a ReLU activation function (Nair and Hinton, 2010) that produces a feature map matrix. A 1-max pooling layer (Boureau et al., 2010) of size 3 is then applied to each feature map. The results of the pooling are fed into two hidden layers of dimensions 512 and 128 in that order, each applied a dropout (Hinton et al., 2012) of 0.5 for regularization. We chose a batch size of 128 and trained for 4 epochs using Adam optimizer (Kingma and Ba, 2014). A softmax function is used to generate the final classifications. We use Keras (Chollet et al., 2015) to implement the CNN architecture.

Baseline Model: As baseline, we present a first-generation model (**CARER**$_\beta$) that employs primitive *enriched patterns*‡[10]. We adopt the CNN architecture used for **CARER**, however, this model differs in that the set of patterns used is significantly smaller as compared to the original size of the enriched patterns. The reason is because a different set of *primitive pattern templates* was used, which captured fewer patterns (187,648). This shows that the proposed method offers flexibility in terms of what templates to use and what size of patterns to generate. This could be useful in cases where there are limited computing and data resources, and for incorporating domain expertise.

Traditional Models: We also compare with various traditional methods (bag of words (**BoW**), character-level (**char**), **n-grams**, and **TF-IDF**) which are commonly used in sentence classification. To train the models we use the default stochastic gradient descent (SGD) classifier provided by scikit-learn (Pedregosa et al., 2011).

Deep Learning Models: Among the works that employ deep learning models for emotion recognition, they vary by the choice of input: *pre-trained word/character embeddings* and *end-to-end learned word/character representations*. Our work differs in that we utilize enriched graph-based representations as input. We compare with convolutional neural networks (**CNNs**), recurrent neural networks (**RNNs**), bidirectional gated recurrent neural networks (**BiGRNNs**), and word embeddings (**word2vec**) (Mikolov et al., 2013).

Emotions	Amount	Hashtags
sadness	214,454	#depressed, #grief
joy	167,027	#fun, #joy
fear	102,460	#fear, #worried
anger	102,289	#mad, #pissed
surprise	46,101	#strange, #surprise
trust	19,222	#hope, #secure
disgust	8,934	#awful, #eww
anticipation	3,975	#pumped, #ready

Table 3: Data statistics.

5 Experiments

5.1 Data

We construct a set of hashtags to collect a separate dataset of English tweets from the Twitter API. Specifically, we use the eight basic emotions: *anger*, *anticipation*, *disgust*, *fear*, *joy*, *sadness*, *surprise*, and *trust*. The hashtags (339 total) serve as noisy labels, which allow annotation via distant supervision as in (Go et al., 2009). To ensure data quality, we follow the pre-processing steps proposed by (Abdul-Mageed and Ungar, 2017), and considered the hashtag appearing in the last position of a tweet as the ground truth. We split the data into training (90%) and testing (10%) datasets. The final distribution of the data and a list of hashtag examples for each emotion are provided in Table 3. In the following section we evaluate the effectiveness of the enriched patterns on several emotion recognition tasks. We use *F1-score* as the evaluation metric, which is commonly used in emotion recognition studies due to the imbalanced nature of the emotion datasets.

5.2 Experimental Results

Traditional Features: As shown in Table 4, **TF-IDF** models produce better results than basic count-based features for both character-level and word-level feature extractors. These findings are consistent with the work of Zhang et al., (2015), where traditional methods, such as **n-gram**, were found to perform comparable to deep neural networks on various sentence classification tasks.

Pattern-based Approaches: The results of **CNN$_{\text{BASIC}}$**[11], which employs the *basic graph-based patterns* proposed in ***Step 6***, perform worse than most of the conventional approaches. Both **CARER**$_\beta$ and **CARER**, which use the *enriched patterns*, acquire better results than **CNN$_{\text{BASIC}}$**

---

[9] We use a zero-padding strategy as in (Kim, 2014).

[10] ‡ hereinafter refers to the primitive enriched patterns.

[11] CNN$_{\text{BASIC}}$ adopts CNN architecture of CARER.

and all the other conventional approaches. In fact, our method obtains the best F1-score on all eight emotions. We observed that there are significant gains in performance (↑27% and ↑12%) when using the enriched patterns as compared to the basic patterns and primitive patterns‡, respectively. This highlights the importance of the pattern enrichment procedure and the benefit of refining the pattern templates. Note that the baseline model, **CARER**$_\beta$, also performs better than all other the comparison models including the state-of-the-art methods (**DeepMoji** and **EmoNet**).

Comparison to state-of-the-art: Felbo et al., (2017) proposed a state-of-the-art emotion prediction model, **DeepMoji**, trained on billions of emoji-labeled tweets. We obtained their pre-trained model[12] and applied it to our dataset. As shown in Table 4, their model performs as well as other traditional methods. However, our model (**CARER**) significantly outperforms theirs (↑20%). Moreover, we re-implemented the GRNN model proposed in (Abdul-Mageed and Ungar, 2017). We also outperform their model (**EmoNet**) which manually trains word embeddings, similar to **DeepMoji**. The **CNN**$_{\mathbf{w2v}}$ model uses word embeddings trained on billions of tweets (Deriu et al., 2017), thus it performs better than all the other approaches, and closer to ours.

Results with Deep Learning: We offer more comparison with other various deep learning models as evaluated on Ekman's six basic emotions (i.e., *sadness*, *disgust*, *anger*, *joy*, *surprise*, and *fear*). For the **RNN**$_{\mathbf{w2v}}$ and **CNN**$_{\mathbf{char}}$ models, different inputs are used, as shown in Table 5. We feed the enriched patterns as embeddings to a **bidirectional GRNN**, which along with **CARER**$_{\mathbf{EK}}$ and **CARER**$_\beta$ outperform all the other methods.

Contextualized Approaches: **DeepMoji** is built on a stack of Bi-LSTM layers and performs much better with *six* emotion classes. However, using the enriched patterns as input, **CARER**$_{\mathbf{EK}}$[13] performs the best (81%). Note that the number of epochs used to train our models is much lower as compared to the other methods, which provides a strong case of the benefit of contextualizing features prior to training the models. Moreover, the important distinction between *connector words* and *subject words* helps to refine and surface relevant contextual information. We also show that the enriched patterns can be applied to other deep learning models besides CNN, such as **BiGRNN**, which leaves an opportunity to explore more complex architectures and fusion models in the future. More importantly, for problems that require deeper understanding of contextualized information, there is a need to go beyond traditional features and distributed representations.

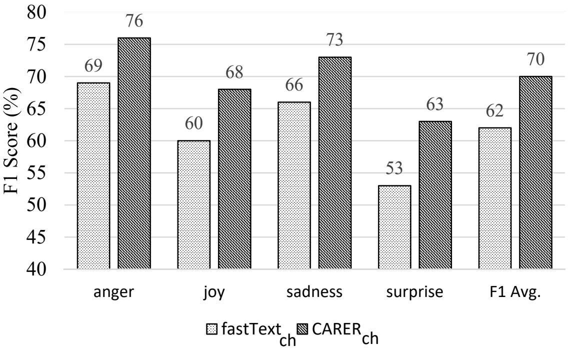

Figure 2: Comparison against Chinese word vectors.

Multilingual Capabilities: We also tested the effectiveness of the proposed feature extraction algorithm for the Chinese language. We collected Traditional Chinese datasets[14] from several of Facebook's fan pages and applied the same procedures as were done for the English datasets. User comments are considered as documents and the associated user reaction to the root post represents the emotion labels. For comparison, we obtained Chinese pre-trained word vectors computed through (Bojanowski et al., 2017), and trained a model (**fastText**$_{\mathbf{ch}}$) using the proposed CNN architecture. For our approach (**CARER**$_{\mathbf{ch}}$), we applied the same CNN architecture on the Chinese-based enriched patterns. As shown in Figure 2, our model performs significantly better on all four emotions (average F1 score of 70%). Overall, we show that the approach is not restricted to any specific language and that the enriched features are applicable to other languages and data sources. In the future, we seek to expand our methods to support other complex languages, such as Japanese, French, and Spanish, where there tends to exist fewer linguistic resources.

6 Analysis of Enriched Patterns

6.1 Pattern Coverage and Consistency

One of the advantages of the contextualized enriched patterns is that they possess high coverage

---

CARER$_{\beta}$	**enriched patterns**‡	0.61	0.31	0.34	0.67	**0.75**	0.68	0.60	0.55	**0.67**
CARER	**enriched patterns**	**0.74**	**0.41**	**0.43**	**0.79**	**0.83**	**0.82**	**0.76**	**0.75**	**0.79**

Table 4: Comparison of our model against various emotion recognition systems: **LIWC** uses a bag of words approach; **CNN$_{\text{w2v}}$** is the proposed CNN model and word vectors obtained from (Deriu et al., 2017); **char** refers to character-level features; **n-gram** employ unigrams, bigrams, and trigrams as features; **CNN$_{\text{BASIC}}$** uses the proposed CNN architecture with basic patterns; **EmoNet** (Abdul-Mageed and Ungar, 2017) and **DeepMoji** (Felbo et al., 2017) are state-of-the-art emotion recognition models.

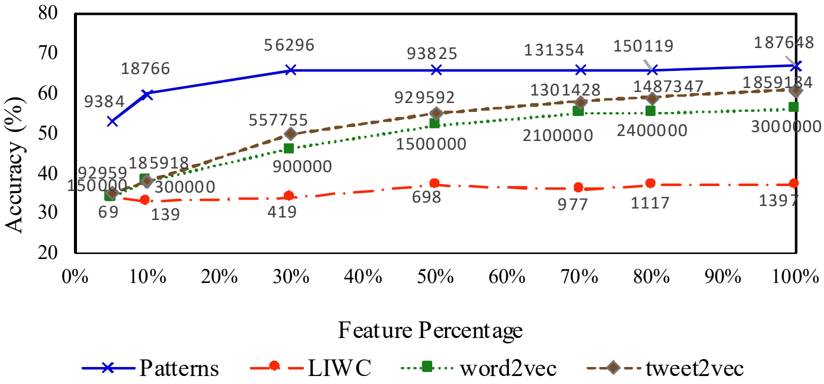

Figure 3: Consistency check for various affect resources.

Model	Input	Epochs	Accuracy
RNN$_{\text{w2v}}$	word2vec (Mikolov et al., 2013)	24	0.53
CNN$_{\text{char}}$	character embeddings (end-to-end)	50	0.63
CNN$_{\text{w2v}}$	word vectors (Deriu et al., 2017)	33	**0.69**
EmoNet	word embeddings (end-to-end)	23	0.58
DeepMoji	word embeddings (end-to-end)	100	0.63
BiGRNN	our enriched patterns‡	12	**0.68**
CARER$_{\beta}$	our enriched patterns‡	12	**0.72**
CARER$_{\text{EK}}$	our enriched patterns	12	**0.81**

Table 5: Comparison of our method against deep learning models, using Ekman's 6 emotions and the accuracy metric.

due to the way they were constructed. High coverage also means that the enriched patterns should demonstrate stability, in terms of how useful they are in an emotion classification task, even when reduced to smaller sizes. There are two cases where this could be useful: *limited data* and *limited computing resources*. Therefore, to test for pattern consistency, we randomly selected several pattern sizes[15] and trained a random forest classifier using the eight emotions dataset. This model performs comparable to **CARER$_{\beta}$** (average F1-score of 65%), and it has the benefit of faster training time, making it suitable for the aforementioned experiment. We compared with the results obtained from the **LIWC** lexicon (affect dimension) (Pennebaker et al., 2007), **word2vec** (Mikolov et al., 2013), and **tweet2vec** (Deriu et al., 2017).[16]

As shown in Figure 3, due to the limited coverage of the **LIWC** lexicon, such resources may not be feasible on evolving, large-scale datasets. In contrast, **word2vec** contains over 3 million unique word embeddings and has been proven effective for text classification. However, if we keep reducing the available word vectors of **word2vec**, which is common when there are limited computing resources, the accuracy keeps dropping at significant rates. **tweet2vec** has a similar effect. In the case of our patterns, the classification results remain relatively stable, even when reducing the patterns to 30% and 10% of the original size. These results show that the proposed features are feasible to address the text-based emotion recognition problem. Moreover, the patterns are highly beneficial where

---

[15] We employed the primitive patterns‡ used in CARER$_{\beta}$.

[16] Models were trained using the random forest implementation (depth=15 and estimators=50) provided by scikit-learn.

	Document	**GT**	**DeepMoji**	**EmoNet**	**CARER$_{\text{EK}}$**	**Enriched Patterns**

	what the fuck is **going** on !?	fear	anger	sadness	fear	**is** { *ends*, *finishes* }

Table 6: Classified documents in the testing data. Words in **bold blue** correspond to the sw component of one of the enriched patterns extracted from the document. Words in *italic green* represent other relevant word examples found in the cluster sw belongs to. Words in **bold pink** denote the connector word/s cw in the pattern; E.g., *"it"* is cw of patterns *"need it"* and *"hoping it"*. **GT** stands for ground truth. **DeepMoji**, **EmoNet**, and **CARER$_{\text{EK}}$** correspond to the models reported in Table 5.

there is shortage of computing and linguistic resources.

6.2 What's captured by CARER?

In Table 6, we provide samples extracted from the testing data. The examples show different cases where the comparison models struggled to capture important contextual information that helps to determine the emotion conveyed in the text. For instance, in the short text, *"damn what a night"*, only our model was able to interpret the statement as *joy* because it uses the *"what a"* pattern and its corresponding subject words to determine that this statement has a stronger association with *joy*. Our model also works well for capturing *rare words* and for *disambiguating* emotional meaning using the enriched and refined contextual information of the patterns. Rare words like *"whaaaaaat"* and *"thee"* help to implicitly convey intense emotional expressions, which are also captured and considered important by our enriched patterns. Emotion-relevant verbs, such as *"want"* and *"going"* are also considered important context that help to convey and interpret emotion. Overall, the enriched patterns efficiently capture important emotional information that other models seem to ignore.

7 Conclusion

We proposed a graph-based feature extraction mechanism to extract emotion-relevant representations in an unsupervised manner. The contextualized affect representations are further enriched with word embeddings and are used to train several deep learning-based emotion recognition models. The patterns capture implicit and explicit linguistic emotional information which significantly improves emotion recognition results.

We offered a detailed analysis demonstrating special cases where the patterns are helpful to further extract and understand emotional information from textual information. For instance, short text is a challenging problem in emotion recognition and various natural language tasks; the proposed contextualized patterns show promising results in addressing this issue by helping the models to capture nuanced information which is useful to determine the overall emotion expressed in a piece of text. The proposed method paves the way for building more interpretable emotion recognition systems which have various implications when investigating human behavioural data (Saravia et al., 2015, 2016b; Chang et al., 2016) and building empathy-aware conversational agents.

In the future work, we aim to investigate the graph-based patterns more in-depth and provide a more comprehensive and advanced theoretical discussion of how they are constructed. We also hope to keep improving the pattern weighting mechanism so as to improve the overall performance on emotion recognition tasks and minimize trade-off between pattern coverage and performance. We plan to employ transfer learning methods with the proposed enriched patterns and test on other emotion-related problems such as sentiment classification and sarcasm detection. The proposed methodology is also being expanded to support Spanish and Japanese emotion recognition tasks.

Abstract

Noise Contrastive Estimation (NCE) is a powerful parameter estimation method for log-linear models, which avoids calculation of the partition function or its derivatives at each training step, a computationally demanding step in many cases. It is closely related to *negative sampling methods*, now widely used in NLP. This paper considers NCE-based estimation of *conditional* models. Conditional models are frequently encountered in practice; however there has not been a rigorous theoretical analysis of NCE in this setting, and we will argue there are subtle but important questions when generalizing NCE to the conditional case. In particular, we analyze two variants of NCE for conditional models: one based on a classification objective, the other based on a ranking objective. We show that the ranking-based variant of NCE gives consistent parameter estimates under weaker assumptions than the classification-based method; we analyze the statistical efficiency of the ranking-based and classification-based variants of NCE; finally we describe experiments on synthetic data and language modeling showing the effectiveness and trade-offs of both methods.

1 Introduction

This paper considers parameter estimation in conditional models of the form

$$p(y|x;\theta) = \frac{\exp\left(s(x,y;\theta)\right)}{Z(x;\theta)} \qquad (1)$$

where $s(x,y;\theta)$ is the unnormalized score of label y in conjunction with input x under parameters θ, $\mathcal{Y}$ is a finite set of possible labels, and $Z(x;\theta) = \sum_{y\in\mathcal{Y}} \exp\left(s(x,y;\theta)\right)$ is the partition function for input x under parameters θ.

It is hard to overstate the importance of models of this form in NLP. In log-linear models, including both the original work on maximum-entropy models (Berger et al., 1996), and later work on conditional random fields (Lafferty et al., 2001), the scoring function $s(x,y;\theta) = \theta \cdot f(x,y)$ where $f(x,y) \in \mathbb{R}^d$ is a feature vector, and $\theta \in \mathbb{R}^d$ are the parameters of the model. In more recent work on neural networks the function $s(x,y;\theta)$ is a non-linear function. In Word2Vec the scoring function is $s(x,y;\theta) = \theta_x \cdot \theta'_y$ where y is a word in the context of word x, and $\theta_x \in \mathbb{R}^d$ and $\theta'_y \in \mathbb{R}^d$ are "inside" and "outside" word embeddings x and y.

In many NLP applications the set $\mathcal{Y}$ is large. Maximum likelihood estimation (MLE) of the parameters θ requires calculation of $Z(x;\theta)$ or its derivatives at each training step, thereby requiring a summation over all members of $\mathcal{Y}$, which can be computationally expensive. This has led to many authors considering alternative methods, often referred to as "negative sampling methods", where a modified training objective is used that does not require summation over $\mathcal{Y}$ on each example. Instead negative examples are drawn from some distribution, and a objective function is derived based on binary classification or ranking. Prominent examples are the binary objective used in word2vec ((Mikolov et al., 2013), see also (Levy and Goldberg, 2014)), and the Noise Contrastive Estimation methods of (Mnih and Teh, 2012; Jozefowicz et al., 2016) for estimation of language models.

In spite of the centrality of negative sampling methods, they are arguably not well understood from a theoretical standpoint. There are clear connections to noise contrastive estimation (NCE) (Gutmann and Hyvärinen, 2012), a negative sampling method for parameter estimation in *joint* models of the form

$$p(y) = \frac{\exp\left(s(y;\theta)\right)}{Z(\theta)}; \quad Z(\theta) = \sum_{y\in\mathcal{Y}} \exp\left(s(y;\theta)\right) \qquad (2)$$

However there has not been a rigorous theoretical analysis of NCE in the estimation of *conditional* models of the form in Eq. 1, and we will argue there are subtle but important questions when generalizing NCE to the conditional case. In particular, the joint model in Eq 2 has a single partition function $Z(\theta)$ which is estimated as a param-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3698–3707
Brussels, Belgium, October 31 - November 4, 2018.

eter of the model (Gutmann and Hyvärinen, 2012) whereas the conditional model in Eq 1 has a separate partition function $Z(x;\theta)$ for each value of x. This difference is critical.

We show the following (throughout we define $K \geq 1$ to be the number of negative examples sampled per training example):

- For any $K \geq 1$, a binary classification variant of NCE, as used by (Mnih and Teh, 2012; Mikolov et al., 2013), gives consistent parameter estimates under the assumption that $Z(x;\theta)$ is constant with respect to x (i.e., $Z(x;\theta) = H(\theta)$ for some function H). Equivalently, the method is consistent under the assumption that the function $s(x,y;\theta)$ is powerful enough to incorporate $\log Z(x;\theta)$.
- For any $K \geq 1$, a ranking-based variant of NCE, as used by (Jozefowicz et al., 2016), gives consistent parameter estimates under the much weaker assumption that $Z(x;\theta)$ can vary with x. Equivalently, there is no need for $s(x,y;\theta)$ to be powerful enough to incorporate $\log Z(x;\theta)$.
- We analyze the statistical efficiency of the ranking-based and classification-based NCE variants. Under respective assumptions, both variants achieve Fisher efficiency (the same asymptotic mean square error as the MLE) as $K \to \infty$.
- We discuss application of our results to approaches of (Mnih and Teh, 2012; Mikolov et al., 2013; Levy and Goldberg, 2014; Jozefowicz et al., 2016) giving a unified account of these methods.
- We describe experiments on synthetic data and language modeling evaluating the effectiveness of the two NCE variants.

2 Basic Assumptions

We assume the following setup throughout:

- We have sets $\mathcal{X}$ and $\mathcal{Y}$, where $\mathcal{X}, \mathcal{Y}$ are finite.
- There is some unknown joint distribution $p_{X,Y}(x,y)$ where $x \in \mathcal{X}$ and $y \in \mathcal{Y}$. We assume that the marginal distributions satisfy $p_X(x) > 0$ for all $x \in \mathcal{X}$ and $p_Y(y) > 0$ for all $y \in \mathcal{Y}$.
- We have training examples $\{x^{(i)}, y^{(i)}\}_{i=1}^{n}$ drawn I.I.D. from $p_{X,Y}(x,y)$.
- We have a scoring function $s(x,y;\theta)$ where θ are the parameters of the model. For example, $s(x,y;\theta)$ may be defined by a neural network.
- We use Θ to refer to the parameter space. We assume that $\Theta \subseteq \mathbb{R}^d$ for some integer d.
- We use $p_N(y)$ to refer to a distribution from which negative examples are drawn in the NCE approach. We assume that p_N satisfies $p_N(y) > 0$ for all $y \in \mathcal{Y}$.

We will consider estimation under the following two assumptions:

Assumption 2.1 *There exists some parameter value $\theta^* \in \Theta$ such that for all $(x,y) \in \mathcal{X} \times \mathcal{Y}$,*

$$p_{Y|X}(y|x) = \frac{\exp(s(x,y;\theta^*))}{Z(x;\theta^*)} \quad (3)$$

where $Z(x;\theta^*) = \sum_{y \in \mathcal{Y}} \exp(s(x,y;\theta^*))$.

Assumption 2.2 *There exists some parameter value $\theta^* \in \Theta$, and a constant $\gamma^* \in \mathbb{R}$, such that for all $(x,y) \in \mathcal{X} \times \mathcal{Y}$,*

$$p_{Y|X}(y|x) = \exp\left(s(x,y;\theta^*) - \gamma^*\right). \quad (4)$$

Assumption 2.2 is stronger than Assumption 2.1. It requires $\log Z(x;\theta^*) \equiv \gamma^*$ for all $x \in \mathcal{X}$, that is, the conditional distribution is perfectly self-normalized. Under Assumption 2.2, it must be the case that $\forall x \in \mathcal{X}$

$$\sum_y p_{Y|X}(y|x) = \sum_y \exp\{s(x,y;\theta^*) - \gamma^*\} = 1$$

There are $|\mathcal{X}|$ constraints but only $d+1$ free parameters. Therefore self-normalization is a non-trivial assumption when $|\mathcal{X}| \gg d$. In the case of language modeling, $|\mathcal{X}| = |V|^k \gg d+1$, where $|V|$ is the vocabulary size and k is the length of the context. The number of constraints grows exponentially fast.

Given a scoring function $s(x,y;\theta)$ that satisfies assumption 2.1, we can derive a scoring function s' that satisfies assumption 2.2 by defining

$$s'(x,y;\theta,\{c_x : x \in \mathcal{X}\}) = s(x,y;\theta) - c_x$$

where $c_x \in \mathbb{R}$ is a parameter for history x. Thus we introduce a new parameter c_x for each possible history x. This is the most straightforward extension of NCE to the conditional case; it is used by (Mnih and Teh, 2012). It has the clear drawback however of introducing a large number of additional parameters to the model.

3 Two Estimation Algorithms

Figure 1 shows two NCE-based parameter estimation algorithms, based respectively on *binary objective* and *ranking objective*. The input to either algorithm is a set of training examples $\{x^{(i)}, y^{(i)}\}_{i=1}^{n}$, a parameter K specifying the number of negative examples per training example, and a distribution $p_N(\cdot)$ from which negative examples are sampled. The algorithms differ only in the choice of objective function being optimized: L_B^n for binary objective, and L_R^n for ranking objective. Binary objective essentially corresponds to a problem where the scoring function $s(x, y; \theta)$ is used to construct a binary classifier that discriminates between positive and negative examples. Ranking objective corresponds to a problem where the scoring function $s(x, y; \theta)$ is used to rank the true label $y^{(i)}$ above negative examples $y^{(i,1)} \ldots y^{(i,K)}$ for the input $x^{(i)}$.

Our main result is as follows:

Theorem 3.1 *(Informal: see section 4 for a formal statement.) For any $K \geq 1$, the binary classification-based algorithm in figure 1 is consistent under Assumption 2.2, but is not always consistent under the weaker Assumption 2.1. For any $K \geq 1$, the ranking-based algorithm in figure 1 is consistent under either Assumption 2.1 or Assumption 2.2. Both algorithms achieve the same statistical efficiency as the maximum-likelihood estimate as $K \to \infty$.*

The remainder of this section gives a sketch of the argument underlying consistency, and discusses use of the two algorithms in previous work.

3.1 A Sketch of the Consistency Argument for the Ranking-Based Algorithm

In this section, in order to develop intuition underlying the ranking algorithm, we give a proof sketch of the following theorem:

Theorem 3.2 *(First part of theorem 4.1 below.) Define $\mathcal{L}_R^{\infty}(\theta) = \mathbb{E}[\mathcal{L}_R^n(\theta)]$. Under Assumption 2.1, $\bar{\theta} \in \arg\max_{\theta} \mathcal{L}_R^{\infty}(\theta)$ if and only if, for all $(x, y) \in \mathcal{X} \times \mathcal{Y}$,*

$$p_{Y|X}(y|x) = \exp(s(x, y; \bar{\theta}))/Z(x, \bar{\theta}).$$

This theorem is key to the consistency argument. Intuitively as n increases $\mathcal{L}_R^n(\theta)$ converges to $\mathcal{L}_R^{\infty}(\theta)$, and the output to the algorithm converges to θ' such that $p(y|x; \theta') = p_{Y|X}(y|x)$ for all x, y. Section 4 gives a formal argument.

Inputs: Training examples $\{x^{(i)}, y^{(i)}\}_{i=1}^{n}$, sampling distribution $p_N(\cdot)$ for generating negative examples, an integer K specifying the number of negative examples per training example, a scoring function $s(x, y; \theta)$. Flags {BINARY = true, RANKING = false} if binary classification objective is used, {BINARY = false, RANKING = true} if ranking objective is used.

Definitions: Define $\bar{s}(x, y; \theta) = s(x, y; \theta) - \log p_N(y)$
Algorithm:

- For $i = 1 \ldots n$, $k = 1 \ldots K$, draw $y^{(i,k)}$ I.I.D. from the distribution $p_N(y)$. For convenience define $y^{(i,0)} = y^{(i)}$.

- If RANKING, define the ranking objective function

$$\mathcal{L}_R^n(\theta) = \frac{1}{n} \sum_{i=1}^{n} \log \frac{\exp(\bar{s}(x^{(i)}, y^{(i,0)}; \theta))}{\sum_{k=0}^{K} \exp(\bar{s}(x^{(i)}, y^{(i,k)}; \theta))},$$

  and the estimator $\widehat{\theta}_R = \operatorname*{argmax}_{\theta \in \Theta} \mathcal{L}_R^n(\theta)$.

- If BINARY, define the binary objective function

$$\begin{aligned} \mathcal{L}_B^n(\theta, \gamma) = &\frac{1}{n} \sum_{i=1}^{n} \Big\{ \log g(x^{(i)}, y^{(i,0)}; \theta, \gamma) \\ &+ \sum_{k=1}^{K} \log \Big(1 - g(x^{(i)}, y^{(i,k)}; \theta, \gamma)\Big) \Big\}, \end{aligned}$$

  and estimator $(\widehat{\theta}_B, \widehat{\gamma}_B) = \operatorname*{argmax}_{\theta \in \Theta, \gamma \in \Gamma} \mathcal{L}_B^n(\theta, \gamma)$, where

$$g(x, y; \theta, \gamma) = \frac{\exp\left(\bar{s}(x, y; \theta) - \gamma\right)}{\exp\left(\bar{s}(x, y; \theta) - \gamma\right) + K}.$$

- Define $\widehat{\theta} = \widehat{\theta}_R$ if RANKING and $\widehat{\theta} = \widehat{\theta}_B$ otherwise. Return $\widehat{\theta}$ and

$$\widehat{p}_{Y|X}(y|x) = \frac{\exp(s(x, y; \widehat{\theta}))}{\sum_{y \in \mathcal{Y}} \exp(s(x, y; \widehat{\theta}))}$$

Figure 1: Two NCE-based estimation algorithms, using ranking objective and binary objective respectively.

We now give a proof sketch for theorem 3.2. Consider the algorithm in figure 1. For convenience define $\bar{y}^{(i)}$ to be the vector $(y^{(i,0)}, y^{(i,1)}, \ldots, y^{(i,K)})$. Define $\alpha(x, \bar{y}) = \sum_{k=0}^{K} p_{X,Y}(x, \bar{y}_k) \prod_{j \neq k} p_N(\bar{y}_j)$, and

$$\begin{aligned} q(k|x, \bar{y}; \theta) &= \frac{\exp(\bar{s}(x, \bar{y}_k; \theta))}{\sum_{k=0}^{K} \exp(\bar{s}(x, \bar{y}_k; \theta))}, \\ \beta(k|x, \bar{y}) &= \frac{p_{X,Y}(x, \bar{y}_k) \prod_{j \neq k} p_N(\bar{y}_j)}{\alpha(x, \bar{y})} \\ &= \frac{p_{Y|X}(\bar{y}_k|x)/p_N(\bar{y}_k)}{\sum_{k=0}^{N} p_{Y|X}(\bar{y}_k|x)/p_N(\bar{y}_k)} \\ \mathrm{C}(x, \bar{y}; \theta) &= -\sum_{k=0}^{K} \beta(k|x, \bar{y}) \log q(k|x, \bar{y}; \theta) \end{aligned}$$

Intuitively, $q(\cdot|x, \bar{y}; \theta)$ and $\beta(\cdot|x, \bar{y})$ are posterior distributions over the true label $k \in \{0 \dots K\}$ given an input $x, \bar{y}$, under the parameters θ and the true distributions $p_{X,\bar{Y}}(x, \bar{y})$ respectively; $\mathrm{C}(x, \bar{y}; \theta)$ is the negative cross-entropy between these two distributions.

The proof of theorem 3.2 rests on two identities. The first identity states that the objective function is the expectation of the negative cross-entropy w.r.t. the density function $\frac{1}{K+1}\alpha(x, \bar{y})$ (see Section B.1.1 of the supplementary material for derivation):

$$\mathcal{L}_R^{\infty}(\theta) = \sum_x \sum_{\bar{y}} \frac{1}{K+1} \alpha(x, \bar{y}) \mathrm{C}(x, \bar{y}; \theta). \quad (5)$$

The second identity concerns the relationship between $q(\cdot|x, \bar{y}; \theta)$ and $\beta(\cdot|x, \bar{y})$. Under assumption 2.1, for all $x, \bar{y}$, $k \in \{0 \dots K\}$,

$$\begin{aligned} & q(k|x, \bar{y}; \theta^*) \\ = \; & \frac{p_{Y|X}(\bar{y}_k|x) Z(x; \theta^*)/p_N(y_k)}{\sum_{k=0}^{K} p_{Y|X}(\bar{y}_k|x) Z(x; \theta^*)/p_N(y_k)} \\ = \; & \beta(k|x, \bar{y}) \end{aligned} \quad (6)$$

It follows immediately through the properties of negative cross entropy that

$$\forall x, \bar{y}, \quad \theta^* \in \operatorname*{argmax}_{\theta} \mathrm{C}(x, \bar{y}; \theta) \quad (7)$$

The remainder of the argument is as follows:

- Eqs. 7 and 5 imply that $\theta^* \in \mathrm{argmax}_{\theta} \mathcal{L}_R^{\infty}(\theta)$.
- Assumption 2.1 implies that $\alpha(x, \bar{y}) > 0$ for all $x, \bar{y}$. It follows that any $\theta' \in \arg\max_{\theta} \mathcal{L}_R^{\infty}(\theta)$ satisfies

$$\begin{aligned} & \text{for all } x, \bar{y}, k, \\ & q(k|x, \bar{y}; \theta') = q(k|x, \bar{y}; \theta^*) = \beta(k|x, \bar{y}) \end{aligned} \quad (8)$$

Otherwise there would be some $x, \bar{y}$ such that $\mathrm{C}(x, \bar{y}; \theta') < \mathrm{C}(x, \bar{y}; \theta^*)$.

- Eq. 8 implies that $\forall x, y, \; p(y|x; \theta') = p(y|x; \theta^*)$. See the proof of lemma B.3 in the supplementary material.

In summary, the identity in Eq. 5 is key: the objective function in the limit, $\mathcal{L}_R^{\infty}(\theta)$, is related to a negative cross-entropy between the underlying distribution $\beta(\cdot|x, \bar{y})$ and a distribution under the parameters, $q(\cdot|x, \bar{y}; \theta)$. The parameters θ^* maximize this negative cross entropy over the space of all distributions $\{q(\cdot|x, \bar{y}; \theta), \theta \in \Theta\}$.

3.2 The Algorithms in Previous Work

To motivate the importance of the two algorithms, we now discuss their application in previous work.

Mnih and Teh (2012) consider language modeling, where $x = w_1 w_2 \dots w_{n-1}$ is a history consisting of the previous $n-1$ words, and y is a word. The scoring function is defined as

$$s(x, y; \theta) = (\sum_{i=1}^{n-1} C_i r_{w_i}) \cdot q_y + b_y - c_x$$

where r_{w_i} is an embedding (vector of parameters) for history word w_i, q_y is an embedding (vector of parameters) for word y, each C_i for $i = 1 \dots n-1$ is a matrix of parameters specifying the contribution of r_{w_i} to the history representation, b_y is a bias term for word y, and c_x is a parameter corresponding to the log normalization term for history x. Thus each history x has its own parameter c_x. The binary objective function is used in the NCE algorithm. The noise distribution $p_N(y)$ is set to be the unigram distribution over words in the vocabulary.

This method is a direct application of the original NCE method to conditional estimation, through introduction of the parameters c_x corresponding to normalization terms for each history. Interestingly, Mnih and Teh (2012) acknowledge the difficulties in maintaining a separate parameter c_x for each history, and set $c_x = 0$ for all x, noting that empirically this works well, but without giving justification.

Mikolov et al. (2013) consider an NCE-based method using the binary objective function for estimation of word embeddings. The skip-gram method described in the paper corresponds to a model where x is a word, and y is a word in the context. The vector v_x is the embedding for word x, and the vector v'_y is an embedding for word y (separate embeddings are used for x and y). The method they describe uses

$$\bar{s}(x, y; \theta) = v'_y \cdot v_x$$

or equivalently

$$s(x, y; \theta) = v'_y \cdot v_x + \log p_N(y)$$

The negative-sampling distribution $p_N(y)$ was chosen as the unigram distribution $p_Y(y)$ raised to the power $3/4$. The end goal of the method was to learn useful embeddings v_w and v'_w for each word in the vocabulary; however the method gives a consistent estimate for a model of the form

$$\begin{aligned} p(y|x) &= \frac{\exp\left(v'_y \cdot v_x + \log p_N(y)\right)}{\sum_y \exp\left(v'_y \cdot v_x + \log p_N(y)\right)} \\ &= \frac{p_N(y)\exp\left(v'_y \cdot v_x\right)}{Z(x;\theta)} \end{aligned}$$

assuming that Assumption 2.2 holds, i.e. $Z(x;\theta) = \sum_y p_N(y)\exp\left(v'_y \cdot v_x\right) \equiv H(\theta)$ which does not vary with x.

Levy and Goldberg (2014) make a connection between the NCE-based method of (Mikolov et al., 2013), and factorization of a matrix of pointwise mutual information (PMI) values of (x,y) pairs. Consistency of the NCE-based method under assumption 2.2 implies a similar result, specifically: if we define $p_N(y) = p_Y(y)$, and define $s(x,y;\theta) = v'_y \cdot v_x + \log p_N(y)$ implying $\bar{s}(x,y;\theta) = v'_y \cdot v_x$, then parameters v'_y and v_x converge to values such that

$$p(y|x) = \frac{p_Y(y)\exp\left(v'_y \cdot v_x\right)}{H(\theta)}$$

or equivalently

$$\text{PMI}(x,y) = \log\frac{p(y|x)}{p(y)} = v'_y \cdot v_x - \log H(\theta)$$

That is, following (Levy and Goldberg, 2014), the inner product $v'_y \cdot v_x$ is an estimate of the PMI up to a constant offset $H(\theta)$.

Finally, Jozefowicz et al. (2016) introduce the ranking-based variant of NCE for the language modeling problem. This is the same as the ranking-based algorithm in figure 1. They do not, however, make the connection to assumptions 2.2 and 2.1, or derive the consistency or efficiency results in the current paper. Jozefowicz et al. (2016) partially motivate the ranking-based variant throught the *importance sampling* viewpoint of Bengio and Senécal (2008). However there are two critical differences: 1) the algorithm of Bengio and Senécal (2008) does not lead to the same objective L_R^n in the ranking-based variant of NCE; instead it uses importance sampling to derive an objective that is similar but not identical; 2) the importance sampling method leads to a biased estimate of the gradients of the log-likelihood function, with the bias going to zero only as $K \to \infty$. In contrast the theorems in the current paper show that the NCE-based methods are *consistent for any value of K*. In summary, while it is tempting to view the ranking variant of NCE as an importance sampling method, the NCE-based view gives stronger guarantees for finite values of K.

4 Theory

This section states the main theorems. The supplementary material contains proofs. Throughout the paper, we use $\mathbb{E}_X[\cdot], \mathbb{E}_Y[\cdot], \mathbb{E}_{X,Y}[\cdot], \mathbb{E}_{Y|X=x}[\cdot]$ to represent the expectation w.r.t. $p_X(\cdot), p_Y(\cdot), p_{X,Y}(\cdot,\cdot), p_{Y|X}(\cdot|x)$. We use $\|\cdot\|$ to denote either the l_2 norm when the operand is a vector or the spectral norm when the operand is a matrix. Finally, we use $\Rightarrow$ to represent converge in distribution. Recall that we have defined

$$\bar{s}(x,y;\theta) = s(x,y;\theta) - \log p_N(y).$$

4.1 Ranking

In this section, we study noise contrastive estimation with ranking objective under Assumption 2.1. First consider the following function:

$$L_R^\infty(\theta) = \sum_{x,y_0,\cdots,y_K} p_{X,Y}(x,y_0)\prod_{i=1}^{K} p_N(y_i) \times \log\left(\frac{\exp(\bar{s}(x,y_0;\theta))}{\sum_{k=0}^{K}\exp(\bar{s}(x,y_k;\theta))}\right).$$

By straightforward calculation, one can find that

$$L_R^\infty(\theta) = \mathbb{E}\left[L_R^n(\theta)\right].$$

Under mild conditions, $L_R^n(\theta)$ converges to $L_R^\infty(\theta)$ as $n \to \infty$. Denote the set of maximizers of $L_R^\infty(\theta)$ by Θ_R^*, that is

$$\Theta_R^* = \arg\max_{\theta\in\Theta} L_R^\infty(\theta).$$

The following theorem shows that any parameter vector $\bar{\theta} \in \Theta_R^*$ if and only if it gives the correct conditional distribution $p_{Y|X}(y|x)$.

Assumption 4.1 *(Identifiability). For any $\theta \in \Theta$, if there exists a function $c(x)$ such that $s(x,y;\theta) - s(x,y;\theta^*) \equiv c(x)$ for all $(x,y) \in \mathcal{X} \times \mathcal{Y}$, then $\theta = \theta^*$ and thus $c(x) = 0$ for all x.*

Theorem 4.1 *Under Assumption 2.1, $\bar{\theta} \in \Theta_R^*$ if and only if, for all $(x,y) \in \mathcal{X} \times \mathcal{Y}$,*

$$p_{Y|X}(y|x) = \exp(s(x,y;\bar{\theta}))/Z(x,\bar{\theta}).$$

In addition, Θ_R^* is a singleton if and only if Assumption 4.1 holds.

Next we consider consistency of the estimation algorithm based on the ranking objective under the following regularity assumptions:

Assumption 4.2 *(Continuity). $s(x, y; \theta)$ is continuous w.r.t. θ for all $(x, y) \in \mathcal{X} \times \mathcal{Y}$.*

Assumption 4.3 *Θ_R^* is contained in the interior of a compact set $\Theta \subset \mathbb{R}^d$.*

For a given estimate $\widehat{p}_{Y|X}$ of the conditional distribution $p_{Y|X}$, define the error metric $d(\cdot, \cdot)$ by

$$d\left(\widehat{p}_{Y|X}, p_{Y|X}\right) = \sum_{x \in \mathcal{X}, y \in \mathcal{Y}} p_{X,Y}(x, y) \times \left(\widehat{p}_{Y|X}(y|x) - p_{Y|X}(y|x)\right)^2 .$$

For a sequence of IID observations $(x^{(1)}, y^{(1)})$, $(x^{(2)}, y^{(2)}), \ldots,$ define the sequences of estimates $(\widehat{\theta}_R^1,\ \widehat{p}_{Y|X}^1)$, $(\widehat{\theta}_R^2,\ \widehat{p}_{Y|X}^2), \ldots$ where the n^{th} estimate $(\widehat{\theta}_R^n,\ \widehat{p}_{Y|X}^n)$ is obtained by optimizing the ranking objective of figure 1 on $(x^{(1)}, y^{(1)}), (x^{(2)}, y^{(2)}), \ldots, (x^{(n)}, y^{(n)})$.

Theorem 4.2 *(Consistency) Under Assumptions 2.1, 4.2, 4.3, the estimates based on the ranking objective are strongly consistent in the sense that for any fixed $K \geq 1$,*

$$\mathbb{P}\left\{ \lim_{n \to \infty} \min_{\theta^* \in \Theta_R^*} \|\widehat{\theta}_R^n - \theta^*\| = 0 \right\} = \mathbb{P}\left\{ \lim_{n \to \infty} d\left(\widehat{p}_{Y|X}^n,\ p_{Y|X}\right) = 0 \right\} = 1$$

Further, if Assumption 4.1 holds,

$$\mathbb{P}\left\{ \lim_{n \to \infty} \widehat{\theta}_R^n = \theta^* \right\} = 1.$$

Remark 4.1 *Thoughout the paper, all NCE estimators are defined for some fixed K. We suppress the dependence on K to simplify notation (e.g. $\widehat{\theta}_R^n$ should be interpreted as $\widehat{\theta}_R^{n,K}$).*

4.2 Classification

Now we turn to the analysis of NCE with binary objective under Assumption 2.2. First consider the following function,

$$L_B^\infty(\theta, \gamma) = \sum_{x,y} \left\{ p_{X,Y}(x, y) \log\left(g(x, y; \theta, \gamma)\right) + K p_X(x) p_N(y) \log\left(1 - g(x, y; \theta, \gamma)\right) \right\}$$

One can find that

$$L_B^\infty(\theta, \gamma) = \mathbb{E}\left[L_B^n(\theta, \gamma)\right].$$

Denote the set of maximizers of $L_B^\infty(\theta, \gamma)$ by Ω_B^* :

$$\Omega_B^* = \arg \max_{\theta \in \Theta, \gamma \in \Gamma} L_B^\infty(\theta, \gamma).$$

Parallel results of Theorem 4.1, 4.2 are established as follows.

Assumption 4.4 *(Identifiability). For any $\theta \in \Theta$, if there exists some constant c such that $s(x, y; \theta) - s(x, y; \theta^*) \equiv c$ for all $(x, y) \in \mathcal{X} \times \mathcal{Y}$, then $\theta = \theta^*$ and thus $c = 0$.*

Assumption 4.5 *Ω_B^* is in the interior of $\Theta \times \Gamma$ where $\Theta \subset \mathbb{R}^d, \Gamma \subset \mathbb{R}$ are compact sets.*

Theorem 4.3 *Under Assumption 2.2, $(\bar{\theta}, \bar{\gamma}) \in \Omega_B^*$ if and only if, for all $(x, y) \in \mathcal{X} \times \mathcal{Y}$,*

$$p_{Y|X}(y|x) = \exp(s(x, y; \bar{\theta}) - \bar{\gamma})$$

for all (x, y). Ω_B^* is a singleton if and only if Assumption 4.4 holds.

Similarly we can define the sequence of estimates $(\widehat{\theta}_B^1,\ \widehat{\gamma}_B^1,\ \widehat{p}_{Y|X}^1)$, $(\widehat{\theta}_B^2,\ \widehat{\gamma}_B^2,\ \widehat{p}_{Y|X}^2), \ldots$ based on the binary objective.

Theorem 4.4 *(Consistency) Under Assumption 2.2, 4.2, 4.5, the estimates defined by the binary objective are strongly consistent in the sense that for any $K \geq 1$,*

$$\mathbb{P}\left\{ \lim_{n \to \infty} \min_{(\theta^*, \gamma^*) \in \Omega_B^*} \|(\widehat{\theta}_B^n, \widehat{\gamma}_B^n) - (\theta^*, \gamma^*)\| = 0 \right\} = \mathbb{P}\left\{ \lim_{n \to \infty} d\left(\widehat{p}_{Y|X}^n,\ p_{Y|X}\right) = 0 \right\} = 1$$

If further Assumption 4.4 holds,

$$\mathbb{P}\left\{ \lim_{n \to \infty} (\widehat{\theta}_B^n, \widehat{\gamma}_B^n) = (\theta^*, \gamma^*) \right\} = 1.$$

4.3 Counterexample

In this section, we give a simple example to demonstrate that the binary classification approach fails to be consistent when assumption 2.1 holds but assumption 2.2 fails (i.e. the partition function depends on the input).

Consider $X \in \mathcal{X} = \{x_1, x_2\}$ with marginal distribution

$$p_X(x_1) = p_X(x_2) = 1/2,$$

and $Y \in \mathcal{Y} = \{y_1, y_2\}$ generated by the conditional model specified in assumption 2.1 with the score function parametrized by $\theta = (\theta_1, \theta_2)$ and

$$s(x_1, y_1; \theta) = \log \theta_1,$$

$s(x_1, y_2; \theta) = s(x_2, y_1; \theta) = s(x_2, y_2; \theta) = \log \theta_2$.

Assume the true parameter is $\theta^* = (\theta_1^*, \theta_2^*) = (1, 3)$. By simple calculation,

$$Z(\theta^*; x_1) = 4,\ Z(\theta^*; x_2) = 6,$$
$$p_{X,Y}(x_1, y_1) = 1/8, p_{X,Y}(x_1, y_2) = 3/8,$$
$$p_{X,Y}(x_2, y_1) = p_{X,Y}(x_2, y_2) = 1/4.$$

Suppose we choose the negative sampling distribution $p_N(y_1) = p_N(y_2) = 1/2$. For any $K \geq 1$, by the Law of Large Numbers, as n goes to infinity, $L_B^n(\theta, \gamma)$ will converge to $L_B^\infty(\theta, \gamma)$. Substitute in the parameters above. One can show that

$$\begin{aligned} L_B^\infty(\theta, \gamma) = & \frac{1}{8} \log \frac{2\theta_1}{2\theta_1 + K\exp(\gamma)} \\ & + \frac{K}{4} \log \frac{K\exp(\gamma)}{2\theta_1 + K\exp(\gamma)} \\ & + \frac{7}{8} \log \frac{2\theta_2}{2\theta_2 + K\exp(\gamma)} \\ & + \frac{3K}{4} \log \frac{K\exp(\gamma)}{2\theta_2 + K\exp(\gamma)}. \end{aligned}$$

Setting the derivatives w.r.t. θ_1, θ_2 to zero, one will obtain

$$\theta_1 = \frac{1}{4}\exp(\gamma),\ \ \theta_2 = \frac{7}{12}\exp(\gamma).$$

So for any $(\widetilde{\theta}_1, \widetilde{\theta}_2, \widetilde{\gamma}) \in \operatorname{argmax}_{\theta,\gamma} L_B^\infty(\theta, \gamma)$, $(\widetilde{\theta}_1, \widetilde{\theta}_2, \widetilde{\gamma})$ will satisfy the equalities above. Then the estimated distribution $\widetilde{p}_{Y|X}$ will satisfy

$$\frac{\widetilde{p}_{Y|X}(y_1|x_1)}{\widetilde{p}_{Y|X}(y_2|x_1)} = \frac{\widetilde{\theta}_1}{\widetilde{\theta}_2} = \frac{1/4}{7/12} = \frac{3}{7},$$

which contradicts the fact that

$$\frac{p_{Y|X}(y_1|x_1)}{p_{Y|X}(y_2|x_1)} = \frac{p_{X,Y}(x_1, y_1)}{p_{X,Y}(x_1, y_2)} = \frac{1}{3}.$$

So the binary objective does not give consistent estimation of the conditional distribution.

4.4 Asymptotic Normality and Statistical Efficiency

Noise Contrastive Estimation significantly reduces the computational complexity, especially when the label space $|\mathcal{Y}|$ is large. It is natural to ask: does such scalability come at a cost? Classical likelihood theory tells us, under mild conditions, the maximum likelihood estimator (MLE) has nice properties like asymptotic normality and Fisher efficiency. More specifically, as the sample size goes to infinity, the distribution of the MLE will converge to a multivariate normal distribution, and the mean square error of the MLE will achieve the Cramer-Rao lower bound (Ferguson, 1996).

We have shown the consistency of the NCE estimators in Theorem 4.2 and Theorem 4.4. In this part of the paper, we derive their asymptotic distribution and quantify their statistical efficiency. To this end, we restrict ourselves to the case where θ^* is identifiable (i.e. Assumptions 4.1 or 4.4 hold) and the scoring function $s(x, y; \theta)$ satisfies the following smoothness condition:

Assumption 4.6 *(Smoothness). The scoring function $s(x, y; \theta)$ is twice continuous differentiable w.r.t. θ for all $(x, y) \in \mathcal{X} \times \mathcal{Y}$.*

We first introduce the following maximum-likelihood estimator.

$$\begin{aligned} \widehat{\theta}^{\,\mathrm{MLE}} &= \arg\min_\theta\ L^n_{\mathrm{MLE}}(\theta) \\ &:= \arg\min_\theta \sum_{i=1}^n \log\left(\frac{\exp(s(x^{(i)}, y^{(i)}; \theta))}{\sum_{y\in\mathcal{Y}} \exp(s(x^{(i)}, y; \theta))}\right). \end{aligned}$$

Define the matrix

$$\mathcal{I}_{\theta^*} = \mathbb{E}_X\left[\mathrm{Var}_{Y|X=x}\left[\nabla_\theta s(x, y; \theta^*)\right]\right].$$

As shown below, $\mathcal{I}_{\theta^*}$ is essentially the Fisher information matrix under the conditional model.

Theorem 4.5 *Under Assumption 2.1, 4.1, 4.3, and 4.6, if $\mathcal{I}_{\theta^*}$ is non-singular, as $n \to \infty$*

$$\sqrt{n}(\widehat{\theta}^{\,MLE} - \theta^*)\ \Rightarrow\ \mathcal{N}(0, \mathcal{I}_{\theta^*}^{-1}).$$

For any given estimator $\widehat{\theta}$, define the scaled asymptotic mean square error by

$$\mathrm{MSE}_\infty(\widehat{\theta}) = \lim_{n\to\infty} \mathbb{E}\left[\left\|\sqrt{\frac{n}{d}}\left(\widehat{\theta} - \theta^*\right)\right\|^2\right],$$

where d is the dimension of the parameter θ^*. Theorem 4.5 implies that,

$$\mathrm{MSE}_\infty(\widehat{\theta}^{\,\mathrm{MLE}}) = \mathrm{Tr}(\mathcal{I}_{\theta^*}^{-1})/d.$$

where $\mathrm{Tr}(\cdot)$ denotes the trace of a matrix. According to classical MLE theory (Ferguson, 1996), under certain regularity conditions, this is the best achievable mean square error. So the next question to answer is: can these NCE estimators approach this limit?

Assumption 4.7 *There exist positive constants* c, C *such that* $\sigma_{\min}(\mathcal{I}_{\theta^*}) \geq c$ *and*

$$\max_{(x,y)\in\mathcal{X}\times\mathcal{Y}} \Big\{ |s(x,y;\theta^*)|, \|\nabla_\theta s(x,y;\theta^*)\|, \\ \|\nabla_\theta^2 s(x,y;\theta^*)\| \Big\} \leq C.$$

where $\sigma_{\min}(\cdot)$ *denotes the smallest singular value.*

Theorem 4.6 (Ranking) *Under Assumption 2.1, 4.1, 4.3, 4.6, 4.7, there exists an integer* K_0 *such that for all* $K \geq K_0$*, as* $n \to \infty$

$$\sqrt{n}\left(\widehat{\theta}_R - \theta^*\right) \Rightarrow \mathcal{N}(0, \mathcal{I}_{R,K}^{-1}), \qquad (9)$$

for some matrix $\mathcal{I}_{R,K}$*. There exists a constant* C *such that for all* $K \geq K_0$*,*

$$|\,\mathrm{MSE}_\infty(\widehat{\theta}_R) - \mathrm{MSE}_\infty(\widehat{\theta}^{MLE})| \leq C/\sqrt{K} \\ \|\mathcal{I}_{R,K}^{-1} - \mathcal{I}_{\theta^*}^{-1}\| \leq C/\sqrt{K}$$

Theorem 4.7 (Binary) *Under Assumption 2.2, 4.4, 4.5, 4.6, 4.7, there exists an integer* K_0 *such that, for any* $K \geq K_0$*, as* $n \to \infty$

$$\sqrt{n}\left(\widehat{\theta}_B - \theta^*\right) \Rightarrow \mathcal{N}(0, \mathcal{I}_{B,K}^{-1}), \qquad (10)$$

for some matrix $\mathcal{I}_{B,K}$*. There exists a constant* C *such that for all* $K \geq K_0$*,*

$$|\,\mathrm{MSE}_\infty(\widehat{\theta}_B) - \mathrm{MSE}_\infty(\widehat{\theta}^{MLE})| \leq C/K \\ \|\mathcal{I}_{B,K}^{-1} - \mathcal{I}_{\theta^*}^{-1}\| \leq C/K.$$

Remark 4.2 *Theorem 4.6 and 4.7 reveal that under respective model assumptions, for any given* $K \geq K_0$ *both NCE estimators are asymptotically normal and* $\sqrt{n}$*-consistent. Moreover, both NCE estimators approach Fisher efficiency (statistical optimality) as* K *grows.*

5 Experiments

5.1 Simulations

Suppose we have a feature space $\mathcal{X} \subset \mathbb{R}^d$ with $|\mathcal{X}| = m_x$, label space $\mathcal{Y} = \{1, \cdots, m_y\}$, and parameter $\theta = (\theta_1, \cdots, \theta_{m_y}) \in \mathbb{R}^{m_y \times d}$. Then for any given sample size n, we can generate observations $(x^{(i)}, y^{(i)})$ by first sampling $x^{(i)}$ uniformly from $\mathcal{X}$ and then sampling $y^{(i)} \in \mathcal{Y}$ by the condional model

$$p(y|x;\theta) = \exp(x'\theta_y) / \sum_{y=1}^{m_y} \exp(x'\theta_y).$$

We first consider the estimation of θ by MLE and NCE-ranking. We fix $d = 4, m_x = 200, m_y = 100$ and generate $\mathcal{X}$ and the parameter θ from separate mixtures of Gaussians. We try different configurations of (n, K) and report the KL divergence between the estimated distribution and true distribution, as summarized in the left panel of figure 2. The observations are:

- The NCE estimators are consistent for any fixed K. For a fixed sample size, the NCE estimators become comparable to MLE as K increases.
- The larger the sample size, the less sensitive are the NCE estimators to K. A very small value of K seems to suffice for large sample size.

Apparently, under the parametrization above, the model is not self-normalized. To use NCE-binary, we add an extra x-dependent bias parameter b_x to the score function (i.e. $s(x,y;\theta) = x'\theta_y + b_x$) to make the model self-normalized or else the algorithm will not be consistent. Similar patterns to figure 2 are observed when varying sample size and K (see Section A.1 of the supplementary material). However this makes NCE-binary not directly comparable to NCE-ranking/MLE since its performance will be compromised by estimating extra parameters and the number of extra parameters depends on the richness of the feature space $\mathcal{X}$. To make this clear, we fix $n = 16000, d = 4, m_y = 100, K = 32$ and experiment with $m_x = 100, 200, 300, 400$. The results are summarized on the right panel of figure 2. As $|\mathcal{X}|$ increases, the KL divergence will grow while the performance of NCE-ranking/MLE is independent of $|\mathcal{X}|$. Without the x-dependent bias term for NCE-binary, the KL divergence will be much higher due to lack of consistency (0.19, 0.21, 0.24, 0.26 respectively).

5.2 Language Modeling

We evaluate the performance of the two NCE algorithms on a language modeling problem, using the Penn Treebank (PTB) dataset (Marcus et al., 1993). We choose (Zaremba et al., 2014) as the benchmark where the conditional distribution is modeled by two-layer LSTMs and the parameters are estimated by MLE (note that the current state-of-the-art is (Yang et al., 2018)). Zaremba et al. (2014) implemented 3 model configurations: "Small" , "Medium" and "Large", which have 200, 650 and 1500 units per layer respectively. We follow their setup (model size, unrolled steps, dropout ratio, etc) but train the model by maximiz-

	Small		Medium		Large	
MLE	111.5		82.7		78.4	
NCE	Ranking	Binary	Ranking	Binary	Ranking	Binary
$K = 200$	113.8	106.8	83.2	82.1	79.3	76.0
$K = 400$	112.9	105.6	82.3	81.5	77.9	75.6
$K = 800$	111.9	105.3	81.4	81.6	77.8	75.7
$K = 1600$	110.6	**104.8**	81.7	81.5	77.5	75.9
reg-MLE	105.4		79.9		77.0	
reg-Ranking ($K = 1600$)	105.4		**79.8**		**75.0**	
reg-Binary ($K = 1600$)	**104.8**		82.5		75.7	

Table 1: Perplexity on the test set of Penn Treebank. We show performance for the ranking v.s. binary loss algorithms, with different values for K, and with/without regularization.

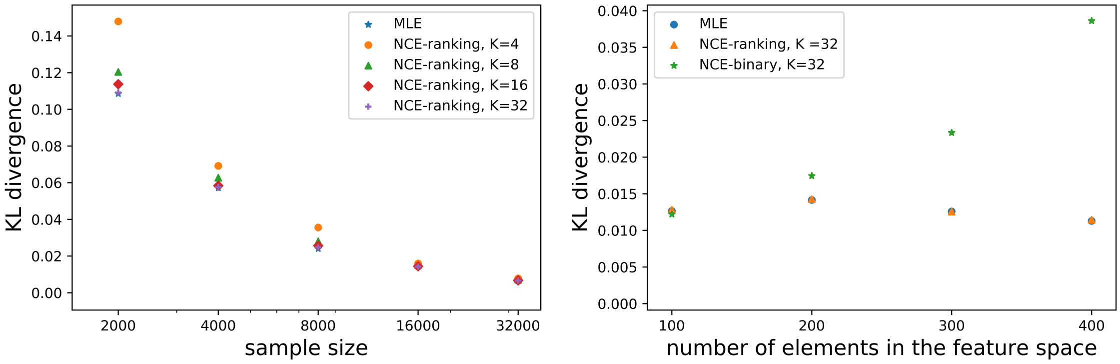

Figure 2: KL divergence between the true distribution and the estimated distribution.

ing the two NCE objectives. We use the unigram distribution as the negative sampling distribution and consider $K = 200, 400, 800, 1600$.

The results on the test set are summarized in table 1. Similar patterns are observed on the validation set (see Section A.2 of the supplementary material). As shown in the table, the performance of NCE-ranking and NCE-binary improves as the number of negative examples increases, and finally outperforms the MLE.

An interesting observation is, without regularization, the binary classification approach outperforms both ranking and MLE. This suggests the model space (two-layer LSTMs) is rich enough as to approximately incorporate the x-dependent partition function $Z(\theta; x)$, thus making the model approximately self-normalized. This motivates us to modify the ranking and MLE objectives by adding the following regularization term:

$$\frac{\alpha}{n}\sum_{i=1}^{n}\left(\log\left(\frac{1}{m}\sum_{j=1}^{m}\exp\left(\bar{s}(x^{(i)}, \widetilde{y}^{(i,j)}; \theta)\right)\right)\right)^2$$
$$\approx \alpha\,\mathbb{E}_X\left[(\log Z(x;\theta))^2\right],$$

where $\widetilde{y}^{(i,j)}, 1 \leq j \leq m$ are sampled from the noise distribution $p_N(\cdot)$. This regularization term promotes a constant partition function, that is $Z(x;\theta) \approx 1$ for all $x \in \mathcal{X}$. In our experiments, we fix m to be 1/10 of the vocabulary size, $K = 1600$ and tune the regularization parameter α. As shown in the last three rows of the table, regularization significantly improves the performance of both the ranking approach and the MLE.

6 Conclusions

In this paper we have analyzed binary and ranking variants of NCE for estimation of conditional models $p(y|x;\theta)$. The ranking-based variant is consistent for a broader class of models than the binary-based algorithm. Both algorithms achieve Fisher efficiency as the number of negative examples increases. Experiments show that both algorithms outperform MLE on a language modeling task. The ranking-based variant of NCE outperforms the binary-based variant once a regularizer is introduced that encourages self-normalization.

Abstract

Maximum-likelihood estimation (MLE) is one of the most widely used approaches for training structured prediction models for text-generation based natural language processing applications. However, besides *exposure bias*, models trained with MLE suffer from *wrong objective* problem where they are trained to maximize the word-level correct next step prediction, but are evaluated with respect to sequence-level discrete metrics such as ROUGE and BLEU. Several variants of policy-gradient methods address some of these problems by optimizing for final discrete evaluation metrics and showing improvements over MLE training for downstream tasks like text summarization and machine translation. However, policy-gradient methods suffers from high sample variance, making the training process very difficult and unstable. In this paper, we present an alternative direction towards mitigating this problem by introducing a new objective (CALCS) based on a differentiable surrogate of longest common subsequence (LCS) measure that captures sequence-level structure similarity. Experimental results on abstractive summarization and machine translation validate the effectiveness of the proposed approach.

1 Introduction

Recently, deep neural networks have achieved state-of-the-art results in various tasks including computer vision, natural language processing, and speech processing. Specifically, neural text generation models, central focus of this work, have led to great progress in central downstream NLP tasks like text summarization, machine translation, and image captioning. For example, the abstractive summarization task, which has previously not been the popular choice for text summarization due to lack of appropriate text generation methods, has gained revived attention with the success of neural sequence-to-sequence models (Sutskever et al., 2014; Bahdanau et al., 2015). There has been several recent work with an impressive progress on this task including (Rush et al., 2015; Chopra et al., 2016; Nallapati et al., 2016; Miao and Blunsom, 2016; See et al., 2017; Tan et al., 2017; Zhou et al., 2017). Machine translation is another central field in NLP where the emergence of neural sequence-to-sequence models has enabled viable alternative approaches (Luong et al., 2015; Bahdanau et al., 2015; Cho et al., 2014; Sutskever et al., 2014) to challenge traditional phrase-based methods (Koehn et al., 2003).

Most of the recent existing works on neural text generation are based on variants of sequence-to-sequence models with attention (Bahdanau et al., 2015) trained with Maximum-likelihood estimation (MLE) with teacher forcing. As Ranzato et al. (2016) points out in a previous work, these models have two major drawbacks. First, they are trained to maximize the probability of correct next word given the entire sequence of previous ground truth words. While, at test time, the models need to generate the entire sequence by feeding its own predictions at previous time steps. This discrepancy is called *exposure bias* and hurts the performance as the model is never exposed to its own predictions during training. The second drawback, called *wrong objective*, is due yet another discrepancy between training and testing. It refers to the critique (Ranzato et al., 2016) that MLE-trained models tend to have suboptimal performance as they are trained to maximize a convenient objective (i.e., maximum likelihood of word-level correct next step prediction) rather than a desirable sequence-level objective that correlates better with the common discrete evaluation metrics such as ROUGE (Lin and Och, 2004) for summarization,

Brussels, Belgium, October 31 - November 4, 2018.

BLEU (Papineni et al., 2002) for translation, and word error rate for speech recognition, not log-likelihood. On the other hand, training models that directly optimize for such discrete metrics as objective is hard due to non-differentiable nature of the corresponding loss functions (Rosti et al., 2011). To address these issues, Ranzato et al. (2016) introduces an incremental learning recipe that uses a hybrid loss function combining REINFORCE (Williams, 1992) and cross-entropy. Recently, Paulus et al. (2018) also explored combining maximum-likelihood and policy gradient training for text summarization.

Towards sequence level optimization, previous works (Ranzato et al., 2016; Wu et al., 2016; Paulus et al., 2018) employ reinforcement learning (RL) with a policy-gradient approach which works around the difficulty of differentiating the reward function by using it as a weight. However, REINFORCE is known to suffer from high sample variance and credit assignment problems which makes the training process difficult and unstable besides resulting in models that are hard to reproduce (Henderson et al., 2018).

In this paper, we propose an alternative approach for sequence-level training with longest common subsequence (LCS) metric that measures the sequence-level structure similarity between two sequences. We essentially introduce a continuous approximation to the discrete LCS metric which can be directly optimized against using standard gradient-based methods. Our proposed approach has the advantage of being able to directly optimize for a surrogate reward as opposed to using the exact reward only as a weight as in RL-inspired works. Hence, it provides a viable alternative perspective to policy-gradient methods for side stepping the non-differentiability with respect to the exact reward. In addition, it simultenuously combats the *exposure bias* problem through exposing the model to its own predictions while computing our approximation to LCS metric.

To this end, we introduce a new learning recipe that incorporates the aformentioned continuous approximation to LCS metric (CALCS) as an additional objective on top of maximum-likelihood loss in existing neural text generation models. We evaluate the proposed approach on abstractive text summarization and machine translation tasks. To this end, we use recently introduced *pointer-generator* network (See et al., 2017) and *transformer* (Vaswani et al., 2017) as underlying baselines for summarization and machine translation, respectively. More precisely, we start from a pre-trained baseline model with cross-entropy loss, and continue training the model to optimize for the proposed differentiable objective based on CALCS. Using this recipe, we conduct various experiments on *CNN/Daily Mail* (Hermann et al., 2015; Nallapati et al., 2016) summarization and *WMT 2014 English-to-German* machine translation tasks. Experimental results validate the effectiveness of the proposed approach on both tasks.

2 Continuously Approximating Longest Common Subsequence Metric

In this work, we explore the potential use of longest common subsequence (LCS) metric from an algorithmic point of view to address the aforementioned *wrong objective* and *exposure bias* problems. LCS metric measures a sequence-level structure similarity between discrete sequences by identifying longest co-occurring in sequence n-grams and it has been shown to correlate well with human judgments for downstream text generation tasks (Lin and Och, 2004). To this end, we propose a way to continuously approximate LCS metric and use this differentiable approximation as the objective to train text generation models rather than the exact LCS measure, which is hard to optimize for due to non-differentiability of the corresponding loss function. Although such differentiable approximation provides a unique advantage from modeling and optimization perspective, the difficulty of controlling its tightness might be a potential drawback in terms of its applicability. In this section, we will first introduce our proposed approximation to LCS metric, and then provide a natural way to control its tightness.

Consider a sequence generation problem conditioned on an input sequence $\mathbf{x} = (x_1, x_2, \ldots, x_n)$ and let $\mathbf{y} = (y_1, y_2, \ldots, y_m)$ denote its corresponding ground-truth output sequence. Let

$$f(\mathbf{x}, \mathbf{\Theta}) = \mathbf{z} = (z_1, z_2, \ldots, z_k)$$

denote hypothesis sequence obtained by greedy decoding from a generic encoder-decoder architecture for input sequence $\mathbf{x}$, where $\mathbf{\Theta}$ represents model parameters. Also, let $p_1, p_2, \ldots, p_k$ be the probability distributions over vocabulary V at decoding time steps from which $z_1, z_2, \ldots, z_k$ are generated via *argmax* operator, respectively.

2.1 CaLcs

In this section, we define our approach to continuously approximate the longest common subsequence measure (LCS), which is an unnormalized version of ROUGE-L metric (Lin and Och, 2004) (See Appendix B) that is commonly used for performance evaluation of text summarization models. The main intuition behind our approach is to relax the common necessity for hard inferences while computing discrete metrics by instead comparing discrete tokens in a soft way. Towards this end, we start by defining LCS metric.

Definition 1. *Given two sequences* $\mathbf{y}$ *and* $\mathbf{z}$ *of tokens, longest common subsequence* $LCS(\mathbf{y}, \mathbf{z})$ *is defined as the longest sequence of tokens that appear left-to-right (but not necessarily in a contiguous block) in both sequences.*

The most common and intuitive solution for computing longest common subsequence is via dynamic programming. We will briefly revisit this here as it will be useful in terms of both recall and notational convenience while describing our surrogate LCS measure. Let $r_{i,j}$ denote the longest common subsequence between prefix sequences $\mathbf{y}_{[:i]} = (y_1, y_2, \ldots, y_i)$ and $\mathbf{z}_{[:j]} = (z_1, z_2, \ldots, z_j)$ of $\mathbf{y}$ and $\mathbf{z}$, respectively. A dynamic programming solution is given by

$$r_{i,j} = \begin{cases} 0 & \text{if } i = 0 \text{ or } j = 0 \\ r_{i-1,j-1} + 1 & \text{if } y_i = z_j \\ max(r_{i-1,j}, r_{i,j-1}) & \text{o/w.} \end{cases} \tag{1}$$

$r_{i,j}$ for all $i = 1, 2, \ldots, m$ and $j = 1, 2, \ldots, k$. It can be computed in mk iterations using the formula in Eqn 1. After computing 2D dynamic programming matrix r, we obtain $\text{LCS}(\mathbf{y}, \mathbf{z}) = r_{m,k}$.

Towards removing the dependence on hard inference for computing LCS, we now define our approximation to longest common subsequence, which we call CaLcs. At high-level, the idea is to continuously relax the original LCS measure. To this end, we leverage output probability distributions $p_1, p_2, \ldots, p_k$ as soft predictions to refine the dynamic programming formulation for original LCS. More precisely, we recursively define soft longest common subsequence $s_{i,j}$ between prefixes $\mathbf{y}_{[:i]}$ and $\mathbf{z}_{[:j]}$ in analogous to $r_{i,j}$ as follows:

$$s_{i,j} = p_j^{(y_i)}(s_{i-1,j-1} + 1) + \tag{2}$$

$$(1 - p_j^{(y_i)}) \max(s_{i-1,j}, s_{i,j-1}) \tag{3}$$

for $i, j > 0$ and $s_{i,0} = s_{0,j} = 0$, where $p_j^{(y_i)}$ denote the probability of generating y_i at j-th decoding step. Intuitively, CaLcs replaces the hard token comparison $\mathbb{1}[y_i = z_j]$ in Eq. 1 with the probability $p_j^{(y_i)}$ as in Eq. 2. Interpreting the probability $p_j^{(y_i)}$ as a continuous relaxation of discrete comparison operator $\mathbb{1}[y_i = z_j]$, $s_{i,j}$ establishes a natural continuous approximation to $r_{i,j}$. Similar to LCS, after iteratively filling up $s_{i,j}$ matrix, we define

$$\text{CaLcs}(\mathbf{y}, \mathbf{z}) = s_{m,k} \tag{4}$$

Although the proposed approximation is a natural way of relaxing/extending the hard binary comparison of discrete tokens, it is not clear how tight the approximation is, which is established in the next section.

2.2 On the Tightness of Approximation

In this section, we first discuss the tightness of the proposed approximation, and then provide a natural way of controlling it.

2.2.1 Bounding the Approximation Error

We now present a bound on the approximation error of the proposed CaLcs compared to the original LCS measure. Characterization of this bound will enable us to theoretically argue about the feasibilty of using the proposed surrogate reward function for our objective as well as controlling its tightness.

LCS measure is intrinsically monotonic by definition. We start by a lemma that establishes a similar monotonicity property for CaLcs.

Lemma 1. *[Monotonicity] The following two inequalities*

$$s_{i,j} \leq s_{i,j+1} \leq s_{i,j} + 1$$

$$s_{i,j} \leq s_{i+1,j} \leq s_{i,j} + 1$$

hold for all $0 \leq i < m$ *and* $0 \leq j < k$.

Proof. See Appendix A for the proof. □

Having established a certain monotonicity property for CaLcs, we will discuss its approximation error to the original LCS measure. Let

$$\delta_{i,j} = s_{i,j} - r_{i,j} \tag{5}$$

denote the *approximation error* of CALCS to LCS measure between generated prefix sequence $\mathbf{y}_{[:i]}$ and the ground-truth prefix $\mathbf{z}_{[:j]}$.

Lemma 2. *Let* $P_{i,j} = \{(0,0),(i_1,j_1),\dots,(i_{q-1},j_{q-1}),(i_q,j_q)\}$ *denote the path of dynamic programming algorithm for LCS ending at* $(i,j) = (i_q,j_q)$ *cell of* $m \times k$ *grid. Then,*

$$|\delta_{i,j}| < \left|\delta_{i_{q-1},j_{q-1}}\right| + (1 - max(p_j)) \tag{6}$$

where $max(p_j) = \max\{p_j^{(1)}, p_j^{(2)}, \dots, p_j^{(|V|)}\}$.

Proof. We will establish the proof by investigating two cases and combining them.

CASE 1: $z_j = y_i$.
In this case, we have

$$r_{i,j} = 1 + r_{i-1,j-1} \tag{7}$$

and

$$(i_{q-1}, j_{q-1}) = (i-1, j-1) \tag{8}$$

by 1. Using Eq. 7, we get

$$\begin{aligned}
\delta_{i,j} &= s_{i,j} - r_{i,j} \\
&= \left(1 - p_j^{(y_i)}\right) \max\left(s_{i-1,j}, s_{i,j-1}\right) \\
&\quad + \ p_j^{(y_i)} \left(s_{i-1,j-1} + 1\right) - \left(1 + r_{i-1,j-1}\right) \\
&= \left(s_{i-1,j-1} - r_{i-1,j-1}\right) \\
&\quad + \ \left(1 - p_j^{(y_i)}\right) \Big[\max(s_{i-1,j}, s_{i,j-1}) \\
&\quad - \ (1 + s_{i-1,j-1})\Big]
\end{aligned}$$

Using the definition of δ and triangle inequality, we get

$$\begin{aligned}
|\delta_{i,j}| &\leq |\delta_{i-1,j-1}| + \left(1 - p_j^{(y_i)}\right) \Big| (1 + s_{i-1,j-1}) \\
&\quad - \ \max\left(s_{i-1,j}, s_{i,j-1}\right) \Big| \\
&\leq |\delta_{i-1,j-1}| + \left(1 - p_j^{(y_i)}\right)
\end{aligned} \tag{9}$$

where inequality 9 follows from the monotonicity established by Lemma 1.

Moreover, $z_j = y_i$ implies $p_j^{(y_i)} = \max(p_j)$ because $\mathbf{z}$ is generated by greedy decoding. Plugging this in Eq. 9 and using Eq. 8, we can immediately conclude that

$$|\delta_{i,j}| < \left|\delta_{i_{q-1},j_{q-1}}\right| + (1 - \max(p_j)) \tag{10}$$

CASE 2: $z_j \neq y_i$.
By definition 1, we have

$$r_{i,j} = \max\left(r_{i-1,j}, r_{i,j-1}\right).$$

Using this identity, we obtain

$$\begin{aligned}
\delta_{i,j} &= s_{i,j} - r_{i,j} \\
&= \left(1 - p_j^{(y_i)}\right) \max\left(s_{i-1,j}, s_{i,j-1}\right) \\
&+ p_j^{(y_i)} \left(s_{i-1,j-1} + 1\right) - \max\left(r_{i-1,j}, r_{i,j-1}\right) \\
&= p_j^{(y_i)} \left[\left(1 + s_{i-1,j-1}\right) - \max\left(s_{i-1,j}, s_{i,j-1}\right)\right] \\
&+ \left[\max\left(s_{i-1,j}, s_{i,j-1}\right) - \max\left(r_{i-1,j}, r_{i,j-1}\right)\right]
\end{aligned}$$

Applying triangle inequality on the last equation above, we get

$$\begin{aligned}
|\delta_{i,j}| \leq \\
&p_j^{(y_i)} \left|\left(1 + s_{i-1,j-1}\right) - \max\left(s_{i-1,j}, s_{i,j-1}\right)\right| \\
&+ \left|\max\left(s_{i-1,j}, s_{i,j-1}\right) - \max\left(r_{i-1,j}, r_{i,j-1}\right)\right| \\
&\leq \\
&p_j^{(y_i)} \left|\left(1 + s_{i-1,j-1}\right) - \max\left(s_{i-1,j}, s_{i,j-1}\right)\right| \\
&+ \max\left(\left|s_{i-1,j} - r_{i-1,j}\right|, \left|s_{i,j-1} - r_{i,j-1}\right|\right)
\end{aligned} \tag{11}$$

$$\begin{aligned}
&= \\
&p_j^{(y_i)} \left|\left(1 + s_{i-1,j-1}\right) - \max\left(s_{i-1,j}, s_{i,j-1}\right)\right| \\
&+ \max\left(\left|\delta_{i-1,j}\right|, \left|\delta_{i,j-1}\right|\right) \\
&\leq p_j^{(y_i)} + \max\left(\left|\delta_{i-1,j}\right|, \left|\delta_{i,j-1}\right|\right)
\end{aligned} \tag{12}$$

where inequality 12 follows from again the monotonicity of $s[\cdot,\cdot]$, and inequality 11 follows from the following identity that holds true for all real numbers $a, b, c, d \geq 0$

$$|\max(a,b) - \max(c,d)| \leq \max(|a-c|, |b-d|)$$

Moreover, since $z_j \neq y_i$, we know that $p_j^{(y_i)} \neq \max(p_j)$, which implies

$$p_j^{(y_i)} \leq 1 - \max(p_i). \tag{13}$$

Combining 11 and 13 completes the proof for this case. Finally, two cases investigated above together establish the proof of Lemma 2. ☐

Lemma 2 leads to the following important corollary.

Corollary 1. *Let* $P_{i,j} = \{(0,0),(i_1,j_1),\dots,(i_q,j_q)\}$ *be the path of dynamic programming algorithm for LCS ending at* $(i,j) = (i_q,j_q)$ *cell of* $m \times k$ *grid. Then,*

$$|\delta_{i,j}| \leq \sum_{w=1}^{q} (1 - \max(p_{j_w})) \tag{14}$$

Proof. Applying Lemma 2 iteratively and using $\delta_{0,0} = 0$, we get

$$\begin{aligned} |\delta_{i,j}| &\leq \left|\delta_{i_{q-1},j_{q-1}}\right| + (1 - \max(p_{j_q})) \\ \left|\delta_{i_{q-1},j_{q-1}}\right| &\leq \left|\delta_{i_{q-2},j_{q-2}}\right| + (1 - \max(p_{j_{q-1}})) \\ \left|\delta_{i_{q-2},j_{q-2}}\right| &\leq \left|\delta_{i_{q-3},j_{q-3}}\right| + (1 - \max(p_{j_{q-2}})) \\ &\vdots \\ |\delta_{i_1,j_1}| &\leq |\delta_{0,0}| + (1 - \max(p_{j_1})) \\ |\delta_{0,0}| &\leq 0 \end{aligned}$$

Summing $(q+1)$-many inequalities above side by side and cancelling out the same terms appearing on both sides of the resulting inequality establishes the proof of corollary. □

2.2.2 Controlling the Tightness of Approximation

Corollary 1 hints for a natural way of controlling the tightness of approximation CALCS by exploiting the peakedness of model's softmax output probability distributions. More precisely, upper bound on the approximation error is represented as a sum of $1 - \max(p_j)$'s, hence the more peaked the model's output probability distributions on average, the smaller the approximation error we are guaranteed by the established bounds.

We exploit this property to control the tightness of approximation by making a modification to computation of the proposed CALCS measure. Formally, let $l_1, l_2, \ldots, l_k$ denote the unnormalized logits of the model output before applying softmax to obtain probabilities $p_1, p_2, \ldots, p_k$ at decoding time steps, respectively. Hence,

$$p_j^{(i)} = \frac{\exp(l_j^{(i)})}{\sum_i \exp(l_j^{(i)})} \tag{15}$$

Recall that CALCS is computed using p_j's. Using *peaked softmax*, we can obtain more peaked probability distributions without causing any change in the actual generated sequence $\mathbf{z}$ via greedy decoding. This is simply because the order of probabilities for corresponding vocabulary words will not change, only the probability disribution p_j will get more peaked. So, we define *peaked softmax* operator with hyperparameter α as

$$p_j^{(i)}(\alpha) = \frac{\exp(l_j^{(i)}/\alpha)}{\sum_i \exp(l_j^{(i)}/\alpha)} \tag{16}$$

By Corollary 1, $|\delta_{i,j}| \to 0$ as $\alpha \to 0$ for CALCS measure computed with $p_j(\alpha)$. One can further attempt to use Corollary 1 as a guide to pinpoint a range of α values to force the approximation error within certain desired limits. We will use α as a hyperparameter in this work.

Corollary 1 is also useful for alternative ways of controlling the tightness of approximation such as incurring penalty for high-entropy output probability distributions or simply penalizing the maximum output probability values less than a desired threshold (that explicitly controls the tightness of the approximation). We leave such options of controlling the approximation error for future work.

With the guidance of Corollary 1 and *peaked softmax* in Eq. 16, we conclude that CALCS establishes a promising approximation for LCS measure. In the next section, we introduce a new objective function using CALCS as a continuously differentiable reward to be directly maximized.

2.3 Sequence Level Optimization via CALCS

In this section, we describe how to leverage CALCS to define a loss function for sequence level optimization. For notational consistency, we will use $f(\mathbf{x}, \mathbf{\Theta})$ to denote an encoder-decoder architecture that takes an input sequence $\mathbf{x}$ and outputs a sequence of tokens $\mathbf{z} = (z_1, z_2, \ldots, z_m)$ via greedy decoding from corresponding probability distributions $p_1, p_2, \ldots, p_m$ at each step.

For a pair of input sequence $\mathbf{x}$ and its corresponding ground-truth output sequence $\mathbf{y}$, we define

$$J_{\text{CALCS}}(\mathbf{x}, \mathbf{y}; \mathbf{\Theta}) = -\log\left(\frac{\text{CALCS}(\mathbf{y}, f(\mathbf{x}, \mathbf{\Theta}))}{|\mathbf{y}|}\right) \tag{17}$$

as the loss function for a sample $(\mathbf{x}, \mathbf{y})$ based on the CALCS, where $|\mathbf{y}|$ denote the length of sequence $\mathbf{y}$. It is important to note here that while computing probability distribution p_t at decoding step t, we feed model's own prediction z_{t-1} at the previous time step to fight *exposure bias*.

It is important to observe here that $J_{\text{CALCS}}(\mathbf{x}, \mathbf{y}; \mathbf{\Theta})$ is differentiable in $p_1, p_2, \ldots, p_k$ by definition and each p_i is differentiable in model parameters $\mathbf{\Theta}$. Hence, $J_{\text{CALCS}}(\mathbf{x}, \mathbf{y}; \mathbf{\Theta})$ is differentiable in model parameters $\mathbf{\Theta}$, which allows us to directly optimize the network parameters with respect to LCS metric. The bound we established on the approximation error and our proposed strategy to control it theoretically ensures the feasibility of using the introduced loss function J_{CALCS} to optimize for LCS metric.

3 Model

In this section, we first briefly revisit the pointer-generator (See et al., 2017) and transformer (Vaswani et al., 2017) networks that are used as the underlying baselines in our experiments. Subsequently, we describe how the proposed objective function and its variants are used to train new summarization and machine translation models.

3.1 Baseline Models

Pointer-Generator Network. We use pointer-generator network (See et al., 2017) as our baseline sequence-to-sequence model for text summarization. It is essentially a hybrid between sequence-to-sequence model with attention (Bahdanau et al., 2015) and a pointer network (Vinyals et al., 2015) that supports two decoding modes, copying and generating, via a soft switch mechanism. This enables the model to copy a word from the input sequence based on the attention distribution. On each decoding time step t, the decoder LSTM is fed the word embedding of the previous word, and computes a decoder state s_t, an attention distribution a^t over the words of input article, and a probability $P_{\text{vocab}}(w)$ of generating word w for summary from output vocabulary V, which is then softly combined with the *copy* mode's probability distribution $P_{\text{copy}}(w)$ via soft switch probability $p_{\text{gen}} \in [0, 1]$ by

$$p_t^{(w)} = p_{\text{gen}} P_{\text{vocab}}(w) + (1 - p_{\text{gen}}) P_{\text{copy}}(w)$$

and

$$P_{\text{copy}}(w) = \sum_{\{i : w_i = w\}} a_i^t$$

where a_i^t indicates the attention probability on i-th word of the input article. The whole network is then trained end-to-end with the negative log-likelihood loss function of

$$J_{\text{PG}}(\mathbf{x}, \mathbf{y}; \mathbf{\Theta}) = -\frac{1}{|y|} \sum_{t=1}^{|y|} \log(p_t^{(y_t)})$$

for a sample article-summary pair $(\mathbf{x}, \mathbf{y})$ where $\mathbf{\Theta}$ denote the learnable model parameters. It is important to note here that we do not use the coverage mechanism introduced by the original work (See et al., 2017) to prevent the potential repetition problem in the summaries generated by the model.

Transformer Network. For machine translation, we use the transformer network (Vaswani et al., 2017), which is a recently published model that achieved state-of-the-art results on *WMT 2014 English-to-German* MT task with less computational time owing to its highly parallelizable architecture. The core idea behind this model is to use stacked self-attention mechanisms along with point-wise, fully connected layers for both encoder and decoder to represent its input and output. For the sake of brevity, we refer the reader to (Vaswani et al., 2017) for further details regarding the architecture. Similar to previously defined loss functions, let $J_{\text{TF}}(\mathbf{x}, \mathbf{y}; \mathbf{\Theta})$ denote the per-example loss function of transformer networks for an input-output translation pair $(\mathbf{x}, \mathbf{y})$ where $\mathbf{\Theta}$ is again indicating the learnable model parameters.

3.2 Model Variants and Training

Let $\{(\mathbf{x}^{(l)}, \mathbf{y}^{(l)})\}_{l=1}^{N}$ denote the set of training examples, where $\mathbf{x}^{(l)}$'s are input sequences, and $\mathbf{y}^{(l)}$'s are their corresponding ground-truth output sequences. Before optimizing for the introduced objective J_{CALCS}, we first train the corresponding baseline network by minimizing

$$J_{\{\text{PG,TF}\}}(\mathbf{\Theta}) = \frac{1}{N} \sum_{l=1}^{N} J_{\{\text{PG,TF}\}}(\mathbf{x}, \mathbf{y}; \mathbf{\Theta}).$$

Unlike J_{CALCS}, loss functions $J_{\{\text{PG,TF}\}}$ for baseline models are computed by teacher forcing, feeding the previous ground-truth word at each decoding step. We will denote the baseline models by POINTGEN for pointer-generator network and TRANSFORMER for transformer network.

To optimize for the proposed objective J_{CALCS}, we initialize the model parameters $\mathbf{\Theta}$ from the pre-trained baseline network and continue training the model by minimizing the joint loss

$$J(\mathbf{\Theta}) = \lambda J_{\text{CALCS}}(\mathbf{\Theta}) + (1 - \lambda) J_{\{\text{PG,TF}\}}(\mathbf{\Theta}) \tag{18}$$

$$J_{\text{CALCS}}(\mathbf{\Theta}) = \frac{1}{N} \sum_{l=1}^{N} J_{\text{CALCS}}(\mathbf{x}, \mathbf{y}; \mathbf{\Theta}) \tag{19}$$

where λ is a hyperparameter controlling the balance between the two losses. During the training with the joint loss, we compute $J_{\text{CALCS}}(\mathbf{x}, \mathbf{y}; \mathbf{\Theta})$, defined in Eq. 17, by performing $|y|$-many decoding steps as a simple strategy to prevent the model from gaming the training objec-

tive by generating longer and longer hypotheses instead of incurring an additional length penalty. We will refer to the resulting model trained with the loss function in Eq. 18 as $\{$POINTGEN, TRANSFORMER$\}$+CALCS depending on the baseline model.

4 Experiments

We numerically evaluate the proposed method on two sequence generation benchmarks: abstractive document-summarization and machine translation. We compare the results of the proposed method against the recently proposed strong baseline models (See et al., 2017) for summarization and and (Vaswani et al., 2017) for machine translation tasks.

4.1 Abstractive Summarization

We use a modified version of the CNN/Daily Mail dataset (Hermann et al., 2015) that is first used for summarization by (Nallapati et al., 2016). However, we follow the processing script provided by (See et al., 2017) to obtain *non-anonymized* version of the data that contains 287,226 training pairs, 13,368 validation pairs, and 11,490 test pairs of news articles (781 tokens on average) and their corresponding ground-truth summaries (56 tokens on average). We refer the reader to (See et al., 2017) for further details of the difference of their version from (Nallapati et al., 2016).

For training our baseline model, we use single layer LSTM encoder (bi-directional) and decoder with hidden dimensions of 512 and 1024, respectively. We use a vocabulary of 50k words for both source and target. Following the original paper, we also do not pre-train word embeddings, which are learned with the rest of model parameters during training. We use the Adam (Kingma and Ba, 2015) optimizer with a learning rate of 0.00001 for training. We pre-train the baseline model for 20k steps by applying greedy scheduled sampling (Bengio et al., 2015) with fixed ground-truth feeding probability of 75%. Once the baseline model training is complete, we start optimizing for CALCS objective as described in the previous section. Also, we set $\lambda = 1.0$ and $\alpha = 1.0$, which are tuned on the development set.

In Table 1, we report our main results on the summarization task. POINTGEN+SS refers to the baseline model trained with scheduled sampling. POINTGEN+SS+CALCS corresponds our model trained with CALCS starting from POINTGEN+SS model. Experimental results demonstrate that training with our proposed objective provides an improvement of 2.2 points in ROUGE-L score. This also provides empirical evidence to justify that our approximate CALCS effectively captures what the original LCS metric is supposed to measure, recalling ROUGE-L is a normalized LCS. The reason why ROUGE-L scores of our models are lower than previously reported is that we evaluate ROUGE-L score by taking the entire summary as a single sequence instead of splitting it into sentences, which is also the way we compute CALCS objective during the model training process. The main motivation behind this approach is to encourage the model to preserve the sentence order within a summary, and evaluate its performance in the same way. We consider the capability of preserving the order across produced sentences as an important attribute a multi-sentence summarization model should have in terms of readability and fluency of its generated summaries as a whole. When POINTGEN*+SS and POINTGEN*+SS+CALCS are evaluated by splitting the generated summaries into sentences, their corresponding ROUGE-L scores become 35.38 and 35.12, respectively. We also observe a nice side-improvement of 1.0 point in ROUGE-1 score over the baseline, which achieves a comparable performance with the long-overdue LEAD-3 baseline score. It might also be comparable to the recently reported state-of-the-art ROUGE-1 result on CNN/DailyMail dataset by Paulus et al. (2018) as they used a different dataset processing pipeline, which makes it difficult to directly compare with ours.

Model	BLEU
GNMT (Wu et al., 2016)	24.61
GNMT+RL (Wu et al., 2016)	24.60
TRANSFORMER (Vaswani et al., 2017)	27.3
WEIGHTED TRANSFORMER (Ahmed et al., 2018)	28.4
TRANSFORMER*	27.6
TRANSFORMER*+CALCS	**27.8**

Table 2: Machine translation results on *WMT 2014 English-to-German* task. TRANSFORMER* corresponds to our training of the original model in (Vaswani et al., 2017).

4.2 Machine Translation

We also evaluate our sequence-level training approach on the *WMT 2014 English-to-German* machine translation task, which contains 4.5M pairs of sentences.

To train our baseline transformer model, we closely follow the small model in the original transformer paper (Vaswani et al., 2017). We use a vocabulary of size 32k. Our encoder and decoder consist of $N = 6$ identical layers each. Following the notation in the original paper, we set the other parameters as $d_{\text{model}} = 512$, $d_{\text{ff}} = 2048$, $h = 8$, $P_{\text{drop}} = 0.1$. We set $\lambda = 0.3$ and $\alpha = 1.0$, which are tuned on the development set.

In Table 2, we show our empirical results on machine translation task. Our first observation is that our trained baseline transformer network achieves a better performance than the one reported in the original paper (Vaswani et al., 2017) by 0.3 BLEU score, which might be solely due to hyperparameter tuning. More importantly, we observe that training with our proposed CALCS objective leads to noticeable 0.2 BLEU point improvements over the baseline, which further reinforces our confidence in effectiveness of our proposed sequence-level training approach and its applicability to other sequence prediction tasks. It is also interesting to note that optimizing for LCS metric via its continuous approximation leads to improvements in evaluation with another discrete metric BLEU. On the other had, optimizing for the exact discrete metric BLEU via reinforcement learning strategy may not improve the evaluation performance in BLEU as reported by (Wu et al., 2016). As a final remark, we would like to note that our proposed approach is orthogonal to advancements in more expressive and powerful architecture designs. Hence it has the potential to provide further improvements over the recently proposed models such as WEIGHTED TRANSFORMER (Ahmed et al., 2018).

5 Related Work

Text Summarization. Before the successful application of neural generative models, most of the existing works on text summarization (Dorr et al., 2003; Durrett et al., 2016) have focused on extractive methods. While some of the early approaches have used a rich set of heuristic rules or sparse features to select textual units to include in the summary, more recent works (Cheng and Lapata, 2016; Nallapati et al., 2017) leverage neural models to select words and sentences from the original text. With the emergence of sequence-to-sequence models (Sutskever et al., 2014) and large-scale datasets like *CNN/Daily Mail* (Hermann et al., 2015; Nallapati et al., 2016) and *NYT* (Paulus et al., 2018), abstractive summarization of longer text have become a more feasible and popular task. Several recent approaches have been proposed to tackle abstractive summarization problem, where Nallapati et al. (2016) exploits hierarchical encoders, See et al. (2017) proposes *pointer-generator* network and coverage mechanism to overcome OOV and repetition problems, Tan et al. (2017) introduces a graph-based attention mechanism and hierarchical beam search strategy, and (Paulus et al., 2018) proposes to optimize for ROUGE metric via reinforcement learning. Although impressive progress has been achieved for sentence-level summarization, attempts on abstractive document summarization task are still in early stages where the simple LEAD-3 baseline performance is only very recently matched (Paulus et al., 2018).

Neural Machine Translation. With the recent success of encoder-decoder architectures (Sutskever et al., 2014; Bahdanau et al., 2015), neural machine translation systems has gained a a lot of attention both from academia (Cho et al., 2014; Luong et al., 2015; Luong and Manning, 2016) and industry (Wu et al., 2016; Vaswani et al., 2017; Ahmed et al., 2018) over statistical machine translation, which has been the dominating translation paradigm for years. Most of these works has focused more on enhancing the architecture design aspect to tackle with various challenges such as different attention mechanisms (Bahdanau et al., 2015; Luong et al., 2015), a character-level decoder (Chung et al., 2016), a translation coverage mechanism (Tu et al., 2016), and so on. However, only very recently, a few works (Wu et al., 2016; Ranzato et al., 2016;

Norouzi et al., 2016; Shen et al., 2016; Bahdanau et al., 2017; Zhukov and Kretov, 2017; Casas et al., 2018) have investigated sequence-level optimization by training to maximize BLEU score.

Neural Sequence Generation with RL. Most neural sequence generation models are trained with the objective of maximizing the probability of the next correct word. However, this results in a major discrepancy between training and test settings of these models because they are trained with cross-entropy loss at word-level, but evaluated based on sequence-level discrete metrics such as ROUGE (Lin and Och, 2004) or BLEU (Papineni et al., 2002). On the other hand, directly optimizing for such evaluation metrics is hard due to non-differentiable nature of the exact objective (Rosti et al., 2011). Recent works (Ranzato et al., 2016; Wu et al., 2016; Bahdanau et al., 2017; Paulus et al., 2018) address the difficulty of differentiating with respect to rewards based on such discrete metrics using variants of reinforcement learning. These methods essentially propose to mitigate the problem by optimizing the reward weighted log-likelihood of the hypothesis sequences generated by the model distribution. In this paper, we propose an alternative solution to tackle this problem by introducing a differentiable approximation to exact LCS metric that can be directly optimized by standard gradient-based methods without RL, while still addressing the *exposure bias* problem.

6 Conclusion and Future Work

In this work we explored an alternative approach for training text generation models with sequence-level optimization to combat *wrong objective* and *exposure bias* problems. We introduced a new objective function based on a continuous approximation of LCS metric that measures sequence-level structure similarity between sentences. We applied our proposed approach to *CNN/Daily Mail* dataset for long document summarization and *WMT 2014 English-to-German* machine translation task. By extending the objectives of strong neural baseline models with our proposed objective, we empirically demonstrated its effectiveness on these two tasks. Our proposed approach suggests a promising alternative to policy-gradient methods to side step the difficulty of differentiating w.r.t reward function while directly optimizing for sequence-level discrete metrics.

A Proof of Lemma 1

[Monotonicity] The following two inequalities

$$s_{i,j} \leq s_{i,j+1} \leq s_{i,j} + 1$$
$$s_{i,j} \leq s_{i+1,j} \leq s_{i,j} + 1$$

hold for all $0 \leq i < m$ and $0 \leq j < k$.

Proof. We will prove this lemma by induction on $i + j$.

Base Case: $i + j = 0$. In this case, we have $i = j = 0$. Since $s_{0,0} = s_{1,0} = s_{0,1} = 0$ by definition, both $s_{0,0} \leq s_{0,1} \leq s_{0,0} + 1$ and $s_{0,0} \leq s_{1,0} \leq s_{0,0} + 1$ hold.

Inductive Step: Assume for $i + j = l$ that

$$s_{i,j} \leq s_{i,j+1} \leq s_{i,j} + 1 \tag{20}$$
$$s_{i,j} \leq s_{i+1,j} \leq s_{i,j} + 1 \tag{21}$$

hold.

We will now prove that the inequalities of inductive hypothesis hold for $i + j = l + 1$.

We will start by showing $s_{i,j+1} \geq s_{i,j}$. By definition, we have

$$s_{i,j+1} = p^{(y_i)}_{j+1}(s_{i-1,j} + 1) + \tag{22}$$
$$(1 - p^{(y_i)}_{j+1}) \max(s_{i-1,j+1}, s_{i,j}) \tag{23}$$
$$\geq p^{(y_i)}_{j+1}(s_{i-1,j} + 1) + (1 - p^{(y_i)}_{j+1}) s_{i,j} \tag{24}$$
$$\geq p^{(y_i)}_{j+1} s_{i,j} + (1 - p_{j+1,y_i}) s_{i,j} \tag{25}$$
$$\geq s_{i,j} \tag{26}$$

where inequality 24 follows from the definition of max operator, and inequality 25 follows from induction assumption 20 because $(i - 1) + j = l$. Hence, final inequality 26 establishes the proof of $s_{i,j+1} \geq s_{i,j}$.

Now, we will show that $s_{i,j+1} \leq s_{i,j} + 1$ holds. Again by definition, we have

$$s_{i,j+1} = p^{(y_i)}_{j+1}(s_{i-1,j} + 1) + \tag{27}$$
$$(1 - p^{(y_i)}_{j+1}) \max(s_{i-1,j+1}, s_{i,j}) \tag{28}$$
$$\leq p^{(y_i)}_{j+1}(s_{i-1,j} + 1) + \tag{29}$$
$$(1 - p^{(y_i)}_{j+1})(s_{i-1,j} + 1) \tag{30}$$
$$\leq s_{i-1,j} + 1 \tag{31}$$
$$\leq s_{i,j} + 1 \tag{32}$$

where inequalities 30 and 32 follow from inequalities 20 and 21 of inductive step as $(i - 1) + j = l$.

Note that 26 and 32 completes the proof of $s_{i,j} \leq s_{i,j+1} \leq s_{i,j} + 1$ for $i + j = l + 1$. Following similar arguments, one can easily establish the correctness of $s_{i,j} \leq s_{i+1,j} \leq s_{i,j} + 1$ for $i + j = l + 1$, which completes the proof of Lemma by induction. ☐

B Definition of Rouge-L

Definition 2. *ROUGE-L is a discrete similarity metric that takes into account sentence level structure similarity by identifying longest co-occurring in-sequence n-grams automatically via longest common subsequence measure. Formally, given two sequences* $\mathbf{y}$ *and* $\mathbf{z}$ *of tokens, we define ROUGE-L*$(\mathbf{y}, \mathbf{z})$ *as the harmonic mean of precision* $\frac{LCS(\mathbf{y},\mathbf{z})}{k}$ *and recall* $\frac{LCS(\mathbf{y},\mathbf{z})}{m}$ *based on LCS measure, where* $k = |z|$ *and* $m = |y|$.

Pathologies of Neural Models Make Interpretations Difficult

Abstract

One way to interpret neural model predictions is to highlight the most important input features—for example, a heatmap visualization over the words in an input sentence. In existing interpretation methods for NLP, a word's importance is determined by either input perturbation—measuring the decrease in model confidence when that word is removed—or by the gradient with respect to that word. To understand the limitations of these methods, we use input reduction, which iteratively removes the least important word from the input. This exposes pathological behaviors of neural models: the remaining words appear nonsensical to humans and are not the ones determined as important by interpretation methods. As we confirm with human experiments, the reduced examples lack information to support the prediction of any label, but models still make the same predictions with high confidence. To explain these counterintuitive results, we draw connections to adversarial examples and confidence calibration: pathological behaviors reveal difficulties in interpreting neural models trained with maximum likelihood. To mitigate their deficiencies, we fine-tune the models by encouraging high entropy outputs on reduced examples. Fine-tuned models become more interpretable under input reduction without accuracy loss on regular examples.

1 Introduction

Many interpretation methods for neural networks explain the model's prediction as a counterfactual: how does the prediction change when the input is modified? Adversarial examples (Szegedy et al., 2014; Goodfellow et al., 2015) highlight the instability of neural network predictions by showing how small perturbations to the input dramatically change the output.

SQuAD	
Context	In 1899, John Jacob Astor IV invested \$100,000 for Tesla to further develop and produce a new lighting system. Instead, Tesla used the money to fund his Colorado Springs experiments.
Original	What did Tesla spend Astor's money on ?
Reduced	did
Confidence	0.78 → 0.91

Figure 1: SQuAD example from the validation set. Given the original *Context*, the model makes the same correct prediction ("Colorado Springs experiments") on the *Reduced* question as the *Original*, with even higher confidence. For humans, the reduced question, "did", is nonsensical.

A common, non-adversarial form of model interpretation is feature attribution: features that are crucial for predictions are highlighted in a heatmap. One can measure a feature's importance by input perturbation. Given an input for text classification, a word's importance can be measured by the difference in model confidence before and after that word is removed from the input—the word is important if confidence decreases significantly. This is the leave-one-out method (Li et al., 2016b). Gradients can also measure feature importance; for example, a feature is influential to the prediction if its gradient is a large positive value. Both perturbation and gradient-based methods can generate heatmaps, implying that the model's prediction is highly influenced by the highlighted, important words.

Instead, we study how the model's prediction is influenced by the *unimportant* words. We use **input reduction**, a process that iteratively removes the unimportant words from the input while maintaining the model's prediction. Intuitively, the words remaining after input reduction should be important for prediction. Moreover, the words

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3719–3728
Brussels, Belgium, October 31 - November 4, 2018.

should match the leave-one-out method's selections, which closely align with human perception (Li et al., 2016b; Murdoch et al., 2018). However, rather than providing explanations of the original prediction, our reduced examples more closely resemble adversarial examples. In Figure 1, the reduced input is meaningless to a human but retains the same model prediction with high confidence. Gradient-based input reduction exposes pathological model behaviors that contradict what one expects based on existing interpretation methods.

In Section 2, we construct more of these counterintuitive examples by augmenting input reduction with beam search and experiment with three tasks: SQUAD (Rajpurkar et al., 2016) for reading comprehension, SNLI (Bowman et al., 2015) for textual entailment, and VQA (Antol et al., 2015) for visual question answering. Input reduction with beam search consistently reduces the input sentence to very short lengths—often only one or two words—without lowering model confidence on its original prediction. The reduced examples appear nonsensical to humans, which we verify with crowdsourced experiments. In Section 3, we draw connections to adversarial examples and confidence calibration; we explain why the observed pathologies are a consequence of the overconfidence of neural models. This elucidates limitations of interpretation methods that rely on model confidence. In Section 4, we encourage high model uncertainty on reduced examples with entropy regularization. The pathological model behavior under input reduction is mitigated, leading to more reasonable reduced examples.

2 Input Reduction

To explain model predictions using a set of important words, we must first define importance. After defining input perturbation and gradient-based approximation, we describe input reduction with these importance metrics. Input reduction drastically shortens inputs without causing the model to change its prediction or significantly decrease its confidence. Crowdsourced experiments confirm that reduced examples appear nonsensical to humans: input reduction uncovers pathological model behaviors.

2.1 Importance from Input Gradient

Ribeiro et al. (2016) and Li et al. (2016b) define importance by seeing how confidence changes when a feature is removed; a natural approximation is to use the gradient (Baehrens et al., 2010; Simonyan et al., 2014). We formally define these importance metrics in natural language contexts and introduce the efficient gradient-based approximation. For each word in an input sentence, we measure its importance by the change in the confidence of the original prediction when we remove that word from the sentence. We switch the sign so that when the confidence decreases, the importance value is positive.

Formally, let $\mathbf{x} = \langle x_1, x_2, \dots x_n \rangle$ denote the input sentence, $f(y \mid \mathbf{x})$ the predicted probability of label y, and $y = \operatorname{argmax}_{y'} f(y' \mid \mathbf{x})$ the original predicted label. The importance is then

$$g(x_i \mid \mathbf{x}) = f(y \mid \mathbf{x}) - f(y \mid \mathbf{x}_{-i}). \qquad (1)$$

To calculate the importance of each word in a sentence with n words, we need n forward passes of the model, each time with one of the words left out. This is highly inefficient, especially for longer sentences. Instead, we approximate the importance value with the input gradient. For each word in the sentence, we calculate the dot product of its word embedding and the gradient of the output with respect to the embedding. The importance of n words can thus be computed with a single forward-backward pass. This gradient approximation has been used for various interpretation methods for natural language classification models (Li et al., 2016a; Arras et al., 2016); see Ebrahimi et al. (2017) for further details on the derivation. We use this approximation in all our experiments as it selects the same words for removal as an exhaustive search (no approximation).

2.2 Removing Unimportant Words

Instead of looking at the words with high importance values—what interpretation methods commonly do—we take a complementary approach and study how the model behaves when the supposedly unimportant words are removed. Intuitively, the important words should remain after the unimportant ones are removed.

Our input reduction process iteratively removes the unimportant words. At each step, we remove the word with the lowest importance value until the model changes its prediction. We experiment with three popular datasets: SQuAD (Rajpurkar et al., 2016) for reading comprehension, SNLI (Bowman et al., 2015) for textual entailment, and VQA (Antol et al., 2015) for visual question answering. We describe each of these tasks and the model we use below, providing full details in the Supplement.

In SQuAD, each example is a context paragraph and a question. The task is to predict a span in the paragraph as the answer. We reduce only the question while keeping the context paragraph unchanged. The model we use is the DrQA Document Reader (Chen et al., 2017).

In SNLI, each example consists of two sentences: a premise and a hypothesis. The task is to predict one of three relationships: entailment, neutral, or contradiction. We reduce only the hypothesis while keeping the premise unchanged. The model we use is Bilateral Multi-Perspective Matching (BiMPM) (Wang et al., 2017).

In VQA, each example consists of an image and a natural language question. We reduce only the question while keeping the image unchanged. The model we use is Show, Ask, Attend, and Answer (Kazemi and Elqursh, 2017).

During the iterative reduction process, we ensure that the prediction does not change (exact same span for SQuAD); consequently, the model accuracy on the reduced examples is identical to the original. The predicted label is used for input reduction and the ground-truth is never revealed. We use the validation set for all three tasks.

Most reduced inputs are nonsensical to humans (Figure 2) as they lack information for *any* reasonable human prediction. However, models make confident predictions, at times even more confident than the original.

To find the shortest possible reduced inputs (potentially the most meaningless), we relax the requirement of removing only the least important word and augment input reduction with beam search. We limit the removal to the k least important words, where k is the beam size, and decrease the beam size as the remaining input is shortened.[1] We empirically select beam size five as it produces comparable results to larger beam sizes with reasonable computation cost. The requirement of maintaining model prediction is unchanged.

SNLI

Premise	Well dressed man and woman dancing in the street
Original	Two man is dancing on the street
Reduced	dancing
Answer	Contradiction
Confidence	0.977 → 0.706

VQA

Original	What color is the flower ?
Reduced	flower ?
Answer	yellow
Confidence	0.827 → 0.819

Figure 2: Examples of original and reduced inputs where the models predict the same *Answer*. *Reduced* shows the input after reduction. We remove words from the hypothesis for SNLI, questions for SQuAD and VQA. Given the nonsensical reduced inputs, humans would not be able to provide the answer with high confidence, yet, the neural models do.

With beam search, input reduction finds extremely short reduced examples with little to no decrease in the model's confidence on its original predictions. Figure 3 compares the length of input sentences before and after the reduction. For all three tasks, we can often reduce the sentence to only one word. Figure 4 compares the model's confidence on original and reduced inputs. On SQuAD and SNLI the confidence decreases slightly, and on VQA the confidence even increases.

2.3 Humans Confused by Reduced Inputs

On the reduced examples, the models retain their original predictions despite short input lengths. The following experiments examine whether these predictions are justified or pathological, based on how humans react to the reduced inputs.

For each task, we sample 200 examples that are correctly classified by the model and generate their reduced examples. In the first setting, we compare the human accuracy on original and reduced examples. We recruit two groups of crowd workers and task them with textual entailment, reading comprehension, or visual question answering. We show one group the original inputs and the other the reduced. Humans are no longer able to give

---

[1] We set beam size to $\max(1, \min(k, L-3))$ where k is maximum beam size and L is the current length of the input sentence.

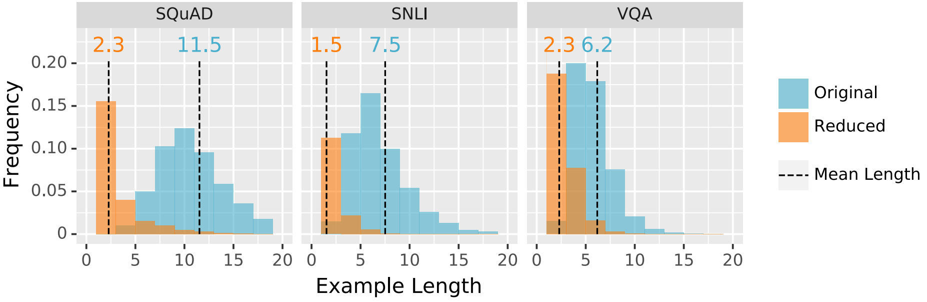

Figure 3: Distribution of input sentence length before and after reduction. For all three tasks, the input is often reduced to one or two words without changing the model's prediction.

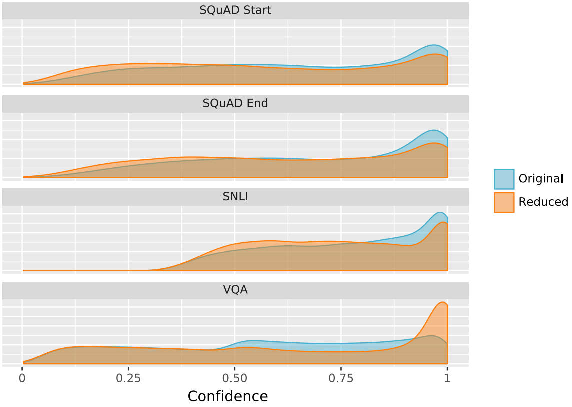

Figure 4: Density distribution of model confidence on reduced inputs is similar to the original confidence. In SQUAD, we predict the beginning and the end of the answer span, so we show the confidence for both.

the correct answer, showing a significant accuracy loss on all three tasks (compare *Original* and *Reduced* in Table 1).

The second setting examines how random the reduced examples appear to humans. For each of the original examples, we generate a version where words are randomly removed until the length matches the one generated by input reduction. We present the original example along with the two reduced examples and ask crowd workers their preference between the two reduced ones. The workers' choice is almost fifty-fifty (the *vs. Random* in Table 1): the reduced examples appear almost random to humans.

These results leave us with two puzzles: why are the models highly confident on the nonsensical reduced examples? And why, when the leave-one-out method selects important words that appear reasonable to humans, the input reduction process selects ones that are nonsensical?

Dataset	Original	Reduced	vs. Random
SQUAD	80.58	31.72	53.70
SNLI-E	76.40	27.66	42.31
SNLI-N	55.40	52.66	50.64
SNLI-C	76.20	60.60	49.87
VQA	76.11	40.60	61.60

Table 1: Human accuracy on *Reduced* examples drops significantly compared to the *Original* examples, however, model predictions are identical. The reduced examples also appear random to humans—they do not prefer them over random inputs (*vs. Random*). For SQUAD, accuracy is reported using F1 scores, other numbers are percentages. For SNLI, we report results on the three classes separately: entailment (-*E*), neutral (-*N*), and contradiction (-*C*).

3 Making Sense of Reduced Inputs

Having established the incongruity of our definition of importance *vis-à-vis* human judgements, we now investigate possible explanations for these results. We explain why model confidence can empower methods such as leave-one-out to generate reasonable interpretations but also lead to pathologies under input reduction. We attribute these results to two issues of neural models.

3.1 Model Overconfidence

Neural models are overconfident in their predictions (Guo et al., 2017). One explanation for overconfidence is overfitting: the model overfits the negative log-likelihood loss during training by learning to output low-entropy distributions over classes. Neural models are also overconfident on examples outside the training data distribution. As Goodfellow et al. (2015) observe for image classification, samples from pure noise can sometimes trigger highly confident predictions. These so-called *rubbish examples* are degenerate inputs that a human would trivially classify as not belonging to any class but for which the model predicts with high confidence. Goodfellow et al. (2015) argue that the rubbish examples exist for the same reason that adversarial examples do: the surprising linear nature of neural models. In short, the confidence of a neural model is not a robust estimate of its prediction uncertainty.

Our reduced inputs satisfy the definition of rubbish examples: humans have a hard time making predictions based on the reduced inputs (Table 1), but models make predictions with high confidence (Figure 4). Starting from a valid example, input reduction transforms it into a rubbish example.

The nonsensical, almost random results are best explained by looking at a complete reduction path (Figure 5). In this example, the transition from valid to rubbish happens immediately after the first step: following the removal of "Broncos", humans can no longer determine which team the question is asking about, but model confidence remains high. Not being able to lower its confidence on rubbish examples—as it is not trained to do so—the model neglects "Broncos" and eventually the process generates nonsensical results.

In this example, the leave-one-out method will not highlight "Broncos". However, this is not a failure of the interpretation method but of the model itself. The model assigns a low importance to "Broncos" in the first step, causing it to be removed—leave-one-out would be able to expose this particular issue by not highlighting "Broncos". However, in cases where a similar issue only appear after a few unimportant words are removed, the leave-one-out method would fail to expose the unreasonable model behavior.

Input reduction can expose deeper issues of model overconfidence and stress test a model's uncertainty estimation and interpretability.

3.2 Second-order Sensitivity

So far, we have seen that the output of a neural model is sensitive to small changes in its input. We call this *first-order* sensitivity, because interpretation based on input gradient is a first-order Taylor expansion of the model near the input (Simonyan et al., 2014). However, the *interpretation* also shifts drastically with small input changes (Figure 6). We call this *second-order* sensitivity.

The shifting heatmap suggests a mismatch between the model's first- and second-order sensitivities. The heatmap shifts when, with respect to the removed word, the model has low first-order sensitivity but high second-order sensitivity.

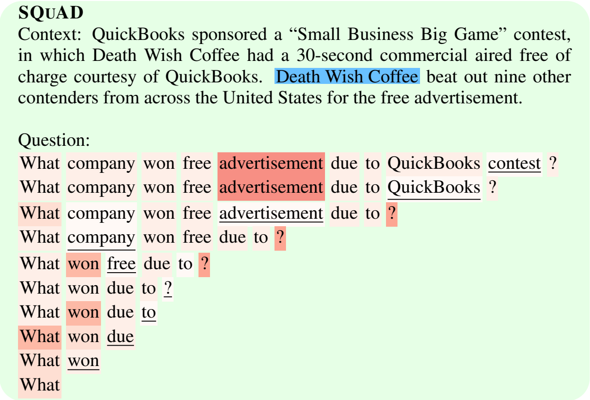
SQuAD
Context: The Panthers used the San Jose State practice facility and stayed at the San Jose Marriott. The Broncos practiced at Stanford University and stayed at the Santa Clara Marriott.

Question:
(0.90, 0.89) Where did the Broncos practice for the Super Bowl ?
(0.92, 0.88) Where did the practice for the Super Bowl ?
(0.91, 0.88) Where did practice for the Super Bowl ?
(0.92, 0.89) Where did practice the Super Bowl ?
(0.94, 0.90) Where did practice the Super ?
(0.93, 0.90) Where did practice Super ?
(0.40, 0.50) did practice Super ?

Figure 5: A reduction path for a SQuAD validation example. The model prediction is always correct and its confidence stays high (shown on the left in parentheses) throughout the reduction. Each line shows the input at that step with an underline indicating the word to remove next. The question becomes unanswerable immediately after "Broncos" is removed in the first step. However, in the context of the original question, "Broncos" is the least important word according to the input gradient.

Similar issues complicate comparable interpretation methods for image classification models. For example, Ghorbani et al. (2017) modify image inputs so the highlighted features in the interpretation change while maintaining the same prediction. To achieve this, they iteratively modify the input to maximize changes in the distribution of feature importance. In contrast, the shifting heatmap we observe occurs by only removing the least impactful features without a targeted optimization. They also speculate that the steepest gradient direction for the first- and second-order sensitivity values are generally orthogonal. Loosely speaking, the shifting heatmap suggests that the direction of the smallest gradient value can sometimes align with very steep changes in second-order sensitivity.

When explaining individual model predictions, the heatmap suggests that the prediction is made based on a weighted combination of words, as in a linear model, which is not true unless the model is indeed taking a weighted sum such as in a DAN (Iyyer et al., 2015). When the model composes representations by a non-linear combination of words, a linear interpretation oblivious to second-order sensitivity can be misleading.



SQuAD

Context: QuickBooks sponsored a "Small Business Big Game" contest, in which Death Wish Coffee had a 30-second commercial aired free of charge courtesy of QuickBooks. Death Wish Coffee beat out nine other contenders from across the United States for the free advertisement.

Question:
What company won free advertisement due to QuickBooks contest ?
What company won free advertisement due to QuickBooks ?
What company won free advertisement due to ?
What company won free due to ?
What won free due to ?
What won due to ?
What won due to
What won due
What won
What

Figure 6: Heatmap generated with leave-one-out shifts drastically despite only removing the least important word (underlined) at each step. For instance, "advertisement", is the most important word in step two but becomes the least important in step three.

4 Mitigating Model Pathologies

The previous section explains the observed pathologies from the perspective of overconfidence: models are too certain on rubbish examples when they should not make *any* prediction. Human experiments in Section 2.3 confirm that the reduced examples fit the definition of rubbish examples. Hence, a natural way to mitigate the pathologies is to maximize model uncertainty on the reduced examples.

4.1 Regularization on Reduced Inputs

To maximize model uncertainty on reduced examples, we use the entropy of the output distribution as an objective. Given a model f trained on a dataset $(\mathcal{X}, \mathcal{Y})$, we generate reduced examples using input reduction for all training examples $\mathcal{X}$. Beam search often yields multiple reduced versions with the same minimum length for each input $\mathbf{x}$, and we collect all of these versions together to form $\tilde{\mathcal{X}}$ as the "negative" example set.

Let $\mathbb{H}(\cdot)$ denote the entropy and $f(y \mid \mathbf{x})$ denote the probability of the model predicting y given $\mathbf{x}$. We fine-tune the existing model to simultaneously maximize the log-likelihood on regular examples and the entropy on reduced examples:

$$\sum_{(\mathbf{x},y)\in(\mathcal{X},\mathcal{Y})} \log(f(y \mid \mathbf{x})) + \lambda \sum_{\tilde{\mathbf{x}}\in\tilde{\mathcal{X}}} \mathbb{H}\left(f(y \mid \tilde{\mathbf{x}})\right), \tag{2}$$

where hyperparameter λ controls the trade-off between the two terms. Similar entropy regularization is used by Pereyra et al. (2017), but not in combination with input reduction; their entropy term is calculated on regular examples rather than reduced examples.

	Accuracy		Reduced length	
	Before	After	Before	After
SQuAD	77.41	78.03	2.27	4.97
SNLI	85.71	85.72	1.50	2.20
VQA	61.61	61.54	2.30	2.87

Table 2: Model *Accuracy* on regular validation examples remains largely unchanged after fine-tuning. However, the length of the reduced examples (*Reduced length*) increases on all three tasks, making them less likely to appear nonsensical to humans.

4.2 Regularization Mitigates Pathologies

On regular examples, entropy regularization does no harm to model accuracy, with a slight increase for SQuAD (*Accuracy* in Table 2).

After entropy regularization, input reduction produces more reasonable reduced inputs (Figure 7). In the SQuAD example from Figure 1, the reduced question changed from "did" to "spend Astor money on ?" after fine-tuning. The average length of reduced examples also increases across all tasks (*Reduced length* in Table 2). To verify that model overconfidence is indeed mitigated—that the reduced examples are less "rubbish" compared to before fine-tuning—we repeat the human experiments from Section 2.3.

Human accuracy increases across all three tasks (Table 3). We also repeat the *vs. Random* experiment: we re-generate the random examples to match the lengths of the new reduced examples from input reduction, and find humans now prefer the reduced examples to random ones. The increase in both human performance and preference suggests that the reduced examples are more reasonable; model pathologies have been mitigated.

While these results are promising, it is not clear whether our input reduction method is necessary to achieve them. To provide a baseline, we fine-tune models using inputs randomly reduced to the same lengths as the ones generated by input reduction. This baseline improves neither the model accuracy on regular examples nor interpretability under input reduction (judged by lengths of reduced examples). Input reduction is effective in generating negative examples to counter model overconfidence.

SQUAD	
Context	In 1899, John Jacob Astor IV invested \$100,000 for Tesla to further develop and produce a new lighting system. Instead, Tesla used the money to fund his Colorado Springs experiments.
Original	What did Tesla spend Astor's money on ?
Answer	Colorado Springs experiments
Before	did
After	spend Astor money on ?
Confidence	0.78 → 0.91 → 0.52
SNLI	
Premise	Well dressed man and woman dancing in the street
Original	Two man is dancing on the street
Answer	Contradiction
Before	dancing
After	two man dancing
Confidence	0.977 → 0.706 → 0.717
VQA	
Original	What color is the flower ?
Answer	yellow
Before	flower ?
After	What color is flower ?
Confidence	0.847 → 0.918 → 0.745

Figure 7: SQUAD example from Figure 1, SNLI and VQA (image omitted) examples from Figure 2. We apply input reduction to models both *Before* and *After* entropy regularization. The models still predict the same *Answer*, but the reduced examples after fine-tuning appear more reasonable to humans.

	Accuracy		vs. Random	
	Before	After	Before	After
SQUAD	31.72	51.61	53.70	62.75
SNLI-E	27.66	32.37	42.31	50.62
SNLI-N	52.66	50.50	50.64	58.94
SNLI-C	60.60	63.90	49.87	56.92
VQA	40.60	51.85	61.60	61.88

Table 3: Human *Accuracy* increases after fine-tuning the models. Humans also prefer gradient-based reduced examples over randomly reduced ones, indicating that the reduced examples are more meaningful to humans after regularization.

5 Discussion

Rubbish examples have been studied in the image domain (Goodfellow et al., 2015; Nguyen et al., 2015), but to our knowledge not for NLP. Our input reduction process gradually transforms a valid input into a rubbish example. We can often determine which word's removal causes the transition to occur—for example, removing "Broncos" in Figure 5. These rubbish examples are particularly interesting, as they are also adversarial: the difference from a valid example is small, unlike image rubbish examples generated from pure noise which are far outside the training data distribution.

The robustness of NLP models has been studied extensively (Papernot et al., 2016; Jia and Liang, 2017; Iyyer et al., 2018; Ribeiro et al., 2018), and most studies define adversarial examples similar to the image domain: small perturbations to the input lead to large changes in the output. HotFlip (Ebrahimi et al., 2017) uses a gradient-based approach, similar to image adversarial examples, to flip the model prediction by perturbing a few characters or words. Our work and Belinkov and Bisk (2018) both identify cases where noisy user inputs become adversarial by accident: common misspellings break neural machine translation models; we show that incomplete user input can lead to unreasonably high model confidence.

Other failures of interpretation methods have been explored in the image domain. The sensitivity issue of gradient-based interpretation methods, similar to our shifting heatmaps, are observed by Ghorbani et al. (2017) and Kindermans et al. (2017). They show that various forms of input perturbation—from adversarial changes to simple constant shifts in the image input—cause significant changes in the interpretation. Ghorbani et al. (2017) make a similar observation about second-order sensitivity, that "the fragility of interpretation is orthogonal to fragility of the prediction".

Previous work studies biases in the annotation process that lead to datasets easier than desired or expected which eventually induce pathological models. We attribute our observed pathologies primarily to the lack of accurate uncertainty estimates in neural models trained with maximum likelihood. SNLI hypotheses contain artifacts that allow *training* a model without the premises (Gururangan et al., 2018); we apply input reduction at *test* time to the hypothesis. Similarly, VQA images are surprisingly unimportant for training a model; we reduce the question. The recent SQUAD 2.0 (Rajpurkar et al., 2018) augments the original reading comprehension task with an uncertainty modeling requirement, the goal being to make the task more realistic and challenging.

Section 3.1 explains the pathologies from the overconfidence perspective. One explanation for overconfidence is overfitting: Guo et al. (2017) show that, late in maximum likelihood training, the model learns to minimize loss by outputting low-entropy distributions without improving validation accuracy. To examine if overfitting can explain the input reduction results, we run input reduction using DRQA model checkpoints from every training epoch. Input reduction still achieves similar results on earlier checkpoints, suggesting that better convergence in maximum likelihood training cannot fix the issues by itself—we need new training objectives with uncertainty estimation in mind.

5.1 Methods for Mitigating Pathologies

We use the reduced examples generated by input reduction to regularize the model and improve its interpretability. This resembles adversarial training (Goodfellow et al., 2015), where adversarial examples are added to the training set to improve model robustness. The objectives are different: entropy regularization encourages high uncertainty on rubbish examples, while adversarial training makes the model less sensitive to adversarial perturbations.

Pereyra et al. (2017) apply entropy regularization on regular examples from the start of training to improve model generalization. A similar method is label smoothing (Szegedy et al., 2016). In comparison, we fine-tune a model with entropy regularization on the reduced examples for better uncertainty estimates and interpretations.

To mitigate overconfidence, Guo et al. (2017) propose *post-hoc* fine-tuning a model's confidence with Platt scaling. This method adjusts the softmax function's temperature parameter using a small held-out dataset to align confidence with accuracy. However, because the output is calibrated using the entire confidence distribution, not individual values, this does not reduce overconfidence on specific inputs, such as the reduced examples.

5.2 Generalizability of Findings

To highlight the erratic model predictions on short examples and provide a more intuitive demonstration, we present paired-input tasks. On these tasks, the short lengths of reduced questions and hypotheses obviously contradict the necessary number of words for a human prediction (further supported by our human studies). We also apply input reduction to single-input tasks including sentiment analysis (Maas et al., 2011) and Quizbowl (Boyd-Graber et al., 2012), achieving similar results.

Interestingly, the reduced examples transfer to other architectures. In particular, when we feed fifty reduced SNLI inputs from each class—generated with the BIMPM model (Wang et al., 2017)—through the Decomposable Attention Model (Parikh et al., 2016),[2] the same prediction is triggered 81.3% of the time.

6 Conclusion

We introduce input reduction, a process that iteratively removes unimportant words from an input while maintaining a model's prediction. Combined with gradient-based importance estimates often used for interpretations, we expose pathological behaviors of neural models. Without lowering model confidence on its original prediction, an input sentence can be reduced to the point where it appears nonsensical, often consisting of one or two words. Human accuracy degrades when shown the reduced examples instead of the original, in contrast to neural models which maintain their original predictions.

We explain these pathologies with known issues of neural models: overconfidence and sensitivity to small input changes. The nonsensical reduced examples are caused by inaccurate uncertainty estimates—the model is not able to lower its confidence on inputs that do not belong to any label. The second-order sensitivity is another issue why gradient-based interpretation methods may fail to align with human perception: a small change in the input can cause, at the same time, a minor change in the prediction but a large change in the interpretation. Input reduction perturbs the input multiple times and can expose deeper issues of model overconfidence and oversensitivity that other methods cannot. Therefore, it can be used to stress test the interpretability of a model.

Finally, we fine-tune the models by maximizing entropy on reduced examples to mitigate the deficiencies. This improves interpretability without sacrificing model accuracy on regular examples.

To properly interpret neural models, it is important to understand their fundamental characteristics: the nature of their decision surfaces, robustness against adversaries, and limitations of their training objectives. We explain fundamental difficulties of interpretation due to pathologies in neural models trained with maximum likelihood. Our

---

work suggests several future directions to improve interpretability: more thorough evaluation of interpretation methods, better uncertainty and confidence estimates, and interpretation beyond bag-of-word heatmap.

Abstract

Universal sentence encoding is a hot topic in recent NLP research. Attention mechanism has been an integral part in many sentence encoding models, allowing the models to capture context dependencies regardless of the distance between elements in the sequence. Fully attention-based models have recently attracted enormous interest due to their highly parallelizable computation and significantly less training time. However, the memory consumption of their models grows quadratically with sentence length, and the syntactic information is neglected. To this end, we propose Phrase-level Self-Attention Networks (PSAN) that perform self-attention across words inside a phrase to capture context dependencies at the phrase level, and use the gated memory updating mechanism to refine each word's representation hierarchically with longer-term context dependencies captured in a larger phrase. As a result, the memory consumption can be reduced because the self-attention is performed at the phrase level instead of the sentence level. At the same time, syntactic information can be easily integrated in the model. Experiment results show that PSAN can achieve the state-of-the-art transfer performance across a plethora of NLP tasks including sentence classification, natural language inference and sentence textual similarity.

1 Introduction

Following the success of word embeddings (Bengio et al., 2003; Mikolov et al., 2013), one of NLP's next challenges has become the hunt for universal sentence encoders. The goal is to learn a general-purpose sentence encoding model on a large corpus, which can be readily transferred to other tasks. The learned sentence representations are able to generalize to unseen combination of words, which makes them highly desirable for downstream NLP tasks, especially for those with relatively small datasets.

Previous models for sentence encoding typically rely on Recurrent Neural Networks (RNNs) (Hochreiter and Schmidhuber, 1997; Chung et al., 2014) or Convolutional Neural Networks (CNNs) (Kalchbrenner et al., 2014; dos Santos and Gatti, 2014; Kim, 2014; Mou et al., 2016) to produce context-aware representation. RNNs encode a sentence by reading words in sequential order, they are capable of learning long-term dependencies but are hard to parallelize and not time-efficient. CNNs focus on local or position-invariant dependencies but do not perform well on many tasks (Shen et al., 2017).

Fully attention-based neural networks have attracted wide interest recently, because they can model both dependencies while being more parallelizable and requiring significantly less time to train. Vaswani et al. (2017) proposed the multi-head attention to project a sentence to multiple semantic subspaces, then apply self-attention in each subspace and concatenate the attention results. Shen et al. (2017) proposed the directional self-attention, they apply forward and backward masks to the alignment score matrix to encode temporal order information, and computed attention at feature level to select the features that can best describe the word's meaning in given context. Effective as their models are, the memory required to store the alignment scores of all the token pairs grows quadratically with the sentence length. Furthermore, the syntactic property that is intrinsic to natural language is not considered at all.

Language is inherently tree structured, and the meaning of a sentence comes largely from composing the meanings of subtrees (Chomsky, 1957). Previous syntactic tree-based sentence encoders (Socher et al., 2013; Tai et al., 2015) mainly rely on recursive networks. Although the composition-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3729–3738
Brussels, Belgium, October 31 - November 4, 2018.

ality can be explicitly modeled, their models need expensive recursion computation and are hard to be trained by batched gradient descent methods.

In this paper, we propose the Phrase-level Self-Attention Networks (PSAN), for RNN/CNN-free sentence encoding, it inherits all the advantages of fully attention-based models while requires much less memory consumption. In addition, syntactic information can be incorporated into the model more easily. In our model, every sentence is split into multiple phrases based on parse tree, self-attention is performed at the phrase level instead of the sentence level, thus the memory consumption reduces rapidly as the number of phrases increases. Furthermore, a gated memory component is employed to refine word representations hierarchically by incorporating longer-term context dependencies. As a result, syntactic information can be integrated into the model without expensive recursion computation. At last, multi-dimensional attention is applied on the refined word representations to obtain the final sentence representation.

Following Conneau et al. (2017), we trained our sentence encoder on the SNLI (Bowman et al., 2015) dataset, and evaluate the quality of the obtained universal sentence representations on a wide range of transfer tasks. The SNLI dataset is extremely suitable for training sentence encoders because it is the largest high-quality human-annotated dataset that involves reasoning about the semantic relationships within sentences.

The main contributions of our work can be summarized as follows:

- We propose the Phrase-level Self-Attention mechanism (PSA) for contextualization. The memory consumption can be reduced because self-attention is performed at the phrase level instead of the sentence level.
- A gated memory updating mechanism is proposed to refine each word representation hierarchically by incorporating different levels of contextual information along the parse tree.
- Our proposed PSAN model outperforms the state-of-the-art supervised sentence encoders on a wide range of transfer tasks with significantly less memory consumption.

2 Proposed Model

In this section, we introduce the Phrase-level Self-Attention Networks (PSAN) for sentence encoding. A phrase is a group of words that carry a specific idiomatic meaning and function as a constituent in the syntax of a sentence. Words in a phrase are syntactically and semantically related to each other. Therefore, it can be advantageous to learn a context-aware representation inside a phrase while filtering out information from outside the phrase using self-attention mechanism. In an attempt to better utilize the tree structure which is intrinsic to language, we propose the gated memory updating mechanism to combine different levels of context information. At last, an attention mechanism is utilized to summarize all the token representations into a fixed-length sentence vector.

2.1 Phrase Division

The phrase structure organizes words into nested constituents which can be successively divided into their parts as we move down the constituency-based parse trees. One phrase division shows only one aspect of context dependency. In order to capture different levels of context dependencies, we can split a sentence at different granularities. The number of levels T is a hyper-parameter to be tuned.

We can break down the nodes at T different layers in the parse tree to capture T levels of context dependencies[1], as illustrated in Figure 1.

2.2 Phrase-level Self-Attention

This is the core component of our model. It aims to learn a context-aware representation for each token inside a phrase. In order to filter out information that is semantically or syntactically distant, self-attention is performed at the phrase level instead of the sentence level.

Similar to directional self-attention network (DiSAN) (Shen et al., 2017), Phrase-level Self-Attention uses multi-dimensional attention to compute the alignment score for each dimension of token embedding. Therefore, it can select the features that can best describe a word's specific meaning in any given context.

Given a phrase $P \in \mathbb{R}^{l \times d}$ represented as a sequence of word embeddings $[\boldsymbol{p}_1, \ldots, \boldsymbol{p}_l]$, where l is the length of the phrase and d is the dimension of word embedding representation, we first compute the alignment score for each token pair in the

---

[1] To avoid the situation that the produced phrases are too small, a phrase will not be further divided if its length is smaller than 4.

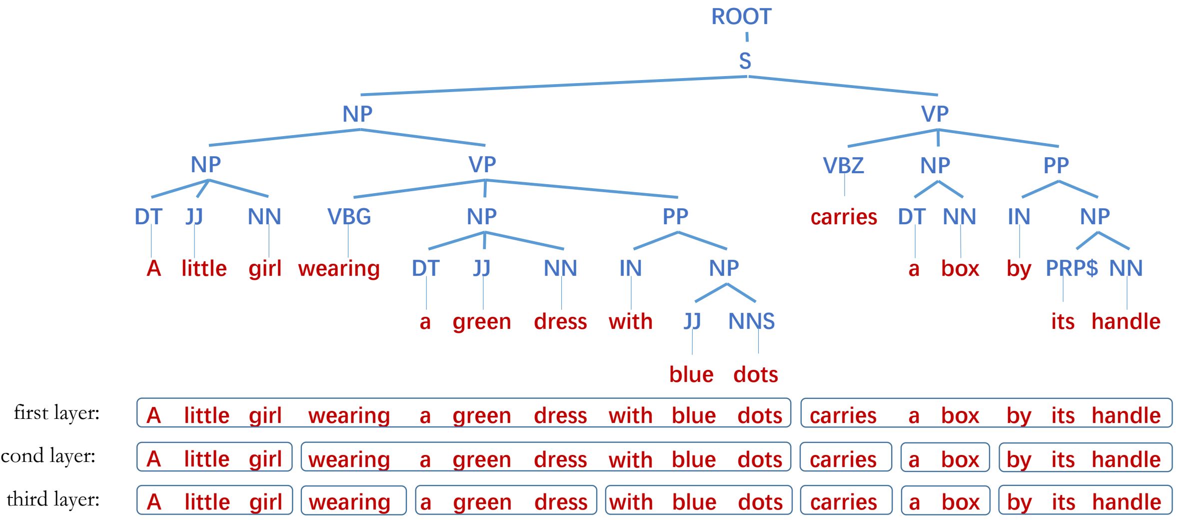

Figure 1: An example of phrase division, the sentence and its parse tree are from the SNLI training data. The division is started from the root of a parse tree. In this example, a phrase will not be further divided if it contains 3 or less words.

phrase:

$$\boldsymbol{a}_{ij} = \sigma\left(W^{a1}\boldsymbol{p}_i + W^{a2}\boldsymbol{p}_j + \boldsymbol{b}^a\right) + M_{ij}$$
$$M_{ij} = \begin{cases} 0, & i \neq j \\ -\infty, & i = j \end{cases} \tag{1}$$

where $\sigma(\cdot)$ is an activation function, $W^{a1}, W^{a2} \in \mathbb{R}^{d\times d}$ and $\boldsymbol{b}^a \in \mathbb{R}^d$ are parameters to be learned, and M is a diagonal-diabled mask (Hu et al., 2017) that aims to prevent a word from being aligned with itself.

The output of the attention mechanism is a weighted sum of embeddings from all tokens for each token in the phrase:

$$\tilde{\boldsymbol{p}}_i = \sum_{j=1}^{l}\left[\frac{\exp(\boldsymbol{a}_{ij})}{\sum_{k=1}^{l}\exp(\boldsymbol{a}_{ik})} \odot \boldsymbol{p}_j\right] \tag{2}$$

where $\odot$ means point-wise product. Note that the alignment score for each token pair is a vector rather than a scalar in the multi-dimensional attention.

The final output of Phrase-level Self-Attention is obtained by comparing each input representation with its attention-weighted counterpart. We use a comparison function based on absolute difference and element-wise multiplication which was similar to Wang and Jiang (2016). This comparison function has the advantage of measuring the semantic similarity or relatedness of two sequences.

$$\boldsymbol{c}_i = \sigma\left(W^c\left[\left|\boldsymbol{p}_i - \tilde{\boldsymbol{p}}_i\right|; \boldsymbol{p}_i \odot \tilde{\boldsymbol{p}}_i\right] + \boldsymbol{b}^c\right) \tag{3}$$

where $W^c \in \mathbb{R}^{d\times 2d}$ and $\boldsymbol{b}^a \in \mathbb{R}^d$ are parameters to be learned. $\boldsymbol{c}_i$ is the representation for the i-th word in the phrase that captures local dependencies within the phrase.

At last, we put together the Phrase-level Self-Attention results for non-overlapping phrases from the same phrase division of a sentence. For the t-th phrase division we can get $C^{(t)} = [\boldsymbol{c}_1, \ldots, \boldsymbol{c}_{l_s}]$, the phrase-level self-attention results for the sentence from the t-th layer split, where l_s is the sentence length.

2.3 Gated Memory Updating

Above describes the Phrase-level Self-Attention (PSA) for one split of the parse tree. The parse tree can be split at different granularities. We propose a novel gated memory updating mechanism to refine each word representation hierarchically with longer-term dependencies captured in a larger granularity. Inspired by the idea of adaptive gate in highway networks (Srivastava et al., 2015), our memory mechanism add a gate to original memory networks (Weston et al., 2014; Sukhbaatar et al., 2015). This gate has the ability to determine the importance of the new input and the original memory in the memory updating.

$$\begin{aligned} C^{(t)} &= PSA\left(M^{(t-1)}\right) \\ G^{(t)} &= sigmoid\left(W^g\left[M^{(t-1)}; C^{(t)}\right] + \boldsymbol{b}^g\right) \\ M^{(t)} &= G^{(t)} \odot \sigma\left(W^m\left[M^{(t-1)}; C^{(t)}\right] + \boldsymbol{b}^m\right) \end{aligned} \tag{4}$$

where $W^g, W^m \in \mathbb{R}^{d\times 2d}$ and $\boldsymbol{b}^g, \boldsymbol{b}^m \in \mathbb{R}^d$ are parameters to be learned. Note that in order to share representation power and to reduce the number of parameters, the parameters of gated memory updating are shared among different layers.

2.4 Sentence Summarization

In this layer, self-attention mechanism is employed to summarize the refined representation of a sentence into a fixed-length vector. The self-attention mechanism can explore the dependencies among tokens within the whole sentence. As a result, global dependencies can also be incorporated in the model.

$$\begin{aligned} \boldsymbol{e}_i &= W^{e2}\sigma\left(W^{e1}\boldsymbol{m}_i^{(T)} + \boldsymbol{b}^{e1}\right) + \boldsymbol{b}^{e2} \\ \boldsymbol{v} &= \sum_{i=1}^{l}\left[\frac{\exp\left(\boldsymbol{e}_i\right)}{\sum_{j=1}^{l}\exp\left(\boldsymbol{e}_j\right)} \odot \boldsymbol{m}_i^{(T)}\right] \end{aligned} \tag{5}$$

where $W^g, W^m \in \mathbb{R}^{d\times d}$ and $\boldsymbol{b}^g, \boldsymbol{b}^m \in \mathbb{R}^d$ are parameters to be learned. After this step, the refined context-aware sentence representation is compressed into a fixed-length vector.

3 Experiments

In this section, we conduct a plethora of experiments to study the effectiveness of the PSAN model. Following Conneau et al. (2017), we train our sentence encoder using the SNLI dataset, and evaluate it across a variety of NLP tasks including sentence classification, natural language inference and sentence textual similarity.

3.1 Model Configuration

300-dimensional GloVe (Pennington et al., 2014) word embeddings (Common Crawl, uncased) are used to represent words. Following Parikh et al. (2016), out-of-vocabulary words are hashed to one of 128 random embeddings initialized by uniform distribution between (-0.05, 0.05). All the word embeddings remain fixed during training. Hidden dimension d is set to 300. All other parameters are initialized with Glorot normal initialization (Glorot and Bengio, 2010). Activation function $\sigma(\cdot)$ is ELU (Clevert et al., 2015) if not specified. Minibatch size is set to 16. The number of levels T is fixed to 3 in all of our experiments. The syntactic parse trees of SNLI are provided within the corpus. parse trees for all test corpus are produced by the Stanford PCFG Parser 3.5.2 (Klein and Manning, 2003), the same parser that produced parse trees for the SNLI dataset.

To train the model, Adadelta optimizer (Zeiler, 2012) with a learning rate of 0.75 is used on the SNLI dataset. The dropout (Srivastava et al., 2014) rate and L2 regularization weight decay factor γ are set to 0.5 and 5e-5. To test the model, the SentEval toolkit (Conneau and Kiela, 2018) is used as the evaluation pipeline for fairer comparison.

3.2 Training Setting

Natural language inference (NLI) is a fundamental task in the field of natural language processing that involves reasoning about the semantic relationship between two sentences, which makes it a suitable task to train sentence encoding models.

We conduct experiments on the Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015). The dataset has 570k human-annotated sentence pairs, each labeled with one of the following pre-defined relationships: $Entailment$ (the premise entails the hypothesis), $Contradiction$ (they contradict each other) and $Neutral$ (they are irrelevant). Following previous work (Bowman et al., 2015; Mou et al., 2016), we remove the instances which annotators can not reach consensus on. In this way we get 549367/9842/9824 sentence pairs for train/validation/test set.

Following the siamese architecture (Bromley et al., 1993), we apply PSAN to both the premise and the hypothesis with their parameters tied. $\boldsymbol{v}^p$ and $\boldsymbol{v}^h$ are fixed-length vector representations for the premise and the hypothesis respectively. The final sentence-pair representation is formed by concatenating the original vectors with the absolute difference and element-wise multiplication between them:

$$\boldsymbol{v}^{inp} = \left[\boldsymbol{v}^p; \boldsymbol{v}^h; \left|\boldsymbol{v}^p - \boldsymbol{v}^h\right|; \boldsymbol{v}^p \odot \boldsymbol{v}^h\right] \tag{6}$$

At last, we feed the sentence-pair representation $\boldsymbol{v}^{inp}$ into a two layer feed-forward network and use a $softmax$ layer to make the classification. This is the de facto scheme for sentence encoders trained on SNLI. (Mou et al., 2016; Liu et al., 2016; Shen et al., 2017)

3.3 Evaluation Setting

To show the modeling capacity and robustness of our proposed model, we evaluate our model across a wide range of tasks that can be solved purely based on the encoded semantics. The set of tasks

dataset	size	task	output	# phrases / sent.			# words / phrase		
				$1st$	$2nd$	$3rd$	$1st$	$2nd$	$3rd$
MR	10662	sentiment	2	2.00	2.89	6.03	10.79	7.47	3.58
CR	3775	product reviews	2	1.99	3.22	6.02	10.11	6.25	3.34
MPQA	10606	opinion polarity	2	1.13	1.52	1.63	2.73	2.03	1.89
SUBJ	10000	subjectivity	2	1.98	3.29	4.51	5.61	3.40	2.48
SST2	70042	sentiment	2	1.95	3.35	5.03	5.53	3.22	2.15
SST5	11855	sentiment	5	2.00	3.53	6.10	10.08	5.71	3.31
TREC	5952	question type	6	2.00	3.73	5.59	5.03	2.98	1.99
SICK-E	9930	inference	3	1.93	3.40	4.92	5.01	2.85	1.97
SICK-R	9930	inference	[0, 5]	1.93	3.40	4.92	5.01	2.85	1.97
STS14	4500	semantic similarity	[0, 5]	1.96	3.58	5.12	5.34	2.92	2.04
MRPC	5803	paraphrase	2	1.99	3.31	4.55	5.59	3.37	2.65

Table 1: Statistics of the evaluation datasets. If the output is an integer, it represents the number of classes of the classification task. If the output is an interval, it represents the output range of the regression task. **# phrases / sent.** represents the average number of phrases per sentence for each layer of phrase division. **# words / phrase** represents the average number of words per phrase for each layer of phrase division.

was selected based on what appears to be the community consensus regarding the appropriate evaluations for universal sentence representations. To facilitate comparison, we use the same sentence evaluation tool as Conneau et al. (2017) to automate evaluation on all the tasks mentioned in this paper.

The transfer tasks used in evaluation can be concluded in the following classes: sentence classification (MR, CR, MPQA, SUBJ, SST2, SST5, TREC), natural language inference (SICK-E, SICK-R), semantic relatedness (STS14) and paraphrase detection (MRPC). Table 1 presents some statistics about the datasets [2].

3.4 Baselines

We compare our model with the following supervised sentence encoders:

- **BiLSTM-Max** (Conneau et al., 2017) is a simple but effective baseline that performs max-pooling over a bi-directional LSTM.
- **AdaSent** (Zhao et al., 2015) forms a hierarchy of representations from words to phrases and then to sentences through recursive gated local composition of adjacent segments.
- **TBCNN** (Mou et al., 2015) is a tree-based CNN model where convolution is applied over the parse tree.
- **DiSAN** (Shen et al., 2017) is composed of a directional self-attention block with temporal order encoded, and a multi-dimensional attention that compresses the sequence into a vector representation.

Model	dim	$\|\boldsymbol{\theta}\|$	SNLI	Micro	Macro
BiLSTM-Max	4096	40M	84.5	85.2	83.7
AdaSent	4096	36M	83 .4	82.0	80.9
TBCNN	300	3.5M	82.1	81.1	79.3
DiSAN	600	2.4M	85.6	84.7	83.4
PSAN	300	2.0M	**86.1**	**85.7**	**84.5**

Table 2: Performance on SNLI and transfer tasks of various sentence encoders. **dim**: the size of sentence representation. $|\boldsymbol{\theta}|$: the number of parameters. Test accuracies on SNLI, micro and macro averages of accuracies of dev set on transfer tasks are chosen as evaluation metrics.

4 Results and Analysis

4.1 Overall Performance

Experiment results of our model and four baselines are shown in Table 2. Micro and macro accuracies are two composite indicators for evaluating transfer performance of tasks whose metric is classification accuracy. Macro accuracy is the proportion of true results in the population of instances from all tasks. Micro accuracy is the arithmetic mean of dev accuracies for each task.

PSAN achieves the state-of-the-art performance

---

[2] For further information on the datasets, please refer to Conneau et al. (2017).

Model	MR	CR	SUBJ	MPQA	SST	TREC	MRPC	SICK-R	SICK-E	STS14
BiLSTM-max	79.9	**84.6**	92.1	89.8	83.3	88.7	**75.1/82.3**	0.885	86.3	.68/.65
AdaSent	77.0	82.0	89.9	87.2	82.3	85.6	72.6/80.0	0.855	83.1	.66/.62

Table 3: Transfer test results for our model and various baselines. Classification accuracy is chosen as evaluation metric for datasets including MR, CR, SUBJ, MPQA, SST, TREC and SICK-E; Classification accuracy and F1-score are chosen for MRPC; Pearson correlation is chosen for SICK-R; Pearson and Spearman correlations are chosen for STS-14.

Model	**Acc(%)**
(1) PSA on the first layer only	84.9
(2) PSA on the second layer only	85.3
(3) PSA on the third layer only	84.6
(4) w/o PSA	85.3
(5) w/o syntactic division	85.5
(6) w/o gated memory updating	85.2
(7) w/o both	84.7
(8) Full Model	**86.1**

Table 4: Ablation studies on the SNLI dataset.

with considerably fewer parameters, outperforming a RNN-based model, a CNN-based model, a fully attention-based model and a model that utilize syntactic information. Especially when compared with previous best model *BiLSTM-Max*, PSAN can outperform their model with only 5% of their parameter numbers, demonstrating the effectiveness of our model at extracting semantically important information from a sentence.

In Table 3, we compare our model with baseline sentence encoders in each transfer task. PSAN can consistently outperform the baselines in almost every task considered. On the SICK dataset, which can be seen as an out-domain version of SNLI, our model can outperform the baselines by a large margin, demonstrating the semantic relationship learned on the SNLI can be well transfered to other domains. On the STS14 dataset, where sentence vectors can be more directly measured by the cosine distance, our model can also achieve the state-of-the-art performance, indicating that our learned sentence representations are of high quality.

4.2 Ablation Study

For thorough comparison, we implement seven extra baselines to analyze the improvements contributed by each part of our PSAN model:

- **PSA on the first/second/third layer only** only uses the Phrase-level Self-Attention at the first/second/third layer of phrase division.
- **w/o PSA** applies self-attention at the sentence level and uses the gated memory updating mechanism to refine each token representation hierarchically.
- **w/o syntactic division** divides each sentence equally into small blocks, and applies PSA within each block. The number of blocks equals the number of phrases in that layer.
- **w/o gated memory updating** concatenates the outputs of Phrase-level Self-Attention from three layers of phrase division and feeds the result to a feed-forward layer.
- **w/o both** applies self-attention at the sentence level, and uses sentence summarization to summarize the attention results into a fixed length vector.

The results are listed in Table 4. We can see that (2) performs best among (1), (2) and (3), demonstrating that the second layer split is more expressive, because the number of words per phrase in the second layer is the most suitable. It is neither too small to capture context dependencies, nor too large to filter out irrelevant noise. (8) outperforms (1), (2) and (3), showing that combining phrase-level information from different granularities can further improve performance.

We also experiment on models where the alignment matrix is calculated at the sentence level or at the syntactic-irrelevant block level. (5) performs quite well, showing that hierarchical refinement on smaller units can bring about reasonable

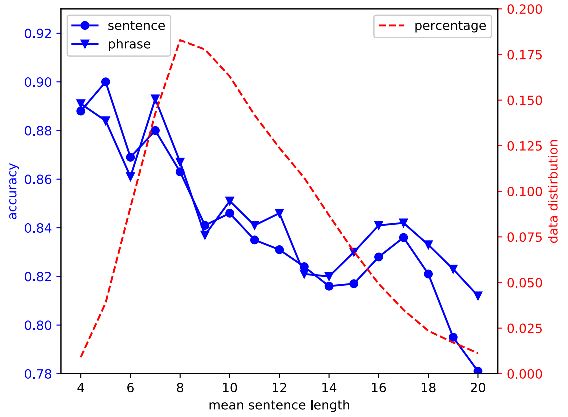

Figure 2: Fine-grained classification accuracies for PSAN and Sentence-level Self-Attention on the SNLI dataset are compared on the left, how data are distributed along sentence length is shown on the right.

performance gain. (8) outperforms (4) and (5), demonstrating syntactic information helps in sentence representation.

When comparing (6) with (8), we can tell that gated memory updating is a better method when used to refine token representation along the parse tree. We assume that memory updating resembles the tree structure of language in that larger phrase is composed in the knowledge of how smaller phrases are composed inside it.

Comparing (7) with (1), (2) and (3), we can find that performing self-attention at the phrase level is generally better than at the sentence level, indicating that reducing attention context into phrase level can effectively filter out words that are syntactically and semantically distant, thus focusing on the interaction with important words. Comparing (7) with (4), we can draw the conclusion that memory updating is effective even when the inputs to each layer are the same.

4.3 Analysis of Sentence Length

Long-term dependencies are typically hard to capture for sequential models like RNNs (Bengio et al., 1994; Hochreiter and Schmidhuber, 1997). We conduct experiments to see how performance changes as the sentence length increases. In Figure 2, we show the relationship between classification accuracy and the average length of sentence pair on the SNLI dataset. Sentence-level Self-Attention (w/o PSA model described in subsection 4.2) is used as a baseline for our model. PSAN

Model	**Memory(MB)**	**Acc(%)**
(1) Multi-head	1508	87.1
(2) DiSAN	2943	87.7
(3) PSAN	1192	**89.1**

Table 5: Memory consumption and test accuracy of three fully attention-based models on the TREC dataset.

outperforms Sentence-level Self-Attention model consistently for longer sentences of length 14 to 20. This demonstrates that incorporating syntactic information by performing self-attention at the phrase level and refining each word's representation hierarchically can help to capture long-term dependencies across words in a sentence.

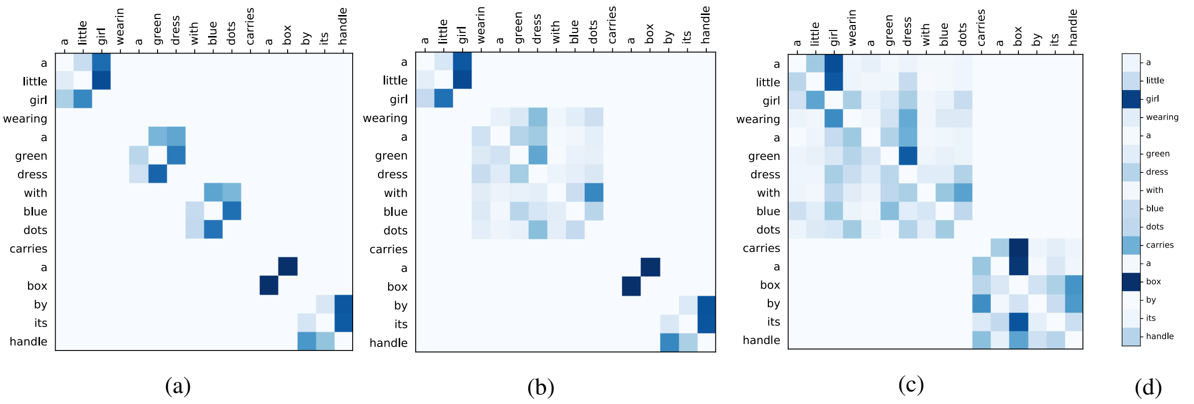
4.4 Analysis of Memory Consumption

We conduct experiments to analyze the memory consumption reduction resulted from Phrase-level Self-Attention. To this end, we re-implement two fully attention-based models (Vaswani et al., 2017; Shen et al., 2017) on the TREC dataset. To make fair comparison, the dimensions of sentence vectors are set to 300, the same number as our model. Table 5 lists the results. Our PSAN model can outperform the other two fully attention-based models, while being more memory efficient. reducing more than 20% of memory consumption.

4.5 Visualization and Case Study

In order to analyze the attention changing process and the importance of each word in the sentence vector, we visualize the attention scores in the alignment matrix of each layer in Phrase-level Self-Attention and sentence summarization layer. To facilitate the visualization of the multi-dimension attention vector, we use the $l2$ norm of the attention vector for representation.

In Figure 3, we can see that, the difference in attention weights between semantically important and unimportant words gets larger as the context becomes larger. This implies that token representation can be gradually refined by the gated memory updating mechanism. Furthermore, the alignment matrix of a phrase can be refined even if the phrase division does not change between layers. For instance, the word "girl" gets larger attention weight in the second layer division than in the first layer. This demonstrates that the memory



(a) (b) (c) (d)

Figure 3: (a) / (b) / (c): attention weights of Phrase-level Self-Attention mechanism in the third / second / first layer phrase division; (d): attention weights of the sentence summarization layer.

updating mechanism can gradually pick out important words for sentence representation. Finally, nouns and verbs dominate the attention weights, while stop words like “a” and “its”, contribute little to the final sentence representation, this indicates that PSAN can effectively pick out semantically important words that are most representative for the meaning of the whole sentence.

5 Related Work

Recently, self-attention mechanism has been successfully applied to the field of sentence encoding, it utilizes the attention mechanism to relate elements at different positions from a single sentence. Due to its direct access to each token representation, both long-term and local dependencies can be modeled flexibly. Liu et al. (2016) leveraged the average-pooled word representation to attend words appear in the sentence itself. Cheng et al. (2016) proposed the LSTMN model for machine reading, an attention vector is produced for each of its hidden states during the recurrent iteration, thus empowering the recurrent network with stronger memorization capability and the ability to discover relations among tokens. Lin et al. (2017) obtained a fixed-size sentence embedding matrix by introducing self-attention. Different from the feature-level attention used in our model, their attention mechanism extracted different aspects of the sentence into multiple vector representations, and utilized a penalization term to encourage the diversity of different attention results.

Syntactic information can be useful for understanding a natural language sentence. Many previous researches utilized syntactic information to build sentence encoder from composing the meanings of subtrees. Tree-LSTM (Tai et al., 2015; Zhu et al., 2015) composed its hidden state from an input vector and the hidden states of arbitrarily many child units. In Tree-based CNN (Mou et al., 2015, 2016), a set of subtree feature detectors slide over the parse tree of a sentence, and a max-pooling layer is utilized to aggregate information along different parts of the tree.

Apart from the models that use parse information, there have been several researches that aimed to learn the hierarchical latent structure of text by recursively composing words into sentence representation. Among them, neural tree indexer (Munkhdalai and Yu, 2017b) utilized LSTM or attentive node composition function to construct full n-ary tree for input text. Gumbel Tree-LSTM (Choi et al., 2018) used Straight-Through Gumbel-Softmax estimator to decide the parent node among candidates dynamically. A major drawback of these models is that the recursion computation can be expensive and hard to be processed in batches.

6 Conclusion

We propose the Phrase-level Self-Attention Networks (PSAN), a fully attention-based model that can utilize syntactic information for universal sentence encoding. By applying self-attention at the phrase level, we can filter out distant and unrelated words and focus on modeling interaction between semantically and syntactically important words, a gated memory updating mechanism is utilized to incorporate different levels of contextual information along the parse tree. Empirical results on a wide range of transfer tasks demonstrate the effectiveness of our model.

Abstract

In this work, we propose a novel method for training neural networks to perform single-document extractive summarization without heuristically-generated extractive labels. We call our approach BANDITSUM as it treats extractive summarization as a contextual bandit (CB) problem, where the model receives a document to summarize (the context), and chooses a sequence of sentences to include in the summary (the action). A policy gradient reinforcement learning algorithm is used to train the model to select sequences of sentences that maximize ROUGE score. We perform a series of experiments demonstrating that BANDITSUM is able to achieve ROUGE scores that are better than or comparable to the state-of-the-art for extractive summarization, and converges using significantly fewer update steps than competing approaches. In addition, we show empirically that BANDITSUM performs significantly better than competing approaches when good summary sentences appear late in the source document.

1 Introduction

Single-document summarization methods can be divided into two categories: extractive and abstractive. Extractive summarization systems form summaries by selecting and copying text snippets from the document, while abstractive methods aim to generate concise summaries with paraphrasing. This work is primarily concerned with extractive summarization. Though abstractive summarization methods have made strides in recent years, extractive techniques are still very attractive as they are simpler, faster, and more reliably yield semantically and grammatically correct sentences.

Many extractive summarizers work by selecting sentences from the input document (Luhn, 1958; Mihalcea and Tarau, 2004; Wong et al., 2008; Kågebäck et al., 2014; Yin and Pei, 2015; Cao et al., 2015; Yasunaga et al., 2017). Furthermore, a growing trend is to frame this sentence selection process as a sequential binary labeling problem, where binary inclusion/exclusion labels are chosen for sentences one at a time, starting from the beginning of the document, and decisions about later sentences may be conditioned on decisions about earlier sentences. Recurrent neural networks may be trained with stochastic gradient ascent to maximize the likelihood of a set of ground-truth binary label sequences (Cheng and Lapata, 2016; Nallapati et al., 2017). However, this approach has two well-recognized disadvantages. First, it suffers from exposure bias, a form of mismatch between training and testing data distributions which can hurt performance (Ranzato et al., 2015; Bahdanau et al., 2017; Paulus et al., 2018). Second, extractive labels must be generated by a heuristic, as summarization datasets do not generally include ground-truth extractive labels; the ultimate performance of models trained on such labels is thus fundamentally limited by the quality of the heuristic.

An alternative to maximum likelihood training

Brussels, Belgium, October 31 - November 4, 2018.

is to use reinforcement learning to train the model to directly maximize a measure of summary quality, such as the ROUGE score between the generated summary and a ground-truth abstractive summary (Wu and Hu, 2018). This approach has become popular because it avoids exposure bias, and directly optimizes a measure of summary quality. However, it also has a number of downsides. For one, the search space is quite large: for a document of length T, there are 2^T possible extractive summaries. This makes the exploration problem faced by the reinforcement learning algorithm during training very difficult. Another issue is that due to the sequential nature of selection, the model is inherently biased in favor of selecting earlier sentences over later ones, a phenomenon which we demonstrate empirically in Section 7. The first issue can be resolved to a degree using either a cumbersome maximum likelihood-based pre-training step (using heuristically-generated labels) (Wu and Hu, 2018), or placing a hard upper limit on the number of sentences selected. The second issue is more problematic, as it is inherent to the sequential binary labeling setting.

In the current work, we introduce BANDITSUM, a novel method for training neural network-based extractive summarizers with reinforcement learning. This method does away with the sequential binary labeling setting, instead formulating extractive summarization as a contextual bandit. This move greatly reduces the size of the space that must be explored, removes the need to perform supervised pre-training, and prevents systematically privileging earlier sentences over later ones. Although the strong performance of Lead-3 indicates that good sentences often occur early in the source article, we show in Sections 6 and 7 that the contextual bandit setting greatly improves model performance when good sentences occur late without sacrificing performance when good sentences occur early.

Under this reformulation, BANDITSUM takes the document as input and outputs an *affinity* for each of the sentences therein. An affinity is a real number in $[0, 1]$ which quantifies the model's propensity for including a sentence in the summary. These affinities are then used in a process of repeated sampling-without-replacement which does not privilege earlier sentences over later ones. BANDITSUM is free to process the document as a whole before yielding affinities, which permits affinities for different sentences in the document to depend on one another in arbitrary ways. In our technical section, we show how to apply policy gradient reinforcement learning methods to this setting.

The contributions of our work are as follows:

- We propose a theoretically grounded method, based on the contextual bandit formalism, for training neural network-based extractive summarizers with reinforcement learning. Based on this training method, we propose the BANDITSUM system for extractive summarization.
- We perform experiments demonstrating that BANDITSUM obtains state-of-the-art performance on a number of datasets and requires significantly fewer update steps than competing approaches.
- We perform human evaluations showing that in the eyes of human judges, summaries created by BANDITSUM are less redundant and of higher overall quality than summaries created by competing approaches.
- We provide evidence, in the form of experiments in which models are trained on subsets of the data, that the improved performance of BANDITSUM over competitors stems in part from better handling of summary-worthy sentences that come near the end of the document (see Section 7).

2 Related Work

Extractive summarization has been widely studied in the past. Recently, neural network-based methods have been gaining popularity over classical methods (Luhn, 1958; Gong and Liu, 2001; Conroy and O'leary, 2001; Mihalcea and Tarau, 2004; Wong et al., 2008), as they have demonstrated stronger performance on large corpora. Central to the neural network-based models is the encoder-decoder structure. These models typically use either a convolution neural network (Kalchbrenner et al., 2014; Kim, 2014; Yin and Pei, 2015; Cao et al., 2015), a recurrent neural network (Chung et al., 2014; Cheng and Lapata, 2016; Nallapati et al., 2017), or a combination of the two (Narayan et al., 2018; Wu and Hu, 2018) to create sentence and document representations, using word embeddings (Mikolov et al., 2013; Pennington et al.,

2014) to represent words at the input level. These vectors are then fed into a decoder network to generate the output summary.

The use of reinforcement learning (RL) in extractive summarization was first explored by Ryang and Abekawa (2012), who proposed to use the TD(λ) algorithm to learn a value function for sentence selection. Rioux et al. (2014) improved this framework by replacing the learning agent with another TD(λ) algorithm. However, the performance of their methods was limited by the use of shallow function approximators, which required performing a fresh round of reinforcement learning for every new document to be summarized. The more recent work of Paulus et al. (2018) and Wu and Hu (2018) use reinforcement learning in a sequential labeling setting to train abstractive and extractive summarizers, respectively, while Chen and Bansal (2018) combines both approaches, applying abstractive summarization to a set of sentences extracted by a pointer network (Vinyals et al., 2015) trained via REINFORCE. However, pre-training with a maximum likelihood objective is required in all of these models.

The two works most similar to ours are Yao et al. (2018) and Narayan et al. (2018). Yao et al. (2018) recently proposed an extractive summarization approach based on deep Q learning, a type of reinforcement learning. However, their approach is extremely computationally intensive (a minimum of 10 days before convergence), and was unable to achieve ROUGE scores better than the best maximum likelihood-based approach. Narayan et al. (2018) uses a cascade of filters in order to arrive at a set of candidate extractive summaries, which we can regard as an approximation of the true action space. They then use an approximation of a policy gradient method to train their neural network to select summaries from this approximated action space. In contrast, BANDITSUM samples directly from the true action space, and uses exact policy gradient parameter updates.

3 Extractive Summarization as a Contextual Bandit

Our approach formulates extractive summarization as a contextual bandit which we then train an agent to solve using policy gradient reinforcement learning. A bandit is a decision-making formalization in which an agent repeatedly chooses one of several actions, and receives a reward based on this choice. The agent's goal is to quickly learn which action yields the most favorable distribution over rewards, and choose that action as often as possible. In a *contextual* bandit, at each trial, a context is sampled and shown to the agent, after which the agent selects an action and receives a reward; importantly, the rewards yielded by the actions may depend on the sampled context. The agent must quickly learn which actions are favorable in which contexts. Contextual bandits are a subset of Markov Decision Processes in which every episode has length one.

Extractive summarization may be regarded as a contextual bandit as follows. Each document is a context, and each ordered subset of a document's sentences is a different action. Formally, assume that each context is a document d consisting of sentences $s = (s_1, \dots, s_{N_d})$, and that each action is a length-M sequence of unique sentence indices $i = (i_1, \dots, i_M)$ where $i_t \in \{1, \dots, N_d\}$, $i_t \neq i_{t'}$ for $t \neq t'$, and M is an integer hyper-parameter. For each i, the extractive summary induced by i is given by $(s_{i_1}, \dots, s_{i_M})$. An action i taken in context d is given a reward $R(i, a)$, where a is the gold-standard abstractive summary that is paired with document d, and R is a scalar reward function quantifying the degree of match between a and the summary induced by i.

A policy for extractive summarization is a neural network $p_\theta(\cdot|d)$, parameterized by a vector θ, which, for each input document d, yields a probability distribution over index sequences. Our goal is to find parameters θ which cause $p_\theta(\cdot|d)$ to assign high probability to index sequences that induce extractive summaries that a human reader would judge to be of high-quality. We achieve this by maximizing the following objective function with respect to parameters θ:

$$J(\theta) = E\left[R(i, a)\right] \tag{1}$$

where the expectation is taken over documents d paired with gold-standard abstractive summaries a, as well as over index sequences i generated according to $p_\theta(\cdot|d)$.

3.1 Policy Gradient Reinforcement Learning

Ideally, we would like to maximize (1) using gradient ascent. However, the required gradient cannot be obtained using usual techniques (e.g. simple backpropagation) because i must be discretely sampled in order to compute $R(i, a)$.

Fortunately, we can use the likelihood ratio gradient estimator from reinforcement learning and stochastic optimization (Williams, 1992; Sutton et al., 2000), which tells us that the gradient of this function can be computed as:

$$\nabla_\theta J(\theta) = E\left[\nabla_\theta \log p_\theta(i|d) R(i,a)\right] \tag{2}$$

where the expectation is taken over the same variables as (1).

Since we typically do not know the exact document distribution and thus cannot evaluate the expected value in (2), we instead estimate it by sampling. We found that we obtained the best performance when, for each update, we first sample one document/summary pair (d, a), then sample B index sequences $i^1, \ldots, i^B$ from $p_\theta(\cdot|d)$, and finally take the empirical average:

$$\nabla_\theta J(\theta) \approx \frac{1}{B}\sum_{b=1}^{B} \nabla_\theta \log p_\theta(i^b|d) R(i^b, a) \tag{3}$$

This overall learning algorithm can be regarded as an instance of the REINFORCE policy gradient algorithm (Williams, 1992).

3.2 Structure of $p_\theta(\cdot|d)$

There are many possible choices for the structure of $p_\theta(\cdot|d)$; we opt for one that avoids privileging early sentences over later ones. We first decompose $p_\theta(\cdot|d)$ into two parts: π_θ, a deterministic function which contains all the network's parameters, and μ, a probability distribution parameterized by the output of π_θ. Concretely:

$$p_\theta(\cdot|d) = \mu(\cdot|\pi_\theta(d)) \tag{4}$$

Given an input document d, π_θ outputs a real-valued vector of *sentence affinities* whose length is equal to the number of sentences in the document (i.e. $\pi_\theta(d) \in \mathbb{R}^{N_d}$) and whose elements fall in the range $[0, 1]$. The t-th entry $\pi(d)_t$ may be roughly interpreted as the network's propensity to include sentence s_t in the summary of d.

Given sentence affinities $\pi_\theta(d)$, μ implements a process of repeated sampling-without-replacement. This proceeds by repeatedly normalizing the set of affinities corresponding to sentences that have not yet been selected, thereby obtaining a probability distribution over unselected sentences, and sampling from that distribution to obtain a new sentence to include. This normalize-and-sample step is repeated M times, yielding M unique sentences to include in the summary.

At each step of sampling-without-replacement, we also include a small probability ϵ of sampling uniformly from all remaining sentences. This is used to achieve adequate exploration during training, and is similar to the ϵ-greedy technique from reinforcement learning.

Under this sampling scheme, we have the following expression for $p_\theta(i|d)$:

$$\prod_{j=1}^{M}\left(\frac{\epsilon}{N_d - j + 1} + \frac{(1-\epsilon)\pi(d)_{i_j}}{z(d) - \sum_{k=1}^{j-1}\pi(d)_{i_k}}\right) \tag{5}$$

where $z(d) = \sum_t \pi(d)_t$. For index sequences that have length different from M, or that contain duplicate indices, we have $p_\theta(i|d) = 0$. Using this expression, it is straightforward to use automatic differentiation software to compute $\nabla_\theta \log p_\theta(i|d)$, which is required for the gradient estimate in (3).

3.3 Baseline for Variance Reduction

Our sample-based gradient estimate can have high variance, which can slow the learning. One potential cause of this high variance can be seen by inspecting (3), and noting that it basically acts to change the probability of a sampled index sequence to an extent determined by the reward $R(i, a)$. However, since ROUGE scores are always positive, the probability of every sampled index sequence is increased, whereas intuitively, we would prefer to decrease the probability of sequences that receive a comparatively low reward, even if it is positive. This can be remedied by the introduction of a so-called baseline which is subtracted from all rewards.

Using a baseline $\overline{r}$, our sample-based estimate of $\nabla_\theta J(\theta)$ becomes:

$$\frac{1}{B}\sum_{i=1}^{B} \nabla_\theta \log p_\theta(i^b|d)(R(i^b, a) - \overline{r}) \tag{6}$$

It can be shown that the introduction of $\overline{r}$ does not bias the gradient estimator and can significantly reduce its variance if chosen appropriately (Sutton et al., 2000).

There are several possibilities for the baseline, including the long-term average reward and the average reward across different samples for one document-summary pair. We choose an approach known as self-critical reinforcement learning, in which the test-time performance of the current model is used as the baseline (Ranzato et al., 2015;

Rennie et al., 2017; Paulus et al., 2018). More concretely, after sampling the document-summary pair (d, a), we greedily generate an index sequence using the current parameters θ:

$$i_{greedy} = \arg\max_{i} p_\theta(i|d) \tag{7}$$

and calculate the baseline for the current update as $\bar{r} = R(i_{greedy}, a)$. This baseline has the intuitively satisfying property of only increasing the probability of a sampled label sequence when the summary it induces is better than what would be obtained by greedy decoding.

3.4 Reward Function

A final consideration is a concrete choice for the reward function $R(i, a)$. Throughout this work we use:

$$R(i, a) = \frac{1}{3}(\text{ROUGE-1}_f(i, a) + \text{ROUGE-2}_f(i, a) + \text{ROUGE-L}_f(i, a)). \tag{8}$$

The above reward function optimizes the average of all the ROUGE variants (Lin, 2004) while balancing precision and recall.

4 Model

In this section, we discuss the concrete instantiations of the neural network π_θ that we use in our experiments. We break π_θ up into two components: a document encoder $f_{\theta 1}$, which outputs a sequence of sentence feature vectors $(h_1, \ldots, h_{N_d})$ and a decoder $g_{\theta 2}$ which yields sentence affinities:

$$h_1, \ldots, h_{N_d} = f_{\theta 1}(d) \tag{9}$$

$$\pi_\theta(d) = g_{\theta 2}(h_1, \ldots, h_{N_d}) \tag{10}$$

Encoder. Features for each sentence in isolation are first obtained by applying a word-level Bidirectional Recurrent Neural Network (BiRNN) to the embeddings for the words in the sentence, and averaging the hidden states over words. A separate sentence-level BiRNN is then used to obtain a representations h_i for each sentence in the context of the document.

Decoder. A multi-layer perceptron is used to map from the representation h_t of each sentence through a final sigmoid unit to yield sentence affinities $\pi_\theta(d)$.

The use of a bidirectional recurrent network in the encoder is crucial, as it allows the network to process the document as a whole, yielding representations for each sentence that take all other sentences into account. This procedure is necessary to deal with some aspects of summary quality such as redundancy (avoiding the inclusion of multiple sentences with similar meaning), which requires the affinities for different sentences to depend on one another. For example, to avoid redundancy, if the affinity for some sentence is high, then sentences which express similar meaning should have low affinities.

5 Experiments

In this section, we discuss the setup of our experiments. We first discuss the corpora that we used and our evaluation methodology. We then discuss the baseline methods against which we compared, and conclude with a detailed overview of the settings of the model parameters.

5.1 Corpora

Three datasets are used for our experiments: the CNN, the Daily Mail, and combined CNN/Daily Mail (Hermann et al., 2015; Nallapati et al., 2016). We use the standard split of Hermann et al. (2015) for training, validating, and testing and the same setting without *anonymization* on the three corpus as See et al. (2017). The Daily Mail corpus has 196,557 training documents, 12,147 validation documents and 10,397 test documents; while the CNN corpus has 90,266/1,220/1,093 documents, respectively.

5.2 Evaluation

The models are evaluated based on ROUGE (Lin, 2004). We obtain our ROUGE scores using the standard pyrouge package[1] for the test set evaluation and a faster python implementation of the ROUGE metric[2] for training and evaluating on the validation set. We report the F1 scores of ROUGE-1, ROUGE-2, and ROUGE-L, which compute the uniform, bigram, and longest common subsequence overlapping with the reference summaries.

5.3 Baselines

We compare BANDITSUM with other extractive methods including: the Lead-3 model, SummaRuNNer (Nallapati et al., 2017), Refresh

---

[1] https://pypi.python.org/pypi/pyrouge/0.1.3

[2] We use the modified version based on https://github.com/pltrdy/rouge

(Narayan et al., 2018), RNES (Wu and Hu, 2018), DQN (Yao et al., 2018), and NN-SE (Cheng and Lapata, 2016). The Lead-3 model simply produces the leading three sentences of the document as the summary.

5.4 Model Settings

We use 100-dimensional Glove embeddings (Pennington et al., 2014) as our embedding initialization. We do not limit the sentence length, nor the maximum number of sentences per document. We use one-layer BiLSTM for word-level RNN, and two-layers BiLSTM for sentence-level RNN. The hidden state dimension is 200 for each direction on all LSTMs. For the decoder, we use a feed-forward network with one hidden layer of dimension 100.

During training, we use Adam (Kingma and Ba, 2015) as the optimizer with the learning rate of $5e^{-5}$, beta parameters $(0, 0.999)$, and a weight decay of $1e^{-6}$, to maximize the objective function defined in equation (1). We employ gradient clipping of 1 to regularize our model. At each iteration, we sample $B = 20$ times to estimate the gradient defined in equation 3. For our system, the reported performance is obtained within two epochs of training[3].

At the test time, we pick sentences sorted by the predicted probabilities until the length limit is reached. The full-length ROUGE F1 score is used as the evaluation metric. For M, the number of sentences selected per summary, we use a value of 3, based on our validation results as well as on the settings described in Nallapati et al. (2017).

6 Experiment Results

In this section, we present quantitative results from the ROUGE evaluation and qualitative results based on human evaluation. In addition, we demonstrate the stability of our RL model by comparing the validation curve of BanditSum with SummaRuNNer (Nallapati et al., 2017) trained with a maximum likelihood objective.

6.1 Rouge Evaluation

Model	ROUGE		
	1	2	L
Lead(Narayan et al., 2018)	39.6	17.7	36.2
Lead-3(ours)	40.0	17.5	36.2
SummaRuNNer	39.6	16.2	35.3
DQN	39.4	16.1	35.6
Refresh	40.0	18.2	36.6
RNES w/o coherence	41.3	**18.9**	**37.6**
BanditSum	**41.5**	18.7	**37.6**

Table 1: Performance comparison of different extractive summarization models on the combined CNN/Daily Mail test set using full-length F1.

Model	CNN			Daily Mail		
	1	2	L	1	2	L
Lead-3	28.8	11.0	25.5	41.2	18.2	37.3
NN-SE	28.4	10.0	25.0	36.2	15.2	32.9
Refresh	30.4	**11.7**	26.9	41.0	18.8	37.7
BanditSum	**30.7**	11.6	**27.4**	**42.1**	**18.9**	**38.3**

Table 2: The full-length ROUGE F1 scores of various extractive models on the CNN and the Daily Mail test set separately.

We present the results of comparing BanditSum to several baseline algorithms[4] on the CNN/Daily Mail corpus in Tables 1 and 2. Compared to other extractive summarization systems, BanditSum achieves performance that is significantly better than two RL-based approaches, Refresh (Narayan et al., 2018) and DQN (Yao et al., 2018), as well as SummaRuNNer, the state-of-the-art maximum liklihood-based extractive summarizer (Nallapati et al., 2017). BanditSum performs a little better than RNES (Wu and Hu, 2018) in terms of ROUGE-1 and slightly worse in terms of ROUGE-2. However, RNES requires pre-training with the maximum likelihood objective on heuristically-generated extractive labels; in contrast, BanditSum is very light-weight and converges significantly faster. We discuss the advantage of framing the extractive summarization based on the contextual bandit (BanditSum) over the sequential binary labeling setting (RNES) in the discussion Section 7.

We also noticed that different choices for the policy gradient baseline (see Section 3.3) in BanditSum affect learning speed, but do not significantly affect asymptotic performance. Models trained with an average reward baseline learned most quickly, while models trained with three different baselines (greedy, average reward in a

---

[3] Our code can be found at `https://github.com/yuedongP/summarization_RL`

[4] Due to different pre-processing methods and different numbers of selected sentences, several papers report different Lead scores (Narayan et al., 2018; See et al., 2017). We use the test set provided by Narayan et al. (2018). Since their Lead score is a combination of Lead-3 for CNN and Lead-4 for Daily Mail, we recompute the Lead-3 scores for both CNN and Daily Mail with the preprocessing steps used in See et al. (2017). Additionally, our results are not directly comparable to results based on the anonymized dataset used by Nallapati et al. (2017).

batch, average global reward) all perform roughly the same after training for one epoch. Models trained without a baseline were found to underperform other baseline choices by about 2 points of ROUGE score on average.

6.2 Human Evaluation

We also conduct a qualitative evaluation to understand the effects of the improvements introduced in BANDITSUM on human judgments of the generated summaries. To assess the effect of training with RL rather than maximum likelihood, in the first set of human evaluations we compare BANDITSUM with the state-of-the-art maximum likelihood-based model SummaRuNNer. To evaluate the importance of using an exact, rather than approximate, policy gradient to optimize ROUGE scores, we perform another human evaluation comparing BANDITSUM and Refresh, an RL-based method that uses the an approximation of the policy gradient.

We follow a human evaluation protocol similar to the one used in Wu and Hu (2018). Given a set of N documents, we ask K volunteers to evaluate the summaries extracted by both systems. For each document, a reference summary, and a pair of randomly ordered extractive summaries (one generated by each of the two models) is presented to the volunteers. They are asked to compare and rank the extracted summaries along three dimensions: overall, coverage, and non-redundancy.

Model	Overall	Coverage	Non-Redundancy
SummaRuNNer	1.67	**1.46**	1.70
BANDITSUM	**1.33**	1.54	**1.30**

Table 3: Average rank of human evaluation based on 5 participants who expressed 57 pairwise preferences between the summaries generated by SummaRuNNer and BANDITSUM. The model with the lower score is better.

Model	Overall	Coverage	Non-Redundancy
Refresh	1.53	**1.34**	1.55
BANDITSUM	**1.50**	1.58	**1.30**

Table 4: Average rank of manual evaluation with 4 participants who expressed 20 pairwise preferences between the summaries generated by Refresh and our system. The model with the lower score is better.

To compare with SummaRuNNer, we randomly sample 57 documents from the test set of DailyMail and ask 5 volunteers to evaluate the extracted summaries. While comparing with Refresh, we use the 20 documents (10 CNN and 10 DailyMail) provided by Narayan et al. (2018) to 4 volunteers. Tables 3 and 4 show the results of human evaluation in these two settings. BANDITSUM is shown to be better than Refresh and SummaRuNNer in terms of overall quality and non-redundancy. These results indicate that the use of the true policy gradient, rather than the approximation used by Refresh, improves overall quality. It is interesting to observe that, even though BANDITSUM does not have an explicit redundancy avoidance mechanism, it actually outperforms the other systems on non-redundancy.

6.3 Learning Curve

Reinforcement learning methods are known for sometimes being unstable during training. However, this seems to be less of a problem for BANDITSUM, perhaps because it is formulated as a contextual bandit rather than a sequential labeling problem. We show this by comparing the validation curves generated by BANDITSUM and the state-of-the-art maximum likelihood-based model – SummaRuNNer (Nallapati et al., 2017) (Figure 1).

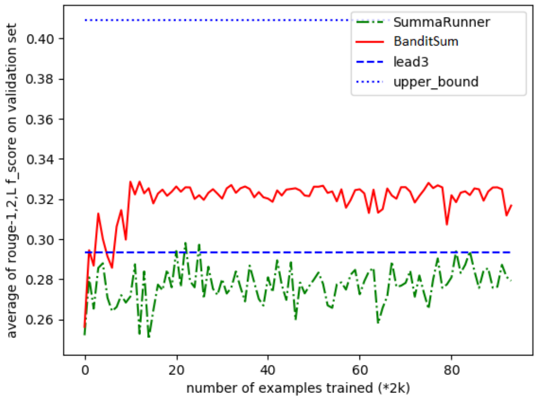

Figure 1: Average of ROUGE-1,2,L F1 scores on the Daily Mail validation set within one epoch of training on the Daily Mail training set. The x-axis (multiply by 2,000) indicates the number of data example the algorithms have seen. The supervised labels in SummaRuNNer are used to estimate the `upper_bound`.

From Figure 1, we observe that BANDITSUM converges significantly more quickly to good results than SummaRuNNer. Moreover, there is less variance in the performance of BANDITSUM.

One possible reason is that extractive summarization does not have well-defined supervised labels. There exists a mismatch between the provided labels and human-generated abstractive summaries. Hence, the gradient, computed from the maximum likelihood loss function, is not optimizing the evaluation metric of interest. Another important message is that both models are still far from the estimated upper bound[5], which shows that there is still significant room for improvement.

6.4 Run Time

On CNN/Daily mail dataset, our model's time-per-epoch is about 25.5 hours on a TITAN Xp. We trained the model for 3 epochs, which took about 76 hours in total. For comparison, DQN took about 10 days to train on a GTX 1080 (Yao et al., 2018). Refresh took about 12 hours on a single GPU to train (Narayan et al., 2018). Note that this figure does not take into account the significant time required by Refresh for pre-computing ROUGE scores.

7 Discussion: Contextual Bandit Setting Vs. Sequential Full RL Labeling

We conjecture that the contextual bandit (CB) setting is a more suitable framework for modeling extractive summarization than the sequential binary labeling setting, especially in the cases when good summary sentences appear later in the document. The intuition behind this is that models based on the sequential labeling setting are affected by the order of the decisions, which biases towards selecting sentences that appear earlier in the document. By contrast, our CB-based RL model has more flexibility and freedom to explore the search space, as it samples the sentences without replacement based on the affinity scores. Note that although we do not explicitly make the selection decisions in a sequential fashion, the sequential information about dependencies between sentences is implicitly embedded in the affinity scores, which are produced by bi-directional RNNs.

We provide empirical evidence for this conjecture by comparing BANDITSUM to the sequential RL model proposed by Wu and Hu (2018) (Figure 2) on two subsets of the data: one with good summary sentences appearing early in the article, while the other contains articles where good summary sentences appear late. Specifically, we construct two evaluation datasets by selecting the first 50 documents (D_{early}, i.e., best summary occurs early) and the last 50 documents (D_{late}, i.e., best summary occurs late) from a sample of 1000 documents that is ordered by the average extractive label index $\overline{idx}$. Given an article with n sentences indexed from $1, \dots, n$ and a greedy extractive labels set with three sentences (i, j, k)[6], the average index for the extractive label is computed by $\overline{idx} = (i + j + k)/3n$.

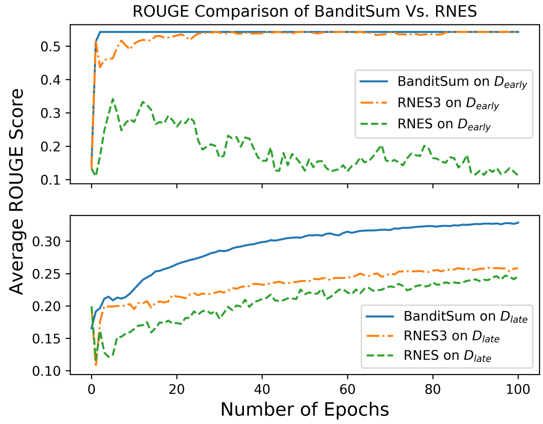

Figure 2: Model comparisons of the average value for ROUGE-1,2,L F1 scores ($\overline{f}$) on D_{early} and D_{late}. For each model, the results were obtained by averaging $\overline{f}$ across ten trials with 100 epochs in each trail. D_{early} and D_{late} consist of 50 articles each, such that the good summary sentences appear early and late in the article, respectively. We observe a significant advantage of BANDITSUM compared to RNES and RNES3 (based on the sequential binary labeling setting) on D_{late}.

Given these two subsets of the data, three different models (BANDITSUM, RNES and RNES3) are trained and evaluated on each of the two datasets without extractive labels. Since the original sequential RL model (RNES) is unstable without supervised pre-training, we propose the RNES3 model that is limited to select no more then three sentences. Starting with random initializations without supervised pre-training, we train each model ten times for 100 epochs and plot the learning curve of the average ROUGE-F1 score computed based on the trained model in Figure 2. We can clearly see that BANDITSUM finds a better so-

---

[5] The supervised labels for the `upper_bound` estimation are obtained using the heuristic described in Nallapati et al. (2017).

[6] For each document, a length-3 extractive summary with near-optimal ROUGE score is selected following the heuristic proposed by Nallapati et al. (2017).

lution more quickly than RNES and RNES3 on both datasets. Moreover, it displays a significantly speed-up in the exploration and finds the best solution when good summary sentences appeared later in the document (D_{late}).

8 Conclusion

In this work, we presented a contextual bandit learning framework, BANDITSUM , for extractive summarization, based on neural networks and reinforcement learning algorithms. BANDITSUM does not require sentence-level extractive labels and optimizes ROUGE scores between summaries generated by the model and abstractive reference summaries. Empirical results show that our method performs better than or comparable to state-of-the-art extractive summarization models which must be pre-trained on extractive labels, and converges using significantly fewer update steps than competing approaches. In future work, we will explore the direction of adding an extra coherence reward (Wu and Hu, 2018) to improve the quality of extracted summaries in terms of sentence discourse relation.

A Word-Complexity Lexicon and A Neural Readability Ranking Model for Lexical Simplification

Mounica Maddela and **Wei Xu**
Department of Computer Science and Engineering
The Ohio State University
{maddela.4, xu.1265}@osu.edu

Abstract

Current lexical simplification approaches rely heavily on heuristics and corpus level features that do not always align with human judgment. We create a human-rated word-complexity lexicon of 15,000 English words and propose a novel neural readability ranking model with a Gaussian-based feature vectorization layer that utilizes these human ratings to measure the complexity of any given word or phrase. Our model performs better than the state-of-the-art systems for different lexical simplification tasks and evaluation datasets. Additionally, we also produce SimplePPDB++, a lexical resource of over 10 million simplifying paraphrase rules, by applying our model to the Paraphrase Database (PPDB).[1]

1 Introduction

Lexical simplification is an important subfield that is concerned with the complexity of words or phrases, and particularly how to measure readability and reduce the complexity using alternative paraphrases. There are three major lexical simplification tasks which effectively resemble a pipeline: (i) Complex Word Identification (Paetzold and Specia, 2016a; Yimam et al., 2017; Shardlow, 2013b) which involves identifying complex words in the sentence; (ii) Substitution Generation (Glavaš and Štajner, 2015; Coster and Kauchak, 2011) which involves finding alternatives to complex words or phrases; and (iii) Substitution Ranking (Specia et al., 2012) which involves ranking the paraphrases by simplicity. Lexical simplification also has practical real-world uses, such as displaying alternative expressions of complex words as reading assistance for children (Kajiwara et al., 2013), non-native speakers (Petersen and Ostendorf, 2007; Pellow and Eskenazi, 2014), lay readers (Elhadad and Sutaria, 2007; Siddharthan and Katsos, 2010), or people with reading disabilities (Rello et al., 2013).

Most current approaches to lexical simplification heavily rely on corpus statistics and surface level features, such as word length and corpus-based word frequencies (read more in §5). Two of the most commonly used assumptions are that simple words are associated with shorter lengths and higher frequencies in a corpus. However, these assumptions are not always accurate and are often the major source of errors in the simplification pipeline (Shardlow, 2014). For instance, the word *foolishness* is simpler than its meaning-preserving substitution *folly* even though *foolishness* is longer and less frequent in the Google 1T Ngram corpus (Brants and Franz, 2006). In fact, we found that 21% of the 2272 meaning-equivalent word pairs randomly sampled from PPDB[2] (Ganitkevitch et al., 2013) had the simpler word longer than the complex word, while 14% had the simpler word less frequent.

To alleviate these inevitable shortcomings of corpus and surface-based methods, we explore a simple but surprisingly unexplored idea – creating an English lexicon of 15,000 words with word-complexity ratings by humans. We also propose a new neural readability ranking model with a Gaussian-based feature vectorization layer, which can effectively exploit these human ratings as well as other numerical features to measure the complexity of any given word or phrase (including those outside the lexicon and/or with sentential context). Our model significantly outperforms the state-of-the-art on the benchmark SemEval-2012 evaluation for Substitution Ranking (Specia et al.,

Brussels, Belgium, October 31 - November 4, 2018.

2012; Paetzold and Specia, 2017), with or without using the manually created word-complexity lexicon, achieving a Pearson correlation of 0.714 and 0.702 respectively. We also apply the new ranking model to identify lexical simplifications (e.g., *commemorate* → *celebrate*) among the large number of paraphrase rules in PPDB with improved accuracy compared to previous work for Substitution Generation. At last, by utilizing the word-complexity lexicon, we establish a new state-of-the-art on two common test sets for Complex Word Identification (Paetzold and Specia, 2016a; Yimam et al., 2017). We make our code, the word-complexity lexicon, and a lexical resource of over 10 million paraphrase rules with improved readability scores (namely SimplePPDB++) all publicly available.

2 Constructing A Word-Complexity Lexicon with Human Judgments

We first constructed a lexicon of 15,000 English words with word-complexity scores assessed by human annotators.[3] Despite the actual larger English vocabulary size, we found that rating the most frequent 15,000 English words in Google 1T Ngram Corpus[4] was effective for simplification purposes (see experiments in §4) as our neural ranking model (§3) can estimate the complexity of any word or phrase even out-of-vocabulary.

We asked 11 non-native but fluent English speakers to rate words on a 6-point Likert scale. We found that an even number 6-point scale worked better than a 5-point scale in a pilot experiment with two annotators, as the 6-point scheme allowed annotators to take a natural two-step approach: first determine whether a word is simple or complex; then decide whether it is 'very simple' (or 'very complex'), 'simple' (or 'complex'), or 'moderately simple' (or 'moderately complex'). For words with multiple capitalized versions (e.g., *nature*, *Nature*, *NATURE*), we displayed the most frequent form to the annotators. We also asked the annotators to indicate the words for which they had trouble assessing their complexity due to ambiguity, lack of context or any other reason. All the annotators reported little difficulty, and explained possible reasons such as that word *bug* is simple regardless of its meaning as an *insect* in biology or an *error* in computer software.[5]

Word	**Avg**	**A1**	**A2**	**A3**	**A4**	**A5**
watch	1.0	1	1	1	1	1
muscles	1.6	2	1	2	2	1
sweatshirts	1.8	2	1	2	3	1
giant	2.0	2	3	1	1	3
pattern	2.4	2	3	2	3	2
Christianity	2.8	3	2	2	3	4
educational	3.2	3	3	3	3	4
revenue	3.6	4	4	3	3	4
cortex	4.2	4	4	4	4	5
crescent	4.6	5	5	5	5	3
Memorabilia	5.4	5	6	6	5	5
assay	5.8	6	6	6	5	6

Table 1: Word-Complexity lexicon consists of English words and their complexity scores obtained by averaging over human ratings. A1, A2, A3, A4 and A5 are ratings by five different annotators on a 6-point Likert scale (1 is the simplest and 6 is the most complex).

With our hired annotators, we were able to have most annotators complete half or the full list of 15,000 words for better consistency, and collected between 5 and 7 ratings for each word. It took most annotators about 2 to 2.5 hours to rate 1,000 words. Table 1 shows few examples from the lexicon along with their human ratings.

In order to assess the annotation quality, we computed the Pearson correlation between each annotator's annotations and the average of the rest of the annotations (Agirre et al., 2014). For our final word-complexity lexicon, we took an average of the human ratings for each word, discarding those (about 3%) that had a difference ≥ 2 from the mean of the rest of the ratings. The overall inter-annotator agreement improved from 0.55 to 0.64 after discarding the outlying ratings. For the majority of the disagreements, the ratings of one annotator and the mean of the rest were fairly close: the difference is ≤ 0.5 for 47% of the annotations; ≤ 1.0 for 78% of the annotations; and ≤ 1.5 for 93% of the annotations on the 6-point scale. We hired annotators of different native languages intentionally, which may have contributed to the variance in the judgments.[6] We leave further investigation and possible crowdsourcing annotation to future work.

---

[3] Download at `https://github.com/mounicam/lexical_simplification`

[4] `https://catalog.ldc.upenn.edu/ldc2006t13`

[5] The word-happiness lexicon (Dodds et al., 2011) of 10,222 words was also similarly created by human rating on the most frequent words without context or word-sense disambiguation.

[6] One recent work similarly observed lower inter-annotator agreement among non-native speakers than native speakers when asked to identify complex words in given text paragraphs (Yimam et al., 2017).

3 Neural Readability Ranking Model for Words and Phrases

In order to predict the complexity of any given word or phrase, within or outside the lexicon, we propose a Neural Readability Ranking model that can leverage the created word-complexity lexicon and take context (if available) into account to further improve performance. Our model uses a Gaussian-based vectorization layer to exploit numerical features more effectively and can outperform the state-of-the-art approaches on multiple lexical simplification tasks with or without the word-complexity lexicon. We describe the general model framework in this section, and task-specific configurations in the experiment section (§4).

3.1 Neural Readability Ranker (NRR)

Given a pair of words/phrases $\langle w_a, w_b \rangle$ as input, our model aims to output a real number that indicates the relative complexity $P(y|\langle w_a, w_b \rangle)$ of w_a and w_b. If the output value is negative, then w_a is simpler than w_b and vice versa. Figure 1 shows the general architecture of our ranking model highlighting the three main components:

1. An input **feature extraction layer** (§3.2) that creates lexical and corpus-based features for each input $f(w_a)$ and $f(w_b)$, and pairwise features $f(\langle w_a, w_b \rangle)$. We also inject the word-complexity lexicon into the model as a numerical feature plus a binary indicator.
2. A **Gaussian-based feature vectorization layer** (§3.3) that converts each numerical feature, such as the lexicon scores and n-gram probabilities, into a vector representation by a series of Gaussian radial basis functions.
3. A feedforward neural network performing regression with one **task-specific output node** that adapts the model to different lexical simplification tasks (§4).

Our model first processes each input word or phrase in parallel, producing vectorized features. All the features are then fed into a joint feedforward neural network.

3.2 Features

We use a combination of rating scores from the word-complexity lexicon, lexical and corpus features (Pavlick and Callison-Burch, 2016) and collocational features (Paetzold and Specia, 2017).

We inject the word-complexity lexicon into the NRR model by adding two features for each input word or phrase: a 0-1 binary feature representing the presence of a word (the longest word in a multi-word phrase) in the lexicon, and the corresponding word complexity score. For out-of-vocabulary words, both features have the value 0. We back-off to the complexity score of the lemmatized word if applicable. We also extract the following features: phrase length in terms of words and characters, number of syllables, frequency with respect to Google Ngram corpus (Brants and Franz, 2006), the relative frequency in Simple Wikipedia with respect to normal Wikipedia (Pavlick and Nenkova, 2015) and ngram probabilities from a 5-gram language model trained on the SubIMDB corpus (Paetzold and Specia, 2016c), which has been shown to work well for lexical simplification. For a word w, we take language model probabilities of all the possible n-grams within the context window of 2 to the left and right of w. When w is a multi-word phrase, we break w into possible n-grams and average the probabilities for a specific context window.

For an input pair of words/phrases $\langle w_a, w_b \rangle$, we include individual features $f(w_1)$, $f(w_2)$ and the differences $f(w_a) - f(w_b)$. We also use pairwise features $f(\langle w_a, w_b \rangle)$ including cosine similarity $cos(\overrightarrow{w}_a, \overrightarrow{w}_b)$ and the difference $\overrightarrow{w}_a - \overrightarrow{w}_b$ between the word2vec (Mikolov et al., 2013) embedding of the input words. The embeddings for a mutli-word phrase are obtained by averaging the embeddings of all the words in the phrase. We use the 300-dimensional embeddings pretrained on the Google News corpus, which is released as part of the word2vec package.[7]

3.3 Vectorizing Numerical Features via Gaussian Binning

Our model relies primarily on numerical features as many previous approaches for lexical simplification. Although these continuous features can be directly fed into the network, it is helpful to exploit fully the nuanced relatedness between different intervals of feature values.

We adopt a smooth binning approach and project each numerical feature into a vector representation by applying multiple Gaussian radial basis functions. For each feature f, we divide its

---

[7] `https://code.google.com/archive/p/word2vec/`

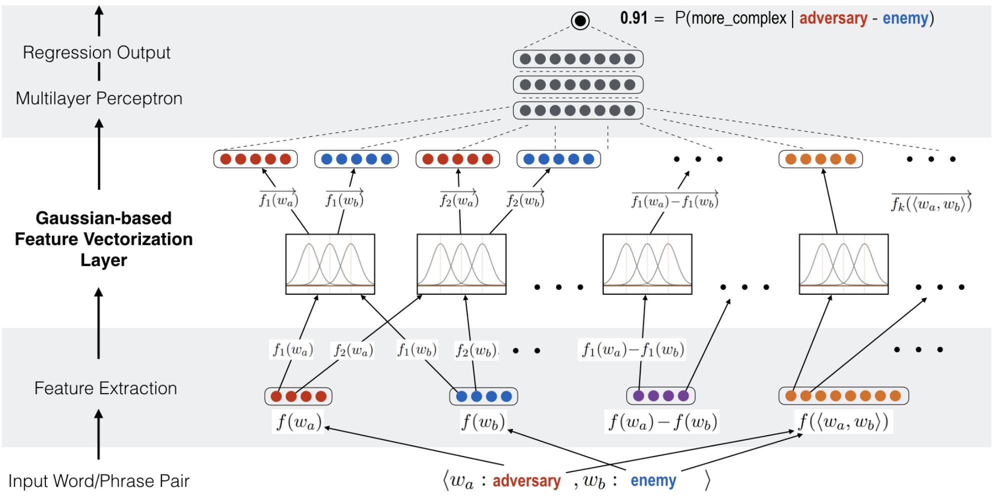

Figure 1: The neural readability ranking (NRR) model.

value range $[f_{min}, f_{max}]$ evenly into k bins and place a Gaussian function for each bin with the mean μ_j ($j \in \{1, 2, \dots, k\}$) at the center of the bin and standard deviation σ. We specify σ as a fraction γ of bin width:

$$\sigma = \frac{1}{k}(f_{max} - f_{min}) \cdot \gamma \tag{1}$$

where γ is a tunable hyperparameter in the model. For a given feature value $f(\cdot)$, we then compute the distance to each bin as follows:

$$d_j(f(\cdot)) = e^{-\frac{(f(\cdot)-\mu_j)^2}{2\sigma^2}} \tag{2}$$

and normalize to project into a k-dimensional vector $\overrightarrow{f(\cdot)} = (d_1, d_2, \dots, d_k)$.

We vectorize all the features except word2vec vectors, $\overrightarrow{f(w_a)}$, $\overrightarrow{f(w_b)}$, $\overrightarrow{f(w_a)-f(w_b)}$, and $\overrightarrow{f(\langle w_a, w_b\rangle)}$, then concatenate them as inputs. Figure 2 presents a motivating t-SNE visualization of the word-complexity scores from the lexicon after the vectorization in our NRR model, where different feature value ranges are gathered together with some distances in between.

3.4 Training and Implementation Details

We use PyTorch framework to implement the NRR model, which consists of an input layer, three hidden layers with eight nodes in each layer and the *tanh* activation function, and a single node linear output layer. The training objective is to minimize the Mean Squared Error (MSE):

$$L(\theta) = \frac{1}{m}\sum_{i=1}^{m}(y_i - \hat{y}_i)^2 \tag{3}$$

where y_i and $\hat{y}_i$ are the true and predicted relative complexity scores of $\langle w_a, w_b\rangle$ which can be configured accordingly for different lexical simplification tasks and datasets, m is the number of training examples, and θ is the set of parameters of the NRR model. We use Adam algorithm (Kingma and Ba, 2014) for optimization and also apply a dropout of 0.2 to prevent overfitting. We set the rate to 0.0005 and 0.001 for experiments in (§4.1) and (§4.2) respectively. For Gaussian binning layer, we set the number of bins k to 10 and γ to 0.2 without extensive parameter tuning. For each experiment,we report results with 100 epochs.

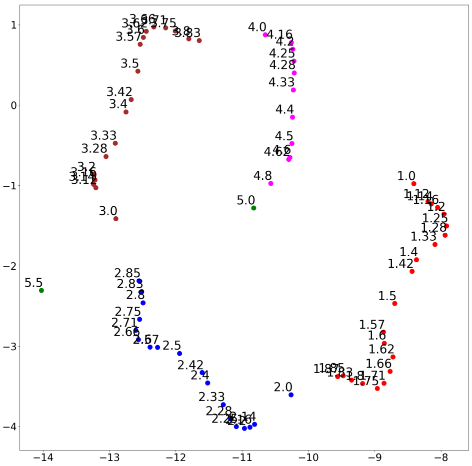

Figure 2: t-SNE visualization of the complexity scores, ranging between 1.0 and 5.0, of 300 random words from the word-complexity lexicon vectorized into 10-dimensional representations by applying Gaussian radial basis functions.

4 Lexical Simplification Applications

As the lexical simplification research field traditionally studies multiple sub-tasks and datasets, we present a series of experiments to demonstrate the effectiveness of our newly created lexicon and neural readability ranking (NRR) model.

4.1 Substitution Ranking

Given an instance consisting of a target complex word in a sentence and a set of candidate substitutions, the goal of the Substitution Ranking task is to rank the candidates in the order of their simplicity. In this section, we show that our proposed NRR model outperforms the state-of-the-art neural model on this task, with or without using the word-complexity lexicon.

Data. We use the dataset from the English Lexical Simplification shared-task at SemEval 2012 (Specia et al., 2012) for evaluation. The training and test sets consist of 300 and 1,710 instances, respectively, with a total of 201 target words (all single word, mostly polysemous) and each in 10 different sentences. One example of such instance contains a target complex word in context:

> *When you think about it, that's pretty terrible.*

and a set of candidate substitutions {*bad*, *awful*, *deplorable*}. Each instance contains at least 2 and an average of 5 candidates to be ranked. There are a total of 10034 candidates in the dataset, 88.5% of which are covered by our word-complexity lexicon and 9.9% are multi-word phrases (3438 unique candidates with 81.8% in-vocabulary and 20.2% multi-word).

Task-specific setup of the NRR model. We train the NRR model with every pair of candidates $\langle c_a, c_b \rangle$ in a candidate set as the input, and the difference of their ranks $r_a - r_b$ as the ground-truth label. For each such pair, we also include another training instance with $\langle c_b, c_a \rangle$ as the input and $r_b - r_a$ as the label. Given a test instance with candidate set C, we rank the candidates as follows: for every pair of candidates $\langle c_a, c_b \rangle$, the model predicts the relative complexity score $S(c_a, c_b)$; we then compute a single score $R(c_a) = \sum_{c_a \neq c_b \in C} S(c_a, c_b)$ for each candidate by aggregating pairwise scores and rank the candidates in the increasing order of these scores.

Comparison to existing methods. We compare with the state-of-the-art neural model (Paetzold and Specia, 2017) for substitution ranking with the best reported results on the SemEval 2012 dataset. Our baselines also include several other existing methods: Biran et al. (2011), Kajiwara et al. (2013), and Glavaš & Štajner (2015), which use carefully designed heuristic scoring functions to combine various information such as corpus statistics and semantic similarity measures from WordNet; Horn et al. (2014) and the Boundary Ranker (Paetzold and Specia, 2015), which respectively use a supervised SVM ranking model and pairwise linear classification model with various features. All of these methods have been implemented as part of the LEXenstein toolkit (Paetzold and Specia, 2015), which we use for the experimental comparisons here. In addition, we also compare to the best system (Jauhar and Specia, 2012) among participants at SemEval 2012, which used SVM-based ranking.

	P@1	Pearson
Biran et al. (2011)	51.3	0.505
Jauhar & Specia (2012)	60.2	0.575

Table 2: Substitution Ranking evaluation on English Lexical Simplification shared-task of SemEval 2012. P@1 and Pearson correlation of our neural readability ranking (NRR) model compared to the state-of-the-art neural model (Paetzold and Specia, 2017) and other methods. $*$ indicates statistical significance ($p < 0.05$) compared to the best performing baseline (Paetzold and Specia, 2017).

Results. Table 2 compares the performances of our NRR model to the state-of-the-art results reported by Paetzold and Specia (2017). We use precision of the simplest candidate (P@1) and Pearson correlation to measure performance. P@1 is equivalent to TRank (Specia et al., 2012), the official metric for the SemEval 2012 English Lexical Simplification task. While P@1 captures the practical utility of an approach, Pearson correlation indicates how well the system's rankings correlate with human judgment. We train our NRR model with all the features (NRR$_{all}$) mentioned in §3.2 except the word2vec embedding features to avoid overfitting on the small training set. Our full model (NRR$_{all+binning+WC}$) exhibits a statistically significant improvement over the state-of-

paraphrases of ***'modification'*** ranked by simplicity	
SimplePPDB	*tweak, modify, process, variable, layout*

SimplePPDB++	*cluster, pool, collection, addition, grouping*
paraphrases of ***'of transnational corporation'***	
SimplePPDB	*of corporation, by corporation, of enterprise, of tncs, of business*
SimplePPDB++	*of business, of firm, of corporation, of company, of enterprise*
paraphrases of ***'should reject'***	
SimplePPDB	*refuse, discard, repudiate, shun, dismiss*
SimplePPDB++	*vote against, set aside, throw out, say no to, turn away*

Table 3: SimplePPDB++ includes lexical and phrasal paraphrases with improved readability ranking scores by our NRR$_{all+binning+WC}$ model. Shown are the top 5 ranked simplifications according to SimplePPDB++ for several input words/phrases, in comparison to the previous work of SimplePPDB (Pavlick and Callison-Burch, 2016).

the-art for both measures. We use paired bootstrap test (Berg-Kirkpatrick et al., 2012; Efron and Tibshirani, 1993) as it can be applied to any performance metric. We also conducted ablation experiments to show the effectiveness of the Gaussian-based feature vectorization layer ($_{+binning}$) and the word-complexity lexicon ($_{+WC}$).

4.2 SimplePPDB++

We also can apply our NRR model to rank the lexical and phrasal paraphrase rules in the Paraphrase Database (PPDB) (Pavlick et al., 2015), and identify good simplifications (see examples in Table 3). The resulting lexical resource, SimplePPDB++, contains all 13.1 million lexical and phrasal paraphrase rules in the XL version of PPDB 2.0 with readability scores in 'simplifying', 'complicating', or 'nonsense/no-difference' categories, allowing flexible trade-off between high-quality and high-coverage paraphrases. In this section, we show the effectiveness of the NRR model we used to create SimplePPDB++ by comparing with the previous version of SimplePPDB (Pavlick and Callison-Burch, 2016) which used a three-way logistic regression classifier. In next section, we demonstrate the utility of SimplePPDB++ for the Substitution Generation task.

Task-specific setup of NRR model. We use the same manually labeled data of 11,829 paraphrase rules as SimplePPDB for training and testing, of which 26.5% labeled as 'simplifying', 26.5% as 'complicating', and 47% as 'nonsense/no-difference'. We adapt our NRR model to perform the three-way classification by treating it as a regression problem. During training, we specify the ground truth label as follows: y = -1 if the paraphrase rule belongs to the 'complicating' class, y = +1 if the rule belongs to the 'simplifying'class, and y = 0 otherwise. For predicting, the network produces a single real-value output $\hat{y} \in [-1, 1]$ which is then mapped to three-class labels based on the value ranges for evaluation. The thresholds for the value ranges are -0.4 and 0.4 chosen by cross-validation.

	Acc.	**P$_{+1}$**	**P$_{-1}$**
Google Ngram Frequency	49.4	53.7	54.0
Number of Syllables	50.1	53.8	53.3
Character & Word Length	56.2	55.7	56.1
W2V	60.4	54.9	53.1
SimplePPDB	62.1	57.6	57.8
NRR$_{all}$	59.4	61.8	57.7
NRR$_{all+binning}$	64.1	62.1	59.8
NRR$_{all+binning+WC}$	**65.3***	**65.0***	**61.8***

Table 4: Cross-validation accuracy and precision of our neural readability ranking (NRR) model used to create SimplePPDB++, in comparison to the SimplePPDB and other baselines. P$_{+1}$ stands for the precision of 'simplifying' paraphrase rules and P$_{-1}$ for the precision of 'complicating' rules. * indicates statistical significance ($p < 0.05$) compared to the best performing baseline (Pavlick and Callison-Burch, 2016).

Comparison to existing methods. We compare our neural readability ranking (NRR) model used to create the SimplePPDB++ against SimplePPDB, which uses a multi-class logistic regression model. We also use several other baselines, including W2V which uses logistic regression with only word2vec embedding features.

Results. Following the evaluation setup in previous work (Pavlick and Callison-Burch, 2016), we compare accuracy and precision by 10-fold cross-validation. Folds are constructed in such a way that the training and test vocabularies are disjoint. Table 4 shows the performance of our model compared to SimplePPDB and other baselines. We use all the features (NRR$_{all}$) in §3.2 except for the context features as we are classifying paraphrase rules in PPDB that come with no context. SimplePPDB used the same features plus additional discrete features, such as POS tags, character unigrams and bigrams. Our neural readability ranking model alone with Gaussian binning (NRR$_{all+binning}$) achieves better accuracy and precision while using less features. Leveraging the lexicon (NRR$_{all+binning+WC}$) shows statistically significant improvements over SimplePPDB rankings based on the paired bootstrap test. The accuracy increases by 3.2 points, the precision for 'simplifying' class improves by 7.4 points and the precision for 'complicating' class improves by 4.0 points.

4.3 Substitution Generation

Substitution Generation is arguably the most challenging research problem in lexical simplification, which involves producing candidate substitutions for each target complex word/phrase, followed by the substitution ranking. The key focus is to not only have better rankings, but more importantly, to have a larger number of simplifying substitutions generated. This is a more realistic evaluation to demonstrate the utility of SimplePPDB++ and the effectiveness of the NRR ranking model we used to create it, and how likely such lexical resources can benefit developing end-to-end sentence simplification system (Narayan and Gardent, 2016; Zhang and Lapata, 2017) in future work.

Data. We use the dataset from (Pavlick and Callison-Burch, 2016), which contains 100 unique target words/phrases sampled from the Newsela Simplification Corpus (Xu et al., 2015) of news articles, and follow the same evaluation procedure. We ask two annotators to evaluate whether the generated substitutions are good simplifications.

Comparison to existing methods. We evaluate the correctness of the substitutions generated by SimplePPDB++ in comparison to several existing methods: Glavaš (Glavaš and Štajner, 2015), Kauchak (Coster and Kauchak, 2011), WordNet Generator (Devlin and Tait, 1998; Carroll et al., 1999), and SimplePPDB (Pavlick and Callison-Burch, 2016). Glavaš obtains candidates with the highest similarity scores in the GloVe (Pennington et al., 2014) word vector space. Kauchak's generator is based on Simple Wikipedia and normal Wikipedia parallel corpus and automatic word alignment. WordNet-based generator simply uses the synonyms of word in WordNet (Miller, 1995). For all the existing methods, we report the results based on the implementations in (Pavlick and Callison-Burch, 2016), which used SVM-based ranking. For both SimplePPDB and SimplePPDB++, extracted candidates are high quality paraphrase rules (quality score $\geq$3.5 for words and $\geq$4.0 for phrases) belonging to the same syntactic category as target word according to PPDB 2.0 (Pavlick et al., 2015).

	#PPs	**MAP**	**P@1**
Glavaš$_{(n=95)}$	—	22.8	13.5
WordNet$_{(n=82)}$	6.63	62.2	50.6
Kauchak$_{(n=48)}$	4.39	**76.4**†	68.9
SimplePPDB$_{(n=100)}$	8.77	67.8	78.0
SimplePPDB++$_{(n=100)}$	**9.52**	69.1	**80.2**

Table 5: Substitution Generation evaluation with Mean Average Precision, Precision@1 and the average number of paraphrases generated per target for each method. n is the number of target complex words/phrases for which the model generated > 0 candidates. Kauchak† has an advantage on MAP because it generates the least number of candidates. Glavaš is marked as '-' because it can technically generate as many words/phrases as are in the vocabulary.

Results. Table 5 shows the comparison of SimplePPDB and SimplePPDB++ on the number of substitutions generated for each target, the mean average precision and precision@1 for the final ranked list of candidate substitutions. This is a fair and direct comparison between SimplePPDB++ and SimplePPDB, as both methods have access to the same paraphrase rules in PPDB as potential candidates. The better NRR model we used in creating SimplePPDB++ allows improved selections and rankings of simplifying paraphrase rules than the previous version of SimplePPDB. As an additional reference, we also include the measurements for the other existing methods based on (Pavlick and Callison-Burch, 2016), which, by evaluation design, are focused on the comparison of precision while PPDB has full coverage.

4.4 Complex Word Identification

Complex Word Identification (CWI) identifies the difficult words in a sentence that need to be simplified. According to Shardlow (2014), this step can improve the simplification system by avoiding mistakes such as overlooking challenging words or oversimplifying simple words. In this section, we demonstrate how our word-complexity lexicon helps with the CWI task by injecting human ratings into the state-of-the-art systems.

Data. The task is to predict whether a target word/phrase in a sentence is 'simple' or 'complex', and an example instance is as follows:

Nine people were killed in the bombardment.

We conduct experiments on two datasets: (i) Semeval 2016 CWI shared-task dataset (Paetzold

	CWI SemEval 2016			CWIG3G2 2018		
	G-score	F-score	Accuracy	G-score	F-score	Accuracy
Length	47.8	10.7	33.2	70.8	65.9	67.7
Senses	57.9	12.5	43.6	67.7	62.3	54.1
SimpleWiki	69.7	16.2	58.3	73.1	66.3	61.6
NearestCentroid	66.1	14.8	53.6	75.1	66.6	76.7
SV000gg	77.3	24.3	77.6	74.9	73.8	78.7
WC-only	68.5	**30.5**	**87.7**	71.1	67.5	69.8
NearestCentroid$_{+WC}$	70.2	16.6	61.8	**77.3**	68.8	78.1
SV000gg$_{+WC}$	**78.1**	26.3	80.0	75.4	**74.8**	**80.2**

Table 6: Evaluation on two datasets for English complex word identification. Our approaches that utilize the word-complexity lexicon (WC) improve upon the nearest centroid (Yimam et al., 2017) and SV000gg (Paetzold and Specia, 2016b) systems. The best performance figure of each column is denoted in **bold** typeface and the second best is denoted by an underline.

CWI SemEval 2016	total (IV%)	unique (IV%)
simple	85621 (94.7%)	14129 (77.6%)
complex	4837 (57.4%)	3836 (54.8%)
CWIG3G2	total (IV%)	unique (IV%)
simple	20451 (89.8%)	5576 (82.1%)
complex	14428 (81.1%)	8376 (76.0%)

Table 7: Statistics of CWI datasets – total number of target words/phrases, number of unique targets, and in-vocabulary (IV) ratio with respect to our word-complexity lexicon.

and Specia, 2016a), which has been widely used for evaluating CWI systems and contains 2,237 training and 88,221 test instances from Wikipedia; and (ii) CWIG3G2 dataset (Yimam et al., 2017), which is also known as English monolingual CWI 2018 shared-task dataset (Yimam et al., 2018) and comprises of 27,299 training, 3,328 development and 4,252 test instances from Wikipedia and news articles. Table 7 shows the coverage of our word-complexity lexicon over the two CWI datasets.

Comparison to existing methods. We consider two state-of-the-art CWI systems: (i) the nearest centroid classifier proposed in (Yimam et al., 2017), which uses phrase length, number of senses, POS tags, word2vec cosine similarities, n-gram frequency in Simple Wikipedia corpus and Google 1T corpus as features; and (ii) SV000gg (Paetzold and Specia, 2016b) which is an ensemble of binary classifiers trained with a combination of lexical, morphological, collocational, and semantic features. The latter is the best performing system on the Semeval 2016 CWI dataset. We also compare to threshold-based baselines that use word length, number of word senses and frequency in the Simple Wikipedia.

Utilizing the word-complexity lexicon. We enhance the SV000gg and the nearest centroid classifier by incorporating the word-complexity lexicon as additional features as described in §3.2. We added our modifications to the implementation of SV000gg in the LEXenstein toolkit, and used our own implementation for the nearest centroid classifier. Additionally, to evaluate the word-complexity lexicon in isolation, we train a decision tree classifier with only human ratings as input (WC-only), which is equivalent to learning a threshold over the human ratings.

Results. We compare our enhanced approaches (SV000gg$_{+WC}$ and NC$_{+WC}$) and lexicon only approach (WC-only), with the state-of-the-art and baseline threshold-based methods. For measuring performance, we use F-score and accuracy as well as G-score, the harmonic mean of accuracy and recall. G-score is the official metric of the CWI task of Semeval 2016. Table 6 shows that the word-complexity lexicon improves the performance of SV000gg and the nearest centroid classifier in all the three metrics. The improvements are statistically significant according to the paired bootstrap test with $p < 0.01$. The word-complexity lexicon alone (WC-only) performs satisfactorily on the CWIG3G2 dataset, which effectively is a simple table look-up approach with extreme time and space efficiency. For CWI SemEval 2016 dataset, WC-only approach gives the best accuracy and F-score, though this can be attributed to the skewed distribution of dataset (only 5% of the test instances are 'complex').

5 Related Work

Lexical simplification: Prior work on lexical simplification depends on lexical and corpus-based features to assess word complexity. For complex word identification, there are broadly two lines of research: learning a frequency-based threshold over a large corpus (Shardlow, 2013b) or training an ensemble of classifiers over a combination of lexical and language model features

(Shardlow, 2013a; Paetzold and Specia, 2016a; Yimam et al., 2017; Kriz et al., 2018). Substitution ranking also follows similar trend. Biran et al. (2011) and Bott et al. (2012) employed simplicity measures based on word length and word frequencies from Wikipedia and Simple Wikipedia. Kajiwara et al. (2013) combined WordNet similarity measures with Simple Wikipedia frequencies. Glavaš and Štajner (2015) averaged the rankings produced by a collection of frequency, language model and semantic similarity features. Horn et al. (2014) trained an SVM classifier over corpus-based features.

Only recently, researchers started to apply neural networks to simplification tasks. To the best of our knowledge, the work by Paetzold and Specia (2017) is the first neural model for lexical simplification which uses a feedforward network with language model probability features. Our NRR model is the first pairwise neural ranking model to vectorize numeric features and to embed human judgments using a word-complexity lexicon of 15,000 English words.

Besides lexical simplification, another line of relevant research is sentence simplification that uses statistical or neural machine translation (MT) approaches (Xu et al., 2016; Nisioi et al., 2017; Zhang and Lapata, 2017; Vu et al., 2018; Guo et al., 2018). It has shown possible to integrate paraphrase rules in PPDB into statistical MT for sentence simplification (Xu et al., 2016) and bilingual translation (Mehdizadeh Seraj et al., 2015), while how to inject SimplePPDB++ into neural MT remains an open research question.

Lexica for simplification: There have been previous attempts to use manually created lexica for simplification. For example, Elhadad and Sutaria (2007) used UMLS lexicon (Bodenreider, 2007), a repository of technical medical terms; Ehara et al. (2010) asked non-native speakers to answer multiple-choice questions corresponding to 12,000 English words to study each user's familiarity of vocabulary; Kaji et al. (2012) and Kajiwara et al. (2013) used a dictionary of 5,404 Japanese words based on the elementary school textbooks; Xu et al. (2016) used a list of 3,000 most common English words; Lee and Yeung (2018) used an ensemble of vocabulary lists of different complexity levels. However, to the best of our knowledge, there is no previous study on manually building a large word-complexity lexicon with human judgments that has shown substantial improvements on automatic simplification systems. We were encouraged by the success of the word-emotion lexicon (Mohammad and Turney, 2013) and the word-happiness lexicon (Dodds et al., 2011, 2015).

Vectorizing features: Feature binning is a standard feature engineering and data processing method to discretize continuous values, more commonly used in non-neural machine learning models. Our work is largely inspired by recent works on entity linking that discussed feature quantization for neural models (Sil et al., 2017; Liu et al., 2016) and neural dependency parsing with embeddings of POS tags as features (Chen and Manning, 2014).

6 Conclusion

We proposed a new neural readability ranking model and showed significant performance improvement over the state-of-the-art on various lexical simplification tasks. We release a manually constructed word-complexity lexicon of 15,000 English words and an automatically constructed lexical resource, SimplePPDB++, of over 10 million paraphrase rules with quality and simplicity ratings. For future work, we would like to extend our lexicon to cover specific domains, different target users and languages.

Abstract

Previous work on grounded language learning did not fully capture the semantics underlying the correspondences between structured world state representations and texts, especially those between numerical values and lexical terms. In this paper, we attempt at learning explicit latent semantic annotations from paired structured tables and texts, establishing correspondences between various types of values and texts. We model the joint probability of data fields, texts, phrasal spans, and latent annotations with an adapted semi-hidden Markov model, and impose a soft statistical constraint to further improve the performance. As a by-product, we leverage the induced annotations to extract templates for language generation. Experimental results suggest the feasibility of the setting in this study, as well as the effectiveness of our proposed framework. [1]

1 Introduction

The meaning of natural language should always be accompanied by a context. *Grounded language acquisition* aims at learning the meaning of language in the context of an observed world state. A solution framework typically addresses the following subproblems: segmenting the text into meaningful phrasal units, determining which world state information is being referred to, and finding proper alignments from these units to the events of values in the world state.

The task has attracted much attention from the NLP community with a special focus on aligning text descriptions onto processed, structured event records (Snyder and Barzilay, 2007; Liang et al., 2009; Hajishirzi et al., 2011). Various statistical models have been proposed, attempting at characterizing the interaction between text spans and categorical values (e.g., *direction*=*'East'*) or strings (e.g., *person names*). The previously addressed term *semantic correspondences* narrowly describes the process of aligning natural language spans to different data fields.

TEAM	WIN	LOSS	PTS	...	PT-QT4
Raptors	33	15	120	...	31
Wizards	31	17	116	...	15

> The Toronto Raptors (33 - 15) barely edged out the Washington Wizards (31 - 17) 120 - 116 in overtime Saturday at the Verizon Center. The Raptors took a great lead before the fourth quarter, but the Wizards fought back by outscoring Toronto 31 - 15 ....

Figure 1: An example of the summary and the corresponding table.

However, there still exists a gap between alignment results and the underlying semantics. People tend to use various phrases to describe information that are inferred from different amounts of numerical values in a data field, or values derived from additional operations over fields. Consider the example description for a basketball game shown in Figure 1. The phrase *edged out* in the first sentence implies the fact that *the Toronto Raptors* had beaten their opponent by a relatively narrow margin. This could only be derived from an operation of subtraction between two scores that correspond to the field `PTS` for both teams in the event table, which leads to a relatively small difference of only four points. Previous efforts on learning semantic correspondences relying on *categorical* distributions (Liang et al., 2009) or *string pattern features* (Hajishirzi et al., 2012; Koncel-Kedziorski et al., 2014) do not have the capability to accurately capture *numerical information*, especially for the part that *does not appear explicitly* in the table and needs to be inferred.

Such kind of language grounding is important both for natural language understanding and for natural language generation. For language understanding, establishing explicit connections between symbols and values beyond ungrounded symbolic meaning representations will be useful for acquisition and inference of numerical commonsense (Narisawa et al., 2013). For language generation, properly aligned information is the key to acquiring patterns of various lexical choices under different world states (Roy and Reiter, 2005).

In this work, we make a step towards more explicit semantic correspondences between structured data and texts. Rather than only producing coarse alignments between data fields and text spans, we try to detect the latent semantics underlying these alignments by prompting explicit semantic annotations. We make the first attempt at utilizing publicly available datasets originally prepared for data-to-text language generation to produce such annotations for words and phrases in natural language without additional supervision.

Specifically, we conduct our study on a recently released dataset of descriptions for NBA basketball games with structured tables of game records. Different from a few popular datasets that have been well conjectured to be produced from rules (Reiter, 2017), the summaries are all written by humans. The text contains some numbers and proper nouns, which are easier to establish correspondence with data. However, the majority of texts contain many informative words, some of which need to be inferred indirectly from various types of values in the data cells. We want to establish explicit correspondences for them.

We derive a set of semantic labels from original data fields (Sec 4.1). These labels could be executed to establish direct correspondences to one or more values in the structured table. No annotation on the original dataset means unsupervised learning from weak distant supervision should be conducted. We design a semi-hidden Markov model to address this problem (Sec 4.2), which could align a semantic label to a word span. In the model, we leverage continuous probability distributions to model the correspondences between numerical values and lexical terms, which has not been well captured in previous work. To address the emerged issue of "garbage collection" that commonly appears in statistical alignment models (Sec 4.5), we add a soft statistical constraint via posterior regularization (Ganchev et al., 2010). As a by-product, we also show how the derived semantic annotations could be used to induce descriptive templates for data-to-text generation (Sec 5). Experimental results (Sec 6) suggest the feasibility of the setting in this study, and show the effectiveness of our proposed framework.

2 Related work

Grounded language acquisition has aroused wide interest in various disciplines (Siskind, 1996; Yu and Ballard, 2004; Gorniak and Roy, 2007; Yu and Siskind, 2013; Chrupała et al., 2015). Later work in the community of natural language processing also moved in this direction by relaxing the amount of supervision to enable a model to learn from ambiguous alignments (Kate and Mooney, 2007; Chen and Mooney, 2008). Some research aimed at establishing coarse alignments between simulated robot soccer game records and commentary sentences (Chen and Mooney, 2008; Chen et al., 2010; Bordes et al., 2010; Hajishirzi et al., 2011). For weather forecast domain, Liang et al. (2009) used a hierarchical hidden Markov model in order to map utterances to world states, which coped with segmentation and alignment together. More recently, Koncel-Kedziorski et al. (2014) tried to obtain the correspondences between real commentaries and structured football (soccer) events in multiple resolutions. We are distinct from this line of work in the fact that we aim at producing explicit semantic annotations that could capture information from structured tables. To achieve this goal, we need additional scaling or operations to enable data fields and values to be faithfully mapped onto texts. This will address the issue of the lack of consideration for the relationship between lexical terms and numerical values. Our approach makes a significant difference in that our framework could generalize to numerical values or value combinations that are unseen in training, and will not be simply reciting cooccurrence patterns of exact values in the training data.

Our work relates to learning executable semantic parsers under weak supervision. Early semantic parsing started from fully supervised training with annotated meaning representations available (Zettlemoyer and Collins, 2005; Ge and Mooney, 2006; Snyder and Barzilay, 2007), but more recent work focused on reducing the amount of supervision required (Artzi and Zettlemoyer, 2013). The intuition behind weakly supervised executable semantic parsing is that once the latent semantic representation has been executed, one could test whether the execution results could match the information with available weak supervision signals such as answers to natural language queries (Clarke et al., 2010; Liang et al., 2011), or task completion from instructional navigations (Misra et al., 2017). Such formulations have been adapted for question answering over structured tables (Pasupat and Liang, 2015; Krishnamurthy et al., 2017). However, the current research focus is to convert a natural language question into executable table queries and to directly retrieve results. They do not have the need of inference involving numerical commonsense implied by various lexical patterns. A few unsupervised approaches exist (Poon and Domingos, 2009; Poon, 2013) but only specific to translating language into queries in the highly structured database and cannot be applied to our domain.

Our approach is implemented as assigning tag annotations over text spans, which is conceptually related to fine-grained named entity tagging (Ling and Weld, 2012). Our setting only requires a rather weak and distant form of supervision from paired tables and texts without annotations for fine-grained alignments between phrases and data cells. Similar modeling and learning strategies could potentially be useful for considerably large tag space derived from structured knowledge bases in the future (Choi et al., 2018).

The feasibility of this work is partly due to the availability of data, mostly comes from the field of data-to-text language generation. Related work in data-to-text generation mainly focused on directly generating summary descriptions for structured data (Mei et al., 2016; Kiddon et al., 2016; Murakami et al., 2017; Wiseman et al., 2017), without establishing underlying semantic correspondences. Texts generated thereby can be fluent but not conforming to the input data, unlike template-based approaches where lexical choices could be directly controlled. In our work, we find the derived semantic correspondences between data and texts to be useful for template induction, either with simple heuristics to automatically extract description patterns (*how to say*) and corresponding triggers (*what & when to say*), or with more crafted discriminative learning approaches (cf. Angeli et al. (2010)).

3 Technical overview

Task Let $\mathcal{S}$ be the set of all world states, $\mathcal{W}$ be the set of all texts, $\mathcal{O}$ be the set of all executable operators, and $\mathcal{V}$ be the output space of $\mathcal{O}$. A world state $s \in \mathcal{S}$ is a table storing some information, or more specifically in this work, a tabular recording for a sports game. An operator $o \in \mathcal{O}$ can be executed on a world state to retrieve values, i.e., each o could be treated as a mapping of $\mathcal{S} \rightarrow \mathcal{V}$. The result of an operation can be a string, a continuous values or a discrete value. Meanwhile, each world state s is accompanied with a piece of description $\mathbf{w} \in \mathcal{W}$. Here $\mathbf{w}$ consists of a sequence of word tokens $\{w_i \in \mathbf{w}\}$. We further define a segmentation variable π, which could convert $\mathbf{w}$ into a sequence of word spans $\mathbf{c}$, containing each span of tokens $c^t \in \mathbf{c}$ that could be interpreted as a phrase. Note that we use superscript t to denote indices of phrases, and subscript i to denote indices of individual words. We further define $\mathbf{l}$ as a sequence of latent labels, and value of each l^t is an operator $o_i \in \mathcal{O}$. [2] For each world state s and corresponding description $\mathbf{w}$, we want to jointly find a proper segmentation π to obtain $\mathbf{c}$, and assign labels to every word span c^t.

We conduct this study on the ROTOWIRE subset of the openly available dataset released by Wiseman et al. (2017), containing text descriptions for NBA basketball games with structured tables of game statistics. Take Figure 1 as an example. The proper nouns (e.g. *Toronto Raptors*) appeared in the sentence can be assigned with a tag `Team_Name` in our tag set, which could then be aligned to the *Team Name* field in the table. Some numbers appearing in the text, such as *15* in the example, can be assigned with the label `Team_Losses`, with the executable annotation to extract the number of previously lost matches of the mentioned team. What we are more interested in is where the phrase *edge out* comes from. We are aiming at a model which is capable to capture the semantics behind the phrase *edge out*, which is used to describe an event that one team has beaten the other with close scores. In our annotation scheme, this phrase should be assigned with the tag `Team_Points_Delta`, and executing that will return the score difference between two teams.

The task is challenging in that there does not

---

[2] We will interchangeably use *labels*, *operators*, *tags* to refer to the latent executable semantic annotations in this paper.

Output Type	Example
String	`Team_City`
Categorical	`Player_Start_Position`
Numerical	`Team_Points_Delta`

Table 1: Examples from the derived tag set, where each tag could correspond to one of three types of values.

exist any other additional supervision signal. The learning process will mostly rely on statistical cooccurrences of information between the structured data and its text descriptions. Note that we assume a consistent structure (schema) throughout the whole dataset upon which the learning process will be performed.

Model To jointly learn word segmentations $\mathbf{c}$ and latent semantic annotations $\mathbf{l}$ between world state s and text $\mathbf{w}$ in a unified framework, we propose a generative model to characterize the joint distribution $P_s(\mathbf{l}, \pi, \mathbf{w}; \theta)$, parameterized by θ.

Learning The data contain paired texts and tables only, thus our model must learn segmentations and latent semantic annotations in an unsupervised fashion. The target is to maximize the complete data likelihood

$$\mathcal{L}(\theta) = \prod_{(s,\mathbf{w})\in\mathcal{D}} \sum_{\mathbf{l},\pi} P_s(\mathbf{l}, \pi, \mathbf{w}; \theta),$$

where $\mathcal{D}$ represents the whole training data. To reduce the search space in inference and to capture some patterns of content planning in the text descriptions, we adopt a Markov assumption over phrase segments, which leads to a hidden semi-Markov model (semi-HMM) (Murphy, 2002; Sarawagi and Cohen, 2005). The key part is to characterize different types of correspondences (Sec 4.2). We derive an expectation-maximization (EM) algorithm to perform maximum likelihood estimation, and introduce a soft statistical regularization to guide the model towards a better solution (Sec 4.5).

Inference Once the model has been trained, we use a Viterbi-like dynamic programming process to perform MAP inference to segment the texts and to assign the most likely tags for each span.

4 Framework

4.1 The set of annotations

We describe the process of how we derived our set of semantic annotations here. There are two kinds of specific tables for each NBA game in the dataset: *Box-Scores* and *Line-Scores*, respectively showing the performance statistics for individual players and the whole teams. The types of possible values for data fields are strings, categorical values and numerical values. *Box-Score* consists of 24 fields, of which four are string-values, one is categorical, the other 19 being numerical. *Line-Score* consists of 16 fields, containing two string-valued, one categorical, and 13 numerical fields. A semantic tag works on a specified kind of field type, from either team statistics or player statistics. For a tag that could align to one single field in the table, we let it return the exact value in the cell that could maximize the likelihood. For example, the tag `Team_City` is used to extract the name of the team in the table that corresponds to the current word span. For fields taking numerical values, we additionally allow tags to be able to perform mathematical operations, such as subtraction, between two values in the same field. [3] For example, the tag `Team_Points_Delta` can be executed to return the score difference between two teams. We list the different types of tags with examples shown in Table 1 and leave the entire tag set to Appendix A. Along with all these tags derived from the original data fields, we also include a special `NULL` tag which are supposed to be assigned to non-informative words or words containing information not contained in the given table.

Note that we impose little prior knowledge in this step. We simply over-generate all possible labels, and let the model figure out which part of them should be eventually used. Although the only compositional operation we used in this work is numeric subtraction, common operations that could produce string, categorical values or numbers could be easily introduced for other domains.

4.2 Semi-HMMs with continuous values

As previously mentioned, we will be modeling the joint distribution of word segmentation $\mathbf{c}$ and the latent semantic annotations $\mathbf{l}$ between paired world state s and text $\mathbf{w}$, which could be factorized as:

$$P_s(\mathbf{l}, \pi, \mathbf{w}) = P_s(\mathbf{w}, \pi|\mathbf{l}) \cdot P_s(\mathbf{l}),$$

and we write $P_s(\mathbf{w}, \pi|\mathbf{l})$ as $P_s(\mathbf{c}|\mathbf{l})$. In this section, we focus on the probability of the alignments between word spans and labels, namely, $P_s(\mathbf{c}|\mathbf{l})$.

Following Liang et al. (2009), we consider two aspects. One is *salience* that captures the intuition

---

[3] We limit the number of arguments within two in this work and leave more complex operators for future study.

that some fields should be more frequently mentioned than others (henceforth some latent tags should be more frequently triggered). The other is (local) *coherence*, which refers to the order in which the writer mentioning certain information tends to follow some patterns. To capture these two phenomena, we define a Markov model:

$$P_s(\mathbf{c}, \mathbf{l}) = \prod_t P(l^t | l^{t-1}) \cdot P_s(c^t | l^t),$$

where l^t is the annotated label at time stamp t, and we assume that the transition probabilities are independent of world state s. It resembles a standard form of HMMs, despite the subscript s in $P_s(\mathbf{c}|\mathbf{l})$. For different types of correspondences between l^t and c^t, we define different probability distributions to model $P_s(c^t|l^t)$:

(1) **Numerics-to-numerics**: The numbers in texts could sometimes be inaccurate due to some rounding customs, thus we use a Gaussian model for this type: $SoftIndicator(x, y|\sigma) = \mathcal{N}(x - y|0, \sigma)$, where $\mathcal{N}$ is the Gaussian density. When the output type of tag l^t is numeric and the word span c^t is a number, we set $P_s(c|l) = SoftIndicator(c, v_l|\sigma_l)$, where σ_l is different for different tags, and v_l is the corresponded value in the table for tag l. Note that when $\sigma \to 0$, $SoftIndicator$ reduces to an indicator function that only allows exact matching.

(2) **String-to-string**: Similarly for strings, since simple matching could fail if the text contains *Bob* to refer to *Bob Smith*. We simply use string matching to model the probability: $P_s(c|l) \propto Match(v_l, c)$, where the $Match$ function returns the number of shared words between cell value v_l and word c.

(3) **Category-to-string**: For labels correspond to discrete categorical values, such as `Sunday`, `PG` (*point guard*, a basketball position), we adopt the same method used by Liang et al. (2009): using a multinomial distribution over all word spans for each possible category:

$$P_s(c|l) = \nu_{c,v_l}, \quad \sum_c \nu_{c,v} = 1, \qquad (1)$$

where v_l is again the output value of tag l.

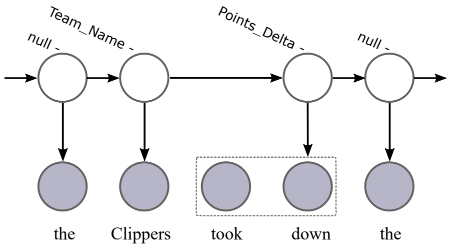

Figure 2: A Semi-HMM that can yield an entire phrase from one tag.

(4) **Numerics-to-string**: When the tag correspond to a numeric value v_l while the word span c is not a number, the problem resembles speech modeling (Huang et al., 1990). Applying the Bayes rule, we get: [4]

$$P_s(c|l) = P(c|l, v_l) \propto P(v_l|c, l) \cdot P(c|l),$$

where we collapse the relevant part from world state s into v_l. The intuition behind $P(v_l|c, l)$ is that when an informative word (e.g. *routed*) appears in the text, the corresponding values should have different chances to happen in the world, e.g. $P(30|routed, \texttt{Points\_Delta}) > P(3|routed, \texttt{Points\_Delta})$.

Due to the lack of prior knowledge on the distribution, we also model this term as Gaussian. [5] The result resembles a Gaussian mixture:

$$P_s(c|l) \propto \mathcal{N}(v_l; \mu_{c,l}, \sigma_{c,l}) \cdot \eta_{c,l},$$
$$\sum_c \eta_{c,l} = 1,$$

where $P(c|l) = \eta_{c,l}$ is also multinomial.

4.3 Modeling phrasal spans

Our model can enable phrase segmentation. Previously, Liang et al. (2009) treated the words inside a phrase individually and independently. This could be problematic in our scenario. For example, *take down* is used to describe a team defeating another, while separately both *take* and *down* are frequent words in general, making them difficult to be jointly assigned with the correct label as a whole. Instead, in our model we treat the phrasal

---

[4] We noticed that in parallel with our work, another study (Zhang et al., 2018) on verb selection for data-to-text generation also use the same strategy of Bayes rule to estimate parameters, and provide a noisy-channel interpretation.

[5] The double tails in Gaussian pdf have different interpretations: unlikely to occur, or unlikely to occur conditionally.

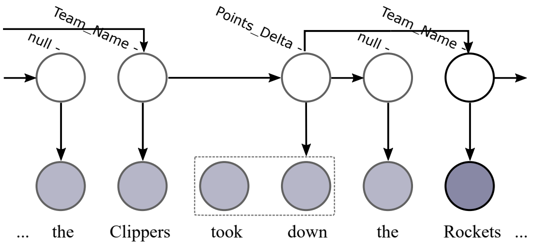

Figure 3: A slightly different Semi-HMM whose transition score is calculated by skipping `NULL` fields.

word span as a unit. The probability is assigned to the whole span of phrase instead of individual words, which will break the token-wise Markov property (Fig. 2, henceforth Semi-HMM). For efficient parameter estimation, We use a variant of the standard forward-backward algorithm by adding a parameter k, which is the maximum length of word spans, onto the Markov chain. We leave detailed descriptions to Appendix B.

4.4 Skipping null labels

Preliminary experiments suggest that the initial model have too many words assigned to the `NULL` tag. Informative alignments may not be adjacent, which breaks the simplest Markov assumptions. In our model, the transition score of two non-`NULL` labels can be calculated by skipping all the `NULL`s in between, as shown in Figure 3. This is implemented without breaking the overall Markov property with the following trick used in earlier work on statistical alignments (Brown et al., 1993): Suppose we have m labels (i.e., m latent states), we can design m different `NULL` labels that share the same emission score, while preserving their original outward-transition probabilities. The types of `NULL` labels are inherited from the previous label. This might seem to be wasteful at first sight as we use two-fold latent states, but the Markov property is successfully preserved, therefore simplifying our implementation.

4.5 Posterior regularization

The structured tables and text descriptions of the dataset were originally crawled from different sources. As a consequence, a non-negligible proportion of texts is in fact describing information outside the given table, such as historical records (e.g., *"win streak"*). Ideally, words in these parts of the text should remain unaligned, or in our setting, be annotated with the `NULL` tag. However, due to the notorious effect of *garbage collection* from statistical alignment (Brown et al., 1993), these words tend to be aligned to some irrelevant fields in the table which are rarely mentioned.

We address this issue by adding a soft statistical constraint in the form of posterior regularization (Ganchev et al., 2010; Graça et al., 2010). With posterior regularization, we could add certain types of statistical constraints to the E-step in the EM procedure, while keeping the inference tractable. The constraints should be in the form of:

$$\mathbb{E}[\mathbf{f}(\mathbf{w},\mathbf{l})] = \sum_i \mathbb{E}[\mathbf{f}(\mathbf{w},l_i)] \le \mathbf{b}_{\mathbf{w}}, \qquad (2)$$

where the features $\mathbf{f}$ should be defined on local cliques for tractable inference.

We use projected gradient descent to solve the E-step sub-problem in this work. The statistical constraint we add to the posterior is rather simple: For each sentence, we "encourage" at least a proportion of words to be aligned to `NULL` labels:

$$\mathbb{E}[-f(\mathbf{w},\mathbf{l})] \le -r_0 \cdot n, \qquad (3)$$

$$f(\mathbf{w},\mathbf{l}) = \sum_{i=1}^{n} \mathbb{1}(l_i = \texttt{NULL}), \qquad (4)$$

where r_0 is a adjustable ratio, n is the length of $\mathbf{w}$. We also tried other constraints but found this simple soft regularization performing well.

5 By-product: template induction

Intuitively, the assigned semantic correspondences could be useful to derive templates and trigger rules for language generation. In this work, we use the most straightforward heuristics to perform template induction, utilizing the established correspondences and inferred parameters. Specifically, we first blank out the correspondences of numerics-to-numerics and string-to-string to be empty slots and replace with the tag names. In the example of Figure 1, we could replace *Raptors* with `Team_Name`, and 120 with `Team_Points`, if they have been correctly aligned.

We also need to know when to use each template. We define a *template trigger* to be a quadruple $(c, l, \mu_{c,l}, \sigma_{c,l})$, where c is a phrase, l is a tag, $\mu_{c,l}$ and $\sigma_{c,l}$ are estimated Gaussian parameters. [6] We assign each template with a score to be the minimum probability for all triggers inside:

$$\text{score}(s,\mathbf{t}) = \min_i \mathcal{N}(t_i.l(s); t_i.\mu, t_i.\sigma), \qquad (5)$$

---

[6] To use a unified notation, for categorical-value triggers we set $\mu_{c,l} = \arg\max_{v_l} \nu_{c,v_l}$ (defined in (1)) and $\sigma_{c,l} = \epsilon$.

where $\mathbf{t} = \{t_i\}$ denotes all possible triggers in the template, and the tag l can be executed over the world state s to retrieve a value $l(s)$. We only consider sentences satisfying both of the following conditions in order to extract templates with high quality: (1) sentences aligned to $\leq$ two teams or one player, and (2) sentences with triggers derived from continuous distributions.

Now that the templates and triggers are ready for use, we will experiment with the following straightforward rules to perform data-to-text generation: For every game, we first generate a sentence describing the scoreline result, followed by three sentences describing other information about team performance. While keeping that no template is repeatedly used, we will then choose the template with the highest score for top ten players sorted by their game points.

6 Experiments

6.1 Experimental setup

We conducted experiments on the ROTOWIRE subset of the Wiseman et al. (2017) dataset. In our experiment, we restricted the maximum length of word span to two as a trade-off of speed and performance. Empirically, most of the phrases in the dataset are at a length of at most two. We empirically set the expected `NULL` ratio to be $r_0 = 0.5$.

We did the following pre-processing steps for all systems in comparison: we lemmatized all tokens in the sentences, and filtered out sentences containing less than five words since they are meaningless short sentences. To utilize the game dates, we converted them from calendar date to the day of week, e.g. 11/28/2016 is converted to *Monday* as a categorical value. Due to the huge noise in the ROTOWIRE dataset, containing many sentences irrelevant with their corresponding tables, we filtered out the sentences that contain no team or player names, or those that mention more than 2 players, as most of them are irrelevant texts.

Following Liang et al. (2009), we also used the parameters of a simpler model without Markov dependency (which was uniformly initialized) to initialize our complete model with obtained parameters, and then trained it until convergence. We adapted Liang et al. (2009)'s framework to the table schema in the ROTOWIRE dataset, and ran experiments accordingly as our baseline model.

6.2 Evaluation

6.2.1 Intrinsic evaluation

It is difficult to evaluate the accuracy of tag assignments for the entire dataset, since the tags are not annotated in the original data. We recruited three human annotators with familiarity in the domain of basketball games to label 300 sentences (around 8,000 tokens in total, and 30% of them are annotated with tags) from the test set. There exists a fraction (18%) where agreements were not made, we included all the proposed tags from the annotators to be correct. Also, because of the ambiguity of annotations, we use the base names of derived tags (e.g. `Rebounds_Delta`) for numerics-to-string relationship evaluation. (e.g. `Rebounds_Delta` is reduced to `Rebounds`) Finally, we calculated the precision and recall for non-`NULL` tag assignments at word-level.

	Precision	Recall	F1
Liang09	0.319	0.643	0.426
Liang09+PR	0.397	0.640	0.490
Semi-HMMs	0.254	0.765	0.381
Semi-HMMs+PR	**0.504**	**0.786**	**0.614**

Table 2: Word-level tag assignment results.

Correspondence type	Proportion	Accuracy
numerics-to-numerics	0.369	0.950
numerics-to-string	0.283	0.402
string-to-string	0.252	0.892
category-to-string	0.095	0.936

Table 3: The performance of Semi-HMMs+PR for different types of correspondences.

The results are shown in Table 2. The Liang et al. (2009) framework could still achieve around 65% recall, because there exist a large proportion of correspondences that could be easily captured by exact matches and simple categorical distributions. Our model without PR achieves lower precision than the baseline, because the baseline did not model numerics-to-string relationships and encountered less severe issues of garbage collection. We can observe that our initial model indeed outperforms the baseline system in recall, while PR helps a lot to avoid distraction from irrelevant information that should be tagged as `NULL`.

We also include more fine-grained results for different types of correspondences, shown in Table 3. As expected, numerics-to-string correspon-

Figure 4: Example of latent tag assignment. Words in blue dashed boxes are phrases recognized by our model. The labels red with asterisks (*) are false assignments. (a), (b), (c) are example of Semi-HMMs-PR, while (d) is produced from the initial Semi-HMMs.

dences are the most difficult part in this study. Another notable thing is that although we found that around 40% of numerics-to-numerics correspondences were ambiguous due to the appearance of identical values from different table cells, our model could still achieve a high accuracy of 95.0%.

6.2.2 Extrinsic evaluation

We also tested how the derived templates could perform in language generation, when compared with the baseline using the same heuristics described in Sec 5. We report automatic metrics including BLEU scores and those based on relation extraction as proposed by Wiseman et al. (2017): precision & number of unique relations in generation (RG), precision & recall for content selection (CS), and content ordering (CO) score. These automatic metrics were designed for various aspects in NLG and may not all suit our main focus well, so we also conducted human evaluation on information correctness (1-5 scale ratings, the higher the better). We asked four human raters who are fluent in English and with familiarity in basketball terms to rate over outputs for 30 random games. Results are shown in Table 4. We can observe that templates derived from our model indeed outperform those from the baseline.

We put some inducted templates and generated text examples in the Appendix.

6.3 Analysis

Figure 4 shows some examples produced from our methods. Some of the alignments are meaningful, for example, the model assigned the word *perfect* with the annotation `FT_Percent`, which represents the percentage of free throws. Without PR, our model performed poorly by aligning many common words to those rarely mentioned cells. In this example, the `FT_Made` and `FT_Attempt` fields in the input table both have the same value 8, making it difficult for a model without proper local coherence modeling to distinguish between them. Because our initial model without PR cannot annotate `NULL` correctly, the Markov transition between these two numbers was intercepted by three meaningless tokens. However, after injecting the PR constraint, most of the unmentioned words were successfully identified. The model captured the pattern that `FT_Attempt` almost always follows `FT_Made`, making it correctly assigned these two labels.

We conducted ablation experiments for some

Model	RG(P%)	RG(#)	CS(P%)	CS(R%)	CO	BLEU	Correctness
Liang09+PR	85.83	33.29	14.33	31.09	6.25	8.34	2.60
Semi-HMMs+PR	90.47	41.79	21.63	50.17	9.63	9.45	3.58
Gold-standard	91.77	12.84	100	100	100	100	4.88

Table 4: Results for data-to-text generation (Kendall's W=0.83 from correctness raters)

of the components (Table 5). When setting the maximum phrase length to be $k = 1$, the model degenerates to a normal HMM. The performance measured by F1-score drops for only a little. One possible reason is that Semi-HMMs tend to output some meaningless combinations of words as phrases, such as the phrase *points on* in Figure 4 (b), which could lead to many redundant annotations that hampers precision albeit its help to recall. We also tried to disable the transition probabilities during both training and inference, which led to lower precision and lower recall naturally as there was no modeling for local coherence. Finally, by canceling the NULL-skipping mechanism, we found that the numerics-to-numerics annotation accuracy dropped from 95.0% to 88.8%. Many of the spurious numerics-to-numerics annotations, such as the *8* - *of* - *8* in Figure 4 (d), could be corrected using transition probabilities under the skipping-NULL mechanism (Figure 4 (c)).

	Precision	Recall	F1
Semi-HMMs+PR	0.504	0.786	0.614
HMM+PR	0.545	0.694	0.610
No transition	0.468	0.633	0.538
No skip	0.454	0.737	0.562

Table 5: Ablation results.

One additional advantage of our model is that we can easily verify what the model has captured. For the latent annotation `Team_Points_Delta`, we sort its corresponding phrases by weights $\frac{P(c|l)}{P(c)}$ and we list the top 12 weighted words in Figure 5. We can observe that most of the displayed phrases have strong semantic relationship with score differences. More interestingly, we found the mean and variance values estimated by the Gaussian distributions rather informative. When l = `Teams_Points_Delta`, we observed that $\mu_{l,\text{narrowly}} \approx 2$ while $\mu_{l,\text{blow out}} \approx 26$. We could infer the conditions under which some phrases should be used, providing useful insights for lexical choices in language generation.

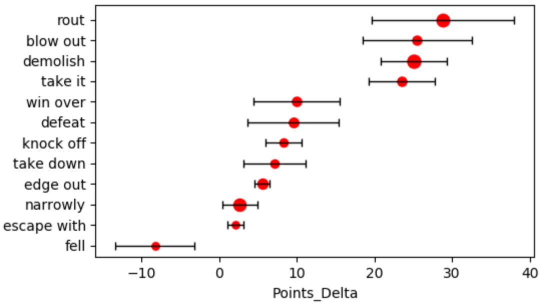

Figure 5: Mean±std for the top 12 weighted phrases assigned with `Team_Points_Delta`. (circle sizes are proportional to weights)

7 Conclusion

In this paper, we attempt to learn executable latent semantic annotations from paired structured tables and texts. We model the joint probability of data fields, texts, phrasal spans, and latent annotations with an adapted semi-hidden Markov model and impose a soft statistical constraint via posterior regularization. Experimental results suggest the feasibility of the setting in study and the effectiveness of our framework.

This is a preliminary study for using weak supervision from structured data and texts to address the challenging problem of language grounding. For future study, one could collect large-scale data and texts in other domains where more complex grounding on phrases such as "increasing trends" should be done. To enhance modeling power, unsupervised discriminative models that utilize rich features (Berg-kirkpatrick et al., 2010) could also be explored. We are also interested in collecting more high-quality parallel data to induce grounded compositional logic representations.

Abstract

We introduce the **syntactic scaffold**, an approach to incorporating syntactic information into semantic tasks. Syntactic scaffolds avoid expensive syntactic processing at runtime, only making use of a treebank during training, through a multitask objective. We improve over strong baselines on PropBank semantics, frame semantics, and coreference resolution, achieving competitive performance on all three tasks.

1 Introduction

As algorithms for the semantic analysis of natural language sentences have developed, the role of *syntax* has been repeatedly revisited. Linguistic theories have argued for a very tight integration of syntactic and semantic processing (Steedman, 2000; Copestake and Flickinger, 2000), and many systems have used syntactic dependency or phrase-based parsers as preprocessing for semantic analysis (Gildea and Palmer, 2002; Punyakanok et al., 2008; Das et al., 2014). Meanwhile, some recent methods forgo explicit syntactic processing altogether (Zhou and Xu, 2015; He et al., 2017; Lee et al., 2017; Peng et al., 2017).

Because annotated training datasets for semantics will always be limited, we expect that syntax—which offers an incomplete but potentially useful view of semantic structure—will continue to offer useful inductive bias, encouraging semantic models toward better generalization. We address the central question: is there a way for semantic analyzers to benefit from syntax without the computational cost of syntactic parsing?

We propose a multitask learning approach to incorporating syntactic information into learned representations of neural semantics models (§2). Our approach, the **syntactic scaffold**, minimizes an auxiliary supervised loss function, derived from a syntactic treebank. The goal is to steer the distributed, contextualized representations of words and spans toward accurate semantic *and* syntactic labeling. We avoid the cost of training or executing a full syntactic parser, and at test time (i.e., runtime in applications) the semantic analyzer has no additional cost over a syntax-free baseline. Further, the method does not assume that the syntactic treebank overlaps the dataset for the primary task.

Many semantic tasks involve labeling spans, including semantic role labeling (SRL; Gildea and Jurafsky, 2002) and coreference resolution (Ng, 2010) (tasks we consider in this paper), as well as named entity recognition and some reading comprehension and question answering tasks (Rajpurkar et al., 2016). These spans are usually syntactic constituents (cf. PropBank; Palmer et al., 2005), making phrase-based syntax a natural choice for a scaffold. See Figure 1 for an example sentence with syntactic and semantic annotations. Since the scaffold task is not an end in itself, we relax the syntactic parsing problem to a collection of independent span-level predictions, with no constraint that they form a valid parse tree. This means we never need to run a syntactic parsing algorithm.

Our experiments demonstrate that the syntactic scaffold offers a substantial boost to state-of-the-art baselines for two SRL tasks (§5) and coreference resolution (§6). Our models use the strongest available neural network architectures for these tasks, integrating deep representation learning (He et al., 2017) and structured prediction at the level of spans (Kong et al., 2016). For SRL, the base-

Brussels, Belgium, October 31 - November 4, 2018.

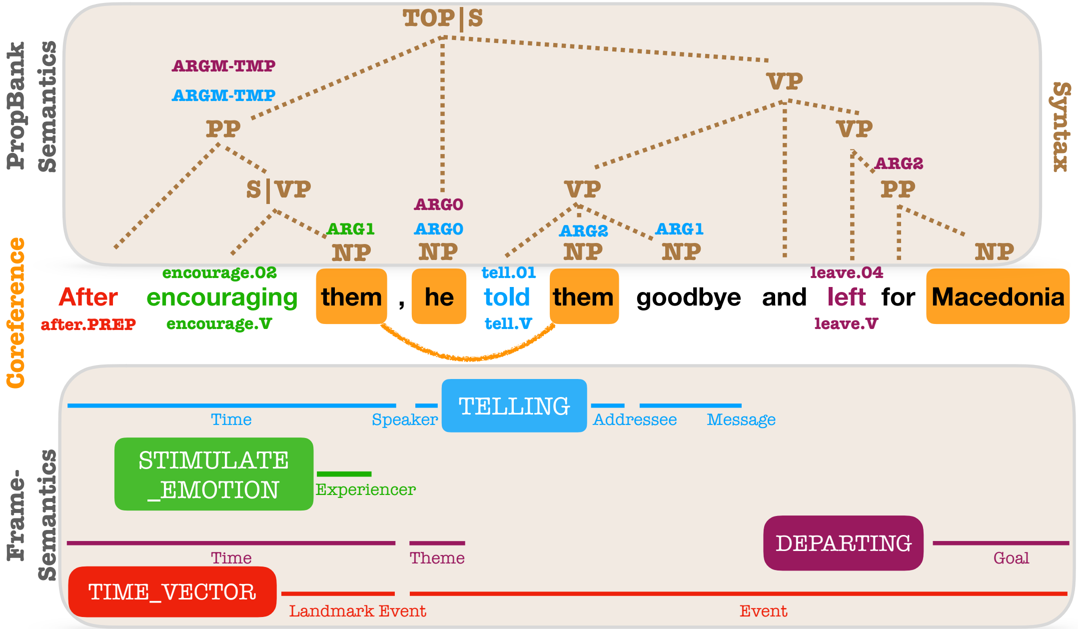

Figure 1: An example sentence with syntactic, PropBank and coreference annotations from OntoNotes, and author-annotated frame-semantic structures. PropBank SRL arguments and coreference mentions are annotated on top of syntactic constituents. All but one frame-semantic argument (Event) is a syntactic constituent. Targets evoke frames shown in the color-coded layers.

line itself is a novel globally normalized structured conditional random field, which outperforms the previous state of the art.[1] Syntactic scaffolds result in further improvements over prior work—3.6 absolute F_1 in FrameNet SRL, 1.1 absolute F_1 in PropBank SRL, and 0.6 F_1 in coreference resolution (averaged across three standard scores). Our code is open source and available at `https://github.com/swabhs/scaffolding`.

2 Syntactic Scaffolds

Multitask learning (Caruana, 1997) is a collection of techniques in which two or more tasks are learned from data with at least some parameters shared. We assume there is only one task about whose performance we are concerned, denoted T_1 (in this paper, T_1 is either SRL or coreference resolution). We use the term "scaffold" to refer to a second task, T_2, that can be combined with T_1 during multitask learning. A scaffold task is *only* used during training; it holds no intrinsic interest beyond biasing the learning of T_1, and after learning is completed, the scaffold is discarded.

A **syntactic scaffold** is a task designed to steer the (shared) model toward awareness of syntactic structure. It could be defined through a syntactic parser that shares some parameters with T_1's model. Since syntactic parsing is costly, we use simpler syntactic prediction problems (discussed below) that do not produce whole trees.

As with multitask learning in general, we do not assume that the same data are annotated with outputs for T_1 and T_2. In this work, T_2 is defined using phrase-structure syntactic annotations from OntoNotes 5.0 (Weischedel et al., 2013; Pradhan et al., 2013). We experiment with three settings: one where the corpus for T_2 does not overlap with the training datasets for T_1 (frame-SRL) and two where there is a complete overlap (PropBank SRL and coreference). Compared to approaches which require multiple output labels over the same data, we offer the major advantage of not requiring any assumptions about, or specification of, the relationship between T_1 and T_2 output.

3 Related Work

We briefly contrast the syntactic scaffold with existing alternatives.

Pipelines. In a typical pipeline, T_1 and T_2 are separately trained, with the output of T_2 used to define the inputs to T_1 (Wolpert, 1992). Using syntax as T_2 in a pipeline is perhaps the most

---

[1] This excludes models initialized with deep, contextualized embeddings (Peters et al., 2018), an approach orthogonal to ours.

common approach for semantic structure prediction (Toutanova et al., 2008; Yang and Mitchell, 2017; Wiseman et al., 2016).[2] However, pipelines introduce the problem of cascading errors (T_2's mistakes affect the performance, and perhaps the training, of T_1; He et al., 2013). To date, remedies to cascading errors are so computationally expensive as to be impractical (e.g., Finkel et al., 2006). A syntactic scaffold is quite different from a pipeline since the output of T_2 is never explicitly used.

Latent variables. Another solution is to treat the output of T_2 as a (perhaps structured) latent variable. This approach obviates the need of supervision for T_2 and requires marginalization (or some approximation to it) in order to reason about the outputs of T_1. Syntax as a latent variable for semantics was explored by Zettlemoyer and Collins (2005) and Naradowsky et al. (2012). Apart from avoiding marginalization, the syntactic scaffold offers a way to use auxiliary syntactically-annotated data as direct supervision for T_2, and it need not overlap the T_1 training data.

Joint learning of syntax and semantics. The motivation behind joint learning of syntactic and semantic representations is that any one task is helpful in predicting the other (Lluís and Màrquez, 2008; Lluís et al., 2013; Henderson et al., 2013; Swayamdipta et al., 2016). This typically requires joint prediction of the outputs of T_1 and T_2, which tends to be computationally expensive at both training and test time.

Part of speech scaffolds. Similar to our work, there have been multitask models that use part-of-speech tagging as T_2, with transition-based dependency parsing (Zhang and Weiss, 2016) and CCG supertagging (Søgaard and Goldberg, 2016) as T_1. Both of the above approaches assumed parallel input data and used both tasks as supervision. Notably, we simplify our T_2, throwing away the structured aspects of syntactic parsing, whereas part-of-speech tagging has very little structure to begin with. While their approach results in improved token-level representations learned via supervision from POS tags, these must still be composed to obtain span representations. Instead, our approach learns span-level representations from phrase-type supervision directly, for semantic tasks. Additionally, these methods explore architectural variations in RNN layers for including supervision, whereas we focus on incorporating supervision with minimal changes to the baseline architecture. To the best of our knowledge, such simplified syntactic scaffolds have not been tried before.

Word embeddings. Our definition of a scaffold task *almost* includes stand-alone methods for estimating word embeddings (Mikolov et al., 2013; Pennington et al., 2014; Peters et al., 2018). After training word embeddings, the tasks implied by models like the skip-gram or ELMo's language model become irrelevant to the downstream use of the embeddings. A noteworthy difference is that, rather than pre-training, a scaffold is integrated directly into the training of T_1 through a multitask objective.

Multitask learning. Neural architectures have often yielded performance gains when trained for multiple tasks together (Collobert et al., 2011; Luong et al., 2015; Chen et al., 2017; Hashimoto et al., 2017). In particular, performance of semantic role labeling tasks improves when done jointly with other semantic tasks (FitzGerald et al., 2015; Peng et al., 2017, 2018). Contemporaneously with this work, Hershcovich et al. (2018) proposed a multitask learning setting for universal syntactic dependencies and UCCA semantics (Abend and Rappoport, 2013). Syntactic scaffolds focus on a primary semantic task, treating syntax as an auxiliary, eventually forgettable prediction task.

4 Syntactic Scaffold Model

We assume two sources of supervision: a corpus $\mathcal{D}_1$ with instances $\mathbf{x}$ annotated for the primary task's outputs $\mathbf{y}$ (semantic role labeling or coreference resolution), and a treebank $\mathcal{D}_2$ with sentences $\mathbf{x}$, each with a phrase-structure tree $\mathbf{z}$.

4.1 Loss

Each task has an associated loss, and we seek to minimize the combination of task losses,

$$\sum_{(\mathbf{x},\mathbf{y})\in\mathcal{D}_1} \mathcal{L}_1(\mathbf{x},\mathbf{y}) + \delta \sum_{(\mathbf{x},\mathbf{z})\in\mathcal{D}_2} \mathcal{L}_2(\mathbf{x},\mathbf{z}) \tag{1}$$

with respect to parameters, which are partially shared, where δ is a tunable hyperparameter. In

---

[2] There has been some recent work on SRL which completely forgoes syntactic processing (Zhou and Xu, 2015), however it has been shown that incorporating syntactic information still remains useful (He et al., 2017).

the rest of this section, we describe the scaffold task. We define the primary tasks in Sections 5–6.

Each input is a sequence of tokens, $\mathbf{x} = \langle x_1, x_2, \ldots, x_n \rangle$, for some n. We refer to a **span** of contiguous tokens in the sentence as $\mathbf{x}_{i:j} = \langle x_i, x_{i+1}, \ldots, x_j \rangle$, for any $1 \leqslant i \leqslant j \leqslant n$. In our experiments we consider only spans up to a maximum length D, resulting in $O(nD)$ spans.

Supervision comes from a phrase-syntactic tree $\mathbf{z}$ for the sentence, comprising a syntactic category $z_{i:j} \in C$ for every span $\mathbf{x}_{i:j}$ in $\mathbf{x}$ (many spans are given a NULL label). We experiment with different sets of labels C (§4.2).

In our model, every span $\mathbf{x}_{i:j}$ is represented by an embedding vector $\mathbf{v}_{i:j}$ (see details in §5.3). A distribution over the category assigned to $z_{i:j}$ is derived from $\mathbf{v}_{i:j}$:

$$p(z_{i:j} = c \mid \mathbf{x}_{i:j}) = \operatorname*{softmax}_{c} \mathbf{w}_c \cdot \mathbf{v}_{i:j} \qquad (2)$$

where $\mathbf{w}_c$ is a parameter vector associated with category c. We sum the log loss terms for all the spans in a sentence to give its loss:

$$\mathcal{L}_2(\mathbf{x}, \mathbf{z}) = - \sum_{\substack{1 \leqslant i \leqslant j \leqslant n \\ j-i \leqslant D}} \log p(z_{i:j} \mid \mathbf{x}_{i:j}). \qquad (3)$$

4.2 Labels for the Syntactic Scaffold Task

Different kinds of syntactic labels can be used for learning syntactically-aware span representations:

- **Constituent identity**: $C = \{0, 1\}$; is a span a constituent, or not?
- **Non-terminal**: c is the category of a span, including a NULL for non-constituents.
- **Non-terminal and parent**: c is the category of a span, concatenated with the category of its immediate ancestor. NULL is used for non-constituents, and for empty ancestors.
- **Common non-terminals**: Since a majority of semantic arguments and entity mentions are labeled with a small number of syntactic categories,[3] we experiment with a three-way classification among (i) noun phrase (or prepositional phrase, for frame SRL); (ii) any other category; and (iii) NULL.

In Figure 1, for the span "*encouraging them*", the constituent identity scaffold label is 1, the non-terminal label is `S|VP`, the non-terminal and parent label is `S|VP+par=PP`, and the common non-terminals label is set to `OTHER`.

5 Semantic Role Labeling

We contribute a new SRL model which contributes a strong baseline for experiments with syntactic scaffolds. The performance of this baseline itself is competitive with state-of-the-art methods (§7).

FrameNet. In the FrameNet lexicon (Baker et al., 1998), a *frame* represents a type of event, situation, or relationship, and is associated with a set of semantic roles, called *frame elements*. A frame can be evoked by a word or phrase in a sentence, called a *target*. Each frame element of an evoked frame can then be realized in the sentence as a sentential span, called an *argument* (or it can be unrealized). Arguments for a given frame do not overlap.

PropBank. PropBank similarly disambiguates predicates and identifies argument spans. Targets are disambiguated to lexically specific *senses* rather than shared frames, and a set of generic roles is used for all targets, reducing the argument label space by a factor of 17. Most importantly, the arguments were annotated on top of syntactic constituents, directly coupling syntax and semantics. A detailed example for both formalisms is provided in Figure 1.

Semantic structure prediction is the task of identifying targets, labeling their frames or senses, and labeling all their argument spans in a sentence. Here we assume gold targets and frames, and consider only the SRL task.

Formally, a single input instance for argument identification consists of: an n-word sentence $\mathbf{x} = \langle x_1, x_2, \ldots, x_n \rangle$, a single target span $t = \langle t_{\text{start}}, t_{\text{end}} \rangle$, and its evoked frame, or sense, f. The argument labeling task is to produce a **segmentation** of the sentence: $\mathbf{s} = \langle s_1, s_2, \ldots, s_m \rangle$ for each input $\mathbf{x}$. A **segment** $s = \langle i, j, y_{i:j} \rangle$ corresponds to a labeled span of the sentence, where the label $y_{i:j} \in \mathcal{Y}_f \cup \{\text{NULL}\}$ is either a role that the span fills, or NULL if the span does not fill any role. In the case of PropBank, $\mathcal{Y}_f$ consists of all possible roles. The segmentation is constrained so that argument spans cover the sentence and do not overlap ($i_{k+1} = 1 + j_k$ for s_k; $i_1 = 1$; $j_m = n$). Segments of length 1 such that $i = j$ are allowed. A separate segmentation is predicted for each target annotation in a sentence.

---

[3] In the OntoNotes corpus, which includes both syntactic and semantic annotations, 44% of semantic arguments are noun phrases and 13% are prepositional phrases.

5.1 Semi-Markov CRF

In order to model the non-overlapping arguments of a given target, we use a semi-Markov conditional random field (**semi-CRF**; Sarawagi et al., 2004). Semi-CRFs define a conditional distribution over labeled segmentations of an input sequence, and are globally normalized. A single target's arguments can be neatly encoded as a labeled segmentation by giving the spans in between arguments a reserved NULL label. Semi-Markov models are more powerful than BIO tagging schemes, which have been used successfully for PropBank SRL (Collobert et al., 2011; Zhou and Xu, 2015, *inter alia*), because the semi-Markov assumption allows scoring variable-length segments, rather than fixed-length label n-grams as under an $(n-1)$-order Markov assumption. Computing the marginal likelihood with a semi-CRF can be done using dynamic programming in $O(n^2)$ time (§5.2). By filtering out segments longer than D tokens, this is reduced to $O(nD)$.

Given an input $\mathbf{x}$, a semi-CRF defines a conditional distribution $p(\mathbf{s} \mid \mathbf{x})$. Every segment $s = \langle i, j, y_{i:j}\rangle$ is given a real-valued score, $\psi(\langle i, j, y_{i:j} = r\rangle, \mathbf{x}_{i:j}) = \mathbf{w}_r \cdot \mathbf{v}_{i:j}$, where $\mathbf{v}_{i:j}$ is an embedding of the span (§5.3) and $\mathbf{w}_r$ is a parameter vector corresponding to its label. The score of the entire segmentation $\mathbf{s}$ is the sum of the scores of its segments: $\Psi(\mathbf{x}, \mathbf{s}) = \sum_{k=1}^{m} \psi(s_k, \mathbf{x}_{i_k:j_k})$. These scores are exponentiated and normalized to define the probability distribution. The sum-product variant of the semi-Markov dynamic programming algorithm is used to calculate the normalization term (required during learning). At test time, the max-product variant returns the most probable segmentation, $\hat{\mathbf{s}} = \arg\max_{\mathbf{s}} \Psi(\mathbf{s}, \mathbf{x})$.

The parameters of the semi-CRF are learned to maximize a criterion related to the conditional log-likelihood of the gold-standard segments in the training corpus (§5.2). The learner evaluates and adjusts segment scores $\psi(s_k, \mathbf{x})$ for every span in the sentence, which in turn involves learning embedded representations for all spans (§5.3).

5.2 Softmax-Margin Objective

Typically CRF and semi-CRF models are trained to maximize a conditional log-likelihood objective. In early experiments, we found that incorporating a structured cost was beneficial; we do so by using a softmax-margin training objective (Gimpel and Smith, 2010), a "cost-aware" variant of log-likelihood:

$$\mathcal{L}_1 = -\sum_{(\mathbf{x},\mathbf{s}^*)\in\mathcal{D}_1} \log \frac{\exp \Psi(\mathbf{s}^*, \mathbf{x})}{Z(\mathbf{x}, \mathbf{s}^*)}, \tag{4}$$

$$Z(\mathbf{x}, \mathbf{s}^*) = \sum_{\mathbf{s}} \exp\{\Psi(\mathbf{s}, \mathbf{x}) + \mathrm{cost}(\mathbf{s}, \mathbf{s}^*)\}. \tag{5}$$

We design the cost function so that it factors by predicted span, in the same way Ψ does:

$$\mathrm{cost}(\mathbf{s}, \mathbf{s}^*) = \sum_{s\in\mathbf{s}} \mathrm{cost}(s, \mathbf{s}^*) = \sum_{s\in\mathbf{s}} \mathbb{I}(s \notin \mathbf{s}^*). \tag{6}$$

The softmax-margin criterion, like log-likelihood, is globally normalized over all of the exponentially many possible labeled segmentations. The following zeroth-order semi-Markov dynamic program (Sarawagi et al., 2004) efficiently computes the new partition function:

$$\alpha_j = \sum_{\substack{s=\langle i,j,y_{i:j}\rangle\\ j-i\leqslant D}} \alpha_{i-1} \exp\{\Psi(s, \mathbf{x}) + \mathrm{cost}(s, \mathbf{s}^*)\}, \tag{7}$$

where $Z = \alpha_n$, under the base case $\alpha_0 = 1$.

The prediction under the model can be calculated using a similar dynamic program with the following recurrence where $\gamma_0 = 1$:

$$\gamma_j = \max_{\substack{s=\langle i,j,y_{i:j}\rangle\\ j-i\leqslant D}} \gamma_{i-1} \exp \Psi(s, \mathbf{x}). \tag{8}$$

Our model formulation enforces that arguments do not overlap. We do not enforce any other SRL constraints, such as non-repetition of core frame elements (Das et al., 2012).

5.3 Input Span Representation

This section describes the neural architecture used to obtain the span embedding, $\mathbf{v}_{i:j}$, corresponding to a span $\mathbf{x}_{i:j}$ and the target in consideration, $t = \langle t_{\text{start}}, t_{\text{end}}\rangle$. For the scaffold task, since the syntactic treebank does not contain annotations for semantic targets, we use the last verb in the sentence as a placeholder target, wherever target features are used. If there are no verbs, we use the first token in the sentence as a placeholder target. The parameters used to learn $\mathbf{v}$ are shared between the tasks.

We construct an embedding for the span using

- $\mathbf{h}_i$ and $\mathbf{h}_j$: contextualized embeddings for the words at the span boundary (§5.3.1),
- $\mathbf{u}_{i:j}$: a span summary that pools over the contents of the span (§5.3.2), and

- $\mathbf{a}_{i:j}$: and a hand-engineered feature vector for the span (§5.3.3).

This embedding is then passed to a feedforward layer to compute the span representation, $\mathbf{v}_{i:j}$.

5.3.1 Contextualized Token Embeddings

To obtain contextualized embeddings of each token in the input sequence, we run a bidirectional LSTM (Graves, 2012) with ℓ layers over the full input sequence. To indicate which token is a predicate, a linearly transformed one-hot embedding $\mathbf{v}$ is used, following Zhou and Xu (2015) and He et al. (2017). The input vector representing the token at position q in the sentence is the concatenation of a fixed pretrained embedding $\mathbf{x}_q$ and $\mathbf{v}_q$. When given as input to the bidirectional LSTM, this yields a hidden state vector $\mathbf{h}_q$ representing the qth token in the context of the sentence.

5.3.2 Span Summary

Tokens within a span might convey different amounts of information necessary to label the span as a semantic argument. Following Lee et al. (2017), we use an attention mechanism (Bahdanau et al., 2014) to summarize each span. Each contextualized token in the span is passed through a feed-forward network to obtain a weight, normalized to give $\sigma_k = \operatorname{softmax}_{i \leqslant k \leqslant j} \mathbf{w}^{\text{head}} \cdot \mathbf{h}_k$, where $\mathbf{w}^{\text{head}}$ is a learned parameter. The weights σ are then used to obtain a vector that summarizes the span, $\mathbf{u}_{i:j} = \sum_{i \leqslant k \leqslant j; j-i<D} \sigma_k \cdot \mathbf{h}_k$.

5.3.3 Span Features

We use the following three features for each span:

- width of the span in tokens (Das et al., 2014)
- distance (in tokens) of the span from the target (Täckström et al., 2015)
- position of the span with respect to the target (*before*, *after*, *overlap*) (Täckström et al., 2015)

Each of these features is encoded as a one-hot-embedding and then linearly transformed to yield a feature vector, $\mathbf{a}_{i:j}$.

6 Coreference Resolution

Coreference resolution is the task of determining clusters of mentions that refer to the same entity. Formally, the input is a document $\mathbf{x} = x_1, x_2, \ldots, x_n$ consisting of n words. The goal is to predict a set of clusters $\mathbf{c} = \{c_1, c_2, \ldots\}$, where each cluster $c = \{s_1, s_2, \ldots\}$ is a set of spans and each span $s = \langle i, j \rangle$ is a pair of indices such that $1 \leqslant i \leqslant j \leqslant n$.

As a baseline, we use the model of Lee et al. (2017), which we describe briefly in this section. This model decomposes the prediction of coreference clusters into a series of span classification decisions. Every span s predicts an antecedent $w_s \in \mathcal{Y}(s) = \{\textsc{null}, s_1, s_2, \ldots, s_m\}$. Labels s_1 to s_m indicate a coreference link between s and one of the m spans that precede it, and NULL indicates that s does not link to anything, either because it is not a mention or it is in a singleton cluster. The predicted clustering of the spans can be recovered by aggregating the predicted links.

Analogous to the SRL model (§5), every span s is represented by an embedding $\mathbf{v}_s$, which is central to the model. For each span s and a potential antecedent $a \in \mathcal{Y}(s)$, pairwise coreference scores $\Psi(\mathbf{v}_s, \mathbf{v}_a, \phi(s, a))$ are computed via feedforward networks with the span embeddings as input. $\phi(s, a)$ are pairwise discrete features encoding the distance between span s and span a and metadata, such as the genre and speaker information. We refer the reader to Lee et al. (2017) for the details of the scoring function.

The scores from Ψ are normalized over the possible antecedents $\mathcal{Y}(s)$ of each span to induce a probability distribution for every span:

$$p(w_s = a) = \operatorname*{softmax}_{a \in \mathcal{Y}(s)} \Psi(\mathbf{v}_s, \mathbf{v}_a, \phi(s, a)) \tag{9}$$

In learning, we minimize the negative log-likelihood marginalized over the possibly correct antecedents:

$$\mathcal{L}_1 = -\sum_{s \in \mathcal{D}} \log \sum_{a^* \in G(s) \cap \mathcal{Y}(s)} p(w_s = a^*) \tag{10}$$

where $\mathcal{D}$ is the set of spans in the training dataset, and $G(s)$ indicates the gold cluster of s if it belongs to one and $\{\textsc{null}\}$ otherwise.

To operate under reasonable computational requirements, inference under this model requires a two-stage beam search, which reduces the number of span pairs considered. We refer the reader to Lee et al. (2017) for details.

Input span representation. The input span embedding, $\mathbf{v}_s$ for coreference resolution and its syntactic scaffold follow the definition used in §5.3, with the key difference of using no target features. Since there is a complete overlap of input sentences between $\mathcal{D}_{\text{sc}}$ and $\mathcal{D}_{\text{pr}}$ as the coreference annotations are also from OntoNotes (Pradhan et al., 2012), we reuse the **v** for the scaffold task. Additionally, instead of the entire document, each sentence in it is independently given as input to the bidirectional LSTMs.

7 Results

We evaluate our models on the test set of FrameNet 1.5 for frame SRL and on the test set of OntoNotes for both PropBank SRL and coreference. For the syntactic scaffold in each case, we use syntactic annotations from OntoNotes 5.0 (Weischedel et al., 2013; Pradhan et al., 2013).[4] Further details on experimental settings and datasets have been elaborated in the supplemental material.

Frame SRL. Table 1 shows the performance of all the scaffold models on frame SRL with respect to prior work and a semi-CRF baseline (§5.1) without a syntactic scaffold. We follow the official evaluation from the SemEval shared task for frame-semantic parsing (Baker et al., 2007).

Prior work for frame SRL has relied on predicted syntactic trees, in two different ways: by using syntax-based rules to prune out spans of text that are unlikely to contain any frame's argument; and by using syntactic features in their statistical model (Das et al., 2014; Täckström et al., 2015; FitzGerald et al., 2015; Kshirsagar et al., 2015).

The best published results on FrameNet 1.5 are due to Yang and Mitchell (2017). In their sequential model (SEQ), they treat argument identification as a sequence-labeling problem using a deep bidirectional LSTM with a CRF layer. In their relational model (REL), they treat the same problem as a span classification problem. Finally, they introduce an ensemble to integerate both models, and use an integer linear program for inference satisfying SRL constraints. Though their model does not do any syntactic pruning, it does use syntactic features for argument identification and labeling.[5]

Notably, all prior systems for frame SRL listed in Table 1 use a pipeline of syntax and semantics. Our semi-CRF baseline outperforms all prior work, without any syntax. This highlights the benefits of modeling spans and of global normalization.

Turning to scaffolds, even the most coarse-grained constituent identity scaffold improves the performance of our syntax-agnostic baseline. The nonterminal and nonterminal and parent scaffolds, which use more detailed syntactic representations, improve over this. The greatest improvements come from the scaffold model predicting common nonterminal labels (`NP` and `PP`, which are the most common syntactic categories of semantic arguments, vs. others): 3.6% absolute improvement in F_1 measure over prior work.

Contemporaneously with this work, Peng et al. (2018) proposed a system for joint frame-semantic and semantic dependency parsing. They report results for joint frame and argument identification, and hence cannot be directly compared in Table 1. We evaluated their output for argument identification only; our semi-CRF baseline model exceeds their performance by 1 F_1, and our common nonterminal scaffold by 3.1 F_1.[6]

---

[4] `http://cemantix.org/data/ontonotes.html`

[5] Yang and Mitchell (2017) also evaluated on the full frame-semantic parsing task, which includes frame-SRL as well as identifying frames. Since our frame SRL performance improves over theirs, we expect that incorporation into a full system (e.g., using their frame identification module) would lead to overall benefits as well; this experiment is left to future work.

[6] This result is not reported in Table 1 since Peng et al. (2018) used a preprocessing which renders the test set slightly larger — the difference we report is calculated using their test set.

Table 3: Coreference resolution results on the test set on the English CoNLL-2012 shared task. The average F_1 of MUC, B^3, and $CEAF_{\phi_4}$ is the main evaluation metric. For fair comparison, we show only non-ensembled models.

PropBank SRL. We use the OntoNotes data from the CoNLL shared task in 2012 (Pradhan et al., 2013) for Propbank SRL. Table 2 reports results using gold predicates.

Recent competitive systems for PropBank SRL follow the approach of Zhou and Xu (2015), employing deep architectures, and forgoing the use of any syntax. He et al. (2017) improve on those results, and in analysis experiments, show that constraints derived using syntax may further improve performance. Tan et al. (2018) employ a similar approach but use feed-forward networks with self-attention. He et al. (2018a) use a span-based classification to jointly identify and label argument spans.

Our syntax-agnostic semi-CRF baseline model improves on prior work (excluding `ELMo`), showing again the value of global normalization in semantic structure prediction. We obtain further improvement of 0.8 absolute F_1 with the best syntactic scaffold from the frame SRL task. This indicates that a syntactic inductive bias is beneficial even when using sophisticated neural architectures.

He et al. (2018a) also provide a setup where initialization was done with deep contextualized embeddings, `ELMo` (Peters et al., 2018), resulting in 85.5 F_1 on the OntoNotes test set. The improvements from `ELMo` are methodologically orthogonal to syntactic scaffolds.

Since the datasets for learning PropBank semantics and syntactic scaffolds *completely* overlap, the performance improvement cannot be attributed to a larger training corpus (or, by extension, a larger vocabulary), though that might be a factor for frame SRL.

A syntactic scaffold can match the performance of a pipeline containing carefully extracted syntactic features for semantic prediction (Swayamdipta et al., 2017). This, along with other recent approaches (He et al., 2017, 2018b) show that syntax remains useful, even with strong neural models for SRL.

Coreference. We report the results on four standard scores from the CoNLL evaluation: MUC, B^3 and $CEAF_{\phi_4}$, and their average F_1 in Table 3. Prior competitive coreference resolution systems (Wiseman et al., 2016; Clark and Manning, 2016b,a) all incorporate synctactic information in a pipeline, using features and rules for mention proposals from predicted syntax.

Our baseline is the model from Lee et al. (2017), described in §6. Similar to the baseline model for frame SRL, and in contrast with prior work, this model does not use any syntax.

We experiment with the best syntactic scaffold from the frame SRL task. We used `NP`, `OTHER`, and NULL as the labels for the common nonterminals scaffold here, since coreferring mentions are rarely prepositional phrases. The syntactic scaffold outperforms the baseline by 0.6 absolute F_1. Contemporaneously, Lee et al. (2018) proposed a model which takes in account higher order inference and more aggressive pruning, as well as initialization with `ELMo` embeddings, resulting in 73.0 average F_1. All the above are orthogonal to our approach, and could be incorporated to yield higher gains.

8 Discussion

To investigate the performance of the syntactic scaffold, we focus on the frame SRL results, where we observed the greatest improvement with respect to a non-syntactic baseline.

We consider a breakdown of the performance by the syntactic phrase types of the arguments, provided in FrameNet[7] in Figure 2. Not surpris-

---

[7] We used FrameNet syntactic phrase annotations for analysis only, and not in our models, since they are annotated only for the gold arguments.

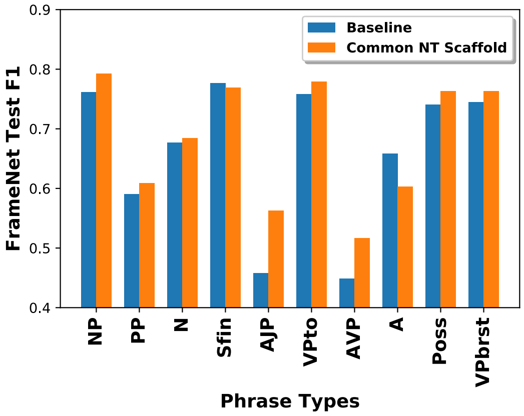

Figure 2: Performance breakdown by argument's phrase category, sorted left to right by frequency, for top ten phrase categories.

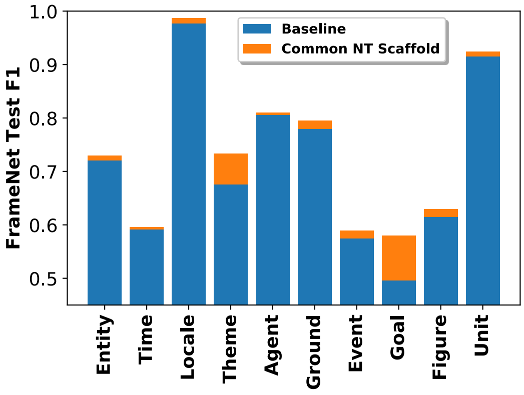

Figure 3: Performance breakdown by top ten frame element types, sorted left to right by frequency.

ingly, we observe large improvements in the common nonterminals used (`NP` and `PP`). However, the phrase type annotations in FrameNet do not correspond exactly to the OntoNotes phrase categories. For instance, FrameNet annotates non-maximal (`A`) and standard adjective phrases (`AJP`), while OntoNotes annotations for noun-phrases are flat, ignore the underlying adjective phrases. This explains why the syntax-agnostic baseline is able to recover the former while the scaffold is not.

Similarly, for frequent frame elements, scaffolding improves performance across the board, as shown in Fig. 3. The largest improvements come for `Theme` and `Goal`, which are predominantly realized as noun phrases and prepositional phrases.

9 Conclusion

We introduced syntactic scaffolds, a multitask learning approach to incorporate syntactic bias into semantic processing tasks. Unlike pipelines and approaches which jointly model syntax and semantics, no explicit syntactic processing is required at runtime. Our method improves the performance of competitive baselines for semantic role labeling on both FrameNet and PropBank, and for coreference resolution. While our focus was on span-based tasks, syntactic scaffolds could be applied in other settings (e.g., dependency and graph representations). Moreover, scaffolds need not be syntactic; we can imagine, for example, *semantic* scaffolds being used to improve NLP applications with limited annotated data. It remains an open empirical question to determine the relative merits of different kinds of scaffolds and multitask learners, and how they can be most productively combined. Our code is publicly available at `https://github.com/swabhs/scaffolding`.

Acknowledgments

We thank several members of UW-NLP, particularly Luheng He, as well as David Weiss and Emily Pitler for thoughtful discussions on prior versions of this paper. We also thank the three anonymous reviewers for their valuable feedback. This work was supported in part by NSF grant IIS-1562364 and by the NVIDIA Corporation through the donation of a Tesla GPU.

Abstract

Scripts define knowledge about how everyday scenarios (such as going to a restaurant) are expected to unfold. One of the challenges to learning scripts is the hierarchical nature of the knowledge. For example, a suspect arrested might plead innocent or guilty, and a very different track of events is then expected to happen. To capture this type of information, we propose an autoencoder model with a latent space defined by a hierarchy of categorical variables. We utilize a recently proposed vector quantization based approach, which allows continuous embeddings to be associated with each latent variable value. This permits the decoder to softly decide what portions of the latent hierarchy to condition on by attending over the value embeddings for a given setting. Our model effectively encodes and generates scripts, outperforming a recent language modeling-based method on several standard tasks, and allowing the autoencoder model to achieve substantially lower perplexity scores compared to the previous language modeling-based method.

1 Introduction

Scripts were originally proposed by Schank and Abelson (1977) as "structures that describe the appropriate sequence of events in a particular context". These event sequences define expectations for how common scenarios (such as going to a restaurant) should unfold, thus enabling better language understanding. Although scripts represented many other factors (roles, entry conditions, outcomes) recent work in script induction (Rudinger et al., 2015; Pichotta and Mooney, 2016; Peng and Roth, 2016) has focused on language modeling (LM) approaches where the "appropriate sequence of events" is the textual order of events (tuples of event predicates and their arguments). Modeling a distribution of text sequences gives the intuitive interpretation of *appropriate* event sequences being roughly equivalent to *probable* textual sequences. We continue with an LM approach, but we tackle two very important LM problems that have not yet been addressed with regards to event sequence modeling.

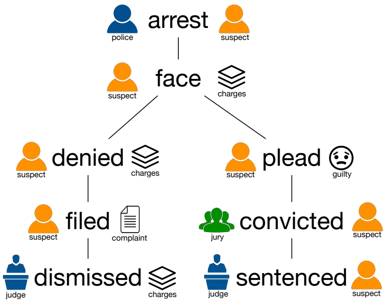

Figure 1: An automatically learned multi-track script. The left track is a dismissed case, and the right is a convicted suspect. Our model generated both tracks through a latent hierarchy.

The first problem to address is that *language models tend towards local coherency*. Count based models are restricted by window size and sparse counts, while neural language models are known to rely on the local context for predictions. Since scripts are meant to describe longer coherent scenarios, this is a major issue. For example, contradictory events like *(he denied charges)* and *(he pleads guilty)* are given high probability in a typical language model. Our model instead captures these variations with learned latent variables.

The second problem with recent work is that *the hierarchical nature of scripts is not explicitly captured*. A high level script (like a suspect getting arrested) can branch off into many possible variations. These variations are called the "tracks" of a script. Figure 1 shows a script with two tracks learned by our model. LM-based approaches often fail to explicitly capture this structure, instead

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3783–3792
Brussels, Belgium, October 31 - November 4, 2018. ©2018 Association for Computational Linguistics

throwing it all into one big distribution. This muddies the water for language understanding, making it difficult to tease apart differences like going to a *fancy* restaurant or a *casual* restaurant.

To remedy these problems, we propose a model that captures hierarchical structure via global latent variables. The latent variables are categorical (representing the various types of scripts and thier possible tracks and variations) and form a tree (or more generally, a DAG)[1], thus capturing hierarchical structure with the top (or bottom) levels of the tree representing high (or low) level features of the script. The top might control for large differences like restaurant vs crime, while the bottom selects between fancy and casual dining.

The overall model, which we describe below, takes the form of an autoencoder, with an encoder network inferring values of the latents and a decoder conditioned on the latents generating scripts. We show the usefulness of these latent representations against a prior RNN language model based system (Pichotta and Mooney, 2016) on several tasks. We additionally evaluate the perplexity of the system against the RNN language model, a task that autoencoder models have typically struggled with (Bowman et al., 2016). We find that the latent tree reduces model perplexity by a significant amount, possibly indicating the usefulness of the model in a more general sense.

2 Background

2.1 Variational Autoencoders

Variational Autoencoders (VAEs, Kingma and Welling (2014)) are generative models which learn latent codes z for the data x by maximizing a lower bound on the data likelihood:

$$\log(p(x)) \geq \mathrm{E}_{q(z|x)}[p(x|z)] - KL[q(z|x)||p(z)]$$

VAEs consist of two components: an encoder which parameterizes the latent posterior $q(z|x)$ and a decoder which parameterizes $p(x|z)$. The objective function can be made completely differentiable via the reparameterization trick, with the full model resembling an autoencoder and the KL term acting as a regularizer.

While VAEs have been useful in continuous domains, they have been less successful in generating discrete domains whose outputs have local syntactic regularities. Part of this is due to the “posterior collapse” problem (Bowman et al., 2016); when VAEs are equipped with powerful autoregressive decoders, they tend to ignore the latent, collapsing the posterior $q(z|x)$ to the (usually zero-mean Gaussian) prior $p(z)$. By doing this, the model takes no penalty from the KL term, but effectively ignores its encoder.

2.2 Vector Quantized Variational Autoencoders

Vector Quantized VAEs (VQ-VAEs, van den Oord et al. (2017)) are a recently proposed class of models which both alleviates the posterior collapse problem and allows the model to use a latent space of discrete values. In VQ-VAEs the latent z is represented as a categorical variable that can take on K values. Each of these values $k \in \{1, ..., K\}$ has associated with it a vector embedding e_k. The posterior of VQ-VAEs are discrete, deterministic, and parameterized as follows:

$$q(z=k|x) = \begin{cases} 1 & \text{k=argmin}_i ||f(x) - e_i||_2 \\ 0 & \text{elsewise} \end{cases}$$

where $f(x)$ is a function defined by an encoder network. The decoding portion of the network is similar to VAEs, where a decoder parameterizes a distribution $p(x|z = k) = g(e_k)$, where g is the decoder network, and e_k is the corresponding embedding, which is fed as input to the decoder. This process can be seen as a ”quantization” operation mapping the continuous encoder output to the latent embedding it falls closest to, and then feeding this latent embedding (in lieu of the encoder output) to the decoder.

The quantization operator is not differentiable, thus during training, the gradient of the loss with respect to the decoder input is used as an estimation to the gradient of the loss with respect to the encoder output. If one assumes a uniform prior over the latents (we do so here), then the KL term in the VAE objective becomes constant and may be ignored. In practice, multiple latent variables z may by used, each with their own (or shared) embeddings space.

3 Hierarchical Quantized Autoencoder

Our goal is to build a model that can generate globally coherent multi-track scripts which allow us to account for the different ways in which a script can unfold. The main idea behind our approach

---

[1] In this work we only look at linear chains of categorical variables, which is enough to encode trees (such as the one in Figure 1)

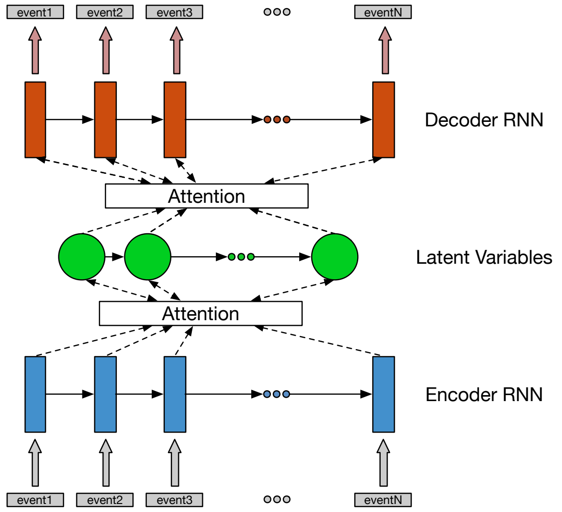

Figure 2: Hierarchical Quantized Autoencoder Architecture

is to use a hierarchical latent space which conditions the generation of the scripts. The VQ-VAE models (described earlier) provide a way to model discrete variables in an autoencoding framework while avoiding the posterior collapse problem. We build on this framework to propose a new HierarchicAl Quantized Autoencoder (HAQAE) model.

HAQAEs are autoencoders with M latent variables, $z_0, ..., z_M$. Each latent variable is categorical taking on K different values. Like in VQ-VAEs, every categorical value k for variable z has an associated embeddings e_{zk}. The latent variables are given a tree structure and the full posterior over all M latents **z** factorizes as:

$$q(\mathbf{z}|x) = q_0(z_0|x)\prod_{i=1}^{M-1} q_i(z_i|pr(z_i), x)$$

where $pr(z_i)$ denotes the parent of z_i in the tree. Since the latent variables are meant to capture the hierarchical categorization of the script, we make the assumption that when a higher level script category (for example, z_0) is observed with the actual sequence of events (x), determining the immediate lower level category (z_1) is a deterministic operation. Thus, similar to VQ-VAEs, we parameterize the individual factors of the posterior, $q_i(z_i = k|pr(z_i), x)$, as:

$$\begin{cases} 1 & \text{k=argmin}_j ||f_i(x, pr(z_i)) - e_{ij}||_2 \\ 0 & \text{elsewise} \end{cases}$$

where $f_i(x, pr(z_i))$ is an encoding function specific to latent z_i and e_{ij} is the jth value embeddings for z_i. The distribution $p(x|\mathbf{z})$ is similarly parameterized by an decoder function $g(\mathbf{z}_e)$, where $\mathbf{z}_e$ is the set of corresponding value embedding for each latent z_i. We describe the forms of the encoder and decoder in the next section.

3.1 HAQAE Encoder and Decoder

During the encoding process, certain parts of the input may provide more evidence towards different parts of the hierarchy. For example, the event *(he ate food)* gives evidence to the high level category of a *restaurant* script, while the more specific event *(he drank wine)* gives more evidence to the lower level category *fancy restaurant*. Thus during encoding, it makes sense to allow each latent to decide which parts of the input to take into consideration, based on its parent latents. This is accomplished by parameterizing the encoding function for latent z_i as an attention over the input x, with the parent of z_i (more specifically, the embedding for the parent's current value) acting as the 'query' vector. As is standard when using attention, the input sequence of events, $x = (x_1, ...x_n)$, is first encoded into a sequence of hidden states $\mathbf{h}_x = (h_1, ..., h_n)$ via a RNN encoder. The full encoding function for latent z_i can thus be written as:

$$f_i(x, pr(z_i)) = attn(\mathbf{h}_x, pr(z_i))$$

Though any attention formulation is possible, we use the bi-linear attention proposed in Luong et al. (2015) in our implementations. For the root of the latent tree (z_0), which has no parents, we use the averaged value of the encoder vectors $\mathbf{h}_x$ as the query vector for its attention.

We can define the decoder in a similar fashion. As is usually done, the distribution $p(x|\mathbf{z}_e)$ can be defined in an autoregressive manner using a RNN decoder network. Like the encoding process, different parts of the hierarchy may affect the generation of different parts of the input. We thus also allow the decoder network $g(\mathbf{z}_e)$ to be a RNN with a standard attention mechanism over the latent value embeddings, $\mathbf{z}_e$. Since the latent root z_0 is supposed to capture the highest level information about the script, we use its embedding value, (passed through an affine transformation and tanh activation) to initialize the hidden state of the decoder. Both encoder and decoder can be trained end to end using the same gradient estimation used for VQ-VAE.

3.2 Training Objective

The training objective for HAQAE is nearly the same as the VQ-VAE objective proposed in van den Oord et al. (2017). For a single training example, x_i the objective can be written as:

$$L = -\log p(x_i|\mathbf{z}) + \frac{1}{M}\sum_{j}^{M} L_j^R + \frac{1}{M}\sum_{j}^{M} L_j^C$$

where L_j^R and L_j^C are the *reconstruct* and *commit* loss for the jth latent variable. As in van den Oord et al. (2017), we let $sg(\cdot)$ stand for a *stop gradient* operator, such that any term passed to it is treated as a constant. The reconstruction loss is defined as:

$$L_j^R = ||sg(f_j(x, pr(z_j))) - e_j^*||_2^2$$

where e_j^* is the argmin value embedding for z_j (for the given input). The reconstruct loss is how the value embeddings for **z** are learned, and pushes the value embeddings to be closer to the output of the f_i. The commit loss is defined as:

$$L_j^C = \beta||f_j(x, pr(z_j)) - sg(e_j^*)||_2^2$$

which forces the encoder to push its output closer to *some* embedding, preventing a situation in which the encoder maps inputs far away from all embeddings. β is a hyperparameter that weighs the commit loss[2]. Note that the commitment loss may be propogated all the way up through the hierarchy of latent nodes. We allow the latent embeddings to receive updates only from the reconstruct and commit loss (*not* from the NLL loss).

4 Training Details

4.1 Dataset and Preprocessing

Dataset We use the New York Times Gigaword Corpus as our dataset. The corpus contains a total of around 1.8 million articles. We hold out 4000 articles from the corpus to construct our development (dev) set for hyperparameter tuning and 6000 articles for the test set. The input and output of the model is in the form of an event sequence. Each event is defined as a 4-tuple, (v, s, o, p), containing the verb, subject, object and preposition. Events without prepositions are given a null token in their preposition slot. The components of the events (the verb, subject, etc.) are all taken to be individual tokens, and can thus be treated more or less like normal text. For example, the events *(he played harp), (he touched moon)*, would be tokenized and given to the model as: *played he harp null tup touched he moon null*, where *null* is the null preposition token and *tup* is a special separation token between events.

We extract event tuples using Open Information Extraction system Ollie (Mausam et al., 2012). We then group together event tuples for 4 subsequent sentences to create a single event sequence. We also ignore tuples with common (*is, are, be, ...*) and repeating predicates. Finally we have 7123097, 19425, and 28667 event sequences for training, dev, and test dataset respectively. For all the experiments we fix the minimum and maximum sequence lengths to be 8 and 50 respectively.

4.2 HAQAE Model Details

The HAQAE model we use across all evaluations uses 5 discrete latent variables, structured in the form of a linear chain (thus no variable has more than one child or parent). Each variable can initially take on $K = 512$ values, with all latents having an embeddings dimension of 256. The encoder RNN that performs the initial encoding of the event sequence is a bidirectional, single layer RNN with GRU cell (Cho et al., 2014) with a hidden dimension of 512. The inputs to this encoder are word embeddings derived from the one-hot encodings of the tokens in the event sequence. The embeddings size is 300. We find initializing the embeddings with pretrained GloVe (Pennington et al., 2014) vectors to be useful. The decoder RNN is also a single layer RNN with GRU cells with a hidden dimension of 512 and 300 dimensional (initialized) word embeddings as inputs. For all experiments we use a vocabulary size of 50k. We train the model using Adam (Kingma and Ba, 2014) with a learning rate of 0.0005, and gradient clipping at 5.0. We find that the training converges around 1.5 epochs on our dataset. Further details can be found in our implementation[3]

4.3 Baselines

We compare the performance of our proposed model against three previous baselines and a modification of our HAQAE model that removes explicit dependencies between latents.

RNN Language Model For our first baseline system we train a RNN sequence model. This

---

[2] In our implementations we set $\beta = 0.25$

[3] `github.com/StonyBrookNLP/HAQAE`

model is 2 layered GRU cells with hidden size 512 and embedding size 300. We use Adam with a learning rate 0.001. To prevent the problem of exploding gradients, we clip the gradients at 10. We use uniform distribution [-0.1, 0.1] for random initialization and biases initialized to zero. We also use a dropout of 0.15 on the input and output embedding layers but none on the recurrent layers. We initialize the word embedding layer with pretrained Glove vectors as it improved the performance and makes the system directly comparable to HAQAE. We refer to this model as **RNNLM** in the following sections.

RNNLM + Role Embeddings We also reproduced the model from Pichotta and Mooney (2016) for comparison. This model is similar to the one above except that at each time step the model has an additional role marker input going into it. The marker guides the language model further by indicating what type of input is being currently fed to it: a subject, object, or predicate. These role embeddings are learned during training itself. Hyperparameters are exactly the same as the RNNLN except that the role embeddings have a dimension of 300. We will refer to this model as **RNNLM+Role**. We perform hyperparameter tuning of both the models using the development set. We use a vocabulary size of 50k. We trained both the baseline models for 2 epochs on the training set.

VAE We report results using a vanilla VAE model similar to the one used in Bowman et al. (2016). The encoder/decoder for the VAE baseline has the same specs as the encoder/decoder for the HAQAE model, with a latent dimension of 300. We use linear KL annealing for the first 15000 steps and 0.5 as the word dropout rate.

Hierarchyless HAQAE (NOHIER) In order to test the effect of explicitly having a hierarchy in the latent variables, we additionally train another HAQAE model with no explicit hierarchical latent space. The model still has 5 discrete latent variables like our original model, however each of the variables are independent of each other (given the input). All five variables are have an attention over the input and take the average of encoder vectors $\mathbf{h}_x$ as the query vector (as done with the latent root z_0 in the original model). We additionally designate one of the variables to be used to initialize the hidden state of the decoder. We found the same training hyperparmaters used in the training of the original model to work well here.

System	validation		test	
	NLL	PPL	NLL	PPL
RNNLM	4.52	91.84	4.51	90.92
RNNLM+Role	4.53	92.76	4.53	92.76
VAE	4.56	95.58	4.55	94.63
NOHIER	3.77	43.38	3.78	43.82
HAQAE	**3.73**	**41.68**	**3.74**	**42.10**

Table 1: Negative log-likelihood (NLL) and perplexity (PPL) measures on the validation and test set. Lower is better for both metrics.

5 Evaluation

5.1 Language Modeling: Perplexity

As our proposed models are essentially language models, it is natural to evaluate their perplexity scores, which can be viewed as an indirect measure of how well the models can identify scripts. We compute per-word perplexity and per-word negative log likelihood on the validation and test sets. We compute these values without considering the end-of-sentence (EOS) token. Table 1 gives these results. A good language model should assign low perplexity (high probability) to the validation and test sets. We observe that HAQAE achieves the minimum negative log likelihood and perplexity scores on both the validation and test sets as compared to the previous RNN-based models. The result is particularly interesting as autoencoders usually perform worse or comparable to other RNN language models in terms of perplexity (negative log likelihood) as is in the case of the vanilla VAE here; similar observations have also been made in Bowman et al. (2016).

5.2 Inverse Multiple Choice Narrative Cloze

Narrative cloze evaluations of event based language models (LMs) start with a sequence of events as input and test whether the LMs correctly predict a single held-out event. The standard narrative cloze task has various issues (Chambers, 2017). In our evaluations we opt instead for the multiple choice variant proposed in Granroth-Wilding and Clark (2016).

One of our goals is to test if our generative model can produce globally coherent scripts by evaluating their ability to generate coherent event sequences. To evaluate this we create a new *in-*

System	validation	test
RNNLM	25.30	26.30
RNNLM+Role	24.60	26.35
VAE	26.54	28.01
NOHIER	31.68	**34.00**
HAQAE	**31.80**	33.85

Table 2: Inverse narrative cloze accuracy(%) on randomly selected 2k validation and test set. Models scored on whether they assign a higher probability to legitimate event sequence over detractor event sequences. Higher is better.

verse narrative cloze task. Instead of being given an event sequence and predicting a single event to go with it, we instead are given only *one event* and the model must identify the rest of the event sequence. The model is identifying sequences of events, not single events. We chose this setup because sequences is what we ultimately want, but also because identifying single events resulted in very high scores (around 98% accuracy). This task proved to be more challenging as an evaluation.

We thus score a model based on the probability it assigns to event sequences that begin with a single input event. A legitimate event sequence should have high probability compared to an event sequence that is stitched together using two random event sequences. We create legitimate event sequences of a fixed length (six) by extracting actual event sequences observed in documents. For every legitimate event sequence, we use the first event in the sequence as a seed event. Then, we construct detractor event sequences for this seed by appending a different sequence of events (number of events being five) from a randomly chosen document. We create five such detractor sequences for every legitimate sequence. We rank the six sequences based on the probabilities assigned by the model and then evaluate the accuracy of the top ranked sequence. A random model will uniformly choose one among the six sequences and thus will score $16 = 16.60\%$ on the task. We report results averaged over 2000 sets of legitimate and detractor sequences.

Results in Table 2 show that the HAQAE is substantially better than both RNN LMs and vanilla VAE and similar to the NOHIER model, which shows the usefulness of the quantized embeddings overall as a global representation. The comparable results of the NOHIER model on this task might also indicate that explicitly modeling the hierarchical structure may not be completely necessary if ones only aim is to capture global coherence. The results on the perplexity task do indicate that overall, modeling the hierarchical structure is useful for better prediction.

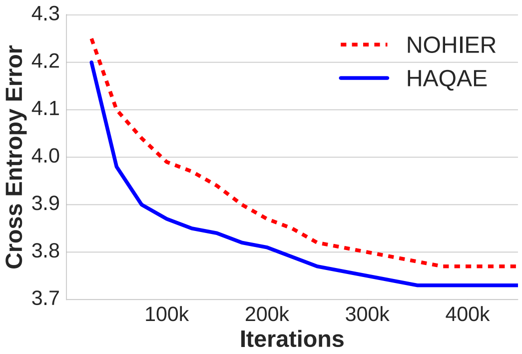

Figure 3: Cross entropy error on dev set of NOHIER (red) and HAQAE (blue) models as training progresses.

5.3 Comparing HAQAE and NOHIER

Both HAQAE and NOHIER models achieve the best results across all tasks. The HAQAE model does better on the perplexity task, while results of the two models on the cloze task are nearly the same. One clear benefit of explicitly connecting the latent variables together appears to be in the efficiency of the learning. The HAQAE model performs comparable or better than the NOHIER model despite (in this case at least) having fewer parameters[4].

The HAQAE model also appears to learn much faster than the NOHIER model. We show this in Figure 3, which shows the per-word cross entropy error on the validation set as training progresses. We observe that the cross entropy error drops much faster in the latter model than the former one. Also, the error is always lower for the HAQAE model.

One possibility is that the NOHIER model learns similar information as the HAQAE model, but due to its lack of explicit inductive bias, takes a longer time to learn this. We leave it as future work to confirm whether this is the case through an in depth study into the properties of the learned discrete latents.

---

[4] NOHIER has more parameters in our case due to each latent taking a bidirectional encoder state as a query vector, as opposed to taking the parent latent vector as the query

5.4 Evaluating Event Schemas

So far, we've evaluated how well the models recognize real textual events (perplexity) and how well the models predict events in scripts (narrative cloze). This section evaluates the script generation ability of the model, and specifically its ability to capture hierarchical information with different tracks in scripts (e.g., *pleading guilty* causes different events to occur than does *pleading innocent*). In many respects, this section illustrates best the power of HAQAE even though the results are partly subjective.

While we presented two automatic evaluations above, we shift to human judgment to evaluate the scripts themselves. We believe this complements the empirical gains already presented. The scripts generated by the models were shown to human judges and scored on several metrics.

Most previous work on script induction starts with a seed event and then grows the script based on measures of event proximity or from sampling the distribution with the seed as context. While effective in generating a bag of events, a major problem in all previous work is that conflicting events are included (sentenced *and* acquitted). While the events are related and part of the same high-level script, they should never appear together in an actual instance of a script.

In order to evaluate our model for this type of knowledge, we instead defined a seed as 2 events: the first event sets the general topic, and the second event starts a specific *track* in that topic. For instance, below are two seeds that are intended to generate two tracks for the same script:

"people reported fire"
"fire spread in neighborhood"

"people reported fire"
"fire spread to forest"

For each seed (2 events in one seed) we select the first 3 events generated by a model conditioned on the seed as context. The 2 events in a seed thus initialize the latent variable values, which then inform the decoder to generate more events (we choose the first 3). The strength of our model is that the second event helps select the more specific script track, and to ignore conflicting events in other tracks.

While generating for both RNNLM+Role and HAQAE models, we additionally enforce a constraint that restricts models from generating events that have a predicate that has already been generated, as well as events whose subject and object are the same.

We evaluated the RNNLM+Role model from Pichotta and Mooney (2016) against our proposed HAQAE. Each model was given 40 seeds (20 first event each with 2 contrasting second seed) and thus generated 40 scripts. The annotators were also shown the seeds (2 events), and then asked to rate each three-event sequence for various metrics described below.

Non-Sensical (Sense): Binary, is each event itself non-sensical or understandable?

Event Relevance (Rel): Binary, each event was scored for being relevant or not to the script topic. This ignored whether it was consistent with the seed's branch.

Coherency with Branch (Coh): 0-2, each event was scored for being coherent with the seed's specific branch (the second event). 0 means not at all, 1 means somewhat, and 2 means yes.

Branching Uniqueness (BranchU): 0-2, each pair of scripts (both branches of the same topic) were scored for overlap of events. 0 means similar events generated for both, 1 means some similar events, and 2 means distinct. This score is important because some RNN decoders might ignore the second event and focus on the general topic only.

Branching Quality (BranchQ): 0-2, each generated branch was scored for branch quality. 0 means the generated events are not specific to the branch, 1 means some are specific, and 2 means most/all events are specific. This is the most important score in measuring how well a model captures hierarchical structure and script tracks.

Two expert annotators evaluated the generated event sequences. In case of disagreements in scores, we also involved a third annotator to resolve these conflicts. Results for this task are shown in Table 3.

Both RNNLM and HAQAE produce sensical events, but the HAQAE model outperforms on all other metrics. It produces more relevant and coherent events for the topic at hand (relevance and coherency). But most important to the goals of this paper, it doubles the RNNLM scores on branching uniqueness and quality. This is because an RNNLM mostly generates from a bag of events after encoding the seed, but the HAQAE utilizes its latent space to produce branch-specific tracks of event sequences. Tables 4 show a few such ex-

System	Sense(%)	Rel(%)	Coh(0-2)	BranchU(0-2)	BranchQ(0-2)
RNNLM+Role	93.13	84.73	1.35	0.65	0.51
HAQAE	93.13	95.37	1.59	1.35	1.00

Table 3: Human evaluation of schemas generated for the seed events. HAQAE consistently performs better than the baseline model. Higher is better for all metrics.

RNN+Role	bomb found in backpack, bomb failed to detonate	bomb killed people, bomb detonated in blast
	bomb found in backpack, bomb detonated	explosion killed people, people injured in blast
	people reported fire, fire spread to forest	fire destroyed building
	people reported fire, fire spread to neighborhood	fire damaged building
HAQAE	bomb found in backpack, bomb failed to detonate	they found evidence, explosive hidden in luggage
	bomb found in backpack, bomb detonated	blast left crater, blast killed people
	people reported fire, fire spread to forest	fire burned acres
	people reported fire, fire spread to neighborhood	fire destroyed building

Table 4: Sample outputs from the baseline and our proposed system. The seeds (what is given to the system) are shown in the left column while the outputs are on the right. HAQAE is able to distinguish between the contrasting seeds. Red highlights the lack of branching quality in the baseline model and Blue highlights the correct behavior as exhibited by HAQAE.

amples.

5.5 Observations about the Latent Variables

We also look at how changing the values of various latent variables change the resulting output, in order to get a small idea as to what properties the variables capture. We find that the root level variable z_0 has the largest effect on the output, and typically corresponds to the domain that the sequence of events belong to. The non root variables generally change the output on a smaller scale, however we find no correspondence between the level of the variable and the amount of output that is affected upon changing its value.

One reason for the difficulty of interpreting the variables is that the model conditions on them through attention, thus changing the value of one does not necessarily need to have any effect.

We do find that changing the lower level latents generally leads to the ending/beginning of the sequence changing or the entities of the sequence changing (but still remaining in the same topical domain). We additionally find that changing the top level latent may often preserve the overall form of the event sequence, and only transform the topic. We provide examples of these output by our system in Table 5.

6 Related Work

Scripts were originally proposed by Schank and Abelson (1975) and further expanded upon in Schank and Abelson (1977). The notion of hierarchies in scripts has been studied in the works of Abbott et al. (1985) and Bower et al. (1979). Mooney and DeJong (1985) present an early non probabilistic system for extracting scripts from text. A highly related work by Miikkulainen (1990) provides an early example of a system explicitly designed to take advantage of the hierarchical nature of scripts, creating a model of scripts based on self organizing maps (Kohonen, 1982). Interestingly, self organizing maps also utilize vector quantization during learning (albeit in a different way than done here).

Recent work starting from Chambers and Jurafsky (2008) has focused on learning scripts as prototypical sequences of events using event co-occurrence. Further work has framed this task as a language modeling problem (Pichotta and Mooney, 2016; Rudinger et al., 2015; Peng and Roth, 2016). Other work has looked at learning more structured forms of script knowledge called *schemas* (Chambers, 2013; Balasubramanian et al., 2013; Nguyen et al., 2015) which focuses on additionally inducing script specific roles to be filled by entities. In this work we treat event components as separate tokens, though work has also looked into methods for composing this components into a single distributed event representation (Modi and Titov, 2014; Modi, 2016; Weber et al., 2018). We leave this as possible future work.

The hierarchical structure of our proposed model is similar to structure of the latent space in other VAE variants (Sonderby et al., 2016; Zhao et al., 2017), with the discrete variables and attentions in our model being the major differences. Hu et al. (2017) present a VAE based model for controllable text generation, with different latents controlling different aspects of the generated text, but requiring labels for semi-supervision. Other methods using discrete variables for VAEs have also been proposed (Rolfe, 2017), as have variations in the VQ-VAE learning process (Sonderby et al., 2017)

7 Conclusion

We proposed a new model, HAQAE, for script learning and generation that is one of the first to model the hierarchy that is inherent in this type of real-world knowledge. Previous work has focused on modeling event sequences with language models, while ignoring the problem of contradictory events and different tracks being jumbled together. The hierarchical latent space of HAQAE instead attends to the choice points in event sequences, and is able to provide some discrimination between tracks of events.

While HAQAE is motivated by the specific need for hierarchies in scripts, it can also be seen as a general event language model. As a language model HAQAE has a substantially lower perplexity on our test set than previous RNN models despite HAQAE's decoder having fewer parameters.

We also presented a new inverse narrative cloze task that is a multiple-choice selection of event sequences. It proved to be a very difficult task with systems producing accuracies in the mid 20% range. HAQAE and NOHEIR were the only systems to break 30 with a top accuracy of 34.0%. This further illustrates that using a latent space to capture script differences helps identify relevant sequences.

To our knowledge, all previous work on script induction has focused on learning single event sequences or bags of events. We view our proposed model as a new step toward learning different details about scripts, such as tracks and hierarchies. Though the proposed model works well empirically, understanding exactly what is learned in the latent variables is non trivial, and is a possible direction for future work.

Abstract

This paper studies semantic parsing for interlanguage (L2[1]), taking semantic role labeling (SRL) as a case task and learner Chinese as a case language. We first manually annotate the semantic roles for a set of learner texts to derive a gold standard for automatic SRL. Based on the new data, we then evaluate three off-the-shelf SRL systems, i.e., the PCFGLA-parser-based, neural-parser-based and neural-syntax-agnostic systems, to gauge how successful SRL for learner Chinese can be. We find two non-obvious facts: 1) the L1-sentence-trained systems performs rather badly on the L2 data; 2) the performance drop from the L1 data to the L2 data of the two parser-based systems is much smaller, indicating the importance of syntactic parsing in SRL for interlanguages. Finally, the paper introduces a new agreement-based model to explore the semantic coherency information in the large-scale L2-L1 parallel data. We then show such information is very effective to enhance SRL for learner texts. Our model achieves an F-score of 72.06, which is a 2.02 point improvement over the best baseline.

1 Introduction

A learner language (interlanguage) is an idiolect developed by a learner of a second or foreign language which may preserve some features of his/her first language. Previously, encouraging results of automatically building the syntactic analysis of learner languages were reported (Nagata and Sakaguchi, 2016), but it is still unknown how semantic processing performs, while parsing a learner language (L2) into semantic representations is the foundation of a variety of deeper analysis of learner languages, e.g., automatic essay scoring. In this paper, we study semantic parsing for interlanguage, taking semantic role labeling (SRL) as a case task and learner Chinese as a case language.

Before discussing a computation system, we first consider the linguistic competence and performance. Can human robustly understand learner texts? Or to be more precise, to what extent, a native speaker can understand the meaning of a sentence written by a language learner? Intuitively, the answer is towards the positive side. To validate this, we ask two senior students majoring in Applied Linguistics to carefully annotate some L2-L1 parallel sentences with predicate–argument structures according to the specification of Chinese PropBank (CPB; Xue and Palmer, 2009), which is developed for L1. A high inter-annotator agreement is achieved, suggesting the robustness of language comprehension for L2. During the course of semantic annotation, we find a non-obvious fact that we can re-use the semantic annotation specification, Chinese PropBank in our case, which is developed for L1. Only modest rules are needed to handle some tricky phenomena. This is quite different from syntactic treebanking for learner sentences, where defining a rich set of new annotation heuristics seems necessary (Ragheb and Dickinson, 2012; Nagata and Sakaguchi, 2016; Berzak et al., 2016).

Our second concern is to mimic the human's robust semantic processing ability by computer programs. The feasibility of reusing the annotation specification for L1 implies that we can reuse *standard* CPB data to train an SRL system to process learner texts. To test the *robustness* of the state-of-the-art SRL algorithms, we evaluate two types of SRL frameworks. The first one is a traditional SRL system that leverages a syntactic parser and heavy feature engineering to obtain *explicit* information of semantic roles (Feng et al., 2012).

---

[1] In this paper, we call sentences written by non-native speakers (henceforth, "L2 sentences"), aligned to their corrections by native speakers (henceforth, "L1 sentences") L2-L1 parallel sentences.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3793–3802
Brussels, Belgium, October 31 - November 4, 2018.

Furthermore, we employ two different parsers for comparison: 1) the PCFGLA-based parser, viz. Berkeley parser (Petrov et al., 2006), and 2) a minimal span-based neural parser (Stern et al., 2017). The other SRL system uses a stacked BiLSTM to implicitly capture local and non-local information (He et al., 2017). and we call it the neural syntax-agnostic system. All systems can achieve state-of-the-art performance on L1 texts but show a significant degradation on L2 texts. This highlights the weakness of applying an L1-sentence-trained system to process learner texts.

While the neural syntax-agnostic system obtains superior performance on the L1 data, the two syntax-based systems both produce better analyses on the L2 data. Furthermore, as illustrated in the comparison between different parsers, the better the parsing results we get, the better the performance on L2 we achieve. This shows that syntactic parsing is important in semantic construction for learner Chinese. The main reason, according to our analysis, is that the syntax-based system may generate correct syntactic analyses for partial grammatical fragments in L2 texts, which provides crucial information for SRL. Therefore, syntactic parsing helps build more generalizable SRL models that transfer better to new *languages*, and enhancing syntactic parsing can improve SRL to some extent.

Our last concern is to explore the potential of a large-scale set of L2-L1 parallel sentences to enhance SRL systems. We find that semantic structures of the L2-L1 parallel sentences are highly consistent. This inspires us to design a novel agreement-based model to explore such semantic coherency information. In particular, we define a metric for comparing predicate–argument structures and searching for relatively good automatic syntactic and semantic annotations to extend the training data for SRL systems. Experiments demonstrate the value of the L2-L1 parallel sentences as well as the effectiveness of our method. We achieve an F-score of 72.06, which is a 2.02 percentage point improvement over the best neural-parser-based baseline.

To the best of our knowledge, this is the first time that the L2-L1 parallel data is utilized to enhance NLP systems for learner texts.

For research purpose, we have released our SRL annotations on 600 sentence pairs and the L2-L1 parallel dataset [2].

2 Semantic Analysis of An L2-L1 Parallel Corpus

2.1 An L2-L1 Parallel Corpus

An L2-L1 parallel corpus can greatly facilitate the analysis of a learner language (Lee et al., 2017). Following Mizumoto et al. (2011), we collected a large dataset of L2-L1 parallel texts of Mandarin Chinese by exploring "language exchange" social networking services (SNS), i.e., Lang-8, a language-learning website where native speakers can freely correct the sentences written by foreign learners. The proficiency levels of the learners are diverse, but most of the learners, according to our judgment, is of intermediate or lower level.

Our initial collection consists of 1,108,907 sentence pairs from 135,754 essays. As there is lots of noise in raw sentences, we clean up the data by (1) ruling out redundant content, (2) excluding sentences containing foreign words or Chinese phonetic alphabet by checking the Unicode values, (3) dropping overly simple sentences which may not be informative, and (4) utilizing a rule-based classifier to determine whether to include the sentence into the corpus.

The final corpus consists of 717,241 learner sentences from writers of 61 different native languages, in which English and Japanese constitute the majority. As for completeness, 82.78% of the Chinese Second Language sentences on Lang-8 are corrected by native human annotators. One sentence gets corrected approximately 1.53 times on average.

In this paper, we manually annotate the predicate–argument structures for the 600 L2-L1 pairs as the basis for the semantic analysis of learner Chinese. It is from the above corpus that we carefully select 600 pairs of L2-L1 parallel sentences. We would choose the most appropriate one among multiple versions of corrections and recorrect the L1s if necessary. Because word structure is very fundamental for various NLP tasks, our annotation also contains *gold* word segmentation for both L2 and L1 sentences. Note that there are no natural word boundaries in Chinese

---

[2] The data is collected from Lang-8 (`www.lang-8.com`) and used as the training data in NLPCC 2018 Shared Task: Grammatical Error Correction (Zhao et al., 2018), which can be downloaded at `https://github.com/pkucoli/srl4il`

Table 1: Inter-annotator agreement.

text. We first employ a state-of-the-art word segmentation system to produce initial segmentation results and then manually fix segmentation errors.

The dataset includes four typologically different mother tongues, i.e., English (ENG), Japanese (JPN), Russian (RUS) and Arabic (ARA). Subcorpus of each language consists of 150 sentence pairs. We take the mother languages of the learners into consideration, which have a great impact on grammatical errors and hence automatic semantic analysis. We hope that four selected mother tongues guarantee a good coverage of typologies. The annotated corpus can be used both for linguistic investigation and as test data for NLP systems.

2.2 The Annotation Process

Semantic role labeling (SRL) is the process of assigning semantic roles to constituents or their head words in a sentence according to their relationship to the predicates expressed in the sentence. Typical semantic roles can be divided into core arguments and adjuncts. The core arguments include *Agent*, *Patient*, *Source*, *Goal*, etc, while the adjuncts include *Location*, *Time*, *Manner*, *Cause*, etc.

To create a *standard* semantic-role-labeled corpus for learner Chinese, we first annotate a 50-sentence trial set for each native language. Two senior students majoring in Applied Linguistics conducted the annotation. Based on a total of 400 sentences, we adjudicate an initial gold standard, adapting and refining CPB specification as our annotation heuristics. Then the two annotators proceed to annotate a 100-sentence set for each language independently. It is on these larger sets that we report the inter-annotator agreement.

In the final stage, we also produce an adjudicated gold standard for all 600 annotated sentences. This was achieved by comparing the annotations selected by each annotator, discussing the differences, and either selecting one as fully correct or creating a hybrid representing the consensus decision for each choice point. When we felt that the decisions were not already fully guided by the existing annotation guidelines, we worked to articulate an extension to the guidelines that would support the decision.

During the annotation, the annotators apply both position labels and semantic role labels. Position labels include *S*, *B*, *I* and *E*, which are used to mark whether the word is an argument by itself, or at the beginning or in the middle or at the end of a argument. As for role labels, we mainly apply representations defined by CPB (Xue and Palmer, 2009). The predicate in a sentence was labeled as *rel*, the core semantic roles were labeled as *AN* and the adjuncts were labeled as *AM*.

2.3 Inter-annotator Agreement

For inter-annotator agreement, we evaluate the precision (P), recall (R), and F1-score (F) of the semantic labels given by the two annotators. Table 1 shows that our inter-annotator agreement is promising. All L1 texts have F-score above 95, and we take this as a reflection that our annotators are qualified. F-scores on L2 sentences are all above 90, just a little bit lower than those of L1, indicating that L2 sentences can be greatly understood by native speakers. Only modest rules are needed to handle some tricky phenomena:

1. The labeled argument should be strictly limited to the core roles defined in the frameset of CPB, though the number of arguments in L2 sentences may be more or less than the number defined.

2. For the roles in L2 that cannot be labeled as arguments under the specification of CPB, if they provide semantic information such as time, location and reason, we would labeled them as adjuncts though they may not be well-formed adjuncts due to the absence of function words.

3. For unnecessary roles in L2 caused by mistakes of verb subcategorization (see examples in Figure 3b), we would leave those roles unlabeled.

Table 2 further reports agreements on each argument (*AN*) and adjunct (*AM*) in detail, according to which the high scores are attributed to the high agreement on arguments (*AN*). The labels of *A3* and *A4* have no disagreement since they are sparse in CPB and are usually used to label specific semantic roles that have little ambiguity.

We also conducted in-depth analysis on inter-annotator disagreement. For further details, please refer to Duan et al. (2018).

3 Evaluating Robustness of SRL

3.1 Three SRL Systems

The work on SRL has included a broad spectrum of machine learning and deep learning approaches to the task. Early work showed that syntactic information is crucial for learning long-range dependencies, syntactic constituency structure and global constraints (Punyakanok et al., 2008; Täckström et al., 2015), while initial studies on neural methods achieved state-of-the-art results with little to no syntactic input (Zhou and Xu, 2015; Wang et al., 2015; Marcheggiani et al., 2017; He et al., 2017). However, the question whether fully labeled syntactic structures provide an improvement for neural SRL is still unsettled pending further investigation.

To evaluate the *robustness* of state-of-the-art SRL algorithms, we evaluate two representative SRL frameworks. One is a traditional syntax-based SRL system that leverages a syntactic parser and manually crafted features to obtain *explicit* information to find semantic roles (Gildea and Jurafsky, 2000; Xue, 2008) In particular, we employ the system introduced in Feng et al. (2012). This system first collects all c-commanders of a predicate in question from the output of a parser and puts them in order. It then employs a first order linear-chain global linear model to perform semantic tagging. For constituent parsing, we use two parsers for comparison, one is Berkeley parser[3] (Petrov et al., 2006), a well-known implementation of the unlexicalized latent variable PCFG model, the other is a minimal span-based neural parser based on independent scoring of labels and spans (Stern et al., 2017). As proposed in Stern et al. (2017), the second parser is capable of achieving state-of-the-art single-model performance on the Penn Treebank. On the Chinese TreeBank (CTB; Xue et al., 2005), it also outperforms the Berkeley parser for the in-domain test. We call the corresponding SRL systems as the **PCFGLA-parser-based** and **neural-parser-based** systems.

The second SRL framework leverages an end-to-end neural model to implicitly capture local and non-local information (Zhou and Xu, 2015; He et al., 2017). In particular, this framework treats SRL as a *BIO* tagging problem and uses a stacked BiLSTM to find informative embeddings. We apply the system introduced in He et al. (2017) for experiments. Because all syntactic information (including POS tags) is excluded, we call this system the **neural syntax-agnostic** system.

To train the three SRL systems as well as the supporting parsers, we use the CTB and CPB data [4]. In particular, the sentences selected for the CoNLL 2009 shared task are used here for parameter estimation. Note that, since the Berkeley parser is based on PCFGLA grammar, it may fail to get the syntactic outputs for some sentences, while the other parser does not have that problem. In this case, we have made sure that both parsers can parse all 1,200 sentences successfully.

3.2 Main Results

The overall performances of the three SRL systems on both L1 and L2 data (150 parallel sentences for each mother tongue) are shown in Table 3. For all systems, significant decreases on different mother languages can be consistently observed, highlighting the weakness of applying L1-sentence-trained systems to process learner texts. Comparing the two syntax-based systems with the neural syntax-agnostic system, we find that the overall ΔF, which denotes the F-score drop from L1 to L2, is smaller in the syntax-based framework

---

[3] `code.google.com/p/berkeleyparser/`

[4] Here we only use the trees that has semantic role annotations for parser training. This setup keeps us from overestimating the contribution of a parser.

Table 3: Performances of the syntax-based and neural syntax-agnostic SRL systems on the L1 and L2 data. "ALL" denotes the overall performance.

than in the syntax-agnostic system. On English, Japanese and Russian L2 sentences, the syntax-based system has better performances though it sometimes works worse on the corresponding L1 sentences, indicating the syntax-based systems are more robust when handling learner texts.

Furthermore, the neural-parser-based system achieves the best overall performance on the L2 data. Though performing slightly worse than the neural syntax-agnostic one on the L1 data, it has much smaller ΔF, showing that as the syntactic analysis improves, the performances on both the L1 and L2 data grow, while the gap can be maintained. This demonstrates again the importance of syntax in semantic constructions, especially for learner texts.

3.3 Analysis

To better understand the overall results, we further look deep into the output by addressing the questions:

1. What types of error negatively impact both systems over learner texts?
2. What types of error are more problematic for the neural syntax-agnostic one over the L2 data but can be solved by the syntax-based one to some extent?

We first carry out a suite of empirical investigations by breaking down error types for more detailed evaluation. To compare two systems, we analyze results on ENG-L2 and JPN-L2 given that they reflect significant advantages of the syntax-based systems over the neural syntax-agnostic system. Note that the syntax-based system here refers to the neural-parser-based one. Finally, a concrete study on the instances in the output is conducted, as to validate conclusions in the previous step.

Operation	Description
Fix Labels (Fix)	Correct the span label if its boundary matches gold.
Move Arg. (Move)	Move a unique core argument to its correct position.
Merge Spans (Merge)	Combine two predicated spans into a gold span if they are separated by at most one word.
Split Spans (Split)	Split a predicated span into two gold spans that are separated by at most one word.
Fix Boundary (Boundary)	Correct the boundary of a span id its label matches an overlapping gold span.
Drop Arg. (Drop)	Drop a predicated argument that does not overlap with any gold span.
Add Arg. (Add)	Add a gold argument that does not overlap with any predicated span.

Table 4: Oracle transformations paired with the relative error reduction after each operation. The operations are permitted only if they do not cause any overlapping arguments

3.3.1 Breaking down Error Types

We employ 6 oracle transformations designed by He et al. (2017) to fix various prediction errors sequentially (see details in Table 4), and observe the relative improvements after each operation, as to obtain fine-grained error types. Figure 1 compares two systems in terms of different mistakes on ENG-L2 and JPN-L2 respectively. After fixing the boundaries of spans, the neural syntax-agnostic system catches up with the other, illustrating that though both systems handle boundary detection poorly on the L2 sentences, the neural syntax-agnostic one suffers more from this type of errors.

Excluding boundary errors (after moving, merg-

ing, splitting spans and fixing boundaries), we also compare two systems on L2 in terms of detailed label identification, so as to observe which semantic role is more likely to be incorrectly labeled. Figure 2 shows the confusion matrices. Comparing (a) with (c) and (b) with (d), we can see that the syntax-based and the neural system often overly label *A1* when processing learner texts. Besides, the neural syntax-agnostic system predicts the adjunct *AM* more than necessary on L2 sentences by 54.24% compared with the syntax-based one.

	A0	A1	A2	A3	AM	O
A0	414	5	0	1	6	12
A1	6	404	4	0	5	6
A2	0	7	37	0	1	1

(d) Neural system, L2

Figure 2: Confusion matrix for each semantic role (here we add up matrices of ENG-L2 and JPN-L2). The predicted labels are only counted in three cases: (1) The predicated boundaries match the gold span boundaries. (2) The predicated argument does not overlap with any the gold span (Gold labeled as "O"). (3) The gold argument does not overlap with any predicted span (Prediction labeled as "O").

3.3.2 Examples for Validation

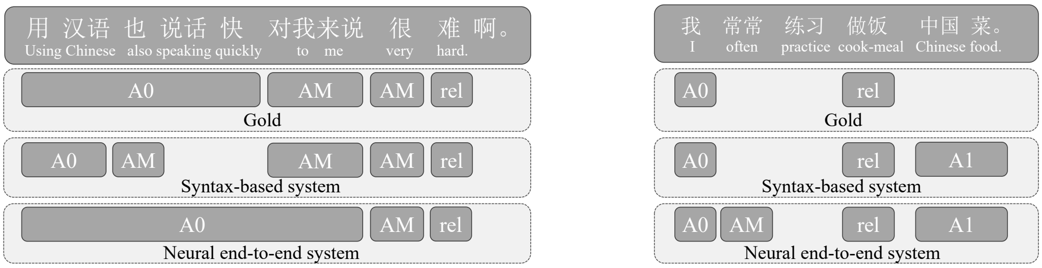
On the basis of typical error types found in the previous stage, specifically, boundary detection and incorrect labels, we further conduct an on-the-spot investigation on the output sentences.

Boundary Detection Previous work has proposed that the drop in performance of SRL systems mainly occurs in identifying argument boundaries (Màrquez et al., 2008). According to our results, this problem will be exacerbated when it comes to L2 sentences, while syntactic structure sometimes helps to address this problem.

Figure 3a is an example of an output sentence. The Chinese word "也" (also) usually serves as an adjunct but is now used for linking the parallel structure "用 汉语 也 说话 快" (using Chinese also speaking quickly) in this sentence, which is ill-formed to native speakers and negatively affects the boundary detection of *A0* for both systems.

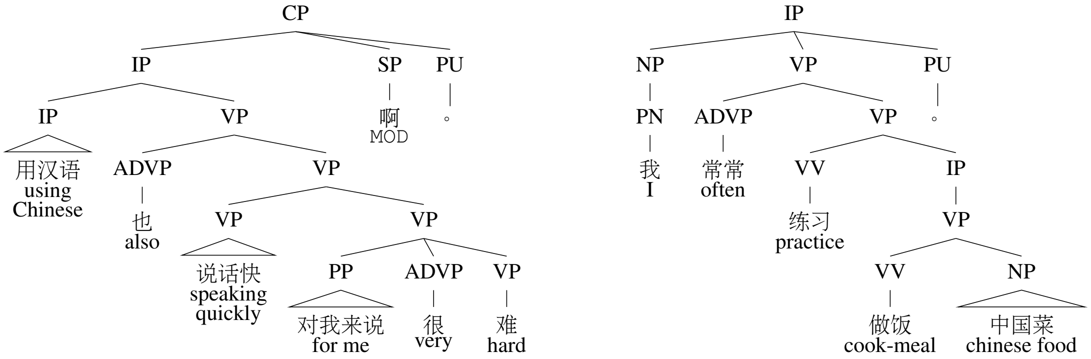
On the other hand, the neural system incorrectly takes the whole part before "很 难" (very hard) as *A0*, regardless of the adjunct "对 我 来说" (for me), while this can be figured out by exploiting syntactic analysis, as illustrated in Figure 3c. The constituent "对 我 来说" (for me) has been recognized as a prepositional phrase (PP) attached to the VP, thus labeled as *AM*. This shows that by providing information of some well-formed sub-trees associated with correct semantic roles, the syntactic system can perform better than the neural one on SRL for learner texts.

Mistaken Labels A second common source of errors is wrong labels, especially for *A1*. Based on our quantitative analysis, as reported in Table 5,



(a) SRL output of both systems for a L2 sentence, “用汉语也说话快对我来说很难” (using Chinese and also speaking quickly is very hard for me).

(b) SRL of both systems for a L2 sentence, “我常常做饭中国菜” (I often cook Chinese food).



(c) Syntactic analysis for the sentence in Figure 3a

(d) Syntactic analysis for the sentence in Figure 3b

Figure 3: Two examples for SRL outputs of both systems and the corresponding syntactic analysis for the L2 sentences

these phenomena are mainly caused by mistakes of verb subcategorization, where the systems label more arguments than allowed by the predicates. Besides, the deep end-to-end system is also likely to incorrectly attach adjuncts *AM* to the predicates.

	Syntax	
Cause of error	YES	NO
Verb subcategorization	62.50%	62.50%
Labeling *A1* to punctuation	12.50%	6.25%
Word order error	6.25%	0.00%
Other types of error	18.75%	31.25%

Table 5: Causes of labeling unnecessary *A1*

Figure 3b is another example. The Chinese verb “做饭” (cook-meal) is intransitive while this sentence takes it as a transitive verb, which is very common in L2. Lacking in proper verb subcategorization, both two systems fail to recognize those verbs allowing only one argument and label the *A1* incorrectly.

As for *AM*, the neural system mistakenly adds the adjunct to the predicate, which can be avoided by syntactic information of the sentence shown in Figure 3d. The constituent “常常” (often) are adjuncts attached to VP structure governed by the verb “练习”(practice), which will not be labeled as *AM* in terms of the verb “做饭”(cook-meal). In other words, the hierarchical structure can help in argument identification and assignment by exploiting local information.

4 Enhancing SRL with L2-L1 Parallel Data

We explore the valuable information about the semantic coherency encoded in the L2-L1 parallel data to improve SRL for learner Chinese. In particular, we introduce an agreement-based model to search for high-quality automatic syntactic and semantic role annotations, and then use these annotations to retrain the two parser-based SRL systems.

4.1 The Method

For the purpose of harvesting the good automatic syntactic and semantic analysis, we consider the consistency between the automatically produced analysis of a learner sentence and its corresponding *well-formed* sentence. Determining the measurement metric for comparing predicate–argument structures, however, presents another challenge, because the words of the L2 sentence and its L1 counterpart do not necessarily match. To solve the problem, we use an automatic word aligner. BerkeleyAligner[5] (Liang et al., 2006), a state-of-the-art tool for obtaining a word alignment, is utilized.

The metric for comparing SRL results of two sentences is based on recall of $\langle w_p, w_a, r\rangle$ tuples, where w_p is a predicate, w_a is a word that is in the argument or adjunct of w_p and r is the corresponding role. Based on a word alignment, we define the shared tuple as a mutual tuple between two SRL results of an L2-L1 sentence pair, meaning that both the predicate and argument words are aligned respectively, and their role relations are the same. We then have two recall values:

- L2-recall is (# of shared tuples) / (# of tuples of the result in L2)
- L1-recall is (# of shared tuples) / (# of tuples of the result in L1)

In accordance with the above evaluation method, we select the automatic analysis of highest scoring sentences and use them to expand the training data. Sentences whose L1 and L2 recall are both greater than a threshold p are taken as good ones. A parser-based SRL system consists of two essential modules: a syntactic parser and a semantic classifier. To enhance the syntactic parser, the automatically generated syntactic trees of the sentence pairs that exhibit high semantic consistency are directly used to extend training data. To improve a semantic classifier, besides the consistent semantic analysis, we also use the outputs of the L1 but not L2 data which are generated by the neural syntax-agnostic SRL system.

4.2 Experimental Setup

Our SRL corpus contains 1200 sentences in total that can be used as an evaluation for SRL systems. We separate them into three data sets. The first data set is used as development data, which contains 50 L2-L1 sentence pairs for each language and 200 pairs in total. Hyperparameters are tuned using the development set. The second data set contains all other 400 L2 sentences, which is used as test data for L2. Similarly, all other 400 L1 sentences are used as test data for L1.

The sentence pool for extracting retraining annotations includes all English- and Japanese-native speakers' data along with its corrections. Table 6 presents the basic statistics. Around 8.5 – 11.9% of the sentence can be taken as high L1/L2 recall sentences, which serves as a reflection that argument structure is vital for language acquisition and difficult for learners to master, as proposed in Vázquez (2004) and Shin (2010). The threshold ($p = 0.9$) for selecting sentences is set upon the development data. For example, we use additional 156,520 sentences to enhance the Berkeley parser.

	ENG	JPN
#All sentence pairs	310,075	484,140
#Selected ($p = 0.9$)	36,979	41,281

Table 6: Statistics of unlabeled data.

4.3 Main Results

Table 7 summarizes the SRL results of the baseline PCFGLA-parser-based model as well as its corresponding retrained models. Since both the syntactic parser and the SRL classifier can be retrained and thus enhanced, we report the individual impact as well as the combined one. We can clearly see that when the PCFGLA parser is retrained with the SRL-consistent sentence pairs, it is able to provide better SRL-oriented syntactic analysis for the L2 sentences as well as their corrections, which are essentially L1 sentences. The outputs of the L1 sentences that are generated by the deep SRL system are also useful for improving the linear SRL classifier. A non-obvious fact is that such a retrained model yields better analysis for not only L1 but also L2 sentences. Fortunately, combining both results in further improvement.

		P	R	F
L2	Baseline	76.50	62.86	69.01
	Parser-retrained	78.74	65.87	71.73
	Classifier-retrained	77.11	64.17	70.05
	Both retrained	78.72	66.43	72.06
L1	Baseline	80.70	66.36	72.83
	Parser-retrained	82.20	68.26	74.59
	Classifier-retrained	80.98	67.57	73.67
	Both retrained	82.04	68.79	74.83

Table 7: Accuracies different PCFGLA-parser-based models on the two test data sets.

Table 8 shows the results of the parallel experiments based on the neural parser. Different from the PCFGLA model, the SRL-consistent trees only yield a slight improvement on the L2

---

[5] `code.google.com/archive/p/berkeleyaligner/`

data. On the contrary, retraining the SRL classifier is much more effective. This experiment highlights the different strengths of different frameworks for parsing. Though for *standard in-domain* test, the neural parser performs better and thus is more and more popular, for some other scenarios, the PCFGLA model is stronger.

		P	R	F
L2	Baseline	78.26	63.38	70.04
	Parser-retrained	78.19	63.78	70.25
	Classifier-retrained	78.88	64.65	71.06
	Both retrained	78.61	65.34	71.36
L1	Baseline	82.17	66.80	73.69
	Parser-retrained	81.95	66.92	73.68
	Classifier-retrained	82.08	67.69	74.20
	Both retrained	82.20	67.85	74.34

Table 8: Accuracies of different neural-parser-based models on the two test data sets.

Table 9 further shows F-scores for the baseline and the both-retrained model relative to each role type in detail. Given that the F-scores for both models are equal to 0 on *A3* and *A4*, we just omit this part. From the figure we can observe that, all the semantic roles achieve significant improvements in performances.

		A0	*A1*	*A2*	*AM*
L2	Baseline	67.95	71.21	51.43	70.20
	Both retrained	70.62	74.75	64.29	72.22
L1	Baseline	69.49	79.78	61.84	71.74
	Both retrained	73.15	80.90	63.35	73.02

Table 9: F-scores of the baseline and the both-retrained models relative to role types on the two data sets. We only list results of the PCFGLA-parser-based system.

5 Conclusion

Statistical models of annotating learner texts are making rapid progress. Although there have been some initial studies on defining annotation specification as well as corpora for syntactic analysis, there is almost no work on semantic parsing for interlanguages. This paper discusses this topic, taking Semantic Role Labeling as a case task and learner Chinese as a case language. We reveal three unknown facts that are important towards a deeper analysis of learner languages: (1) the robustness of language comprehension for interlanguage, (2) the weakness of applying L1-sentence-trained systems to process learner texts, and (3) the significance of syntactic parsing and L2-L1 parallel data in building more generalizable SRL models that transfer better to L2. We have successfully provided a better SRL-oriented syntactic parser as well as a semantic classifier for processing the L2 data by exploring L2-L1 parallel data, supported by a significant numeric improvement over a number of state-of-the-art systems. To the best of our knowledge, this is the first work that demonstrates the effectiveness of large-scale L2-L1 parallel data to enhance the NLP system for learner texts.

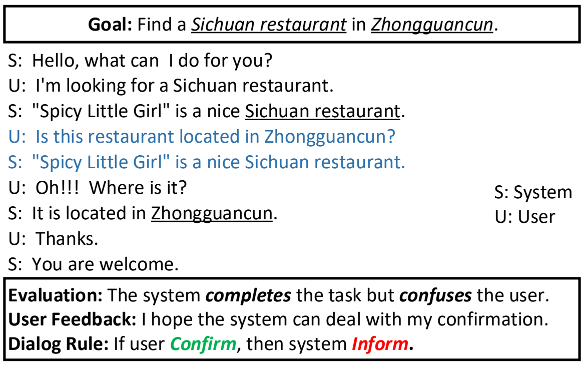
Abstract

Reinforcement learning (RL) is an attractive solution for task-oriented dialog systems. However, extending RL-based systems to handle new intents and slots requires a system redesign. The high maintenance cost makes it difficult to apply RL methods to practical systems on a large scale. To address this issue, we propose a practical teacher-student framework to extend RL-based dialog systems without retraining from scratch. Specifically, the "student" is an extended dialog manager based on a new ontology, and the "teacher" is existing resources used for guiding the learning process of the "student". By specifying constraints held in the new dialog manager, we transfer knowledge of the "teacher" to the "student" without additional resources. Experiments show that the performance of the extended system is comparable to the system trained from scratch. More importantly, the proposed framework makes no assumption about the unsupported intents and slots, which makes it possible to improve RL-based systems incrementally.

1 Introduction

With the flourish development of virtual personal assistants (e.g., Amazon Alexa and Google Assistant), task-oriented dialog systems, which can help users accomplish tasks naturally, have been a focal point in both academic and industry research. In the early work, the task-oriented dialog system is merely a set of hand-crafted mapping rules defined by experts. This is referred to as a rule-based system. Although rule-based systems often have acceptable performance, they are inconvenient and difficult to be optimized. Recently, reinforcement learning approaches have been applied to optimize dialog systems through interaction with a user simulator or employed real users online (Gašić et al., 2011; Su et al., 2016a; Li et al., 2016, 2017b). It has been proven that RL-based dialog systems can abandon hand-crafted dialog manager and achieve more robust performance than rule-based systems (Young et al., 2013).



Goal: Find a *Sichuan restaurant* in *Zhongguancun*.

S: Hello, what can I do for you?
U: I'm looking for a Sichuan restaurant.
S: "Spicy Little Girl" is a nice Sichuan restaurant.
U: Is this restaurant located in Zhongguancun?
S: "Spicy Little Girl" is a nice Sichuan restaurant.
U: Oh!!! Where is it?
S: It is located in Zhongguancun.
U: Thanks.
S: You are welcome.

S: System
U: User

Evaluation: The system ***completes*** the task but ***confuses*** the user.
User Feedback: I hope the system can deal with my confirmation.
Dialog Rule: If user ***Confirm***, then system ***Inform***.

Figure 1: An example of a task-oriented dialog after the system comes online. The user is confused because the "*confirm*" intent has not been considered in the deployed system. Dialog rules should be embedded in a new system to handle such situations.

Typically, the first step of building RL-based dialog systems is defining a user model[1] and necessary system actions to complete a specific task (e.g., seek restaurants information or book hotels). Based on such ontology, developers can extract dialog features and train the dialog manager model in an interaction environment. Such systems work well if real users are consistent with the predefined user model. However, as shown in Fig. 1, the unanticipated actions[2] of real users will lead to a poor user experience.

In this situation, the original system should be extended to support new user actions based on user feedback. However, adding new intents or slots will change the predefined ontology. As a consequence, developers need to extract additional

---

[1] The user model defines what users can do in a dialog system, including domain specific intents and slots.

[2] User actions consist of intents and slots.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3803–3812
Brussels, Belgium, October 31 - November 4, 2018. ©2018 Association for Computational Linguistics

dialog features based on new ontology. Besides, new system actions may be added to deal with new user actions. The network architecture of the new system and the original one will be different. The new system can not inherit the parameters from the old one directly. It will make the original dialog manager model invalid. Therefore, developers have to retrain the new system by interacting with users from scratch. Though there are many methods to train a RL-based dialog manager efficiently (Su et al., 2016a, 2017; Lipton et al., 2017; Chang et al., 2017; Chen et al., 2017), the unmaintainable RL-based dialog systems will still be put on the shelf in real-world applications (Paek and Pieraccini, 2008; Paek, 2006).

To alleviate this problem, we propose a teacher-student framework to maintain the RL-based dialog manager without training from scratch. The idea is to transfer the knowledge of existing resources to a new dialog manager.

Specifically, after the system is deployed, if developers find some intents and slots missing before, they can define a few simple dialog rules to handle such situations. For example, under the condition shown in Fig. 1, a reasonable strategy is to inform the user of the location of this restaurant. Then we encode information of such hand-crafted logic rules into the new dialog manager model. Meanwhile, user logs and dialog policy of the original system can guide the new system to complete tasks like the original one. Under the guidance of the "teacher" (logic rules, user logs, and original policy), we can reforge an extended dialog manager (the "student") without a new interaction environment.

We conduct a series of experiments with simulated and real users on restaurant domain. The extensive experiments demonstrate that our method can overcome the problem brought by the unpredictable user behavior after deployment. Owing to reuse of existing resources, our framework saves time in designing new interaction environments and retraining RL-based systems from scratch. More importantly, our method does not make any assumptions about the unsupported intents and slots. So the system can be incrementally extended once developers find new intents and slots that are not taken into account before. As far as we know, we are the first to discuss the maintainability of deep reinforcement learning based dialog systems systematically.

2 Related Work

Dialog Manager The dialog manager of task-oriented dialog systems, which consists of a state tracker and a dialog policy module, controls the dialog flow. Recently, deep reinforcement learning (Mnih et al., 2013, 2015) has been applied to optimize the dialog manager in an "end-to-end" way, including *deep Q-Network* (Lipton et al., 2017; Li et al., 2017b; Peng et al., 2017; Zhao and Eskenazi, 2016) and *policy gradient* methods (Williams et al., 2017; Su et al., 2016b; Dhingra et al., 2017). RL methods have shown great potential in building a robust dialog system automatically. However, RL-based approaches are rarely used in real-world applications because of the maintainability problem (Paek and Pieraccini, 2008; Paek, 2006). To extend the domain of dialog systems, Gašic et al. (2014) explicitly defined kernel functions between the belief states that come from different domains. However, defining an appropriate kernel function is non-trivial when the ontology has changed drastically. Shah et al. (2016) proposed to integrate turn-level feedback with a task-level reward signal to learn how to handle new user intents. This approach alleviates the problem that arises from the difference between training and deployment phases. But it still fails when the developers have not considered all user actions in advance. Lipton et al. (2017) proposed to use BBQ-Networks to extend the domain. However, similar to Shah et al. (2016), the BBQ-Networks have reserved a few bits in the feature vector for new intents and slots. And system actions for handling new user actions have been considered in the original system design. This assumption is not practical enough. Compared to the existing domain extension methods, our work addresses a more practical problem: new intents and slots are unknown to the original system. If we need to extend the dialog system, we should design a new network architecture to represent new user actions and take new system actions into account.

Knowledge Distillation Our proposed framework is inspired by recent work in knowledge distillation (Bucilu et al., 2006; Ba and Caruana, 2014; Li et al., 2014). Knowledge distillation means training a compact model to mimic a larger teacher model by approximating the function learned by the teacher. Hinton et al. (2015) introduced knowledge distillation to transfer knowledge from

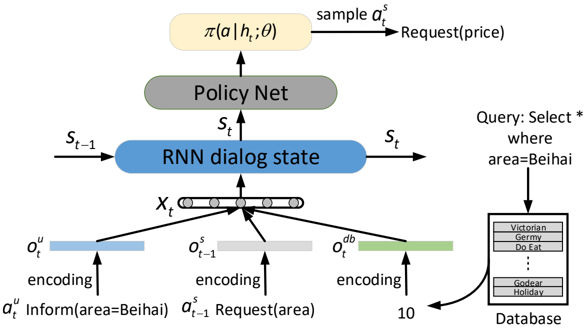


Figure 2: An overview of the RL-based dialog manager used in our work[3]. In the last turn, the system inquires "Where do you want to go?". In current turn, the user input is "Find a restaurant in Beihai.".

a large highly regularized model into a smaller model. The knowledge which can be transferred has not been restricted to models. Stewart and Ermon (2017) proposed to distill the physics and domain knowledge to train neural networks without labeled data. Hu et al. (2016) enabled a neural network to learn simultaneously from labeled instances as well as logic rules. Zhang et al. (2017) integrated multiple prior knowledge sources into neural machine translation using posterior regularization. Our experiments are based on such insights. Through defining appropriate regularization terms, we can distill different knowledge (e.g., trained model or prior knowledge) to a new designed model, alleviating the need for new labeled data or expensive interaction environments.

3 RL-based Dialog Manager

Before going to the details of our method, we provide some background on the RL-based dialog manager in this section. Fig. 2 shows an overview of such dialog manager. We describe each of the parts briefly below.

Feature Extraction At the *t-th* turn of a dialog, the user input u_t is parsed into domain specific intents and slots to form a semantic frame a_t^u by a language understanding (LU) module. o_t^u and o_{t-1}^s are the one-hot representations of such semantic frames for the current user input and the last system output respectively. Alternatively, o_t^u can be a simple n-grams representation of u_t. But the vocabulary size is relatively large in real-world applications. It will yield slow convergence in the absence of a LU module. Based on the slot-value pair output with the highest probability, a query is sent to a database to retrieve user requested information. o_t^{db} is the one-hot representation of the database result. As a result, the observable information x_t is the concatenation of o_t^u, o_{t-1}^s and o_t^{db}.

State Representation Based on the extracted feature vector x_t and previous internal state s_{t-1}, recurrent neural networks (RNNs) are used to infer the latent representation of dialog state s_t at step t. Current state s_t can be interpreted as the summary of dialog history h_t up to current step.

Dialog Policy Next, the dialog state representation s_t is fed into a policy network. The output $\pi(a|h_t;\theta)$ of the policy network is a probability distribution over a predefined system action set A_s. Lastly, the system samples an action $a_t^s \in A_s$ based on $\pi(a|h_t;\theta)$ and receives a new observation x_{t+1} with an assigned reward r_t. The policy parameters θ can be learned by maximizing the expected discounted cumulative rewards:

$$\mathcal{J}(\theta) = E\left(\sum_{k=0}^{T-t} \gamma^k r_{t+k}\right) \tag{1}$$

where T is the maximal step, and γ is the discount factor. Usually the parameters θ can be iteratively updated by *policy gradient* (Williams, 1992) approach. The policy gradient can be empirically estimated as:

$$\nabla_\theta \mathcal{J}(\theta) \approx \frac{1}{N} \sum_{i=1}^{N} \sum_{t=1}^{T} \nabla_\theta \, log \, \pi(a_{i,t}^s|h_{i,t};\theta)(G_{i,t} - b) \tag{2}$$

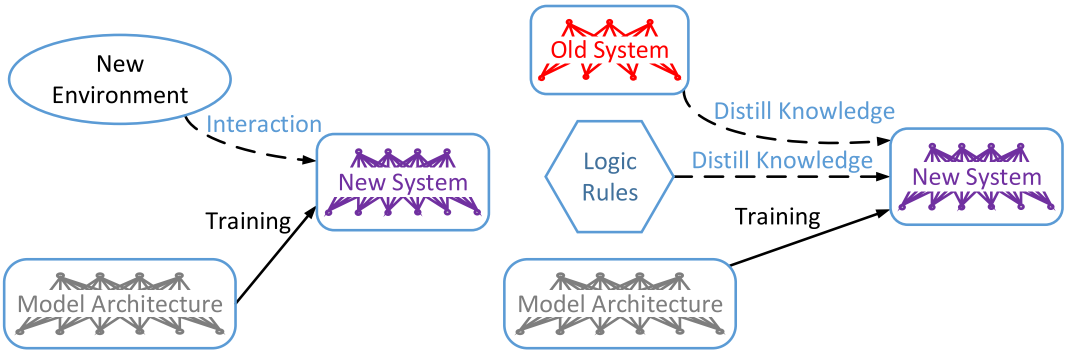
where N is the number of sampled episodes in a batch, $G_{i,t} = \sum_{k=0}^{T-t} \gamma^k r_{i,t+k}$ is the sum of discounted reward at step t in the episode i, and b is a baseline to estimate the average reward of current policy.

4 Notations and Problem Definition

Let A_u and A_s denote the supported user and system action sets in the original system design respectively. u_t denotes the user input in the *t-th* turn. The LU module converts u_t into a domain specific intent and associated slots to form a user action $a_t^u \in A_u$. The system will return an action $a_t^s \in A_s$ according to the dialog manager $\pi(\theta)$. Note that not all user actions are taken into account at the beginning of system design.

---

[3] Similar dialog model architectures can be found in recent work (Liu and Lane, 2017; Williams et al., 2017; Su et al., 2016b). But designing a dialog model architecture is not our main purpose. We focus on endowing RL-based dialog systems with maintainability and scalability. The dialog model used in our work can be replaced with the similar architectures in the related work.



(a) Retraining a new system from scratch. (b) An overview of our proposed teacher-student framework.

Figure 3: Two kinds of strategies to extend the original system. (a) means redesigning and retraining a new system in an expensive interaction environment from scratch and (b) means transferring knowledge from existing resources to a new system. The network in red indicates the old system based on the original ontology. The networks in gray and purple represent the initialized and trained dialog manager models based on a new ontology respectively. On account of the change in ontology, the extended system has a different network architecture. The dash lines in (a) and (b) show the ability of a new model derives from various sources.

After deployment, the developers can find that some user actions A_{u_new} cannot be handled by the original system based on the human-machine interaction logs D. Generally speaking, A_{u_new} consists of new intents and slots. Our goal is to extend the original system to support the new user action set $A'_u = A_u \cup A_{u\_new}$. The extended dialog manager and new system action set are denoted as $\pi(\theta')$ and A'_s respectively. To handle new user actions, more system actions may be added to the new system. It means that A_s is a subset of A'_s.

5 Approach

Fig. 3 shows two kinds of strategies to extend the original system. The first strategy requires a new interaction environment. However, building a user simulator or hiring real users once the system needs to be extended is costly and impractical in real-world applications. By contrast, our method enhances the reuse of existing resources. The basic idea is to use the existing user logs, original dialog policy model and logic rules (“teacher”) to guide the learning process of a new dialog manager (“student”). Without an expensive interaction environment, the developers can maintain RL-based dialog systems as efficiently and straightforwardly as in rule-based systems.

5.1 Distill Knowledge from the Original System

Although the ontology of the new system is different from the original one, the extended dialog manager can still reuse dialog policy of the ill-considered system circuitously. Given user logs D and the original dialog manager $\pi(\theta)$, we define a loss $\mathcal{L}(\theta'; D, \theta)$ to minimize the difference between new dialog manager $\pi(\theta')$ and the old one:

$$\mathcal{L}(\theta'; D, \theta) = \sum_{d \in D} \sum_{t=1}^{|d|} KL(\, \pi(a|h_t; \theta) \,||\, \pi(a|h_t; \theta')\,) \quad (3)$$

where $\pi(a|h_t;\theta)$ and $\pi(a|h_t;\theta')$ are the policy distributions over A_s and A'_s given the same dialog history h_t. $|d|$ means turns of a specific dialog $d \in D$. To deal with unsupported user actions, A_s will be a subset of A'_s. As a result, the KL term in equation (3) can be defined as follows:

$$\begin{aligned} & KL(\, \pi(a|h_t; \theta) \,||\, \pi(a|h_t; \theta')\,) \\ = & \sum_{k=1}^{|A_s|} \pi(a_k|h_t;\theta) \left(log\pi(a_k|h_t;\theta) - log\pi(a_k|h_t;\theta') \right) \end{aligned} \quad (4)$$

As the original policy parameters θ are fixed, the loss function in equation (3) can be rewritten as:

$$\mathcal{L}(\theta'; D, \theta) = -\sum_{d \in D} \sum_{t=1}^{|d|} \sum_{k=1}^{|A_s|} \pi(a_k|h_t;\theta) log\pi(a_k|h_t;\theta') \quad (5)$$

This objective will transfer knowledge of the original system to the “student” at the turn level. Under the guidance of the original system, the extended system will be equipped with the primary strategy to complete a task.

5.2 Distill Knowledge from Logic Rules

It’s easy for the developers to give logic rules on the system responses to handle new user actions.

For example, if users ask to confirm a slot, the system should inform the value of that slot immediately. Note that these system actions which handle new user actions may not exist in the old model. It means the architecture of the new system is different from the old one.

We define a set of logic constraints $\mathcal{R} = \{(h_l, a_l)\}_{l=1}^{L}$, where $h_l \in H_\mathcal{R}$ indicates the dialog context condition in the l-th rule, and $a_l \in A'_s$ is the corresponding system action. The number of logic rules L is equal to the number of new user actions. These rules can be seen as triggers: if dialog context h_t in current turn t meets the context condition h_l defined in logic rules, then the system should execute a_l. In our work, we use the output of the LU module to judge whether the current dialog context meets the condition defined by logic rules. An alternative method is simple rules matching. To distill the knowledge of rules to a new system, we define a loss function $\mathcal{L}(\theta'; D, \mathcal{R})$ to embed such constraints in the new system:

$$\mathcal{L}(\theta'; D, \mathcal{R}) = -\sum_{d\in D}\sum_{t=1}^{|d|}\sum_{h_l\in H_\mathcal{R}} \mathbb{1}\{h_t = h_l\} \times \sum_{k=1}^{|A'_s|} \mathbb{1}\{a_k = a_l\}\, log\, \pi(a_k|h_t; \theta') \qquad (6)$$

Where $\mathbb{1}\{\cdot\}$ is the indicate function. Equation (6) suggests the new dialog manager $\pi(\theta')$ will be penalized if it violates the instructions defined by the dialog rules. Note that, for simplicity, we assume these rules are absolutely correct and mutually exclusive. Although this hypothesis may lead to a non-optimal dialog system, these rules define reasonable system actions to corresponding dialog contexts. It implies that the new system can be further refined by reinforcement learning once a new interaction environment is available.

5.3 Extension of Dialog Manager

In the absence of a new training environment, learning is made possible by exploiting structure that holds in the new dialog manager. On one hand, we expect the new system can complete tasks like the original one. On the other hand, it should satisfy the constraints defined by dialog rules. So, the learning objective of new dialog manager $\pi(\theta')$ can be defined as follows:

$$\mathcal{L}(\theta'; D, \theta, \mathcal{R}) = \begin{cases} \mathcal{L}(\theta'; D, \mathcal{R}) & \text{if } h_t \in H_\mathcal{R}\,; \\ \mathcal{L}(\theta'; D, \theta) & \text{else} \end{cases} \qquad (7)$$

When the dialog context h_t in the t-th turn satisfies a condition defined in $H_\mathcal{R}$, we distill knowledge of rules into the new system. Otherwise, we distill knowledge of the original system into the new one. Instead of retraining from scratch, developers can extend RL-based systems by reusing existing resources.

6 Experiments

To evaluate our method, we conduct experiments on a dialog system extension task of restaurant domain.

6.1 Domain

The dialog system provides restaurant information in Beijing. The database we use includes 2988 restaurants. This domain consists of 8 slots (*name*, *area*, *price range*, *cuisine*, *rating*, *number of comments*, *address* and *phone number*) in which the first four slots (*inform slots*) can be used for searching the desirable restaurant and all of these slots (*request slots*) can be asked by users. In each dialog, the user has a goal containing a set of slots, indicating the constraints and requests from users. For example, an *inform slot*, such as "*inform(cuisine=Sichuan cuisine)*", indicates the user finding a Sichuan restaurant, and a *request slot*, such as "*request(area)*", indicates the user asking for information from the system (Li et al., 2016, 2017b; Peng et al., 2017).

6.2 Measurements

A main advantage of our approach is that the unconsidered user actions can be handled in the extended system. In addition to traditional measurements (e.g., success rate, average turns and average reward), we define an objective measurement called "Satis." (user satisfaction) to verify this feature in the simulated evaluation. "Satis." indicates the rate at which the system takes reasonable actions in unsupported dialog situations. It can be calculated as follows:

$$Satis. = \frac{\sum_{d\in D}\sum_{t=1}^{|d|}\sum_{l=1}^{L}\mathbb{1}\{h_t = h_l\}\mathbb{1}\{a_t^s = a_l\}}{\sum_{d\in D}\sum_{t=1}^{|d|}\sum_{l=1}^{L}\mathbb{1}\{h_t = h_l\}} \qquad (8)$$

where h_t and a_t^s are the dialog history and system action in the t-th turn, h_l and a_l are dialog context condition and corresponding system action defined in the l-th rules. Intuitively, an unreasonable system reply will frustrate users and low "Satis." indicates a poor user experience.

	*Sim*1				*Sim*2			
LU Error Rate	Succ.	Turn	Reward	Satis.	Succ.	Turn	Reward	Satis.
0.00	0.962	13.6	3.94	-	0.901	13.2	2.95	0.57
0.05	0.937	13.7	3.41	-	0.877	14.4	2.41	0.48
0.10	0.910	14.3	2.65	-	0.841	13.9	1.41	0.47
0.20	0.845	15.2	0.58	-	0.784	14.7	0.01	0.47

Table 1: Performance of the original system when interacting with different user simulators. LU error means simulating slot errors and intent errors in different rates. Succ.: success rate, Turn: average turns, Reward: average reward.

LU Error Rate	0.00	0.05	0.10	0.20
Total	25857	26166	27077	28385
New User Actions	1853	1859	1998	1912

Table 2: Statistics of turns when S_1 interacts with *Sim*2.

Although “Satis.” is obtained based on our handcrafted dialog rules, it approximately measures the subjective experience of real users after system deployment.

6.3 User Simulator

Training RL-based dialog systems requires a large number of interactions with users. It’s common to use a user simulator to train RL-based dialog systems in an online fashion (Pietquin and Dutoit, 2006; Scheffler and Young, 2002; Li et al., 2016). As a consequence, we construct an agenda-based user simulator, which we refer to as *Sim*1, to train the original RL-based system. The user action set of *Sim*1 is denoted as A_u, which includes such intents[4]: “*hello*”, “*bye*”, “*inform*”, “*deny*”, “*negate*”, “*affirm*”, “*request*”, “*reqalts*” and “*null*”. The slots of *Sim*1 are shown in section 6.1. In each turn, the user action consists of a intent and slots and we append the value of slots according to the user goal.

6.4 Implementation of the Original System

For the original RL-based dialog system, a feature vector x_t of size 191 is extracted. This vector is the concatenation of encodings of LU results, the previous system reply, database results and the current turn number. The LU module is implemented with an SVM[5] for intent detection and a CRF[6] for slot filling. The language generation module is implemented by a rule-based method. The hidden dialog state representation is inferred by a GRU (Chung et al., 2014). We set the hidden states of the GRU to be 120. The policy network is implemented as a Multilayer Perceptron (MLP) with one hidden layer. The size of the hidden layer is 80. The output dimension of policy network is 15, which corresponds to the number of system actions. To encourage shorter interaction, we set a small per-turn negative reward $R_{turn} = -1$. The maximal turn is set to be 40. If the user goal is satisfied, the policy will be encouraged by a large positive reward $R_{succ} = 10$; otherwise the policy will be penalized by a negative reward $R_{fail} = -10$. Discounted factor $\gamma = 0.9$. The baseline b of current policy is estimated on sampled episodes in a batch. The batch size N is set to be 32. Adadelta (Zeiler, 2012) method is used to update model parameters. The **original system** S_1 is trained by interacting with *Sim*1. After about 2400 interactions, the performance of S_1 starts to converge.

6.5 Simulated Evaluation

To evaluate our approach, we design another user simulator, which we denote as *Sim*2, to simulate the unpredictable real customers. The user action set of *Sim*2 is denoted as A'_u. The difference between A_u and A'_u is reflected on the domain specific intents[7]. Specifically, in addition to the intents of *Sim*1, A'_u includes the “*confirm*” intent. The difference in user action sets will result in different interaction strategies between *Sim*1 and *Sim*2. To verify whether a recommended restaurant meets his (her) constraints, *Sim*1 can **only** request what the value of a specific slot is, but *Sim*2 can request or confirm.

After obtaining the original system S_1, we deploy it to interact with *Sim*1 and *Sim*2 respectively, under different LU error rates (Li et al., 2017a). In each condition, we simulate 3200 episodes to obtain the performance. Table 1 shows the

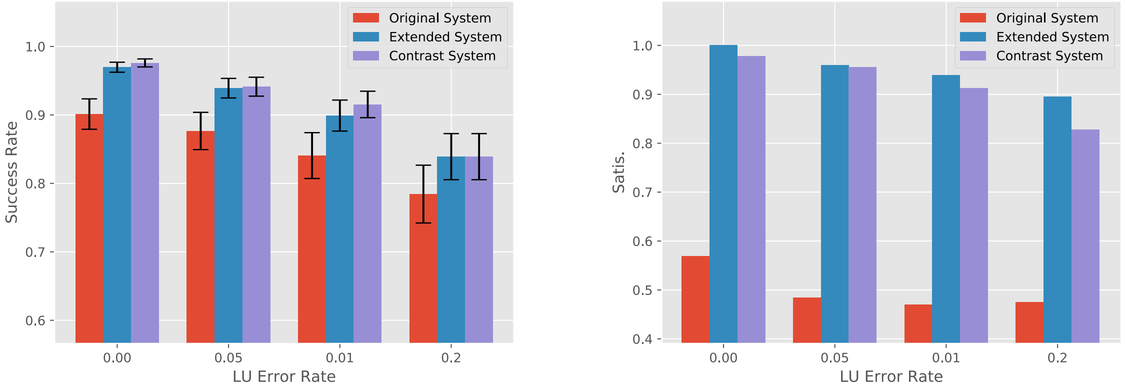
---

[4] A detail explanation of these intents is in DSTC2 (Henderson et al., 2013).

[5] We use the publicly available SVM tool at http://scikit-learn.org.

[6] We use the publicly available CRF tool at https://pypi.python.org/pypi/sklearn-crfsuite.

[7] A more complex situation is shown in the human evaluation.



(a) Dialog success rate of different systems.

(b) Satis. of different systems.

Figure 4: Performance of different systems under simulation. The original, extended and contrast systems are shown in red, blue and purple bars. We test these systems by interacting with *Sim*2.

details of the test performance. Table 2 shows the statistics of turns when S_1 interacts with *Sim*2.

As shown in Table 1, S_1 achieves higher dialog success rate and rewards when testing with *Sim*1. When interacting with *Sim*2, nearly half of the responses to unsupported user actions are not reasonable. Notice even though *Sim*2 contains new user actions, some of the new actions might be appropriately handled by S_1. It may be due to the robustness of our RL-based system. But it's far from being desired. The unpredictable real user behavior in the deployment stage will lead to a poor user experience in real-world applications. It proves the importance of a maintainable system.

To maintain the original system, we define a few simple logic rules to handle unsupported user actions: if users confirm the value of a slot in current turn, the system should inform users of that value. These rules[8] are intuitive and reasonable to handle queries such as "Is this restaurant located in Zhongguancun?". There are four slots[9] that can be used for confirmation, so we define four logic rules in all. Due to the change in ontology, we add a new status in dialog features to represent the "confirm" intent of users. It leads to a change in the model architecture of extended dialog manager. Then we distill knowledge of the S_1 and logic rules into the **extended system**. No additional data is used to obtain the extended system.

For comparison, we retrain another new system (**contrast system**) from scratch by interacting with *Sim*2. After about 2600 interactions with *Sim*2, the performance of contrast system starts to converge. Note that in order to build the contrast system, the developers need to redesign a new user simulator or hire real users. It's expensive and impractical in industrial applications. Then we simulate 3200 interactions with *Sim*2 to obtain its performance. Fig. 4 illustrates the performance of different systems.

As can be seen, the extended system performs better than the original system in terms of dialog success rate and "Satis.". This is to a large degree attributed to the consideration of new user actions. Fig. 4(a) shows that the contrast system achieves higher dialog success rate than the extended system. But the gap is negligible. However, the contrast system is trained from scratch under a new interaction environment and the extended system is trained by transferring knowledge of the original system and logic rules. To train the contrast system, about 2600 episodes are sampled by interacting with a new interaction environment. But no additional data is used to train the extended system.

In Fig. 4(b), the "Satis." of the extended system is slightly higher than the contrast system. This is due to the fact that the extended system learns how to deal with new user actions from logic rules but the contrast system obtains dialog policy by exploring the environment. As a result, the contrast system learns a more flexible dialog policy than the extended system[10]. However, the "Satis." has a bias to the suboptimal rules,

---

[8] In the practical dialog system, we can inject more complex logic rules and take dialog history into account. These rules are not limited to question/answer mapping.

[9] They are "*name*", "*area*", "*price range*" and "*cuisine*".

[10] Table 6 in the Appendix shows sample dialogs from the extended system and contrast system.

Table 3: Details of the real user logs. Users are encouraged to interact with the original system by unsupported intents and slots. We find there are 14 user actions unseen before.

Dialog Condition	System Action
takeTaxi	API call
bookTable	API call
inform unseen slots	recommend a restaurant
request unseen slots	offer information of slots
confirm unseen slots	offer information of slots

Table 4: Different types of rules for new user actions. Left column shows the dialog context condition; Right column shows the corresponding system action. We define 14 rules in all to handle newfound intents and slots shown in Table 3.

rather than the optimal policy gained from the environment. It suggests the extended system can be further refined by reinforcement learning once a new interaction environment is available.

6.6 Human Evaluation

In any case, the developers can't guarantee all user actions are considered. Fortunately, our method makes no assumptions about the new user actions and new dialog model architecture. As a result, the system can be extended over multiple iterations.

To evaluate this characteristic, we deploy the extended system[11] in section 6.5 to interact with real human users. Users are given a goal sampled from our corpus for reference. To elicit more complex situations, they are encouraged to interact with our system by new intents and slots related to the restaurant domain. At the end of each dialog, they are asked to give a subjective rating on the scale from 1 to 5 based on the naturalness of the system (1 is the worst, 5 is the best.). After filtering dialog sessions unrelated to our task, we collect 315 episodes in total. Table 3 shows the details of the user logs. As shown in Table 3, after deployment, there are a few slots and intents unseen before. For example, users may ask for the discount information or take a taxi to the restaurant. To represent the new intents and slots, the dimension of extracted dialog features is extended to 236. Meanwhile, the number of system actions is extended to 29 to handle new user actions. To deal with the newfound user actions, we define 14 rules in total. Table 4 shows the details of new defined logic rules. Then we distill the knowledge of the original system and logic rules into a new system. Fig. 5 shows the comparison in user ratings. The extended system significantly gets a higher subjective rating than the original one. It proves that the extended system can give reasonable responses in unseen dialog situations.

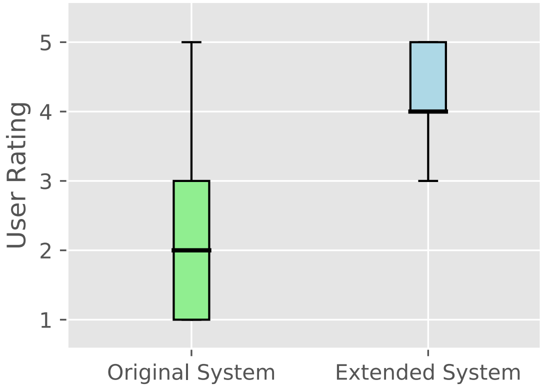

Figure 5: Distribution of user ratings.

Table 5 shows sample dialogs from the original system and extended system with real users. We can see that the extended system is much more coherent since it takes new user actions into account. It inspires us that a complicated RL-based dialog system can start from a simple one and be improved incrementally based on our framework. This design pattern will be much more efficient if the interaction environment is hard to access.

7 Conclusion

In this paper, we present a practical solution to maintain RL-based dialog systems without retraining from scratch. By reusing existing resources, developers can extend the RL-based dialog manager to deal with unpredictable user actions after deployment. Furthermore, our method holds no constraints on the architecture of the new system and retains the key benefit of data-driven methods. It means the new system can be maintained iteratively and further refined by RL once a new interaction environment is available. The sim-

Abstract

This paper presents a Discriminative Deep Dyna-Q (D3Q) approach to improving the effectiveness and robustness of Deep Dyna-Q (DDQ), a recently proposed framework that extends the Dyna-Q algorithm to integrate planning for task-completion dialogue policy learning. To obviate DDQ's high dependency on the quality of simulated experiences, we incorporate an RNN-based discriminator in D3Q to differentiate simulated experience from real user experience in order to control the quality of training data. Experiments show that D3Q significantly outperforms DDQ by controlling the quality of simulated experience used for planning. The effectiveness and robustness of D3Q is further demonstrated in a domain extension setting, where the agent's capability of adapting to a changing environment is tested.[1]

1 Introduction

There are many virtual assistants commercially available today, such as Apple's Siri, Google's Home, Microsoft's Cortana, and Amazon's Echo. With a well-designed dialogue system as an intelligent assistant, people can accomplish tasks via natural language interactions. Recent advance in deep learning has also inspired many studies in neural dialogue systems (Wen et al., 2017; Bordes et al., 2017; Dhingra et al., 2017; Li et al., 2017).

A key component in such task-completion dialogue systems is *dialogue policy*, which is often formulated as a reinforcement learning (RL) problem (Levin et al., 1997; Young et al., 2013). However, learning dialogue policy via RL from the scratch in real-world systems is very challenging, due to the inevitable dependency on the environment from which a learner acquires knowledge and receives rewards. In a dialogue scenario, real users act as the environment in the RL framework, and the system communicates with real users constantly to learn dialogue policy. Such process is very time-consuming and expensive for online learning.

One plausible strategy is to leverage user simulators trained on human conversational data (Schatzmann et al., 2007; Li et al., 2016), which allows the agent to learn dialogue policy by interacting with the simulator instead of real users. The user simulator can provide infinite simulated experiences without additional cost, and the trained system can be deployed and then fine-tuned through interactions with real users (Su et al., 2016; Lipton et al., 2016; Zhao and Eskenazi, 2016; Williams et al., 2017; Dhingra et al., 2017; Li et al., 2017; Liu and Lane, 2017; Peng et al., 2017b; Budzianowski et al., 2017; Peng et al., 2017a; Tang et al., 2018).

However, due to the complexity of real conversations and biases in the design of user simulators, there always exists the discrepancy between real users and simulated users. Furthermore, to the best of our knowledge, there is no universally accepted metric for evaluating user simulators for dialogue purpose (Pietquin and Hastie, 2013). Therefore, it remains controversial whether training task-completion dialogue agent via simulated users is a valid and effective approach.

A previous study, called Deep Dyna-Q (DDQ) (Peng et al., 2018), proposed a new strategy to learn dialogue policies with real users by combining the Dyna-Q framework (Sutton, 1990) with deep learning models. This framework incorporates a learnable environment model (*world model*) into the dialogue policy learning pipeline, which simulates dynamics of the environment and generates simulated user behaviors to supplement the limited amount of real user experience. In DDQ, real user experiences play two pivotal roles:

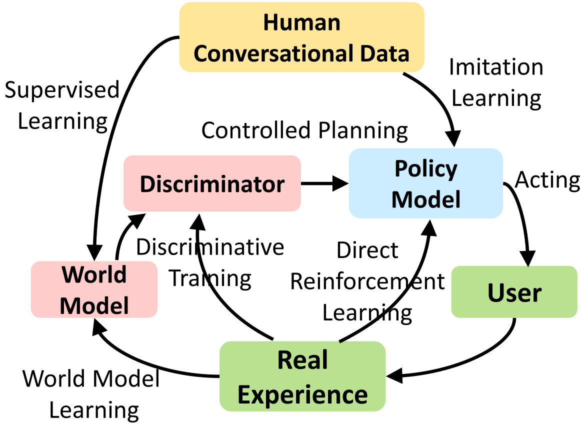

Figure 1: Proposed D3Q for dialogue policy learning.

1) directly improve the dialogue policy via RL; 2) improve the world model via supervised learning to make it behave more human-like. The former is referred to as *direct reinforcement learning*, and the latter *world model learning*. Respectively, the policy model is trained via real experiences collected by interacting with real users (*direct reinforcement learning*), and simulated experiences collected by interacting with the learned world model (*planning* or *indirect reinforcement learning*).

However, the effectiveness of DDQ depends upon the quality of simulated experiences used in planning. As pointed out in (Peng et al., 2018), although at the early stages of dialogue training it is helpful to perform planning aggressively with large amounts of simulated experiences regardless their quality, in the late stages when the dialogue agent has been significantly improved, low-quality simulated experiences often hurt the performance badly. Since there is no established method of evaluating the world model which generates simulated experiences, Peng et al. (2018) resorts to heuristics to mitigate the negative impact of low-quality simulated experiments, e.g., reducing the planning steps in the late stage of training. These heuristics need to be tweaked empirically, thus limit DDQ's applicability in real-world tasks.

To improve the effectiveness of planning without relying on heuristics, this paper proposes Discriminative Deep Dyna-Q (D3Q), a new framework inspired by generative adversarial network (GAN) that incorporates a discriminator into the planning process. The discriminator is trained to differentiate simulated experiences from real user experiences. As illustrated in Figure 1, all simulated experiences generated by the world model need to be *judged* by the discriminator, only the high-quality ones, which cannot be easily detected by the discriminator as being simulated, are used for planning. During the course of dialogue training, both the world model and discriminator are refined using the real experiences. So, the quality threshold held by the discriminator goes up with the world model and dialogue agent, especially in the late stage of training.

By employing the world model for planning and a discriminator for controlling the quality of simulated experiences, the proposed D3Q framework can be viewed as a model-based RL approach, which is generic and can be easily extended to other RL problems. In contrast, most model-based RL methods (Tamar et al., 2016; Silver et al., 2016; Gu et al., 2016; Racanière et al., 2017) are developed for simulation-based, synthetic problems (e.g., games), not for real-world problems. In summary, our main contributions in this work are two-fold:

- The proposed Discriminative Deep Dyna-Q approach is capable of controlling the quality of simulated experiences generated by the world model in the planning phase, which enables effective and robust dialogue policy learning.
- The proposed model is verified by experiments including simulation, human evaluation, and domain-extension settings, where all results show better sample efficiency over the DDQ baselines.

2 Discriminative Deep Dyna-Q (D3Q)

As illustrated in Figure 2, the D3Q framework consists of six modules: (1) an LSTM-based natural language understanding (NLU) module (Hakkani-Tür et al., 2016) for identifying user intents and extracting associated slots; (2) a state tracker (Mrkšić et al., 2017) for tracking dialogue states; (3) a dialogue policy that selects next action based on the current state; (4) a model-based natural language generation (NLG) module for generating natural language response (Wen et al., 2015); (5) a world model for generating simulated user actions and simulated rewards; and (6) an RNN-based discriminator for controlling the quality of simulated experience. Note that the controlled planning phase is realized through the world model and the discriminator, which are not

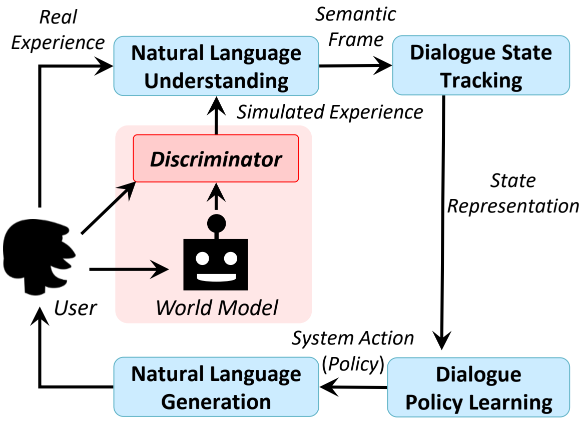

Figure 2: Illustration of the proposed D3Q dialogue system framework.

included in traditional framework of dialogue systems.

Figure 1 illustrates the whole process: starting with an initial dialogue policy and an initial world model (both are trained with pre-collected human conversational data), D3Q training consists of four stages: (1) *direct reinforcement learning*: the agent interacts with real users, collects real experiences and improves dialogue policy; (2) *world model learning*: the world model is learned and refined using real experience; (3) *discriminator learning*: the discriminator is learned and refined to differentiate simulated experience from real experience; and (4) *controlled planning*: the agent improves the dialogue policy using the high-quality simulated experience generated by the world model and the discriminator.

2.1 Direct Reinforcement Learning

In this stage, we use the vanilla deep Q-network (DQN) method (Mnih et al., 2015) to learn the dialogue policy based on real experience. We consider task-completion dialogue as a Markov Decision Process (MDP), where the agent interacts with a user through a sequence of actions to accomplish a specific user goal.

At each step, the agent observes the dialogue state s, and chooses an action a to execute, using an ϵ-greedy policy that selects a random action with probability ϵ or otherwise follows the greedy policy $a = \text{argmax}_{a'} Q(s, a'; \theta_Q)$. $Q(s, a; \theta_Q)$ which is the approximated value function, implemented as a Multi-Layer Perceptron (MLP) parameterized by θ_Q. The agent then receives reward r, observes next user response, and updates the state to s'. Finally, we store the experience tuple (s, a, r, s') in the replay buffer B^u. This cycle continues until the dialogue terminates.

We improve the value function $Q(s, a; \theta_Q)$ by adjusting θ_Q to minimize the mean-squared loss function as follows:

$$\begin{aligned} \mathcal{L}(\theta_Q) &= \mathbb{E}_{(s,a,r,s')\sim B^u}[(y_i - Q(s,a;\theta_Q))^2], \\ y_i &= r + \gamma \max_{a'} Q'(s', a'; \theta_{Q'}), \end{aligned} \tag{1}$$

where $\gamma \in [0, 1]$ is a discount factor, and $Q'(.)$ is the target value function that is only periodically updated (i.e., fixed-target). The dialogue policy can be optimized through $\nabla_{\theta_Q} \mathcal{L}(\theta_Q)$ by mini-batch deep Q-learning.

2.2 World Model Learning

To enable planning, we use a world model to generate simulated experiences that can be used to improve dialogue policy. In each turn of a dialogue, the world model takes the current dialogue state s and the last system action a (represented as an one-hot vector) as the input, and generates the corresponding user response o, reward r, and a binary variable t (indicating if the dialogue terminates). The world model $G(s, a; \theta_G)$ is trained using a multi-task deep neural network (Liu et al., 2015) to generate the simulated experiences. The model contains two classification tasks for simulating user responses o and generating terminal signals t, and one regression task for generating the reward r. The lower encoding layers are shared across all three tasks, while the upper layers are task-specific. $G(s, a; \theta_G)$ is optimized to mimic human behaviors by leveraging real experiences in the replay buffer B^u. The model architecture is illustrated in the left part of Figure 3.

$$\begin{aligned} h &= \tanh(W_h(s,a) + b_h), \\ r &= W_r h + b_r, \\ o &= \texttt{softmax}(W_a h + b_a), \\ t &= \texttt{sigmoid}(W_t h + b_t), \end{aligned}$$

where (s, a) is the concatenation of s and a, and all W and b are weight matrices and bias vectors, respectively.

2.3 Discriminator Learning

The discriminator, denoted by D, is used to differentiate simulated experience from real experience. D is a neural network model with its architecture illustrated in the right part of Figure 3. D employs

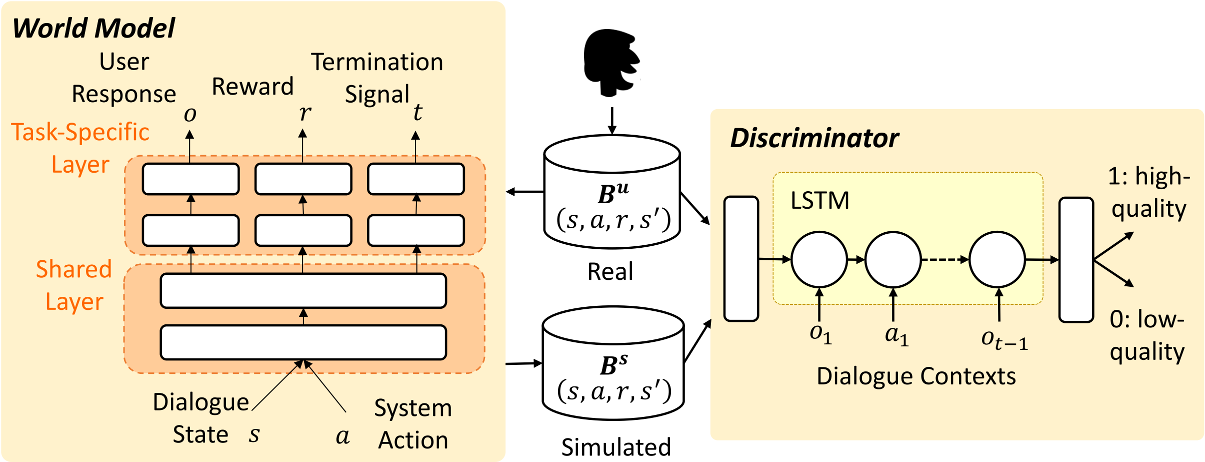

Figure 3: The model architectures of the world model and the discriminator for controlled planning.

an LSTM to encode a dialogue as a feature vector, and a Multi-Layer Perceptron (MLP) to map the vector to a probability indicating whether the dialogue looks like being generated by real users.

D is trained using the simulated experience generated by the world model G and the collected real experience x. We use the objective function as

$$\mathbb{E}_{real}[\log D(x)] + \mathbb{E}_{simu}[\log(1 - D(G(.)))]. \quad (2)$$

Practically, we use the mini-batch training and the objective function can be rewritten as

$$\frac{1}{m}\sum_{i=1}^{m}[\log D(x^{(i)}) + \log(1 - D(G(.)^{(i)}))], \quad (3)$$

where m represents the batch size.

2.4 Controlled Planning

In this stage, we apply the world model G and the discriminator D to generate high-quality simulated experience to improve dialogue policy. The D3Q method uses three replay buffers, B^u for storing real experience, B^s for simulated experience generated by G, and B^h for high-quality simulated experience generated by G and D. Learning and planning are implemented by the same DQN algorithm, operating on real experience in B^u for learning and on simulated experience in B^h for planning. Here we only describe how the high-quality simulated experience is generated.

At the beginning of each dialogue session, we uniformly draw a user goal (C, R) (Schatzmann et al., 2007), where C is a set of constraints and R is a set of requests. For example, in movie-ticket booking dialogue, *constraints* are the slots with specified values, such as the name, the date of the movie and the number of tickets to buy. And *requests* can contain slots which the user plans to acquire the values for, such as the start time of the movie. The first user action o_1 can be either a `request` or an `inform` dialogue act. A request dialogue act consists of a request slot, multiple constraint slots and the corresponding values, uniformly sampled from R and C. For example, `request(theater; moviename=avergers3)`. An inform dialogue act contains constraint-slots only. Semantic frames can also be transformed into natural language via NLG component, e.g., "*which theater will play the movie avergers3?*"

For each dialogue episode with a sampled user goal, the agent interacts with world model $G(s, a; \theta_G)$ to generate a simulated dialogue session, which is a sequence of simulated experience tuples (s, a, r, s'). We always store the G-generated session in B^s, but only store it in B^h if it is selected by discriminator D. We repeat the process until K simulated dialogue sessions are added in B^h, where K is a pre-defined planning step size. This can be viewed as a sampling process. In theory if the world model G is not well-trained this process could take forever to generate K high-quality samples accepted by D. Fortunately, this never happened in our experiments because D is trained using the simulated experience generated by G and D is updated whenever G is refined.

Now, we compare controlled planning in D3Q with the planning process in the original DDQ (Peng et al., 2018). In DDQ, after each step of di-

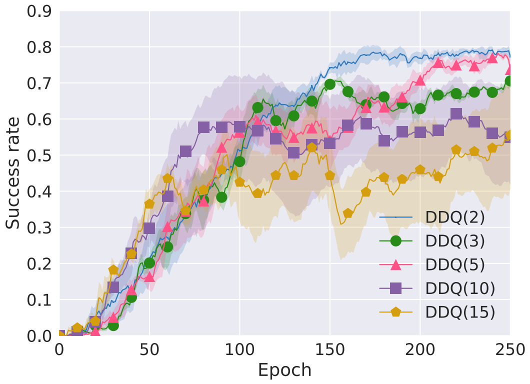

Figure 4: The learning curves of DDQ(K) agents where $(K-1)$ is the number of planning steps.

rect reinforcement learning, the agent improves its policy via K steps of planning. A larger planning step means that more simulated experiences generated by G are used for planning. Theoretically, larger amounts of *high-quality* simulated experiences can boost the performance of the dialogue policy more quickly. However, the world model by no means perfectly reflects real human behavior, and the generated experiences, if of low quality, can have negative impact on dialogue policy learning. Prior work resorts to heuristics to mitigate the impact. For example, Peng et al. (2018) proposed to reduce planning steps at the late stage of policy learning, thus forcing all DDQ agents to converge to the same one trained with a small number of planning steps.

Figure 4 shows the performance of DDQ agents with different planning steps without heuristics. It is observable that the performance is unstable, especially for larger planning steps, which indicates that the quality of simulated experience is becoming more pivotal as the number of planning steps increases.

D3Q resolves this issue by introducing a discriminator and allows only high-quality simulated experience, judged by the discriminator, to be used for planning. In the next section, we will show that D3Q does not suffer from the problem of DDQ and the D3Q training is quite stable even with large sizes of planning steps.

3 Experiments

We evaluate D3Q on the movie-ticket booking task with both simulated users and real users in two settings: full domain and domain extension.

Full Domain & Domain Extension	
Intent	request, inform, deny, confirm_question, confirm_answer, greeting, closing, not_sure, multiple_choice, thanks, welcome
Full Domain	
Slot	city, closing, date, distanceconstraints, greeting, moviename, numberofpeople, price, starttime, state, taskcomplete, theater, theater_chain, ticket, video_format, zip
Domain Extension	
Slot	city, closing, date, distanceconstraints, greeting, moviename, numberofpeople, price, starttime, state, taskcomplete, theater, theater_chain, ticket, video_format, zip, genre, other

Table 1: The data schema for full domain and domain extension settings.

3.1 Dataset

Raw conversational data in a movie-ticket booking scenario was collected via Amazon Mechanical Turk. The dataset has been manually labeled based on a schema defined by domain experts, as shown in Table 1, consisting of 11 intents and 16 slots in the full domain setting, while there are 18 slots in the domain extension setting. Most of these slots can be both "inform slots" and "request slots", except for a few. For example, the slot `number_of_people` is categorized as an inform slot but not a request slot, because arguably the user always knows how many tickets she/he wants. In total, the dataset contains 280 annotated dialogues, the average length of which is approximately 11 turns.

3.2 Baselines

To verify the effectiveness of D3Q, we developed different versions of task-completion dialogue agents as baselines to compare with.

- A **DQN** agent is implemented with only direct reinforcement learning in each episode.

- The **DQN(K)** has K times more real experiences than the DQN agent. The performance of DQN(K) can be viewed as the upper bound of DDQ(K) and D3Q(K) with the same number of planning steps $(K-1)$, as these models have the same training settings and the same amount of training samples during the entire learning process.

- The **DDQ(K)** agents are learned with an initial world model pre-trained on human conversational data, with $(K-1)$ as the number of planning steps. These agents store the simulated experience without being judged by the discriminator.

Proposed D3Q

- The **D3Q(K)** agents are learned through the process described in Section 2.4.
- The **D3Q(K, fixed θ_D)** agents are learned as described in Section 2.4 without training discriminator. The D3Q(K, fixed θ_D) agents are only evaluated in the simulation setting.

3.3 Implementation

Settings and Hyper-parameters ϵ-greedy is always applied for exploration. We set the discount factor γ = 0.9. The buffer size of B^u and B^h is set to 2000 and 2000 $\times K$ *planning steps*, respectively. The batch size is 16, and the learning rate is 0.001. To prevent gradient explosion, we applied gradient clipping on all the model parameters to maximum norm = 1. All the NN models are randomly initialized. The high-quality simulated experience buffer B^h and the simulated experience buffer B^s are initialized as empty. The target network is updated at the beginning of each training episode. The optimizer for all the neural networks is RMSProp (Hinton et al., 2012). The maximum length of a simulated dialogue is 40. If exceeding the maximum length, the dialogue fails. To make dialogue training efficient, we also applied a variant of imitation learning, called Reply Buffer Spiking (RBS) (Lipton et al., 2016), by building a simple and straightforward rule-based agent based on human conversational dataset. We then prefilled the real experience replay buffer B^u with experiences of 50 dialogues, before training for all the variants of models. The batch size for collecting experiences is 10, which means if the running agent is DDQ/D3Q(K), 10 real experience tuples and 10 $\times$ ($K - 1$) simulated experience tuples are stored into the buffers at every episode.

Agents For all the models (DQN, DDQ, and D3Q) and their variants, the value networks $Q(.)$ are MLPs with one hidden layer of size 80 and ReLU activation.

World Model For all the models (DDQ and D3Q) and their variants, the world models $M(.)$ are MLPs with one shared hidden layer of size 160, hyperbolic-tangent activation, and one encoding layer of hidden size 80 for each state and action input.

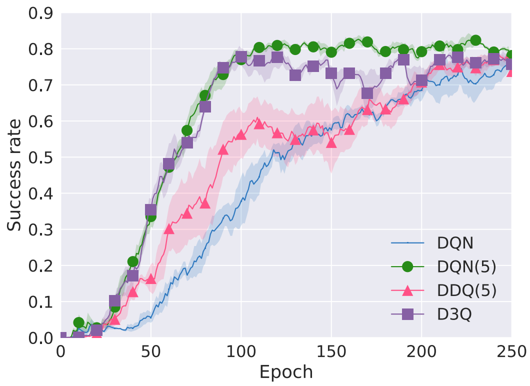

Figure 5: The learning curves of agents (DQN, DDQ, and D3Q) under the full domain setting.

Discriminator In the proposed D3Q framework, the LSTM cell is utilized, the hidden size is 128. The encoding layer for the current state and output layer are MLPs with single hidden layer of size 80. The threshold interval is set to range between 0.45 and 0.55, i.e., only when $0.45 \leq D(x) \leq 0.55$ that x would be stored into the buffer B^h.

3.4 Simulation Evaluation

In this setting, the dialogue agents are optimized by interacting with the user simulators instead of with real users. In another word, the world model is trained to mimic user simulators. In spite of the discrepancy between simulators and real users, this setting endows us with the flexibility to perform a detailed analysis of models without much cost, and to reproduce experimental results easily.

User Simulator We used an open-sourced task-oriented user simulator (Li et al., 2016) in our simulated evaluation experiments (Appendix A for more details). The simulator provides the agent with a simulated user response in each dialogue turn along with a reward signal at the end of the dialogue. A dialogue is considered successful if and only if a movie ticket is booked successfully, and the information provided by the agent satisfies all the constraints of the sampled user goal. At the end of each dialogue, the agent receives a positive reward $2 * L$ for success, or a negative reward $-L$ for failure, where L is the maximum number of turns in each dialogue, and is set to 40 in our experiments. Furthermore, in each turn, a reward -1 is provided to encourage shorter dialogues.

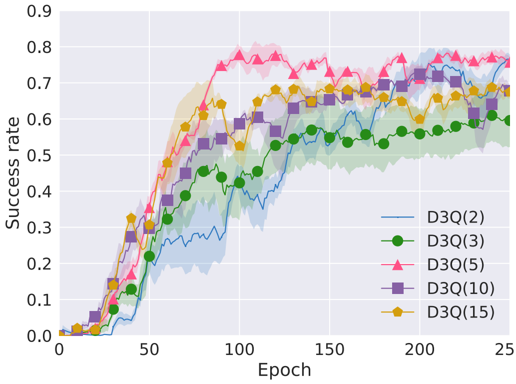

Figure 6: The learning curves of D3Q(K) agents which (K-1) is the number of planning steps (K = 2, 3, 5, 10, 15).

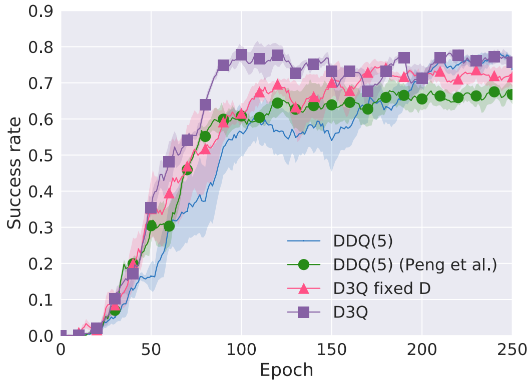

Figure 7: The learning curves of D3Q, DDQ(5), DDQ(5) (Peng et al., 2018), and D3Q fixed θ_D agents.

Full Domain The learning curves of the models in the full domain setting are depicted in the figure 5. The results show that the proposed D3Q agent (the pink curve) significantly outperforms the baselines DQN and DDQ(5), and has similar training efficiency to DQN(5). Note that here the planning steps of D3Q is 4, which means D3Q (pink) and DDQ(5) (purple) use the same amount of training samples (both real and simulated experiences) to update the agent throughout the whole training process. The difference between these two agents is that D3Q employs a discriminator as a quality judge. The experimental result shows that our proposed framework could boost the learning efficiency even without any pre-training on the discriminator. Furthermore, D3Q (pink) uses the same amount of training samples as DQN(5) (green), while the proposed model uses only 20% of real experience from human. The efficacy and feasibility of D3Q is hereby justly verified.

As mentioned in the previous section, a large number of planning steps means leveraging a large amount of simulated experience to train the agents. The experimental result (Figure 4) shows that the DDQ agents are highly sensitive to the quality of simulated experience. In contrast, the proposed D3Q framework demonstrates robustness to the number of planning steps (Figure 6). Figure 7 shows that D3Q also outperforms DDQ original setting (Peng et al., 2018) and D3Q without training discriminator. The performance detail including success rate, reward, an number of turns is shown in Table 2. From the table, with fewer simulated experiences, the difference between DDQ and D3Q may not be significant, where DDQ agents achieve about 50%-60% success rate and D3Q agents achieve higher than 68% success rate after 100 epochs. However, when the number of

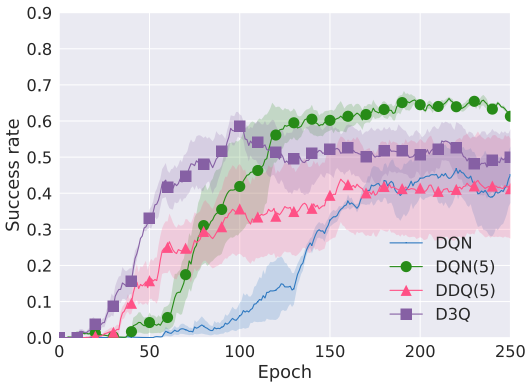

Figure 8: The learning curves of agents (DQN, DDQ, and D3Q) under the domain extension setting.

planning steps increases, more fake experiences significantly degrade the performance for DDQ agents, where DDQ(10, fixed θ_G) suffers from bad simulated experiences after 300 epochs and achieves 0% success rate.

Domain Extension In the domain extension experiments, more complicated user goals are adopted. Moreover, we narrow down the action space into a small subspace instead of that used in full-domain setting, and gradually introduce more complex user goals and expand the action space as the training proceeds. Specifically, we start from a set of necessary slots and actions to accomplish most of the user goals, and then extend the action space and complexity of user goals once every 20 epoch (after epoch 50). Note that the domain will keep extending and become full-domain after epoch 130. Such experimental setting makes the training environment more complicated and unstable than the previous full-domain one.

The results summarized in Figure 8 show that D3Q significantly outperforms the baseline methods, demonstrating its robustness. Furthermore, D3Q shows remarkable learning efficiency while extending the domain, which even outperforms DQN(5). A potential reason might be that the world model could improve exploration in such unstable and noisy environment.

3.5 Human Evaluation

In the human evaluation experiments, real users interact with different models without knowing which agent is behind the system. At the beginning of each dialogue session, one of the agents was randomly picked to converse with the user.

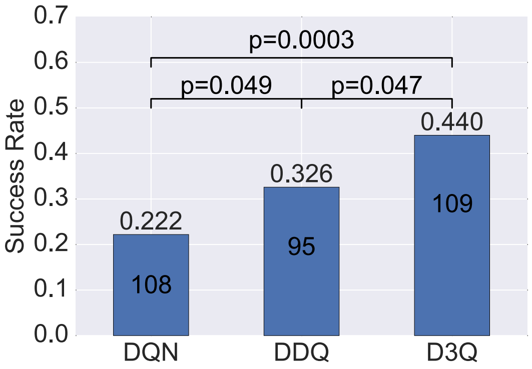

Figure 9: The human evaluation results of D3Q, DDQ(5), and D3Q in the full domain setting, the number of test dialogues indicated on each bar, and the p-values from a two-sided permutation test (difference in mean is significant with $p < 0.05$).

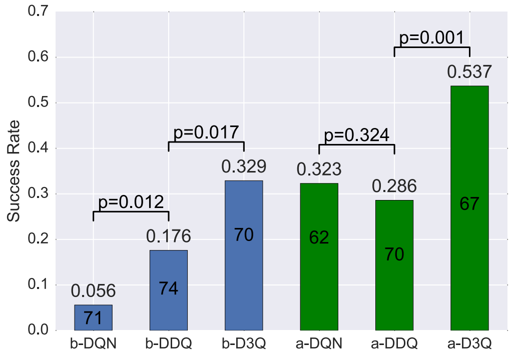

Figure 10: The human evaluation results of DQN, DDQ(5), and D3Q in the domain extension setting, the number of test dialogues indicated on each bar. The prefix 'b-' implies that the trained models are picked before the environment extends to full domain, while the prefix 'a-' indicates that the trained models are picked after the environment becomes full domain (difference in mean is significant with $p < 0.05$).

The user was instructed to converse with the agent to complete a task given a user goal sampled from the corpus. The user can abandon the task and terminate the dialogue at any time, if she or he believes that the dialogue was unlikely to succeed, or simply because the dialogue drags on for too many turns. In such cases, the dialogue session is considered as failure.

Full Domain Three agents (DQN, DDQ(5), and D3Q) trained in the full domain setting (Figure 5) at epoch 100 are selected for testing. As illustrated in Figure 9, the results of human evaluation are consistent with those in the simulation evaluation (Section 3.4), and the proposed D3Q significantly outperforms other agents.

Domain Extension To test the adaptation capability of the agents to the complicated, dynamically changing environment, we selected three trained agents (DQN, DDQ(5), and D3Q) at epoch 100 before the environment extends to full domain, and another three agents trained at epoch 200 after the environment becomes full domain. Figure 10 shows that the results are consistent with those in the simulation evaluation (Figure 8), and the proposed D3Q significantly outperforms other agents in both stages.

4 Conclusions

This paper proposes a new framework, Discriminative Deep Dyna-Q (D3Q), for task-completion dialogue policy learning. With a discriminator as judge, the proposed approach is capable of controlling the quality of simulated experience generated in the planning phase, which enables efficient and robust dialogue policy learning. Furthermore, D3Q can be viewed as a generic model-based RL approach easily-extensible to other RL problems.

We validate the D3Q-trained dialogue agent on a movie-ticket-booking task in the simulation, human evaluation, and domain-extension settings. Our results show that the D3Q agent significantly outperforms the agents trained using other state-of-the-art methods including DQN and DDQ.

A User Simulator

In the task-completion dialogue setting, the entire conversation is around a user goal implicitly, but the agent knows nothing about the user goal explicitly and its objective is to help the user to accomplish this goal. Generally, the definition of user goal contains two parts:

- *inform_slots* contain a number of slot-value pairs which serve as constraints from the user.
- *request_slots* contain a set of slots that user has no information about the values, but wants to get the values from the agent during the conversation. ticket is a default slot which always appears in the *request_slots* part of user goal.

To make the user goal more realistic, we add some constraints in the user goal: slots are split into two groups. Some of slots must appear in the user goal, we called these elements as *Required slots*. In the movie-booking scenario, it includes moviename, theater, starttime, date, numberofpeople; the rest slots are *Optional slots*, for example, theater_chain, video_format etc.

We generated the user goals from the labeled dataset using two mechanisms. One mechanism is to extract all the slots (known and unknown) from the first user turns (excluding the greeting user turn) in the data, since usually the first turn contains some or all the required information from user. The other mechanism is to extract all the slots (known and unknown) that first appear in all the user turns, and then aggregate them into one user goal. We dump these user goals into a file as the user-goal database. Every time when running a dialogue, we randomly sample one user goal from this user goal database.

A Self-Attentive Model with Gate Mechanism for Spoken Language Understanding

Abstract

Spoken Language Understanding (SLU), which typically involves intent determination and slot filling, is a core component of spoken dialogue systems. Joint learning has shown to be effective in SLU given that slot tags and intents are supposed to share knowledge with each other. However, most existing joint learning methods only consider joint learning by sharing parameters on surface level rather than semantic level. In this work, we propose a novel self-attentive model with gate mechanism to fully utilize the semantic correlation between slot and intent. Our model first obtains intent-augmented embeddings based on neural network with self-attention mechanism. And then the intent semantic representation is utilized as the gate for labelling slot tags. The objectives of both tasks are optimized simultaneously via joint learning in an end-to-end way. We conduct experiment on popular benchmark ATIS. The results show that our model achieves state-of-the-art and outperforms other popular methods by a large margin in terms of both intent detection error rate and slot filling F1-score. This paper gives a new perspective for research on SLU.

1 Introduction

One long-term goal in artificial intelligence field is to build an intelligent human-machine dialogue system, which is capable of understanding human's language and giving smooth and correct responses. A typical dialogue system is designed to execute the following components: (i) automatic speech recognition converts a spoken query into transcription, (ii) spoken language understanding component analyzes the transcription to extract semantic representations, (iii) dialogue manager interprets the semantic information and decides the best system action, according to which the system response is further generated either as a natural language output(Jurafsky, 2000).

In this paper, we focus on spoken language understanding which is a core component of a spoken dialogue system. It typically involves two major tasks, intent determination and slot filling. Intent determination aims to automatically identify the intent of the user as expressed in natural language. Slot filling aims to extract relevant semantic constituents from the natural language sentence towards achieving a goal.

Usually, intent detection and slot filling are carried out separately. However, separate modeling of these two tasks is constrained to take full advantage of all supervised signals. Joint learning of intent detection and slot filling is worthwhile for three reasons. Firstly, the two tasks usually appear simultaneously in SLU systems. Secondly, the information of one task can be utilized in the other task to promote each other and a joint prediction can be made (Zhang and Wang, 2016). For example, if the intent of a utterance is to find a flight, it is likely to contain the departure and arrival cities, and vice versa. Lastly, slot tags and intents, as semantics representations of user behaviours, are supposed to share knowledge with each other.

Recently, joint model for intent detection and slot filling has achieved much progress. (Xu and Sarikaya, 2013) proposed using CNN based triangular CRF for joint intent detection and slot filling. (Guo et al., 2014) proposed using a recursive neural network that learns hierarchical representations of the input text for the joint task. (Liu and Lane, 2016b) describes a recurrent neural network (RNN) model that jointly performs intent detection, slot filling and language modeling. The neural network models keep updating the intent prediction as word in the transcribed utterance arrives and uses it as contextual features in the joint model.

In this work, we propose a novel model for

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3824–3833
Brussels, Belgium, October 31 - November 4, 2018.

joint intent determination and slot filling by introducing self-attention and gating mechanism. Our model can fully utilize the semantic correlation between slot and intent. To the best of our knowledge, this is the first attempt to utilize intent-augmented embedding as a gate to guide the learning of slot filling task. To fully evaluate the efficiency of our model, we conduct experiment on Airline Travel Information Systems (ATIS) dataset (Hemphill et al., 1990), which is popularly used as benchmark in related work. And empirical results show that our independent model outperforms the previous best result by 0.54% in terms of F1-score on slot filling task, and gives excellent performance on intent detection task. Our joint model further promotes the performance and achieves state-of-the-art results on both tasks.

The rest of our paper is structured as follows: Section 2 discusses related work, Section 3 gives a detailed description of our model, Section 4 presents experiments results and analysis, and Section 5 summarizes this work and the future direction.

2 Related Work

There is a long research history for spoken dialogue understanding, which emerged in the 1990s from some call classification systems (Gorin et al., 1997) and the ATIS project. In this section, we describe some typical works on intent classification and slot-filling, which are both core tasks of SLU (De Mori, 2007).

For intent detection task, the early traditional method is to employ n-grams as features with generic entities, such as locations and dates (Zhang and Wang, 2016). This type of method is restricted to the dimensionality of the input space. Another line of popular approaches is to train machine learning models on labeled training data (Young, 2002; Hahn et al., 2011). For example, SVM (Haffner et al., 2003) and Adaboost (Schapire and Singer, 2000) have been explored to improve intent detection. Approaches based on neural network architecture have shown good performance on intent detection task. Deep belief networks (DBNs) have been first used in call routing classification (Deoras and Sarikaya, 2013). More recently, RNNs have shown excellent performance on the intent classification task (Ravuri and Stolcke, 2015).

For slot-filling task, traditional approaches are based on conditional random fields (CRF) architecture, which has strong ability on sequence labelling (Raymond and Riccardi, 2007). Recently, models based on neural network and its extensions have shown excellent performance on the slot filling task and outperform traditional CRF models. For example, (Yao et al., 2013) proposed to take words as input in a standard recurrent neural network language model, and then to predict slot labels rather than words on the output side. (Yao et al., 2014b) improved RNNs by using transition features and the sequence-level optimization criterion of CRF to explicitly model dependencies of output labels. (Mesnil et al., 2013) tried bi-directional and hybrid RNN to investigate using RNN for slot filling. (Yao et al., 2014a) introduced LSTM architecture for this task and obtained a marginal improvement over RNN. Besides, following the success of attention based models in the NLP field, (Simonnet et al., 2015) applied the attention-based encoder-decoder to the slot filling task, but without LSTM cells.

Recently, there has been some work on learning intent detection and slot filling jointly exploited by neural networks. Slot labels and intents, as semantics of user behaviors, are supposed to share knowledge with each other. (Guo et al., 2014) adapted recursive neural networks (RNNs) for joint training of intent detection and slot filling. (Xu and Sarikaya, 2013) described a joint model for intent detection and slot filling based on convolutional neural networks (CNN). The proposed architecture can be perceived as a neural network version of the triangular CRF model (TriCRF). (Hakkani-Tür et al., 2016) proposed a single recurrent neural network architecture that integrates the three tasks (domain detection, intent detection and slot filling for multiple domains) in a model. (Liu and Lane, 2016a) proposed an attention-based neural network model for joint intent detection and slot filling. Their joint model got the best performance of 95.98% slot filling F1-score and 1.57% intent error rate in the ATIS dataset.

Despite the great progress those methods have achieved, it is still a challenging and open task for intent detection and slot filling. Therefore, we are motivated to design a powerful model, which can improve the performance of SLU systems.

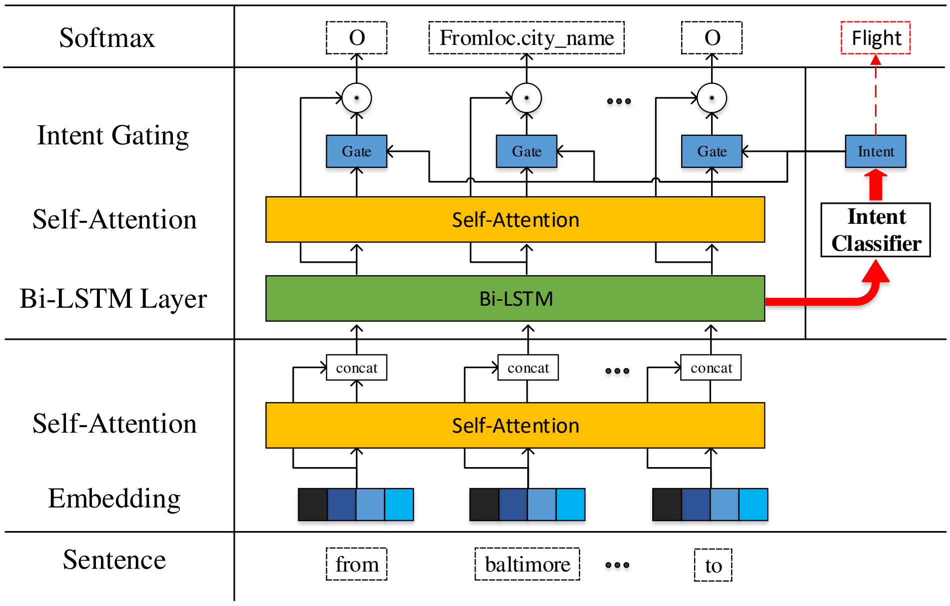

Figure 1: Illustration of our proposed model for joint intent detection and slot filling. Red arrows represent the intent classification task based on the weighted average of BiLSTM outputs. The embeddings coloured with different intensity values denote word-level and char-level embeddings (three kinds of convolution kernels).

3 Model

In this section, we present our model for the joint learning of intent detection and slot filling. Figure 1 gives an overview of our model.

The first layer maps input sequence into vectors by concatenating its word-level embeddings and character-level embeddings (obtained by convolution). And we use these vectors as merged embeddings in downstream layers. In many situations, contextual information is useful in sequence labelling. In this paper, we introduce an approach that leverages context-aware features at each time step. In particular, we make use of self-attention to produce context-aware representations of the embeddings. Then a bidirectional recurrent layer takes as input the embeddings and context-aware vectors to produce hidden states. In the last step, we propose to exploit the intent-augmented gating mechanism to match the slot label. The gate for a specific word is obtained by taking a linear transformation of the intent embedding and another contextual representation of this word computed by self-attention. We apply element-wise dot-product between the gate and each BiLSTM output.

Finally, a softmax layer is added to classify the slot labels on top of the gate layer. For simplicity, we only take the weighted average of BiLSTM outputs to predict the intent label.

The design of this structure is motivated by the effectiveness of multiplicative interaction among vectors and by self-attention mechanism which has been used successfully in a variety of tasks (Cheng et al., 2016; Vaswani et al., 2017; Lin et al., 2017). It also typically corresponds to our finding that the intent is highly correlated with slot label in some cases, so the semantics of intent should be useful for detecting the slot labels.

3.1 Embedding Layer

We first convert the indexed words $\mathbf{w} = (w_1, w_2, ..., w_T)$ to word-level embeddings $E^w = [e_1^w, e_2^w, ..., e_T^w]$, and character-level embeddings $E^c = [e_1^c, e_2^c, ..., e_T^c]$. Although word embeddings are sufficient for many NLP task, provided by a well-pretrained glove[1] or word2vec[2], character-level information provides some more prior knowledge (e.g. morphemes) to the embedding learning procedure. Some morphemic correlated words are more close in vector space, which is useful for identifying the slot labels. Character embeddings also alleviate the out-of-vocabulary (OOV) problem in the testing phase. In this paper we focus on a character-aware convolution layer used in (Kim et al., 2016) for words. The

---

[1] http://nlp.stanford.edu/projects/glove/

[2] https://code.google.com/p/word2vec/

character-level embeddings are generated by convolution over characters in the word with multiple window size to extract n-gram features.

Let $\mathcal{C}$ be the vocabulary of characters, $\mathcal{V}$ be the vocabulary of words. The dimensions of character-level embedding and word-level embedding are denoted as d_c and d_w, respectively. For each word $w_t \in \mathcal{V}$, characters in w_t constitute the matrix $C^t \in \mathbb{R}^{d_c \times l}$, where the columns corresponds to l character embeddings.

A narrow convolution is applied between C^t and a filter (or kernel) $H \in \mathbb{R}^{d_c \times w}$. Here we suppose the filter width is w. After that, we obtain a feature map $\mathbf{f}^t \in \mathbb{R}^{l-w+1}$ by adding a nonlinearity activation. The final n-gram features is generated by taking the max-over-time:

$$\mathbf{f}^t[i] = relu(H \cdot C^t[:, i : i+w-1] + b) \tag{1}$$

$$c^t = \max_i \mathbf{f}^t[i] \tag{2}$$

where $C^t[:, i : i+w-1]$ is the i-to-(i+w-1)-th column of C^t, and the character-level embedding e_t^c is made up of multiple c^t generated by different convolution kernels.

3.2 Self-Attention

Attention mechanism is usually used to guide the forming of sentence embedding, extra knowledge is also used to weigh the CNN or LSTM hidden states (i.e. document words sometimes attend to question information). However in slot filling task, the input to our model is just one sequence. So the attention mechanism used here is called self-attention, that is to say, the word at each time step attends to the whole words in this sentence. And it helps to determine which region is likely to be a slot. Since the embedding at each time step consists of multiple parts (i.e. word embedding and character embeddings of different kernel width), each part has its own semantic meaning. As shown in Figure 2, we divide the embedding into multiple parts and the attention of each part is processed within its corresponding dimension. In this approach, we restrict the interaction among different aspects of the embedding. We hypothesize that different semantic parts are relatively independent and play different roles in our network.

Suppose $M \in \mathbb{R}^{d_m \times T}$ to be the matrix containing sentence hidden vectors $[m_1, ..., m_T]$, where d_m is the dimension of these T vectors. Considering the characteristics of slot filing task, our aim is to encode each hidden vector into a context-aware representation. We achieve that by using attention over all the sentence hidden vectors M. Firstly, We linearly map all the vectors in M to three feature spaces by different projection parameters W_a, W_b and W_c, so the resulting vectors are expressed as M_a, M_b and M_c with the same shape as M. These matrices are shared across all time steps. Considering the structure of embedding which consists of K different parts (we use 4 kinds of embeddings with the same dimension), these transformed matrices are equally split into K parts. Furthermore, the attention weight is computed by dot product between M_a and M_b. Lastly, the attention output is a weighted sum of M_c.

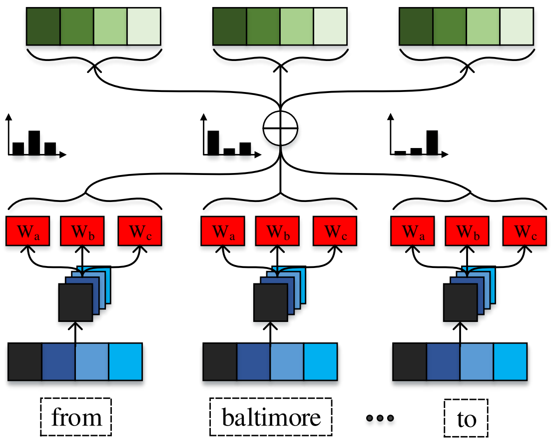

Figure 2: The structure of self-attention layer. Red coloured rectangles stand for matrices which map the input to different subspaces. These transformed vectors are divided into multiple parts for computing self-attention.

Specifically, we consider different K parts in detail for $k = 1, .., K$:

$$\begin{bmatrix} M_a \\ M_b \\ M_c \end{bmatrix} = \begin{bmatrix} W_a M \\ W_b M \\ W_c M \end{bmatrix} \tag{3}$$

$$\alpha_{k,t} = \text{softmax}(m_{k,a,t}^{\mathrm{T}} M_{k,b}) \tag{4}$$

$$\text{S-Att}(m_t, M) = [M_{1,c}\alpha_{1,t}^{\mathrm{T}}, ..., M_{K,c}\alpha_{K,t}^{\mathrm{T}}] \tag{5}$$

where $M_{k,a} \in \mathbb{R}^{(d_m/K) \times T}$ is the k-th part of M_a which is transformed from M by W_a. Index t is word position ranging over T time steps and $m_{k,a,t} \in \mathbb{R}^{d_m/K}$ is the t-th column of $M_{k,a}$. $\alpha_{k,t}$

is the attention weights over $M_{k,c}$. The output of self-attention module generated at time step t is the concatenation of K parts by using Equation 5.

3.3 BiLSTM

Character embeddings and word embeddings are both important features in our task. To further utilize these features, we associate each embedding with a context-aware representation which is typically implemented by self-attention mechanism. For current word w_t, the input of the recurrent layer at time step t is represented as x_t:

$$e_t^a = \text{S-Att}([e_t^c, e_t^w], E) \tag{6}$$

$$x_t = [e_t^c, e_t^w, e_t^a] \tag{7}$$

e_t^a is the context-aware vector of w_t which is obtained by applying self-attention mechanism on the concatenated embeddings $E = [e_1^c \parallel e_1^w, ..., e_T^c \parallel e_T^w]$.

It was difficult to train RNNs to capture long-term dependencies because the gradients tend to either vanish or explode. Therefore, some more sophisticated activation functions with gating units were designed. We use LSTM (Hochreiter and Schmidhuber, 1997) in this work:

$$i_t = \sigma(W_i x_t + U_i h_{t-1} + b_i) \tag{8}$$

$$f_t = \sigma(W_f x_t + U_f h_{t-1} + b_f) \tag{9}$$

$$o_t = \sigma(W_o x_t + U_o h_{t-1} + b_o) \tag{10}$$

$$\widetilde{c}_t = tanh(W_c x_t + U_c h_{t-1} + b_c) \tag{11}$$

$$c_t = i_t \odot \widetilde{c}_t + f_t \odot c_{t-1} \tag{12}$$

$$h_t = o_t \odot tanh(c_t) \tag{13}$$

Where $\odot$ denotes element-wise product of two vectors. To consider both the previous history and the future history, we use BiLSTM as encoder in advance. The bi-directional LSTM (BiLSTM), a modification of the LSTM, consists of a forward and a backward LSTM. The encoder reads the input vectors $\mathbf{x} = (x_1, x_2, ..., x_T)$ and generates T hidden states by concatenating the forward and backward hidden states of BiLSTM:

$$\overrightarrow{h}_t = \overrightarrow{LSTM}(x_t, \overrightarrow{h}_{t-1}) \tag{14}$$

$$\overleftarrow{h}_t = \overleftarrow{LSTM}(x_t, \overleftarrow{h}_{t+1}) \tag{15}$$

$$h_t = [\overrightarrow{h}_t, \overleftarrow{h}_t] \tag{16}$$

where $\overleftarrow{h}_t$ is the hidden state of backward pass in BLSTM and $\overrightarrow{h}_t$ is the hidden state of forward pass in BLSTM at time t.

3.4 Intent-Augmented Gating Mechanism

As described above, intent information is useful for slot filling task. To measure the probability of words in target slots and attend to the ones relevant to the intent, we add a gate to the output of BiLSTM layer. Let $H \in \mathbb{R}^{2d \times T}$ be a matrix consisting of hidden vectors $[h_1, ..., h_T]$ produced by BiLSTM. For each word, we use self-attention mechanism to form another context-aware representation, the gate vector h_t^* is calculated by linearly transforming the concatenation of the context-aware representation and the intent embedding vector v^{int} with a multi-layer perceptron (MLP) network. The intent label is provided by correct label during training phase, and by the output from intent classification layer in the test phase. Specifically, for $t = 1, ...T$:

$$s_t = \text{Self-Attention}(h_t, H) \tag{17}$$

$$h_t^* = \text{MLP}([s_t, v^{int}]) \tag{18}$$

$$o_t = h_t \odot h_t^* \tag{19}$$

We use element-wise multiplication to model the interaction between BiLSTM outputs and the gate vector.

3.5 Task Learning

The bidirectional recurrent layer converts a sequence of words $\mathbf{w} = (w_1, w_2, ..., w_T)$ into hidden states $H = [h_1, ..., h_T]$ which are shared by two tasks. We use simple attention pooling function denoted as f_{att} over H to get an attention-sum vector for intent label classification. The classified label y^{int} is transformed to an embedding v^{int} by matrix E^{int} for gate computing.

$$h^{int} = f_{att}(H) \tag{20}$$

$$y^{int} = \text{softmax}(W^{int} h^{int} + b^{int}) \tag{21}$$

During the training phase, model parameters are updated w.r.t. a cross-entropy loss between the predicted probabilities and the true label. The label with maximum probability will be selected as the predicted intent during the testing phase.

For another task, the hidden states processed by our gating layer are used for predicting slot labels.

$$y_t^{slot} = \text{softmax}(W^{slot} o_t + b^{slot}) \tag{22}$$

Slot filling can be defined as a sequence labelling problem which is to map a utterance sequence $\mathbf{w} = (w_1, ..., w_T)$ to its corresponding slot label sequence $\mathbf{y} = (y_1, ..., y_T)$. The objective is to maximize the likelihood of a sequence:

$$P(\mathbf{y}^{slot}|\mathbf{w}) = \prod_{t=1}^{T} P(y_t^{slot}|\mathbf{w}) \quad (23)$$

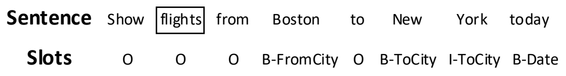
It is equal to minimize Negative Log-likelihood (NLL) of the correct labels for the predicted sequence $\mathbf{y}^{slot}$.

4 Experiments

4.1 Dataset

In order to evaluate the efficiency of our proposed model, we conduct experiments on ATIS (Airline Travel Information Systems) dataset, which is widely used as benchmark in SLU research (Price, 1990).

Figure 3 gives one example of sentence in ATIS dataset. The words are labelled with their value according to certain semantic frames. The slot labels of the words are represented in an In-Out-Begin (IOB) format and the intent is highlighted with a box surrounding it.



Sentence	Show	flights	from	Boston	to	New	York	today
Slots	O	O	O	B-FromCity	O	B-ToCity	I-ToCity	B-Date

Figure 3: Example of sentence annotated by slots sampled from ATIS corpus, the black boxed word indicates the intent.

In this paper, we use the ATIS corpus setting following previous related works (Liu and Lane, 2016a; Mesnil et al., 2015; Liu and Lane, 2015; Xu and Sarikaya, 2013; Tur et al., 2010). The training set contains 4978 utterances from ATIS-2 and ATIS-3 datasets, and test set contains 893 utterances from ATIS-3 NOV93 and DEC94 datasets. The number of slot labels is 127 and the intent has 18 different types.

4.2 Metrics

The performance of slot filling task is measured by the F1-score, while intent detection task is evaluated with prediction error rate that is the ratio of the incorrect intent of the test data.

4.3 Training Details

We preprocess the ATIS following (Yao et al., 2013; Liu and Lane, 2016a). To deal with unseen words in the test set, we mark those words that appear only once in the training set as ⟨UNK⟩, and use this label to represent those unseen words in the test set. Besides, each number is converted to the string DIGIT.

The model is implemented in the Tensorflow framework (Abadi et al., 2016). At training stage, we use LSTM cell as suggested in (Sutskever et al., 2014) and the cell dimension d is set to be 128 for both the forward and backward LSTM.

We set the dimension of word embedding d_w to be 64 and the dimension of character embedding d_c to be 128. We generate three character-level embeddings using multiple widths and filters (the convolution kernel width $w \in \{2, 3, 4\}$ with 64 filters each) followed by a max pooling layer over time. Then, the dimension of concatenated embeddings is 256. We make the dimensions of each parts equal for the convenience of dimension splitting during the self-attention in later stage. All the parameters in the network are randomly initialized with uniform distribution (Sussillo and Abbott, 2014) which are fine-tuned during training. We use the stochastic gradient descent algorithm (SGD) for updating parameters. And the learning rate is controlled by Adam algorithm (Kingma and Ba, 2014). The model is trained on all the training data with mini-batch size of 16. In order to enhance our model to generalize well, the maximum norm for gradient clipping is set to 5. We also apply layer normalization (Ba et al., 2016) on the self-attention layer after we add a residul connection between the output and input. Meanwhile, dropout rate 0.5 is applied on recurrent cell projection layer (Zaremba et al., 2014) and on each attention activation.

4.4 Independent Learning

The results of separate training for slot filling and intent detection are reported in Table 1 and Table 2 respectively. On the independent slot filling task, we fixed the intent information as the ground truth labels in the dataset. But on the independent intent detection task, there is no interaction with slot labels.

Table 1 compares F1-score of slot filling between our proposed architecture and some previous works. Our model achieves state-of-the-art results and outperforms previous best model by 0.56% in terms of F1-score. We attribute the improvement of our model to the following reasons: 1) The attention used in (Liu and Lane, 2016a) is vanilla attention, which is used to compute the de-

Methods	F1-score

coding states. It is not suitable for our model since the embeddings are composed of several parts. Self-attention allows the model to attend to information jointly from different representation parts, so as to better understand the utterance. 2) intent-augmented gating layer connects the semantics of sequence slot labels, which captures complex interactions between the two tasks.

Table 2 compares the performance of our proposed model to previously reported results on intent detection task. Our model gives good performance in terms of classification error rate, but not as good as Attention Encoder-Decoder (with aligned inputs) method (Liu and Lane, 2016a). As their published state-of-the-art result described in (Liu and Lane, 2016a), their attention-based model is based on word-level embeddings. While in our model, we introduce character-level embeddings to improve the performance of joint learning. But independent learning for intent classification aims at capturing the global information of an utterance, not caring much about the details of specific word. The character-level embeddings introduced in our model bring very little hurt to independent learning of intent detection, as a trade-off in performance between both criterion.

4.5 Joint Learning

We compare our model against the following baseline models based on joint learning:

- **Recursive NN:** (Guo et al., 2014) employed recursive neural networks for joint training of two tasks.
- **Recursive NN + Viterbi:** (Guo et al., 2014) applied the Viterbi algorithm on Recursive NN to improve the result on slot filling.
- **Attention Enc-Dec:** (Liu and Lane, 2016a) proposed Attention Encoder-Decoder (with aligned inputs) which introduced context vector as the explicit aligned inputs at each decoding step.
- **Attention BiRNN:** (Liu and Lane, 2016a) introduced attention to the alignment-based RNN sequence labeling model. Such attention provides additional information to the intent classification and slot label prediction.

Methods	F1	Error(%)
Recursive NN (Guo et al., 2014)	93.22	4.60
Recursive NN+Viterbi (Guo et al., 2014)	93.96	4.60
Attention Enc-Dec (Liu and Lane, 2016a)	95.87	1.57
Attention BiRNN (Liu and Lane, 2016a)	95.98	1.79
Our Model	**96.52**	**1.23**

Table 3: Results of joint training for slot filling and intent detection.

Table 3 compares our joint model with reported results from previous works. We can see that our model achieves state-of-the-art results and outperforms previous best result by 0.54% in terms of F1-score on slot filling, and by 0.34% in terms of error rate on intent detection. This improvement is statistically significant. Besides, the joint learning
