Examining the generated output for the Django dataset in Table 3, we can see that in the first example, our retrieval model can successfully generate the correct code when YN17 fails. This difference suggests that our retrieval model benefits from the action subtrees from the retrieved sentences. In the second example, although our generated code does not perfectly match the reference code, it has a higher BLEU score compared to the output of YN17 because our model can predict part of the code (`timesince(d, now, reversed)`) correctly. The third example shows where our method fails to apply the correct action as it cannot cast `s` to `str` type while YN17 can at least cast `s` into a type (`bool`). Another common type of error that we found RECODE's generated outputs is incorrect variable copying, similarly to what is discussed in Yin and Neubig (2017) and Rabinovich et al. (2017).

Table 4 presents a result on the HS dataset[4]. We can see that our retrieval model can handle complex code more effectively.

6 Related Work

Several works on code generation focus on domain specific languages (Raza et al., 2015; Kushman and Barzilay, 2013). For general purpose code generation, some data-driven work has been

---

[4] More example of HS code is provided in the supplementary material.

done for predicting input parsers (Lei et al., 2013) or a set of relevant methods (Raghothaman et al., 2016). Some attempts using neural networks have used sequence-to-sequence models (Ling et al., 2016) or tree-based architectures (Dong and Lapata, 2016; Alvarez-Melis and Jaakkola, 2017). Ling et al. (2016); Jia and Liang (2016); Locascio et al. (2016) treat semantic parsing as a sequence generation task by linearizing trees. The closest work to ours are Yin and Neubig (2017) and Rabinovich et al. (2017) which represent code as an AST. Another close work is Dong and Lapata (2018), which uses a two-staged structure-aware neural architecture. They initially generate a low-level sketch and then fill in the missing information using the NL and the sketch.

Recent works on retrieval-guided neural machine translation have been presented by Gu et al. (2018); Amin Farajian et al. (2017); Li et al. (2018); Zhang et al. (2018). Gu et al. (2018) use the retrieved sentence pairs as extra inputs to the NMT model. Zhang et al. (2018) employ a simpler and faster retrieval method to guide neural MT where translation pieces are n-grams from retrieved target sentences. We modify Zhang et al. (2018)'s method from textual n-grams to n-grams over subtrees to exploit the code structural similarity, and propose methods to deal with complex statements and rare words.

In addition, some previous works have used subtrees in structured prediction tasks. For example, Galley et al. (2006) used them in syntax-based translation models. In Galley et al. (2006), subtrees of the input sentence's parse tree are associated with corresponding words in the output sentence.

7 Conclusion

We proposed an action subtree retrieval method at test time on top of an AST-driven neural model for generating general-purpose code. The predicted surface code is syntactically correct, and the retrieval component improves the performance of a previously state-of-the-art model. Our successful result suggests that our idea of retrieval-based generation can be potentially applied to other tree-structured prediction tasks.

Abstract

Previous work approaches the SQL-to-text generation task using vanilla Seq2Seq models, which may not fully capture the inherent graph-structured information in SQL query. In this paper, we first introduce a strategy to represent the SQL query as a directed graph and then employ a graph-to-sequence model to encode the global structure information into node embeddings. This model can effectively learn the correlation between the SQL query pattern and its interpretation. Experimental results on the WikiSQL dataset and Stackoverflow dataset show that our model significantly outperforms the Seq2Seq and Tree2Seq baselines, achieving the state-of-the-art performance.

1 Introduction

The goal of the SQL-to-text task is to automatically generate human-like descriptions interpreting the meaning of a given structured query language (SQL) query (Figure 1 gives an example). This task is critical to the natural language interface to a database since it helps non-expert users to understand the esoteric SQL queries that are used to retrieve the answers through the question-answering process (Simitsis and Ioannidis, 2009) using varous text embeddings techniques (Kim, 2014; Arora et al., 2017; Wu et al., 2018a).

Earlier attempts for SQL-to-text task are rule-based and template-based (Koutrika et al., 2010; Ngonga Ngomo et al., 2013). Despite requiring intensive human efforts to design temples or rules, these approaches still tend to generate rigid and stylized language that lacks the natural text of the human language. To address this, Iyer et al. (2016) proposes a sequence-to-sequence (Seq2Seq) network to model the SQL query and natural language jointly. However, since the SQL is designed to express graph-structured query intent, the sequence encoder may need an elaborate design to fully capture the global structure information. Intuitively, varous graph encoding techniques base on deep neural network (Kipf and Welling, 2016; Hamilton et al., 2017; Song et al., 2018) or based on Graph Kernels (Vishwanathan et al., 2010; Wu et al., 2018b), whose goal is to learn the node-level or graph-level representations for a given graph, are more proper to tackle this problem.

(SQL): **SELECT** company **WHERE** assets > val$_0$ **AND** sales > val$_0$ **AND** industry_rank <= val$_2$ **AND** revenue = val$_3$

Interpretation:
which company has both the market value and assets higher than val$_{0,}$ ranking in top val$_2$ and revenue of val$_3$

Figure 1: An example of SQL query and its interpretation.

In this paper, we first introduce a strategy to represent the SQL query as a directed graph (see §2) and further make full use of a novel graph-to-sequence (Graph2Seq) model (Xu et al., 2018) that encodes this graph-structured SQL query, and then decodes its interpretation (see §3). On the encoder side, we extend the graph encoding work of Hamilton et al. (2017) by encoding the edge direction information into the node embedding. Our encoder learns the representation of each node by aggregating information from its K-hop neighbors. Different from Hamilton et al. (2017) which neglects the edge direction, we classify the neighbors of a node according to the edge direction, say v, into two classes, i.e., forward nodes (v directs to) and backward nodes (direct to v). We apply two distinct aggregators to aggregate the information of these two types of nodes, resulting two representations. The node embedding of v is the concatenation of these two representations. Given the learned node embeddings, we further introduce a pooling-based and an aggregation-based method to generate the graph embedding.

On the decoder side, we develop an RNN-based decoder which takes the graph vector representation as the initial hidden state to generate the sequences while employing an attention mechanism over all node embeddings. Experimental results show that our model achieves the state-of-the-art performance on the WikiSQL dataset and Stackoverflow dataset. Our code and data is available at https://github.com/IBM/SQL-to-Text.

2 Graph Representation of SQL Query

Representing the SQL query as a graph instead of a sequence could better preserve the inherent structure information in the query. An example is illustrated in the blue dashed frame in Figure 2. One can see that representing them as a graph instead of a sequence could help the model to better learn the correlation between this graph pattern and the interpretation "*...both X and Y higher than Z...*". This observation motivates us to represent the SQL query as a graph. In particular, we use the following method to transform the SQL query to a graph:[1]

SELECT Clause. For the SELECT clause such as "SELECT company", we first create a node assigned with text attribute *select*. This SELECT node connects with column nodes whose text attributes are the selected column names such as *company*. For SQL queries that contain aggregation functions such as `count` or `max`, we add one aggregation node which is connected with column nodes. Similarly, their text attributes are the aggregation function names.

WHERE Clause. The WHERE clause usually contains more than one condition. For each condition, we use the same process as for the SELECT clause to create nodes. For example, in Figure 2, we create node *assets* and $>val_0$ for the first condition, the node *sales* and $>val_0$ for the second condition. We then integrate the constraint nodes that have the same text attribute (e.g., $>val_0$ in Figure 2). For a logical operator such as AND, OR and NOT, we create a node that connects with all column nodes that the operator works on. Finally, these logical operator nodes connect with the SELECT node.

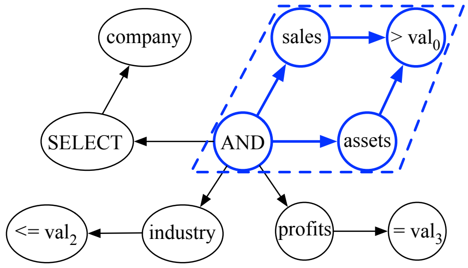

Figure 2: The graph representation of the SQL query in Figure 1.

3 Graph-to-sequence Model

Based on the constructed graphs for the SQL queries, we make full use of a novel graph-to-sequence model (Xu et al., 2018), which consists of a graph encoder to learn the embedding for the graph-structured SQL query, and a sequence decoder with attention mechanism to generate sentences. Conceptually, the graph encoder generates the node embedding for each node by accumulating information from its K-hop neighbors, and produces a graph embedding for the entire graph by abstracting all node embeddings. Our decoder takes the graph embedding as the initial hidden state and calculates the attention over all node embeddings on the encoder side to generate natural language interpretations.

Node Embedding. Given the graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, since the text attribute of a node may include a list of words, we first use a Long Short Term Memory (LSTM) to generate the feature vector $\mathbf{a}_v$ for all nodes $\forall v \in \mathcal{V}$ from v's text attribute. We use these feature vectors as initial node embeddings. Then, our model incorporates information from a node's neighbors within K hop into its representation by repeating the following process K times:

$$\mathbf{h}^0_{v\vdash} = \mathbf{a}_v, \mathbf{h}^0_{\vdash v} = \mathbf{a}_v, \forall v \in \mathcal{V} \tag{1}$$

$$\mathbf{h}^k_{\mathcal{N}_\vdash(v)} = \mathbf{M}^k_\vdash(\{\mathbf{h}^{k-1}_{u\vdash}, \forall u \in \mathcal{N}_\vdash(v)\}) \tag{2}$$

$$\mathbf{h}^k_{v\vdash} = \sigma(\mathbf{W}^k \cdot \text{CONCAT}(\mathbf{h}^{k-1}_{v\vdash}, \mathbf{h}^k_{\mathcal{N}_\vdash(v)})) \tag{3}$$

$$\mathbf{h}^k_{\mathcal{N}_\dashv(v)} = \mathbf{M}^k_\dashv(\{\mathbf{h}^{k-1}_{u\dashv}, \forall u \in \mathcal{N}_\dashv(v)\}) \tag{4}$$

$$\mathbf{h}^k_{v\dashv} = \sigma(\mathbf{W}^k \cdot \text{CONCAT}(\mathbf{h}^{k-1}_{v\dashv}, \mathbf{h}^k_{\mathcal{N}_\dashv(v)})) \tag{5}$$

where $k \in \{1, ..., K\}$ is the iteration index, $\mathcal{N}$ is the neighborhood function[2], $\mathbf{h}^k_{v\vdash}$ ($\mathbf{h}^k_{v\dashv}$) is node v's forward (backward) representation which aggregates the information of nodes in $\mathcal{N}_\vdash(v)$ ($\mathcal{N}_\dashv(v)$),

---

[1] This method could be simply extended to cope with more general SQL queries that have complex syntaxes such as JOIN and ORDER BY.

[2] $\mathcal{N}_\vdash(v)$ returns the nodes that v directs to and $\mathcal{N}_\dashv(v)$ returns the nodes that direct to v.

$\mathbf{M}_{\vdash}^{k}$ and $\mathbf{M}_{\dashv}^{k}$ are the forward and backward aggregator functions, $\mathbf{W}^{k}$ denotes weight matrices, σ is a non-linearity function.

For example, for node $v \in \mathcal{V}$, we first aggregate the forward representations of its immediate neighbors $\{\mathbf{h}_{u\vdash}^{k-1}, \forall u \in \mathcal{N}_{\vdash}(v)\}$ into a single vector $\mathbf{h}_{\mathcal{N}_{\vdash}(v)}^{k}$ (equation 2). Note that this aggregation step only uses the representations generated at previous iteration and its initial representation is $\mathbf{a}_v$. Then we concatenate v's current forward representation $\mathbf{h}_{v\vdash}^{k-1}$ with the newly generated neighborhood vector $\mathbf{h}_{\mathcal{N}_{\vdash}(v)}^{k}$. This concatenated vector is fed into a fully connected layer with nonlinear activation function σ, which updates the forward representation of v to be used at the next iteration (equation 3). Next, we update the backward representation of v in the similar fashion (equation 4$\sim$5). Finally, the concatenation of the forward and backward representation at last iteration K, is used as the resulting representation of v. Since the neighbor information from different hops may have the different impact on the node embedding, we learn a distinct aggregator function at each step. This aggregator feeds each neighbor's vector to a fully-connected neural network and an element-wise max-pooling operation is applied to capture different aspects of the neighbor set.

Graph Embedding. Most existing works of graph convolution neural networks focus more on node embeddings rather than graph embeddings (GE) since their focus is on the node-wise classification task. However, graph embeddings that convey the entire graph information are essential to the downstream decoder, which is crucial to our task. For this purpose, we propose two ways to generate graph embeddings, namely, the Pooling-based and Node-based methods.

Pooling-based GE. This method feeds the obtained node embeddings into a fully-connected neural network and applies the element-wise *max*-pooling operation on all node embeddings. In experiments, we did not observe significant performance improvement using min-pooling and average-pooling.

Node-based GE. Following (Scarselli et al., 2009), this method adds a **super** node v_s that is connected to all other nodes by a special type of edge. The embedding of v_s, which is treated as graph embedding, is produced using node embedding generation algorithm mentioned above.

Sequence Decoding. The decoder is an RNN which predicts the next token y_i given all the previous words $y_{<i} = y_1, ..., y_{i-1}$, the RNN hidden state s_i for time-step i and the context vector c_i that captures the attention of the encoder side. In particular, the context vector c_i depends on a set of node representations ($\mathbf{h}_1$,...,$\mathbf{h}_{\mathcal{V}}$) to which the encoder maps the input graph. The context vector c_i is dynamically computed using attention mechanism over the node representations. Our model is jointly trained to maximize the conditional log-probability of the correct description given a source graph with respect to the parameters θ of the model:

$$\theta^* = \arg\max_{\theta} \sum_{n=1}^{N} \sum_{t=1}^{T_n} \log p(y_t^n | y_{<t}^n, x^n)$$

where (x^n, y^n) is the n-th SQL-interpretation pair in the training set, and T_n is the length of the n-th target sentence y^n. In the inference phase, we use the beam search algorithm with beam size = 5.

4 Experiments

We evaluate our model on two datasets, WikiSQL (Zhong et al., 2017) and Stackoverflow (Iyer et al., 2016). WikiSQL consists of a corpus of 87,726 hand-annotated SQL query and natural language question pairs. These SQL queries are further split into training (61,297 examples), development (9,145 examples) and test sets (17,284 examples). StackOverflow consists of 32,337 SQL query and natural language question pairs, and we use the same train/development/test split as (Iyer et al., 2016). We use the BLEU-4 score (Papineni et al., 2002) as our automatic evaluation metric and also perform a human study. For human evaluation, we randomly sampled 1,000 predicted results and asked three native English speakers to rate each interpretation against both the correctness conforming to the input SQL and grammaticality on a scale between 1 and 5. We compare some variants of our model against the template, Seq2Seq, and Tree2Seq baselines.

***Graph2Seq*-PGE.** This method uses the **P**ooling method for generating **G**raph **E**mbedding.

***Graph2Seq*-NGE.** This method uses the **N**ode based **G**raph **E**mbedding.

Template. We implement a template-based method which first maps each element of a SQL query to an utterance and then uses simple rules to assemble these utterances. For example, we

	BLEU-4	Grammar.	Correct.
Template	15.71	1.50	-
Seq2Seq	20.91	2.54	62.1%
Seq2Seq + Copy	24.12	2.65	64.5%
Tree2Seq	26.67	2.70	66.8%
Graph2Seq-PGE	**38.97**	**3.81**	**79.2%**
Graph2Seq-NGE	34.28	3.26	75.3%
(Iyer et al., 2016)	18.4	3.16	64.2%
Graph2Seq-PGE	**23.3**	**3.23**	**70.2%**
Graph2Seq-NGE	21.9	2.97	65.1%

Table 1: Results on the WikiSQL (above) and Stackoverflow (below).

SQL Query & Interpretations
1. COUNT Player WHERE starter = val$_0$ AND touchdowns = val$_1$ AND position = val$_2$
S: How many players played in position val$_2$
G: number of players with starter val$_0$ and get touchdowns val$_1$ for val$_2$
2. SELECT Tires WHERE engine = val$_0$ AND chassis = val$_1$ AND team = val$_2$
S: which tire has engine val$_0$ and chassis val$_1$ and val$_2$
G: which tire does val$_2$ run with val$_0$ engine and val$_1$ chassis

Table 2: Example of SQL queries and predicted interpretations where S and G denotes Seq2Seq and Graph2Seq models, respectively.

map SELECT to *which*, WHERE to *where*, $>$ to *more than*. This method translates the SQL query of Figure 1 to *which company where assets more than val$_0$ and sales more than val$_0$ and industry less than or equal to val$_1$ and profits equals val$_2$*.

Seq2Seq. We choose two Seq2Seq models as our baselines. The first one is the attention-based Seq2Seq model proposed by Bahdanau et al. (2014), and the second one additionally introduces the copy mechanism in the decoder side (Gu et al., 2016). To evaluate these models, we employ a template to convert the SQL query into a sequence: "SELECT + <*aggregation function*> + <Split Symbol> + <*selected column*> + WHERE + <*condition*$_0$> + <Split Symbol> + <*condition*$_1$> + ... ".

Tree2Seq. We also choose a tree-to-sequence model proposed by (Eriguchi et al., 2016) as our baseline. We use the SQL Parser tool[3] to convert a SQL query into the tree structure[4] which is fed to the Tree2Seq model.

Our proposed models are trained using the Adam optimizer (Kingma and Ba, 2014), with mini-batch size 30. Our hyper-parameters are set based on performance on the validation set. The learning rate is set to 0.001. We apply the dropout strategy (Srivastava et al., 2014) with the ratio of 0.5 at the decoder layer to avoid overfitting. Gradients are clipped when their norm is bigger than 20. We initialize word embeddings using GloVe word vectors from Pennington et al. (2014), and the word embedding dimension is 300. For the graph encoder, the hop size K is set to 6, the non-linearity function σ is implemented as ReLU (Glorot et al., 2011), the parameters of weight matrices $\mathbf{W}^k$ are randomly initialized. The decoder has one layer, and its hidden state size is 300.

Results and Discussion Table 1 summarizes the results of our models and baselines. Although the template-based method achieves decent BLEU scores, its grammaticality score is substantially worse than other baselines. We can see that on both two datasets, our Graph2Seq models perform significantly better than the Seq2Seq and Tree2Seq baselines. One possible reason is that in our graph encoder, the node embedding retains the information of neighbor nodes within K hops. However, in the tree encoder, the node embedding only aggregates the information of descendants while losing the knowledge of ancestors. The pooling-based graph embedding is found to be more useful than the node-based graph embedding because *Graph2Seq*-NGE adds a nonexistent node into the graph, which introduces the noisy information in calculating the embeddings of other nodes. We also conducted an experiment that treats the SQL query graph as an undirected graph and found the performance degrades.

By manually analyzing the cases in which the Graph2Seq model performs better than Seq2Seq, we find the Graph2Seq model is better at interpreting two classes of queries: (1) the complicated queries that have more than two conditions (Query 1); (2) the queries whose columns have implicit relationships (Query 2). Table 2 lists some such SQL queries and their interpretations. One possible reason is that the Graph2Seq model can better learn the correlation between the graph pattern and natural language by utilizing the global structure information.

We find the hop size has a significant impact on our model since it determines how many neighbor nodes to be considered during the node embedding generation. As the hop size increasing, the performance is found to be significantly improved. However, after the hop size reaches 6,

---

[3] `http://www.sqlparser.com`

[4] See Appendix for details.

increasing the hop size can not boost the performance on WikiSQL anymore. By analyzing the most complicated queries (around 6.2%) in WikiSQL, we find there are average six hops between a node and its most distant neighbor. This result indicates that the selected hop size should guarantee each node can receive the information from others nodes in the graph.

5 Conclusions

Previous work approaches the SQL-to-text task using an Seq2Seq model which does not fully capture the global structure information of the SQL query. To address this, we proposed a Graph2Seq model which includes a graph encoder, an attention based sequence decoder. Experimental results show that our model significantly outperforms the Seq2Seq and Tree2Seq models on the WikiSQL and Stackoverflow datasets.

Appendix

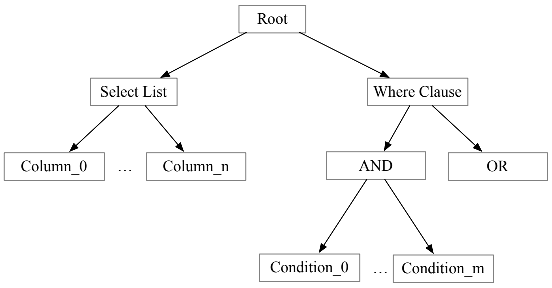

Figure 3: Tree representation of the SQL query.

We apply the SQL Parser tool[5] to convert an SQL query to a tree whose structure is illustrated in Figure 3. More specifically, the root has two child nodes, namely *Select List* and *Where Clause*. The child nodes of *Select List* represent the selected columns in the SQL query. The *Where Clause* has the logical operators occurred in the SQL query as its children. The children of a logical operator node are the conditions on which this operator works.

Abstract

We study the automatic generation of syntactic paraphrases using four different models for generation: data-to-text generation, text-to-text generation, text reduction and text expansion, We derive training data for each of these tasks from the WebNLG dataset and we show (i) that conditioning generation on syntactic constraints effectively permits the generation of syntactically distinct paraphrases for the same input and (ii) that exploiting different types of input (data, text or data+text) further increases the number of distinct paraphrases that can be generated for a given input.

1 Introduction

The ability to automatically generate paraphrases (alternative phrasings of the same content) has been shown to be useful in many areas of Natural Language Processing such as question answering (Riezler et al., 2007), semantic parsing (Berant and Liang, 2014)), machine translation (Kauchak and Barzilay, 2006; Zhou et al., 2006), sentence compression (Napoles et al., 2011) and sentence representation (Wieting et al., 2015). From a linguistic standpoint, the automatic generation of paraphrases is an important task in its own right as it demonstrates the capacity of NLP techniques to handle a key feature of natural language.

In this paper, we focus on the automatic generation of *syntactic paraphrases* that is, texts which share the same meaning but differ in their syntax. Our work makes the following contributions. We show that conditioning text generation on syntactic information permits generating distinct syntactic paraphrases for the same input. We provide a systematic exploration of how different types of generation tasks impact paraphrasing and show that exploiting different types of input permits increasing the number of paraphrases produced for a given input. We make available four training corpora for syntactically constrained, data- and text-to-text generation, text expansion and text reduction.

2 Related Work

Previous work on paraphrase generation falls into three main groups. Based mainly on monolingual data, earlier approaches use data-driven, (Lin and Pantel, 2001), grammar- or thesaurus-based methods (Madnani et al., 2007; McKeown, 1983; Hassan et al., 2007; Kozlowski et al., 2003; Quirk et al., 2004; Zhao et al., 2008). In contrast, the pivot-based approach exploits bilingual data and machine translation methods to extract and generate paraphrases (Callison-Burch, 2008; Ganitkevitch and Callison-Burch, 2014; Ganitkevitch et al., 2011). Finally, neural approaches build upon the encoder-decoder architecture to learn paraphrase generation models (Mallinson et al., 2017; Prakash et al., 2016).

(Prakash et al., 2016) uses a stacked residual LSTM network with residual connections between LSTM layers and show that their model outperforms sequence to sequence, attention-based, and bi- directional LSTM model on three datasets (PPDB, WikiAnswers, and MSCOCO).

(Mallinson et al., 2017) introduces a neural model for multi-lingual, multi-pivot backtranslation and show that it outperforms a paraphrase model trained with a commonly used Statistical Machine Translation system (SMT) on three tasks, namely, correlation with human judgments of paraphrase quality; paraphrase and similarity detection; and sentence-level paraphrase generation.

(Iyyer et al., 2018) also use backtranslation as a mean to provide training data. In addition, it uses syntax to control paraphrase generation. Given

a syntactic template T and an input sentence S, the model first generates a full syntactic parse P_T. Next this syntactic parse is used together with the input sentence to predict a syntactic paraphrase of S which realises the input syntactic template T.

Our approach is closest to (Iyyer et al., 2018) but differs from it in that instead of restricting paraphrase generation to a text rewriting problem, we explore how various sources of input impacts the number and the type of generated paraphrases. It also differs from the former two approaches (Prakash et al., 2016; Mallinson et al., 2017) in that we focus on syntactic paraphrases and condition generation on syntax. In that sense, our approach also shares similarities with recent models for controllable text generation (Hu et al., 2017; Semeniuta et al., 2017), which use variational autoencoders to model holistic properties of sentences such as style, topic and various other syntactic features. Our work is arguably conceptually simpler, focuses on syntactic paraphrases and introduces a new text production mode based on hybrid "data and text" input.

3 Generating Syntactic Paraphrases

In order to generate syntactically distinct paraphrases, we formulate the generation task as a structured prediction task conditioned on both some input I and some syntactic constraint k. In this way, the same input I can be mapped to several output T_i each satisfying a different syntactic constraint k_i. Table 1 shows some examples.

In addition, we consider different, semantically equivalent, sources of information. That is, we compare the paraphrases obtained when generating text from data, from text or from text and data. For the later, we consider two subtasks namely text expansion and text reduction. For each of these two tasks, the input is a text and a data unit. For text expansion, the output is a text verbalising both the input text and the input data. Conversely, for text reduction, the output is a text verbalising the input text minus the text verbalising the input data. Table 2 shows some example input and output for text expansion and text reduction.

4 Training and Test Data

Training data. The WEBNLG dataset (Gardent et al., 2017) associates sets of RDF triples with one or more texts verbalising these sets of triples. We derive training corpora for syntactically constrained generation from this dataset as follows.

We enrich the WEBNLG texts with labels indicating syntactic structures that are realised by these texts by first, parsing[1] these texts and then using syntactic templates to identify the target structures occurring in those texts. We use the following list of syntactic labels: subject relative, object relative, sentence coordination, VP coordination, passive voice, apposition, possessive relative, pied piping, transitive clause, prepositional object, ditransitive clause, predicative clause.

Based on the resulting, syntactically enriched, WEBNLG corpus, we then build four training corpora (T2T_{syn}, TX_{syn}, D2T_{syn}, TR_{syn}) using the sets of RDF triples as pivots to relate paraphrases. For data-to-text generation (D2T_{syn}), the input is a linearised and delexicalised version of the set of RDF triples representing the meaning of the output text, for text-to-text generation (T2T_{syn}), the input is a text and for hybrid data-and-text-to-text generation (TX_{syn} and TR_{syn}), the input is a text and a linearised RDF triple.

For the text-to-text datasets, we additionally require that, for any corpus instance $\langle k, T_i, T_o \rangle$, T_o differs from T_i on exactly one syntactic label[2].

Test data. For any input $\langle k, I \rangle$ occuring in the test data, we ensure that $\langle k, I \rangle$ does not occur in the training data. (where I is either a set of RDF triples, a text or a text and an RDF triple).

5 Experimental Setup

Models and Baselines D2T_{5best} and T2T_{5best} For each generation task, we aim to learn a model that maximises the likelihood $P(T|I;k;\theta)$ of a text given some input I, some model parameters θ and some syntactic constraint k. We use a simple encoder-decoder model where both encoder and decoder are bidirectional LSTMs and the encoder receives as input a sequence including both the input I and the syntactic constraint k.

We compare our models with the output produced by beam search when no syntactic constraint applies. For D2T_{5best}, we take the 5 best output generated from data. For T2T_{5best}, there may be several input sentences associated with the same meaning: we take the 5 best output for each

---

[1] We used the Stanford CoreNLP dependency parser version 3.8, 2018-06-09

[2] $K(T_i) = (K(T_i) \cap K(T_o)) \cup \{k\}$ and $K(T_o) = (K(T_i) \cap K(T_o)) \cup \{k'\}$ for some $k \neq k'$.

of these sentences hence T2T$_{5best}$ may (and does) in fact yield more than 5 output per input meaning. Finally, ALL$_{syn}$ groups together all output generated by the four syntactically constrained models for a given meaning.

Implementation Details We use the OpenNMT$_{py}$ sequence-to-sequence model (Klein et al., 2017) with attention and a bidirectional LSTM encoder. The encoder and decoder have two layers. Models were trained for 13 epochs, with a mini-batch size of 64, a dropout rate of 0.3, and a word embedding size of 500. They were optimised with SGD with a starting learning rate of 1.0.

Evaluation. We assess both the linguistic/syntactic adequacy of the generated texts and the diversity of the paraphrases being generated.

Syntactic and Linguistic Adequacy (BLEU, Synt, BLEU$_{syn}$). For the syntactically constrained models, given an input syntactic constraint k, the BLEU score[3] is computed with respect to those references which satisfy k. In that way, the BLEU score indicates how close to the syntactic target the generated sentence is and therefore how well the model succeeds in generating the required syntactic constructs – as the number of references varies across inputs, we use BLEU at the sentence level (Papineni et al., 2002). In addition, we compute the proportion of output satisfying the input syntactic constraint (Synt) and the BLEU score for these output which satisfy the input syntactic constraint (BLEU$_{syn}$). The number of output satisfying the input syntactic constraint is computed by first parsing the generated output and then applying the templates used for the automatic annotation of the training data.

Diversity (Sim, #Txt/Mg). To measure the level of paraphrasing obtained, we group together inputs which share the same meaning (i.e., inputs that are linked in the WEBNLG dataset to the same set of RDF triples) and we compute the number of distinct texts generated per meaning (# Txt/Mg). We further analyse these sets by computing the average pairwise similarity (Sim) of the texts present in these sets. We use the Ratcliff/Obershelp algorithm (Black, 2004) to compute similarity[4]. A low similarity indicates more diversity across the set of outputs sharing the same meaning.

Human Evaluation (% SPar). For each model, we manually examined for 50 meanings, a maximum of 10 randomly chosen output and recorded the average number (# SPar) of syntactically correct paraphrases per input.

6 Results

Table 3 summarises the results.

Diversity. The results for ALL$_{syn}$ (aggregating all output texts generated for a given meaning) shows that combining different generation models increases diversity (# Txt/Mg:13.25, Sim:0.61)) while maintaining a good level of linguistic (BLEU:62.87) and syntactic adequacy (Synt:0.91).

The human evaluation further shows that the distinct outputs generated by the ALL$_{syn}$ model are indeed syntactic, not purely lexical, variants. Table 1 shows some example output for ALL$_{syn}$.

Expansion, Reduction and Generation. Interestingly, the text expansion and reduction models markedly improve on traditional T2T and D2T models both in terms of linguistic adequacy (higher BLEU score) and in terms of diversity (higher number of distinct output per meaning, lower similarity between texts generated from the same meaning). The comparison with T2T generation is particularly striking as the training data is 3 to 5 times larger for the T2T$_{syn}$ model than for the TX$_{syn}$ and the TR$_{syn}$ model respectively. Similarly, it is noticable that although the T2T$_{syn}$ training corpus is 3 times larger than the D2T$_{syn}$ corpus, the T2T$_{syn}$ and the D2T$_{syn}$ models show similar results. This is in line with results from (Aharoni and Goldberg, 2018) which shows that rephrasing is a difficult task.

Linguistic Adequacy. Overall the linguistic adequacy of the syntactically constrained models is high with a BLEU score with respect to a single reference ranging from 46.20 (D2T$_{syn}$) to 83.87 (TX$_{syn}$). Moreover, the generated sentences show close similarity with the reference sentence realising the input constraint (BLEU$_{syn}$: from 48.16 to 89.32).

---

[3] We use the sacrebleu script with BLEU-4.

[4] The Ratcliff/Obershelp similarity score varies between O and 1 where 1 is a complete match. It is expressed by the formula $sim(S1, S2) = \frac{2*match(S1,S2)}{len(S1)+len(S2)}$ where a match is defined as the sum of the length of the matching segments ($match(S1, S2) = \sum_{m \in overlap(S1,S2)} len(m)$.

Model	BLEU	Synt	BLEU$_{syn}$	Sim test	# Txt/Mg	# Corpora	# SPar/Mg
	-	-	-	(vs ref)	(# txt/Mg ref)		(# outputs)
T2T$_{5best}$	6.21	N/A	N/A	0.76 (0.61)	5.85 (44.98)	715910	3.98 (5.5)
D2T$_{5best}$	4.71	N/A	N/A	0.81 (0.63)	4.71 (5.98)	27156	1.86 (4.42)
TR$_{syn}$	66.63	0.70	80.45	0.62 (0.63)	2.92 (6.10)	40936	2.56 (3.9)
TX$_{syn}$	83.87	0.88	89.32	0.68 (0.68)	2.56 (6.55)	74844	0.92 (1.16)
T2T$_{syn}$	49.95	0.98	50.23	0.72 (0.68)	1.92 (18.49)	202218	1.58 (1.70)
D2T$_{syn}$	46.20	0.84	48.16	0.81 (0.61)	1.04 (3.87)	66595	1 (1.1)
ALL$_{syn}$	62.87	0.91	65.11	0.61 (0.62)	13.25 (68.95)	NA	6.3 (15)

Table 3: Results and Corpora Size (BLEU score wrt reference satisfying the input constraint k, Synt: proportion of output satisfying k; BLEU$_{syn}$: BLEU score for output satisfying k; Sim: average pair-wise similarity between sentences output for a given (data or text) input (in brackets: the similarity score calculated on the reference corpus); # Txt/Mg: avg nb of distinct text generated per meaning (in brackets: the average number of texts per meaning occurring in the reference data); # Corpora : size of the corpora; # SPar/Mg (%): Avg number of syntactic paraphrases per meaning found by human evaluation (in brackets: the average total number of output considered)

While the baseline models underperform in terms of BLEU scores, the manual evaluation (# SPar/Mg) indicates that they, in fact, produce acceptable output. The low BLEU scores for these models are probably due to the fact that each output is evaluated against a single reference while the dataset is constructed to maximise the number of paraphrases available for a given input.

7 Some examples

Table 1 shows some example outputs illustrating the main differences between the D2T$_{5best}$, T2T$_{5best}$ and the ALL$_{syn}$ model. As these examples show, syntactically constrained generation (ALL$_{syn}$) outputs a much larger number of paraphrases. The difference is due both to the fact that ALL$_{syn}$ groups together the output of 4 (syntactically driven) generation models and to the input syntactic constraint, which ensures greater diversity. Thus in the example shown, ALL$_{syn}$ yields 15 paraphrases each with strong syntactic differences as summarised below.

Sentence Segmentation. The number of verb phrases, clauses and sentences used to verbalise the same input varies. One output text is made of 2 sentences and one VP coordination, another of 3 coordinated clauses and a third of two coordinated clauses and a VP coordination.

Syntax. The same input property is realised by different syntactic structures. For instance, the property *operatingOrganisation* is alternatively realised by an active verb (*operates*), a passive verb (*is operated by*), a participial apposition (*,operated by ..,*), a subject relative (*which is operated by*), a nominal predicative construction (*is the operation organization*) and a preposed participial (*Operated by .., *).

Word Order. The same content is verbalised using varying word order and clause ordering. Thus the ALL$_{syn}$ output shows four different ways of ordering the realisation of the three properties *operatinOrganization (oO), runwayLength (rL), runwayName (rN)* contained in the input namely, *rL-oO-rN* (once), *oO-rN-rL* (6 times), *oO-rL-rN* (6 times) and *rN-rL-oO* (once).

By constrast, the baseline models output a much smaller range of syntactic paraphrases. The D2T$_{5best}$ model is particularly weak as among the five best outputs it produces, only three are distinct and all have almost identical syntax. The T2T$_{5best}$ model produces more outputs (8 against 3 for the D2T$_{5best}$ model and 15 for the ALL$_{syn}$ model). One reason for this is that, contrary to the D2T$_{5best}$ model which has a single input (namely a set of RDF triples), this model can have several inputs for the same set of RDF triples.

8 Conclusion

We have proposed new syntactically constrained models for text generation and shown that their use effectively supports the generation of syntactic paraphrases. In future work, we plan to investigate to what extent these methods can be used to support the automatic generation of grammar exercises.

Abstract

We present a model for semantic proto-role labeling (SPRL) using an adapted bidirectional LSTM encoding strategy that we call *Neural-Davidsonian*: predicate-argument structure is represented as pairs of hidden states corresponding to predicate and argument head tokens of the input sequence. We demonstrate: (1) state-of-the-art results in SPRL, and (2) that our network naturally shares parameters between attributes, allowing for learning new attribute types with limited added supervision.

1 Introduction

Universal Decompositional Semantics (UDS) (White et al., 2016) is a contemporary semantic representation of text (Abend and Rappoport, 2017) that forgoes traditional inventories of semantic categories in favor of bundles of simple, interpretable properties. In particular, UDS includes a practical implementation of Dowty's theory of *thematic proto-roles* (Dowty, 1991): arguments are labeled with properties typical of Dowty's *proto-agent* (AWARENESS, VOLITION ...) and *proto-patient* (CHANGED STATE ...).

Annotated corpora have allowed the exploration of *Semantic Proto-role Labeling* (SPRL) [1] as a natural language processing task (Reisinger et al., 2015; White et al., 2016; Teichert et al., 2017). For example, consider the following sentence, in which a particular pair of predicate and argument heads have been emphasized: "The cat *ate* the rat." An SPRL system must infer from the context of the sentence whether the rat had VOLITION, CHANGED-STATE, and EXISTED-AFTER the *eating* event (see Table 2 for more properties).

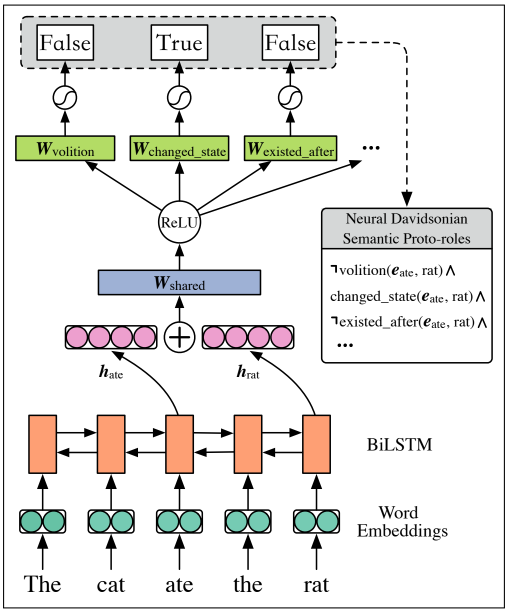

Figure 1: BiLSTM sentence encoder with SPR decoder. Semantic proto-role labeling is with respect to a specific predicate and argument within a sentence, so the decoder receives the two corresponding hidden states.

We present an intuitive neural model that achieves state-of-the-art performance for SPRL.[2] As depicted in Figure 1, our model's architecture is an extension of the bidirectional LSTM, capturing a Neo-Davidsonian like intuition, wherein select pairs of hidden states are concatenated to yield a dense representation of predicate-argument structure and fed to a prediction layer for end-to-end training. We include a thorough quantitative analysis highlighting the contrasting errors between the proposed model and previous (non-neural) state-of-the-art.

In addition, our network naturally shares a subset of parameters between attributes. We demonstrate how this allows learning to predict new at-

---

[1] SPRL and SPR refer to the labeling task and the underlying semantic representation, respectively.

SPR Property	Explanation of Property	🐈	🐀
INSTIGATION	`Arg` caused the `Pred` to happen?	✓	✗
VOLITIONAL	`Arg` chose to be involved in the `Pred`?	✓	✗
AWARE	`Arg` was/were aware of being involved in the `Pred`?	✓	✓
PHYSICALLY EXISTED	`Arg` existed as a physical object?	✓	✓
EXISTED AFTER	`Arg` existed after the `Pred` stopped?	✓	✗
CHANGED STATE	The `Arg` was/were altered or somehow changed during or by the end of the `Pred`?	✓	✓

Table 1: Example SPR annotations for the toy example "The cat ate the rat," where the `Predicate` in question is "*ate*" and the `Argument` in question is either "cat" or "rat." Note that not all SPR properties are listed, and the binary labels (✓, ✗) are coarsened from a 5-point Likert scale.

tributes with limited supervision: a key finding that could support efficient expansion of new SPR attribute types in the future.

2 Background

Davidson (1967) is credited for representations of meaning involving propositions composed of a fixed arity predicate, all of its core arguments arising from the natural language syntax, and a distinguished event variable. The earlier example could thus be denoted (modulo tense) as $(\exists e)\mathbf{eat}[(e, \textsc{cat}, \textsc{rat})]$, where the variable e is a *reification* of the eating event. The order of the arguments in the predication implies their role, where leaving arguments unspecified (as in "The cat eats") can be handled either by introducing variables for unstated arguments, e.g., $(\exists e)(\exists x)[\mathbf{eat}(e, \textsc{cat}, x)]$, or by creating new predicates that correspond to different arities, e.g., $(\exists e)\mathbf{eat\_intransitive}[(e, \textsc{cat})]$.[3] The Neo-Davidsonian approach (Castañeda, 1967; Parsons, 1995), which we follow in this work, allows for variable arity by mapping the argument positions of individual predicates to generalized *semantic roles*, shared across predicates,[4] e.g., AGENT, PATIENT and THEME, in: $(\exists e)[\mathbf{eat}(e) \wedge \mathbf{Agent}(e, \textsc{cat}) \wedge \mathbf{Patient}(e, \textsc{rat})]$.

Dowty (1991) conjectured that the distinction between the role of a prototypical **Agent** and prototypical **Patient** could be decomposed into a number of semantic properties such as *"Did the argument change state?"*. Here we formulate this as a Neo-Davidsonian representation employing *semantic proto-role* (SPR) attributes:

$$\begin{aligned}&(\exists e)\,[\mathbf{eat}(e)\\ &\qquad \wedge\, \mathbf{volition}(e, \textsc{cat}) \wedge \mathbf{instigation}(e, \textsc{cat})\ldots\\ &\qquad \wedge\, \neg\mathbf{volition}(e, \textsc{rat}) \wedge \mathbf{destroyed}(e, \textsc{rat})\ldots\,]\end{aligned}$$

Dowty's theory was empirically verified by Kako (2006), followed by pilot (Madnani et al., 2010) and large-scale (Reisinger et al., 2015) corpus annotation efforts, the latter introducing a logistic regression baseline for SPRL. Teichert et al. (2017) refined the evaluation protocol,[5] and developed a CRF (Lafferty et al., 2001) for the task, representing existing state-of-the-art.

Full details about the SPR datasets introduced by Reisinger et al. (2015) and White et al. (2016), which we use in this work, are provided in Appendix B. For clarity, Table 1 shows a toy SPRL example, including a few sample SPR properties and explanations.

3 "Neural-Davidsonian" Model

Our proposed SPRL model (Fig. 1) determines the value of each attribute (e.g., VOLITION) on an *argument* (a) with respect to a particular *predication* (e) as a function on the latent states associated with the pair, (e, a), in the context of a full sentence. Our architecture encodes the sentence using a shared, one-layer, bidirectional LSTM (Hochreiter and Schmidhuber, 1997; Graves et al., 2013). We then obtain a continuous, vector representation $\boldsymbol{h}_{ea} = [\boldsymbol{h}_e; \boldsymbol{h}_a]$, for each predicate-argument pair as the concatenation of the hidden BiLSTM

---

[3] This formalism aligns with that used in PropBank (Palmer et al., 2005), which associated numbered, core arguments with each sense of a verb in their corpus annotation.

[4] For example, as seen in FrameNet (Baker et al., 1998).

[5] Splitting train/dev/test along Penn Treebank boundaries and casting the SPRL task as multi-label binary classification.

states $\boldsymbol{h}_e$ and $\boldsymbol{h}_a$ corresponding to the syntactic head of the predicate of e and argument a respectively. These heads are obtained over gold syntactic parses using the predicate-argument detection tool, PredPatt (White et al., 2016).[6]

For each SPR attribute, a score is predicted by passing $\boldsymbol{h}_{ea}$ through a separate two-layer perceptron, with the weights of the first layer shared across all attributes:

$$\text{Score}(\text{attr}, \boldsymbol{h}_{ea}) = \boldsymbol{W}_{\text{attr}} \left[g \left(\boldsymbol{W}_{\text{shared}} \left[\boldsymbol{h}_{ea} \right] \right) \right]$$

This architecture accomodates the definition of SPRL as multi-label binary classification given by Teichert et al. (2017) by treating the score as the log-odds of the attribute being present (i.e. $\text{P}(\text{attr}|\boldsymbol{h}_{ea}) = \frac{1}{1+\exp[-\text{Score}(\text{attr},\boldsymbol{h}_{ea})]}$). This architecture also supports SPRL as a *scalar* regression task where the parameters of the network are tuned to directly minimize the discrepancy between the predicted score and a reference scalar label. The loss for the binary and scalar models are negative log-probability and squared error, respectively; the losses are summed over all SPR attributes.

Training with Auxiliary Tasks A benefit of the shared neural-Davidsonian representation is that it offers many levels at which multi-task learning may be leveraged to improve parameter estimation so as to produce semantically rich representations $\boldsymbol{h}_{ea}$, $\boldsymbol{h}_e$, and $\boldsymbol{h}_a$. For example, the sentence encoder might be pre-trained as an encoder for machine translation, the argument representation $\boldsymbol{h}_a$ can be jointly trained to predict word-sense, the predicate representation, $\boldsymbol{h}_e$, could be jointly trained to predict factuality (Saurí and Pustejovsky, 2009; Rudinger et al., 2018), and the predicate-argument representation, $\boldsymbol{h}_{ea}$, could be jointly trained to predict other semantic role formalisms (e.g. PropBank SRL—suggesting a neural-Davidsonian *SRL* model in contrast to recent BIO-style neural models of SRL (He et al., 2017)).

To evaluate this idea empirically, we experimented with a number of multi-task training strategies for SPRL. While all settings outperformed prior work in aggregate, simply initializing the BiLSTM parameters with a pretrained English-to-French machine translation encoder[7] produced the best results,[8] so we simplify discussion by focusing on that model. The efficacy of MT pretraining that we observe here comes as no surprise given prior work demonstrating, e.g., the utility of bitext for paraphrase (Ganitkevitch et al., 2013), that NMT pretraining yields improved contextualized word embeddings[9] (McCann et al., 2017), and that NMT encoders specifically capture useful features for SPRL (Poliak et al., 2018).

Full details about each multi-task experiment, including a full set of ablation results, are reported in Appendix A; details about the corresponding datasets are in Appendix B.

Except in the ablation experiment of Figure 2, our model was trained on only the SPRL data and splits used by Teichert et al. (2017) (learning all properties jointly), using GloVe[10] embeddings and with the MT-initialized BiLSTM. Models were implemented in PyTorch and trained end-to-end with Adam optimization (Kingma and Ba, 2014) and a default learning rate of 10^{-3}. Each model was trained for ten epochs, selecting the best-performing epoch on dev.

Prior Work in SPRL We additionally include results from prior work: "LR" is the logistic-regression model introduced by Reisinger et al. (2015) and "CRF" is the CRF model (specifically `SPRL`*) from Teichert et al. (2017). Although White et al. (2016) released additional SPR annotations, we are unaware of any benchmark results on that data; however, our multi-task results in Appendix A do use the data and we find (unsurprisingly) that concurrent training on the two SPR datasets can be helpful. Using only data and splits from White et al. (2016), the scalar regression architecture of Table 6 achieves a Pearson's ρ of 0.577 on test.

There are a few noteworthy differences between our neural model and the CRF of prior work. As an adapted BiLSTM, our model easily ex-

ploits the benefits of large-scale pretraining, in the form of GloVe embeddings and MT pretraining, both absent in the CRF. Ablation experiments (Appendix A) show the advantages conferred by these features. In contrast, the discrete-featured CRF model makes use of gold dependency labels, as well as joint modeling of SPR attribute pairs with explicit joint factors, both absent in our neural model. Future SPRL work could explore the use of models like the LSTM-CRF (Lample et al., 2016; Ma and Hovy, 2016) to combine the advantages of both paradigms.

4 Experiments

Table 2 shows a side-by-side comparison of our model with prior work. The full breakdown of F1 scores over each individual property is provided. For every property except EXISTED DURING, EXISTED AFTER, and CREATED we are able to exceed prior performance. For some properties, the absolute F1 gains are quite large: DESTROYED (+24.2), CHANGED POSSESSION (+19.2.0), CHANGED LOCATION (+10.1), STATIONARY (+26.0) and LOCATION (+35.3). We also report performance with a scalar regression version of the model, evaluated with Pearson correlation. The scalar model is with respect to the original SPR annotations on a 5-point Likert scale, instead of a binary cut-point along that scale (> 3).

		phys. contact			volition		
		# DIFFER	Δ FALSE–	Δ FALSE+	# DIFFER	Δ FALSE–	Δ FALSE+
1	ALL	80	−14	6	80	−14	−10
2	PROPERNOUN	18	−2	−2	21	4	−5
3	ORG.	15	−9	2	31	−6	−1
4	PRONOUN	10	0	8	12	0	0
5	PHRASEVERB	14	−6	0	9	−4	1
6	METAPHOR	11	−5	−2	6	−2	0
7	LIGHTVERB	5	−2	1	5	−1	2

Table 3: Manual error analysis on a sample of instances (80 for each property) where outputs of CRF and the binary model from Table 2 differ. **Negative** Δ FALSE+ and Δ FALSE– indicate the neural model represents a **net *reduction* in type I and type II errors** respectively over CRF. Positive values indicate a net increase in errors. Each row corresponds to one of several (overlapping) subsets of the 80 instances in disagreement: (1) all (sampled) instances; (2) argument is a proper noun; (3) argument is an organization or institution; (4) argument is a pronoun; (5) predicate is phrasal or a particle verb construction; (6) predicate is used metaphorically; (7) predicate is a light-verb construction. #DIFFER is the size of the respective subset.

Manual Analysis We select two properties (VOLITION and MAKES PHYSICAL CONTACT) to perform a manual error analysis with respect to CRF [11] and our binary model from Table 2. For each property, we sample 40 dev instances with gold labels of “True” (> 3) and 40 instances of “False” (≤ 3), restricted to cases where the two system predictions disagree.[12] We manually label each of these instances for the six features shown in Table 3. For example, given the input “He *sits* down at the piano and plays,” our neural model correctly predicts that He makes physical contact during the *sitting*, while CRF does not. Since He is a pronoun, and *sits down* is phrasal, this example contributes −1 to Δ FALSE– in rows 1, 4 and 5.

---

[11] We obtained the CRF dev system predictions of Teichert et al. (2017) via personal communication with the authors.

[12] According to the reference, of the 1071 dev examples, 150 have physical contact and 350 have volition. The two models compared here differed in phy. contact on 62 positive and 44 negative instances and for volition on 43 positive and 54 negative instances.

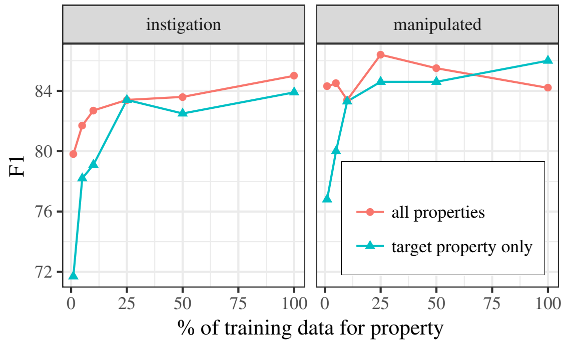

Figure 2: Effect of using only a fraction of the training data for a property while either ignoring or co-training with the full training data for the other SPR1 properties. Measurements at 1%, 5%, 10%, 25%, 50%, and 100%.

For both properties our model appears more likely to correctly classify the argument in cases where the predicate is a phrasal verb. This is likely a result of the fact that the BiLSTM has stronger language-modeling capabilities than the CRF, particularly with MT pretraining. In general, our model increases the false-positive rate for MAKES PHYSICAL CONTACT, but especially when the argument is pronominal.

Learning New SPR Properties One motivation for the decompositional approach adopted by SPRL is the ability to incrementally build up an inventory of annotated properties according to need and budget. Here we investigate (1) the degree to which having less training data for a single property degrades our F1 for that property on held-out data and (2) the effect on degradation of concurrent training with the other properties. We focus on two properties only: INSTIGATION, a canonical example of a proto-agent property, and MANIPULATED, which is a proto-patient property. For each we consider six training set sizes (1, 5, 10, 25, 50 and 100 percent of the instances). Starting with the same randomly initialized BiLSTM[13], we consider two training scenarios: (1) ignoring the remaining properties or (2) including the model's loss on other properties with a weight of $\lambda = 0.1$ in the training objective.

Results are presented in Figure 2. We see that, in every case, most of the performance is achieved with only 25% of the training data. The curves also suggest that training simultaneously on all SPR properties allows the model to learn the target property more quickly (i.e., with fewer training samples) than if trained on that property in isolation. For example, at 5% of the training training data, the "all properties" models are achieving roughly the same F1 on their respective target property as the "target property only" models achieves at 50% of the data.[14] As the SPR properties currently annotated are by no means semantically exhaustive,[15] this experiment indicates that future annotation efforts may be well served by favoring breadth over depth, collecting smaller numbers of examples for a larger set of attributes.

5 Conclusion

Inspired by: (1) the SPR decomposition of predicate-argument relations into overlapping feature bundles and (2) the neo-Davidsonian formalism for variable-arity predicates, we have proposed a straightforward extension to a BiLSTM classification framework in which the states of pre-identified predicate and argument tokens are pairwise concatenated and used as the target for SPR prediction. We have shown that our *Neural-Davidsonian* model outperforms the prior state of the art in aggregate and showed especially large gains for properties of CHANGED-POSSESSION, STATIONARY, and LOCATION. Our architecture naturally supports discrete or continuous label paradigms, lends itself to multi-task initialization or concurrent training, and allows for parameter sharing across properties. We demonstrated this sharing may be useful when some properties are only sparsely annotated in the training data, which is suggestive of future work in efficiently increasing the range of annotated SPR property types.

---

[13] Note that this experiment does not make use of MT pretraining as was used for Table 2, to best highlight the impact of parameter sharing across attributes.

[14] As we observed the same trend more clearly on the dev set, we suspect some over-fitting to the development data which was used for independently select a stopping epoch for each of the plotted points.

[15] E.g., annotations do not include any questions relating to the *origin* or *destination* of an event.

A Mult-Task Investigation

Multi-task learning has been found to improve performance on many NLP tasks, particularly for neural models, and is rapidly becoming *de rigueur* in the field. The strategy involves optimizing for multiple training objectives corresponding to different (but usually related) tasks. Collobert and Weston (2008) use multi-task learning to train a convolutional neural network to perform multiple core NLP tasks (POS tagging, named entity recognition, etc.). Multi-task learning has also been used to improve sentence compression (Klerke et al., 2016), chunking and dependency parsing (Hashimoto et al., 2017). Related work on UDS (White et al., 2016) shows improvements on event factuality prediction with multi-task learning on BiLSTM models (Rudinger et al., 2018). To complete the basic experiments reported in the main text, here we include an investigation of the impact of multi-task learning for SPRL.

We borrow insights from Mou et al. (2016) who explore different multi-task strategies for NLP including approach of initializing a network by training it on a related task ("INIT") versus interspersing tasks during training ("MULT"). Here we employ both of these strategies, referring to them as *pretraining* and *concurrent* training. We also use the terminology *target task* and *auxiliary task* to differentiate the primary task(s) we are interested in from those that play only a supporting role in training. In order to tune the impact of auxiliary tasks on the learned representation, Luong et al. (2016) use a *mixing parameter*, α_i, for each task i. Each parameter update consists of selecting a task with probability proportional to its α_i and then performing one update with respect to that task alone. They show that the choice of α has a large impact on the effect of multi-task training, which influences our experiments here.

Please refer to Appendix B for details on the datasets used in this section. In particular, with a few exceptions, White et al. (2016) annotates for the same set of properties as Reisinger et al. (2015), but with slightly different protocol and on a different genre. However, in this section we treat the two datasets as if they were separate tasks. To avoid cluttering the results in the main text, we exclusively present results there on what we call *SPR1* which consists of the data from Reisinger et al. (2015) and the train/dev/test splits of Teichert et al. (2017). We refer to the analogous tasks built on the data and splits of White et al. (2016) using the term SPR2. (We are not aware of any prior published results on property prediction for the SPR2.)

In addition to the binary and scalar SPR architectures outlined in Section 3 of the main paper, we also considered concurrently training the BiLSTM on a fine-grained word-sense disambiguation task or on joint SPR1 and SPR2 prediction. We also experimented with using machine translation and PropBank SRL to initialize the parameters of the BiLSTM. Preliminary experimentation on dev data with other combinations helped prune down the set of interesting experiments to those listed in Table 4 which assigns names to the models explored here. Our ablation study in Section 4 of the main paper uses the model named SPR1 while the other results in the main paper correspond to MT:SPR1 in the case of binary prediction and MT:SPR1S in the case of scalar prediction. After detailing the additional components used for pretraining or concurrent training, we present aggregate results and for the best performing models (according to dev) we present property-level aggregate results.

A.1 Auxiliary Tasks

Each auxiliary task is implemented in the form of a task-specific decoder with access to the hidden states computed by the shared BiLSTM encoder. In this way, the losses from these tasks backpropagate through the BiLSTM. Here we describe each task-specific decoder.

PropBank Decoder The network architecture for the auxiliary task of predicting abstract role types in PropBank is nearly identical to the architecture for SPRL described in Section 3 of the main paper. The main difference is that the PropBank task is a single-label, categorical classification task.

$$\mathrm{P}(\mathrm{role}_i|\boldsymbol{h}_{ea}) = \mathrm{softmax}_i\left(\boldsymbol{W}_{\mathrm{propbank}}\left[\boldsymbol{h}_{ea}\right]\right)$$

The loss from this decoder is the negative log of the probability assigned to the correct label.

Supersense Decoder The word sense disambiguation decoder computes a probability distribution over 26 WordNet supersenses with a simple single-layer feedforward network:

$$\mathrm{P}(\mathrm{supersense}_i|\boldsymbol{h}_a) = \mathrm{softmax}_i(\boldsymbol{W}\left[\boldsymbol{h}_a\right])$$

where $\boldsymbol{W} \in \mathbb{R}^{1200\times 26}$ and $\boldsymbol{h}_a$ is the RNN hidden state corresponding to the argument head token we wish to disambiguate. Since the gold label in the supersense prediction task is a *distribution* over supersenses, the loss from this decoder is the cross-entropy between its predicted distribution and the gold distribution.

French Translation Decoder Given the encoder hidden states, the goal of translation is to generate the reference sequence of tokens $Y = y_1, \cdots, y_n$ in the target language, i.e., French. We employ the standard decoder architecture for neural machine translation. At each time step i, the probability distribution of the decoded token y_i is defined as:

$$P(y_i) = \mathrm{softmax}\big(\tanh(\boldsymbol{W}_{\mathrm{fr}}\left[\boldsymbol{s_i}; \boldsymbol{c_i}\right] + \boldsymbol{b}_{\mathrm{fr}})\big)$$

where $\boldsymbol{W}_{\mathrm{fr}}$ is a transform matrix, and $\boldsymbol{b}_{\mathrm{fr}}$ is a bias. The inputs are the decoder hidden state $\boldsymbol{s_i}$ and the context vector $\boldsymbol{c_i}$. The decoder hidden state $\boldsymbol{s_i}$ is computed by:

$$\boldsymbol{s_i} = \mathrm{RNN}(\boldsymbol{y_{i-1}}, \boldsymbol{s_{i-1}})$$

where RNN is a recurrent neural network using L-layer stacked LSTM, $\boldsymbol{y_{i-1}}$ is the word embedding of token y_{i-1}, and $\boldsymbol{s_0}$ is initialized by the last encoder left-to-right hidden state.

	micro-F1	macro-F1

PS-MS	**82.9**	69.5

Table 5: Overall test performance for all settings described in Experiments 1 and 1a-d. The target task is SPR1 as binary classification. Micro- and macro-F1 are computed over all properties. (*Baseline macro-F1 scores are computed from property-specific precision and recall values in Teichert et al. (2017) and may introduce rounding errors.)

The context vector $\boldsymbol{c_i}$ is computed by an attention mechanism (Bahdanau et al., 2014; Luong et al., 2015),

$$\boldsymbol{c_i} = \sum_t \alpha_{i,t}\boldsymbol{h_t},$$

$$\alpha_{i,t} = \frac{\exp\left(\boldsymbol{s_i}^\top(\boldsymbol{W_\alpha h_t} + \boldsymbol{b_\alpha})\right)}{\sum_k \exp\left(\boldsymbol{s_i}^\top(\boldsymbol{W_\alpha h_k} + \boldsymbol{b_\alpha})\right)},$$

where $\boldsymbol{W_\alpha}$ is a transform matrix and $\boldsymbol{b_\alpha}$ is a bias. The loss is the negative log-probability of the decoded sequence.

A.2 Results

In this section, we present a series of experiments using different components of the neural architecture described in Section 3, with various training regimes. Each experimental setting is given a name (in SMALLCAPS) and summarized in Table 4. Unless otherwise stated, the target task is SPR1 (classification). To ease comparison, we include results from the main paper as well as additional results.

Experiment 0: Embeddings By default, all models reported in this paper employ pretrained word embeddings (GloVe). In this experiment we replaced the pretrained embeddings in the vanilla

Table 6: Breakdown by property of binary classification F1 on SPR1. All new results outperforming prior work (CRF) in bold.

SPR1 model (SPR1) with randomly initialized word embeddings (SPR1-RAND). The results (Table 5) reveal substantial gains from the use of pretrained embeddings; this is likely due to the comparatively small size of the SPR1 training data.

Experiment 1a: Multi-task Pretraining We pretrained the BiLSTM encoder with two separate auxiliary tasks: **French Translation** and **PropBank Role Labeling**. There are three settings: (1) Translation pretraining only (MT:SPR1), (2) PropBank pretraining only (PB:SPR1), and (3) Translation pretraining followed by PropBank pretraining (MT:PB:SPR1). In each case, after pretraining, the SPRL decoder is trained end-to-end, as in Experiment 0 (on SPR1 data).

Experiment 1b: Multi-task Concurrent One auxiliary task (**Supersense** or **SPR2**) is trained concurrently with SPR1 training. In one epoch of training, a training example is sampled at random (without replacement) from either task until all training instances have been sampled. The loss from the auxiliary task (which, in both cases, has more training instances than the target SPRL task) is down-weighted in proportion to ratio of the dataset sizes:

$$\alpha = \frac{|\text{target task}|}{|\text{auxiliary task}|}$$

Table 7: SPR1 and SPR2 as scalar prediction tasks. Pearson correlation between predicted and gold values.

The auxiliary task loss is further down-weighted by a hyperparameter $\lambda \in \{1, 10^{-1}, 10^{-2}, 10^{-3}, 10^{-4}\}$ which is chosen based on dev results. We apply this training regime with the auxiliary task of Supersense prediction (SPR1+WSD) and the scalar SPR2 prediction task (SPR1+SPR2), described in Experiment 2.

Experiment 1c: Multi-task Combination This setting is identical to Experiment 1b, but includes MT pretraining (the best-performing pretraining setting on dev), as described in 1a. Accordingly, the two experiments are MT:SPR1+WSD and MT:SPR1+SPR2.

Experiment 1d: Property-Specific Model Selection (PS-MS) Experiments 1a–1c consider a variety of pretraining tasks, co-training tasks, and weight values, λ, in an effort to improve aggregate F1 for SPR1. However, the SPR properties are diverse, and we expect to find gains by choosing training settings on a property-specific basis. Here, for each property, we select from the set of models considered in experiments 1a–1c the one that achieves the highest dev F1 for the target property. We report the results of applying those property-specific models to the test data.

SPR1S	0.743	SPR2	**0.591**
MT:SPR1S	**0.753**	MT:SPR2	0.577
PB:SPR1S	0.731	PB:SPR2	0.568
MT:PB:SPR1S	0.720	MT:PB:SPR2	0.564

Table 8: SPR1 and SPR2 as scalar prediction tasks. The overall performance for each experimental setting is reported as the average Pearson correlation over all properties. Highest SPR1 and SPR2 results are in bold.

Experiment 2: SPR as a scalar task In Experiment 2, we trained the SPR decoder to predict properties as scalar instead of binary values. Performance is measured by Pearson correlation and reported in Tables 8 and 7. In this case, we treat SPR1 and SPR2 both as target tasks (separately). By including SPR1 as a target task, we are able to compare (1) SPR as a binary task and a scalar task, as well as (2) SPR1 and SPR2 as scalar tasks. These results constitute the first reported numbers on SPR2.

We observe a few trends. First, it is generally the case that properties with high F1 on the SPR1 binary task also have high Pearson correlation on the SPR1 scalar task. The higher scoring properties in SPR1 scalar are also generally the higher scoring properties in SPR2 (where the SPR1 and SPR2 properties overlap), with a few notable exceptions, like INSTIGATION. Overall, correlation values are lower in SPR2 than SPR1. This may be the case for a few reasons. (1) The underlying data in SPR1 and SPR2 are quite different. The former consists of sentences from the Wall Street Journal via PropBank (Palmer et al., 2005), while the latter consists of sentences from the English Web Treebank (Bies et al., 2012) via the Universal Dependencies; (2) certain filters were applied in the construction of the SPR1 dataset to remove instances where, e.g., predicates were embedded in a clause, possibly resulting in an easier task; (3) SPR1 labels came from a single annotator (after determining in pilot studies that annotations from this annotator correlated well with other annotators), where SPR2 labels came from 24 different annotators with scalar labels averaged over two-way redundancy.

Discussion With SPR1 binary classification as the target task, we see overall improvements from various multi-task training regimes (Experiments 1a-d, Tables 5 and 6), using four different auxiliary tasks: machine translation into French, PropBank abstract role prediction, word sense disambiguation (WordNet supersenses), and SPR2.[16] These auxiliary tasks exhibit a loose trade-off in terms of the quantity of available data and the semantic relatedness of the task: MT is the least related task with the most available (parallel) data, while SPR2 is the most related task with the smallest quantity of data. While we hypothesized that the relatedness of PropBank role labeling and word sense disambiguation tasks might lead to gains in SPR performance, we did not see substantial gains in our experiments (PB:SPR1, SPR1+WSD). We did, however, see improvements over the target-task only model (SPR1) in the cases where we added MT pretraining (MT:SPR1) or SPR2 concurrent training (SPR1+2). Interestingly, combining MT pretraining with SPR2 concurrent training yielded no further gains (MT:SPR1+2).

B Data

SPR1 The SPR1.0 ("SPR1") dataset introduced by Reisinger et al. (2015) contains proto-role annotations on 4,912 Wall Street Journal sentences from PropBank (Palmer et al., 2005) corresponding to 9,738 predicate-argument pairs with 18 properties each, in total 175,284 property annotations. All annotations were performed by a single, trusted annotator. Each annotation is a rating from 1 to 5 indicating the likelihood that the property applies, with an additional "N/A" option if the question of whether the property holds is nonsensical in the context.

To compare with prior work (Teichert et al., 2017), we treat the SPR1 data as a binary prediction task: the values 4 and 5 are mapped to **True** (property holds), while the values 1, 2, 3, and "N/A" are mapped to **False** (property does not hold). In additional experiments, we move to treating SPR1 as a scalar prediction task; in this case, "N/A" is mapped to 1, and all other annotation values remain unchanged.

SPR2 The second SPR release (White et al., 2016) contains annotations on 2,758 sentences from the English Web Treebank (EWT) (Bies et al., 2012) portion of the Universal Dependencies (v1.2) (Silveira et al., 2014)[17], corresponding

---

[16] Note that in some cases we treat SPR2 as an auxiliary task, and in others, the target task.

[17] We exclude the SPR2 pilot data; if included, the SPR2

to 6,091 predicate-argument pairs. With 14 proto-role properties each, there are a total of 85,274 annotations, with two-way redundancy. As in SPR1, the value of each annotation is an integral value 1-5 or "N/A." We treat SPR2 as a scalar prediction task, first mapping "N/A" to 1, and then averaging the two-way redundant annotation values to a single value.

Word Sense Disambiguation Aligned with proto-role property annotations in the SPR2 release are word sense disambiguation judgments for the head tokens of arguments. Candidate word senses (fine-grained) from WordNet (Fellbaum, 1998) were presented to Mechanical Turk workers (at least three annotators per instance), who selected every applicable sense of the word in the given context. In this work, we map the fine-grained word senses to one of 26 coarse-grained WordNet noun supersenses (e.g., `noun.animal`, `noun.event`, `noun.quantity`, etc.). In many cases, a word may be mapped to more than one supersense. We treat the supersense label on a word as a distribution over supersenses, where the probability assigned to one supersense is proportional to the number of annotators that (indirectly) selected that supersense. In practice, the entropy of these resulting supersense distributions is low, with an average perplexity of 1.42.

PropBank The PropBank project consists of predicate-argument annotations over corpora for which gold Penn TreeBank-style constituency parses are available. We use the Unified PropBank release (Bonial et al., 2014; Ide and Pustejovsky, 2017), which contains annotations over OntoNotes as well as the English Web TreeBank (EWT). Each predicate in each corpus is annotated for word sense, and each argument of each predicate is given a label such as ARG0, ARG1, etc., where the interpretation of the label is defined relative to the word sense. We use PropBank Frames to map these sense-specific labels to 16 sense-independent labels such as PAG (proto-agent), PPT (proto-patient), etc., and then formulate a task to predict the abstracted labels. Because our model requires knowledge of predicate and argument head words, we ran the Stanford Universal Dependencies converter (Schuster and Manning, 2016) over the gold constituency parses to obtain Universal Dependency parses, which were then processed by the PredPatt framework (Zhang et al., 2017; White et al., 2016) to identify head words.

English-French Data The 10^9 French-English parallel corpus (Callison-Burch et al., 2009) contains 22,520,376 French-English sentence pairs, made up of 811,203,407 French words and 668,412,817 English words. The corpus was constructed by crawling the websites of international organizations such as the Canadian government, the European Union, and the United Nations.

Abstract

Styles of leaders when they make decisions in groups vary, and the different styles affect the performance of the group. To understand the key words and speakers associated with decisions, we initially formalize the problem as one of predicting leaders' decisions from discussion with group members. As a dataset, we introduce conversational meeting records from a historical corpus, and develop a hierarchical RNN structure with attention and pre-trained speaker embedding in the form of a, Conversational Decision Making Model (CDMM). The CDMM outperforms other baselines to predict leaders' final decisions from the data. We explain why CDMM works better than other methods by showing the key words and speakers discovered from the attentions as evidence.

1 Introduction

Decision making in groups refers to the process of making choices to resolve issues by discussing the issues with group members (Lunenburg, 2011). It has various styles based on the balance of the participation between the leader and members from autocratic, democratic, *laissez-faire* (let go) to delegation types of groups (Lewin et al., 1939; Vroom and Jago, 1988). Social psychologists note that decision making affects the group performance and the satisfaction of its members (Yang, 2010), and that leadership plays a role (Larson Jr et al., 1998). In this paper, we study the key factors that are closely related to the decision making process used by leaders.

First, we build conversational meeting records from *The Annals of the Joseon Dynasty* (henceforth referred to as the AJD), after which, we formalize our research problem as predicting leaders' decisions in conversational discussions from the data (Sec 2). The AJD consists of the records of kings who governed the Korean peninsula from 1392 to 1910. In the AJD, the kings discuss the issues with government officials and decide upon a course of action. Many discussion corpora are available such as Augmented Multi-party Interaction (AMI) (Carletta et al., 2005) which is meeting recordings as video, and are used to identify and summarize decisions in the conversation (Hsueh and Moore, 2007; Fernández et al., 2008; Bui et al., 2009). However, the AJD has more speakers than AMI, and it is a longitudinal corpus spanning over 400 years.

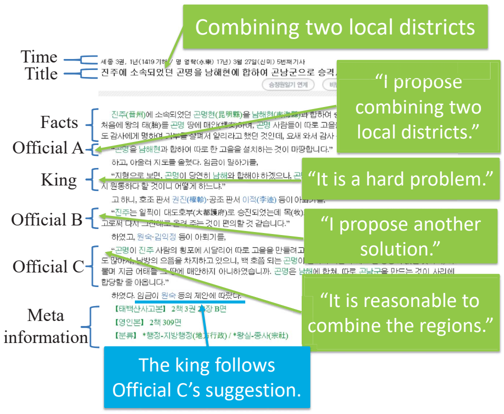

Figure 1: Screenshot and structure of an article in the annals of the Joseon dynasty

To predict the decisions in the corpus, we develop a model which we term the Conversational Decision-Making Model (CDMM) (Sec 3). CDMM is based on the hierarchical RNN structure with attention (Yang et al., 2016), but we add speaker information with pre-trained embedding. We also devise a way to make the speaker embedding using co-occurrence document network (Sec 3.3). In comparison with several other methods, CDMM shows the highest macro-averaged F1 score (Sec 4). We also show why CDMM works better with key words and speakers by examining the attention values (Sec 5).

Table 1: Statistics of a conversational meeting records and king's decisions from the AJD

2 Meeting Records from the AJD

Historiographers recorded the behaviors of kings and events in the country, and compiled these records as books when the king died or abdicated the throne. Each article of the AJD consists of the time, title, body and meta-information such as categories.

Meeting articles in the AJD consist of who said what on an issue in dialogue form, and the king's decision. Figure 1 shows an example of a meeting record article[1]. In the article, the king and government officials discuss the issue of combining two local regions. The king asks for a solution to the issue from the officials, and they state their opinions. At the end of the article, the king decided to follow official C's suggestion to solve this issue.

We build a corpus from the AJD using the following process. We crawl the AJD website to retrieve the documents and select articles that have three or more speakers per document. We identify the king's final decision in each article by examining the final sentence and the title as summarized by historians. We initially determine whether or not the final sentence of the subject is that by a king, as some issues are dealt with by others, such as the king's mother. We also extract the verbs in the final sentence and the title that indicates the decisions. From these, we categorize each king's decisions into six types: *Order*, *Approve*, *Disapprove*, *Accept* and *Reject*. Some articles include a discussion of an issue, but the king's final decision is not explicitly recorded or the king postpones the decision. We treat this type of decision as *Discuss*, i.e., the sixth category. Finally, we choose fifteen kings with more than 200 articles that have his final decisions. Table 1 shows the basic statistics of our meeting records data from the AJD.

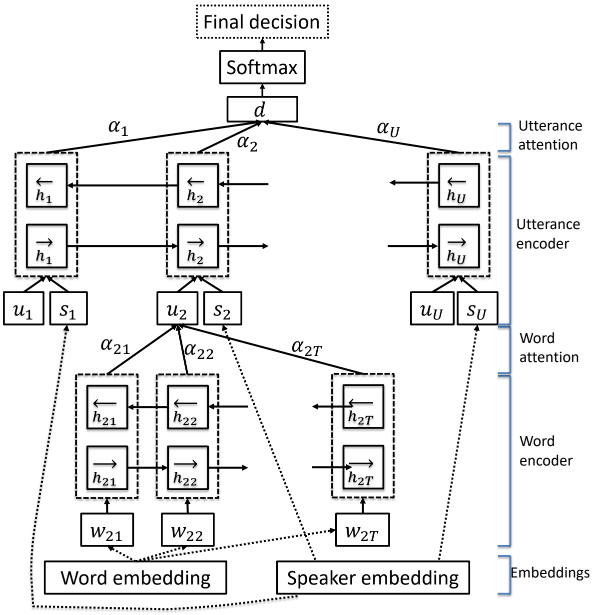

Figure 2: Conversational Decision-Making Model

3 Conversational Decision Making Model

This section describes our model, the Conversational Decision-Making Model (CDMM), for identifying leaders' decisions from meeting records. CDMM is based on the Hierarchical Attention Network (HAN) (Yang et al., 2016), but we change the sentence level to the utterance level and use speaker information (described in Section 3.2). To encode the speaker information, we build the speaker embedding from co-occurrence document network (described in Section 3.3).

3.1 Word Encoder

To encode the t-th word of i-th utterance x_{it}, $t \in \{1, \dots, T\}$, we initially change the word x_{it} to word vector w_{it} using the word embedding matrix W_w, $w_{it} = W_w x_{it}$. We use a bi-directional GRU (Bahdanau et al., 2014), and concatenate the hidden states $h_{it} = [\overrightarrow{h_{it}}; \overleftarrow{h_{it}}]$. Then, we use the attention mechanism in HAN to find important words to classify the decision. Each word has an attention value α_{it}, and we compute the utterance word vector, $u_i = \sum_{t=1}^{T} \alpha_{it} h_{it}$.

3.2 Utterance Encoder with Speaker

In CDMM, the i-th utterance has word sequence representation vector u_i and speaker vector s_i. First, we change the speaker z_i to vector s_i using

---

[1] `http://sillok.history.go.kr/id/kda_10103027_005`

the speaker embedding matrix $W_s, s_i = W_s z_i$. To encode a length U of the utterances $(u_i, s_i), i \in \{1, \ldots, U\}$, we suggest encoders based on GRU (Bahdanau et al., 2014), which can learn u_i and s_i simultaneously, as follows:

$$\begin{aligned}
h_i &= (1 - z_i) \odot h_{i-1} + z_i \odot \tilde{h}_i \\
z_i &= \sigma(W_{zu} u_i + W_{zs} s_i + U_z h_{i-1} + b_z) \\
r_i &= \sigma(W_{ru} u_i + W_{rs} s_i + U_r h_{i-1} + b_r) \\
\tilde{h}_i &= \tanh(W_{hu} u_i + W_{hs} s_i + r_i \odot (U_h h_{i-1}) + b_h)
\end{aligned}$$

Here, h_i is the i-th utterance hidden state, and z_i and r_i denote the update and reset gate, respectively. This is similar to earlier work (Li et al., 2016), but we add the speaker vector to the utterance level, not the word level.

As in the word encoder, we use the bidirectional GRU with the utterance encoder and concatenate the hidden states $h_i = [\overrightarrow{h_i}; \overleftarrow{h_i}]$. We use the same attention mechanism to find important utterances. Each utterance has an attention value of α_i, and for the conversation vector we use $d = \sum_{i=1}^{U} \alpha_i h_i$.

With vector d, CDMM predicts the decision using softmax $p = softmax(W_c d + b_c)$, and a dropout scheme (Srivastava et al., 2014) to avoid over-fitting.

3.3 Pre-trained Speaker Embedding

Unlike word embedding which is pre-trained from news or Wikipedia articles (Mikolov et al., 2013; Bojanowski et al., 2017), pre-trained speaker embedding for the AJD does not exist. To overcome this limitation, we suggest the building of speaker embedding from the co-occurrence document network in the AJD. The AJD contains not only meeting records but also personnel management reports and explanations of the officials. We therefore build a co-occurrence network. The vertices are people, and two individuals are connected if they appear in the same article. The weight of the edge is the number of co-occurrences in the same article. With this network, we realize speaker embedding using the node2vec algorithm (Grover and Leskovec, 2016), which generates node vector representation.

4 Experiments

This section describes the experiments and results of CDMM as well as other methods for classifying the king's decisions in the AJD.

4.1 Experiment Setting

We split the data as 80/10/10 for training/validation/test. Because the meeting records contain fifteen kings, we split the data randomly for each king and merge each part into the entire training, validation and test set.

We compare CDMM with the following methods. The majority of classes predicts all test examples as the major class, *Discuss*. We apply Naive Bayes and the SVM with the linear kernel. To use these methods, we remove words whose document frequency is smaller than twenty. To see the power of the speaker information, we run these baselines on words and speaker features together. We also run fastText (Joulin et al., 2017), which is a classifier with n-gram features and hierarchical softmax, and is similar to CBOW (Mikolov et al., 2013). We use pre-trained Korean word vectors[2] (Grave et al., 2018) to fastText and CDMM. We create the speaker embedding from the AJD. For a fair comparison, we exclude the valid and test articles to construct the co-occurrence network. We use node2vec implementation[3] for speaker embedding. We set the GRU hidden state size to 200, the dimension of the speaker embedding to 200 and the dropout probability to 0.5 for CDMM.

4.2 Predictions of the King's Decision Results

Table 2 shows the results. CDMM performs better than all other methods for macro-average and weighted-averaged metrics. The majority of classes shows the lowest performance. Naive Bayes and SVM outperform the baseline. fastText with pre-trained word vectors outperforms its counterpart, in accordance with an earlier result (Lample et al., 2016). CDMM without a speaker performs equally to HAN, the only difference being that HAN encodes sentences and CDMM encodes utterances. It does not show good performance as it models only the hierarchical structure of the conversation. However, when we add speaker information, the performance increases even with random initialization of speaker embedding. The performances of Naive Bayes and SVM also increase when they are assigned speakers as features. These observations signal that speaker information is helpful for predicting the king's decisions. Finally, CDMM with pre-trained speaker

embedding shows better results compared to all other methods.

5 Discussion

Here, we investigate the attention values to determine the important words and speakers for predicting the king's decisions. We also obtain evidence showing why CDMM with pre-trained speaker embedding outperforms the others.

5.1 Key Words and Speakers

We investigate the important words using word attention values. To find the important words, we compute the mutual information (Christopher et al., 2008) of words that have the top 10% of attention values in the utterances among the classes.

Figure 3 shows the attention weight distributions of the two examples of the top words "Wish to do" and "Okay". The word "Wish to do" is usually used to make a request to the king. The peak of the attention weight distribution of "Wish to do" for the *Approve* class is around 0.7, whereas it is around 0.3 for *Order* and *Discuss*. We can interpret this to mean that CDMM assigns greater attention to that word to predict *Approve* compared to *Order* and *Discuss*. The word "Okay" is used to consent to the opinions of others. CDMM assigns a high attention value to the word to predict *Order* and *Accept* compared to *Discuss*.

However, the attention values differ according to the speaker. As shown in Figure 4, CDMM gives a high attention score to the word "Okay" for

Name (Eng)	Position	Class
Sin Sukju	Secretary	*Order*
Jeong Changson	Secretary	*Order*
Kim Jonkyung	Local gov	*Approve*
Kim Neuk	Local gov	*Approve*
Gwon Jin	Local gov	*Disapprove*
Kim Seup	Remonstrator	*Disapprove*
Hwang Hui	Central gov	*Accept*
Han Myeonghoe	Central gov	*Accept*
Kim Jikyung	Remonstrator	*Reject*
Sung Damnyeon	Remonstrator	*Reject*

Table 3: Name (translated in English) and position of the speakers who have high mutual information scores for the classes. Local gov is the local government official and Central gov is the central government official. Remonstrator is the official who remonstrates to the king. The position of the speaker is important to predict the king's decision.

Accept as compared to the other classes when the speaker is king. However, when officials use this word, CDMM assigns a high attention value to the word in the *Order* class. Despite the fact that the same word is used, the king's decision is changed based on the speaker. This is additional evidence showing why the speaker information is useful to predict the decision.

5.2 Position of the Speaker

We investigate the key speakers from utterance attention values. To determine the important person, we use the same technique of finding important words.

We find that high ranking person's positions are shared for each class. Table 3 shows the top ranked speakers and their positions for each class. The chief secretary who takes orders from the king has a high rank in the *Order* class. For *Approve* and *Disapprove*, local authorities are highly ranked. For *Accept*, central government officials have high MI values. Interestingly, officials who remonstrate to the king have high scores in the *Disapprove* and *Reject* class. We can thus say that the kings refuse admonitions commonly from officials.

From these results, we can gain insight into why pre-trained speaker embedding is helpful to predict the king's decisions. People in the same organization are in the same community of co-occurrence news article network (Özgür et al., 2008). Therefore, the AJD network contains the community information, and node2vec generates the node's closeness via embedding. CDMM can have this knowledge in the model therefore outperforms the other methods.

6 Conclusion

In this paper, we created conversational meeting data from the Annals of the Joseon Dynasty (AJD). We presented Conversational Decision-Making Model (CDMM) to predict leaders' decisions from the data. We also suggested the use of speaker embedding from co-occurrence document network with node2vec. With this data, we showed that CDMM outperforms other methods in terms of most metrics. We implemented CDMM using tensorflow (Abadi et al., 2016), and published the code and data in public[4]. We also analyzed the reasoning behind the success of CDMM and the key words and speakers by investigating the concept of attention.

Studies of small group dynamics can be helpful when attempting to understand group decision making behavior (Backstrom et al., 2006). Prior work which analyzed small group dynamics relied on a hidden Markov model (Magdon-Ismail et al., 2003), a dynamic Bayesian network (Mathur et al., 2012) or a layered probabilistic model (Cheng et al., 2014) for various datasets such as networks or recorded video. We suggest CDMM, which combine two types of data to predict leaders' decision. We can also apply this idea to other group dynamics analyses.

Acknowledgments

We would like to thank Jooyeon Kim for the helpful discussion and the anonymous reviewers for the inspiring questions and comments. This work was supported by Institute for Information & communications Technology Promotion (IITP) grant funded by the Korea government (MSIT) (No.2017-0-01778, Development of Explainable Human-level Deep Machine Learning Inference Framework).

Toward Fast and Accurate Neural Discourse Segmentation

Yizhong Wang **Sujian Li** **Jingfeng Yang**
MOE Key Lab of Computational Linguistics, School of EECS, Peking University
`{yizhong, lisujian, yjfllpyym}@pku.edu.cn`

Abstract

Discourse segmentation, which segments texts into Elementary Discourse Units, is a fundamental step in discourse analysis. Previous discourse segmenters rely on complicated hand-crafted features and are not practical in actual use. In this paper, we propose an end-to-end neural segmenter based on BiLSTM-CRF framework. To improve its accuracy, we address the problem of data insufficiency by transferring a word representation model that is trained on a large corpus. We also propose a restricted self-attention mechanism in order to capture useful information within a neighborhood. Experiments on the RST-DT corpus show that our model is significantly faster than previous methods, while achieving new state-of-the-art performance. [1]

1 Introduction

Discourse segmentation, which divides text into proper discourse units, is one of the fundamental tasks in natural language processing. According to Rhetorical Structure Theory (RST) (Mann and Thompson, 1988), a complex text is composed of non-overlapping Elementary Discourse Units (EDUs), as shown in Table 1. Segmenting text into such discourse units is a key step in discourse analysis (Marcu, 2000) and can benefit many downstream tasks, such as sentence compression (Sporleder and Lapata, 2005) or document summarization (Li et al., 2016).

Since EDUs are initially designed to be determined with lexical and syntactic clues (Carlson et al., 2001), existing methods for discourse segmentation usually design hand-crafted features to capture these clues (Feng and Hirst, 2014). Especially, nearly all previous methods rely on syntactic parse trees to achieve good performance. But extracting such features usually takes a long time, which contradicts the fundamental role of discourse segmentation and hinders its actual use. Considering the great success of deep learning on many NLP tasks (Lu and Li, 2016), it's a natural idea for us to design an end-to-end neural model that can segment texts fast and accurately.

[Mr. Rambo says]$_{e_1}$ [that a 3.2-acre property]$_{e_2}$ [overlooking the San Fernando Valley]$_{e_3}$ [is priced at \$4 million]$_{e_4}$ [because the late actor Erroll Flynn once lived there.]$_{e_5}$

Table 1: A sentence that is segmented into five EDUs

The first challenge of applying neural methods to discourse segmentation is data insufficiency. Due to the limited size of labeled data in existing corpus (Carlson et al., 2001), it's quite hard to train a data-hungry neural model without any prior knowledge. In fact, some traditional features, such as the POS tags or parse trees, naturally provide strong signals for identifying EDUs. Removing them definitely increases the difficulty of learning an accurate model. Secondly, many EDU boundaries are actually not determined locally. For example, to recognize the boundary between e_3 and e_4 in Table 1, our model has to be aware that e_3 is an embedded clauses starting from "overlooking", otherwise it could regard "San Fernando Valley" as the subject of e_4. Such kind of long-distance dependency can be precisely extracted from parse trees but is difficult for neural models to capture.

To address these challenges, in this paper, we propose a neural discourse segmenter based on the BiLSTM-CRF (Huang et al., 2015) framework and further improve it from two aspects. Firstly, since the discourse segmentation corpus is too small to learn precise word representations, we transfer a word representation model trained on a large corpus into our task, and show that this trans-

---

[1] Our code is available at `https://github.com/PKU-TANGENT/NeuralEDUSeg`

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 962–967
Brussels, Belgium, October 31 - November 4, 2018.

ferred model can provide very useful information for our task. Secondly, in order to model long-distance dependency, we employ the self-attention mechanism (Vaswani et al., 2017) when encoding the text. Different from previous self-attention, we restrict the attention area to a neighborhood of fixed size. The motivation is that effective information for determining the boundaries is usually collected from adjacent EDUs, while the whole text may contain many disturbing words, which could mislead the model into incorrect decisions. In summary, the contributions of this work are as follows:

- Our neural discourse segmentation model doesn't rely on any syntactic features, while it can outperform other state-of-the-art systems and achieve significant speedup.
- To our knowledge, we are the first to transfer word representations learned from large corpus into discourse segmentation task and show that they can significantly alleviate the data insufficiency problem.
- Based on the nature of discourse segmentation, we propose a restricted attention mechanism , which enables the model to capture useful information within a neighborhood but ignore unnecessary faraway noises.

2 Neural Discourse Segmentation Model

We model discourse segmentation as a sequence labeling task, where the start word of each EDU (except the first EDU) is supposed to be labeled as 1 and other words are labeled as 0. Figure 1 gives an overview of our segmentation model. We will introduce the BiLSTM-CRF framework in Section 2.1, and describe the two key components of our model in Section 2.2, 2.3.

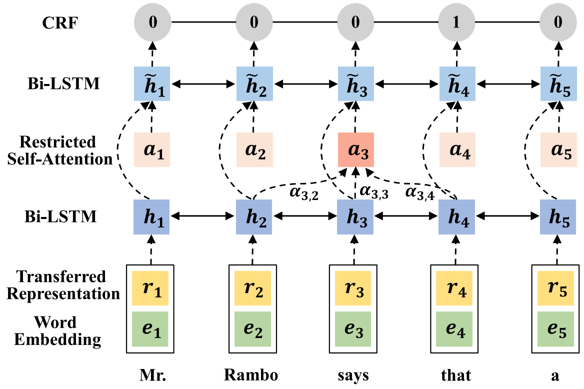

Figure 1: Overview of our model for discourse segmentation

2.1 BiLSTM-CRF for Sequence Labeling

Conditional Random Fields (CRF) (Lafferty et al., 2001) is an effective method to sequence labeling problem and has been widely used in many NLP tasks (Sutton and McCallum, 2012). To approach our discourse segmentation task in a neural way, we adopt the BiLSTM-CRF model (Huang et al., 2015) as the framework of our system. Formally, given an input sentence $\mathbf{x} = \{x_t\}_{t=1}^{n}$, we first embed each word into a vector $\mathbf{e}_t$. Then these word embeddings are fed into a bi-directional LSTM layer to model the sequential information:

$$\mathbf{h}_t = \text{BiLSTM}(\mathbf{h}_{t-1}, \mathbf{e}_t) \qquad (1)$$

where $\mathbf{h}_t$ is the concatenation of the hidden states from both forward and backward LSTMs. After encoding this sentence, we make labeling decisions for each word. Instead of modeling the decisions independently, the CRF layer computes the conditional probability $p(\mathbf{y}|\mathbf{h}; \mathbf{W}, \mathbf{b})$ over all possible label sequences $\mathbf{y}$ given $\mathbf{h}$ as follows:

$$p(\mathbf{y}|\mathbf{h}; \mathbf{W}, \mathbf{b}) = \frac{\prod_{i=1}^{n} \psi_i(y_{i-1}, y_i, \mathbf{h})}{\sum\limits_{y' \in \mathcal{Y}} \prod_{i=1}^{n} \psi_i(y'_{i-1}, y'_i, \mathbf{h})} \qquad (2)$$

where $\psi_i(y_{i-1}, y_i, \mathbf{h}) = \exp(\mathbf{w}^T \mathbf{h}_i + b)$ is the potential function and $\mathcal{Y}$ is the set of possible label sequences. The training objective is to maximize the conditional likelihood of the golden label sequence. During testing, we search for the label sequence with the highest conditional probability.

2.2 Transferring Representations Learned from Large Corpus

Due to the large parameter space, neural models usually require much more training data in order to achieve good performance. However, to the best of our knowledge, nearly all existing discourse segmentation corpora are limited in size. After we remove all the syntactic features, which has been proven useful in many previous work (Bach et al., 2012; Feng and Hirst, 2014; Joty et al., 2015), it's expected that our neural model will not achieve very satisfying results.

To tackle this issue, we propose to leverage model learned from other large datasets, aiming that this transferred model has been well trained to encode text and capture useful signals. Instead of training the transferred model by ourselves, in this paper, we adopt the ELMo word representations (Peters et al., 2018), which are derived from a bidirectional language model (BiLM) trained on one billion word benchmark corpus (Chelba et al., 2014). Specifically, this BiLM has one character convolution layer and two biLSTM layers, and correspondingly there are three internal representations for each word x_t, which are denoted as $\{\mathbf{h}_{t,l}^{\text{LM}}\}_{l=1}^{3}$. Following (Peters et al., 2018), we compute the ELMo representation $\mathbf{r}_t$ for word x_t as follows:

$$\mathbf{r}_t = \gamma^{\text{LM}} \sum_{l=0}^{3} s_l^{\text{LM}} \mathbf{h}_{t,l}^{\text{LM}} \tag{3}$$

where $\mathbf{s}^{\text{LM}}$ are normalized weights and γ^{LM} controls the scaling of the entire ELMo vector. Then we concatenate $\mathbf{r}_t$ with the word embedding $\mathbf{e}_t$, and take them as the input of Equation (1).

2.3 Restricted Self-Attention

As we have introduced in Section 1, some EDU boundaries rely on relatively long-distance signals to recognize, while normal LSTM model is still weak at this. Recently, self-attention mechanism, which relates different positions of a single sequence, has been successfully applied to many NLP tasks (Vaswani et al., 2017; Wang et al., 2017) and shows its superiority in capturing long dependency. However, we found that most boundaries are actually only influenced by nearby EDUs, thereby forcing the model to attend to the whole sequence will bring in unnecessary noises. Therefore, we propose a restricted self-attention mechanism, which only collects information from a fixed neighborhood. To do this, we first compute the similarity between current word x_i and each nearby word x_j within a window:

$$s_{i,j} = \mathbf{w}_{attn}^{T}[\mathbf{h}_i, \mathbf{h}_j, \mathbf{h}_i \odot \mathbf{h}_j] \tag{4}$$

Then the attention vector $\mathbf{a}_i$ is computed as a weighted sum of nearby words:

$$\alpha_{i,j} = \frac{e^{s_{i,j}}}{\sum_{k=-K}^{K} e^{s_{i,i+k}}} \tag{5}$$

$$\mathbf{a}_i = \sum_{j=-K}^{K} \alpha_{i,i+k} \mathbf{h}_{i+k} \tag{6}$$

where hyper-parameter K is the window size. This attention vector $\mathbf{a}_i$ is then put into another BiLSTM layer together with $\mathbf{h}_i$ in order to fuse the information:

$$\tilde{\mathbf{h}}_t = \text{BiLSTM}(\tilde{\mathbf{h}}_{t-1}, [\mathbf{h}_t, \mathbf{a}_t]) \tag{7}$$

We use $\tilde{\mathbf{h}}_t$ as the new input to the CRF layer.

3 Experiments and Results

3.1 Dataset and Metrics

We conduct experiments on the RST Discourse Treebank (RST-DT) (Carlson et al., 2001). The original corpus contains 385 Wall Street Journal articles from the Penn Treebank, which are divided in to training set (347 articles, 6132 sentences) and test set (38 articles, 991 sentences). We randomly sample 34 (10%) articles from the train set as validation set in order to tune the hyper-parameters and only train our model on the remained train set. We follow mainstream studies (Soricut and Marcu, 2003; Joty et al., 2015) to measure segmentation accuracy only with respect to the intra-sentential segment boundaries, and we report Precision (P), Recall (R) and F1-score (F1) for segmentation performance.

3.2 Implementation Details

We tune all the hyper-parameters according to the model performance on the separated validation set. The 300-D Glove embeddings (Pennington et al., 2014) are employed and kept fixed during training. We use the AllenNLP toolkit (Gardner et al., 2018) to compute the ELMo word representations. The hidden size of our model is set to be 200 and the batch size is 32. L2 regularization is applied to trainable variables with its weight as 0.0001 and we use dropout between every two layers, where the dropout rate is 0.1. For model training, we employ the Adam algorithm (Kingma and Ba, 2014) with its initial learning rate as 0.0001 and we clip the gradients to a maximal norm 5.0. Exponential moving average is applied to all trainable variables with a decay rate 0.9999. The window size K for restricted attention is set to be 5.

3.3 Performance

The results of our model and other competing systems on the test set of RST-DT are shown in Table 2. We compare our results against the following systems: (1) **SPADE** (Soricut and Marcu, 2003) is an early system using simple lexical and syntactic features; (2) **NNDS** (Subba and Di Eugenio, 2007) uses a neural network classifier to do the

Model	Tree	P(%)	R(%)	F1(%)
SPADE	Gold	84.1	85.4	84.7
NNDS	Gold	85.5	86.6	86.0
CRFSeg	Gold	92.7	89.7	91.2
Reranking	Gold	**93.1**	94.2	93.7
CRFSeg	Stanford	91.0	87.2	89.0
CODRA	BLLIP	88.0	92.3	90.1
Reranking	Stanford	91.5	90.4	91.0
Two-Pass	BLLIP	92.8	92.3	92.6
Our Model	No	92.9	**95.7**	**94.3**
- Attention	No	92.4	94.8	93.6
- ELMo	No	87.9	84.5	86.2
- Both	No	87.0	82.8	84.8
Human	No	98.5	98.2	98.3

Table 2: Performance of our model and other systems on the RST-DT test set [3]

segmentation after extracting features; (3) **CRFSeg** (Hernault et al., 2010) is the first discourse segmenter using CRF model; (4) **CODRA** (Joty et al., 2015) uses fewer features and a simple logistic regression model to achieve impressive results; (5) **Reranking** (Bach et al., 2012) reranks the N-best outputs of a base CRF segmenter; (6) **Two-Pass** (Feng and Hirst, 2014) conducts a second segmentation after extracting global features from the first segmentation result. All these methods rely on tree features and we list their performance given different parse trees, where **Gold** are the trees extracted from the Penn Treebank (Prasad et al., 2005), **Stanford** represents trees from the Stanford parser (Klein and Manning, 2003) and **BLLIP** represents those from the BLLIP parser (Charniak and Johnson, 2005). It should be noted that the results of SPADE and CRFSeg are taken from Bach et al. (2012) since the original papers adopt different evaluation metrics. All the other results are taken from the corresponding original papers.

From Table 2, we can see that our model achieves state-of-the-art performance without extra parse trees. Especially, if no gold parse trees are provided, our system outperforms other methods by more than 1.7 points in F1 score. Since the gold parse trees are not available when processing new sentences, this improvement becomes more valuable when the system is put into use.

System	Speed (Sents/s)	Speedup
Two-Pass	1.39	1.0x
SPADE	3.78	2.7x
Ours (Batch=1)	9.09	6.5x
Ours (Batch=32)	76.23	54.8x

Table 3: Speed comparison with two open-sourced discourse segmenter

To further explore the influence of different components in our model, we also report the results of ablation experiments in Table 2. We can see that the transferred ELMo representations provide the most significant improvement. This accords with our assumption that the RST-DT corpus itself is not large enough to train an expressive neural model sufficiently. With the help of the transferred representations, we are capable of capturing more semantic and syntactic signals. Also, comparing the models with and without the restricted self-attention, we find that this attention mechanism can further boost the performance. Especially, if there are no ELMo vectors, the improvement provided by the attention mechanism is more noticeable.

3.4 Speed Comparison

We also measure the speedup of our model against traditional systems in Table 3. The **Two-Pass** system has the best performance among all existing methods, while **SPADE** is much simpler with less features. We test these systems on the same machine (CPU: Intel Xeon E5-2690, GPU: NVIDIA Tesla P100). The results show that our system is 2.4-6.5 times faster than the compared systems if the batch size is 1. Moreover, if we process the test sentences in parallel, we can achieve 20.2-54.8 times speedup with the batch size as 32. This makes our system more practical in actually use.

3.5 Effect of Restricted Self-Attention

We propose to restrict the self-attention within a neighborhood instead of the whole sequence. Table 4 demonstrates the performance of our model over different window size K. We can see that all these results is better than the performance our model without attention mechanism. However, a proper restriction window is helpful for the attention mechanism to take better effect.

---

[3] In parallel with our work, Li et al. (2018) proposes another neural model with its performance as: P-91.6, R-92.8, F1-92.2. We didn't see their paper at the time of submission, but it's worth mentioning here for the readers' reference.

Window Size	1	5	10	∞
F1-score	94.0	94.3	94.2	93.8

Table 4: Performance of our model over different attention window size

4 Conclusion

In this paper, we propose a neural discourse segmenter that can segment text fast and accurately. Different from previous methods, our segmenter doesn't rely on any hand-crafted features, especially the syntactic parse tree. To achieve our goal, we propose to leverage the word representations learned from large corpus and we also propose a restricted self-attention mechanism. Experimental results on RST-DT show that our system can achieve state-of-the-art performance together with significant speedup.

A Dataset for Telling the Stories of Social Media Videos

Spandana Gella[1*] **Mike Lewis**[2] **Marcus Rohrbach**[2]

`spandana.gella@ed.ac.uk`, {`mikelewis,mrf`}`@fb.com`

Abstract

Video content on social media platforms constitutes a major part of the communication between people, as it allows everyone to share their stories. However, if someone is unable to consume video, either due to a disability or network bandwidth, this severely limits their participation and communication. Automatically telling the stories using multi-sentence descriptions of videos would allow bridging this gap. To learn and evaluate such models, we introduce VideoStory, a new large-scale dataset for video description as a new challenge for multi-sentence video description. Our VideoStory captions dataset is complementary to prior work and contains 20k videos posted publicly on a social media platform amounting to 396 hours of video with 123k sentences, temporally aligned to the video.

1 Introduction

Telling stories about what we experience is a central part of human communication (Mateas and Sengers, 2003). Increasingly, stories about our experiences are captured in the form of videos and then shared on social media platforms. One goal of automatically understanding and describing such videos with natural language is to generate multi-sentence descriptions which convey the story, making them accessible to situationally (e.g. bandwidth) or physically ("blind") disabled people. However, it is still a challenge for vision and language models to automatically encode and describe temporal content in videos with multi-sentence descriptions (Rohrbach et al., 2014; Zhou et al., 2018b). To better understand the stories shared on social media we collect and annotate a novel dataset consisting of videos from a social media platform. Importantly, we collect descriptions containing multiple sentences, as single sentences would typically not be able to capture the narration and plot of the video.

We introduce a large-scale multi-sentence description dataset for videos. To build a dataset of high quality, diverse and narratively interesting videos, we choose videos that had high engagement on a social media platform. Existing video captioning datasets, such as ActivityNet Captions (Krishna et al., 2017) or cooking video datasets (Regneri et al., 2013; Zhou et al., 2018a), have focused on sets of pre-selected human activities, whereas social media videos contain a great diversity of topics. Videos with high engagement tend to be narratively interesting, because humans find very predictable videos less enjoyable, meaning that captioning of the videos accurately requires integrating information from the entire video to describe a sequence of events (see Figure 1). Together, this creates a diverse and challenging new benchmark for video and language understanding.

We present a thorough analysis of the new benchmark, demonstrating that linguistic and video context is crucial to accurate captioning and that the captions have a temporal consistency. We also show baseline results using state-of-the-art models.

2 Multi-Sentence VideoStory Dataset

In Table 1 we summarize existing video description datasets; most provide only single-sentence descriptions or are restricted to narrow domains. Other multi-sentence description datasets are proposed for story narration of sets of images taken from a Flickr album (Huang et al., 2016; Krause et al., 2017). Other related work includes visual summarization of Flickr photo albums (Sigurdsson et al., 2016a) or videos (De Avila et al., 2011; Zhang et al., 2016) where the idea is to pick the key images or frames that summarize the visual content.

Table 1: Comparison of our dataset with other video description datasets. Avg.D: Average duration of the video/clip. #ActL: No. of action labels. Loc: temporally localized language descriptions; multi-sent: multi-sentence descriptions; overlap: allows overlap among segments. (✓) indicates datasets with multiple sentences, however they are mainly used to generate individual clip descriptions.

We select videos posted on a social media platform to create our dataset because of the variability in topics, length, viewpoints, and quality. They also tend to represent a good distribution of stories communicated by humans. We select videos from social media that are public and popular with a large number of comments and shares that triggered interactions between people. In total, our dataset consists of 20k videos with duration ranging from 20s-180s and spanning across diverse topics that are observed on social media platforms. We follow Krishna et al. (2017) to create temporally annotated sentences where each task is divided into two steps: (i) describing the video in multiple sentences, covering objects, situations and important details of the video; (ii) aligning each sentence in the paragraph with the corresponding timestamps in the video. We refer to these as video segments. In Figure 1, we present two example annotated videos describing (i) a scene where two girls are playing with horses; (ii) a wedding with a bride walking down the aisle.

We summarize the statistics of our dataset in Table 2 and compare it to prior work in Table 1. Each of the 20k videos in our VideoStory dataset is annotated with a paragraph which has on average 4.67 temporally localized sentences. As we have three paragraphs per video for validation and test set, we have a total of 26,245 paragraphs with a total of 123k sentences. Each sentence in the dataset

Split	#Videos	#Clips	#Para	#W/P	Original	shuffled
train	17,098	80,598	17,098	61.76	-	-
val	999	13,796	2,997	59.88	20.95	24.82
test	1,011	14,093	3,033	59.77	21.12	24.95
test_blind	1,039	14,139	3,117	69.45	23.81	27.99
total	20,147	122,626	26,245	62.23	-	-

Table 2: VideoStory dataset: Dataset statistics (#V: No.of unique videos. #Para: No.of unique paragraphs. #W/P: Average number of words per paragraph.) and perplexity scores for original and shuffled sentences.

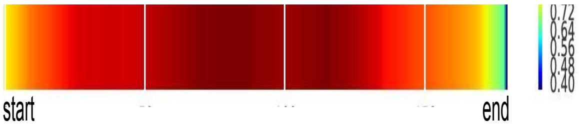

Figure 2: Distribution of annotations in time in VideoStory dataset. Most of the videos have majority of it annotated except the first few and last few seconds—which, in our analysis, correlated with the page/logo information.

has an average length of 13.32 words, and each video has the average paragraph length of 62.23 words. Each sentence is aligned to a clip of on average 18.33 seconds which covers on average 26.04% of the full video. However, the entire paragraph for each video on average describes 96.7% of the whole video, demonstrating that each paragraph annotation covers the majority of the video. Furthermore, we found that 22% of the temporal descriptions overlap, showing that our annotation allows co-occurring or simultaneous events. We divide our dataset in training (17098 videos), validation (999), test (1011) and blind test splits (1039). Each video in the training set has a single annotation, but videos in validation, test, and blind test splits have three temporally localized paragraph annotations, for evaluation. While the test set can be used to compare model variants in a paper, only the best model per paper should be evaluated on the blind test set annotations, which will only be possible on an evaluation server. Annotations for the blind test set will not be released.

To explore the different domains in our dataset vs. ActivityNet captions we use the normalized pointwise mutual information to identify the words most closely associated with each dataset. Highest ranked words for ActivityNet are almost exclusively sports related, whereas in our dataset they include animals, baby, and words related to social events such as weddings. Most dominant actions in ActivityNet are either sports or household activity related whereas actions in our dataset are related to social activities such as laughing, waving, cheering etc. Our analysis of the distribution of POS categories show that nouns are the most dominant category observed in the VideoStory captions dataset with 24% of the total tokens followed by verbs (18.5%), determiners (15.9%), adjectives (4.36%), adverbs (5.16%) and propositions (5.04%). We also observe the similar distribution of POS categories in ActivityNet captions.

We also find that ActivityNet has 50% of the videos where at least one segment in the video describes more than half of the video duration whereas in our dataset only 30% of videos have that phenomenon. In Figure 2, we show the distribution of sentence/segment annotations in time. The average number of (temporally localized) sentences is 4.67 compared to 3.65 in ActivityNet, despite having shorter videos, indicating the high information content of our videos.

In Table 3 we present all three paragraph annotations for a video showing a wedding ceremony. Out of 3 annotations, Annotation 2 is more descriptive compared to 1 and 3. However, it misses details about the presence of the photographer and taking the pictures.

Temporal Analysis. High quality video descriptions are more than bags of single-sentence captions; they should tell a coherent story. To identify the importance of sentence ordering or temporal coherence in our video paragraphs, we train a neural language model (Merity et al., 2017) on the training paragraphs of the VideoStory dataset and report perplexity on the correct order of sentences vs. randomly shuffled order of sentences in the descriptions created to understand the importance of temporal coherence in the video descriptions of our dataset. Results in Table 2 show that shuffled sentences have higher perplexity scores, demonstrating that order of sentences in the paragraphs are important for the coherence in the story.

3 Baseline Captioning Models

We explore learning to caption the videos using ground truth video segments.

Image Captioning Models. To understand if the temporal component of the video is contributing

Annotation 1: A bride walks down the aisle to her waiting bridegroom. As the bride walks, a photographer captures photos. At the end of the aisle the man giving the bride away shakes hands and hugs the bridegroom. The bride and bridegroom then interlock arms and face forward together.

Annotation 2: A large group of people have gathered inside of a room for a wedding. A woman walks down the aisle with a man slowly as people watch. The two of them get to the end of the aisle where a groom stands waiting.The man shakes hands with the groom and gives the woman a kiss on her forehead. The man who walked her down the aisle steps away towards the side of the room as the couple take each others arms.

Annotation 3: A groom is standing at the end of an aisle as a photographer takes a photo. The bride and father then come into view and walk down the aisle to the waiting groom. They stop at the grooms spot and the bride's father then shakes the grooms hand and gives a hug and walks to his spot. The groom then holds arms with the bride to begin the wedding ceremony.

Table 3: Example video description annotations in our VideoStory set. Each video has multiple paragraphs and localized time-interval annotations for every sentence in the paragraph.

to the description, we trained image captioning models on a frame sampled from the middle of the each segment of a video. We use the Show and Tell (Vinyals et al., 2015) image captioning architecture to generate captions.

Video Captioning Models. We study various video captioning models. First, we use sequence to sequence (seq-seq) recurrent neural network (RNN) model which has a two-layer encoder RNN to encode video features and a decoder RNN to generate descriptions. In the seq-seq approach we treat each description/segment individually and use an RNN decoder to describe each segment of the video, similar to Venugopalan et al. (2015), but using Gated Recurrent Units, GRUs, (Cho et al., 2014) for both the encoder and decoder.

In most videos, events are correlated with previous and future events. For example, for the first video description shown in Figure 1 once the girl is thrown into the water, she gets hold of herself, and the horse shakes off water on her. To capture such contextual correlations, we incorporate context from previous segment description into the captioning module. We build a model (seq-seq + context) which takes current segment video features and hidden representation of previous segment's sentence generation RNN at every timestamp in the decoder. For a given video segment, with hidden encoded video representation h_i^v and hidden representation of previous segment h_{i-1}^s, the concatenation of (h_i^v, h_{i-1}^s) is fed as input to the decoder that describes the segment (shown in Figure 3). Prior work has shown using previous video context has improved generated captions (Krishna et al., 2017).

Visual representation. For the image captioning models, we used features extracted from pre-trained ResNet-152 on ImageNet (He et al., 2016). For video captioning models we extract features from pre-trained 3D convolution ResNext-101 architecture trained on Kinetics (Kay et al., 2017), denoted as R3D, which achieved state-of-the-art results on various activity recognition tasks (Hara et al., 2018). Since a significant percentage of our videos has objects other than humans (e.g., animals) we also experiment with image-video fusion features(denoted by RNEXT, R3D) i.e., concatenation of ResNext-101 features extracted from pre-trained ImageNet with R3D features described above. We extract image features from the same frames which were used to extract R3D features.

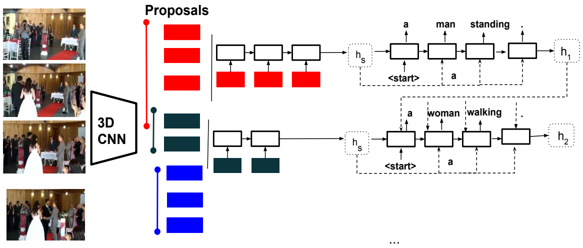

Figure 3: Our seq-seq+context model

4 Experiments and Results

For every segment, we set the maximum number of the sequence of features to 120 (i.e., 16X120 frames from the video) and maximum sentence length to 30. We trained using Adam optimizer with learning rate 0.0001. We use GRU as recurrent architecture to encode frames and decode captions with 512 dimensional hidden representation. We measure the captioning performance with most

GT (Ground Truth): A baby is playing outside with two dogs. The baby rolls the ball and the dog brings the ball back to the baby. The baby tosses the ball again and again for the dogs. One of the dogs walk away but the other stays and plays with the baby.	**I** (Image): The dog is standing on the bed . The dog is looking at the dog . The dog is walking on the ground . The dog is walking around the room .
seq-seq (RNEXT,R3D): A dog is walking in the water with a baby . The dog runs up and down the water . The dog runs up and down the slide . A baby is walking around the house with a baby .	**seq-seq+context** (RNEXT,R3D): A dog is standing in the middle of a house . The dog runs around the room and the dog jumps up and down . The dog is walking on the floor and the dog walks away . the girl runs around the house and the other dog runs away .

Table 4: Qualitative results: Descriptions generated by all variations of our baseline models.

Table 5: Captioning results from VideoStory Dataset using ground-truth test video segments. We report BLEU (B) and METEOR (M), ROUGE-L(R) and CIDEr (C). Best scores are in bold.

commonly-used evaluation metrics: BLEU{3,4}, METEOR, ROUGE-L, and CIDEr following previous works of image and video captioning (Papineni et al., 2002; Lin, 2004; Banerjee and Lavie, 2005; Vedantam et al., 2015).

In Table 5, we present the performance of our baseline models on VideoStory test dataset. We observe that models that consider context (seq-seq+context) from the previously generated sentence have better performance than the corresponding models without context (seq-seq), with both 3D convolution based features (R3D) as well as image-video fusion features (RNEXT,R3D). This indicates that our model benefited from contextual information, and that sentences in our stories are contextual, rather than independent.

To validate the strength of our baseline model, we train our best performing model on ActivityNet Captions. It achieves 10.92 (METEOR) and 43.42 (CIDEr) on the val set, close to state-of-the-art results of 11.06 and 44.71 by Zhou et al. (2018b), indicating that it is a strong baseline. However, when evaluating our ActivityNet model on our VideoStory dataset (Table 5, last row), we see significantly lower performance compared to a model trained on our dataset, highlighting the complementary nature of our dataset.

Our image only (single frame) model has the lowest scores across all metrics suggesting that a single image is not enough to generate contextual descriptions. We observed that our fusion models consistently outperform models with video-only R3D features, indicating features extracted using pre-trained ImageNet complement activity based R3D features. We show qualitative results from the variants of our models in Table 4. We observe that single frame models tend to repeat same captions and seq-seq model without context repeats phrases in the descriptions.

5 Conclusions

This paper introduces a dataset which we sourced from videos on social media and annotated with multi-sentence descriptions. We benchmark strong baseline approaches on the dataset, and our evaluations show that our dataset is complementary from prior work due to more diverse topics and the selection of engaging videos which tell a story. Our VideoStory dataset can serve as a good benchmark to build models for story understanding and multi-sentence video description.

Acknowledgements

We would like to thank Ranjay Krishna for providing the annotation interface used in Krishna et al. (2017) which we adapted to collect our dataset. We would also like to thank Haoqi Fan, Boris Vassilev, Jamie Ray, Sasha Sheng, Nikhila Ravi, and Evan Numbers for their help collecting the dataset, Devi Parikh for feedback on the annotation interface and Anna Rohrbach for useful feedback on drafts of this paper.

Abstract

Visual reasoning is a special visual question answering problem that is multi-step and compositional by nature, and also requires intensive text-vision interactions. We propose CMM: Cascaded Mutual Modulation as a novel end-to-end visual reasoning model. CMM includes a multi-step comprehension process for both question and image. In each step, we use a Feature-wise Linear Modulation (FiLM) technique to enable textual/visual pipeline to mutually control each other. Experiments show that CMM significantly outperforms most related models, and reach state-of-the-arts on two visual reasoning benchmarks: CLEVR and NLVR, collected from both synthetic and natural languages. Ablation studies confirm that both our multi-step framework and our visual-guided language modulation are critical to the task. Our code is available at `https://github.com/FlamingHorizon/CMM-VR`.

1 Introduction

It is a challenging task in artificial intelligence to perform reasoning with both textual and visual inputs. Visual reasoning task is designed for researches in this field. It is a special visual question answering (VQA) (Antol et al., 2015) problem, requiring a model to infer the relations between entities in both image and text, and generate a textual answer to the question correctly. Unlike other VQA tasks, questions in visual reasoning often contain extensive logical phenomena, and refer to multiple entities, specific attributes and complex relations. Visual reasoning datasets such as CLEVR (Johnson et al., 2017a) and NLVR (Suhr et al., 2017) are built on unbiased, synthetic images, with either complex synthetic questions or natural-language descriptions, facilitating in-depth analyses on reasoning ability itself.

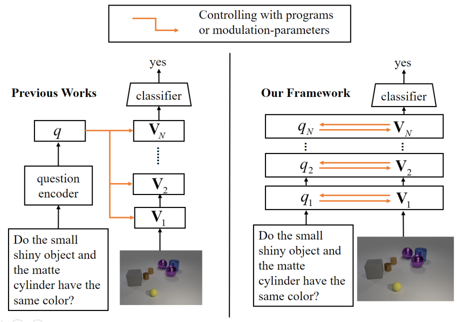

Figure 1: Connections and differences between previous "program-generating" works and our model: other models generate/control multi-step image-comprehension processes with single question representation, while we put more attention on language logics and let multi-modal information modulate each other in each step. The question and image are taken as a visual-reasoning example from CLEVR dataset.

Most previous visual reasoning models focus on using the question to guide the multi-step computing on visual features (which can be defined as a image-comprehension "program"). Neural Module Networks (NMN) (Andreas et al., 2016a,b) and Program Generator + Execution Engine (PG+EE) (Johnson et al., 2017b) learn to combine specific image-processing modules, guided by question semantics. Feature-modulating methods like FiLM (De Vries et al., 2017; Perez et al., 2018) control image-comprehension process using modulation-parameters generated from the question, allowing models to be trained end-to-end. However, the image-comprehension program in visual reasoning tasks can be extremely long and sophisticated. Using a single question representation to generate or control the whole image-comprehension process raises difficulties in learning. Moreover, since information comes from multiple modalities, it is not intuitive to assume

---

that one (language) is the "program generator", and the other (image) is the "executor". One way to avoid making this assumption is to perform multiple steps of reasoning with each modality being generator and executor alternately in each step. For these two reasons, we propose Cascaded Mutual Modulation (Figure 1), a novel visual reasoning model to solve the problem that previous "program-generating" models lack a method to use visual features to guide multi-step reasoning on language logics. CMM reaches state-of-the-arts on two benchmarks: CLEVR (complex synthetic questions) and NLVR (natural-language).

2 Related Work

Perez et al. (2018) proposed FiLM as an end-to-end feature-modulating method. The original ResBlock+GRU+FiLM structure uses single question representation, and conditions all image-modulation-parameters on it, without sufficiently handling multi-step language logics. In contrast, we modulate both image and language features alternately in each step, and condition the modulation-parameters on the representations from previous step. We design an image-guided language attention pipeline and use it in combination with FiLM in our CMM framework, and significantly outperform the original structure.

Other widely-cited works on CLEVR/NVLR include Stacked Attention Networks (SAN) (Yang et al., 2016), NMN (Andreas et al., 2016b), N2NMN (Hu et al., 2017), PG+EE (Johnson et al., 2017b) and Relation Networks (RN) (Santoro et al., 2017). The recent CAN model (Hudson and Manning, 2018) also uses multiple question representations and has strong performances on CLEVR. However, these representations are not modulated by the visual part as in our model.

In other VQA tasks, DAN (Nam et al., 2017) is the only multi-step dual framework related to ours. For comparison, in every time step, DAN computes textual and visual attention *in parallel* with the same key-vector, while we perform textual attention and visual modulation (instead of attention) in a *cascaded* manner.

3 Model

We review and extend FiLM in Section 3.1-3.2, and introduce CMM model in Section 3.3-3.4.

3.1 Visual Modulation

Perez et al. (2018) proposed **F**eature-w**i**se **L**inear **M**odulation (FiLM), an affine transformation on intermediate outputs of a neural network (v stands for visual):

$$FiLM^v(\mathbf{F}_{i,c}|\gamma_{i,c},\beta_{i,c}) = \gamma_{i,c}\mathbf{F}_{i,c} + \beta_{i,c}, \quad (1)$$

where $\mathbf{F}_{i,c}$ is the c-th feature map (C in total) generated by Convolutional Neural Networks (CNN) in the i-th image-comprehension step. Modulation-parameters $\gamma_{i,c}$ and $\beta_{i,c}$ can be conditioned on any other part of network (in their work the *single* question representation q). If the output tensor $\mathbf{V}_i$ of a CNN block is of size $C \times H \times W$, then $\mathbf{F}_{i,c}$ is a single slice of size $1 \times H \times W$. H and W are the height and width of each feature map.

Unlike (Perez et al., 2018), in each step i, we compute a new question vector q_i. Modulation-parameters γ_i and β_i ($C \times 1$ vectors, $\gamma_i = [\gamma_{i,1}, ..., \gamma_{i,C}]$, etc.) are conditioned on the previous question vector q_{i-1} instead of a single q:

$$\gamma_i, \beta_i = MLP^i(q_{i-1}). \quad (2)$$

MLP stands for fully connected layers with linear activations. The weights and biases are not shared among all steps.

3.2 Language Modulation

In each step i, we also apply FiLM to modulate every language "feature map". If the full question representation is a $D \times T$ matrix, a question "feature map" $\mathbf{f}_{i,d}$ is defined as a $1 \times T$ vector gathering T features along a single dimension. D is the hidden-state dimension of language encoder, and T is a fixed maximum length of word sequences.

$$FiLM^l(\mathbf{f}_{i,d}|\gamma_{i,d},\beta_{i,d}) = \gamma_{i,d}\mathbf{f}_{i,d} + \beta_{i,d}, \quad (3)$$

where l stands for language. Concatenated modulation-parameters γ_i and β_i ($D \times 1$) are conditioned on the visual features $\mathbf{V}_i$ computed in the same step:

$$\gamma_i, \beta_i = g_m(\mathbf{V}_i), \quad (4)$$

where g_m (Section 3.4) is an interaction function that converts 3-d visual features to language-modulation-parameters. The weights in g_m are shared among all N steps.

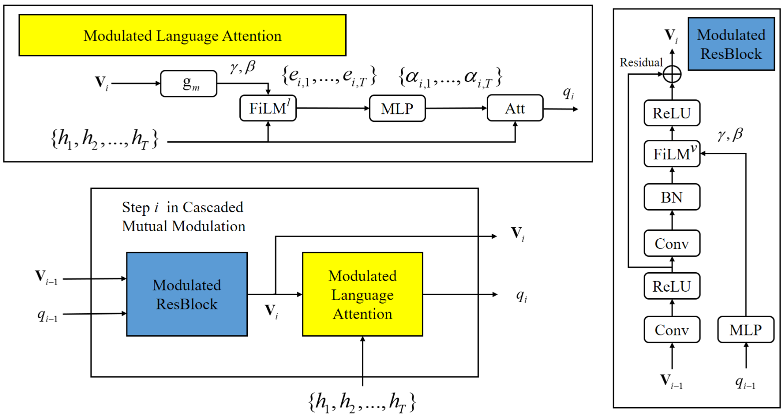

Figure 2: Details in CMM step i (middle), with a modulated ResBlock (right) and a modulated textual attention pipeline (top). Visual and textual features modulate each other in each step to compute new representations.

3.3 Cascaded Mutual Modulation

The whole pipeline of our model is built up with multiple *steps*. In each step i (N in total), previous question vector q_{i-1} and the visual features $\mathbf{V}_{i-1}$ are taken as input; q_i and $\mathbf{V}_i$ are computed as output. Preprocessed questions/images are encoded by language/visual encoders to form q_0 and $\mathbf{V}_0$.

In each step, we cascade a FiLM-ed ResBlock with a modulated textual-attention. We feed $\mathbf{V}_{i-1}$ into the ResBlock modulated by parameters from q_{i-1} to compute $\mathbf{V}_i$, and then control the textual attention process with modulation-parameters from $\mathbf{V}_i$, to compute the new question vector q_i. (Figure 2, middle).

Each ResBlock contains a 1×1 convolution, a 3×3 convolution, a batch-normalization (Ioffe and Szegedy, 2015) layer before FiLM modulation, followed by a residual connection (He et al., 2016). (Figure 2, right. We keep the same ResBlock structure as (Perez et al., 2018)). To be consistent with (Johnson et al., 2017b; Perez et al., 2018), we concatenate the input visual features $\mathbf{V}_{i-1}$ of each ResBlock i with two "coordinate feature maps" scaled from -1 to 1, to enrich representations of spatial relations. All CNNs in our model use ReLU as activation functions; batch-normalization is applied before ReLU.

After the ResBlock pipeline, we apply language modulation on the full language features $\{h_1, ..., h_T\}$ ($D \times T$) conditioned on $\mathbf{V}_i$ and rewrite along the time dimension, yielding:

$$e_{i,t} = FiLM^l(h_t | g_m(\mathbf{V}_i)), \qquad (5)$$

and compute visual-guided attention weights:

$$\alpha_{i,t} = \mathrm{softmax}_t(\mathbf{W}_i^{att} e_{i,t} + b_i^{att}), \qquad (6)$$

and weighted summation over time:

$$q_i = \sum_{t=1}^{T} \alpha_{i,t} h_t. \qquad (7)$$

In equation (6), $W_i^{att} \in \mathbb{R}^{1 \times D}$ and $b_i^{att} \in \mathbb{R}^{1 \times 1}$ are network weights and bias; h_t is the t-th language state vector ($D \times 1$), computed using a bi-directional GRU (Chung et al., 2014) from word embeddings $\{w_1, ..., w_T\}$. In each step i, the language pipeline does not re-compute h_t, but re-modulate it as $e_{i,t}$ instead. (Figure 2, top.)

3.4 Feature Projections

We use a function g_p to project the last visual features $\mathbf{V}_N$ into a final representation:

$$u_{final} = g_p(\mathbf{V}_N). \qquad (8)$$

g_p includes a convolution with K 1×1 kernels, a batch-normalization afterwards, followed by global max pooling over all pixels ($K = 512$).

We also need a module g_m (equation (4)) to compute language-modulations with $\mathbf{V}_i$, since $\mathbf{V}_i$ is 3-d features (not a weighted-summed vector as in traditional visual-attention). We choose g_m to have the same structure as g_p, except that K equals to the total number of modulation-parameters in each step. This design is critical (Section 4.3).

We use a fully connected layer with 1024 ReLU hidden units as our answer generator. It takes u_{final} as input, and predicts the most probable answer in the answer vocabulary.

Model	Overall	Count	Exist	Compare Numbers	Query Attribute	Compare Attribute
Human	92.6	86.7	96.6	86.5	95.0	96.0
SAN (Yang et al., 2016)	76.7	64.4	82.7	77.4	82.6	75.4
N2NMN (Andreas et al., 2016a)	83.7	68.5	85.7	84.9	90.0	88.7
PG+EE-9K	88.6	79.7	89.7	79.1	92.6	96.0
PG+EE-700K (Johnson et al., 2017b)	96.9	92.7	97.1	98.7	98.1	98.9
RN (Santoro et al., 2017)	95.5	90.1	97.8	93.6	97.9	97.1
COG-model (Yang et al., 2018)	96.8	91.7	99.0	95.5	98.5	98.8
FiLM	97.7	94.3	99.1	96.8	99.1	99.1
FiLM-raw (Perez et al., 2018)	97.6	94.3	99.3	93.4	99.3	99.3
DDRprog (Suarez et al., 2018)	98.3	96.5	98.8	98.4	99.1	99.0
CAN (Hudson and Manning, 2018)	98.9	97.1	**99.5**	**99.1**	99.5	**99.5**
CMM-single (ours)	98.6	96.8	99.2	97.7	99.4	99.1
CMM-ensemble (ours)	**99.0**	**97.6**	**99.5**	98.5	**99.6**	99.4

Table 1: Accuracies on CLEVR test set. N2NMN and PG+EE need extra supervision to train with reinforcement learning. FiLM-raw uses raw image as input (others use pre-extracted features). Another work (Mascharka et al., 2018) gets 99.1% accuracy but uses strong program supervision, which is a totally different setting.

4 Experiments

We are the first to achieve top results on both datasets (CLEVR, NLVR) with one structure. See Appendix for more ablation and visualization results.

4.1 CLEVR

CLEVR (Johnson et al., 2017a) is a commonly-used visual reasoning benchmark containing 700,000 training samples, 150,000 for validation and test. Questions in CLEVR cover several typical elements of reasoning: counting, comparing, querying the memory, etc. Many well-designed models on VQA have failed on CLEVR, revealing the difficulty to handle the multi-step and compositional nature of logical questions.

On CLEVR dataset, we embed the question words into a 200-dim continuous space, and use a bi-directional GRU with 512 hidden units to generate 1024-dim question representations. Questions are padded with NULL token to a maximum length $T = 46$. As the first-step question vector in CMM, q_0 can be arbitrary RNN hidden state in the set $\{h_1, ..., h_T\}$ (Section 3.3). We choose the one at the end of the unpadded question.

In each ResBlock, the feature map number C is set to 128. Images are pre-processed with a ResNet101 network pre-trained on ImageNet (Russakovsky et al., 2015) to extract $1024 \times 14 \times 14$ visual features (this is also common practice on CLEVR). We use a trainable one-layer CNN with 128 kernels (3×3) to encode the extracted features into $\mathbf{V}_0$ ($128 \times 14 \times 14$). Convolutional paddings are used to keep the feature map size to be 14×14 through the visual pipeline.

We train the model with an ADAM (Kingma and Ba, 2014) optimizer using a learning rate of 2.5e-4 and a batch-size of 64 for about 90 epoches, and switch to an SGD with the same learning rate and 0.9 momentum, fine-tuning for another 20 epoches. SGD generally brings around 0.3 points gains to CMM on CLEVR.

We achieve 98.6% accuracy with single model (4-step), significantly better than FiLM and other related work, only slightly lower than CAN, but CAN needs at least 8 model-blocks for >98% (and 12 for best). We achieve state-of-the-art of 99.0% with ensemble of 4/5/6 step CMM models. Table 1 shows test accuracies on all types of questions. The main improvements over program-generating models come from "Counting" and "Compare Numbers", indicating that CMM framework significantly enhances language (especially numeric) reasoning without sophisticated memory design like CAN.

4.2 NLVR

NLVR (Suhr et al., 2017) is a visual reasoning dataset proposed by researchers in NLP field. NLVR has 74,460 samples for training, 5,940 for validation and 5,934 for public test. In each sample, there is a human-posed natural language description on an image with 3 sub-images, and requires a false/true response.

We use different preprocessing methods on NLVR. Before training, we reshape NLVR images into 14×56 raw pixels and use them directly as visual inputs $\mathbf{V}_0$. For language part, we correct some obvious typos among the rare words (frequency < 5) in the training set, and pad the sentences to a maximum length of 26. Different from

CLEVR, LSTM works better than GRU on the real-world questions. For training, we use ADAM with a learning rate of 3.5e-4 and a batch-size of 128 for about 200 epoches, without SGD fine-tuning.

Our model (3-step, 69.9%) outperforms all proposed models on both validation and public test set, showing that CMM is also suitable for real-world languages (Table 2).

Model	Dev	Test-P
Text only	56.6	57.2
Image only	55.4	56.1
CNN+RNN (Suhr et al., 2017)	56.6	58.0
NMN (Andreas et al., 2016b)	63.1	66.1
FiLM (our run)	59.0	61.3
CNN-BiAtt (Tan and Bansal, 2018)	66.9	69.7
CMM-3-steps (ours)	**68.0**	**69.9**

Table 2: Accuracies on valid and test set of NLVR.

4.3 Ablation Studies

We list CMM ablation results in Table 3. Ablations on CLEVR show that CMM is robust to step number but sensitive to g_m structure because it's the key to multi-modal interaction. Section 3.4 is temporarily a best choice. CMM performs over 7-point higher than FiLM on NLVR in a setting of same hyper-parameters and ResBlocks, showing the importance of handling *language* logics (see also difficult CLEVR subtasks in Table 1).

CLEVR		NLVR		
Model	Val	Model	Dev	Test-P

6-step	98.4	1-step	65.3	66.9
g_m-CNN	93.3	2-step	67.7	66.8
g_m w/o BN	94.1	3-step	68.5	68.4
g_m-NS	97.0	4-step	67.2	66.5
4-step	98.6	3-step-LSTM	68.0	69.9

Table 3: Ablation studies on CLEVR/NLVR. g_m-CNN means using 2-layer-CNN with 3×3 kernels, followed by concatenation and MLP, as g_m. BN means batch-normalization in g_m. NS means not sharing weights. "FiLM-hyp" uses all the same hyper-parameters as the 3-step CMM (both use GRU as question encoder).

4.4 A Case Study

We select an image-question pair from the validation set of CLEVR for visualization. In Table 4, we visualize the multi-step attention weights on question words, and the distribution of argmax position in the global max-pooling layer of g_p (equivalent to the last visual "attention map" although there isn't explicit visual attention in our image-comprehension pipeline). On the bottom right is the original image, and on the top right is the distribution of argmax positions in the global max-pooling, multiplied by the original image.

Words	Block 1	Block 2	Block 3	Visual Attention Map
<START>	0.017	0.030	0.052	Is	0.006	0.048	0.501	
there	0.010	0.041	0.299	
a	0.006	0.031	0.015	
big	0.008	0.031	0.001	
brown	0.049	0.040	0.002	
object	0.149	0.265	0.003	
of	0.032	0.063	0.003	
the	0.030	0.029	0.004	
same	0.062	0.032	0.002	
shape	0.345	0.152	0.007	
as	0.233	0.031	0.001	
the	0.000	0.005	0.004	
green	0.003	0.014	0.004	
thing	0.012	0.075	0.011	
<END>	0.006	0.036	0.025	

Table 4: Visualization of CMM intermediate outputs on a sample from CLEVR validation set. We colour the largest attention weight with dark gray, and top four attention weights in the rest with light gray.

Our model attends to phrases "same shape as" and "brown object" in the first two reasoning steps. These phrases are meaningful because "same shape as" is the core logic in the question, and "brown object" is the key entity to generating the correct answer. In the last step, the model attends to the phrase "is there". This implicitly classifies the question into question-type "exist", and directs the answer generator to answer "no" or "yes". The visual map, guided by question-based modulation parameters, concentrates on the green and brown object correctly.

The result shows that visual features can guide the comprehension of question logics with textual modulation. On the other hand, question-based modulation parameters enable the ResBlocks to filter out irrelative objects.

5 Conclusion

We propose CMM as a novel visual reasoning model cascading visual and textual modulation in each step. CMM reaches state-of-the-arts on visual reasoning benchmarks with both synthetic and real-world languages.

How agents see things:
On visual representations in an emergent language game

Abstract

There is growing interest in the language developed by agents interacting in emergent-communication settings. Earlier studies have focused on the agents' symbol usage, rather than on their representation of visual input. In this paper, we consider the referential games of Lazaridou et al. (2017), and investigate the representations the agents develop during their evolving interaction. We find that the agents establish successful communication by inducing visual representations that almost perfectly align with each other, but, surprisingly, do not capture the conceptual properties of the objects depicted in the input images. We conclude that, if we are interested in developing language-like communication systems, we must pay more attention to the visual semantics agents associate to the symbols they use.

1 Introduction

There has recently been a revival of interests in language emergence simulations involving agents interacting in visually-grounded games. Unlike earlier work (e.g., Briscoe, 2002; Cangelosi and Parisi, 2002; Steels, 2012), many recent simulations consider realistic visual input, for example, by playing referential games with real-life pictures (e.g., Jorge et al., 2016; Lazaridou et al., 2017; Havrylov and Titov, 2017; Lee et al., 2018; Evtimova et al., 2018). This setup allows us to address the exciting issue of whether the needs of goal-directed communication will lead agents to associate visually-grounded conceptual representations to discrete symbols, developing natural-language-like word meanings. However, while most studies present some analysis of the agents' symbol usage, they pay little or no attention to the representation of the visual input that the agents develop as part of their evolving interaction.

We study here agent representations following the model and setup of Lazaridou et al. (2017). This is an ideal starting point, since it involves an extremely simple signaling game (Lewis, 1969), that is however played with naturalistic images, thus allowing us to focus on the question of how the agents represent these images, and whether such representations meet our expectations for natural word meanings. In their first game, Lazaridou's Sender and Receiver are exposed to the same pair of images, one of them being randomly marked as the "target". The Sender always sees the target in the left position, and it must pick one discrete symbol from a fixed vocabulary to send to the Receiver. The Receiver sees the images in random order, together with the sent symbol, and it tries to guess which image is the target. In case of success, both players get a payoff of 1. Since an analysis of vocabulary usage brings inconclusive evidence that the agents are using the symbols to represent natural concepts (such as *beaver* or *bayonet*), Lazaridou and colleagues next modify the game, by presenting to the Sender and the Receiver different images for each of the two concepts (e.g., the Sender must now signal that the target is a *beaver*, while seeing a different beaver from the one shown to the Receiver). This setup should encourage concept-level thinking, since the two agents should not be able to communicate about low-level perceptual characteristics of images they do not share. Lazaridou and colleagues present preliminary evidence suggesting that, indeed, agents are now developing conceptual symbol meanings. We replicate Lazaridou's games, and we find that, in both, the agents develop successfully aligned representations that, however, are not capturing conceptual properties at all. In what is perhaps our most striking result, agents trained in either version of the game succeed at communicating about pseudo-images generated from random noise (Fig. 2). We conclude that, if we want interactive agents to

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 981–985
Brussels, Belgium, October 31 - November 4, 2018.

develop a vocabulary of words denoting natural meanings, more attention must be paid to the way in which they are representing their perceptual input.

2 Experimental setup

Architecture We re-implement Lazaridou's Sender and Receiver architectures (using their better-behaved "informed" Sender). Both agents are feed-forward networks. The **Sender** takes image representations as input, it projects them into its own representational space, compares them, and finally outputs a probability distribution over vocabulary symbols, from which a single discrete symbol is then sampled. We report here results obtained with an output vocabulary of 100 symbols, but the same patterns were observed using a range of sizes from 2 to $1,000$. The **Receiver** takes as input the target and distractor input image representations in random order, as well as the symbol produced by the sender (as a vocabulary-sized one-hot vector). It embeds the images and the symbol into its own representational space, where it performs a symbol-to-image comparison, producing a probability distribution over the two images, one of which is selected by sampling from this distribution. If the Receiver selected the target image, a reward of 1 is assigned to both agents. The whole architecture is jointly trained by letting the agents play, and updating their parameters with Reinforce (Williams, 1992). See Lazaridou et al. (2017) for details.

Data Following Lazaridou et al. (2017), for each of the 463 concepts they used, we randomly sample 100 images from ImageNet (Deng et al., 2009). We construct $50,000$ mini-batches of 32 image pairs during training and $1,024$ pairs for validation. We construct a held-out test set in the same way by sampling 10 images per concept from ImageNet (for 2 concepts, we were not able to assemble enough further images), for a total of $4,610$. We compute RSA scores (see below) on the cross-product of these images. We also use the held-out set to construct mini-batches of images pairs to compute test performance. Following Lazaridou, the images are passed through a pre-trained VGG ConvNet (Simonyan and Zisserman, 2015). The input vector fed to the agents is the second-to-last 4096-D fully connected layer[1].

Games We re-implement both Lazaridou's **same-image** game, where Sender and Receiver are shown the same two images (always of different concepts), and their **different-image** game, where the Receiver sees different images than the Sender's. We repeat all experiments using 100 random initialization seeds. As we faithfully reproduced the setup of Lazaridou et al. (2017), we refer the reader there for hyper-parameters and training details.

3 Experiments

We first asked in which way playing the game affects the way agents "see" the input data, that is, in which way their image embeddings differ from the input image representations, and from each other. Concerning Sender and Receiver, a reasonable expectation is that successful communication implies a convergence of representations. How should these representations relate to the input? Recall that input representations are from one of the top layers of a state-of-the-art ConvNet trained on ImageNet concept categorization, and the top layers of such networks are known to capture high-level concept semantics (Zeiler and Fergus, 2014). The game image pairs are always sampled from different concepts. So, it would make sense for the agents to simply learn to carry through the similarity structure of the input space, in order to communicate about distinct concepts. Consequently, we predicted that, as training proceeds, Sender and Receiver representations will become closer to each other, and to the input ones.

In order to compare the similarity structure of input, Sender and Receiver spaces, we borrow *representational similarity analysis* (RSA) from computational neuroscience (Kriegeskorte et al., 2008). Given two sets r_1 and r_2 of representations of the same item collection (e.g., r_1 is the collection of input images mapped in Sender embedding space and r_2 is the same collection represented by Receiver), we first compute s_1 as all possible pairwise (cosine) similarities between the representations in r_1, and s_2 as those in r_2. We then compute the (Spearman) correlation between the similarity vectors s_1 and s_2. This latter value, which we will call *RSA score*, measures the global agreement between s_1 and s_2, relative to the chosen input collection. If N is the number of items in the collection that we compute representations for, both similarity vectors s_1 and s_2 are of length

---

[1] We found very similar results with the top 1000-D softmax layer.

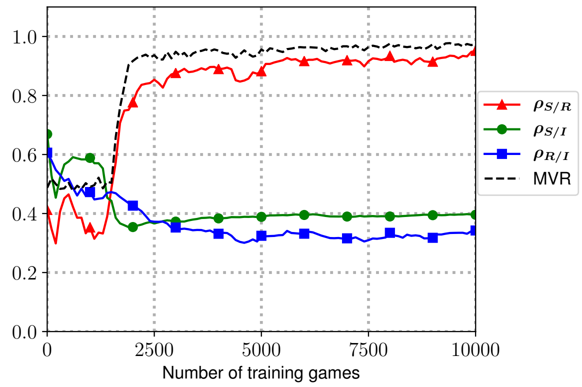

Figure 1: RSA scores of the two agents ($\rho_{S/R}$), and of each agent with the input ($\rho_{S/I}$ and $\rho_{R/I}$), during the first $10,000$ training games. S refers to Sender, R to Receiver, I to input. Values remain stable until end of training. Best viewed in color.

$N(N-1)$. Therefore, it is not necessary for representations r_1 and r_2 to belong to the same space (for example, in our case, input and agent vectors have different dimensionality).

Figure 1 shows RSA and mean validation reward (MVR) development curves for the cross-validated best seed in the same-image game. At the beginning of training, the RSA scores are non-zeros, which is expected as the two agents architectures are similar and randomly initialized the same way. They are also somewhat correlated with the input, which we attribute to the fact that untrained neural networks can already extract relevant image features (Jarrett et al., 2009). As training converges, Sender and Receiver similarity spaces also converge. However, contrary to our prediction, the agent similarity spaces are not strongly correlated with the input visual space. We note that, during the first few hundred games, the Sender (green curve) aligns with the input, but the Receiver (blue curve) does not. Therefore, it seems that, in order to establish communication, the two agents have to drift from the input. Indeed, when communication is successfully established at the end of training,[2] the two agents have a RSA score of $\rho_{S/R} = 0.98$. However either agent's score with the input is a much lower $\rho_{S/I} = \rho_{R/I} = 0.33$.[3] On the contrary, when the agents fail to establish communication, by the end of training their RSA score is just $\rho_{S/R} = 0.39$, but they stay closer to the input ($\rho_{S/I} = 0.58$ and $\rho_{R/I} = 0.42$).[4]

The drift of the agents from input similarity could be attributed to the characteristics of the game they are playing. Since they are only asked to distinguish between pictures of different concepts, they have no incentive to keep different instances of a concept distinct (if the agents are never asked to distinguish one dog from another, they might eventually become unable to tell dogs apart). That is, we might be assisting to the inception of a form of categorical perception (Goldstone and Hendrickson, 2010), whereby the agents lose sensitivity to within-category differences. If this is the case, we should observe that same-concept image similarity is *higher* in Sender (or Receiver) space with respect to input space. However, this turns out not to be the case. To the contrary, average pairwise same-concept similarity is consistently *lower* in Sender space than in the input (mean z-normalized same-concept similarity in input space is at 1.94 vs. 0.57 in Sender space, averaged across successful seeds). A similar effect is observed by looking at higher-class (*mammal*, *furniture*, etc.) similarities: images from the same classes become less similar in Sender space (0.61 z-normalized within-class input similarity vs. 0.30 in Sender space). This suggests that the agents are becoming less proficient at capturing the similarity among instances of the same concept or of the same class. The same conclusion is qualitatively supported by the pairs of images that underwent the largest shift between input and Sender space. For example, for two test images of avocados which have an input similarity of 0.82 (and are reasonably similar to the human eye), the Sender similarity is at the low value of -0.27 (Receiver similarity is -0.59). Contrarily, for an image of a cabin in a field and an image of a telephone that have an intuitively correct very low input similarity of 0.02, the Sender similarity for these images is 0.94 (Receiver similarity is 0.95).

Lazaridou et al. (2017) designed their second game to encourage more general, concept-like referents. Unfortunately, we replicate the anomalies above in the different-image setup, although to a less marked extent. When successful communication is established at the end of training, the agents have $\rho_{S/R} = 0.90$. But again, the agents' representation do not align with the input space: their scores with the input are at lower values of $\rho_{S/I} =$

[2] We consider training successful if MVR $\geq$ 80%.

[3] Values averaged over the 96 successful seeds.

[4] Values averaged over the 4 failing seeds.

		Test		
		Same im.	Diff. im.	Noise
Train	Same im.	100	72	95
	Diff. im.	98	83	87

Table 1: Percentage average rewards on the same-image, different-image and noise test sets for agents trained in the same- and different-image games (chance level at 50%). For each game, values are averaged on 10 test runs consisting of $1,000$ games of mini-batches of 32 image pairs, using the cross-validated best seed.

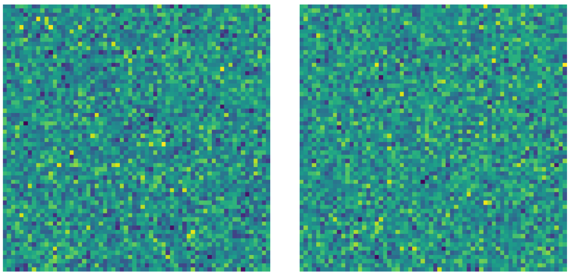

Figure 2: Noise vectors agents trained on the same-image game successfully communicate about.

0.40 and $\rho_{R/I} = 0.37$.[5] In case of communication failure, by the end of training their RSA score is at the lower value of $\rho_{S/R} = 0.74$, and their values with respect to the input are $\rho_{S/I} = 0.36$ and $\rho_{R/I} = 0.34$.[6] Again, same-concept images drift apart in agent space, although now to a lesser extent (1.94 z-normalized mean similarity in input space vs. 1.07 in Sender space). More encouragingly, we don't find the same pattern for within-class mean similarities (0.61 input space vs. 0.75 Sender space).

We must conjecture that the agents are comparing low-level properties of the image pairs, independently of the game they play. As an extreme way to test this, we look at how agents trained to play the two games behave when tested with input pairs that are just random noise vectors drawn from a standard Normal distribution.[7] If the agents are indeed indifferent to the objects represented by images, the radical shift in the nature of the input to the game should not affect them much.

Results are shown in Table 1. We confirm that the same-image game is the easiest, and we observe that agents trained in one game perform reasonably well on the other. More importantly, no matter which game they are trained on, the agents perform very well on noise input! This confirms our hypothesis that the Sender and Receiver are able to communicate about input data that contain no conceptual content at all, which in turn suggests that they haven't extracted any concept-level information (e.g., features that would allow them to recognize instances of the *dog* or *chair* category) during training. To get a sense of the sort of noise pairs agents succeed to communicate about, Figure 2 provides an example.

Finally, we draw $1,000$ noise pairs (z_1, z_2), and present each to the Sender with either z_1 or z_2 as target. We then compare, pair by pair, whether the highest probability symbol changes when the target is swapped. We average across 10 random runs using the best cross-validated seed. In both versions of the game, for more than 99% of the pairs, the symbol with highest probability changes when the target is swapped. This suggests that the agents perform a *relative* comparison of the two inputs, rather than an absolute one, in line with the general conclusion that they are not using the vocabulary to denote stable conceptual properties of the objects depicted in the images.

4 Discussion

Existing literature in game theory already showed that convergence towards successful communication is ensured under specific conditions (see Skyrms (2010) and references therein). However, the important contribution of Lazaridou et al. (2017) is to play a signaling game with real-life images instead of artificial symbols. This raises new empirical questions that are not answered by the general mathematical results, such as: When the agents do succeed at communicating, what are the input features they rely upon? Do the internal representations they develop relate to the conceptual properties of the input? Our study suggests that the agents' representations are not capturing general conceptual properties of different objects, but they are rather specifically tuned to successfully distinguish images based on inscrutable low-level relational properties.

Interestingly, our conclusions can be aligned with findings in psycholinguistic experimental literature on dialogue. In order to achieve communication, the agents develop a form of ''conceptual

---

[5] Values averaged over the 19 successful seeds.

[6] Values averaged over the 81 failing seeds.

[7] As during training inputs are divided by their norm, we also normalize each noise vector, so multiple noise variances would have no effect.

pact" (Brennan and Clark, 1996): Their internal representations align while at the same time drifting away from human-level properties of the input. The agents agree on a shared use of the vocabulary, that does not correspond to concepts in the input data.

In future work, we would like to encourage the development of more natural word meanings by enforcing the agent representations to stay more faithful to the perceptual input they receive. Moving ahead, it is fundamental to design setups where agents would have stronger reasons to develop human-like communication strategies.

Abstract

A capsule is a group of neurons, whose activity vector represents the instantiation parameters of a specific type of entity. In this paper, we explore the capsule networks used for relation extraction in a multi-instance multi-label learning framework and propose a novel neural approach based on capsule networks with attention mechanisms. We evaluate our method with different benchmarks, and it is demonstrated that our method improves the precision of the predicted relations. Particularly, we show that capsule networks improve multiple entity pairs relation extraction[1].

1 Introduction

This paper focus on the task of relation extraction. One popular method for relation extraction is the multi-instance multi-label learning framework (MIML) (Surdeanu et al., 2012) with distant supervision, where the mentions for an entity pair are aligned with the relations in Freebase (Bollacker et al., 2008). The recently proposed neural network (NN) models (Zeng et al., 2014; Ye et al., 2017; Yang et al., 2018; Wang et al., 2018a) achieve state-of-the-art performance. However, despite the great success of these NNs, some disadvantages remain. First, the existing models focus on, and heavily rely on, the quality of instance representation. Using a vector to represent a sentence is limited because languages are delicate and complex. Second, CNN subsampling fails to retain the precise spatial relationships between higher-level parts. The structural relationships such as the positions in sentences are valuable. Besides, existing aggregation operations summarizing the sentence meaning into a fixed-size vector such as max or average pooling are lack of guidance by task information. Self-attention (Lin et al., 2017) can select task-dependent information. However, the context vectors are fixed once learned (Gong et al., 2018).

More importantly, most state-of-the-art systems can only predict one most likely relation for a single entity pair. However, it is very common that one sentence may contain multiple entity pairs and describe multiple relations. It is beneficial to consider other relations in the context while predicting the relations (Sorokin and Gurevych, 2017). For example, given the sentence "*[**Swag It Out**] is the official debut single by American [**singer**] [**Zendaya**]*", our model can predict multi-relations for these multiple entity pairs simultaneously.

In our work, we present a novel architecture based on capsule networks (Sabour et al., 2017) for relation extraction. We regard the aggregation as a routing problem of how to deliver the messages from source nodes to target nodes. This process enables the capsule networks to decide what and how much information need to be transferred as well as identify complex and interleaved features. Furthermore, the capsule networks convert the multi-label classification problem into a multiple binary classification problem. We also import word-level attention by considering the different contribution of the words. The experimental results show that our model achieves improvements in both single and multiple relation extraction.

2 Related Work

Neural Relation Extraction: In the recent years, NN models have shown superior performance over approaches using hand-crafted features in various tasks. CNN is the first one of the deep learning models that have been applied to relation ex-

---

[1] In this paper, multiple entity pairs relation extraction refers to multiple entity pairs in a single sentence and each pair of entities contains only one relation label.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 986–992
Brussels, Belgium, October 31 - November 4, 2018.

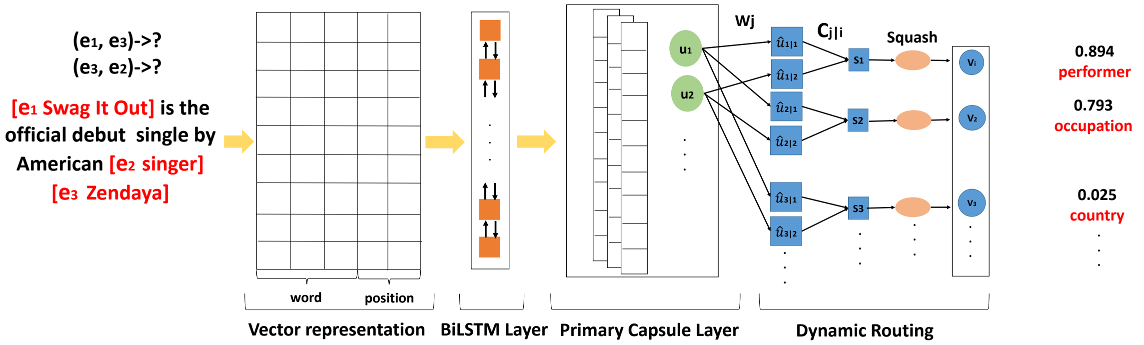

Figure 1: Architecture of capsule networks for relation extraction

traction (Santos et al., 2015). Variants of convolutional networks include piecewise-CNN (PCNN) (Zeng et al., 2015), instance-level selective attention CNN (Lin et al., 2016), rank CNN (Ye et al., 2017), attention and memory CNN (Feng et al., 2017) and syntax-aware CNN (He et al., 2018). Recurrent neural networks (RNN) are another popular choice, and have been used in recent works in the form of attention RNNs (Zhou et al., 2016), context-aware long short-term memory units (LSTMs) (Sorokin and Gurevych, 2017), graph-LSTMs (Peng et al., 2017) and ensemble LSTMs (Yang et al., 2018).

Capsule Network: Recently, the capsule network has been proposed to improve the representation limitations of CNNs and RNNs. (Sabour et al., 2017) replaced the scalar-output feature detectors of CNNs with vector-output capsules and max-pooling with routing-by-agreement. (Hinton et al., 2018)) proposed a new iterative routing procedure among capsule layers, based on the EM algorithm. For natural language processing tasks, (Zhao et al., 2018) explored capsule networks for text classification. (Gong et al., 2018) designed two dynamic routing policies to aggregate the outputs of RNN/CNN encoding layer into a final encoding vector. (Wang et al., 2018b) proposed a capsule model based on RNN for sentiment analysis. To the best of our knowledge, there has been no work that investigates the performance of capsule networks in relation extraction tasks at present.

3 Methodology

In this section, we first introduce the MIML framework, and then describe the model architecture we propose for relation extraction, which is shown in Figure 1.

3.1 Preliminaries

In MIML, the set of text sentences for the single entity pair or multiple entity pairs[2] (maximum two entity pairs in this paper) is denoted by $X = \{x_1, x_2, ..., x_n\}$. Assumed that there are E predefined relations (including NA) to extract. Formally, for each relation r, the prediction target is denoted by $P(r|x_1, ..., x_n)$.

3.2 Neural Architectures

Input Representation: For each sentence x_i, we use pretrained word embeddings to project each word token onto the d_w-dimensional space. We adopt the position features as the combinations of the relative distances from the current word to M entities and encode these distances in M d_p-dimensional vectors[3]. For single entity pair relation extraction, $M = 2$; for multiple entity pairs relation extraction, we limit the maximum number of entities in a sentence to four (i.e. two entity pairs). As three entities in one instance is possible when two tuples have a common entity, we set the relative distance to the missing entity to a very large number. Finally, each sentence is transformed into a matrix $x_i = \{w_1, w_2, ..., w_L\} \in R^{L \times V}$, where L is the sentence length with padding and $V = d_w + d_p * M$.

Bi-LSTM Layer: We make use of LSTMs to deeply learn the semantic meaning of a sentence. We concatenate the current memory cell hidden state vector h_t of LSTM from two directions as the output vector $h_t = [\overrightarrow{h}_t, \overleftarrow{h}_t] \in R^{2B}$ at time t, where B denotes the dimensionality of LSTM.

---

[2] Since the number of sentences with multiple entity pairs is relatively small, we make use of all the sentences as training samples.

[3] We also adopt an attention mechanism similar to word-level attention in Bi-LSTM layer by considering the different contribution of the M position embeddings.

We import word-level attention mechanism as only a few words in a sentence that are relevant to the relation expressed (Jat et al., 2018). The scoring function is $g_t = h_t \times A \times r$, where $A \in R^{E \times E}$ is a square matrix and $r \in R^{E \times 1}$ is a relation vector. Both A and r are learned. After obtaining g_t, we feed them to a softmax function to calculate the final importance $\alpha_t = softmax(g_t)$. Then, we get the representation $\tilde{x}_t = \alpha_t h_t$.

For a given bag of sentences, the learning is done using the setting proposed by (Zeng et al., 2015), where the sentence with highest probability of expressing the relation in a bag is selected to train the model in each iteration.

Primary Capsule Layer: Suppose $u_i \in R^d$ denotes the instantiated parameters set of a capsule, where d is the dimension of the capsule. Let $W^b \in R^{2 \times 2B}$ be the filter shared across different windows. We have a window sliding each 2-gram vector in the sequence $\tilde{x} \in R^{L \times 2B}$ with stride 1 to produce a list of capsules $U \in R^{(L+1) \times C \times d}$, totally $C \times d$ filters.

$$u_{ij} = squash(W_i^b \otimes S_{j-1:j} + b_1) \qquad (1)$$

where $0 \leq i \leq C \times d$, $0 \leq j \leq L+1$, $squash(x) = \frac{||x||^2}{0.5+||x||^2}\frac{x}{||x||}$, b_1 is the bias term. For all $C \times d$ filters, the generated capsule feature maps can be rearranged as $U = \{u_1, u_2, ..., u_{(L+1) \times C}\}$, where totally $(L+1) \times C$ d-dimensional vectors are collected as capsules.

Algorithm 1 Dynamic Routing Algorithm

```
procedure ROUTING($\hat{u}_{j|i}, \hat{a}_{j|i}, r, l$)
Initialize the logits of coupling coefficients $b_{j|i} = 0$
for $r$ iterations do
    for all capsule $i$ in layer $l$ and capsule $j$ in layer $l+1$ do
        $c_{j|i} = \hat{a}_{j|i} \cdot softmax(b_{j|i})$
    for all capsule $j$ in layer $l+1$ do
        $v_j = squash(\sum_i c_{j|i}\hat{u}_{j|i}), a_j = ||v_j||$
    for all capsule $i$ in layer $l$ and capsule $j$ in layer $l+1$ do
        $b_{j|i} = b_{j|i} + \hat{u}_{j|i} \cdot v_j$
return $v_j, a_j$
```

Dynamic Routing: We explore the transformation matrices to generate the prediction vector $u_{j|i} \in R^d$ from a child capsule i to its parent capsule j. The transformation matrices share weights $W^c \in R^{E \times d \times d}$ across the child capsules, where E is the number relations (parent capsules) in the layer above. Formally, each corresponding vote can be computed by:

$$\hat{u}_{j|i} = W_j^c u_i + \hat{b}_{j|i} \in R^d \qquad (2)$$

The basic idea of dynamic routing is to design a nonlinear map:

$$\{\hat{u}_{j|i} \in R^d\}_{i=1,...,H, j=1,...,E} \mapsto \{v_j \in R^d\}_{j=1}^{E}$$

where $H = (L+1) \times C$.

Inspired by (Zhao et al., 2018), we attempt to use the probability of existence of parent capsules to iteratively amend the connection strength, which is summarized in Algorithm 1. The length of the vector v_j represents the probability of each relation. We use a separate margin loss L_k for each relation capsule k:

$$\begin{aligned} L_k &= Y_k max(0, m^+ - ||v_k||)^2 \\ &+ \lambda(1 - Y_k) max(0, ||v_k|| - m^-)^2 \end{aligned} \qquad (3)$$

where $Y_k = 1$ if the relation k is present, $m^+ = 0.9$, $m^- = 0.1$ and $\lambda = 0.5$. The total loss can be formulated as: $L_{total} = \sum_{k=1}^{E} L_k$

3.3 Prediction

For single entity pair relation extraction, we calculate the length of the vector v_j which represents the probability of each relation. For multiple entity pairs relation extraction, we choose relations with top two probability meanwhile bigger than the threshold (We empirically set the threshold 0.7). Finally, we may get one or two predicted relations r. Given entity pair (e_1, e_2), in order to choose which relationship the tuple belongs to, we adopt the pretrained embeddings of entities and relations[4] and calculate $r_k = \arg\min_k |t - h - r_k|$, where t, h are the embeddings of entities e_1, e_2 respectively and r_k is the relation embedding. The relation with the closest embedding to the entity embedding difference is the predicted category.

4 Experiments

We test our model on the NYT dataset (NYT) developed by (Riedel et al., 2010) for single entity pair relation extraction and the Wikidata dataset (Sorokin and Gurevych, 2017) for multiple entity pairs relation extraction. We exclude sentences longer than L . All code is implemented in Tensorflow (Abadi et al., 2016). We adopt the Adam

---

[4] http://openke.thunlp.org

optimizer (Kingma and Ba, 2014) with learning rate 0.001, batch size 128, LSTMs' unit size 300, $L = 120$, $d_p = 5$, $d = 8$, $C = 32$, dropout rate 0.5, routing iteration 3.

4.1 Practical Performance

NYT dataset (Single entity pair):

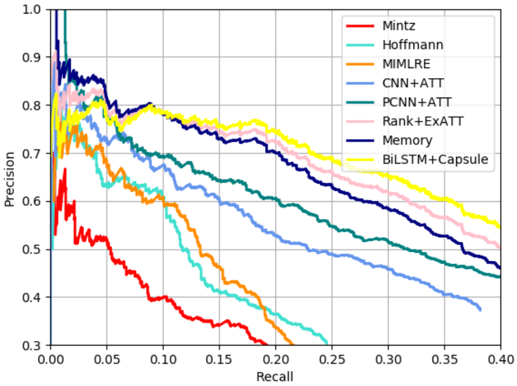

Figure 2: Performance comparison on the NYT dataset.

We utilize the word embeddings released by (Lin et al., 2016)[5]. The precision-recall curves for different models on the test set are shown in Figure 2. Our model BiLSTM+Capsule achieves comparable results compared with all baselines, where Mintz refers to (Mintz et al., 2009), Hoffmann refers to (Hoffmann et al., 2011), MIMLRE refers to (Surdeanu et al., 2012), CNN+ATT refers to (Zeng et al., 2015), PCNN+ATT refers to (Lin et al., 2016), Rank+ExATT refers to (Ye et al., 2017) and Memory refers to (Feng et al., 2017). We also show the precision numbers for some particular recalls as well as the AUC in Table 1, where our model generally leads to better precision. Interestingly, we observe our model achieve comparable results to predict multi-relation compared with Rank+ExATT in Figure 3. Given an entity tuple (South Korea, Seoul) which has two relations: /location/./administrative_divisions and /location/./capital. We observe these two relations have the highest scores among the other relations in our model which demonstrate the ability of multi-relations prediction.

Wikidata dataset (Multiple entity pairs):

We train word embeddings using Glove (Pennington et al., 2014)[6] on the Wikipedia Corpus.

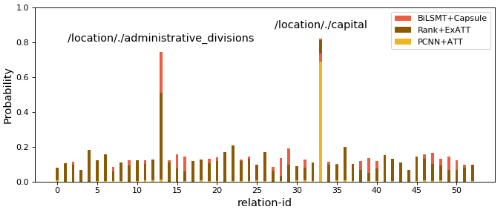

Figure 3: Normalized output relation scores.

Table 1: Precisions on the NYT dataset.

Recall	0.1	0.2	0.3	0.4	AUC
PCNN+ATT	0.698	0.606	0.518	0.446	0.323
Rank+ExATT	0.789	0.726	0.620	0.514	0.395
Our Model	0.788	**0.743**	**0.654**	**0.546**	**0.397**

We show the precision numbers for some particular recalls as well as the AUC in Table 2, where PCNN+ATT (1) refers to train sentences with two entities and one relation label, PCNN+ATT (m) refers to train sentences with four entities[7] and two relation labels. We observe that our model exhibits the best performances. Moreover, in the process of predicting the existence of relations for a sentence, our approach is more convenient , as the PCNN-ATT (1) has to predict all possible pairs of entities in the sentence while our approach can predict multiple relations simultaneously.

Table 2: Precisions on the Wikidata dataset.

Recall	0.1	0.2	0.3	AUC
Rank+ExATT	0.584	0.535	0.487	0.392
PCNN+ATT (m)	0.365	0.317	0.213	0.204
PCNN+ATT (1)	0.665	0.517	0.413	0.396
Our Model	0.650	0.519	0.422	**0.405**

Ablation study: To better demonstrate the performance of capsule net and attention mechanism, we remove the primary capsule layer and dynamic routing to make Bi-LSTM layer followed by a fully connected layer instead. We also remove the word-level attention separately. The experimental results on Wikidata dataset are summarized in Table 3. The results of "-Word-ATT" row refers to the results without word-level attention. According to the table, the drop of precision demonstrates that the word-level attention is quite useful. Generally, all two proposed strategies contribute to the effectiveness of our model.

---

[5] $d_w = 50$

[6] $d_w = 200$

[7] Two additional position embeddings.

Table 3: Ablation study of capsule net and word-level attention on Wikidata dataset.

Recall	0.1	0.2	0.3	AUC
-Word-ATT	0.648	0.515	0.395	0.389

Our Model	0.650	0.519	0.422	0.405

4.2 Discussion

CNN vs Capsule: Capsule networks achieve comparable results compared with baselines. In fact, the capsule combines features by clustering. A nonlinear map is constructed in an iterative manner, ensuring the output of each capsule to be sent to an appropriate parent in the subsequent layer. Dynamic routing may be more effective than the strategies such as max-pooling in CNN, which essentially detects whether a feature is present in any position of the text or not, but loses spatial information of the feature. Additionally, capsule achieves comparable results to predict multi-relations in the case of single entity pair, and performs better in the case of multiple entity pairs relation extraction.

Choice of d: In the experiments, the larger the dimension of the capsule, the more the capabilities of the feature information it contains. However, larger dimension increases the computational complexity. We test different levels of dimensions of capsules. The model is trained on two Nvidia GTX1080ti GPUs with 64G RAM and six Intel(R) Core(TM) i7-6850K CPU 3.60GHz. As the table 4 depicts, the training time increases with the growth of d. When $d = 32$, we observe that the loss decreases very slowly and the model is difficult to converge. So we only train 2 epochs and stop training. We set the parameter $d = 8$ empirically to balance the precision and training time cost.

Table 4: Precisions on the Wikidata dataset with different choice of d.

Recall	0.1	0.2	0.3	AUC	Time
$d = 1$	0.602	0.487	0.403	0.367	4h
$d = 32$	0.645	0.501	0.393	0.370	-
$d = 16$	0.655	0.518	0.413	0.413	20h
$d = 8$	0.650	0.519	0.422	0.405	8h

Effects of Iterative Routing:

We also study how the iteration number affect the performance on the Wikidata dataset. Table 5 shows the comparison of 1 - 5 iterations. We find that the performance reach the best when iteration is set to 3. The results indicate the dynamic routing is contributing to improve the performance. Specifically, in the iteration algorithm, the $b_{j|i} = b_{j|i} + \hat{u}_{j|i} \cdot v_j$. When the number of iteration is very large, v_j becomes either 0 or 1, which means each underlying capsule is only linked to a single upper capsule. Therefore, the iteration times should not be too large.

Table 5: Precisions on the Wikidata dataset with different number of dynamic routing iterations.

Recall	0.1	0.2	0.3	AUC
Iteration=1	0.531	0.455	0.353	0.201
Iteration=2	0.592	0.498	0.385	0.375
Iteration=3	0.650	0.519	0.422	0.405
Iteration=4	0.601	0.505	0.422	0.385
Iteration=5	0.575	0.495	0.394	0.376

4.3 Conclusion

We propose a relation extraction approach based on capsule networks with attention mechanism. Although we use Bi-LSTM as sentence encoding in this paper, the other encoding method, such as convolved n-gram, could be alternatively used. Experimental results of two benchmarks show that the model improves the precision of the predicted relations.

In the future, we tend to resolve the situation of how to assign predicted relationship to multi entity pairs when two entities have multi-relations by utilizing prior knowledge such as entity type and joint training with named entity recognition. We will also try to optimize the model in terms of speed and focus on other problems by leveraging class ties between labels, specially on multi-label learning problems. Besides, dynamic routing could also be useful to improve other natural language processing tasks such as the sequence-to-sequence task and so on.

Abstract

Entity typing aims to classify semantic types of an entity mention in a specific context. Most existing models obtain training data using distant supervision, and inevitably suffer from the problem of noisy labels. To address this issue, we propose entity typing with language model enhancement. It utilizes a language model to measure the compatibility between context sentences and labels, and thereby automatically focuses more on context-dependent labels. Experiments on benchmark datasets demonstrate that our method is capable of enhancing the entity typing model with information from the language model, and significantly outperforms the state-of-the-art baseline. Code and data for this paper can be found from `https://github.com/thunlp/LME`.

1 Introduction

Entity typing classifies semantic types of an entity mention in a context sentence, and can be beneficial for a large number of natural language processing tasks (Neelakantan and Chang, 2015), such as entity linking (Chabchoub et al., 2016), relation extraction (Miwa and Sasaki, 2014), and question answering (Yahya et al., 2013). Fine-grained entity typing (FET) (Ling and Weld, 2012; Yosef et al., 2012; Yao et al., 2013; Gillick et al., 2014; Del Corro et al., 2015; Yogatama et al., 2015; Yaghoobzadeh and Schütze, 2015; Ren et al., 2016a; Yuan and Downey, 2018) is based on a large set of fine-grained types and is therefore more challenging. So far, neural models (Dong et al., 2015; Shimaoka et al., 2017; Xin et al., 2018) have achieved state-of-the-art results on FET.

All current FET models rely on distant supervision (DS) (Mintz et al., 2009) to obtain training data, due to the lack of large-scale human-labeled data. Such reliance on DS has been a significant problem for entity typing. In DS, an entity mention in the context sentence is first linked to a named entity in the knowledge base (KB). The entity has type labels[1] stored in the KB, and all labels will be assigned to this entity mention. In other words, these are noisy global labels without considering the specific context of the entity mention. On the other hand, entity typing aims to predict context-dependent types of the entity mention, and test datasets are all human-labeled. The difference between DS and human annotation leads to a huge gap in performances between training/development and test dataset.[2]

Raw	**Schwarzenegger** was elected to be the governor. **Schwarzenegger** acted in the film *Terminator*.

Bad	(An) `actor` was elected to be the governor. (A) `politician` acted in the film *Terminator*.

Table 1: Examples of entity mention—type name replacement.

To address this problem, we propose Entity Typing with **L**anguage **M**odel **E**nhancement (LME). It is able to measure the compatibility between the context sentence and each distantly supervised label, in an *unsupervised* manner using meaning of the label.

In previous works, the hierarchical structure of labels has been considered (Ren et al., 2016b; Karn et al., 2017; Xu and Barbosa, 2018). However, to the best of our knowledge, precious

---

[1] Since entities are classified into labels of types, *type* and *label* have the same meaning in this paper.

[2] In the WIKI dataset, strict accuracies and macro-F1 scores are respectively 72.3%/89.2% on the development set and 59.7%/79.0% on the test set, using the model NFGEC from (Shimaoka et al., 2017).

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 993–998
Brussels, Belgium, October 31 - November 4, 2018.

information inside names of labels has never been used. For example, whether the label is `/person/actor` or `/foo/bar` makes no difference. We argue that, the meaning of entity mention words can also be expressed by the name of its **context-dependent type**, to some extent. Based on this argument, replacements with context-dependent types make more sense than those with global-but-context-irrelevant ones. We provide an example in Table 1. The entity *Schwarzenegger* has types `/actor` and `/politician`, and we can see that replacements with context-dependent types produce better sentences.

The natural way to evaluate the soundness of sentences is language modeling (Bengio et al., 2003; Mikolov et al., 2010). Our method employs a language model to evaluate the soundness of each synthetic sentence generated by replacing the entity mention with its type's name. It is able to focus more on context-dependent types.

We conduct experiments to compare our model with the state-of-the-art baseline on two widely used datasets. The results demonstrate that LME is capable of improving entity typing systems by considering the meaning of labels, and alleviating the problem of noise in distantly-supervised entity typing.

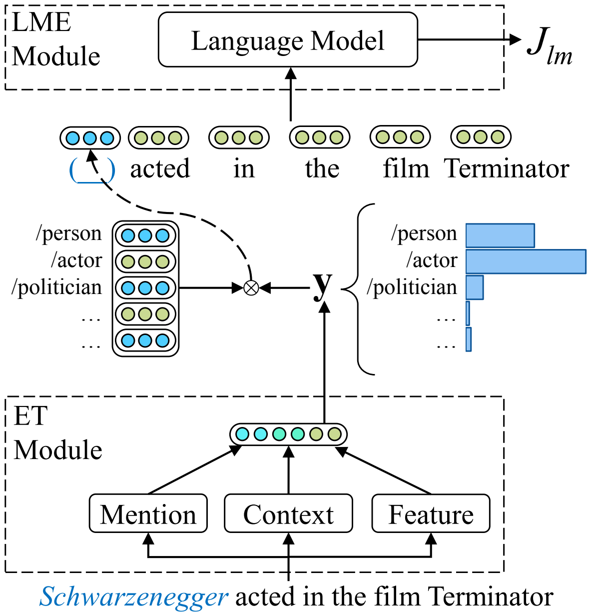

Figure 1: Our model: an entity typing (ET) module and a language model enhancement (LME) module.

2 Model

Our model (Figure 1) consists of two parts: an entity typing (ET) module, and a language model enhancement (LME) module.

ET predicts a probability distribution vector $\mathbf{y}$ for an entity mention, where each entry $\mathbf{y}_i$ represents the predicted probability for each type label.

In the training phase, LME optimizes a language model whose input includes $\mathbf{y}$, and also back-propagates gradients through $\mathbf{y}$ to parameters inside ET. In the testing phase, LME is **not** involved and $\mathbf{y}$ is directly used for inference: if $\mathbf{y}_i$ is greater than a threshold 0.5, the i$^{\text{th}}$ type is considered true; if all entries are below the threshold, the type with the greatest entry is considered true.

2.1 Entity Typing Module

Entity typing is defined on an ontology $\mathcal{T}$ (the set of all labels). Given an entity mention e and its context sentence $s = \{l_1, l_2, ..., e, r_1, r_2, ...\}$ (l_i and r_i are left and right context words), the typing model predicts a vector $\mathbf{y}$ indicating the probability distribution over all labels in the ontology:

$$\mathbf{y} = \sigma(\mathbf{W}_y \; [\mathbf{v}_M; \mathbf{v}_C; \mathbf{v}_F]), \qquad (1)$$

where σ is the sigmoid function, $\mathbf{W}_y$ is a parameter matrix, and $[;;]$ denotes concatenation. Three vectors: **M**ention, **C**ontext and **F**eature, are built from e and s as follows:

Entity mention vector There may be multiple words $e_1, e_2, ...$ in the entity mention, and $\mathbf{v}_M$ is the average of word embeddings of these words.

Context vector Two bi-directional LSTMs (Hochreiter and Schmidhuber, 1997; Schuster and Paliwal, 1997) are used for left and right context words. The outputs of BiLSTMs further go through a self-attention layer. $\mathbf{v}_C$ is the concatenation of the attention-layer outputs.

Hand-crafted feature vector A sparse feature vector $\mathbf{f}$ is built from the entity mention e. The features are adopted from those used by Gillick et al. (2014) and Yogatama et al. (2015). $\mathbf{v}_F$ is a dense projection of $\mathbf{f}$:

$$\mathbf{v}_F = \mathbf{W}_f \mathbf{f}, \qquad (2)$$

where $\mathbf{W}_f$ is the projection matrix.

After $\mathbf{y}$ is calculated, DS provides a label vector $\mathbf{y}^* \in \{0,1\}^{|\mathcal{T}|}$, where $|\mathcal{T}|$ is the number of labels. The loss function for typing is the cross-entropy between $\mathbf{y}$ and $\mathbf{y}^*$:

$$J_{type} = H(\mathbf{y}^*, \mathbf{y}) \\ = -\sum_i y_i^* \log(y_i) + (1 - y_i^*) \log(1 - y_i), \tag{3}$$

2.2 Language Model Enhancement Module

The core part of the LME module is an LSTM language model (Sundermeyer et al., 2012). The language model takes a sentence $\{w_1, w_2, ..., w_n\}$ as input, and assigns a probability to this sentence. Concretely, at step i, the LSTM reads the word sub-sequence $\{w_1, ..., w_i\}$, and predicts the probability of w_{i+1} succeeding the sub-sequence. A well trained language model predicts high probability for a reasonable sentence.

Before applying the LME module to enhance the ET module, the language model is pre-trained with sentences from the training set. The loss function for s in the pre-train phase is:

$$J_{pre} = \texttt{LM}(\{\mathbf{l}_1, \mathbf{l}_2, ..., \mathbf{e}, \mathbf{r}_1, \mathbf{r}_2, ...\}), \tag{4}$$

where bold face letters are word embeddings for corresponding words. $\texttt{LM}(\cdot)$ is the language model loss function: accumulative step-wise log-probability of each word of the input sequence. A well-trained language model calculates smaller loss for a more reasonable sentence.

After pre-training the language model, the LME module is combined with the ET module. Concretely, we assign an embedding vector $\mathbf{L}_i$ for each label, and take the sum of label embeddings weighted by $\mathbf{y}$. The sum $\mathbf{h}$ replaces $\mathbf{e}$ in the input sequence of the language model:

$$\mathbf{h} = \sum_{i=1}^{T} \mathbf{y}_i \mathbf{L}_i, \tag{5}$$

$$J_{lm} = \texttt{LM}(\{\mathbf{l}_1, \mathbf{l}_2, ..., \mathbf{h}, \mathbf{r}_1, \mathbf{r}_2, ...\}), \tag{6}$$

where $\mathbf{L}$ is the matrix of all label embeddings, and J_{lm} is loss function of the language model used in the training phase. In order to ensure that label embeddings are in the same semantic space with word embeddings, $\mathbf{L}$ is initialized with word embeddings of the labels' names.

In the training phase, parameters of the ET module are updated w.r.t.

$$J_{train} = J_{type} + \lambda J_{lm}, \tag{7}$$

where λ is the weight to balance the loss.

The ET module has a much smaller parameter space than the language model. In order to make full use of the gradients, we only update parameters of the ET module and **fix** the language model in the training phase. Now that the language model is fixed, when J_{lm} is being minimized, it adjusts the probability distribution in $\mathbf{y}$. If a label i is compatible with the context sentence, its corresponding entry $\mathbf{y}_i$ is expected to have a high value. Gradients are back-propagated through $\mathbf{y}$ and update parameters of the ET module. In this way, $\mathbf{y}$ can learn to be more context-dependent.

3 Experiments

3.1 Dataset

We employ two well-established and widely-used dataset for evaluating our model: WIKI (Ling and Weld, 2012) and ONTONOTES (Gillick et al., 2014).

Training parts of both datasets are labeled with DS, and testing parts are annotated by human. Therefore they are suitable for evaluating how our model can narrow the gap between DS and ground-truth context-dependent labels. Statistics of the two datasets are provided in Table 2.

Dataset	Train	Development	Test
WIKI	2,000,000	10,000	563
ONTONOTES	251,039	2,202	8,963

Table 2: Number of instances in each part of datasets.

3.2 Experiment Settings

The baseline for comparison is the hybrid model NFGEC proposed by Shimaoka et al. (2017). It is described as the ET module of our model. Our own model is referred to as NFGEC+LME.

We implement our model based on the source code of NFGEC.[3] For a fair comparison, the ET module is unchanged, including all hyperparameters and methods of parameter random initialization. Word embeddings are initialized with pre-trained embeddings provided by Pennington et al. (2014).

There are a few additional hyperparameters in our model. The most important one is λ, the weight between two parts of the loss function. Other ones include the learning rate r for pretraining the language model and the hidden size h of LSTM used in the language model. We perform

---

[3] `https://github.com/shimaokasonse/NFGEC`

a grid-search based on performances on the development set, and set $r = 0.005$ and $h = 500$. Details of λ will be discussed in Section 3.4.

3.3 Overall Results

We compare vanilla NFGEC and NFGEC+LME in Table 3. The results of NFGEC come from the paper by Shimaoka et al. (2017). For running NFGEC+LME, λ is set to 0.005 in WIKI and 0.001 in ONTONOTES.

Evaluation metrics include strict accuracy, macro-F1 score and micro-F1 score (Ling and Weld, 2012).

Dataset	WIKI			ONTONOTES		
Metric	**Strict**	Macro	Micro	**Strict**	Macro	Micro
NFGEC	59.68	78.97	75.36	50.89	70.80	64.93
+LME	62.88	80.61	76.95	52.90	72.41	65.17

Table 3: Performance of entity typing, evaluated by strict accuracy, macro-F1 and micro-F1 score. (%)

From the results we see that:

(1) In both datasets, LME consistently helps NFGEC to better classify entity mentions into their context-dependent types. We can see improvements in all metrics. This is because LME is capable of evaluating the appropriateness of each label and distinguishing context-dependent ones from global-but-context-irrelevant ones. Therefore LME helps the system to focus on more reasonable types.

(2) Among all metrics, the improvement on strict accuracy is the most significant. Strict accuracy is the proportion of entity mentions whose predicted types are completely identical with human annotation. It is therefore the most important metric for evaluating how robust the system is against noisy labels. The ability of LME alleviating noises from DS contributes to improving strict accuracy most.

3.4 Analysis of λ

We choose the optimal λ values for results in Table 3 according to their performances on the *development* set. After they are chosen, we compare the results on the *test* set under different values of λ in Figure 2.

Conclusions from the previous subsection can be seen again: when λ is set to a proper value, our model can consistently outperform the baseline over all metrics; strict accuracy is the metric with the most significant improvements.

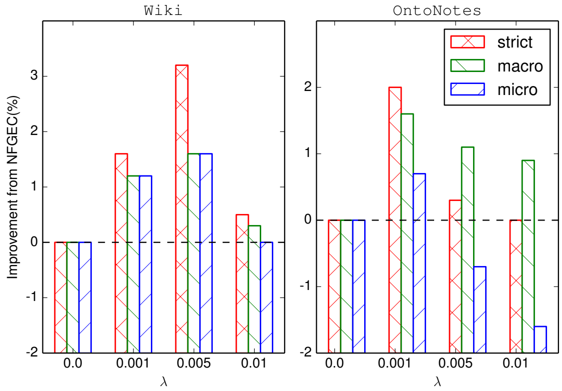

Figure 2: The performance under different λ values. $\lambda = 0$ is the vanilla NFGEC. Note that values of the vertical axis are improvements compared to vanilla NFGEC.

Also, we notice that the performances deteriorate when λ grows too large, and may even be worse than the baseline. The reason is that LME is a kind of *regularization*: its role is only in the training phase, exchanging the performance on training set with that on test set. So λ, as a regularization coefficient, must be carefully chosen.

3.5 Qualitative Analysis

In order to have an intuitive feeling of the model, we provide an example of LME's effect.

In the following sentence (from the test set of WIKI), both models try to predict the type of **Lake Placid** which, in this very context, is a town in New York. We show all labels with at least one score over the threshold 0.5, or is annotated true by human in Table 4.

> *Scaringe dismissed Brian Barrett of **Lake Placid** as one of his defense attorneys.*

Type	NFGEC	+LME	Human
`/person`	0.622	0.150	False
`/location`	0.323	0.627	True
`/location/city`	0.024	0.208	True

Table 4: An example, showing the scores by two models as well as human annotation.

NFGEC predicts a high score for `/person` and a low score for `/location`, probably because both words of the entity mention are first-letter capitalized and thus look like a person's name. LME, however, may consider the sentence structure *person of location* to be more reasonable than *person of person*, and makes the correct judgment between these two labels. As for `/location/city`, LME also shows higher confidence than NFGEC, but it is still regretfully below the threshold. This also demonstrates a weakness of LME: limited by the performance of the ET module. Addressing this limitation can be considered as a future direction for improvement.

4 Conclusion

In this paper, we propose a novel architecture LME to improve entity typing systems. It utilizes a language model and a set of label embeddings to judge the compatibility between labels and context sentences, and reduces noises introduced by DS. Experiments demonstrate that LME is capable of helping NFGEC, a state-of-the-art entity typing model, to alleviate the problem of noisy labels, and reaching a new state-of-the-art performance. Since the LME module does not depend on the ET module, we are confident that LME can be adapted to other entity typing systems as well.

Future Work Utilizing meaning of labels to alleviate the problem of noises from DS is an interesting direction. We make the first attempt in this paper, and we believe the direction is worth further exploring. For example, (1) how to train a language model that is sensitive with incorrect labels; (2) how to combine meaning of labels with the hierarchical structure of types; (3) how to find the optimal λ easily for a new dataset. LME may also be extended to other tasks that also suffer from noises and incompleteness of DS, such as relation extraction (Takamatsu et al., 2012; Ritter et al., 2013; Lin et al., 2016). However, since a relation does not have a specific location in the sentence, it needs more effort than a simple replacement.

Abstract

Detecting events and classifying them into predefined types is an important step in knowledge extraction from natural language texts. While the neural network models have generally led the state-of-the-art, the differences in performance between different architectures have not been rigorously studied. In this paper we present a novel GRU-based model that combines syntactic information along with temporal structure through an attention mechanism. We show that it is competitive with other neural network architectures through empirical evaluations under different random initializations and training-validation-test splits of ACE2005 dataset.

1 Introduction

Events are the lingua franca of news stories and narratives and describe important changes of state in the world. Identifying events and classifying them into different types is a challenging aspect of understanding text. This paper focuses on the task of *event detection*, which includes identifying the "trigger" words that indicate events and classifying the events into refined types. Event detection is the necessary first step in inferring more semantic information about the events including extracting the arguments of events and recognizing temporal and causal relationships between different events.

Neural network models have been the most successful methods for event detection. However, most current models ignore the syntactic relationships in the text. One of the main contributions of our work is a new DAG-GRU architecture (Chung et al., 2014) that captures the context and syntactic information through a bidirectional reading of the text with dependency parse relationships. This generalizes the GRU model to operate on a graph by novel use of an attention mechanism.

Following the long history of prior work on event detection, ACE2005 is used for the precise definition of the task and the data for the purposes of evaluation. One of the challenges of the task is the size and sparsity of this dataset. It consists of 599 documents, which are broken into a training, development, testing split of 529, 30, and 40 respectively. This split has become a de-facto evaluation standard since (Li et al., 2013). Furthermore, the test set is small and consists only of newswire documents, when there are multiple domains within ACE2005. These two factors lead to a significant difference between the training and testing event type distribution. Though some work had been done comparing method across domains (Nguyen and Grishman, 2015), variations in the training/test split including all the domains has not been studied. We evaluate the sensitivity of model accuracy to changes in training and test set splits through a randomized study.

Given the limited amount of training data in comparison to other datasets used by neural network models, and the narrow margin between many high performance methods, the effect of the initialization of these methods needs to be considered. In this paper, we conduct an empirical study of the sensitivity of the system performance to the model initialization.

Results show that our DAG-GRU method is competitive with other state-of-the-art methods. However, the performance of all methods is more sensitive to the random model initialization than expected. Importantly, the ranking of different methods based on the performance on the standard training-validation-test split is sometimes different from the ranking based on the average over multiple splits, suggesting that the community should move away from single split evaluations.

2 Related Work

Event detection and extraction are well-studied tasks with a long history of research.

Nguyen and Grishman (2015) used CNNs to represent windows around candidate triggers. Each word is represented by a concatenation of its word and entity type embeddings with the distance to candidate trigger. Global max-pooling summarizes the CNN filter and the result is passed to a linear classifier.

Nguyen and Grishman (2016) followed up with a skip-gram based CNN model which allows the filter to skip non-salient or otherwise unnecessary words in the middle of word sequences.

Feng et al. (2016) combined a CNN, similar to (Nguyen and Grishman, 2015), with a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) to create a hybrid network. The output of both networks was concatenated together and fed to a linear model for final predictions.

Nguyen et al. (2016) uses a bidirectional gated recurrent units (GRUs) for sentence level encoding, and in conjunction with a memory network, to jointly predict events and their arguments.

Liu et al. (2016) created a probablistic soft logic model incorporating the semantic frames from Framenet (Baker et al., 1998) in the form of extra training examples. Based on the intuition that entity and argument information is important for event detection, Liu et al. (2017) built an attention model over annotated arguments and the context surrounding event trigger candidates.

Liu et al. (2018) created a cross language attention model for event detection and used it for event detection in both the English and Chinese portions of the ACE2005 data.

Recently, Nguyen and Grishman (2018) used graph-CNN (GCCN) where the convolutional filters are applied to syntactically dependent words in addition to consecutive words. The addition of the entity information into the network structure produced the state-of-the-art CNN model.

Another neural network model that includes syntactic dependency relationships is DAG-based LSTM (Qian et al., 2018). It combines the syntactic hidden vectors by weighted average and adds them through a dependency gate to the output gate of the LSTM model. To the best of our knowledge, none of the neural models combine syntactic information with attention, which motivates our research.

3 DAG GRU Model

Event detection is often framed as a multi-class classification problem (Chen et al., 2015; Ghaeini et al., 2016). The task is to predict the event label for each word in the test documents, and *NIL* if the word is not an event. A sentence is a sequence of words $x_1 \ldots x_n$, where each word is represented by a k-length vector. The standard GRU model works as follows:

$$
\begin{aligned}
r_t &= \sigma(W_r x_t + U_r h_{t-1} + b_r) \\
z_t &= \sigma(W_z x_t + U_z h_{t-1} + b_z) \\
\tilde{h}_t &= \tanh(W_h x_t + r_t \odot U_h h_{t-1} + b_h) \\
h_t &= (1 - z_t) \odot h_{t-1} + z_t \odot \tilde{h}_t
\end{aligned}
$$

The GRU model produces a hidden vector h_t for each word x_t by combining its representation with the previous hidden vector. Thus h_t summarizes both the word and its prior context.

Our proposed DAG-GRU model incorporates syntactic information through dependency parse relationships and is similar in spirit to (Nguyen and Grishman, 2018) and (Qian et al., 2018). However, unlike those methods, DAG-GRU uses attention to combine syntactic and temporal information. Rather than using an additional gate as in (Qian et al., 2018), DAG-GRU creates a single combined representation over previous hidden vectors and then applies the standard GRU model. Each relationship is represented as an edge, (t, t', e), between words at index t and t' with an edge type e. The standard GRU edges are included as $(t, t-1, temporal)$.

Each dependency relationship may be between any two words, which could produce a graph with cycles. However, back-propagation through time (Mozer, 1995) requires a directed acyclic graph (DAG), Hence the sentence graph, consisting of temporal and dependency edges E, is split into two DAGs: a “forward” DAG G_f that consists of only of edges (t, t', e) where $t' < t$ and a corresponding “backward” DAG G_b where $t' > t$. The dependency relation between t and t' also includes the parent-child orientation, e.g., $nsubj\text{-}parent$ or $nsubj\text{-}child$ for a $nsubj$ (subject) relation.

An attention mechanism is used to combine the multiple hidden vectors. The matrix D_t is formed at each word x_t by collecting and transforming all the previous hidden vectors coming into node t, one per each edge type e. α gives the attention, a distribution weighting importance over the edges.

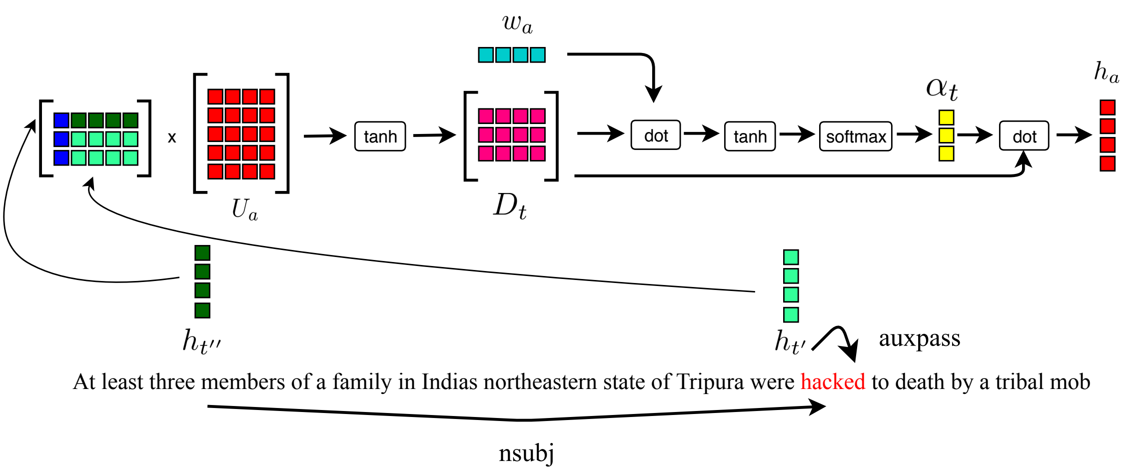

Figure 1: The hidden state of "hacked" is a combination of previous output vectors. In this case, three vectors are aggregated with DAG-GRU's attention model. $h_{t''}$, is included in the input for the attention model since it is accessible through the "subj" dependency edge. $h_{t'}$ is included twice because it is connected through a narrative edge and a dependency edge with type "auxpass." The input matrix is non-linearly transformed by U_a and tanh. Next, w_a determines the importance of each vector in D_t. Finally, the attention a_t is produced by tanh followed by softmax then applied to D_t. The subject "members" would be distant under a standard RNN model, however the DAG-GRU model can focus on this important connection via dependency edges and attention.

Finally, the combined hidden vector h_a is created by summing D_t weighted by attention.

$$D_t^T = [\tanh(U_e h_{t'}) | (t, t', e) \in E]$$
$$\alpha = \text{softmax}(\tanh(D_t w_a))$$
$$h_a = D_t^T \alpha$$

However, having a set of parameters U_e for each edge type e is over-specific for small datasets. Instead a shared set of parameters U_a is used in conjunction with an edge embedding v_e.

$$D_t^T = [\tanh(U_a h_{t'} \circ v_e) | (t, t', e) \in E]$$

The edge type embedding v_e is concatenated with the hidden vector $h_{t'}$ and then transformed by the shared weights U_a. This limits the number of parameters while flexibly weighting the different edge types. The new combined hidden vector h_a is used instead of h_{t-1} in the GRU equations.

The model is run forward and backward with the output concatenated, $h_{c,t} = h_{f,t} \odot h_{b,t}$, for a representation that includes the entire sentence's context and dependency relations. After applying dropout (Srivastava et al., 2014) with 0.5 rate to $h_{c,t}$, a linear model with softmax is used to make predictions for each word at index t.

4 Experiments

We use the ACE2005 dataset for evaluation. Each word in each document is marked with one of the thirty-three event types or *Nil* for non-triggers. Several high-performance models were reproduced for comparison. Each is a good faith reproduction of the original with some adjustments to level the playing field.

For word embeddings, Elmo was used to generate a fixed representation for every word in ACE2005 (Peters et al., 2018). The three vectors produced per word were concatenated together for a single representation. We did not use entity type embeddings for any method. The models were trained to minimize the cross entropy loss with Adam (Kingma and Ba, 2014) with L2 regularization set at 0.0001. The learning rate was halved every five epochs starting from 0.0005 for a maximum of 30 epochs or until convergence as determined by F1 score on the development set.

The same training method and word embeddings were used across all the methods. Based on preliminary experiments, these settings resulted in better performance than those originally specified. However, notably both GRU (Nguyen et al., 2016) and DAG-LSTM (Qian et al., 2018) were not used as joint models. Further, the GRU implementation did not use a memory network, instead we used the final vectors from the forward and backward pass concatenated to each timestep's output for additional context. For CNNs (Nguyen and Grishman, 2015) the number of filters was reduced to 50 per filter size. The CNN+LSTM (Feng et al.,

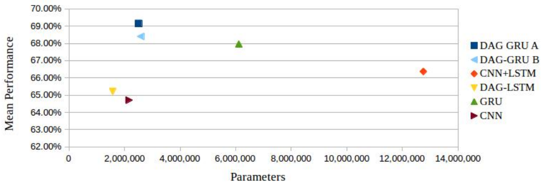

Figure 2: A comparison of mean performance versus number of parameters.

2016) model had no other modifications. DAG-GRU used a hidden layer size of 128. Variant A of the DAG-GRU model utilized the attention mechanism, while variant B used averaging, that is:

$$D_t = \frac{1}{|E(t)|} \sum_{(t',e) \in E(t)} \tanh(U_a h_{t'} \circ v_e)$$

4.1 Effects of Random Initialization

Given that ACE2005 is small as far as neural network models are concerned, the effect of the random initialization of these models needs to be studied. Although some methods include tests of significance, the type of statistical test is often not reported. Simple statistical significance tests, such as the t-test, are not compatible with a single F1 score, instead the average of F1 scores should be tested (Wang et al., 2015).

We reproduced and evaluated five different systems with different initializations to empirically assess the effect of initialization. The experiments were done on the standard ACE2005 split and the aggregated results over 20 random seeds were given in Table 1. The random initializations of the models had a significant impact on their performance. The variation was large enough that the observed range of the F1 scores overlapped across almost all the models. However the differences in average performances of different methods, except for CNN and DAG-LSTM, were significant at $p < 0.05$ according to the t-test, not controlling for multiple hypotheses.

Both the GRU (Nguyen et al., 2016) and CNN (Nguyen and Grishman, 2015) models perform well with their best scores being close to the reported values. The CNN+LSTM model's results were significantly lower than the published values, though this method has the highest variation. It is possible that there is some unknown factor such as the preprocessing of the data that significantly impacted the results or that the value is an outlier. Likewise, the DAG-LSTM model underperformed. However, the published results were based on a joint event and argument extraction model and probably benefited from the additional entity and argument information.

DAG-GRU A consistently and significantly outperforms the other methods in this comparison. The best observed F1 score, 71.1%, for DAG-GRU is close to the published state-of-the-art scores of DAG-LSTM and GCNN at 71.9% and 71.4% respectively. With additional entity information, GCNN achieves a score of 73.1%. Also, the attention mechanism used in DAG-GRU A shows a significant improvement over the averaging method of DAG-GRU B. This indicates that some syntactic links are more useful than others and that the weighting attention applies is necessary to utilize that syntactic information.

Another source of variation was the distributional differences between the development and testing sets. Further, the testing set only include newswire articles whereas the training and dev. sets contain informal writing such as web log (WL) documents. The two sets have different proportions of event types and each model saw at least a 2% drop in performance between dev. and test on average. At worst, the DAG-LSTM model's drop was 5.26%. This is a problem for model selection, since the dev. score is used to choose the best model, hyperparameters, or random initialization. The distributional differences mean that methods which outperform others on the dev. set do not necessarily perform as well on the test set. For example, DAG-GRU A performs worse that DAG-GRU B on the dev. set, however it achieves a higher mean score on the testing set.

One method of model selection over random initializations is to train the model k times and pick the best one based on the dev. score. Repeating this model selection procedure many times for each model is prohibitively expensive, so the experiment was approximated by bootstrapping the twenty samples per model (Efron, 1992). For each model, 5 dev. & test score pairs were sampled with replacement from the twenty available pairs. The initialization with the best dev. score was selected and the corresponding test score was taken. This model selection process of picking the best of 5 random samples was repeated 1000 times and the results are shown in Table 2. This process did not substantially increase the average performance beyond the results in Table 1, although it did reduce the variance, except for the CNN model. It ap-

Model	Dev Mean	Mean	Min	Max	Std. Dev.	Published

Table 2: Bootstrap estimates on 1000 samples for each model after model selection based on dev set scores.

pears that using the dev. score for model selection is only marginally helpful.

4.2 Randomized Splits

In order to explore the effect of the training/testing split popularized by (Li et al., 2013), a randomized cross validation experiment was conducted. From the set of 599 documents in ACE2005, 10 random splits were created maintaining the same 529, 30, 40 document counts per split, training, development, testing, respectively. This method was used to evaluate the effect of the standard split, since it maintains the same data proportions while only varying the split. The results of the experiment are found in Table 3.

The effect of the split is substantial. Almost all models' performance dropped except for DAG-LSTM, however the variance increased across all models. In the worst case, the standard deviation increased threefold from 0.86% to 2.60% for the GRU model. In fact, the increased variation of the splits means that the confidence intervals for all the models overlap. This aligns with cross domain analysis, some domains such as WL are known to be much more difficult than the newswire domain which comprises all of the test data under the standard split (Nguyen and Grishman, 2015). Further, the effect of the difference in splits also negates the benefits of the attention mechanism of DAG-GRU A. This is likely due to the test partitions' inclusion of WL and other kinds of informal writing. The syntactic links are much more likely to be noisy for informal writing, reducing the syntactic information's usefulness and reliability.

Method	Dev Mean	Mean	Min	Max	Std. Dev.
DAG-GRU A	71.4%	68.4% ± 1.85%	65.7%	74.1%	2.59%
DAG-GRU B	70.9%	68.4% ± 1.88%	64.19%	73.59	2.63%
DAG-LSTM	68.9%	67.3% ± 1.43%	63.5%	70.7%	2.00%
GRU	69.8%	66.6% ± 1.86%	62.5%	71.1%	2.60%
CNN+LSTM	69.8%	66.3% ± 2.03%	60.1%	70.3%	2.83%
CNN	68.0%	65.4% ± 1.59%	60.7%	69.2%	2.22%

Table 3: Average results on 10 randomized splits.

All these sources of variation are greater than most advances in event detection, so quantifying and reporting this variation is essential when assessing model performance. Further, understanding this variation is important for reproducibility and is necessary for making any valid claims about a model's relative effectiveness.

5 Conclusions

We introduced and evaluated a DAG-GRU model along with four previous models in two different settings, the standard ACE2005 split with multiple random initializations and the same dataset with multiple random splits. These experiments demonstrate that our model, which utilizes syntactic information through an attention mechanism, is competitive with the state-of-the-art. Further, they show that there are several significant sources of variation which had not been previously studied and quantified. Studying and mitigating this variation could be of significant value by itself. At a minimum, it suggests that the community should move away from evaluations based on single random initializations and single training-test splits.

Abstract

Publication information in a researcher's academic homepage provides insights about the researcher's expertise, research interests, and collaboration networks. We aim to extract all the publication strings from a given academic homepage. This is a challenging task because the publication strings in different academic homepages may be located at different positions with different structures. To capture the positional and structural diversity, we propose an end-to-end hierarchical model named PubSE based on Bi-LSTM-CRF. We further propose an alternating training method for training the model. Experiments on real data show that PubSE outperforms the state-of-the-art models by up to 11.8% in F1-score.

1 Introduction

Researchers often list their publications in their academic homepages. These publications provide insights about the researchers' expertise, research interests, and collaboration networks. Extracting publications from a researcher's homepage is an essential step in extracting the researcher's profile (Tang et al., 2010). In this study, we aim to extract every publication from a researcher's homepage. For ease of discussion, we call such a publication item a *publication string*. Figure 1 illustrates the studied problem. There are two publications on the homepage shown in the figure, a journal article and a conference paper. We aim to extract them as two separate publication strings.

Extracting publication strings from academic homepages helps bypass the problem of name ambiguity (*i.e.*, different authors with the same name) (Zhu et al., 2018) in extracting publication strings from indexing sites such as DBLP and PubMed. However, extracting publication strings from academic homepages directly has its own challenges: (i) The list of publications may be located anywhere in a homepage with varying contexts. The structure of the list and the formatting styles of a publication string can vary vastly across different homepages. For example, some researchers like to list some of their publications with more details, such as full venue names, volume and page information, while listing the other publication in a concise way. Also, some researchers like to group their publication by year or by topic. (ii) A publication string may contain multiple lines of text (cf. Figure 1), and there may not be a clear boundary between two publications strings. (iii) There may be strings in an academic homepage that share very similar structures and styles with publication strings, such as records of conference presentations (cf. Figure 1). Previous work (Hong et al., 2009; Chung et al., 2012) focuses on feature and rule engineering and cannot accommodate the above challenges.

Figure 1: Part of a homepage with publication strings

To address these challenges, we propose a model named *PubSE* to extract every publication string from an academic homepage. PubSE has two characteristics: (i) The model structure reflects the structure of a list of publications, by its loss-functions at both text line-level and webpage-level. (ii) The training process of the

model utilizes both text line-level and webpage-level information via an alternating training procedure to reduce overfitting. Our PubSE model can extract publication strings in non-trivial cases, such as multi-line publication strings from a non-continuous publication list. We make the following contributions: (i) We create a dataset of 2,500 homepages[1], in which each publication string is labeled. (ii) We address the problem of publication string extraction by end-to-end learning, without feature engineering. (iii) We propose a model that can learn the structures of publication lists and the styles of publication strings. We also propose an alternating training method that can reduce overfitting and further improve the prediction accuracy.

2 Related Work

Earlier studies extract publication strings from research papers (Peng and McCallum, 2006; Councill et al., 2008; Tkaczyk et al., 2015). Such a problem is simpler for two reasons: (i) The reference list of a research paper usually appears at a fixed position (e.g., end of paper) and is continuous. (ii) The references are usually well-formatted and have few format variations since they may be generated by software such as LaTeX.

For extracting publication strings from academic homepages, previous studies use either rule-based (Hong et al., 2009; Yang and Ho, 2010) or a hybrid of machine learning and rule-based methods (Chung et al., 2012).

For example, Chung et al. (2012) develop a system named PRM that first segments an HTML DOM tree and its contents based on HTML tags. Then, PRM uses a linear chain CRF model to label the different parts of the tree. Based on the labels, it refines the publication string boundaries by heuristic rules to produce final predictions.

Relying on the HTML DOM tree structure makes it difficult to train a machine learning based model for publication extraction because: (i) Text in a publication string may be separated in many different DOM tree nodes. (ii) The DOM tree structure, which previous web data record extraction systems (Liu et al., 2003; Furche et al., 2014; Omari et al., 2016) rely on, may vary given the same webpage content.

As a result, we do not use HTML tags in our model. Instead, we work on the visible text contents. To the best of our knowledge, no existing studies for publication string extraction can effectively model the structure of publication lists.

3 Dataset

To the best of our knowledge, there is no public dataset of academic homepages that has labeled publication strings.

We downloaded 2,500 academic homepages from 100 universities around the world. We use Selenium, an open-source automated rendering software, to render the webpages. We collect visible texts from the webpages and then manually tag all the publication strings in them. During tagging, we mark the beginning and ending byte offsets of each publication string. Among the 2,500 academic homepages, 723 homepages (28.9%) contain publication lists, which consist of a total of 13,237 publication strings. Among the 723 homepages that contain publication strings, there are 117 homepages (16.2%) that contain multi-line publication strings. On average, there are 732.1 (std=1583.3) tokens, 89.9 (std=141.6) lines, and 18.3 (std=35.4) publication strings per homepage. We call this dataset *HomePub*.

Each publication string in HomePub dataset is annotated by two annotators. Disagreement is resolved by a third annotator. On publication string level, annotators agree on 83.76% publications, and the Cohen's kappa is 0.2084.

We have developed a program *PageTagger*[2] to assist the annotation. On average, it takes about 2.5 minutes to annotate one academic homepage when using the PageTagger tool.

Note that our annotation does not consider the following as publication strings: (i) Master or PhD theses; (ii) working papers; (iii) seminars, invited talks, or presentations; and (iv) patents. Our annotation also excludes the numbers (e.g., [1] or [i]) if the publication strings are in a numbered list.

4 Methods

We summarize the baseline models in Section 4.1 and present our PubSE model in Section 4.2.

4.1 Baselines

PRM: Chung et al. (2012) develop a publication string extraction system based on region boundary

---

[2] `https://github.com/yiqingzhang/page-tagger`

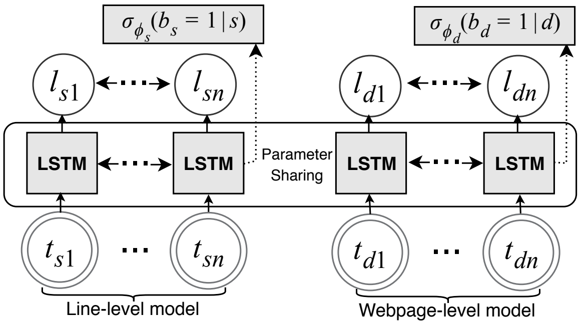

Figure 2: PubSE model

analysis and CRF. We train their system on 60% of the HomePub dataset.

ParsCit: ParsCit (Councill et al., 2008) is a CRF-based document structure analysis and reference parsing tool. We use ParsCit as an off-the-shelf tool on the HomePub dataset.

CNN-Sentence: In the HomePub dataset, over 80% of the publication strings are in a single line. The problem of extracting publication strings can be viewed as a single-line text classification problem (Kim, 2014; Yang et al., 2016; Joulin et al., 2017). Following Kim (2014), we implement a line-level classification model. We use the GloVe (300 dimensions) pre-trained embedding on this model (the same embedding is used across all the models that require word embeddings as the input). This model predicts whether each line in the webpage is a publication string.

Bi-LSTM-CRF: The problem of extracting publication strings can also be viewed as a sequence labeling task (Lample et al., 2016; Gui et al., 2017; Liu et al., 2017), where there are two possible labels for each token, publication (`I`) or non-publication (`O`). A consecutive sequence of `I` tokens forms a publications string. Sequence labeling approaches can capture correlations of labels and words, as well as words themselves. Following Ma and Hovy (2016), we implement a Bi-LSTM-CRF model. We concatenate token-level with character-level embeddings as the model input, to better deal with out-of-vocabulary tokens.

4.2 PubSE Model

To capture the hierarchical structure of a homepage and address the issue of multi-line publication strings, we propose a hierarchical model named *PubSE* with an alternating training method, which alternates between training a line-level and a webpage-level model to reduce overfitting. Figure 2 illustrates the model structure.

We incorporate both line-level and webpage-level information in the model since the predictions depend on both local (line-level) and global (webpage-level) context. On one hand, local information such as word embeddings and morphology information is crucial for the predictions over individual lines. On the other hand, global information is also necessary, e.g., to help identify the starting and ending positions of a publication list and the boundaries between multi-line publications strings.

Line-level model: As shown in Figure 2, the left Bi-LSTM network $\pi_\theta(\ell|s)$ specializes in line-level inputs, where each mini batch of input composes of lines in a webpage. On top of this sub-module, we add another layer $\sigma_{\phi_s}(b_s|s)$ to model whether each line contains a publication string:

$$\mathcal{L}_{line} = \lambda_{\theta_s}\mathcal{L}(\pi_\theta(\ell|s), y_t) + \lambda_{\phi_s}\mathcal{L}(\sigma_{\phi_s}(b_s|s), y_l),$$

where ℓ denotes the predicted labels for tokens t_{si} in a line s, and b_s denotes the predicted label for a line, *i.e.*, whether the line contains a publication string or not; y_t and y_l denote the ground truth label for each token and line. Hyperparameters λ_{θ_s} and λ_{ϕ_s} are the coefficients for token-level and line-level, while θ and ϕ_s are the parameters of the two networks; $\mathcal{L}$ is the cross-entropy loss:

$$\mathcal{L}(\hat{y}, y) = -(1-y)log(1-\hat{y}) - ylog(\hat{y}),$$

where $\hat{y}$ denotes the predicted label, and y denotes the ground truth label.

The inputs to the line-level model are each line in the form of $\langle(e_1, c_1), (e_2, c_2), ..., (e_n, c_n)\rangle$, where e_k and c_k are the word embedding and character embedding of the token t_{sk}. Network $\pi_\theta(\ell|s)$ outputs a label for each token, while network $\sigma_{\phi_s}(b_s|s)$ gives binary output for each line, indicating whether it contains a publication string. Extraction result is based on the output of $\pi_\theta(\ell|s)$.

Webpage-level model: Similarly, the right Bi-LSTM sub-module $\pi_\theta(\ell|d)$ in Figure 2 specializes in webpage-level inputs, where the whole homepage d is supplied to the model as a long sequence of token embeddings. We add another layer $\sigma_{\phi_d}(b_d|d)$ to reflect whether the homepage contains publication strings:

$$\mathcal{L}_{page} = \lambda_{\theta_d}\mathcal{L}(\pi_\theta(\ell|d), y_t) + \lambda_{\phi_d}\mathcal{L}(\sigma_{\phi_d}(b_d|d), y_w),$$

where b_d denotes whether the document contains publication or not; λ_{θ_d} and λ_{ϕ_d} are token-level and webpage-level coefficients; y_w denotes the ground truth label for a webpage; θ and ϕ_d are network parameters. Note that the left and right sub-modules collaborate by sharing network weights θ.

Table 1: Performance of different models on the HomePub dataset. The first and second groups show the performance on the whole test dataset. The third group shows the exact matching performance on the subset that contains multi-line publications.

Alternating training method: Inspired by the training procedure of curriculum learning (Bengio et al., 2009) and soft-landing (He et al., 2016), we adopt an alternating training procedure controlled by the following function:

$$f(k) = H(cos(k/T)),$$

where T controls the period of the function, and k is the number of epochs. The H denotes the Heaviside step function. In the k^{th} epoch, we will train only one of the submodules, given by

$$\mathcal{L} = f(k)\mathcal{L}_{line} + f(k+1)\mathcal{L}_{page}.$$

Our intuition is that the training of line-level and webpage-level networks can reinforce each other and reduce overfitting. If we only train the model on the line-level input, the model will lose all the long-term dependency information. For example, a string that describes a thesis resembles that of a conference paper. To filter such strings, we need to rely on indicators that may reside in a different line such as a heading “Dissertations supervised”. On the other hand, if we only train the model on webpage-level input, the model may be dominated by the longest line on the homepage, such as biography information. Our alternating training procedure balances the two factors and can better model the hierarchical structure of a publication list.

The PubSE model can capture and exploit information on the webpage from four different perspectives: (i) character-level information such as word morphology; (ii) token-level information such as word context; (iii) line-level information such as whether a line is a publication string; and (iv) webpage-level information such as whether a webpage contains publication strings.

5 Experiments

Settings and Evaluation: We divide the HomePub dataset by a 60-40 split and train our model on 60% of the total data. We use 20% of the training set as a validation set for early stopping and hyperparameter tuning. The optimal hyperparameters are obtained with a standard grid search procedure on the validation set. We use 40 as the batch size for the line-level model and 1 for the webpage-level model. We set $\lambda_{\theta_s}, \lambda_{\phi_s}, \lambda_{\theta_d}, \lambda_{\phi_d}, T$ as 1, 0.05, 1, 0.3, $1/\pi$, respectively.

We use precision, recall, and F1-score to measure the performance, and we report both exact and relaxed matching performance. In exact matching, a publication string is considered to be correctly extracted only if it exactly matches a publication string in the ground truth. In relax matching, we allow mismatching 15% of publication strings. (*i.e.*, a publication string is considered correct if it contains at least 85% of the tokens of a publication string in the ground truth.) We also list the model performance on webpages in the test set that contain multi-line publication strings.

Results: We report the experiment results in Table 1. The result shows that the proposed PubSE model consistently outperforms all the baselines with a statistically significant margin, and the advantage is up to 11.8%. In particular, the use of the webpage-level sub-module helps PubSE to handle multi-line publication strings, which yields a significant performance gain.

In comparison, PRM struggles in determining which part of a page contains publications. ParsCit requires well-formatted inputs. For example, if publication strings do not contain page numbers, ParsCit will be reluctant to separate the list of publication strings into individual records. CNN-Sentence and Bi-LSTM-CRF give poor results in pages that contain multi-line publication strings.

Methods	Exact Match	85% Match	Multi-line

Rhetoric
[Roer, H. 2013 The Oxford Guide to the Historical Reception of Augustine. Pollmann, K. (ed.). Oxford: Oxford University Press, Vol. 3, p. 1650-1657 7 p.]

Figure 3: Typical errors of various models. Underlined tokens are labeled as `I` (publication). "[" and "]" are not part of the text. They are used to highlight the boundary of publication strings.

is made by training the model with webpage-level input (`W`) since it is difficult to extract multi-line publication strings without a global view of the whole webpage.

The effect of the alternating training method (`L`+`W`) is also significant. The webpage-level model (`W`) may not handle short lines too well, e.g., a line with text "Conference paper (peer-reviewed)" as shown in Figure 1. This problem is solved by combining the line-level model with the webpage-level model (`L`+`W`).

Error analysis: Figure 3 shows typical errors made by various models. Examples 1 shows errors occurred in line-level model prediction results. The line-level model does not handle multi-line publication strings well since the predictions of different lines are independent, so the model fails to capture dependency relationships in different lines.

Example 2 shows prediction results given by the webpage-level model. We see that the webpage-level model can make a more accurate prediction for multi-line publications. However, it may make false positive predictions for short lines (e.g., "Chapter (peer-reviewed)"), while the line-level model seldom makes such mistakes. This is the motivation for us to integrate both the line-level and the webpage-level models.

PubSE can avoid most of the errors shown in Examples 1 and 2. Nevertheless, PubSE still makes mistakes in some challenging cases. Example 3 shows such a case, where PubSE does not recognize that "Rhetoric" is a publication title. A possible explanation is that such a short publication title is less common.

6 Conclusions and Future work

We studied publication string extraction and proposed a model named PubSE for the problem. PubSE models the publication list structure with its hierarchical structure and loss functions. We proposed an alternating training scheme that combines both line-level and webpage-level information, which are crucial for predicting multi-line publication strings. Experiments show that the proposed PubSE model outperforms the state-of-the-art models by up to 11.8% in F1-score.

For future work, we aim to expand our experimental study to a larger scale. We further consider extracting publication strings from academic homepages of the same organization. Such homepages may share similar templates, which may help improve the extraction accuracy. We also plan to investigate adaptive alternating model training schemes as well as external memory mechanism such as memory networks.

Acknowledgments

Abstract

It is common that entity mentions can contain other mentions recursively. This paper introduces a scalable transition-based method to model the nested structure of mentions. We first map a sentence with nested mentions to a designated forest where each mention corresponds to a constituent of the forest. Our shift-reduce based system then learns to construct the forest structure in a bottom-up manner through an action sequence whose maximal length is guaranteed to be three times of the sentence length. Based on Stack-LSTM which is employed to efficiently and effectively represent the states of the system in a continuous space, our system is further incorporated with a character-based component to capture letter-level patterns. Our model achieves the state-of-the-art results on ACE datasets, showing its effectiveness in detecting nested mentions.[1]

1 Introduction

There has been an increasing interest in named entity recognition or more generally recognizing entity mentions[2] (Alex et al., 2007; Finkel and Manning, 2009; Lu and Roth, 2015; Muis and Lu, 2017) that the nested hierarchical structure of entity mentions should be taken into account to better facilitate downstream tasks like question answering (Abney et al., 2000), relation extraction (Mintz et al., 2009; Liu et al., 2017), event extraction (Riedel and McCallum, 2011; Li et al., 2013), and coreference resolution (Soon et al., 2001; Ng and Cardie, 2002; Chang et al., 2013). Practically, the mentions with nested structures frequently exist in news (Doddington et al., 2004) and biomedical documents (Kim et al., 2003). For example in Figure 1, "UN Secretary General" of type Person also contains "UN" of type Organization.

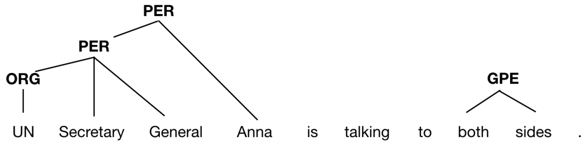

Figure 1: An example sentence of nested mentions represented in the structure of forest. PER:Person, ORG:Organization, GPE:Geo-Political Entity.

Traditional sequence labeling models such as conditional random fields (CRF) (Lafferty et al., 2001) do not allow hierarchical structures between segments, making them incapable to handle such problems. Finkel and Manning (2009) presented a chart-based parsing approach where each sentence with nested mentions is mapped to a rooted constituent tree. The issue of using a chart-based parser is its cubic time complexity in the number of words in the sentence.

To achieve a scalable and effective solution for recognizing nested mentions, we design a transition-based system which is inspired by the recent success of employing transition-based methods for constituent parsing (Zhang and Clark, 2009) and named entity recognition (Lou et al., 2017), especially when they are paired with neural networks (Watanabe and Sumita, 2015). Generally, each sentence with nested mentions is mapped to a forest where each outermost mention forms a tree consisting of its inner mentions. Then our transition-based system learns to construct this forest through a sequence of shift-reduce actions. Figure 1 shows an example of such a forest. In contrast, the tree structure by Finkel and Manning (2009) further uses a root node to connect all tree elements. Our forest representation eliminates the root node so that the number of actions required to

---

[1] We make our implementation available at `https://github.com/berlino/nest-trans-em18`.

[2] Mentions are defined as references to entities that could be named, nominal or pronominal (Florian et al., 2004).

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1011–1017
Brussels, Belgium, October 31 - November 4, 2018.

construct it can be reduced significantly.

Following (Dyer et al., 2015), we employ Stack-LSTM to represent the system's state, which consists of the states of input, stack and action history, in a continuous space incrementally. The (partially) processed nested mentions in the stack are encoded with recursive neural networks (Socher et al., 2013) where composition functions are used to capture dependencies between nested mentions. Based on the observation that letter-level patterns such as capitalization and prefix can be beneficial in detecting mentions, we incorporate a character-level LSTM to capture such morphological information. Meanwhile, this character-level component can also help deal with the out-of-vocabulary problem of neural models. We conduct experiments in three standard datasets. Our system achieves the state-of-the-art performance on ACE datasets and comparable performance in GENIA dataset.

2 Related Work

Entity mention recognition with nested structures has been explored first with rule-based approaches (Zhang et al., 2004; Zhou et al., 2004; Zhou, 2006) where the authors first detected the innermost mentions and then relied on rule-based post-processing methods to identify outer mentions. McDonald et al. (2005) proposed a structured multi-label model to represent overlapping segments in a sentence. but it came with a cubic time complexity in the number of words. Alex et al. (2007) proposed several ways to combine multiple conditional random fields (CRF) (Lafferty et al., 2001) for such tasks. Their best results were obtained by cascading several CRF models in a specific order while each model is responsible for detecting mentions of a particular type. However, such an approach cannot model nested mentions of the same type, which frequently appear.

Lu and Roth (2015) and Muis and Lu (2017) proposed new representations of mention hypergraph and mention separator to model *overlapping mentions*. However, the nested structure is not guaranteed in such approaches since overlapping structures additionally include the *crossing structures*[3], which rarely exist in practice (Lu and Roth, 2015). Also, their representations did not model the dependencies between nested mentions explicitly, which may limit their performance. In contrast, the chart-based parsing method (Finkel and Manning, 2009) can capture the dependencies between nested mentions with composition rules which allow an outer entity to be influenced by its contained entities. However, their cubic time complexity makes them not scalable to large datasets.

$$\begin{array}{cc}
\text{Initial State} & [\phi, 0, \phi] \\
\text{Final State} & [S, n, A] \\
\\
\textsc{Shift} & \dfrac{[S,\ i,\ A]}{[S|w,\ i{+}1,\ A|\textsc{Shift}]} \\
\\
\textsc{Reduce-X} & \dfrac{[S|t_1 t_0,\ i,\ A]}{[S|X,\ i,\ A|\textsc{Reduce-X}]} \\
\\
\textsc{Unary-X} & \dfrac{[S|t_0,\ i,\ A]}{[S|X,\ i,\ A|\textsc{Unary-X}]}
\end{array}$$

Figure 2: Deduction rules. $[S, i, A]$ denotes stack, buffer front index and action history respectively.

As neural network based approaches are proven effective in entity or mention recognition (Collobert et al., 2011; Lample et al., 2016; Huang et al., 2015; Chiu and Nichols, 2016; Ma and Hovy, 2016), recent efforts focus on incorporating neural components for recognizing nested mentions. Ju et al. (2018) dynamically stacked multiple LSTM-CRF layers (Lample et al., 2016), detecting mentions in an inside-out manner until no outer entities are extracted. Katiyar and Cardie (2018) used recurrent neural networks to extract features for a hypergraph which encodes all nested mentions based on the BILOU tagging scheme.

3 Model

Specifically, given a sequence of words $\{x_0, x_1, \ldots, x_n\}$, the goal of our system is to output a set of mentions where nested structures are allowed. We use the forest structure to model the nested mentions scattered in a sentence, as shown in Figure 1. The mapping is straightforward: each outermost mention forms a tree where the mention is the root and its contained mentions correspond to constituents of the tree.[4]

3.1 Shift-Reduce System

Our transition-based model is based on the shift-reduce parser for constituency parsing (Watan-

---

[3] For example, in a four-word sentence ABCD, the phrase ABC and BCD together form a crossing structure.

[4] Note that words that are not contained in any mention each forms a single-node tree.

abe and Sumita, 2015), which adopts (Zhang and Clark, 2009; Sagae and Lavie, 2005). Generally, our system employs a stack to store (partially) processed nested elements. The system's state is defined as $[S, i, A]$ which denotes stack, buffer front index and action history respectively. In each step. an action is applied to change the system's state.

Our system consists of three types of transition actions, which are also summarized in Figure 2:

- SHIFT pushes the next word from buffer to the stack.
- REDUCE-X pops the top two items t_0 and t_1 from the tack and combines them as a new tree element $\{\mathrm{X} \rightarrow t_0 t_1\}$ which is then pushed onto the stack.
- UNARY-X pops the top item t_0 from the stack and constructs a new tree element $\{\mathrm{X} \rightarrow t_0\}$ which is pushed back to the stack.

Since the shift-reduce system assumes unary and binary branching, we binarize the trees in each forest in a left-branching manner. For example, if three consecutive words A, B, C are annotated as Person, we convert it into a binary tree $\{Person \rightarrow \{Person{*} \rightarrow A, B\}, C\}$ where $Person{*}$ is a temporary label for $Person$. Hence, the X in reduce- actions will also include such temporary labels.

Note that since most words are not contained in any mention, they are only shifted to the stack and not involved in any reduce- or unary- actions. An example sequence of transitions can be found in Figure 3. Our shift-reduce system is different from previous parsers in terms of the terminal state. 1) It does not require the terminal stack to be a rooted tree. Instead, the final stack should be a forest consisting of multiple nested elements with tree structures. 2) To conveniently determine the ending of our transition process, we add an auxiliary symbol \$ to each sentence. Once it is pushed to the stack, it implies that all deductions of actual words are finished. Since we do not allow unary rules between labels like X1 $\rightarrow$ X2, the length of maximal action sequence is $3n$.[5]

3.2 Action Constraints

To make sure that each action sequence is valid, we need to make some hard constraints on the action to take. For example, reduce- action can only be conducted when there are at least two elements in the stack. Please see the Appendix for the full list of restrictions. Formally, we use $\mathcal{V}(S, i, A)$ to denote the valid actions given the parser state. Let us denote the feature vector for the parser state at time step k as $\mathbf{p}_k$. The distribution of actions is computed as follows:

$$p(z_k \mid \mathbf{p}_k) = \frac{\exp\left(\mathbf{w}_{z_k}^{\top} \mathbf{p}_k + b_{z_k}\right)}{\sum_{z' \in \mathcal{V}(S,i,A)} \exp\left(\mathbf{w}_{z'}^{\top} \mathbf{p}_k + b_{z'}\right)} \tag{1}$$

where $\mathbf{w}_z$ is a column weight vector for action z, and b_z is a bias term.

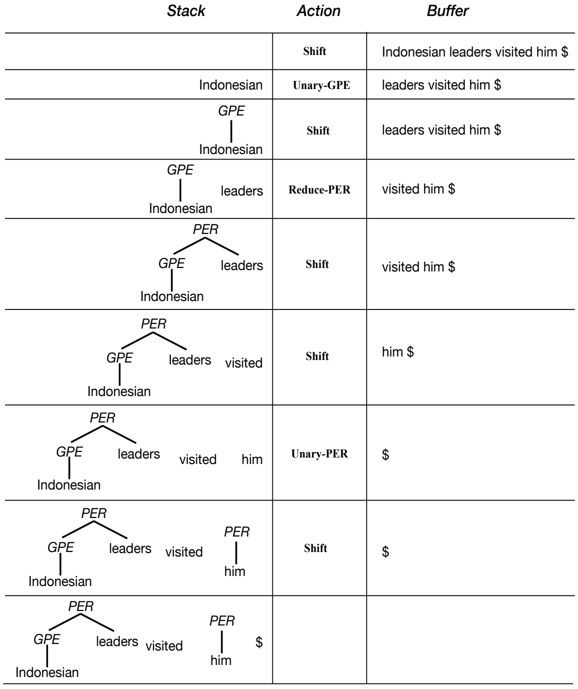

Figure 3: An example sequence of transition actions for the sentence "Indonesian leaders visited him". \$ is the special symbol indicating the termination of transitions. PER:Person, GPE:Geo-Political Entity.

3.3 Neural Transition-based Model

We use neural networks to learn the representation of the parser state, which is $\mathbf{p}_k$ in (1).

Representation of Words

Words are represented by concatenating three vectors:

$$\mathbf{e}_{x_i} = [\mathbf{e}_{w_i}, \mathbf{e}_{p_i}, \mathbf{c}_{w_i}] \tag{2}$$

where $\mathbf{e}_{w_i}$ and $\mathbf{e}_{p_i}$ denote the embeddings for i-th word and its POS tag respectively. $\mathbf{c}_{w_i}$ denotes the representation learned by a character-level model

---

[5] In this case, each word is shifted (n) and involved in a unary action (n). Then all elements are reduced to a single node ($n - 1$). The last action is to shift the symbol \$.

using a bidirectional LSTM. Specifically, for character sequence $s_0, s_1, \dots, s_n$ in the i-th word, we use the last hidden states of forward and backward LSTM as the character-based representation of this word, as shown below:

$$\mathbf{c}_{w_i} = [\overrightarrow{\text{LSTM}_\text{c}}(s_0, \dots, s_n), \overleftarrow{\text{LSTM}_\text{c}}(s_0, \dots, s_n)] \tag{3}$$

Representation of Parser States

Generally, the buffer and action history are encoded using two vanilla LSTMs (Graves and Schmidhuber, 2005). For the stack that involves popping out top elements, we use the Stack-LSTM (Dyer et al., 2015) to efficiently encode it.

Formally, if the unprocessed word sequence in the buffer is $x_i, x_{i+1}, \dots, x_n$ and action history sequence is $a_0, a_1, \dots, a_{k-1}$, then we can compute buffer representation $\mathbf{b}_k$ and action history representation $\mathbf{a}_k$ at time step k as follows:

$$\mathbf{b}_k = \overleftarrow{\text{LSTM}_\text{b}}[\mathbf{e}_{x_i}, \dots, \mathbf{e}_{x_n}] \tag{4}$$

$$\mathbf{a}_k = \overrightarrow{\text{LSTM}_\text{a}}[\mathbf{e}_{a_0}, \dots, \mathbf{e}_{a_{k-1}}] \tag{5}$$

where each action is also mapped to a distributed representation $\mathbf{e}_a$.[6] For the state of the stack, we also use an LSTM to encode a sequence of tree elements. However, the top elements of the stack are updated frequently. Stack-LSTM provides an efficient implementation that incorporates a stack-pointer.[7] Formally, the state of the stack $\mathbf{b}_k$ at time step k is computed as:

$$\mathbf{s}_k = \text{Stack-LSTM}[\mathbf{h}_{t_m}, \dots, \mathbf{h}_{t_0}] \tag{6}$$

where $\mathbf{h}_{t_i}$ denotes the representation of the i-th tree element from the top, which can be computed recursively similar to Recursive Neural Network (Socher et al., 2013) as follows:

$$\mathbf{h}_{parent} = \mathbf{W}_{u,l}^{\top} \mathbf{h}_{child} + \mathbf{b}_{u,l} \tag{7}$$

$$\mathbf{h}_{parent} = \mathbf{W}_{b,l}^{\top} [\mathbf{h}_{lchild}, \mathbf{h}_{rchild}] + \mathbf{b}_{u,l} \tag{8}$$

where $\mathbf{W}_{u,l}$ and $\mathbf{W}_{b,l}$ denote the weight matrices for unary(u) and binary(b) composition with parent node being label(l). Note that the composition function is distinct for each label l. Recall that the leaf nodes of each tree element are raw words. Instead of representing them with their original embeddings introduced in Section 3.3, we found that concatenating the buffer state in (5) are beneficial during our initial experiments. Formally, when a word x_i is shifted to the stack at time step k, its representation is computed as:

$$\mathbf{h}_{leaf} = \mathbf{W}_{leaf}^{\top} [\mathbf{e}_{x_i}, \mathbf{b}_k] + \mathbf{b}_{leaf} \tag{9}$$

Models	ACE04	ACE05	GENIA	w/s
Finkel and Manning (2009)	-	-	70.3	$38^{\dagger}$

Ju et al. (2018) [8]	-	72.2	**74.7**	-
Ours	**73.3**	**73.0**	73.9	1445
- char-level LSTM	72.3	71.9	72.1	1546
- pre-trained embeddings	71.3	71.5	72.0	1452
- dropout layer	71.7	72.0	72.7	1440

Table 1: Main results in terms of F_1 score (%). w/s: # of words decoded per second, number with † is retrieved from the original paper.

Finally, the state of the system $\mathbf{p}_k$ is the concatenation of the states of buffer, stack and action history:

$$\mathbf{p}_k = [\mathbf{b}_k, \mathbf{s}_k, \mathbf{a}_k] \tag{10}$$

Training

We employ the greedy strategy to maximize the log-likelihood of the local action classifier in (1). Specifically, let z_{ik} denote the k-th action for the i-th sentence, the loss function with ℓ_2 norm is:

$$\mathcal{L}(\theta) = -\sum_i \sum_k \log p(z_{ik}) + \frac{\lambda}{2} \|\theta\|^2 \tag{11}$$

where λ is the ℓ_2 coefficient.

4 Experiments

We mainly evaluate our models on the standard ACE-04, ACE-05 (Doddington et al., 2004), and GENIA (Kim et al., 2003) datasets with the same splits used by previous research efforts (Lu and Roth, 2015; Muis and Lu, 2017). In ACE datasets, more than 40% of the mentions form nested structures with some other mention. In GENIA, this number is 18%. Please see Lu and Roth (2015) for the full statistics.

4.1 Setup

Pre-trained embeddings GloVe (Pennington et al., 2014) of dimension 100 are used to initialize the

---

[6] Note that LSTM_b runs in a right-to-left order such that the output can represent the contextual information of x_i.

[7] Please refer to Dyer et al. (2015) for details.

[8] Note that in ACE2005, Ju et al. (2018) did their experiments with a different split from Lu and Roth (2015) and Muis and Lu (2017) which we follow as our split.

word vectors for all three datasets.[9] The embeddings of POS tags are initialized randomly with dimension 32. The model is trained using Adam (Kingma and Ba, 2014) and a gradient clipping of 3.0. Early stopping is used based on the performance of development sets. Dropout (Srivastava et al., 2014) is used after the input layer. The ℓ_2 coefficient λ is also tuned during development process.

4.2 Results

The main results are reported in Table 1. Our neural transition-based model achieves the best results in ACE datasets and comparable results in GENIA dataset in terms of F_1 measure. We hypothesize that the performance gain of our model compared with other methods is largely due to improved performance on the portions of nested mentions in our datasets. To verify this, we design an experiment to evaluate how well a system can recognize nested mentions.

Handling Nested Mentions

The idea is that we split the test data into two portions: sentences with and without nested mentions. The results of GENIA are listed in Table 2. We can observe that the margin of improvement is more significant in the portion of nested mentions, revealing our model's effectiveness in handling nested mentions. This observation helps explain why our model achieves greater improvement in ACE than in GENIA in Table 1 since the former has much more nested structures than the latter. Moreover, Ju et al. (2018) performs better when it comes to non-nested mentions possibly due to the CRF they used, which globally normalizes each stacked layer.

Decoding Speed

Note that Lu and Roth (2015) and Muis and Lu (2017) also feature linear-time complexity, but with a greater constant factor. To compare the decoding speed, we re-implemented their model with the same platform (PyTorch) and run them on the same machine (CPU: Intel i5 2.7GHz). Our model turns out to be around 3-5 times faster than theirs, showing its scalability.

	GENIA					
	Nested			Non-Nested

Ablation Study

To evaluate the contribution of neural components including pre-trained embeddings, the character-level LSTM and dropout layers, we test the performances of ablated models. The results are listed in Table 1. From the performance gap, we can conclude that these components contribute significantly to the effectiveness of our model in all three datasets.

5 Conclusion and Future Work

In this paper, we present a transition-based model for nested mention recognition using a forest representation. Coupled with Stack-LSTM for representing the system's state, our neural model can capture dependencies between nested mentions efficiently. Moreover, the character-based component helps capture letter-level patterns in words. The system achieves the state-of-the-art performance in ACE datasets.

One potential drawback of the system is the greedy training and decoding. We believe that alternatives like beam search and training with exploration (Goldberg and Nivre, 2012) could further boost the performance. Another direction that we plan to work on is to apply this model to recognizing overlapping and entities that involve discontinuous spans (Muis and Lu, 2016) which frequently exist in the biomedical domain.

Appendix

The action constraints are listed as follows:

- The SHIFT action is valid only when the buffer is not empty.
- The UNARY-X actions are valid only when the stack is not empty.
- The REDUCE-X actions are valid only when the stack has two or more elements.
- If the top element of the stack is labeled, then unary actions are not valid. That is, $\{X1 \rightarrow X2\}$ is not allowed.
- If only one of the top two elements of the stack is temporary, say X*, then among all reduce actions, only REDUCE-X* and REDUCE-X are valid.
- If the top two elements of the stack are both temporary, then all reduce actions are not allowed.
- If one of the elements in the stack is temporary, say X*, which means it is not finished, then last terminal symbol $ cannot be shifted until it is reduced to X.

Genre Separation Network with Adversarial Training for Cross-genre Relation Extraction

Abstract

Relation Extraction suffers from dramatical performance decrease when training a model on one genre and directly applying it to a new genre, due to the distinct feature distributions. Previous studies address this problem by discovering a shared space across genres using manually crafted features, which requires great human effort. To effectively automate this process, we design a genre-separation network, which applies two encoders, one genre-independent and one genre-shared, to explicitly extract genre-specific and genre-agnostic features. Then we train a relation classifier using the genre-agnostic features on the source genre and directly apply to the target genre. Experiment results on three distinct genres of the ACE dataset show that our approach achieves up to 6.1% absolute F1-score gain compared to previous methods. By incorporating a set of external linguistic features, our approach outperforms the state-of-the-art by 1.7% absolute F1 gain. We make all programs of our model publicly available for research purpose [1] .

1 Introduction

Relation extraction aims to identify and categorize the semantic relation between two entity mentions based on the contexts within the sentence. Supervised learning approaches have shown to be effective on this task. However, as relation extraction highly depends on information about entities and their contexts, a supervised model trained in one genre suffers from dramatical performance decrease when applied to a new genre, due to the distinct contexts among various genres.

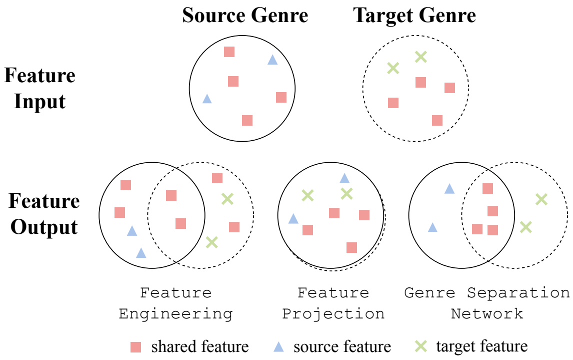

Figure 1: Comparison of Genre Separation Methods.

Previous studies (Plank and Moschitti, 2013; Nguyen and Grishman, 2014, 2015; Yu et al., 2015; Gormley et al., 2015) tackle this problem by manually crafting genre-agnostic features such as word clusters and word embeddings, to train a genre-shared relation extractor. These methods suffer from information loss due to the limited human knowledge to capture all genre-agnostic features. As depicted in Figure 1, where red rectangles are features shared by two genres, and blue and green triangles are source and target genre features respectively, *Feature Engineering* only captures a portion of the genre-agnostic features. Fu et al. (2017), depicted as *Feature Projection*, applies a domain adversarial neural network to automatically project the source and target genre features into one unified feature space. However, it unnecessarily introduces genre-specific features which undermine the overall performance.

To address these problems, we propose a genre-separation network, which consists of two separate Convolutional Neural Networks (CNNs) to automatically separates genre-specific and genre-agnostic features for each genre, which is depicted as *Genre Separation Network* in Figure 1. To avoid information loss during feature encoding, we reconstruct the original input from the two separate feature spaces via a novel reconstruction loss. Then we use an adversarial similarity loss to limit the genre-agnostic features into one fea-

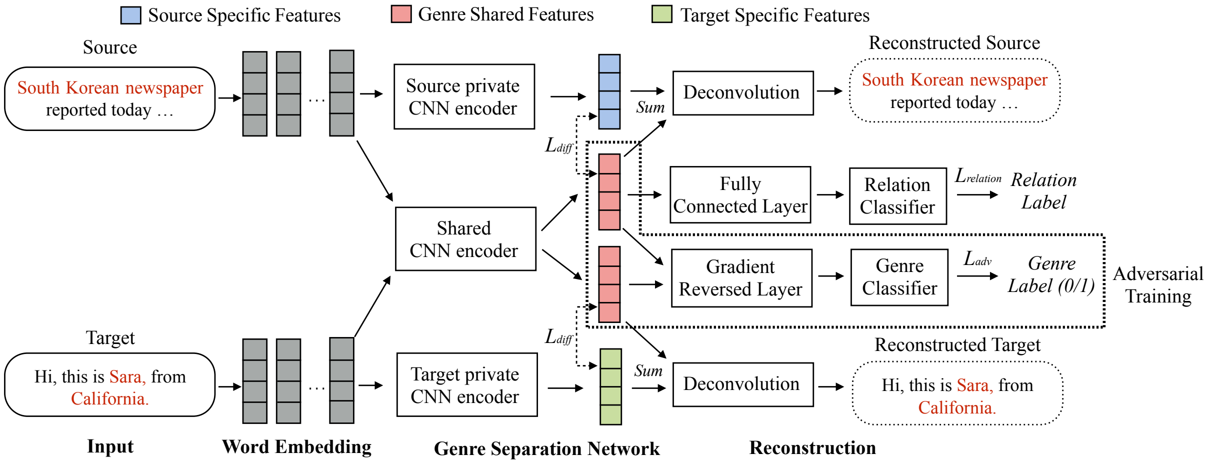

Figure 2: Overall genre separation framework for cross-genre relation extraction

ture space. The genre-agnostic features are finally used to predict entity relations in the source and target genres.

2 Approach

2.1 Overview

An overview of our framework is presented in Figure 2. We formulate the task as follows: given a labeled source genre corpus $S = \{(s_1, e_{11}, e_{12}, r_1), ..., (s_n, e_{n1}, e_{n2}, r_n)\}$, where $s_i = [w_{i1}, ..., w_{im}]$ denotes a sentence. e_{i1} and e_{i2} denote two entity mentions, and r_i denotes the relation between e_{i1} and e_{i2}, we build a relation extraction model on S and apply it to a different target genre corpus $T = \{(\hat{s_1}, \hat{e_{11}}, \hat{e_{12}}), ..., (\hat{s_n}, \hat{e_{n1}}, \hat{e_{n2}})\}$.

2.2 Genre Separation Network (GSN)

As shown in Figure 1, our goal is to distinguish the genre-agnostic features (red rectangles) and genre-specific features (blue triangles and green crosses). Using source genre as an example, we apply a source private CNN encoder on the source sentence to generate the source-specific feature representation f_s^p, and a shared CNN encoder to generate genre-agnostic feature f_s^c. Similarly, we get f_t^p and f_t^c from the target private CNN encoder and the shared CNN encoder respectively. To separate f_s^p from f_s^c and separate f_t^p from f_t^c, we introduce a *difference loss* following previous studies (Bousmalis et al., 2016; Liu et al., 2017). More details will be elaborated below.

Formally, given a source sentence (s, e_1, e_2, r) where $s = [w_1, ..., w_m]$, for each word w_{ik}, we generate a multi-type embedding: $\tilde{v}_i = [v_i, p_i, \tilde{p}_i, t_i, \tilde{t}_i, c_i, \eta_i]$ where v_i denotes a pre-trained word embedding. p_i and $\tilde{p}_i$ are position embeddings (Al-Badrashiny et al., 2017) indicating the distance from w_i to e_1 and e_2 respectively. t_i and $\tilde{t}_i$ are entity type embedding (Ren et al., 2016; Huang et al., 2016) of e_1 and e_2. c_i is the chunking embedding, and η_i is a binary digit indicating whether the word is within the shortest dependency path between e_1 and e_2 (Bunescu and Mooney, 2005; Liu et al., 2015; Huang et al., 2017). All these embeddings except pre-trained word embedding are randomly initialized and optimized during training. Thus the input layer is a sequence of word representations $V = \{\tilde{v}_1, \tilde{v}_2, ..., \tilde{v}_n\}$. We then apply the convolution weights W to each sliding n-gram phrase g_j with a biased vector b, i.e., $g_j^{'} = \tanh(W \cdot V) + b$. All n-gram representations $g_j^{'}$ are further used to get an overall vector representation f by max-pooling.

Once we obtain f_s^p, f_s^c, f_s^p and f_s^c, we compute the *difference loss*:

$$L_{diff} = ||f_s^{p\top} \cdot f_s^c + f_t^{p\top} \cdot f_t^c||_2^F$$

where $||.||_2^F$ represents the squared Frobenius norm.

To limit the genre-agnostic features from various genres into a shared feature space, we further design a genre adversarial training component. We take the genre-agnostic features from both source genre and target genre as input to a Gradient Reversed Layer(GRL) (Ganin et al., 2016), which acts as a general hidden layer in forward process and reverses the gradient in loss backward phase to confuse the genre classifier, so that it cannot distinguish the input features from the source genre to the target genre:

$$L_{adv} = \sum_{i=0}^{N_s+N_t} d_i l \log(\hat{d_i}) + (1-d_i)\log(1-\hat{d_i})$$

where $d_i \in \{0,1\}$ indicates the samples from the source genre or the target genre, and N_s, N_t refer to the number of examples in the source genre and the target genre respectively. The term $\hat{d_i}$ represents the probability of the sample from the source genre, which is acquired by a linear function of the genre classifier.

2.3 Genre Reconstruction

Till now, we can separate the features of each genre into two separated feature spaces by optimizing L_{diff} and L_{adv}. However, there is no guarantee that the separated feature spaces are actually meaningful. From equation L_{diff}, we can see that the f_s^p, f_t^p would be easily optimized to zero if we did not place a constraint, in which case the model would fail to train. Therefore, we further reconstruct the input sentence from both genre-specific features and genre-agnostic features.

For each genre, e.g., the source genre, we first sum the genre-specific feature vector f_s^p and genre-agnostic feature vector f_s^c, i.e., $f_s = f_s^p + f_s^c$. We take f_s as input to an unpooling layer (Zeiler and Fergus, 2014) followed by a deconvolutional neural netowrk (DcNN) (Xu et al., 2014). The output of DcNN will include the same number of decoded vectors $V^* = \{\tilde{v}_1^*, \tilde{v}_2^*, ..., \tilde{v}_n^*\}$ as input $V = \{\tilde{v}_1, \tilde{v}_2, ..., \tilde{v}_n\}$. We optimize the DcNN with the following reconstruction loss:

$$L_{rec} = 1 - \sum_{i=0}^{n} |cos(\tilde{v}_i, \tilde{v}_i^*)|$$

where n indicates the total number of words in the input sentence, $\tilde{v}_i$ represents the input word representation described in Section 2.2, and $\tilde{v}_i^*$ is the corresponding reconstructed vector from DcNN.

2.4 Cross Genre Relation Extraction

We next utilize the genre-agnostic features from the source genre f_s^c to train a relation classifier. We first feed f_s^c into a fully connected layer and obtain a dense vector, then we use a linear projection function with a softmax as the relation classifier to determine the relation type

$$L_{relation} = \sum_{i=0}^{N_s}\sum_{k=0}^{K} -x_k \log(x_k)$$

where K is the total number of relation types. x_k represents the probability of entities being classified to category k.

We finally linearly combine all the loss functions and jointly optimize the model using SGD (Bottou, 2010).

$$L = L_{relation} + \alpha L_{diff} + \beta L_{rec} + \gamma L_{adv}$$

where α, β, γ denote the weights of various losses.[2]

3 Experiments

3.1 Data and Parameters

We evaluate our approach on the English portion of ACE2005 dataset (Walker et al., 2006; Ji et al., 2010; Hong et al., 2015; Yu et al., 2016). It covers 6 genres: Newswire (nw), Broadcast Conversation (bc), Broadcast News (bn), Telephone Speech (cts), Usenet Newsgroups (un), and Weblogs (wl) and 11 relation types. Following previous work (Yu et al., 2015; Nguyen and Grishman, 2015; Gormley et al., 2015), we use newswire and broadcast news (nw&bn) as training data, half of bc as development set, and test the model on the remaining half of bc, cts, wl. We conduct the same preprocessing steps as previous work and yield 43,497 entity pairs in total for training.

Table 3.1 shows the hyper-parameters that we use to train our model.

Hyper-parameters	Value
# of Filters in Shared/Private CNN encoder	800
Filter Width	3
Hidden Size of Fully Connected Layer	300
Position Embedding Size	25
Entity Type/Chunking Embedding Size	25
Optimizer	SGD
Learning rate	0.001
Pre-trained Word Embedding	Glove-100[3]

Table 1: Hyper-parameters

3.2 Baseline Models

We compare our approach with the following methods:

FCM (Gormley et al., 2015) is a feature combination model which composes word embeddings with traditional linguistic features.

Hybrid FCM (Gormley et al., 2015) incorporates many more selected linguistic features compared to FCM.

---

[2] We set $\alpha = 0.075, \beta = 0.01, \gamma = 0.25$ when the model performs the best on the development set.

LRFCM (Yu et al., 2015) is a feature compositional model which scales to more features and more labels.

Log-linear & DNN (Nguyen and Grishman, 2015) explores CNN, Bi-GRU, Forward GRU, Backward GRU, and log-linear model for relation extraction. We compare against the performances of individual models instead of assembled models.

CNN+DANN (Fu et al., 2017) utilizes domain adversarial training to automatically extract genre-agnostic features for source and target genre within one feature space.

3.3 Comparison and Analysis

Table 2 shows the cross-genre relation extraction performance among various methods. Our approach significantly outperforms all previous baselines by 1.2%-1.7% (F1). Table 3 presents the results without using extra linguistic features (only embedding based features), our approach achieves 2.9%-6.1% absolute gain over baselines. The ablation test by removing each component at a time justifies the contribution of each method. The difference and reconstruction components ensure the features to be separated into shared and private spaces, and they can remove redundant genre-specific features to some extent. That's why we got a significant F-score improvement when only utilizing these two components. The adversarial training component can further encourage the features of each genre from the shared encoder to be close to each other, thus the performance is further improved. We also conduct ablation experiments on each feature components. Among the linguistic features we used, the entity type and position features contribute the most to the performance. For example, the relation extraction performance decreases by about 8% if removing the entity type feature. We analyze the reasons and find that the entity type feature is vital to ensure the types of two entity mentions to be consistent with the hard entity type constraint of each relation type defined in ACE schema.

For the remaining errors, we notice that our model easily fails to predict relations between nested entity mentions. For example, in "*Our president has put homeland security in the hands of failed Republican hacks.*", our model mistakenly predicts the relationship between *Republican* and *failed Republican hacks* as *None* instead of *organization-affiliation*, due to the lack of context information. Besides, we also observe some failed cases where the two entities are separated with a extreme wide context, which suggests us to incorporate dependency path based deep neural networks into the framework.

4 Related Work

Previous studies on cross-genre relation extraction either manually or automatically extract genre-agnostic features (Plank and Moschitti, 2013; Nguyen and Grishman, 2014; Yu et al., 2015; Gormley et al., 2015; Nguyen and Grishman, 2015), suffering from human labor and limited coverage of effective features, or automatically project source and target genres into one unified feature space and learn genre shared features (Fu et al., 2017), which inevitably introduces noise from genre specific features. Compared with these methods, our approach separates genre-specific features from genre-agnostic features first, and then automatically extracts meaningful features for cross-genre relation extraction.

Our work is also related to studies on domain separation networks (Bousmalis et al., 2016; Liu et al., 2017; Chen et al., 2017), which explicitly extracts features from two separate subspaces: domain-specific and domain-agnostic. We adopt a similar framework for cross-genre relation extraction and introduce a novel reconstruction component which is proved to be suitable to relation extraction.

5 Conclusions

We propose a genre separation framework for cross-genre relation extraction. Without requiring human crafted features, this framework can effectively separate genre-specific features from genre-agnostic ones, and automatically extract meaningful features for the task. To ensure the separation of features within each genre and enforce the genre agnostic features from source genre and target genre to be in the same feature space, we design a difference loss and an adversarial training component. Experiments on various genres demonstrate the effectiveness of our framework. In the future, we will extend our framework to cross-lingual and cross-domain information extraction tasks.

Effective Use of Context in Noisy Entity Linking

Abstract

To disambiguate between closely related concepts, entity linking systems need to effectively distill cues from a mention's textual context. We investigate several techniques for using these cues in the task of noisy entity linking on short texts. Our starting point is a state-of-the-art attention-based model from prior work; while this model's attention typically identifies context that is topically relevant, it fails to identify some of the most indicative context words, especially those exhibiting lexical overlap with the true title. Augmenting the model with convolutional networks over characters still leaves it largely unable to pick up on these cues compared to sparse features that target them directly, indicating that automatically learning how to identify relevant character-level context features is a hard problem. Armed with these sparse features, our final system[1] outperforms past work on the WikilinksNED test set by 2.8% absolute.

1 Introduction

Effectively using an entity mention's context to disambiguate it is the crux of the entity linking task: in isolation, the mention *Richard Wright* could refer to three possible entities in Wikipedia's knowledge base corresponding to an artist, a musician, or an author. Previous work in this area has distilled context information by exploiting tf-idf features (Cucerzan, 2007; Milne and Witten, 2008; Ratinov et al., 2011), global link coherence (Hoffart et al.; Sil and Florian, 2016), cues from coreference (Cheng and Roth, 2013; Hajishirzi et al., 2013; Durrett and Klein, 2014), convolutional neural networks (Sun et al.; Francis-Landau et al., 2016), or more sophisticated neural architectures (Gupta et al., 2017; Sil et al., 2018). These approaches typically focus on aggregating information from a mix of sources, including long-range information from the textual context or other linked entities. While this approach is suitable for entity linking settings such as newswire (Bentivogli, 2010) and Wikipedia (Ratinov et al., 2011), we cannot always rely on this information in other settings like Twitter (Guo et al., 2013; Fang and Chang, 2014; Huang et al., 2014; Dredze et al., 2016), Snapchat (Moon et al., 2018), other web platforms (Eshel et al., 2017), or dialogue systems (Bowden et al., 2018). We need models that can make effective use of limited context windows in noisy settings.

In this work, we investigate this problem of effectively using context in the setting of the WikilinksNED dataset from Eshel et al. (2017). The examples in this dataset, which consists of 3.2 million entity disambiguation examples derived from Wikilinks (Singh et al., 2012), have at most 20 words of context on either side and usually no other mentions of the entity being disambiguated. We build off a state-of-the-art attentive LSTM model from prior work (Eshel et al., 2017) and show that despite its good performance, it fails to resolve some examples that human readers would find trivial. For example, disambiguating the identity of the song *Down* in Figure 1 is easy if we can recognize the nearby string *Jay Sean* in the context, but the model sometimes fails to do this.

We explore the performance of a standard attention mechanism as well as two modifications. First, we inject character information into the model through character-level CNNs; these give the model a deeper ability to recognize character correspondences between the context and entity title. However, these convolutional filters struggle to learn useful features in this noisy context and ultimately do not help performance. By contrast, sparse features explicitly targeting these overlaps

---

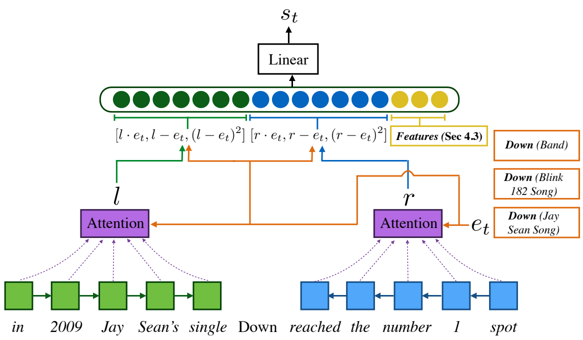

Figure 1: Neural entity linking model. *Down* has three possible link targets: in the attentive variants of our model, each target computes attention weights over GRUs that consume the left and right context. These representations are passed into a layer that compares them to the entity's embedding, yielding a final score which is normalized over all possible link targets.

appear to be more successful. We investigate the relation between our model's attention and what the sparse features learn. Our final model, using these features, achieves an accuracy of 75.8% on this dataset, substantially outperforming our baseline model as well as results from prior work.

2 Basic Model

The WikilinksNED dataset consists of entity mentions in context scraped from the web, with gold annotation derived from the fact that those mentions originally appeared with hyperlinks to Wikipedia. We denote the mention text (i.e., anchor text of the hyperlink) by m, and denote the left and right context of the mention by c_l and c_r respectively; these are at most 20 words. For this dataset, we can assume that the possible linked titles for a mention have been seen in training, and the main task is instead to disambiguate between them and identify the gold title t^*. We therefore follow prior work (Eshel et al., 2017) and take as candidates all gold entities in the training set whose mention was m rather than relying on a separate candidate generation scheme.

Our model places a distribution over titles $P(t|m, c_l, c_r)$, where t takes values in the set of candidate Wikipedia titles for that mention. This model, depicted in Figure 1, roughly follows that of Eshel et al. (2017), with some key differences, as we discuss in the rest of this section.

Embedding contexts Given an example of the form (m, c_l, c_r), our model first uses a GRU layer (Cho et al., 2014) over each context to convert c_l and c_r into continuous vector representations l and r, respectively. Our word embeddings are trained over Wikipedia as described in the following paragraph.

Embedding entities We follow the method of Eshel et al. (2017) for generating entity embeddings, using `word2vecf` (Levy and Goldberg, 2014) to jointly train word and entity embeddings simultaneously using Wikipedia article text. Each title t is associated in turn with each content word w in the article, yielding a set of (w, t) pairs that are consumed by the training procedure. This yields a set of title embeddings e_t which we can treat as distributed representations of entities.

Entity-context comparison We systematically compare the representations for l, r, and e_t as follows:

$$[l \cdot e_t, r \cdot e_t, l - e_t, r - e_t, (l - e_t)^2, (r - e_t)^2]$$

where $\cdot$ denotes the conventional dot product and the other comparisons are elementwise. These features form the input to a final feedforward layer which produces a real-valued score s_t for the given title. Repeating this computation for each title, our model's distribution is $P(t|m, c_l, c_r) = \text{softmax}_t(s_t)$.

Training Because our model involves substantial computation for each possible title, we want to limit the set of titles considered during training. For each example we consider, we construct a set T containing the gold title and 4 negative "distractor" titles from the candidate set. Unlike Eshel et al. (2017), we structure training as a multiclass decision among these titles rather than a binary prediction problem over each title as gold or not. We run our model over the candidates $t \in T$ to produce the distribution $P(t|m, c_l, c_r)$ and train to maximize the log probablity $\log P(t^*|m, c_l, c_r)$ of the gold title.

Results The model set forth in this section is the basis for the remaining models in this paper; we call it the GRU model as that is the only context encoding mechanism it uses. As shown in Table 1, this GRU model gets a score of 73.4 on the WikilinksNED development set. In the next section, we explore techniques for using the context in a more sophisticated way to improve further on this result.

Model	Accuracy on Test (%)
Eshel et al. (2017)	73.0
Eshel system release	72.2
GRU+ATTN	74.5
GRU+ATTN+FEATS	**75.8**
Model	**Accuracy on Dev (%)**
GRU	73.4
GRU+ATTN	74.4
GRU+ATTN+FEATS	**74.9**
GRU+ATTN+CNN	73.8

Table 1: Results on the WikilinksNED dev and test sets. Our model including features achieves state-of-the-art performance on the test set, compared to both the reported numbers from Eshel et al. (2017) as well as their released software. Incorporating character CNNs surprisingly leads to lower performance compared to these simple features.

3 Exploiting Context Cues

3.1 Attention

One way to improve over the basic GRU model is to use attention over the context based on the title under consideration. The attention we use is a modified version of the dot product attention (Luong et al., 2015) used by Eshel et al. (2017), allowing the model to weight the importance of the outputs of the GRU at each time step. Each context (left and right) has its own attention weights. For a given side of context and candidate t, the attention first computes a transformation of the entity embedding e_t as follows: $q_t = \tanh(We_t)$. This allows the model to learn an attention query q_t distinct from the candidate embedding e_t. The model then computes attention probabilities α_i for each GRU output o_i, normalized over the entire sequence of GRU outputs (of length n):

$$\alpha_i = \text{softmax}_i(q_t \cdot o_i)$$

The resulting probability distribution is used to take a weighted sum of GRU outputs to get a representation a:

$$a = \sum_i^n \alpha_i o_i$$

We compute a_l and a_r independently and symmetrically for the left and right context. These vectors are then fed forward through the model as the final continuous representation of the left or right context, l or r respectively.

Results In Table 1, we see that our model with attention (GRU+ATTN) outperforms our basic GRU model by around 1% absolute. It also outperforms the roughly similar model of Eshel et al. (2017) on the test set: this gain is due to a combination of factors including the improved training procedure and some small modeling changes.[2] However, our attention scheme is not without its shortcomings, as we now discuss.

3.2 Shortcomings of Attention

One common and frustrating error our model makes is failing to correctly disambiguate mentions whose contexts share similar words or character overlap with the gold entity's actual Wikipedia title. In these instances, the model fails to attend correctly to words that we, as human readers, would most likely see as disambiguating terms. For instance, in this example's left context:

> ...known also for the B.P. Koirala Institute of Health Sciences, one of the biggest government hospital. The indigenous **people** of Dharan are *Limbu* ...

the model fails to identify **people** as a critical term for disambiguation. This failure is partially due to the model's sole reliance on distributed representations: the embedding for **people** and the title embedding for *Limbu People* need to somehow contain enough common information for the model to associate these, identify **people** as an important token, and use it to disambiguate between candidate titles such as *Limbu People*, *Limbu Language*, and *Limbu Alphabet*. Moreover, with such noisy, unstructured context, it is difficult for the model to learn to rely on other grammatical or semantic cues (such as *are* indicating that the title is probably a plural noun, which *alphabet* and *language* are not).

3.3 Character CNNs

One way to address these issues in the model is to exploit more fine-grained character-level information. This circumvents the need to separately learn a distributed correspondence between terms with lexical overlap, and is especially useful when these terms may be unknown words; for example, a year mentioned within a context is often

---

[2] Note that in Eshel et al. (2017), the authors point out that their dataset has a high percentage of errors (35% of the errors made by their model are spurious), meaning that the skyline on this task is likely not higher than 90%.

unknown and therefore assigned an UNK embedding, even if that year matches exactly with a year in the gold candidate's title.

One solution to this is to allow our model to consult character-level information, which past models have done successfully for named entity recognition (Chiu and Nichols, 2015; Lample et al., 2016; Ma and Hovy, 2016), text classification (Zhang et al., 2015), and POS tagging (Santos and Zadrozny, 2014). We use convolutional neural networks (CNNs) to distill character representations of words into vectors that we concatenate with our word representations. We additionally use character CNNs over entity titles and concatenate these representations with the title embeddings e_t, to allow the model to learn to characterize similarities between contexts and entity titles. Our CNNs use window sizes of 6 and 100 filters each; these values were selected through hyperparameter tuning on the development set.

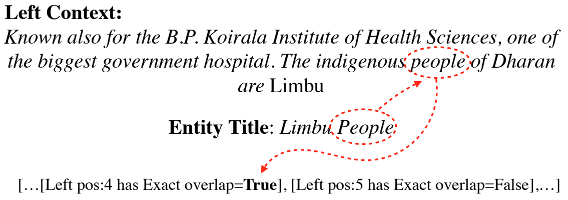
Table 1 shows the impact of incorporating character CNNs (GRU+ATTN+CNN). Surprisingly, these have a mild negative impact on performance. One possible explanation of this is that it causes the model to split its attention between semantically important and lexically similar context terms. Consider the following example:

> really think Final Fight could be a lot of a fun as a vigilante justice **movie** with a high quotient of hand-to-hand fight sequences. Think *The Warriors*

The gold title is *The Warrior (film)* and the base model correctly places 90% of its attention weight on the word **movie** when calculating attention for this title. However, the character-level CNN model only places 60% of its attention weight on it, distributing its attention values more evenly across the rest of the words. Such cases are frequent: the average highest weight given by attention in GRU+ATTN+CNN is about 6% lower than the average highest attention weight given by GRU+ATTN. The CNNs seem to have generally decreased the model's confidence in what context clues are key for disambiguation, leading to lower performance. We will return to more analysis of this in Section 4.

3.4 Lexical Feature Set

To determine whether character level overlap between the entity title and context is useful, we take a more direct approach to incorporating that information into our model and build a set of sparse features that directly target it.



Left Context:
Known also for the B.P. Koirala Institute of Health Sciences, one of the biggest government hospital. The indigenous people of Dharan are Limbu

Entity Title: *Limbu People*

[…[Left pos:4 has Exact overlap=**True**], [Left pos:5 has Exact overlap=False],…]

Figure 2: An example of feature generation from an example. Here, because the word *people* occurs in the title and in the left context 4 words away from the mention, the indicator feature [Pos=4,Match=ExactWord,Context=Left] fires in the feature set.

Figure 2 shows an example of how our features are computed. We fire features on each word in the context that is either an exact match or a substring of a word in the candidate title; *people* is the relevant token here. We conjoin that match information with whether the word is in the left or right context along with the bucketed offset of the word from the mention. This feature set is then appended to the vector comparison features to form the input to the model's feedforward layer (see Figure 1).

Table 1 shows the results of stacking these features on top of our model with attention (GRU+ATTN+FEATS). We see our highest development set performance and correspondingly high test performance from this model. This indicates that character-level information is useful for disambiguation, but character CNNs as we incorporated them are not able to distill it as effectively as sparse features can. Our model augmented with these sparse features achieves state-of-the-art results on the test set.

4 Attention and "Obvious" Terms

Now that we have identified features which seem useful for this entity linking problem, we can ask how the tokens attended by our attention mechanism compare to those singled out by the features.

Table 2 contains statistics regarding the attention values of our GRU+ATTN and GRU+ATTN+CNN model on a subset of examples that both models got wrong. We define accuracy as the percentage of examples in which the model gives the highest attention to a word

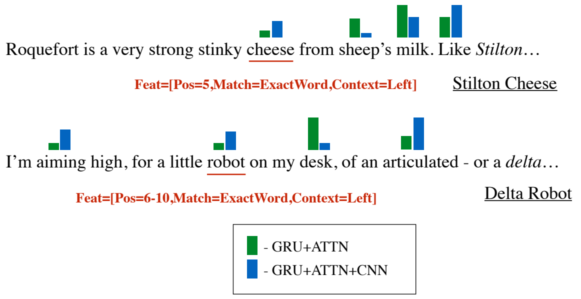


Figure 3: Examples of our models putting high attention weight into irrelevant context words, not acknowledging the relevance of disambiguating terms that share lexical overlap with the correct title. We display the weight given to the top 4 attended words above each word for two of our models.

that contains one of our lexical features, out of all examples where such a feature exists anywhere. The reported probability mass is the total attention mass that the model puts into words that associated with lexical features, averaged over all examples where such features exist. We see that the model frequently fails to exploit this information, and moreover the addition of CNNs does not strongly improve this.

Figure 3 shows examples of this behavior. In the first example, rather than identifying *cheese* as a salient term, both models instead focus more heavily on *milk* and *like*. Similarly, in the second example, the model fails to recognize the importance of *robot* in the context.

One possible reason that CNNs don't help more is that the sparse features only trigger on a subset of examples. Because the CNNs process every example, they may not see enough examples of lexical overlap to pick up on it, and instead try to augment what the word embedding model is already doing with subword information, which ends up being unstable for this task. Naturally, words with these overlap characteristics are not always the most disambiguating term. However, in light of noisy contexts, when the standard representation of context fails to be sufficient for allowing the model to disambiguate, we want the model to be able to leverage this character level information to help it make intuitive decisions, which the CNN fails to do.

Context	**Acc (%)**	**Prob Mass (%)**
GRU+ATTN L	0.41	0.32
GRU+ATTN R	0.36	0.30
GRU+ATTN+CNN L	0.46	0.32
GRU+ATTN+CNN R	0.36	0.28

Table 2: Our models' attention "accuracy": how often each model's maximally-attended word also triggered a feature to fire. Prob Mass indicates the average sum of attention scores over feature-triggering words. All values are computed over a sample of 10,000 examples that each model got wrong.

5 Conclusion

In this paper, we observed that in noisy entity linking settings on short texts, neural models relying on attention do not always pick up on the correct context clues, even when those clues exhibit very obvious surface overlap with the correct entity title. These models can perform better when augmented with sparse features explicitly targeting this kind of lexical overlap: our system using these features achieves state-of-the-art disambiguation accuracy on the WikilinksNED dataset. By contrast, automatically learning learning fine-grained character-level features with CNNs in this context is hard. More exploration is needed to better understand what inductive biases are necessary for an entity linking system to make maximally effective use of the information available to it.

Abstract

The task of event detection involves identifying and categorizing event triggers. Contextual information has been shown effective on the task. However, existing methods which utilize contextual information only process the context once. We argue that the context can be better exploited by processing the context multiple times, allowing the model to perform complex reasoning and to generate better context representation, thus improving the overall performance. Meanwhile, dynamic memory network (DMN) has demonstrated promising capability in capturing contextual information and has been applied successfully to various tasks. In light of the multi-hop mechanism of the DMN to model the context, we propose the trigger detection dynamic memory network (TD-DMN) to tackle the event detection problem. We performed a five-fold cross-validation on the ACE-2005 dataset and experimental results show that the multi-hop mechanism does improve the performance and the proposed model achieves best F_1 score compared to the state-of-the-art methods.

1 Introduction

According to ACE (Automatic Content Extraction) event extraction program, an event is identified by a word or a phrase called event trigger which most represents that event. For example, in the sentence "No major *explosion* we are aware of", an event trigger detection model is able to identify the word "*explosion*" as the event trigger word and further categorize it as an *Attack* event. The ACE-2005 dataset also includes annotations for event arguments, which are a set of words or phrases that describe the event. However, in this work, we do not tackle the event argument classification and focus on event trigger detection.

The difficulty of the event trigger detection task lies in the complicated interaction between the event trigger candidate and its context. For instance, given a sentence at the end of a passage:

they are going over there to do a mission they believe in and as we said, 250 *left* yesterday.

It's hard to directly classify the trigger word "*left*" as an "*End-Position*" event or a "*Transport*" event because we are not certain about what the number "250" and the pronoun "they" are referring to. But if we see the sentence:

we are seeing these soldiers head out.

which is several sentences away from the former one, we now know the "250" and "they" refer to "the soldiers", and from the clue "these soldiers head out" we are more confident to classify the trigger word "*left*" as the "*Transport*" event.

From the above, we can see that the event trigger detection task involves complex reasoning across the given context. Exisiting methods (Liu et al., 2017; Chen et al., 2015; Li et al., 2013; Nguyen et al., 2016; Venugopal et al., 2014) mainly exploited sentence-level features and (Liao and Grishman, 2010; Zhao et al., 2018) proposed document-level models to utilize the context.

The methods mentioned above either not directly utilize the context or only process the context once while classifying an event trigger candidate. We argue that processing the context multiple times with later steps re-evaluating the context with information acquired from the previous steps improves the model performance. Such a mechanism allows the model to perform complicated reasoning across the context. As in the example, we are more confident to classify "*left*" as a "*Tranport*" event if we know "250" and "they" refer to "soldiers" in previous steps.

We utilize the dynamic memory network (DMN) (Xiong et al., 2016; Kumar et al., 2016) to capture the contextual information of the given trigger word. It contains four modules: the input module for encoding reference text where the an-

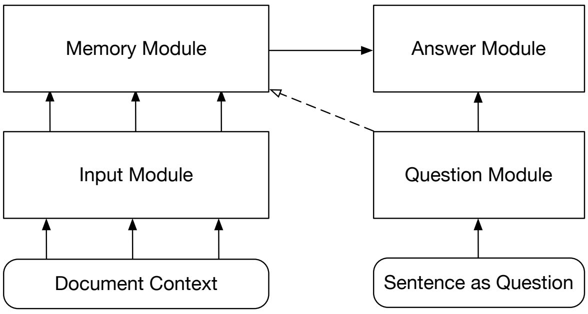

Figure 1: Overview of the TD-DMN architecture

swer clues reside, the memory module for storing knowledge acquired from previous steps, the question module for encoding the questions, and the answer module for generating answers given the output from memory and question modules.

DMN is proposed for the question answering task, however, the event trigger detection problem does not have an explicit question. The original DMN handles such case by initializing the question vector produced by the question module with a zero or a bias vector, while we argue that each sentence in the document could be deemed as a question. We propose the trigger detection dynamic memory network (TD-DMN) to incorporate this intuition, the question module of TD-DMN treats each sentence in the document as implicitly asking a question "What are the event types for the words in the sentence given the document context". The high-level architecture of the TD-DMN model is illustrated in Figure 1.

We compared our results with two models: DMCNN(Chen et al., 2015) and DEEB-RNN(Zhao et al., 2018) through 5-fold cross-validation on the ACE-2005 dataset. Our model achieves best F_1 score and experimental results further show that processing the context multiple times and adding implicit questions do improve the model performance. The code of our model is available online.[1]

2 The Proposed Approach

We model the event trigger detection task as a multi-class classification problem following existing work. In the rest of this section, we describe four different modules of the TD-DMN separately along with how data is propagated through these modules. For simplicity, we discuss a single document case. The detailed architecture of our model is illustrated in Figure 2.

2.1 Input Module

The input module further contains two layers: the sentence encoder layer and the fusion layer. The sentence encoder layer encodes each sentence into a vector independently, while the fusion layer gives these encoded vectors a chance to exchange information between sentences.

Sentence encoder layer Given document d with l sentences $(s_1, \dots, s_l)$, let s_i denotes the i-th sentence in d with n words $(w_{i1}, \dots, w_{in})$. For the j-th word w_{ij} in s_i, we concatenate its word embedding $\boldsymbol{w_{ij}}$ with its entity type embedding[2] $\boldsymbol{e_{ij}}$ to form the vector $\boldsymbol{W_{ij}}$ as the input to the sentence encoder Bi-GRU(Cho et al., 2014) of size H_s. We obtain the hidden state $\boldsymbol{h_{ij}}$ by merging the forward and backward hidden states from the Bi-GRU:

$$\boldsymbol{h_{ij}} = \overrightarrow{\mathrm{GRU}_s}(\boldsymbol{W_{ij}}) + \overleftarrow{\mathrm{GRU}_s}(\boldsymbol{W_{ij}}) \quad (1)$$

where + denotes element-wise addition.

We feed $\boldsymbol{h_{ij}}$ into a two-layer perceptron to generate the unnormalized attention scalar u_{ij}:

$$u_{ij} = \tanh(\boldsymbol{h_{ij}} \cdot W_{s_1}) \cdot W_{s_2} \quad (2)$$

where W_{s_1} and W_{s_2} are weight parameters of the perceptron and we omitted bias terms. u_{ij} is then normalized to obtain scalar attention weight α_{ij}:

$$\alpha_{ij} = \frac{\exp(u_{ij})}{\sum_{k=1}^{n} \exp(u_{ik})} \quad (3)$$

The sentence representation $\boldsymbol{s_i}$ is obtained by:

$$\boldsymbol{s_i} = \sum_{j=1}^{n} \alpha_{ij} \boldsymbol{h_{ij}} \quad (4)$$

Fusion layer The fusion layer processes the encoded sentences and outputs fact vectors which contain exchanged information among sentences. Let $\boldsymbol{s_i}$ denotes the i-th sentence representation obtained from the sentence encoder layer. We generate fact vector $\boldsymbol{f_i}$ by merging the forward and backward states from fusion GRU:

$$\boldsymbol{f_i} = \overrightarrow{\mathrm{GRU}_f}(\boldsymbol{s_i}) + \overleftarrow{\mathrm{GRU}_f}(\boldsymbol{s_i}) \quad (5)$$

Let H_f denotes the hidden size of the fusion GRU, we concatenate fact vectors $\boldsymbol{f_1}$ to $\boldsymbol{f_l}$ to obtain the matrix $\boldsymbol{F}$ of size l by H_f, where the i-th row in $\boldsymbol{F}$ stores the i-th fact vector $\boldsymbol{f_i}$.

---

[1] https://github.com/AveryLiu/TD-DMN

[2] The ACE-2005 includes entity type (including type "NA" for none-entity) annotations for each word, the entity type embedding is a vector associated with each entity type.

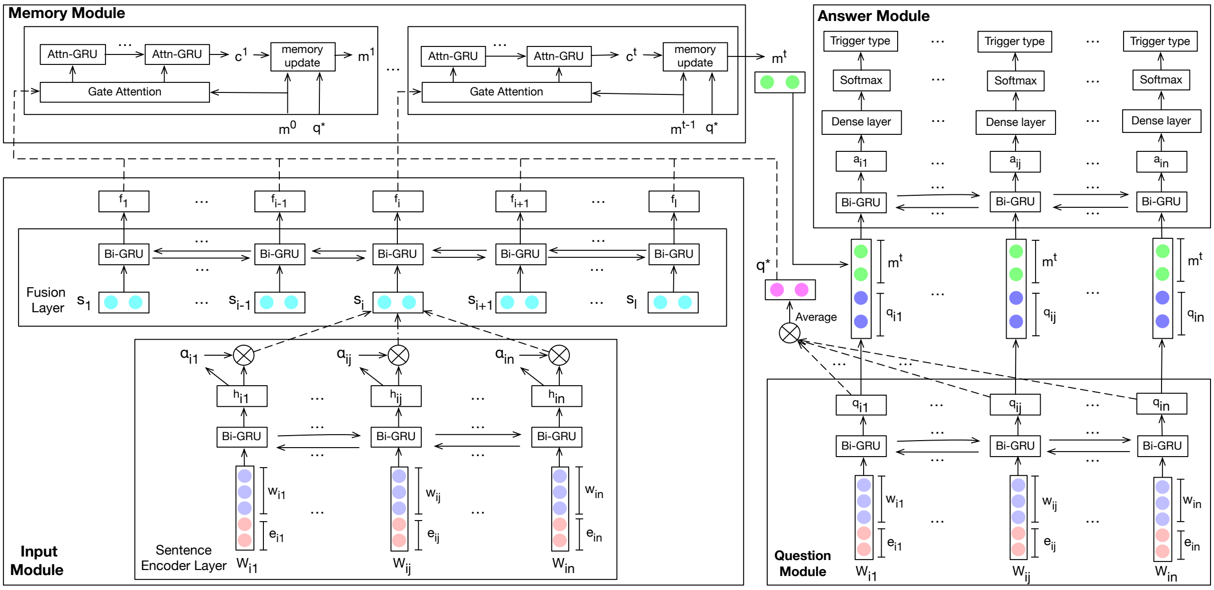

Figure 2: The detailed architecture of the TD-DMN model. The figure depicts a simplified case where a single document d with l sentences is the input to the input module and a sentence s_i of d with n words is the input to the question module. The input module encodes document d into a fact matrix $\{\boldsymbol{F}|\boldsymbol{f_1}, \ldots, \boldsymbol{f_l}\}$. The question module encodes sentence s_i into the question vector $\boldsymbol{q^*}$. The memory module initializes $\boldsymbol{m_0}$ with $\boldsymbol{q^*}$ and iteratively processes for t times, at each time k it produces a memory vector $\boldsymbol{m_k}$ using fact matrix $\boldsymbol{F}$, question vector $\boldsymbol{q^*}$ and previous memory state $\boldsymbol{m_{k-1}}$. The answer module outputs the predicted trigger type for each word in s_i using the concatenated tensor of the hidden states of the question module and the last memory state $\boldsymbol{m_t}$.

2.2 Question Module

The question module treats each sentence s in d as implicitly asking a question: What are the event types for each word in the sentence s given the document d as context? For simplicity, we only discuss the single sentence case. Iteratively processing from s_1 to s_l will give us all encoded questions in document d.

Let $\boldsymbol{W_{ij}}$ be the vector representation of j-th word in s_i, the question GRU generates hidden state $\boldsymbol{q_{ij}}$ by:

$$\boldsymbol{q_{ij}} = \overrightarrow{\mathrm{GRU}}_q(\boldsymbol{W_{ij}}) + \overleftarrow{\mathrm{GRU}}_q(\boldsymbol{W_{ij}}) \quad (6)$$

The question vector $\boldsymbol{q^*}$ is obtained by averaging all hidden states of the question GRU:

$$\boldsymbol{q^*} = \frac{1}{n}\sum_{j=1}^{n} \boldsymbol{q_{ij}} \quad (7)$$

Let H_q denotes the hidden size of the question GRU, $\boldsymbol{q^*}$ is a vector of size H_q, the intuition here is to obtain a vector that represents the question sentence. $\boldsymbol{q^*}$ will be used for the memory module.

2.3 Memory Module

The memory module has three components: the attention gate, the attentional GRU(Xiong et al., 2016) and the memory update gate. The attention gate determines how much the memory module should attend to each fact given the facts $\boldsymbol{F}$, the question $\boldsymbol{q^*}$, and the acquired knowledge stored in the memory vector $\boldsymbol{m_{t-1}}$ from the previous step.

The three inputs are transformed by:

$$\boldsymbol{u} = [\boldsymbol{F} * \boldsymbol{q^*}; |\boldsymbol{F} - \boldsymbol{q^*}|; \boldsymbol{F} * \boldsymbol{m_{t-1}}; |\boldsymbol{F} - \boldsymbol{m_{t-1}}|] \quad (8)$$

where ; is concatenation. $*$, $-$ and $|.|$ are element-wise product, subtraction and absolute value respectively. $\boldsymbol{F}$ is a matrix of size (m, H_f), while $\boldsymbol{q^*}$ and $\boldsymbol{m_{t-1}}$ are vectors of size $(1, H_q)$ and $(1, H_m)$, where H_m is the output size of the memory update gate. To allow element-wise operation, H_f, H_q and H_m are set to a same value H. Meanwhile, $\boldsymbol{q^*}$ and $\boldsymbol{m_{t-1}}$ are broadcasted to the size of (m, H). In equation 8, the first two terms measure the similarity and difference between facts and the question. The last two terms have the same functionality for facts and the last memory state.

Let $\boldsymbol{\beta}$ of size l denotes the generated attention vector. The i-th element in $\boldsymbol{\beta}$ is the attention weight for fact $\boldsymbol{f_i}$. $\boldsymbol{\beta}$ is obtained by transforming $\boldsymbol{u}$ using a two-layer perceptron:

$$\boldsymbol{\beta} = \mathrm{softmax}(\tanh(\boldsymbol{u} \cdot W_{m_1}) \cdot W_{m_2}) \quad (9)$$

Methods	Fold 1			Fold 2			Fold 3			Fold 4			Fold 5			Avg

Table 1: 5-fold cross-validation results on the ACE-2005 dataset. The results are rounded to a single digit. The F_1 of the last column are calculated by averaging F_1 scores of all folds.

where W_{m_1} and W_{m_2} are parameters of the perceptron and we omitted bias terms.

The attentional GRU takes facts $\boldsymbol{F}$, fact attention $\boldsymbol{\beta}$ as input and produces context vector $\boldsymbol{c}$ of size H_c. At each time step t, the attentional GRU picks the $\boldsymbol{f_t}$ as input and uses β_t as its update gate weight. For space limitation, we refer reader to (Xiong et al., 2016) for the detailed computation.

The memory update gate outputs the updated memory $\boldsymbol{m_t}$ using question $\boldsymbol{q^*}$, previous memory state $\boldsymbol{m_{t-1}}$ and context $\boldsymbol{c}$:

$$\boldsymbol{m_t} = \mathrm{relu}([\boldsymbol{q^*}; \boldsymbol{m_{t-1}}; \boldsymbol{c}] \cdot W_u) \qquad (10)$$

where W_u is the parameter of the linear layer.

The memory module could be iterated several times with a new $\boldsymbol{\beta}$ generated for each time. This allows the model to attend to different parts of the facts in different iterations, which enables the model to perform complicated reasoning across sentences. The memory module produces $\boldsymbol{m_t}$ as the output at the last iteration.

2.4 Answer Module

Answer module predicts the event type for each word in a sentence. For each question GRU hidden state $\boldsymbol{q_{ij}}$, the answer module concatenates it with the memory vector $\boldsymbol{m_t}$ as the input to the answer GRU with hidden size H_a. The answer GRU outputs $\boldsymbol{a_{ij}}$ by merging its forward and backward hidden states. The fully connected dense layer then transforms $\boldsymbol{a_{ij}}$ to the size of the number of event labels O and the softmax layer is applied to output the probability vector $\boldsymbol{p_{ij}}$. The k-th element in $\boldsymbol{p_{ij}}$ is the probability for the word w_{ij} being the k-th event type. Let y_{ij} be the true event type label for word w_{ij}. Assuming all sentences are padded to the same length n, the cross-entropy loss for the single document d is applied as:

$$J(\boldsymbol{y}, \boldsymbol{p}) = -\sum_{i=1}^{l}\sum_{j=1}^{n}\sum_{k=1}^{O} \mathrm{I}(y_{ij} = k) \log p_{ij}^{(k)} \qquad (11)$$

where $I(\cdot)$ is the indicator function.

3 Experiments

3.1 Dataset and Experimental Setup

Dateset

Different from prior work, we performed a 5-fold cross-validation on the ACE 2005 dataset. We partitioned 599 files into 5 parts. The file names of each fold can be found online[3]. We chose a different fold each time as the testing set and used the remaining four folds as the training set.

Baselines

We compared our model with two other models: DMCNN (Chen et al., 2015) and DEEB-RNN (Zhao et al., 2018). DMCNN is a sentence-level event detection model which enhances traditional convolutional networks with dynamic multiple pooling mechanism customized for the task. The DEEB-RNN is a state-of-the-art document-level event detection model which firstly generate a document embedding and then use it to aid the event detection task.

Evaluation

We report precision, recall and F_1 score of each fold along with the averaged F_1 score of all folds. We evaluated all the candidate trigger words in each testing set. A candidate trigger word is correctly classified if its event subtype and offsets match its human annotated label.

Implementation Details

To avoid overfitting, we fixed the word embedding and added a 1 by 1 convolution after the embedding layer to serve as a way of fine tuning but with a much smaller number of parameters. We removed punctuations, stop words and sentences which have length less equal than 2. We used the Stanford corenlp toolkit(Manning et al., 2014) to

---

[3] https://github.com/AveryLiu/TD-DMN/data/splits

separate sentences. We down-sampled negative samples to ease the unbalanced classes problem.

The setting of the hyperparameters is the same for different hops of the TD-DMN model. We set H, H_s, H_c, and H_a to 300, the entity type embedding size to 50, W_{s_1} to 300 by 600, W_{s_2} to 600 by 1, W_{m_1} to 1200 by 600, W_{m_2} to 600 by 1, W_u to 900 by 300, the batch size[4] to 10. We set the down-sampling ratio to 9.5 and we used Adam optimizer (Kingma and Ba, 2014) with weight decay set to $1e^{-5}$. We set the dropout(Srivastava et al., 2014) rate before the answer GRU to 0.4 and we set all other dropout rates to 0.2. We used the pre-trained word embedding from (Le and Mikolov, 2014).

3.2 Results on the ACE 2005 Corpus

The performance of each model is listed in table 1. The first observation is that models using document context drastically outperform the model that only focuses on the sentence level feature, which indicates document context is helpful in event detection task. The second observation is that increasing number of hops improves model performance, this further implies that processing the context for multiple times does better exploit the context. The model may have exhausted the context and started to overfit, causing the performance drop at the fourth hop.

The performance of reference models is much lower than that reported in their original papers. Possible reasons are that we partitioned the dataset randomly, while the testing set of the original partition mainly contains similar types of documents and we performed a five-fold cross-validation.

3.3 The Impact of the Question Module

To reveal the effects of the question module, we ran the model in two different settings. In the first setting, we initialized the memory vector $\boldsymbol{m_0}$ and question vector $\boldsymbol{q^*}$ with a zero vector, while in the second setting, we ran the model untouched. The results are listed in the table 2. The two models perform comparably under the 1-hop setting, this implies that the model is unable to distinguish the initialization values of the question vector well in the 1-hop setting. For higher number of hops, the untouched model outperforms the modified one. This indicates that with a higher number of memory iterations, the question vector $\boldsymbol{q^*}$ helps the model to better exploit the context information.

Methods	F_1	F_1^*
TD-DMN 1-hop	65.48	65.52
TD-DMN 2-hop	65.69	65.46
TD-DMN 3-hop	**65.78**	65.51
TD-DMN 4-hop	65.57	65.40

Table 2: The impact of the question module, F_1^* indicates results with empty questions.

We still observe the increase and drop pattern of the F_1 for the untouched model. However, such a pattern is not obvious with empty questions. This implies that we are unable to have a steady gain without the question module in this specific task.

4 Future Work

In this work, we explored the TD-DMN architecture to exploit document context. Extending the model to include wider contexts across several similar documents may also be of interest. The detected event trigger information can be incorporated into question module when extending the TD-DMN to the argument classification problem. Other tasks with document context but without explicit questions may also benefit from this work.

5 Conclusion

In this paper, we proposed the TD-DMN model which utilizes the multi-hop mechanism of the dynamic memory network to better capture the contextual information for the event trigger detection task. We cast the event trigger detection as a question answering problem. We carried five-fold cross-validation experiments on the ACE-2005 dataset and results show that such multi-hop mechanism does improve the model performance and we achieved the best F_1 score compared to the state-of-the-art models.

Acknowledgments

We thank Prof. Huawei Shen for providing mentorship in the rebuttal phase. We thank Jinhua Gao for discussion on the paper presentation. We thank Yixing Fan and Xiaomin Zhuang for providing advice regarding hyper-parameter tuning. We thank Yue Zhao for the initial discussion on event extraction. We thank Yaojie Lu for providing preprocessing scripts and the results of DMCNN. We thank anonymous reviewers for their advice. The first author personally thank Wei Qi for being supportive when he was about to give up.

Do explanations make VQA models more predictable to a human?

Abstract

A rich line of research attempts to make deep neural networks more transparent by generating human-interpretable ‘explanations’ of their decision process, especially for interactive tasks like Visual Question Answering (VQA). In this work, we analyze if existing explanations indeed make a VQA model – its responses as well as failures – more predictable to a human. Surprisingly, we find that they do not. On the other hand, we find that human-in-the-loop approaches that treat the model as a black-box do.

1 Introduction

As technology progresses, we are increasingly collaborating with AI agents in *interactive* scenarios where humans and AI work together as a team, e.g., in AI-assisted diagnosis, autonomous driving, etc. Thus far, AI research has typically only focused on the AI in such an interaction – for it to be more accurate, be more human-like, understand our intentions, beliefs, contexts, and mental states.

In this work, we argue that for human-AI interactions to be more effective, humans must also understand the AI’s beliefs, knowledge, and quirks.

Many recent works generate human-interpretable ‘explanations’ regarding a model’s decisions. These are usually evaluated offline based on whether human judges found them to be ‘good’ or to improve trust in the model. However, their contribution in an interactive setting remains unclear. In this work, we evaluate the role of explanations towards making a model predictable to a human.

We consider an AI trained to perform the multi-modal task of Visual Question Answering (VQA) (Malinowski and Fritz, 2014; Antol et al., 2015), i.e., answering free-form natural language questions about images. VQA is applicable to scenarios where humans actively elicit information from visual data, and naturally lends itself to human-AI interactions. We consider two tasks that demonstrate the degree to which a human understands their AI teammate (we call Vicki) – Failure Prediction (FP) and Knowledge Prediction (KP). In FP, we ask subjects on Amazon Mechanical Turk to predict if Vicki will correctly answer a given question about an image. In KP, subjects predict Vicki’s exact response.

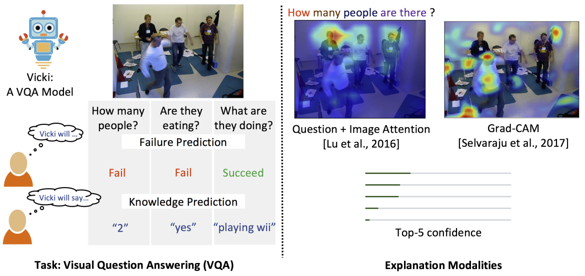

Figure 1: We evaluate the extent to which explanation modalities (right) and familiarization with a VQA model help humans predict its behavior – its responses, successes, and failures (left).

We aid humans in forming a mental model of Vicki by (1) familiarizing them with its behavior in a ‘training’ phase and (2) exposing them to its internal states via various explanation modalities. We then measure their FP and KP performance.

Our key findings are that (1) humans are indeed capable of predicting successes, failures, and outputs of the VQA model better than chance, (2) explicitly training humans to familiarize themselves with the model improves their performance, and (3) existing explanation modalities do not enhance human performance.

2 Related Work

Explanations in deep neural networks. Several works generate explanations based on inter-

---

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1036–1042
Brussels, Belgium, October 31 - November 4, 2018.

nal states of a decision process (Zeiler and Fergus, 2014; Goyal et al., 2016b), while others generate justifications that are consistent with model outputs (Ribeiro et al., 2016; Hendricks et al., 2016). Another popular form of providing explanations is to visualize regions in the input that contribute to a decision – either by explicitly attending to relevant input regions (Bahdanau et al., 2014; Xu et al., 2015), or exposing implicit attention for predictions (Selvaraju et al., 2017; Zhou et al., 2016).

Evaluating explanations. Several works evaluate the role of explanations in developing trust with users (Cosley et al., 2003; Ribeiro et al., 2016) or helping them achieve an end goal (Narayanan et al., 2018; Kulesza et al., 2012). Our work, however, investigates the role of machine-generated explanations in improving the *predictability* of a VQA model.

Failure prediction. While Bansal et al. (2014) and Zhang et al. (2014) predict failures of a model using simpler statistical models, we explicitly train a person to do this.

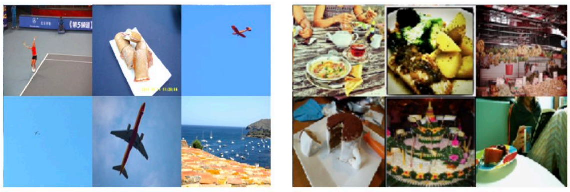
Legibility. Dragan et al. (2013) describe the intent-expressiveness of a robot as its trajectory being expressive of its goal. Analogously, we evaluate if explanations of the intermediate states of a VQA model are expressive of its output.

Humans adapting to technology. Wang et al. (2016) and Pelikan and Broth (2016) observe humans' strategies while adapting to the limited capabilities of an AI in interactive language games. In our work we explicitly measure to what extent humans can form an accurate model of an AI, and the role of familiarization and explanations.

3 Setup

Agent. We use the VQA model by Lu et al. (2016) as our AI agent (that we call Vicki). The model processes the question at multiple levels of granularity (words, phrases, entire question) and at each level, has explicit attention mechanisms on both the image and the question[1]. It is trained on the train split of the VQA-1.0 dataset (Antol et al., 2015). Given an image and a question about the image, it outputs a probability distribution over 1000 answers. Importantly, the model's image and question attention maps provide access to its 'internal states' while making a prediction.

Vicky is *quirky* at times, i.e., has biases, albeit in a predictable way. Agrawal et al. (2016) outlines several such quirks. For instance, Vicki has a limited capability to understand the image – when asked the color of a small object in the scene, say a soda can, it may simply respond with the most dominant color in the scene. Indeed, it may answer similarly even if no soda can is present, i.e. if the question is irrelevant.



What color is the grass? Blue

What are the people doing? Eating

How many people are there? 4

What is the man holding? Fire Hydrant

Figure 2: These montages highlight some of Vicki's quirks. For a given question, Vicki has the same response to each image in a montage. Common visual patterns (that Vicki presumably picks up on) within each montage are evident.

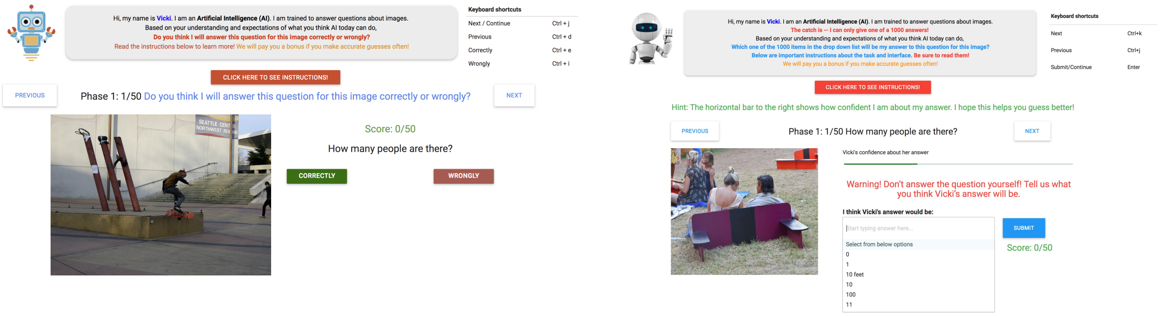
Further, Vicki has a limited capability to understand free-form natural language, and in many cases, answers questions based only on the first few words of the question. It is also generally poor at answering questions requiring "common sense" reasoning. Moreover, being a discriminative model, Vicki has a limited vocabulary (1k) of answers. Additionally, the VQA 1.0 dataset contains label biases; therefore, the model is very likely to answer "white' to a "what color" question (Goyal et al., 2016a).

To get a sense for this, see Fig. 2 which depicts a clear pattern. In top-left, even when there is no grass, Vicki tends to latch on to one of the dominant colors in the image. For top-right, even when there are no people in the image, it seems to respond with what people could *plausibly* do in the scene if they were present. In this work, we measure to what extent lay people can pick up on these quirks by interacting with the agent, and whether existing explanation modalities help do so.

Tasks: Failure Prediction (FP). Given an image and a question about the image, we measure how well a person can predict if Vicki will successfully answer the question. A person can presumably predict the failure modes of Vicki well if they have a good sense of its strengths and weaknesses.

---

[1] We use question-level attention maps in our experiments.



Hi, my name is Vicki. I am an **Artificial Intelligence (AI)**. I am trained to answer questions about images.
Based on your understanding and expectations of what you think AI today can do,
Do you think I will answer this question for this image correctly or wrongly?
Read the instructions below to learn more! We will pay you a bonus if you make accurate guesses often!

Phase 1: 1/50 Do you think I will answer this question for this image correctly or wrongly?

Score: 0/50

How many people are there?

(a) The Failure Prediction (FP) interface.

Hi, my name is Vicki. I am an **Artificial Intelligence (AI)**. I am trained to answer questions about images.
The catch is -- I can only give one of a 1000 answers!
Based on your understanding and expectations of what you think AI today can do,
Which one of the 1000 items in the drop down list will be my answer to this question for this image?
Below are important instructions about the task and interface. Be sure to read them!
We will pay you a bonus if you make accurate guesses often!

Hint: The horizontal bar to the right shows how confident I am about my answer. I hope this helps you guess better!

Phase 1: 1/50 How many people are there?

Vicki's confidence about her answer

Warning! Don't answer the question yourself! Tell us what you think Vicki's answer will be.

I think Vicki's answer would be:

Score: 0/50

(b) The Knowledge Prediction (KP) interface.

Figure 3: (a) A person guesses if a VQA model (Vicki) will answer this question for this image correctly or wrongly. (b) A person guesses what Vicki's exact answer will be for this QI–pair.

Knowledge Prediction (KP). In this task, we aim to obtain a fine-grained measure of a person's understanding of Vicki's behavior. Given a QI–pair, a subject guesses Vicki's exact response from a set of its output labels. Snapshots of our interfaces can be seen in Fig. 3.

4 Experimental Setup

In this section we investigate ways to make Vicki's behavior more predictable to a subject. We approach this by – providing instant feedback about Vicki's actual behavior on each QI pair once the subject responds, and exposing subjects to various explanation modalities that reveal Vicki's internal states before they respond.

Data. We identify a subset of questions in the VQA-1.0 (Antol et al., 2015) validation split that occur more than 100 times. We select 7 diverse questions[2] from this subset that are representative of the different types of questions (counting, yes/no, color, scene layout, activity, etc.) in the dataset. For each of the 7 questions, we sample a set of 100 images. For FP, the 100 images are random samples from the set of images on which the question was asked in VQA-1.0 val. For the KP task, these 100 images are random images from VQA-1.0 val. Ray et al. (2016) found that randomly pairing an image with a question in the VQA-1.0 dataset results in about 79% of pairs being irrelevant. This combination of relevant and irrelevant QI-pairs allows us to test subjects' ability to develop a robust understanding of Vicki's behavior across a wide variety of inputs.

Study setup. We conduct our studies on Amazon Mechanical Turk. Each task (HIT) comprises of 100 QI-pairs where for simplicity (for the subject), a single question is asked across all 100 images. The annotation task is broken down into a train and test phase of 50 QI-pairs each. Over all settings, 280 workers took part in our study (1 unique worker per HIT), resulting in 28k human responses. Subjects were paid an average of \$3 base plus \$0.44 performance bonus, per HIT.

There are some challenges involved in scaling data-collection in this setting: (1) Due to the presence of separate train and test phases, our AMT tasks tend to be unusually long (mean HIT durations across the tasks of FP and KP $= 10.11 \pm 1.09$ and 24.49 ± 1.85 min., respectively). Crucially, this also reduces the subject pool to only those willing to participate in long tasks. (2) Once a subject participates in a task, they cannot do another because their familiarity with Vicki would leak over. This constraint causes our analyses to require as many subjects as tasks. Since work division in crowdsourcing tasks follows a Pareto principle (Little, 2009), this makes data collection very slow.

In light of these challenges, we focus on a small set of questions to systematically evaluate the role of training and exposure to Vicki's internal states.

4.1 Evaluating the role of familiarization

To familiarize subjects with Vicki, we provide them with instant feedback during the train phase. Immediately after a subject responds to a QI–pair, we show them whether Vicki actually answered the question correctly or not (in FP) or what Vicki's response was (in KP), along with a running score of how well they are doing. Once training is complete, no further feedback is provided and subjects are asked to make predictions for the test phase. At the end, they are shown their

---

[2] What kind of animal is this? What time is it? What are the people doing? Is it raining? What room is this? How many people are there? What color is the umbrella?

score and paid a bonus proportional to the score.

Failure Prediction. In FP, always guessing that Vicki answers 'correctly' results in 58.29% accuracy, while subjects do slightly better and achieve 62.66% accuracy, even without prior familiarity with Vicki (No Instant Feedback (IF)). Further, we find that subjects that receive training via instant feedback (IF) achieve 13.09% higher mean accuracies than those who do not (see Fig 4; IF vs No IF for FP (left)).

Knowledge Prediction. In KP, answering each question with Vicki's most popular answer overall ('no') would lead to an accuracy of 13.4%. Additionally, answering each question with its most popular answer *for that question* leads to an accuracy of 31.43%. Interestingly, subjects who are unfamiliar with Vicki (No IF) achieve 21.27% accuracy – better than the most popular answer overall, but worse than the question-specific prior over its answers. The latter is understandable as subjects unfamiliar with Vicki do not know which of its 1000 possible answers the model is most likely to predict for each question.

We find that mean performance in KP with IF is 51.11%, 29.84% higher than KP without IF (see Fig 4; IF vs No IF for KP (right)). It is apparent that just from a few (50) training examples, subjects succeed in building a mental model of Vicki's behavior that generalizes to new images. Additionally, the 29.84% improvement over No IF for KP is significantly larger than that for FP (13.09%). This is understandable because a priori (No IF), KP is a much harder task as compared to FP due to the increased space of possible subject responses given a QI-pair, and the combination of relevant and irrelevant QI-pairs in the test phase.

Questions such as 'Is it raining?' have strong language priors – to these Vicki often defaults to the most popular answer ('no'), irrespective of image. On such questions, subjects perform considerably better in KP once they develop a sense for Vicki's inherent biases via instant feedback. For open-ended questions like 'What time is it?', feedback helps subjects (1) narrow down the 1000 potential options to the subset that Vicki typically answers with – in this case time periods such as 'daytime' rather than actual clock times and (2) identify correlations between visual patterns and Vicki's answer. In other cases like 'How many people are in the image?' the space of possible answers is clear a priori, but after IF subjects realize that Vicki is bad at detailed counting and bases its predictions on coarse signals of the scene layout.

4.2 Evaluating the role of explanations

In this setting, we show subjects an image, a question, and one of the explanation modalities described below. We experiment with 3 qualitatively different modalities (see Fig.1, right):

Confidence of top-5 predictions. We show subjects Vicki's confidence in its top-5 answer predictions from its vocabulary as a bar plot (of course, we do not show the actual top-5 predictions). **Attention maps.** Along with the image we show subjects the spatial attention map over the image and words of the question which indicate the regions that Vicki is looking at and listening to, respectively. **Grad-CAM.** We use the CNN visualization technique by Selvaraju et al. (2017), using the (implicit) attention maps corresponding to Vicki's most confident answer.

Automatic approaches. We also evaluate automatic approaches to detect Vicki's failure from its internal states. We find that both, a decision stump on Vicki's confidence in its top answer, and on the entropy of its softmax output, result in an FP accuracy of 60% on our test set. A Multi-layer Perceptron (MLP) trained on Vicki's output 1000-way softmax to predict success vs failure, achieves an FP accuracy of 81%. Training on just top-5 softmax outputs achieves an FP accuracy of 61.43%. Training an MLP which takes as input question features (average word2vec embeddings (Mikolov et al., 2013) of words in the question) concatenated with image features (fc7 from VGG-19) to predict success vs failure (which we call ALERT following (Zhang et al., 2014)) achieves an FP accuracy of 65%. Training an MLP on identical question features as above but concatenated with Grad-CAM saliency maps leads to FP accuracy of 73.14%. [3] Note that we only report machine results to put human accuracies in perspective. We do not draw any inferences about the relative capabilities of both.

Results. Average performance of subjects in the test phases of FP and KP, for different experimental settings are summarized in Fig. 4. In the first setting, we show subjects an explanation modality with instant feedback (IF+Explanation). For reference, also see performance of subjects provided with IF and no explanation modality (IF).

---

[3] These methods are trained on 66% of VQA-1.0 val. The remaining data is used for validation.

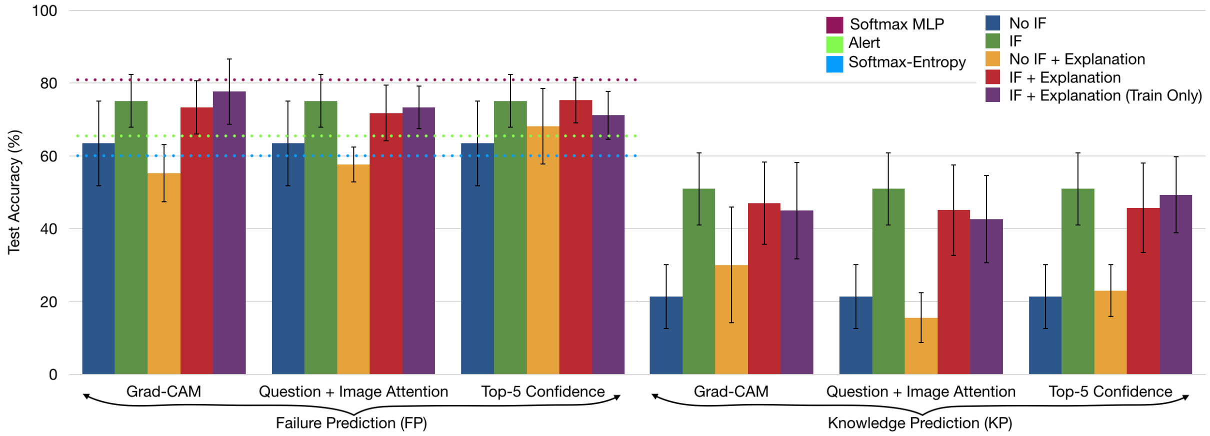


Figure 4: Average performance across subjects for Failure Prediction and Knowledge Prediction, across different settings: with or without (1) Instant feedback (IF) in the train phase, and (2) an explanation modality. Explanation modalities are shown in both train and test phases unless stated otherwise. Error bars are 95% confidence intervals from 1000 bootstrap samples. Note that the dotted lines are various machine approaches applied to FP.

We observe that on both FP and KP, subjects who received an explanation along with IF show no statistically significant difference in performance compared to those who did not. We see in Fig. 4, that both bootstrap based standard error (95% confidence intervals) overlap significantly.

Seeing that explanations in addition to IF does not outperform an IF baseline, we next measure whether explanations help a user not already familiar with Vicki via IF. That is, we evaluate if explanations help against a No IF baseline by providing an explanation only in the *test* phase, and no IF (see Fig 4; No IF + Explanation). Additionally, we also experiment with providing IF and an explanation *only* during the train phase (see Fig 4; IF + Explanation (Train Only)), to measure whether access to internal states during training can help subjects build better intuitions for model behavior without needing access to internal states at test time. In both settings however, we observe no statistically significant difference in performance over the No IF and IF baselines, respectively. [4]

5 Conclusion

As technology progresses, human-AI teams are inevitable. We argue that for these teams to be more effective, we should also be pursuing research directions to help humans understand the strengths, weaknesses, quirks, and tendencies of AI. We instantiate these ideas in the domain of Visual Question Answering (VQA), by proposing two tasks that help measure how well a human 'understands' a VQA model (we call Vicki) – Failure Prediction (FP) and Knowledge Prediction (KP). We find that lay people indeed get better at predicting Vicki's behavior using just a few 'training' examples, but surprisingly, existing popular explanation modalities do not help make its failures or responses more predictable. While previous works have typically assessed their interpretability or their role in improving human trust, our preliminary hypothesis is that these modalities may not yet help performance of human-AI teams in a goal-driven setting. Clearly, much work remains to be done in developing improved explanation modalities that can improve human-AI teams.

Future work involves closing the loop and evaluating the extent to which improved human performance at FP and KP translates to improved success of human-AI teams at accomplishing a shared goal. Co-operative human-AI games may be a natural fit for such an evaluation.

Acknowledgements. We thank Satwik Kottur for his help with data analysis, and for many fruitful discussions. We thank Aishwarya Agrawal and Akrit Mohapatra for their help with experiments. We would also like to acknowledge the workers on Amazon Mechanical Turk for their effort. This work was supported in part by NSF, AFRL, DARPA, Siemens, Google, Amazon, ONR YIP and ONR Grants N00014-16-1-2713.

Abstract

This work introduces fact salience: The task of generating a machine-readable representation of the most prominent information in a text document as a set of facts. We also present SALIE, the first fact salience system. SALIE is unsupervised and knowledge agnostic, based on open information extraction to detect facts in natural language text, PageRank to determine their relevance, and clustering to promote diversity. We compare SALIE with several baselines (including positional, standard for saliency tasks), and in an extrinsic evaluation, with state-of-the-art automatic text summarizers. SALIE outperforms baselines and text summarizers showing that facts are an effective way to compress information.

1 Introduction

Automatic knowledge acquisition at large scale requires the transformation of human-readable knowledge into a machine-understandable format. Machine-readable information is usually structured in the form of facts, in which a given relation links a set of arguments [e.g., *("US", "withdraws from", "Iran nuclear deal")*]. Facts are at the core of several natural language understanding applications such as knowledge-base (KB) construction (Nguyen et al., 2017), question answering (Abujabal et al., 2018), structured search (Bast et al., 2014), or entity-linking (Cheng and Roth, 2013).

Different approaches aim to discover facts from natural language text. In the extremes of the spectrum, relation extraction (Mintz et al., 2009) looks for all facts linkable to a KB, whereas open information extraction (Banko et al., 2007) extracts facts over an unconstrained set of arguments and relations. In this paper, we aim to additionally score facts according to their prominence.

We define *fact salience* as the task of discovering the most prominent facts in a text document. A fact is salient if it carries the essential information that the text conveys. A higher salient score denotes higher prominence, determining a ranking across all facts in the document. This ranking must reflect relevance and diversity: We want the top-k facts to compress the most relevant information in the smallest number of facts.

Fact salience is closely related to automatic text summarization (Erkan and Radev, 2004) as both try to capture the essential information in a document. However, fact salience output is required to be interpreted by machines to a certain extent. Text summarization, on the contrary, is meant to be understood by humans alone; it is often composed by ungrammatical text and isolated keywords, making it difficult to structure in a machine-readable form ex-post.

Here we present SALIE (Salient Information Extraction), the first fact salience system able to output a ranking of salient open facts from a text document. SALIE is unsupervised and knowledge agnostic. It uses facts as atomic units and PageRank to detect their relevance. It also exploits the fact structure to promote diversity via clustering.

We evaluated SALIE on a real-world dataset and compared it with the strong positional baseline (facts appearing first are more relevant) and, in an extrinsic evaluation, with two top text summarizers (one reimplemented to work at fact level). SALIE outperforms baselines and text summarization competitors particularly when the size of the output is restricted, suggesting that facts, as atomic units expressing a single proposition (Del Corro and Gemulla, 2013), are an effective way to compress information.

The source code and the processed datasets are

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1043–1048
Brussels, Belgium, October 31 - November 4, 2018.

publicly available[1] to encourage further developments of the fact salience task.

2 Fact Salience

Fact salience is the task of extracting *salient* facts from a text document. *Salient* facts must fulfil two requirements: (i) *relevance* and (ii) *diversity*.

A fact is relevant if it carries the essential information that the text conveys. A fact is not relevant per se but in a specific context. In an article about the US-Iran nuclear deal the fact *("US", "withdraws from", "Iran Nuclear Deal")* is more relevant that *("Washington", "is", "US capital")*.

The output of a fact salience system must ensure that the top-k facts contain the maximum information in the smallest number of facts. This implies a dependency between facts as less relevant facts should be penalized when they carry information already contained in more relevant ones.

3 Related Work

Fact salience is close to automatic text summarization (Erkan and Radev, 2004); both must detect the most prominent information in the text. However, while text summarization generates summaries for humans, fact salience output must be interpretable by machines. Fluency and language cohesion are not requirements for fact salience.

Triple scoring in KBs (Bast et al., 2017) is also related. However, while in fact salience a fact is not relevant per se but locally in a textual context, triple KB scoring asses the global relevance of a KB fact for a specific entity [*("T. Burton", "profession", "actor")* vs. *("T. Burton", "profession", "director")*] .

Typically, a text summarization system splits the text into atomic units (usually sentences) that are scored and ranked (Allahyari et al., 2017). Diversity is generally guaranteed by clustering them in topics and selecting the most representative members from each cluster. Once selected, the atomic units are compressed to ensure minimality.

Generating a machine-readable representation from text summarization output is difficult. This output can be incomplete or ungrammatical, given the use of compression techniques (Zajic et al., 2007), or the inclusion of keywords or short unconnected phrases with topical information (Hasan and Ng, 2014). Open information extractors will most likely fail to generate meaningful facts in these circumstances. However, text summarization techniques to score the atomic units can be exploited for fact salience.

Open facts have been already used in text summarization for redundancy, using synonymity (Christensen et al., 2013) or as input for a classifier (Christensen et al., 2014). In this case, we use facts as atomic units. Working at the fact level provides a natural framework to detect essential information in a text document, since facts are minimal comprehensive atomic units expressing a single proposition (Del Corro and Gemulla, 2013). This helps to avoid working with sentences that might express more than one proposition or arbitrary chunking the input text. Compression is also more principled at a fact level as the fact hierarchical structure is clearly defined (Gashteovski et al., 2017). Additionally, we exploit the fact structure to promote diversity.

Several supervised and unsupervised methods have been used in text summarization to determine the relative prominence of the atomic units. For instance, two of the top performer systems Durrett et al. (2016) and Mihalcea and Tarau (2004), which we include in our extrinsic evaluation, are based on ILP and an unsupervised graph algorithm respectively. Other approaches include LDA (Pouriyeh et al., 2017), ontology-based (Baralis et al., 2013) or clustering (Yang et al., 2014), and more recently neural-based methods (See et al., 2017). As in Mihalcea and Tarau (2004) or Erkan and Radev (2004) we use PageRank to establish the relative prominence of the atomic units (Sec. 4.1). However, we weight the graph edges using word vectors to allow more expressive semantics, avoiding the sparsity of frequency-based methods.

Different approaches have also been explored to promote diversity. Xiong and Luo (2014), for example, use LSA, and Chien and Chang (2013) rely on topic models. In our case, we generate diversity by exploiting the fact structure (Sec. 4.2). We cluster facts in terms of their subjects as a way to have the most relevant information about the different entities appearing in the text. The subject is typically the topic of the clause or proposition (Quirk et al., 1985).

4 SALIE: Salient Information Extraction

SALIE is a graph-based method for the extraction of *salient* open facts in text documents. Open facts are a structured machine-readable representation of the information in text. Its arguments are not linked to an existing KB. SALIE takes as input all open facts detected by an open information extraction system (in our implementation we use MINIE (Gashteovski et al., 2017)).

SALIE works in two stages: (i) relevance and (ii) diversification. First, a graph with open facts as nodes is instantiated so that PageRank assesses their relative relevance. Later, a clustering algorithm selects a diversified set of facts.

4.1 Fact Relevance

SALIE computes fact *relevance* by growing a complete graph of open facts $G_{OF} = (V, E)$ extracted from the input text. *Coherence* is induced by weighting the edges E between nodes V, whereas a *relevance* prior is induced via the instantiation of the PageRank's teleport vector.

Step 1 – Facts as Nodes. Each node is a fact extracted by MINIE. Undefined facts (with no clear co-reference) [*("He", "plays", "softball")*] or facts with constituents composed by single words (generally uninformative or noisy) [*("doorman", "has", "age")*] are removed.

Step 2 – Coherence: Edge Weighting. We want related facts to get a higher weight assuming that the most relevant facts will be those more central. We weight each edge (u, v) with the *semantic similarity* between u and v as the cosine between the centroid of the word embeddings in the facts. Stanovsky et al. (2015) have shown that learning word embeddings with open facts allows the generation of higher quality vectors . The assumption is that the relatedness of words within a fact is stronger than with words outside. This provides the basis for more accurate contextualization. Accordingly, in our implementation we use GloVe (Pennington et al., 2014) trained on the Wikipedia corpus using open facts extracted by MINIE for co-occurence context.

Step 3 – Relevance Prior. We introduce a prior for each fact by computing a score used to instantiate the PageRank's teleport vector. The assumption is that authors tend to express the most relevant facts at the beginning. We instantiated each fact teleport as $factPrior(i) = \frac{x_i}{\|X\|}$, where $x_i = |V| - i$ and i is the fact index. This is important especially for news where the lead paragraph is the most important part of the article. That's why the positional baseline is so strong in tasks as text summarization or entity salience (Ponza et al., 2018).

Step 4 – Relevance Computation. This stage runs PageRank on the graph. The stationary distribution will capture the *relevance* of each open fact. This distribution reflects the semantic centrality of each fact weighted by its relevance prior.

4.2 Fact Diversification

In this stage SALIE diversifies the set of *relevant* facts computed in the previous stage. Facts are clustered exploiting the fact structure, and the most relevant facts in each cluster are selected according to the relevance scores.

Facts have clear semantics regarding the role of each of its constituents (i.e., subject, relation, and object) in the proposition. SALIE exploits this by clustering together those facts that have the same head in the subject's constituent. As the subject is typically the theme (or topic) of a the clause (Quirk et al., 1985), the intuition here is that facts with the same subject express information about the same entity. Therefore, each cluster will contain a ranked set of facts about each entity in the document.

After the facts have been clustered, we iteratively select facts from each cluster according to its relevance until we reach the desired number of facts as output. The number of facts in the output is a parameter of the system.

5 Experiments

Methodology. Given a document we want to evaluate how salient the top-k facts are. The number of facts in the ranking is a parameter of the model so we evaluate 5 configurations: top-1 to top-5 facts.
Dataset. As there is no dataset to directly asses the saliency of facts, we compare the extracted facts in each ranking with a manually generated summary. We use the New York Times (Sandhaus, 2008) corpus, consisting of 3956 news articles and summaries from 2007 (with summaries larger than 50 tokens) as described by Durrett et al. (2016).
Metrics. To measure how close is the ranking to the summary, we use the ROUGE package[2], standard for document summarization (Lin,

(b) MinIE *aggressive* mode.

Table 1: Top-3 salient facts automatically extracted from a sample of two NYT documents with two different MinIE modes. For Berkeley (which does not return facts) we show its produced summary. On the top of each table we show the summary written by a human for the input document.

2004). ROUGE-1 measures the presence of single words between the salient facts and the summary; ROUGE-L identifies the longest common subsequence (LCS) with maximum length between facts and summary; ROUGE-1.2W measures the weighted LCS by taking into account spatial relations and giving higher values to consecutive matches; ROUGE-SU is the number of occurring bigrams between the facts and summary with arbitrary gaps. For each metric we report the F_1 performance, all computed with a 95% confidence interval, run with stemming and stopword removal[3].

To compute the ROUGE score, the facts were flattened and concatenated into a sequence of tokens respecting the ranking order. For the computation, this sequence is considered equivalent to a summary, so the same conditions apply: If all the extracted tokens fully cover the gold standard summary, the ROUGE score reaches its highest value.

Note that we do not take into account the correctness of the facts (i.e., if they are well-structured). All systems implemented, except the Berkeley summarizer (Durrett et al., 2016), use the same open facts extracted by MinIE. Also for the Berkeley summarizer, we do not evaluate the structure or fluency of the summary.

SalIE. Outputs top-k facts per article. We show results for two MinIE configurations: *safe* and *aggressive*, which differ in the fact average size.

Intrinsic Evaluation. As there is no direct fact salience competitor, we designed three baselines: The standard *Position* baseline which ranks facts with respect to their order of appearance, *Tf-Idf* which ranks them with respect to the subject's head tf-idf and the *Context* baseline which ranks facts with respect to the cosine-similarity between the document and the fact embedding's centroid.

Extrinsic Evaluation. We used two state-of-the-art document summarizers, i.e., the unsupervised graph-based TextRank (Mihalcea and Tarau, 2004) and the supervised Berkeley summa-

(b) MINIE *aggressive* mode.

Table 2: Results on the NYT dataset with two different MINIE modes.

rizer (Durrett et al., 2016). We adapted TextRank to work with facts instead of sentences. For the Berkeley summarizer, we used the model online[4]. As the size of the summaries is a parameter of the summarizer, we set it to match the average size of MINIE facts (*safe* is 10 and *aggressive* is 6), For example, for the top-5 configuration in the aggressive mode, the summary length is set to 30.

Tab. 1 shows example outputs for the position baseline, the text summarizers and SALIE.

5.1 Results

Tabs. 2a and 2b show the results for all the systems and baselines. We use colors **black**, **gray** and **light gray** for the first, second and third best performing methods. In each ROUGE configuration, we show results for five rankings: top-1 to top-5. The difference between SALIE and the best competitor is reported in the last line of the tables.

Tab. 2a shows the results where facts have been extracted with MINIE's *safe* mode. SALIE outperforms all other methods and baselines for the first three rankings (top-1 to top-3), although Berkeley summarizer comes first in top-4 and 5 facts as a higher budget takes the system closer to the gold standard human-readable summaries. TextRank has an opposite behavior compared to Berkeley, performing well in top-1 and 2 but lagging behind as more facts are added probably due to the lack of a diversification stage. It is interesting to note that systems working at the fact level do well in constrained settings, suggesting that facts may be an effective way to compress information.

Tab. 2b shows the results when MINIE is used in *aggressive* mode. In this experiment, we aim to analyze the behavior of the systems in a restricted scenario with a very small budget size (6 tokens per fact). SALIE achieves the highest performance overall metrics independently the number of facts used, with the only exception on the ROUGE-1.2W and ROUGE-SU score when 4 or 5 facts are used. The second and third best performing methods are Position and TextRank. Again, in this case, it is suggested that facts are an appropriate mechanism to compress information.

Overall SALIE shows a more stable balance across all rankings in both settings. It always ranks first or second (except in ROUGE-SU top-5 where it comes third). Compared to TextRank it seems to significantly better manage redundancy, while compared to the Berkeley it does better at detecting relevant information in constrained settings. This is due to the use of facts as a mean to compress information.

6 Conclusions

We introduced the fact salience task. We also presented SALIE, the first fact salience system. SALIE outperformed standard baselines but also state-of-the-art automatic text summarizer. We showed that working at the fact level allows to more effectively compress information.

Entity Tracking Improves Cloze-style Reading Comprehension

Abstract

Reading comprehension tasks test the ability of models to process long-term context and remember salient information. Recent work has shown that relatively simple neural methods such as the Attention Sum-Reader can perform well on these tasks; however, these systems still significantly trail human performance. Analysis suggests that many of the remaining hard instances are related to the inability to track entity-references throughout documents. This work focuses on these hard entity tracking cases with two extensions: (1) additional entity features, and (2) training with a multi-task tracking objective. We show that these simple modifications improve performance both independently and in combination, and we outperform the previous state of the art on the LAMBADA dataset, particularly on difficult entity examples.

1 Introduction

There has been tremendous interest over the past several years in Cloze-style (Taylor, 1953) reading comprehension tasks, datasets, and models (Hermann et al., 2015; Hill et al., 2016; Kadlec et al., 2016; Dhingra et al., 2016; Cui et al., 2016). Many of these systems apply neural models to learn to predict answers based on contextual matching, and have inspired other work in long-form generation and question answering. The extent and limits of these successes have also been a topic of interest (Chen et al., 2016; Chu et al., 2017). Recent analysis by Chu et al. (2017) suggests that a significant portion of the errors made by standard models, especially on the LAMBADA dataset (Paperno et al., 2016), derive from the inability to correctly track entities or speakers, or a failure to handle various forms of reference.

This work targets these shortcomings by designing a model and training scheme targeted towards *entity tracking*. Specifically we introduce two simple changes to a stripped down model: (1) simple, entity-focused features, and (2) two multi-task objectives that target entity tracking. Our ablation analysis shows that both independently improve entity tracking, which is the primary source of overall model's improvement. Together they lead to state-of-the-art performance on LAMBADA dataset and near state-of-the-art on CBT dataset (Hill et al., 2016), even with a relatively simple model.

usually , that teen behavior was directed toward a parent , but since [julie] had somewhat filled the role of both parents for amy , [she] knew that **amy** was now directing that rebellion at [her] . `` i 'm sorry , marsh , '' [**julie**] glanced at [her] friend out of the corner of [her] eye as [she] drove . `` do n't be . '' `` do n't apologize for me , [**julie***]

Figure 1: A LAMBADA example where the final word "julie" (with reference chain in brackets) is the answer, y, to be predicted from the preceding context x. A system must know the two speakers and the current dialogue turn, simple context matching is not sufficient. Here, our model's predictions before and after adding multi-task objective are shown.

2 Background and Related Work

Cloze-style reading comprehension uses a passage of word tokens $x = x_{1:n}$ (the *context*), with one token x_j masked; the task is to fill in the masked word y, which was originally at position j. These datasets aim to present a benchmark challenge requiring some understanding of the context to select the correct word. This task is a prerequisite for problems like long-form generation and document-based question answering.

A number of datasets in this style exist with dif-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1049–1055
Brussels, Belgium, October 31 - November 4, 2018.

ferent focus. Here we considered the LAMBADA dataset and the named entity portion of the Children's Book Test dataset (CBT-NE). LAMBADA uses novels where examples consist of 4-5 sentences and the last word to be predicted is masked, x_n. The dataset is constructed carefully to focus on examples where humans needed the context to predict the masked word. CBT-NE examples, on the other hand, include 21 sentences where the masked word is a named entity extracted from the last sentence, with $j \leq n$, and is constructed in a more automated way. We show an example from LAMBADA in Figure 1. In CBT, as well as the similar CNN/Daily Mail dataset (Hermann et al., 2015), the answer y is always contained in x whereas in LAMBADA it may not be. Chu et al. (2017) showed, however, that training only on examples where y *is* in x leads to improved overall performance, and we adopt this approach as well.

Related Work The first popular neural network reading comprehension models were the Attentive Reader and its variant Impatient Reader (Hermann et al., 2015). Both were the first to use bidirectional LSTMs to encode the context paragraph and the query separately. The Stanford Reader (Chen et al., 2016) is a simpler version with fewer layers for inference. These models use an encoder to map each context token x_i to a vector $\boldsymbol{u}_i$. Following the terminology of Wang et al. (2017), *explicit reference models* calculate a similarity measure $s_i = s(\boldsymbol{u}_i, \boldsymbol{q})$ between each context vector $\boldsymbol{u}_i$ and a query vector $\boldsymbol{q}$ derived for the masked word. These similarity scores are projected to an attention distribution $\boldsymbol{\alpha} = \mathrm{softmax}(\{s_i\})$ over the context positions in $1, \ldots, n$, which are taken to be candidate answers.

The Attention Sum Reader (Kadlec et al., 2016) is a further simplified version. It computes $\boldsymbol{u}_i$ and $\boldsymbol{q}$ with separate bidirectional GRU (Chung et al., 2014) networks, and s_i with a dot-product. It is trained to minimize:

$$\begin{aligned}\mathcal{L}^0(\boldsymbol{\theta}) &= -\ln p(y \,|\, x, \boldsymbol{q}) \\ &= -\ln \sum_{i: x_i = y} p(x_i \,|\, \boldsymbol{q}) = -\ln \sum_{i: x_i = y} \alpha_i,\end{aligned}$$

where $\boldsymbol{\theta}$ is the set of all parameters associated with the model, and y is the correct answer. At test time, a *pointer sum attention* mechanism is used to predict the word type with the highest aggregate attention as the answer. The Gated Attention Reader (Dhingra et al., 2016) leverages the same mechanism for prediction and introduces an attention gate to modulate the joint context-query information over multiple hops.

The Recurrent Entity Networks (Henaff et al., 2016) uses a custom gated recurrent module, Dynamic Memory, to learn and update entity representations as new examples are received. Their gate function is combined of (1) a similarity measure between the input and the hidden states, and (2) a set of trainable "key" vectors which could learn any attribute of an entity such as its location or other entities it is interacting with in the current context. The Query Reduction Networks (Seo et al., 2016) is also a gated recurrent network which tracks state in a paragraph and uses a hidden query vector to keep pointing to the answer at each step. The query is successively transformed with each new sentence to a reduced state that's easier to answer given the new information.

Model In this work, we were particularly interested in the shortcomings of simple models and exploring whether or how much entity tracking could help, since Chu et al. (2017) has pointed out this weakness. As a result, we adapt a simplified Attention Sum (AttSum) reader throughout all experiments. Our version uses only a single bidirectional GRU for both $\boldsymbol{u}_i$ and $\boldsymbol{q}$. This GRU is of size $2d$, using the first d states for the context and second d for the query. Formally, let $\overrightarrow{\boldsymbol{h}}_i$ and $\overleftarrow{\boldsymbol{h}}_i$ (both in $\mathbb{R}^{2d}$) represent the forward and backward states of a bidirectional GRU run over x, and let $\overrightarrow{\boldsymbol{h}}_{i,\uparrow}$ and $\overrightarrow{\boldsymbol{h}}_{i,\downarrow}$ be the first and second d states respectively, and define $||$ as the concatenation operator. The context vectors are constructed as $\boldsymbol{u}_i = \overrightarrow{\boldsymbol{h}}_{i,\uparrow} || \overleftarrow{\boldsymbol{h}}_{i,\uparrow}$. For datasets using the last word, the query is constructed as $\boldsymbol{q} = \overrightarrow{\boldsymbol{h}}_{n,\downarrow} || \overleftarrow{\boldsymbol{h}}_{1,\downarrow}$. When the masked word can be anywhere, the query is constructed as $\boldsymbol{q} = \overrightarrow{\boldsymbol{h}}_{j-1,\downarrow} || \overleftarrow{\boldsymbol{h}}_{j+1,\downarrow}$.

Our main contribution is the extension of this simple model to incorporate entity tracking. Other authors have explored extending neural reading comprehension models with linguistic features, particularly Dhingra et al. (2017) who use a modified GRU with knowledge such as coreference relations and hypernymy. In Dhingra et al. (2018), the most recent coreferent antecedent for each token is incorporated into the update equations of the GRU unit to bias the reader towards coreferent recency. In this work, we instead use a much sim-

pler set of features and compare to this and several other models as baseline approaches.

3 Learning to Track Entities

Analysis on reading comprehension has indicated that neural models are strong at matching local context information but weaker at following entities through the discourse (Chen et al., 2016; Chu et al., 2017). We consider two straightforward ways for extending the Attention Sum baseline to better track entities.

Method 1: Features We introduce a short-list of features in Table 1 to augment the representation of each word in x. These features are meant to help the system to identify and use the relationships between words in the passage.[1] Features 2-5 apply only to words tagged PERSON by the NER tagger. Features 6-7 apply only to words between opening and closing quotation marks. Feature 6 indicates the index of the quote in the document, and Feature 7 gives the assumed speaker of the quote using some simple rules; we provide the rules in the Supplementary Material. Though most of these features are novel, they are motivated by recent analysis (Wang et al., 2015; Chen et al., 2016; Wang et al., 2017).

All features are incorporated into a word's representation by embedding each discrete feature into a vector of the same size as the original word embedding, adding the vectors as well as a bias, and applying a $\tanh$ nonlinearity.

Method 2: Multitasking We additionally encourage the neural model to keep track of entities by multitasking with simple auxiliary entity-tracking tasks. Examples such as Figure 1 suggest that keeping track of which entities are currently in scope is useful for answering reading comprehension questions. There, *amy* and *julie* are conversing, and being able to track that *amy* is the speaker of the final quote helps to rule her out as a candidate answer. We consider two tasks:

For Task 1 ($\mathcal{L}^1$) we train the same model to predict repeated named entities. For all named entities x_j such that there is a $x_i = x_j$ with $i < j$, we attempt to mask and predict the word type x_j. This is done by introducing another Cloze prediction, but now setting the target $y = x_j$, reducing the context to preceding words $x_{1:j-1}$ with $\mathbf{u_i} = \vec{\boldsymbol{h}}_i$, and the query $\boldsymbol{q} = \vec{\boldsymbol{h}}_{j-1}$. (Note that unlike above, both of these only use the forward states of the GRU). We use a bilinear similarity score $s_i = \boldsymbol{q}^\top \boldsymbol{Q}\, \boldsymbol{u}_i$, for this prediction where $\boldsymbol{Q}$ is a learned transformation in $\mathbb{R}^{2d\times 2d}$. This task is inspired by the antecedent ranking task in coreference (Wiseman et al., 2015, 2016).

For Task 2 ($\mathcal{L}^2$) we train to predict the order index in which a named entity has been introduced. For example, in Figure 1, *julie* would be 1, *amy* would be 2, *marsh* would be 3, etc. The hope here is that learning to predict when entities reappear will help the model track their reoccurences. For the blue labeled *julie*, the model would aim to predict 1, even though it appears later in the context. This task is inspired by the One-Hot Pointer Reader of Wang et al. (2017) on the Who-did-What dataset (Onishi et al., 2016). Formally, letting $\widehat{\mathrm{idx}}(x_j)$ be the predicted index for x_j, we minimize:

$$\begin{aligned}\mathcal{L}^2(\boldsymbol{\theta}) &= -\ln p(\widehat{\mathrm{idx}}(x_j) = \mathrm{idx}(x_j) \mid x_{1:j-1}) \\ &= -\ln \mathrm{softmax}(\boldsymbol{W}\vec{\boldsymbol{h}}_j)_{\mathrm{idx}(x_j)},\end{aligned}$$

where $\boldsymbol{W} \in \mathbb{R}^{|\mathcal{E}|\times 2d}$ and $\mathcal{E}$ is the set of entity word types in the document. Note that this is a simpler computation, requiring only $O(|\mathcal{E}| \times n)$ predictions per $\boldsymbol{x}$, whereas $\mathcal{L}^1$ requires $O(n^2)$.

The full model minimizes a multi-task loss: $\mathcal{L}^0(\boldsymbol{\theta}) + \gamma_1\mathcal{L}^1(\boldsymbol{\theta}) + \gamma_2\mathcal{L}^2(\boldsymbol{\theta})$. Using $\mathcal{L}^1$ and $\mathcal{L}^2$ simultaneously did not lead to improved performance however, and so either γ_1, γ_2 is always 0. We believe that this is because, while the learning objectives for $\mathcal{L}^1$ and $\mathcal{L}^2$ are mathematically different, they are both designed to similarly track the entities mentioned so far in the document and thus do not provide complementary information to each other.

We found it useful to have two hyperparameters per auxiliary task governing the number of distinct

---

[1] POS tags are produced with the NLTK library (Bird et al., 2009), and NER tags with the Stanford NER tagger (Finkel et al., 2005). We additionally found it useful to tag animate words as PERSONs on the CBT-NE data, using the animate word list of Bergsma and Lin (2006).

named entity word *types* and *tokens* used in defining the losses $\mathcal{L}^1$ and $\mathcal{L}^2$. In particular, per document these hyperparameters control in a top-to-bottom order the number of distinct named entity word types we attempt to predict, as well as the number of tokens of each type considered.

4 Experiments

Methods This section highlights several aspects of our methodology; full hyperparameters are given in the Supplementary Material. For the training sets, we exclude examples where the answer is not in the context. The validation and test sets are not modified however and the model with the highest accuracy on the validation set is chosen for testing. For both tasks, the context words are mapped to learned embeddings; importantly, we initialize the first 100 dimensions with the 100-dimensional GLOVE embeddings (Pennington et al., 2014). Named entity words are anonymized, as is done in the CNN/Daily Mail corpus (Hermann et al., 2015) and in some of the experiments of Wang et al. (2017). The model is regularized with dropout (Srivastava et al., 2014) and optimized with ADAM (Kingma and Ba, 2014). For all experiments we performed a random search over hyperparameter values (Bergstra and Bengio, 2012), and report the results of the models that performed best on the validation set. Our implementation is available at `https://github.com/harvardnlp/readcomp`.

Results and Discussion Table 2 shows the full results of our best models on the LAMBADA and CBT-NE datasets, and compares them to recent, best-performing results in the literature.

For both tasks the inclusion of either entity features or multi-task objectives leads to large statistically significant increases in validation and test score, according to the McNemar test ($\alpha = 0.05$) with continuity correction (Dietterich, 1998). Without features, AttSum + $\mathcal{L}^2$ achieves the best test results, whereas with features AttSum-Feat + $\mathcal{L}^1$ performs best on CBT-NE. The results on LAMBADA indicate that entity tracking is a very important overlooked aspect of the task. Interestingly, with features included, AttSum-Feat + $\mathcal{L}^2$ appears to hurt test performance on LAMBADA and leaves CBT-NE performance essentially unchanged, amounting to a negative result for $\mathcal{L}^2$. On the other hand, the effect of AttSum-Feat + $\mathcal{L}^1$ is pronounced on CBT-NE, and while our simple models do not increase the state-of-the-art test performance on CBT-NE, they outperform "attention-over-attention" in addition to reranking (Cui et al., 2016), and is outperformed only by architectures supporting "multiple-hop" inference over the document (Dhingra et al., 2016). Our best model on CBT-NE test set, AttSum-Feat + $\mathcal{L}^1$, is very close to the current state-of-the-art result. On the validation sets for both LAMBADA and CBT-NE, the improvements from adding features to AttSum + $\mathcal{L}^i$ are statistically significant (for full results refer to our supplementary material). On LAMBADA, the $\mathcal{L}^1$ multi-tasked model is a 3.5-point increase on the state of the art.

Our method also employs fewer parameters than other richer models such as the GA Reader in (Dhingra et al., 2016). More specifically, in terms of number of parameters, our models are very similar to a 1-hop GA Reader. In contrast, all published experiments of the latter use 3 hops where each hop requires 2 separate Bi-GRUs, one

LAMBADA	Val	Test
GA Reader (Chu et al., 2017)	-	49.00
MAGE (48) (Dhingra et al., 2017)	51.10	51.60

Table 3: Ablation results on validation sets, see text for definitions of the numeric columns and models.

to model the document and one for the query. This constitutes the largest difference in model size between the two approaches.

Table 3 considers the performance of the different models based on a segmentation of the data. Here we consider examples where: (1) Entity - if the answer is a named entity; (2) Speaker - if the answer is a named entity and the speaker of quote; (3) Quote - if the answer is found within a quoted speech. Note that Speaker and Quote categories, while mutually exclusive, are subsets of the overall Entity category. We see that both the additional features and multi-task objectives independently result in a clear improvement in all categories, but that the gains are particularly pronounced for named entities and specifically for Speaker and Quote examples. Here we see sizable increases in performance, particularly in the Speaker category. We see larger increases in the more dialog heavy LAMBADA task.

As a qualitative example of the improvement afforded by multi-task training, in Figure 1 we show the different predictions made by our model with and without $\mathcal{L}^1$ (colored as blue and red, respectively). Note that *amy* and *julie* are both entities that have been repeated twice in the passage. In addition to the final answer, our model with the $\mathcal{L}^1$ loss was also able to predict these entities (at the colored locations) given preceding words. Further qualitative analysis reveals that these augmentations improved the model's ability to eliminate non-entity choices from predictions. Some examples are shown in Figure 2.

after a few more minutes axel left patrick at the wall and went for a walk around the **village** . he stopped wherever he saw people and chatted . lifting spirits , cracking jokes , giving advice . the **vicar** was holding a service in the village square . a short and simple one . ` when you go out to war against your enemies , ' said the [vicar]

as the piece of rock fell off and was accelerating its way to the ground , he kicked it toward the robot and destroyed it upon contact . **lance** watched on the screen through the point of **view** of the last robot as the rock flew speedily toward it and then his screen cut into black . a soldier quickly walked in and went up to [lance]

Figure 2: LAMBADA examples where AttSum incorrectly predicts a non-entity answer whereas AttSum-Feat and AttSum + $\mathcal{L}^i$ choose correctly.

5 Conclusion

This work demonstrates that learning to track entities with features and multi-task learning significantly increases the performance of a baseline reading comprehension system, particularly on the difficult LAMBADA dataset. This result indicates that higher-level word relationships may not be modeled by simple neural systems, but can be incorporated with minor additional extensions. This work hints that it is difficult for vanilla models to learn long-distance entity relations, and that these may need to be encoded directly through features or possibly with better pre-trained representations.

Abstract

We address the problem of detecting duplicate questions in forums, which is an important step towards automating the process of answering new questions. As finding and annotating such potential duplicates manually is very tedious and costly, automatic methods based on machine learning are a viable alternative. However, many forums do not have annotated data, i.e., questions labeled by experts as duplicates, and thus a promising solution is to use domain adaptation from another forum that has such annotations. Here we focus on adversarial domain adaptation, deriving important findings about when it performs well and what properties of the domains are important in this regard. Our experiments with *StackExchange* data show an average improvement of 5.6% over the best baseline across multiple pairs of domains.

1 Introduction

Recent years have seen the rise of community question answering forums, which allow users to ask questions and to get answers in a collaborative fashion. One issue with such forums is that duplicate questions easily become ubiquitous as users often ask the same question, possibly in a slightly different formulation, making it difficult to find the best (or one correct) answer (Hoogeveen et al., 2018; Lai et al., 2018). Many forums allow users to signal such duplicates, but this can only be done after the duplicate question has already been posted and has possibly received some answers, which complicates merging the question threads. Discovering possible duplicates at the time of posting is much more valuable from the perspective of both (*i*) the forum, as it could prevent a duplicate from being posted, and (*ii*) the users, as they could get an answer immediately.

Duplicate question detection is a special case of the more general problem of question-question similarity. The latter was addressed using a variety of textual similarity measures, topic modeling (Cao et al., 2008; Zhang et al., 2014), and syntactic structure (Wang et al., 2009; Filice et al., 2016; Da San Martino et al., 2016; Barrón-Cedeño et al., 2016; Filice et al., 2017). Another approach is to use neural networks such as feed-forward (Nakov et al., 2016a), convolutional (dos Santos et al., 2015; Bonadiman et al., 2017; Wang et al., 2018), long short-term memory (Romeo et al., 2016), and more complex models (Lei et al., 2016; Nicosia and Moschitti, 2017; Uva et al., 2018; Joty et al., 2018; Zhang and Wu, 2018). Translation models have also been popular (Zhou et al., 2011; Jeon et al., 2005; Guzmán et al., 2016a,b).

The above work assumes labeled training data, which exists for question-question similarity, e.g., from SemEval-2016/2017 (Agirre et al., 2016; Nakov et al., 2016b, 2017), and for duplicate question detection, e.g., SemEval-2017 task 3 featured four StackExchange forums, *Android*, *English*, *Gaming*, and *Wordpress*, from CQADupStack (Hoogeveen et al., 2015, 2016). Yet, such annotation is not available for many other forums, e.g., the *Apple* community on StackExchange.

In this paper, we address this lack of annotation using adversarial domain adaptation (ADA) to effectively use labeled data from another forum. Our contributions can be summarized as follows:

- we are the first to apply adversarial domain adaptation to the problem of duplicate question detection across different domains;[1]
- on the StackExchange family of forums, our model outperforms the best baseline with an average relative improvement of 5.6% (up to 14%) across all domain pairs.

---

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1056–1063
Brussels, Belgium, October 31 - November 4, 2018.

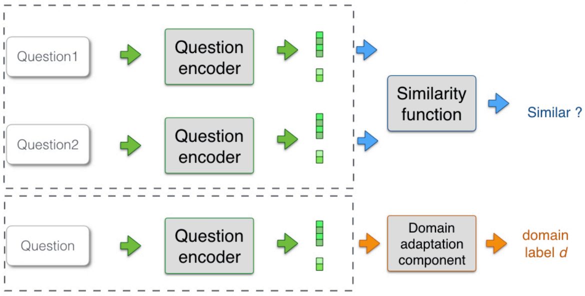

Figure 1: Our cross-domain question-question similarity model. The Question encoder is common for the questions from the source domain and from the target domain. The model and its training procedure are described in Section 2.

- we study when transfer learning performs well and what properties of the domains are important in this regard; and
- we show that adversarial domain adaptation can be efficient even for unseen target domains, given some similarity of the target domain with the source one and with the regularizing adversarial domain.

Adversarial domain adaptation (ADA) was proposed by Ganin and Lempitsky (2015), and was then used for NLP tasks such as sentiment analysis and retrieval-based question answering (Chen et al., 2016; Ganin et al., 2016; Li et al., 2017; Liu et al., 2017; Yu et al., 2018; Zhang et al., 2017), including cross-language adaptation (Joty et al., 2017) for question-question similarity.[2]

The rest of this paper is organized as follows: Section 2 presents our model, its components, and the training procedure. Section 3 describes the datasets we used for our experiments, stressing upon their nature and diversity. Section 4 describes our adaptation experiments and discusses the results. Finally, Section 5 concludes with possible directions for future work.

2 Method

Our ADA model has three components: (*i*) question encoder, (*ii*) similarity function, and (*iii*) domain adaptation component, as shown in Figure 1.

The encoder E maps a sequence of word tokens $x = (x_1, .., x_n)$ to a dense vector $\mathbf{v} = E(x)$. The similarity function f takes two question vectors, $\mathbf{v}_1$ and $\mathbf{v}_2$, and predicts whether the corresponding questions are duplicates.

The domain classifier g takes a question vector $\mathbf{v}$ and predicts whether the question is from the source or from the target domain. We train the encoder not only to do well on the task for the source data, but also to fool the domain classifier, as shown in Algorithm 1. We describe the design choices considered for our domain adaptation model in the following two subsections.

2.1 Question Similarity Function

We consider two options for our similarity function $f(\mathbf{v}_1, \mathbf{v}_2)$:
(*i*) a logistic function that computes the probability that two questions are similar/duplicates, which is trained with the cross-entropy loss:

$$\text{sigmoid}\left(\mathbf{W}^\top(\mathbf{v}_1 \odot \mathbf{v}_2) + \mathbf{b}\right)$$

where $\odot$ is an element-wise vector product between unit encodings of questions;

(*ii*) a simple cosine similarity function, i.e., $cosine(\mathbf{v}_1, \mathbf{v}_2)$, trained using the pairwise hinge loss with a margin m:

$$\sum_i max(\{(1-y^i)f(\mathbf{v}_1^i, \mathbf{v}_2^i) + m - y^i f(\mathbf{v}_1^i, \mathbf{v}_2^i)\}, 0)$$

Our experiments reported in Table 3 show that the $cosine$ similarity function performs far better.

2.2 Domain Adaptation Components

The adversarial component is responsible for reducing the difference between the source and the target domain distributions. There are two common approaches to achieve this: (*i*) classification-based (Ganin and Lempitsky, 2015) and (*ii*) Wasserstein (Arjovsky et al., 2017).

The main difference between them is in the way the domain discrepancy loss is computed. In the classification-based approach, the adversarial component is a classifier trained to correctly predict the domain (source vs. target) of the input question. In contrast, the question encoder is optimized to confuse the domain classifier, which, as a result, encourages domain invariance. Arjovsky and Bottou (2017) showed that this adversarial optimization process resembles minimizing the Jenson-Shannon (JS) divergence between the source P_s and the target distribution P_t:

$$JS(P_s, P_t) = KL(P_s, P_m) + KL(P_g, P_m)$$

where $P_m = (P_s + P_t)/2$ and KL is the Kullback-Leibler divergence.

---

[2] Prior work on cross-language adaptation for question-question similarity used cross-language tree kernels (Da San Martino et al., 2017).

Algorithm 1: Training Procedure

```
Input: source data $X^s$; target data $X^t$
Hyper-parameters: learning rates $\alpha_1, \alpha_2$; batch size $m$; adversarial importance $\lambda$
Parameters to be trained: question encoder $\theta_e$, question similarity classifier $\theta_s$ and domain classifier $\theta_d$
Similarity classification loss $L_c$ is either the cross-entropy loss or hinge loss, described in Section 2.1
Adversarial loss $L_d$, described in Section 2.2
repeat
    for each batch do
        Construct a sub-batch of similar and dissimilar question pairs from the annotated source data $\{(x^s_{i_1}, x^s_{i_2}), y^s_i\}^m_{i=1}$
        Calculate the classification loss $L_c$ using $\theta_e$ and $\theta_s$ for this sub-batch
        Construct a sub-batch of questions $\{x^s_i, x^t_j\}^m_{i=1}$ from the corpora of source and target domains
        Calculate the domain discrepancy loss $L_d$ using $\theta_e$ and $\theta_d$ for this sub-batch
        Total loss $L = L_c - \lambda L_d$
        $\theta_e = \theta_e - \alpha_1 \nabla_{\theta_e} L$
        $\theta_s = \theta_s - \alpha_1 \nabla_{\theta_s} L$
        $\theta_d = \theta_d + \alpha_2 \nabla_{\theta_d} L$
    end for
until $\theta_e$, $\theta_s$ and $\theta_d$ converge
```

In contrast, the Wasserstein method attempts to reduce the approximated Wasserstein distance (also known as *Earth Mover's Distance*) between the distributions for the source and for the target domain as follows:

$$W(P_s, P_t) = \underset{||f||_L \leq 1}{sup} \; \mathbb{E}_{x\sim P_s}[f(x)] - \mathbb{E}_{x\sim P_t}[f(x)]$$

where f is a Lipchitz-1 continuous function realized by a neural network.

Arjovsky et al. (2017) have shown that the Wasserstein method yields more stable training for computer vision tasks.

2.3 Training Procedure

Algorithm 1 describes the procedure to train the three components of our model. Adversarial training needs two kinds of training data: (*i*) annotated question pairs from the source domain, and (*ii*) unlabeled questions from the source and the target domains.

The question encoder is trained to perform well on the source domain using the similarity classification loss L_c. In order to enforce good performance on the target domain, the question encoder is simultaneously trained to be incapable in discriminating between question pairs from the source vs. the target domain. This is done through the domain classification loss L_d.

Dataset	Questions	Duplicates	Train	Dev	Test
AskUbuntu	257,173	27,289	9,106	1,000	1,000
SuperUser	343,033	11,407	9,106	1,000	1,000
Apple	80,466	2,267	–	1,000	1,000
Android	42,970	2,371	–	1,000	1,000
Sprint	31,768	23,826	9,100	1,000	1,000
Quora	537,211	149,306	9,100	–	–

Table 1: Statistics about the datasets. The table shows the number of question pairs that have been manually marked as similar/duplicates by the forum users (i.e., positive pairs). We further add 100 negative question pairs per duplicate question by randomly sampling from the full corpus of questions.

3 Datasets

The datasets we use can be grouped as follows:

- **Stack Exchange** is a family of technical community support forums. We collect questions (composed by title and body) from the XML dumps of four forums: *AskUbuntu*, *SuperUser*, *Apple*, and *Android*. Some pairs of similar/duplicate questions in these forums are marked by community users.
- **Sprint FAQ** is a newly crawled dataset from the Sprint technical forum website. It contains a set of frequently asked questions and their paraphrases, i.e., three similar questions, paraphrased by annotators.
- **Quora** is a dataset of pairs of similar questions asked by people on the Quora website. They cover a broad set of topics touching upon philosophy, entertainment and politics.

Note that these datasets are quite heterogeneous: the *StackExchange* forums focus on specific technologies, where questions are informal and users tend to ramble on about their issues, the *Sprint FAQ* forum is technical, but its questions are concise and shorter, and the *Quora* forum covers many different topics, including non-technical.

Statistics about the datasets are shown in Table 1. Moreover, in order to quantify the differences and the similarities, we calculated the fraction of unigrams, bigrams and trigrams that are shared by pairs of domains. Table 2 shows statistics about the n-gram overlap between *AskUbuntu* or *Quora* as the source and all other domains as the target. As one might expect, there is a larger overlap within the *StackExchange* family.

Source	Target	Unigrams	Bigrams	Trigrams
AskUbuntu	Android	0.989	0.926	0.842
	Apple	0.991	0.926	0.853
	SuperUser	0.990	0.921	0.822
	Sprint	0.959	0.724	0.407
	Quora	0.922	0.696	0.488
Quora	AskUbuntu	0.949	0.647	0.326
	Apple	0.969	0.721	0.426
	Android	0.973	0.762	0.473
	SuperUser	0.958	0.663	0.338
	Sprint	0.942	0.647	0.310

Table 2: Proportion of n-grams that are shared between the source and the target domains.

4 Experiments and Evaluation

4.1 Experimental Setup

Baselines We compare our ADA model to the following baselines: (*a*) *direct transfer*, which directly applies models learned from the source to the target domain without any adaptation; and (*b*) the standard unsupervised *BM25* (Robertson and Zaragoza, 2009) scoring provided in search engines such as Apache Lucene (McCandless et al., 2010).

Models We use a bi-LSTM (Hochreiter and Schmidhuber, 1997) encoder that operates on 300-dimensional GloVe word embeddings (Pennington et al., 2014), which we train on the combined data from all domains. We keep word embeddings fixed in our experiments. For the adversarial component, we use a multi-layer perceptron.

Evaluation Metrics As our datasets may contain some duplicate question pairs, which were not discovered and thus not annotated, we end up having false negatives. Metrics such as MAP and MRR are not suitable in this situation. Instead, we use AUC (area under the curve) to evaluate how well the model ranks positive pairs vs. negative ones. AUC quantifies how well the true positive rate (tpr) grows at various false positive rates (fpr) by calculating the area under the curve starting from $fpr = 0$ to $fpr = 1$. We compute the area integrating the false positive rate (x-axis) from 0 up to a threshold t, and we normalize the area to $[0, 1]$. This score is known as AUC(t). It is more stable than MRR and MAP in our case when there could be several false negatives.[3]

Adaptation	Similarity	AUC(0.05)	AUC(0.1)
—	Sigmoid	0.431	0.557
—	Cosine	0.692	0.782
Classification	Cosine	0.791	0.862
Wasserstein	Cosine	0.795	0.869

Table 3: Duplicate question detection: direct transfer vs. adversarial domain adaptation from *AskUbuntu* to *Android*.

Source	Target	Direct	BM25	Adv.
AskUbuntu	Android	0.692	0.681	**0.790**
	Apple	0.828	0.747	**0.855**
	SuperUser	0.908	0.765	**0.911**
	Sprint	0.917	**0.956**	0.937
SuperUser	AskUbuntu	0.730	0.644	**0.796**
	Apple	0.828	0.747	**0.861**
	Android	0.770	0.681	**0.790**
	Sprint	0.928	**0.956**	0.932

Table 4: Domain adaptation for the *StackExchange* source-target domain pairs when using the *Direct* approach, *BM25*, and our adaptation model, measured with AUC(0.05).

4.2 Choosing the Model Components

Model Selection We select the best components for our domain adaptation model via experimentation on the *AskUbuntu–Android* domain pair. Then, we apply the model with the best-performing components across all domain pairs.

Hyperparameters We fine-tune the hyperparameters of all models on the development set for the target domain.

Similarity Function Table 3 shows the AUC at 0.05 and 0.1 for different models of question similarity, training on *AskUbuntu* and testing on *Android*. The first row shows that using cosine similarity with a hinge loss yields much better results than using a cross-entropy loss. This is likely because (*i*) there are some duplicate question pairs that were not tagged as such and that have come up as negative pairs in our training set, and the hinge loss deals with such outliers better. (*ii*) The cosine similarity is domain-invariant, while the weights of the feed-forward network of the softmax layers capture source-domain features.

Domain Adaptation Component We can see that the Wasserstein and the classification-based methods perform very similarly, after proper hyper-parameter tuning. However, Wasserstein yields better stability, achieving an AUC variance 17 times lower than the one for classification across hyper-parameter settings. Thus, we chose it for all experiments in the following subsections.

---

[3] For illustration, say of 100 candidates, 2 false negatives are ranked higher than the correct pair, the AUC score drops by 3 points (linear drop), as compared to the 66.67 point drop for MRR. We can avoid the expensive manually tagging of the negative pairs for experiments by using the AUC score.

Source	**Target**	**Direct**	**BM25**	**Adv.**
Sprint	AskUbuntu	0.615	**0.644**	0.615
	Apple	0.719	**0.747**	0.728
	Android	0.627	**0.681**	0.648
	Sprint	0.977	0.956	–
	SuperUser	0.795	0.765	**0.795**
Quora	AskUbuntu	0.446	**0.644**	0.446
	Apple	0.543	**0.747**	0.543
	Android	0.443	**0.681**	0.460
	Sprint	0.786	**0.956**	0.794
	SuperUser	0.624	**0.765**	0.649

Table 5: Domain adaptation results when using *Sprint* and *Quora* as the source domains with the *Direct* approach, *BM25*, and our adaptation model, measured with AUC(0.05).

4.3 When Does Adaptation Work Well?

Tables 4 and 5 study the impact of domain adaptation when applied to various source-target domain pairs, using the *Direct* approach, *BM25*, and our adaptation model. We can make the following observations:

- For almost all source–target domain pairs from the *StackExchange* family, domain adaptation improves over both baselines, with an average relative improvement of 5.6%. This improvement goes up to 14% for the *AskUbuntu–Android* source–target domain pair.
- Domain adaptation on the *Sprint* dataset performs better than direct transfer, but it is still worse than *BM25*.
- Domain adaptation from *Quora* performs the worst, with almost no improvement over direct transfer, which is far behind *BM25*.
- The more similar the source and the target domains, the better our adaptation model performs.

Table 2 shows that *AskUbuntu* has high similarity to other *StackExchange* domains, lower similarity to *Sprint*, and even lower similarity to *Quora*. The Pearson coefficient (Myers et al., 2010) between the n-gram fractions and the domain adaptation effectiveness for unigrams, bigrams and trigrams is 0.57, 0.80 and 0.94, respectively, which corresponds to moderate-to-strong positive correlation. This gives insight into how simple statistics can predict the overall effectiveness of domain adaptation.

Pivot\Target	SuperUser	Apple	Android
SuperUser	0.911	0.827	0.678
Apple	0.900	0.855	**0.711**
Android	0.904	**0.843**	0.790
Quora	0.906	0.815	0.673
Direct	0.908	0.828	0.692

Table 6: AUC(0.05) of ADA to unseen domains, with *AskUbuntu* as a source.

4.4 Adapting to Unseen Domains

We also experiment with domain adaptation to a target domain that was not seen during training (even adversarial training). We do so by training to adapt to a pivot domain different from the target. Table 6 shows that this yields better AUC compared to *direct transfer* when using *Apple* and *Android* as the pivot/target domains. We hypothesize that this is due to *Apple* and *Android* being closely related technical forums for iOS and Android devices. This sheds some light on the generality of adversarial regularization.

5 Conclusion and Future Work

We have applied and analyzed adversarial methods for domain transfer for the task of duplicate question detection; to the best of our knowledge, this is the first such work. Our experiments suggest that (*i*) adversarial adaptation is rather effective between domains that are similar, and (*ii*) the effectiveness of adaptation is positively correlated with the n-gram similarity between the domains.

In future work, we plan to develop better methods for adversarial adaptation based on these observations. One idea is to try source-pivot-target transfer, similarly to the way this is done for machine translation (Wu and Wang, 2007). Another promising direction is to have an attention mechanism (Luong et al., 2015) for question similarity which can be adapted across domains.[4]

Acknowledgments

This research was carried out in collaboration between the MIT Computer Science and Artificial Intelligence Laboratory (CSAIL) and the Qatar Computing Research Institute (QCRI), HBKU.

---

[4] In our experiments, we found that using attention was lowering the adaptation performance. Upon analysis, we found that adversarial techniques alone were not enough to make the attention weights domain-invariant.

Abstract

Sequence-to-sequence (SEQ2SEQ) models have been successfully applied to automatic math word problem solving. Despite its simplicity, a drawback still remains: a math word problem can be correctly solved by more than one equations. This non-deterministic transduction harms the performance of maximum likelihood estimation. In this paper, by considering the uniqueness of expression tree, we propose an equation normalization method to normalize the duplicated equations. Moreover, we analyze the performance of three popular SEQ2SEQ models on the math word problem solving. We find that each model has its own specialty in solving problems, consequently an ensemble model is then proposed to combine their advantages. Experiments on dataset Math23K show that the ensemble model with equation normalization significantly outperforms the previous state-of-the-art methods.

1 Introduction

Developing computer systems to automatically solve math word problems (MWPs) has been an interest of NLP researchers since 1963 (Feigenbaum et al., 1963; Bobrow, 1964). A typical MWP is shown in Table 1. Readers are asked to infer how many pens and pencils Jessica have in total, based on the textual problem description provided. Statistical machine learning-based methods (Kushman et al., 2014; Amnueypornsakul and Bhat, 2014; Zhou et al., 2015; Mitra and Baral, 2016; Roy and Roth, 2018) and semantic parsing-based methods (Shi et al., 2015; Koncel-Kedziorski et al., 2015; Roy and Roth, 2015; Huang et al., 2017) are proposed to tackle this problem, yet they still require considerable manual efforts on feature or template designing. For more literatures about solving math word problems automatically, refer to a recent survey paper Zhang et al. (2018).

Problem: Dan has 5 pens and 3 pencils, Jessica has 4 more pens and 2 less pencils than him. How many pens and pencils does Jessica have in total?
Equation: $x = 5 + 4 + 3 - 2$; **Solution:** 10

Table 1: A math word problem

Recently, the Deep Neural Networks (DNNs) have opened a new direction towards automatic MWP solving. Ling et al. (2017) take multiple-choice problems as input and automatically generate rationale text and the final choice. Wang et al. (2018) then make the first attempt of applying deep reinforcement learning to arithmetic word problem solving. Wang et al. (2017) train a deep neural solver (DNS) that needs no hand-crafted features, using the SEQ2SEQ model to automatically learn the problem-to-equation mapping.

Although promising results have been reported, the model in (Wang et al., 2017) still suffers from an equation duplication problem: a MWP can be solved by multiple equations. Taking the problem in Table 1 as an example, it can be solved by various equations such as $x = 5 + 4 + 3 - 2$, $x = 4 + (5 - 2) + 3$ and $x = 5 - 2 + 3 + 4$. This duplication problem results in a non-deterministic output space, which has a negative impact on the performance of most data-driven methods. In this paper, by considering the uniqueness of expression tree, we propose an equation normalization method to solve this problem.

Given the success of different SEQ2SEQ models on machine translation (such as recurrent encoder-decoder (Wu et al., 2016), Convolutional SEQ2SEQ model (Gehring et al., 2017) and Trans-

---

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1064–1069
Brussels, Belgium, October 31 - November 4, 2018.

former (Vaswani et al., 2017)), it is promising to adapt them to MWP solving. In this paper, we compare the performance of three state-of-the-art SEQ2SEQ models on MWP solving. We observe that different models are able to correctly solve different MWPs, therefore, as a matter of course, an ensemble model is proposed to achieve higher performance. Experiments on dataset Math23K show that by adopting the equation normalization and model ensemble techniques, the accuracy boosts from 60.7% to 68.4%.

The remaining part of this paper is organized as follows: we first introduce the SEQ2SEQ Framework in Section 2. Then the equation normalization process is presented in Section 3, following which three SEQ2SEQ models and an ensemble model are applied to MWP solving in Section 4. The experimental results are presented in Section 5. Finally we conclude this paper in Section 6.

2 SEQ2SEQ Framework

The process of using SEQ2SEQ model to solve MWPs can be divided into two stages (Wang et al., 2017). In the first stage (number mapping stage), significant numbers (numbers that will be used in real calculation) in problem P are mapped to a list of number tokens $\{n_1, \ldots, n_m\}$ by their natural order in the problem text. Throughout this paper, we use the significant number identification (SNI) module proposed in (Wang et al., 2017) to identify whether a number is significant. In the second stage, SEQ2SEQ models can be trained by taking the problem text as the source sequence and equation templates (equations after number mapping) as the target sequence.

Taking the problem P in Table 1 as an example, first we can obtain a number mapping $M : \{n_1 = 5; \quad n_2 = 3; \quad n_3 = 4; \quad n_4 = 2;\}$, and transform the given equation $E_P : x = 5+4+3-2$ to an equation template $T_P : x = n_1+n_3+n_2-n_4$. During training, the objective of our SEQ2SEQ model is to maximize the conditional probability $P(T_p|P)$, which will be decomposed to token-wise probabilities. During decoding, we use beam search to approximate the most likely equation template. After that, we replace the number tokens with actual numbers and calculate the solution S with a math solver.

3 Equation Normalization

In the number mapping stage, the equations E_P have been successfully transformed to equation templates T_P. However, due to the equation duplication problem introduced in Section 1, this problem-equation templates formalization is a non-deterministic transduction that will have adverse effects on the performance of maximum likelihood estimation. There are two types of equation duplication: 1) order duplication such as "$n1 + n3 + n2$" and "$n1 + n2 + n3$", 2) bracket duplication such as "$n_1 + n_3 - n_2$" and "$n1 + (n_3 - n_2)$".

To normalize the order-duplicated templates, we define two normalization rules:

- Rule 1: Two duplicated equation templates with unequal length should be normalized to the shorter one. For example, two equation templates "$n_1 + n_2 + n_3 + n_3 - n_3$", "$n_1 + n_2 + n_3$" should be normalized to the latter one.

- Rule 2: The number tokens in equation templates should be ordered as close as possible to their order in number mapping. For example, three equation templates "$n_1+n_3+n_2$", "$n_1 + n_2 + n_3$" and "$n_3 + n_1 + n_2$" should be normalized to "$n_1 + n_2 + n_3$".

To solve the bracket duplication problem, we further normalize the equation templates to an expression tree. Every inner node in the expression tree is an operator with two children, while each leaf node is expected to be a number token. An example of expressing equation template $n_1 + n_2 + n_3 - n_4$ as the unique expression tree is shown in Figure 1.

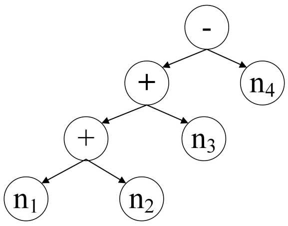

Figure 1: A Unique Expression Tree

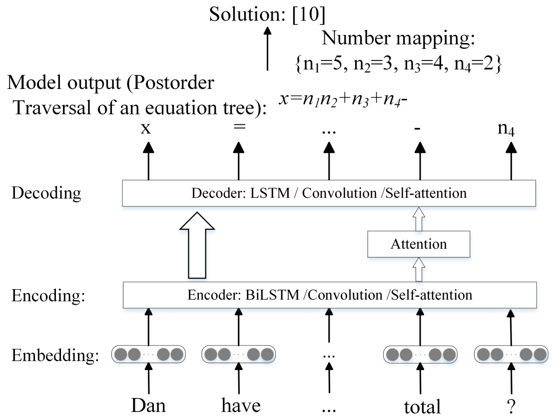
After equation normalization, the SEQ2SEQ models can solve MWPs by taking problem text as source sequence and the postorder traversal of an unique expression tree as target sequence, as shown in Figure 2.



Model input (Problem text after number mapping): Dan has n_1 pens and n_2 pencils, Jessica has n_3 more pens and n_4 less pencils than him. How many pens and pencils does Jessica have in total?

Figure 2: Framework of SEQ2SEQ models

4 Models

In this section, we present three types of SEQ2SEQ models to solve MWPs: bidirectional Long Short Term Memory network (BiLSTM) (Wu et al., 2016), Convolutional SEQ2SEQ model (Gehring et al., 2017), and Transformer (Vaswani et al., 2017). To benefit the output accuracy with all three architectures, we propose to use a simple ensemble method.

4.1 BiLSTM

The BiLSTM model uses two LSTMs (forward and backward) to learn the representation of each token in the sequence based on both the past and the future context of the token. At each time step of decoding, the deocder uses a global attention mechanism to read those representations.

In more detail, we use two-layer Bi-LSTM cells with 256 hidden units as encoder, and two layers LSTM cells with 512 hidden units as decoder. In addition, we use Adam optimizer with learning rate $1e^{-3}$, $\beta_1 = 0.9$, and $\beta_2 = 0.99$. The epochs, minibatch size, and dropout rate are set to 100, 64, and 0.5, respectively.

4.2 ConvS2S

ConvS2S (Gehring et al., 2017) uses a convolutional architecture instead of RNNs. Both encoder and decoder share the same convolutional structure that uses n kernels striding from one side to the other, and uses gate linear units as nonlinearity activations over the output of convolution.

Our ConvS2S model adopts a four layers encoder and a three layers decoder, both using kernels of width 3 and hidden size 256. We adopt early stopping and learning rate annealing and set max-epochs equals to 100.

4.3 Transformer

Vaswani et al. (2017) proposed the Transformer based on an attention mechanism without relying on any convolutional or recurrent architecture. Both encoder and decoder are composed of a stack of identical layers. Each layer contains two parts: a multi-head self-attention module and a position-wise fully-connected feed-forward network.

Our transformer is four layers deep, with $n_{head} = 16$, $d_k = 12$, $d_v = 32$, and $d_{model} = 512$, where n_{head} is the number of heads of its self-attention, d_k is the dimension of keys, d_v is the dimension of values, and d_{model} is the output dimension of each sub-layer. In addition, we use Adam optimizer with learning rate $1e^{-9}$, $\beta_1 = 0.9$, $\beta_2 = 0.99$, and dropout rate of 0.3.

4.4 Ensemble Model

Through careful observation (detailed in Section 5.2), we find that each model has a speciality in solving problems. Therefore, we propose an ensemble model which selects the result according to models' generation probability:

$$p(\mathbf{y}) = \prod_{t=1}^{T} p(y_t | y_{<t}, \mathbf{x})$$

where $\mathbf{y} = \{y_1, ..., y_T\}$ is the target sequence, and $\mathbf{x} = \{x_1, ..., x_S\}$ is the source sequence. Finally, the output of the model with the highest generation probability is selected as the final output.

5 Experiment

In this section, we conduct experiments on dataset Math23K to examine the performance of different SEQ2SEQ models. Our main experimental result is to show a significant improvement over the baseline methods. We further conduct a case study to analyze why different SEQ2SEQ models can solve different kinds of MWPs.

Dataset: Math23K[1] collected by Wang et al. (2017) contains 23,162 labeled MWPs. All these

	Bi-LSTM	Transformer	ConvS2S
w/o EN	59.6	59.0	61.5
+ SE	63.1	59.9	62.2
+ OE	63.7	60.7	62.9
+ EB	65.3	61.2	62.9

Table 3: The ablation study of three equation normalization methods. SE is the first Rule mentioned in Section 3. OE is the second rule mentioned in Section 3. EB means eliminating the brackets.

problems are linear algebra questions with only one unknown variable.

Baselines: We compare our methods with two baselines: DNS and DNS-Hybrid. Both of them are proposed in (Wang et al., 2017), with state-of-the-art performance on dataset Math23K. The DNS is a vanilla SEQ2SEQ model that adopts GRU (Chung et al., 2014) as encoder and LSTM as decoder. The DNS-Hybrid is a hybrid model that combines DNS and a retrieval-based solver to achieve better performance.

5.1 Results

In experiments, we use the testing set in Math23K as the test set, and randomly split 1, 000 problems from the training set as validation set. Evaluation results are summarized in Table 2. First, to examine the effectiveness of equation normalization, model performance with and without equation normalization are compared. Then the performance of DNS, DNS-Hybrid, Bi-LSTM, ConvS2S, Transformer, and Ensemble model are examined on the dataset.

Several observations can be made from the results. First, the equation normalization process significantly improves the performance of each model. The accuracy of different models gain increases from 2.7% to 7.1% after equation normalization. Second, Bi-LSTM, ConvS2S, Transformer can achieve much higher performance than DNS, which means that popular machine translation models are also efficient in automatic MWP solving. Third, by combining the SEQ2SEQ models, our ensemble model gains additional 1.7% increase on accuracy.

In addition, we have further conducted three extra experiments to disentangle the benefits of three different EN techniques. Table 3 gives the details of the ablation study of the three SEQ2SEQ models. Taking Bi-LSTM as an example, accuracies of rule 1 (SE), rule 2 (OE) and eliminating brackets (EB) are 63.1%, 63.7% and 65.3%, respectively. Obviously, the performance of SEQ2ESQ models benefits from the equation normalization technologies.

5.2 Case Study

Further, we conduct a case analysis on the capability of different SEQ2SEQ models and provide three examples in Table 4. Our analysis is summarized as follows: 1) Transformer occasionally generates mathematically incorrect templates, while Bi-LSTM and ConvS2S almost do not, as shown in Example 1. This is probably because the size of training data is still not enough to train the multi-head self-attention structures; 2) In Example 2, the Transformer is adapted to solve problems that require complex inference. It is mainly because different heads in a self-attention structure can model various types of relationships between number tokens; 3) The multi-layer convolutional block structure in ConvS2S can properly process the context information of number tokens. In Example 3, it is the only one that captures the relationship between stamp A and stamp B.

6 Conclusion

In this paper, we first propose an equation normalization method that normalizes duplicated equation templates to an expression tree. We test different SEQ2SEQ models on MWP solving and propose an ensemble model to achieve higher performance. Experimental results demonstrate that the proposed equation normalization method and the ensemble model can significantly improve the state-of-the-art methods.

Abstract

State-of-the-art networks that model relations between two pieces of text often use complex architectures and attention. In this paper, instead of focusing on architecture engineering, we take advantage of small amounts of labelled data that model semantic phenomena in text to encode matching features directly in the word representations. This greatly boosts the accuracy of our reference network, while keeping the model simple and fast to train. Our approach also beats a tree kernel model that uses similar input encodings, and neural models which use advanced attention and compare-aggregate mechanisms.

1 Introduction

Modeling a match between pieces of text is at the core of many NLP tasks. Recently, manual feature engineering methods have been shadowed by neural network approaches. These networks model the interaction of two pieces of text, or word-to-word interactions across sentences, using sophisticated attention mechanisms (Wang et al., 2016a; Santos et al., 2016) and compare-aggregate frameworks (He and Lin, 2016; Wang et al., 2017).

Architectural complexity is tied to longer training times [1]. Meaningful features may take long time to emerge by only leveraging word representations and the training data of the task at hand. This is especially problematic with little data, as it often happens in question answering (QA) tasks, e.g., answer sentence selection (Wang et al., 2007; Yang et al., 2015). Thus, effective word representations are crucial in neural network models to get state-of-the-art performance.

In this work, we try to answer the following research questions: (i) in addition to lexical links, can we incorporate higher-level semantic links between the words in a question and a candidate answer passage, and (ii) can we show that such information has an impact on the quality of our model, and also allows us to keep the architecture simple?

We show that modeling semantic relations improves the performance of a neural network for answer sentence selection with (i) a little number of semantic annotations, and (ii) a little increase in training time w.r.t. more complex architecture.

2 Related Work

Traditional work on QA makes heavily use of syntactic and semantic features (Hickl et al., 2007; Ferrucci et al., 2010). A different direction consists in using structural kernels on text encoded as trees (Severyn and Moschitti, 2012; Severyn et al., 2013a,b; Tymoshenko et al., 2014; Tymoshenko and Moschitti, 2015). Recently, deep learning methods have been very successful in NLP tasks. Words and sentences are mapped into low dimensional representations using convolutional (Krizhevsky et al., 2012) and recurrent networks (Schuster and Paliwal, 1997), and then adoperated for classification. Complex networks for such a task include attentive networks and compare-aggregate networks.

Attentive Networks (Bahdanau et al., 2015; Parikh et al., 2016; Yin et al., 2016) build a sentence representation by also considering the other sentence, weighting the contribution of its parts with the so-called attention mechanism.

Compare-Aggregate Networks (Wang and Jiang, 2017) apply several decompositions to each sentence in a pair. The resulting vectors are compared or composed with multiple functions, and possibly some attention mechanisms. All the

Brussels, Belgium, October 31 - November 4, 2018.

intermediate results are then aggregated into a fixed size vector to quantify the final match.

In this work, we take some elements of the traditional QA research, i.e., semantic features, and use them to model relationships between sentence pairs, in the context of a neural network, which is less complex than attentive and compare-aggregate counterparts.

3 Question Analysis

Question Analysis is an important part of a QA system (Lally et al., 2012) and can give us syntactic and semantic clues that greatly help in scoring answer passages, and in identifying the final answer. Leveraging a relatively small number of annotated examples, we can automatically extract question properties that may be exploited by a QA model to increase the accuracy of its answers. We use classifiers to extract the *question category* and the *question focus*.

Question Category. Questions can be broadly classified into categories according to a given taxonomy. When the category is indicative of the answer type, the latter can be furtherly characterized by the Lexical Answer Type (LAT), which according to Lally et al. (2012) is a word or noun phrase in the question that specifies the type of the answer without any attempt to understand its semantics.

Question Focus. In the literature there are multiple definitions of question focus. According to Ferrucci et al. (2010), the focus is the question part that substituted with the answer, renders the question a stand-alone statement. According to Bunescu and Huang (2010), the focus is the "set of all maximal noun phrases in the question that corefer with the answer". Their definition allows a question to have multiple focuses or an implicit focus. Additionally, it is more tied to the LAT and indeed the focus can be used to infer the answer type. We adopt such definition since we build our question focus identifier using the annotated data they provide. Note that we do not consider multi-word or implicit focus.

4 Answer Sentence Selection with CNNs

Given a query or question q and a candidate answer passage a, the task of answer selection can be defined as learning a function $f(q, a)$ that outputs a relevancy probability $s \in [0, 1]$. Multiple answers associated with a question are sorted in descending order by the score s. A good answer selection system places the highest number of correct answers at the top of a candidate answer list. In this paper, we use convolutional neural networks, referred to as CNNs (Kim, 2014; Kalchbrenner et al., 2014), to (i) classify a question into a category, (ii) identify the focus word in a question, and (iii) build a question and answer representations for QA.

4.1 Sentence Matrix Encoding

A sentence s of length n is a sequence of words (w_1, ..., w_n), which are drawn from a vocabulary V. Each word is encoded with an integer id from 1 to $|V|$, and then represented as a vector, $\mathbf{w} \in \mathbb{R}^d$, looked up into an embedding matrix, $\mathbf{E} \in \mathbb{R}^{d \times |V|}$. The matrix $\mathbf{E}$ is obtained by concatenating all the embeddings of the words in V. The id 0 is used for padding and it is mapped to the zero vector. The i^{th} column in $\mathbf{E}$ corresponds to the word with integer id i to facilitate the lookup.

4.2 Question Analysis Networks

We use CNNs for question analysis. The **question category network** applies convolutions of different width and then pooling on the question. The results are concatenated and fed to a multilayer perceptron (MLP) that outputs a probability distribution over the possible categories seen during training. The **question focus network** applies convolutions that operate on windows centered on each question word. Therefore, the input and output resolutions are the same. We stack a number of convolutions to increase the receptive field. Every output vector from the last convolution of the stack is passed through an MLP, which produces a scalar value. All those values are normalized across each sentence with a softmax, to form a probability distribution over the sentence tokens.

4.3 Answer Sentence Selection Network

Our neural model is based on the Severyn and Moschitti (2015, 2016) model (S&M from now on), showed in Figure 1. This model is simple, fast and well studied. It has also been reproduced in other work (Rao et al., 2017; Chen et al., 2017; Sequiera et al., 2017).

The S&M model embeds the question and answer passage and operates independent convolutional and max-pooling layers on each. A bilinear transformation (Bordes et al., 2014) produces a similarity value x_{sim} for the pair. The similarity, the encoded question and passage, and a vec-

Table 1: Mapping between question categories and OntoNotes entity types.

tor of real valued features x_{feat} are concatenated in the join layer. The latter is fed to a hidden layer with a non-linearity, and the final softmax layer outputs the matching probability. The word vectors of the question and the answer are augmented with an additional feature, which is embedded in a small dimensional space. This feature signals if a word appears in both the question and answer. We found that the real valued features and the similarity matrix do not increase the network accuracy and we removed them from our model. This finding is consistent with recent reproduction papers by Rao et al. (2017); Sequiera et al. (2017).

4.4 Our QA Network with Semantic Overlap

We propose to add semantic features to the sentence matrix to establish links between words that go beyond lexical matching. Figure 2 describes our network. The key addition to the S&M model is the semantic overlap vector. Each word is therefore represented by concatenating three vectors: the word embedding vector, a feature embedding vector which can represent two values – if a word is contained or not in both question and answer – and the semantic overlap embedding vector. The semantic vector $\mathbf{w}_{so}$, with dimensionality s, embeds a feature so which can assume $C+1$ values, if we consider the C question classes plus a no-match value. Each feature value is looked up into an embedding matrix $\mathbf{W}_{so} \in \mathbb{R}^{s \times |C|+1}$. Analogously, the word overlap binary feature is looked up into an embedding matrix $\mathbf{W}_{wo} \in \mathbb{R}^{r \times |2|}$. The final word representation will be the concatenation of all these vectors: $\mathbf{w}^{'} = [\mathbf{w}; \mathbf{w}_{wo}; \mathbf{w}_{so}]$.

Here we describe how the semantic word overlap feature is computed. For each question we collect the output of our question analysis CNNs. The question focus CNN determines which word in the question is the focus. The question category CNN assigns a class to the question. After that, each word is associated with a semantic overlap feature so (which will eventually be embedded using $\mathbf{W}_{wo}$) according to the following strategy:

1. for each word in the question which is not the question focus so is equal to 0. For the question focus word so is equal to the id of the question category (the question focus and category are output by our CNN classifiers);
2. for each answer word so is equal to 0, with the exeception of words covered by named entities (NEs), for which so is equal to the id of the question category that is compatible with their entity type, according to the mapping in Table 1.

The $\mathbf{W}_{wo}$ and $\mathbf{W}_{so}$ matrices are parameters of the model, and they are learned during training. The question category and question focus annotations for the QA datasets are produced by our neural network classifiers. The NEs are obtained with an off-the-shelf processor [2], trained on OntoNotes (Weischedel et al., 2012).

5 Experimental Results

Here we describe how we train our networks for question analysis and then we present the answer sentence selection experiments. More details about preprocessing, training and hyperparameter choice can be found in the appendix.

5.1 Question Classification

Dataset. The CNN question classifier is trained on the UIUC dataset (Li and Roth, 2006). We use the 6 coarse classes to train the classifier.

---

[2] In the future, we will also train the NE recognizer.

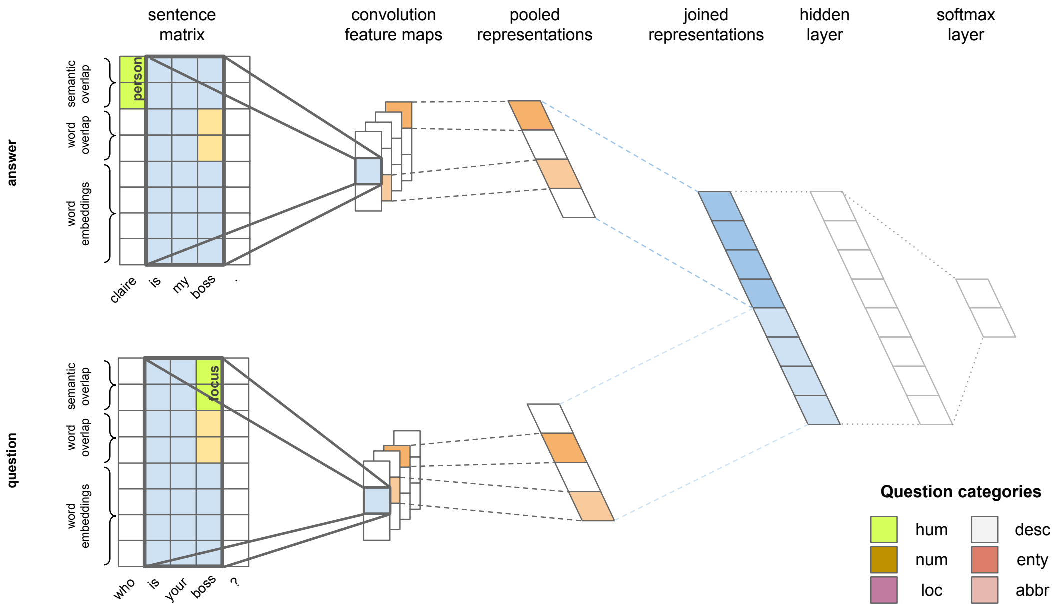

Figure 2: Our model with word and semantic overlap vectors. The convolution of size 3 is not padded, and the filters are 4. The semantic overlap vectors of the question focus word *boss*, and the answer word *claire* are the same, because the latter is an entity of type *Person*. The question has HUM category. Ignoring stopwords, the word *boss* appears in the question and the answer, and this is reflected in the word overlap embedding space.

Results. The classifier has accuracy of 91.2% on the UIUC test set. Our goal is to annotate new questions with reasonable accuracy. Since the model convergences well, we annotate the questions in the QA datasets after training on the UIUC data, and select the best model on the test data.

5.2 Question Focus Identification

Dataset. The CNN focus identifier is trained on the dataset from Bunescu and Huang (2010), which contains the first 2,000 UIUC questions annotated with focus information. After removing the questions with implicit and multi-focus, we end up with 1,030 questions.

Results. The cross-validation accuracy of the classifier is 92.3%. After convergence, we annotate the focus words in the QA datasets.

5.3 TrecQA

Dataset. We test our model on TrecQA (Wang et al., 2007), one of the most popular benchmarks for answer selection. The dataset contains factoid questions and candidate answer sentences.

CNN$_{WO+SO}$ TRAIN-ALL	77.93 (0.7)	84.89 (0.9)

Table 2: MAP and MRR (%) on the TrecQA Clean dataset.

We use the same splits of the original data, but we run our experiments using the larger provided training set (TRAIN-ALL). This is noisier data, which, on the other hand, gives us more examples for training. We remove from the dev. and test sets questions without answers, and questions with only correct or incorrect answer sentence candidates. The resulting dev. and test sets contain respectively 65 and 68 questions. This setting follows a standard in recent work on TREC-QA which is referred to as TrecQA Clean (See Shen et al. (2017)).

Results. Table 2 contains results from previous work, and the performance of our models. CNN$_{WO}$ is our variant of the S&M model. It has comparable performance in terms of MAP, but it is 2.4% points higher in MRR. Our model CNN$_{WO+SO}$ that integrates the semantic overlap improves over CNN$_{WO}$ by 1.44% points in MAP, and 0.67% points in MRR. It approaches the model by Rao et al. (2016), which uses a triplet ranking loss, and several strategies to build

training instances with difficult negative examples. Our system beats several others that use word alignments and attention mechanisms. The better systems employ expensive bidirectional networks, sophisticated attention mechanisms, and extract multiple views of questions and answers for comparing and aggregating them.

5.4 WikiQA

Dataset. TrecQA and its test set are small, so results may be unstable. In addition, lexical overlap between questions and answer candidates is high (Yih et al., 2013). This means that simple lexical similarity features are highly discriminative. Therefore, we also experiment with WikiQA (Yang et al., 2015), which is an order of magnitude larger than TrecQA. We use the Yin et al. (2016) experimental setting.

Results. Table 3 contains the results on WikiQA. Again the MAP score is comparable with the S&M model, while the MRR is slightly higher. Our model CNN$_{WO+SO}$ improves over CNN$_{WO}$ by 2.71% points in MAP, and 2.56% points in MRR, with a higher margin with respect to TrecQA. Interestingly, our approach improves upon the Tymoshenko et al. (2016) tree-kernel model by 1 MAP point. This model includes relational information in terms of question focus, entities and question categories too, but uses additional syntactic information (i.e., syntactic trees). Our network is able to make better use of the provided semantic clues. Surprisingly, CNN$_{WO+SO}$ also achieves higher MAP than the model by Wang et al. (2017), which is a state-of-the-art complex approach mixing attention and interaction factors of multiple sentence perspectives.

5.5 Discussion

The results with the CNN$_{WO+SO}$ model suggest that the semantic overlap vectors are an effective way of linking questions and answers. This is especially true, given the results on WikiQA, where the questions and answers have little lexical overlap. With the additional semantic information, the CNN is able to better model the relevancy of candidate passages. It also surpasses the accuracy of more complex systems, which have higher training time. The annotation networks (which can be trained only once) and the answer selection networks take little time to train: from 10 to 20 minutes in total, depending on the number of question/answer pairs. CNNs are faster at training and inference time with respect to RNNs, especially when the latter incorporate attention mechanisms, which increase the number of computations. We argue that annotating a relatively small number of examples with semantic information, could be time well spent to increase model accuracy, without increasing its architectural complexity. We would like to add that we also experimented with RNNs (LSTM and GRU) in place of the CNN sentence model. Such encoders easily overfitted, requiring careful regularization, and did not yield better results for us.

6 Conclusion and Future Work

In this paper, we presented a neural network that models semantic links between questions and answers, in addition to lexical links. The annotations for establishing such links are produced by a set of fast neural components for question analysis, trained on publicly available datasets. The evaluation on two QA datasets shows that our approach can achieve state-of-the-art performance using a simple CNN, leading to a low complexity and training time. Our approach is an interesting first step towards a future architecture, in which we will jointly optimize the semantic annotators and the answer sentence selection model, in an end-to-end fashion.

A dataset and baselines for sequential open-domain question answering

Ahmed Elgohary[*], Chen Zhao[*], Jordan Boyd-Graber
Department of Computer Science
University of Maryland, College Park
`{elgohary, chenz, jbg}@cs.umd.edu`

Abstract

Previous work on question-answering systems mainly focuses on answering individual questions, assuming they are independent and devoid of context. Instead, we investigate sequential question answering, asking multiple related questions. We present QBLink, a new dataset of fully human-authored questions. We extend existing strong question answering frameworks to include previous questions to improve the overall question-answering accuracy in open-domain question answering. The dataset is publicly available at `http://sequential.qanta.org`.

1 Introduction

The framework of combining information retrieval and neural reading comprehension has been the basis of several systems for answering open-domain questions over unstructured text (Chen et al., 2017; Wang et al., 2018; Clark and Gardner, 2018; Htut et al., 2018). Typically, such systems take one input question at a time, retrieving and ranking multiple paragraphs that potentially contain the answer. A reading comprehension model then produces a ranked list of candidate answer spans from each paragraph. The final answer is then selected from the produced spans.

In information-seeking dialogs, e.g., personal assistants, users interact with a question answering system by asking a sequence of related questions, where questions share the same predicate, entities, or at least a topic. Answering each question in isolation is sub-optimal as information from previously asked questions and previously obtained answers can help better answer the current question.

Lead-in: Only twenty-one million units in this system will ever be created. For 10 points each:
Question 1: Name this digital payment system whose transactions are recorded on a "block chain".
Answer: Bitcoin
Question 2: Bitcoin was invented by this person, who, according to a dubious Newsweek cover story, is a 64-year-old Japanese-American man who lives in California.
Answer: Satoshi Nakamoto
Question 3: This online drugs marketplace, Chris Borglum's one-time favorite, used bitcoins to conduct all of its transactions. It was started in 2011 by Ross Ulbricht using the pseudonym Dread Pirate Roberts.
Answer: Silk Road

Figure 1: An example sequence of questions from QBLink. The lead-in and question 1 are asking about the same object/answer. The subject of question 2 is the same as the object of question 1. All questions are about a narrow topic, Bitcoin.

We study the task of sequential open-domain question answering. We ask how a standard open-domain question answering system can incorporate connections between question-answer pairs in the same sequence. We introduce QBLink, a new dataset of about 18,000 question sequences (Figure 1), each sequence consists of three naturally occurring human-authored questions (totaling around 56,000 unique questions). The sequences themselves are also naturally occurring (i.e., we do not artificially combine individually-authored questions to form sequences), which allows us to focus more on the important connections between questions that should be incorporated to improve the end-to-end question answering accuracy.

We compare sequence-aware models to baselines that process each question separately. For our sequence-aware models, we tweak the retrieval component by incorporating previous questions and their answers together with the current question to better rank the retrieved paragraphs. For the reader, we use the semantic relations between entities in previous questions (or their corresponding answers) and entities mentioned in the paragraph

---

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1077–1083
Brussels, Belgium, October 31 - November 4, 2018.

being read (candidate answers) to better choose the answer entity. Both the retrieval and reading steps can be slightly improved by incorporating sequence information.

Our contributions are two-fold: first, we present a new dataset for sequential question answering. Our dataset is composed of complex questions about a variety of topics. We make the dataset publicly available to encourage future research. Second, we use our dataset to compare baselines in the open-domain question answering setup with the goal of showing that incorporating sequential connections between questions is advantageous.

2 Sequential Question Answering Task

We define the task of open-domain sequential question answering: given a document collection D and questions grouped into disjoint sequences $\{S_i \,|\, i = 1 \ldots n\}$ where each S_i is an ordered sequence of question, answer pairs, and a subset of documents $S_i = ((q_i^j,\ a_i^j,\ D_i^j) \,|\, j = 1 \ldots m)$, the task is to answer questions $q_i^{\hat{j}}$ with document evidences $D_i^{\hat{j}}$ given access to previously asked questions in the same sequence and their corresponding answers $\{(q_i^j,\ a_i^j) \,|\, j < \hat{j}\}$.

Following Chen et al. (2017), we split the task into two steps—a retrieval step and a reading step. In the retrieval step the current question $q_i^{\hat{j}}$ and previous questions and answers $\{(q_i^j,\ a_i^j) \,|\, j < \hat{j}\}$ are used to retrieve a ranked list of paragraphs $D_i^{\hat{j}}$ from D that are likely to contain the correct answer to the current question $q_i^{\hat{j}}$. The retrieved paragraphs $D_i^{\hat{j}}$ are the input to the reading step that selects a span from $D_i^{\hat{j}}$ as the answer to $q_i^{\hat{j}}$. The reading step has access to previous questions and answers $\{(q_i^j,\ a_i^j) \,|\, j < \hat{j}\}$ as well.

3 Dataset Construction

This section describes QBLink's construction. QBLink is based on the *bonus questions* of **Q**uiz **B**owl tournaments. Unlike previous work that only uses the starter (or tossup) questions (Boyd-Graber et al., 2012), bonus questions are not interruptable (players always hear the complete question) and have greater variability in difficulty. Bonus questions start with a lead-in text, which sets the stage for the rest of the question, followed by a sequence of related questions. Figure 1 shows an example of a sequence of three questions.

Num. Questions (Num. Sequences) × 3	
Training	45,747 (15,249)
Developme	3,630 (1,210)
Testing	6,555 (2,185)
Num. Sequences per Domain	
Current Events	240
Fine Arts	2,588

Philosophy	692
Religion	746
Science	4,028
Social Science	827
Trash	453
Num. Questions Tokens	
Training	32.6 ± 9.6
Developme	33.5 ± 9.9
Testing	32.1 ± 10.24
Num. TagMe Entities	
Training	2.46 ± 1.68
Developme	2.49 ± 1.68
Testing	2.48 ± 1.77
Num. Unique Answers	43,597
Num. Unique Answer Pages	18,529

Table 1: Statistics about QBLink. Most questions are fairly long and contain 2.5 entity mentions in average which demonstrates the complexity of the questions.

Specifically, we collect bonus questions from `http://quizdb.org` for the tournaments in 2008–2018. Each question is categorized by topic as history, literature, science, geography, fine arts, philosophy, religion, mythology, social sciences, current events or trash. We filter out too short questions (fewer than ten tokens), and only keep questions with exactly three sub-questions.

We map the answers to unambiguous Wikipedia pages using combination of rule based matching and fuzzy string matching, then filter out the questions whose answers are not mapped to any Wikipedia page (12.5% of the questions).

To keep our development and test set intact and and of a reasonable percentage of questions, we use the questions in 2014 tournament (the year with the largest number of questions) for development and testing, and the rest of the questions are used for training. Table 1 shows the number of question sequences and questions per split as well as tokens and linked Wikipedia mentions per question. We use TagMe (Ferragina and Scaiella, 2010) for mention detection and linking question text to Wikipedia.

4 Baselines

We build our baselines on the DrQA framework of Chen et al. (2017) for open-domain question answering over Wikipedia.[1] The framework operates in a retrieval phase followed by a reading phase.

The retrieval phase uses a simple tf-idf (Salton and Buckley, 1987) ranking of Wikipedia articles given a question as the query.

The reading phase is a multi-layer recurrent neural network model that extracts an answer span from the top d retrieved paragraphs. The reader model computes a contextualized representation of each token $\mathbf{t_i}$ by running the token sequence through a multi-layer bidirectional long short-term memory network (BiLSTM) (Hochreiter and Schmidhuber, 1997) and taking the corresponding hidden state to each token at the top layer. The question itself is encoded in a vector $\mathbf{q}$ as a weighted average of the hidden states of a BiLSTM over the word embeddings of its individual tokens. The model then computes an unnormalized probability score of t_i as the start and end token of the answer span,

$$\begin{aligned} Start(i) &= \exp(\mathbf{t_i}^T \mathbf{W_{start}} \mathbf{q}); \\ End(i) &= \exp(\mathbf{t_i}^T \mathbf{W_{end}} \mathbf{q}). \end{aligned} \tag{1}$$

To find the answer in multiple paragraphs at test time, we merge all paragraphs before feeding them to the reader (Clark and Gardner, 2018).

4.1 Answering Question in Isolation

We experiment with three models that ignore the sequential connections between questions and answer each question in isolation. Our first model is a simple information retrieval (IR) baseline that only uses the retrieval component: the title of the top-1 Wikipedia article is predicted as the answer.

Our second baseline is the full DrQA baseline whose reader is trained/tuned on the training/development questions of our dataset. To assign paragraphs to each of the training questions, we follow a similar distant-supervision approach to Chen et al. (2017). We retrieve the top twenty Wikipedia articles for each question, exclude the paragraphs that do not contain the gold answer, and then rank the remaining paragraphs using tf-idf. Each of the top ten paragraphs is paired with the question to form a data instance for training the reader.

Finally, we tweak the DrQA reader to limit the candidate answer spans to entity mentions that are linked to Wikipedia. We set the pre-normalization start and end scores of spans that are not detected mentions to zero.

4.2 Incorporating Context in Retrieval

To incorporate the sequential connections between questions in the retrieval phase, we append the previously asked questions to the current question. We also compare appending the predicted answers (top-1 span) to each of the previous questions as well as the gold answers to the current question.

4.3 Incorporating Context in Reader

In addition to encoding which entities have appeared in previous questions, we also want to provide our models with *relationship* information. However, pre-defined relationships from knowledge bases tend to be brittle. Instead, we use a continuous representation of relationships (Iyyer et al., 2016). For example, suppose we want to encode the relationships for an entity (answer candidate) that starts at i and ends at j. We summarize that entities relationships from each of possible k relation-spans. A relation-span is a sequence of tokens from Wikipedia that contains both the answer candidate and an answer to a previous question (For example, the correct answer in Figure 2 has a relation-span *"He is best known for defending President Ronald Reagan during the assassination attempt by John Hinckley Jr."* with the previous answer *"Ronald Reagan"*). This is summarized in a vector $\mathbf{r}_{ij}$ by merging all k relation-spans in a single span that is then fed through a BiLSTM whose hidden states are combined as a weighted sum where the weights are computed with self-attention (Lin et al., 2017).

The stronger the similarity between the relation that the question is asking about and the relation-spans, the higher the score of the candidate answer should be. We estimate that similarity r by concatenating the elementwise absolute difference and hadamard product between $\mathbf{r}_{ij}$ and the question embedding $\mathbf{q}$. Then, we use a trainable weight vector $\mathbf{w_{rel}}$ to combine the components of the concatenation output and produce a single similarity score as

$$r = \mathbf{w_{rel}}^T [|\mathbf{q} - \mathbf{r_{ij}}|; \mathbf{q} \circ \mathbf{r_{ij}}].$$

This can then influence the final selection of the answer span by adding the relation similarity

Table 2: Incorporating sequence information in the retrieval and the reading step slightly improves overall accuracy compared to answering questions in isolation.

score r to the start and end scores of the candidate answer (Equation 1) as

$$\begin{aligned} Start(i) &= \exp(\mathbf{t_i}^T W_{start}\mathbf{q} + r) \\ End(j) &= \exp(\mathbf{t_j}^T W_{end}\mathbf{q} + r). \end{aligned} \qquad (2)$$

The relation embedding module is trained jointly with the reader.

5 Baseline Results

We use QBLink to compare the baselines' question answering accuracy. Incorporating previous questions and answers slightly improves the accuracy (Table 2).

We set the maximum number of retrieved documents to ten, and each document is divided into paragraphs each of 400 tokens. At test time, we merge the top ten ranked such paragraphs and feed them to the reader. We use the reader network of Chen et al. (2017). We limit the number of relation description spans for each entity pair to five. We used an LSTM of one hidden layer and 128 hidden units for the paragraph, question, and relation description encoders. Each reader was trained for twenty epochs.

Table 2 summarizes the results of the baselines (Section 4). Question-answering accuracy is exact-match accuracy since we limit the answer spans to entity mentions whose boundaries are fixed for all models.

Question: This man attempted to impress Jodie Foster by shooting Ronald Reagan, but he failed to kill the President. At trial, he was found not guilty by reason of insanity.
Gold answer to previous question: Ronald Reagan
Predict without relation span: George H. W. Bush
Correct answer: John Hinckley Jr.
Relation span: He is best known for defending President Ronald Reagan during the assassination attempt by John Hinckley Jr.

Figure 2: Modeling the relation between *President Ronald Reagan* and *John Hinckley Jr.* expressed by relation span helps the reader select the correct answer entity.

Incorporating the previous answer in the retrieval and the reading components slightly improves the overall question answering accuracy (Table 2). The accuracy drops by more than 3% when using the entire text of previous questions in the retrieval phase. Modeling relations reduces the accuracy slightly compared to augmenting paragraphs with relation spans. One possible explanation is that our relation embedding model ends up being under-trained since we could not retrieve any relation-spans for many questions. Replacing Wikipedia with a larger corpus (e.g., ClueWeb) might help improve the training of the relation embedding model. Unsurprisingly, the gold answers to previous questions are more useful than the predicted answers, which highlights a need for models that take into account the uncertainty about previous answers when gold previous answers are not available. However, providing answers to previous questions is consistent for most Quiz Bowl tournament play.

Figure 2 gives an example of how explicit relation embedding helps reader get a correct prediction. Without the relation span, the model predicts George H. W. Bush (vice president at that time) as correct answer. Including the direct relation span between Reagan and John Hinckley Jr., the model gets the correct answer.

6 Related Work and Discussion

We adopt the open-domain question answering framework (Wang et al., 2018; Chen et al., 2017). Previous work considers improving that base framework itself (Clark and Gardner, 2018; Swayamdipta et al., 2018, inter alia). But retains the assumption of answering individual questions.

Aside from the open-domain setup, much of the recent work on question answering has focused on the sub-problem of reading-comprehension, where the gold answer to each question is assumed to exist in a given single paragraph for the model to read (Hermann et al., 2015; Rajpurkar et al., 2016; Seo et al., 2017). Another line of work on question answering is question answering over structured knowledge-bases (Berant et al., 2013; Berant and Liang, 2014; Yao and Van Durme, 2014; Gardner and Krishnamurthy, 2017). Although we focus on the more general open-domain setup, QBLink can be adapted to be usable in the reading-comprehension setup as well as the question answering over knowledge-bases setup.

Several question answering datasets have been proposed (Berant et al., 2013; Joshi et al., 2017; Trischler et al., 2017; Rajpurkar et al., 2018, inter alia). However, all of them were limited to answering individual questions.

Saha et al. (2018) study the problem of sequential question answering, and introduce a dataset for the task. However, we differ from them in two aspects: 1) They consider question-answering over structured knowledge-bases. 2) Their dataset construction was overly synthetic: templates were collected by human annotators given knowledge-base predicates. Further, sequences were constructed synthetically as well by grouping individual questions by predicate or subjects.

Both Iyyer et al. (2017) and Talmor and Berant (2018) answer complex questions by decomposing each into a sequence of simple questions. Iyyer et al. (2017) adopt a semantic parsing approach to answer questions over semi-structured tables. They construct a dataset of around 6,000 question sequences by asking humans to rewrite a set of 2,000 complex questions into simple sequences. Talmor and Berant (2018) consider the setup of open-domain question answering over unstructured text, but their dataset is constructed synthetically (with human paraphrasing) by combining simple questions with a few rules.

In parallel to our work, Choi et al. (2018) and Reddy et al. (2018) introduce sequential question answering datasets (QuAC and CoQA) that focus on the reading comprehension setup (i.e., a single text snippet is pre-specified for answering the given questions). QBLink is entirely naturally occurring (all questions and answers were authored independently from any knowledge sources) and is primarily designed to challenge human players.

The idea of our baseline to improving the reading step by incorporating additional relation description spans is similar as Weissenborn et al. (2017) and Mihaylov and Frank (2018), who integrate background commonsense knowledge into reading-comprehension systems. Both rely on structured knowledge bases to extract information about semantic relations that hold between entities. On the other hand, we extract text spans that mention each pair of entities and encoded them into vector representations of the relations between entities.

7 Conclusions and Future Work

We introduce QBLink, a dataset of 56,000 naturally occurring sequential question, answer pairs. The questions are designed primarily to challenge human players in Quiz Bowl tournaments. We use QBLink to evaluate baselines for sequential open-domain question answering. We show that incorporating sequential information helps slightly improve question answering accuracy.

In the future, we would like to invest in building better sequential question answering models that push the accuracy beyond the presented baselines. Specifically, we will look at how to better model the interaction between the reader and the relation embedding model and how to improve the relation embedding model itself by adopting ideas from the relation extraction literature (Miwa and Bansal, 2016; Peng et al., 2017; Ammar et al., 2017).

Abstract

Recently, string kernels have obtained state-of-the-art results in various text classification tasks such as Arabic dialect identification or native language identification. In this paper, we apply two simple yet effective transductive learning approaches to further improve the results of string kernels. The first approach is based on interpreting the pairwise string kernel similarities between samples in the training set and samples in the test set as features. Our second approach is a simple self-training method based on two learning iterations. In the first iteration, a classifier is trained on the training set and tested on the test set, as usual. In the second iteration, a number of test samples (to which the classifier associated higher confidence scores) are added to the training set for another round of training. However, the ground-truth labels of the added test samples are not necessary. Instead, we use the labels predicted by the classifier in the first training iteration. By adapting string kernels to the test set, we report significantly better accuracy rates in English polarity classification and Arabic dialect identification.

1 Introduction

In recent years, methods based on string kernels have demonstrated remarkable performance in various text classification tasks ranging from authorship identification (Popescu and Grozea, 2012) and sentiment analysis (Giménez-Pérez et al., 2017; Popescu et al., 2017) to native language identification (Popescu and Ionescu, 2013; Ionescu et al., 2014, 2016; Ionescu and Popescu, 2017), dialect identification (Ionescu and Popescu, 2016b; Ionescu and Butnaru, 2017; Butnaru and Ionescu, 2018) and automatic essay scoring (Cozma et al., 2018). As long as a labeled training set is available, string kernels can reach state-of-the-art results in various languages including English (Ionescu et al., 2014; Giménez-Pérez et al., 2017; Cozma et al., 2018), Arabic (Ionescu, 2015; Ionescu et al., 2016; Ionescu and Butnaru, 2017; Butnaru and Ionescu, 2018), Chinese (Popescu et al., 2017) and Norwegian (Ionescu et al., 2016). Different from all these recent approaches, we use unlabeled data from the test set to significantly increase the performance of string kernels. More precisely, we propose two transductive learning approaches combined into a unified framework. We show that the proposed framework improves the results of string kernels in two different tasks (cross-domain sentiment classification and Arabic dialect identification) and two different languages (English and Arabic). To the best of our knowledge, transductive learning frameworks based on string kernels have not been studied in previous works.

2 Transductive String Kernels

String kernels. Kernel functions (Shawe-Taylor and Cristianini, 2004) capture the intuitive notion of similarity between objects in a specific domain. For example, in text mining, string kernels can be used to measure the pairwise similarity between text samples, simply based on character n-grams. Various string kernel functions have been proposed to date (Lodhi et al., 2002; Shawe-Taylor and Cristianini, 2004; Ionescu et al., 2014). Perhaps one of the most recently introduced string kernels is the histogram intersection string kernel (Ionescu et al., 2014). For two strings over an alphabet Σ, $x, y \in \Sigma^*$, the intersection string kernel is formally defined as follows:

$$k^{\cap}(x,y) = \sum_{v \in \Sigma^p} \min\{\text{num}_v(x), \text{num}_v(y)\}, \quad (1)$$

where $\text{num}_v(x)$ is the number of occurrences of n-gram v as a substring in x, and p is the length of v. The spectrum string kernel or the presence bits string kernel can be defined in a similar fashion

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1084–1090
Brussels, Belgium, October 31 - November 4, 2018.

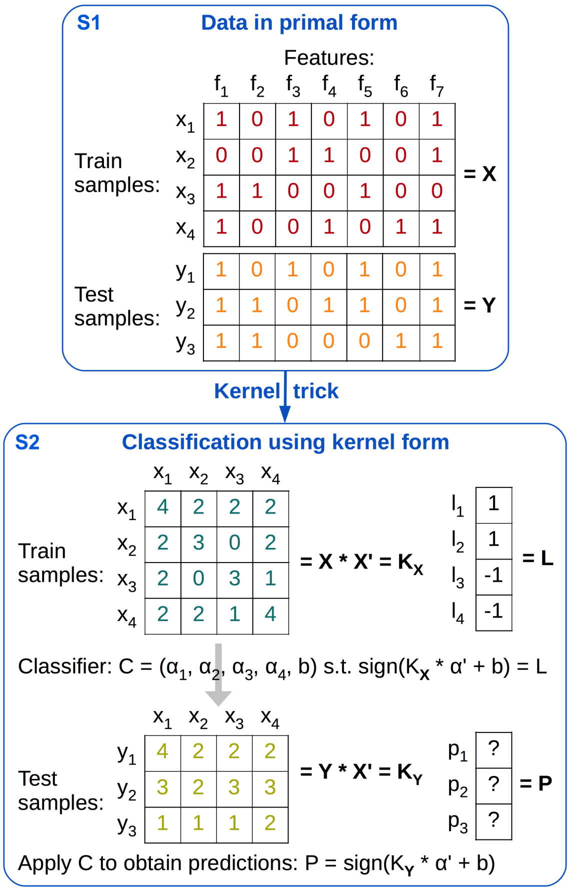

Figure 1: The standard kernel learning pipeline based on the linear kernel. Kernel normalization is not illustrated for simplicity. Best viewed in color.

(Ionescu et al., 2014). The standard kernel learning pipeline is presented in Figure 1. String kernels help to efficiently (Popescu et al., 2017) compute the dual representation directly, thus skipping the first step in the pipeline illustrated in Figure 1.

Transductive string kernels. We propose a simple and straightforward approach to produce a transductive similarity measure suitable for strings, as illustrated in Figure 2. We take the following steps to derive transductive string kernels. For a given kernel (similarity) function k, we first build the full kernel matrix K, by including the pairwise similarities of samples from both the train and the test sets (step $S1$ in Figure 2) . For a training set $X = \{x_1, x_2, ..., x_m\}$ of m samples and a test set $Y = \{y_1, y_2, ..., y_n\}$ of n samples, such that $X \cap Y = \emptyset$, each component in the full kernel matrix is defined as follows (step $S2$ in Figure 2):

$$K_{ij} = k(z_i, z_j), \tag{2}$$

where z_i and z_j are samples from the set $Z = X \cup Y = \{x_1, x_2, ..., x_m, y_1, y_2, ..., y_n\}$, for all $1 \le i, j \le m + n$. We then normalize the kernel matrix by dividing each component by the square

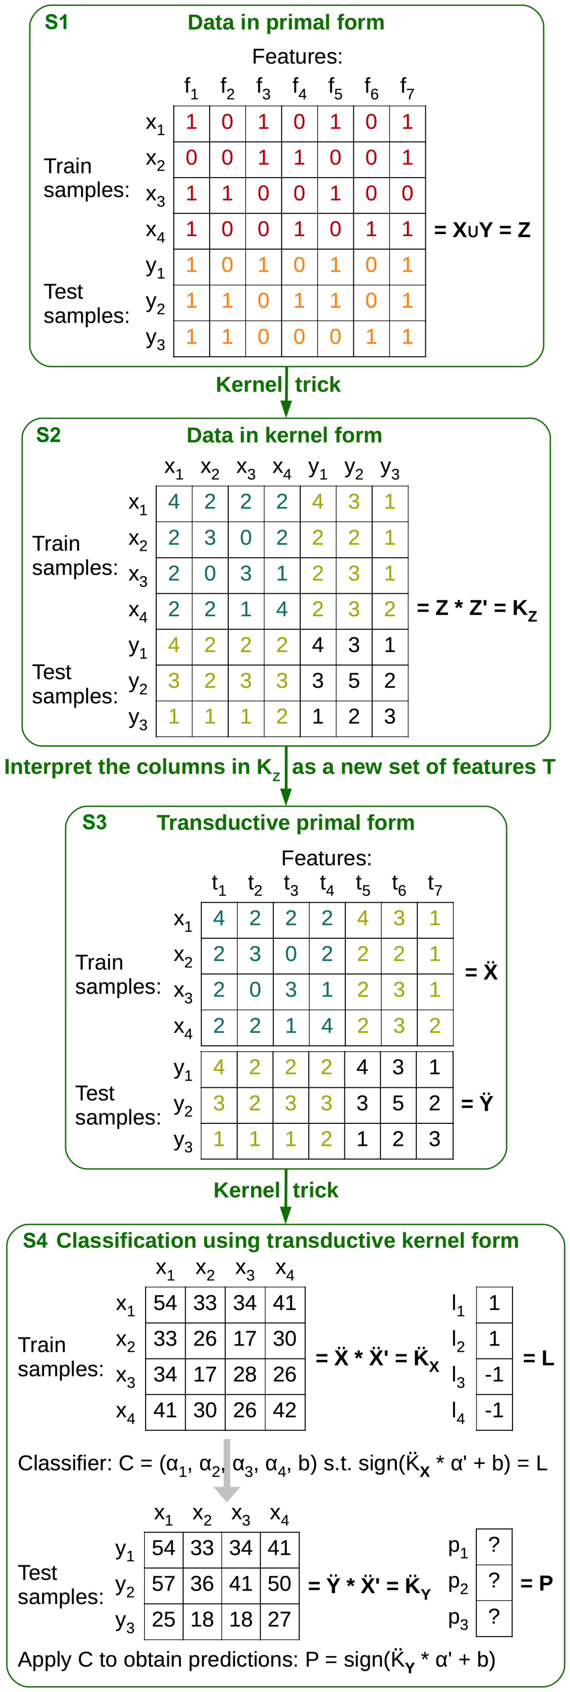

Figure 2: The transductive kernel learning pipeline based on the linear kernel. Kernel normalization and RBF kernel transformation are not illustrated for simplicity. Best viewed in color.

root of the product of the two corresponding diagonal components:

$$\hat{K}_{ij} = \frac{K_{ij}}{\sqrt{K_{ii} \cdot K_{jj}}}. \quad (3)$$

We transform the normalized kernel matrix into a radial basis function (RBF) kernel matrix as follows:

$$\tilde{K}_{ij} = exp\left(-\frac{1 - \hat{K}_{ij}}{2\sigma^2}\right). \quad (4)$$

As the kernel matrix is already normalized, we can choose $\sigma^2 = 0.5$ for simplicity. Therefore, Equation (4) becomes:

$$\tilde{K}_{ij} = exp\left(-1 + \hat{K}_{ij}\right). \quad (5)$$

Each row in the RBF kernel matrix $\tilde{K}$ is now interpreted as a feature vector, going from step $S2$ to step $S3$ in Figure 2. In other words, each sample z_i is represented by a feature vector that contains the similarity between the respective sample z_i and all the samples in Z (step $S3$ in Figure 2). Since Z includes the test samples as well, the feature vector is inherently adapted to the test set. Indeed, it is easy to see that the features will be different if we choose to apply the string kernel approach on a set of test samples Y', such that $Y' \neq Y$. It is important to note that through the features, the subsequent classifier will have some information about the test samples at training time. More specifically, the feature vector conveys information about how similar is every test sample to every training sample. We next consider the linear kernel, which is given by the scalar product between the new feature vectors. To obtain the final linear kernel matrix, we simply need to compute the product between the RBF kernel matrix and its transpose (step $S4$ in Figure 2):

$$\ddot{K} = \tilde{K} \cdot \tilde{K}'. \quad (6)$$

In this way, the samples from the test set, which are included in Z, are used to obtain new (transductive) string kernels that are adapted to the test set at hand.

Transductive kernel classifier. After obtaining the transductive string kernels, we use a simple transductive learning approach that falls in the category of self-training methods (McClosky et al., 2006; Chen et al., 2011). The transductive approach is divided into two learning iterations. In the first iteration, a kernel classifier is trained on the training data and applied on the test data, just as usual. Next, the test samples are sorted by the classifier's confidence score to maximize the probability of correctly predicted labels in the top of the sorted list. In the second iteration, a fixed number of samples (1000 in the experiments) from the top of the list are added to the training set for another round of training. Even though a small percent (less than 8% in all experiments) of the predicted labels corresponding to the newly included samples are wrong, the classifier has the chance to learn some useful patterns (from the correctly predicted labels) only visible in the test data. The transductive kernel classifier (TKC) is based on the intuition that the added test samples bring more useful information than noise, since the majority of added test samples have correct labels. Finally, we would like to stress out that *the ground-truth test labels are never used in our transductive algorithm.*

The proposed transductive learning approaches are used together in a unified framework. As any other transductive learning method, the main disadvantage of the proposed framework is that the *unlabeled* test samples from the target domain need to be used in the training stage. Nevertheless, we present empirical results indicating that our approach can obtain *significantly better* accuracy rates in cross-domain polarity classification and Arabic dialect identification compared to state-of-the-art methods based on string kernels (Giménez-Pérez et al., 2017; Ionescu and Butnaru, 2017). We also report better results than other domain adaptation methods (Pan et al., 2010; Bollegala et al., 2013; Franco-Salvador et al., 2015; Sun et al., 2016; Huang et al., 2017).

3 Polarity Classification

Data set. For the cross-domain polarity classification experiments, we use the second version of Multi-Domain Sentiment Dataset (Blitzer et al., 2007). The data set contains Amazon product reviews of four different domains: Books (B), DVDs (D), Electronics (E) and Kitchen appliances (K). Reviews contain star ratings (from 1 to 5) which are converted into binary labels as follows: reviews rated with more than 3 stars are labeled as positive, and those with less than 3 stars as negative. In each domain, there are 1000 positive and 1000 negative reviews.

Baselines. We compare our approach with several methods (Pan et al., 2010; Bollegala et al., 2013; Franco-Salvador et al., 2015; Sun et al., 2016; Giménez-Pérez et al., 2017; Huang et al.,

Method	DEK→B	BEK→D	BDK→E	BDE→K

$\ddot{K}_{\cap}$ + TKC	83.8*	83.5*	85.0*	**87.1***

Table 1: Multi-source cross-domain polarity classification accuracy rates (in %) of our transductive approaches versus a state-of-the-art (sota) baseline based on string kernels (Giménez-Pérez et al., 2017), as well as SST (Bollegala et al., 2013) and KE-Meta (Franco-Salvador et al., 2015). The best accuracy rates are highlighted in bold. The marker * indicates that the performance is significantly better than the best baseline string kernel according to a paired McNemar's test performed at a significance level of 0.01.

2017) in two cross-domain settings. Using string kernels, Giménez-Pérez et al. (2017) reported better performance than SST (Bollegala et al., 2013) and KE-Meta (Franco-Salvador et al., 2015) in the multi-source domain setting. In addition, we compare our approach with SFA (Pan et al., 2010), KMM (Huang et al., 2007), CORAL (Sun et al., 2016) and TR-TrAdaBoost (Huang et al., 2017) in the single-source setting.

Evaluation procedure and parameters. We follow the same evaluation methodology of Giménez-Pérez et al. (2017), to ensure a fair comparison. Furthermore, we use the same kernels, namely the presence bits string kernel ($K_{0/1}$) and the intersection string kernel ($K_{\cap}$), and the same range of character n-grams (5-8). To compute the string kernels, we used the open-source code provided by Ionescu and Popescu (2016a). For the transductive kernel classifier, we select $r = 1000$ unlabeled test samples to be included in the training set for the second round of training. We choose Kernel Ridge Regression (Shawe-Taylor and Cristianini, 2004) as classifier and set its regularization parameter to 10^{-5} in all our experiments. Although Giménez-Pérez et al. (2017) used a different classifier, namely Kernel Discriminant Analysis, we observed that Kernel Ridge Regression produces similar results ($\pm 0.1\%$) when we employ the same string kernels. As Giménez-Pérez et al. (2017), we evaluate our approach in two cross-domain settings. In the multi-source setting, we train the models on all domains, except the one used for testing. In the single-source setting, we train the models on one of the four domains and we independently test the models on the remaining three domains.

Results in multi-source setting. The results for the multi-source cross-domain polarity classification setting are presented in Table 1. Both the transductive presence bits string kernel ($\ddot{K}_{0/1}$) and the transductive intersection kernel ($\ddot{K}_{\cap}$) obtain better results than their original counterparts. Moreover, according to the McNemar's test (Dietterich, 1998), the results on the DVDs, the Electronics and the Kitchen target domains are significantly better than the best baseline string kernel, with a confidence level of 0.01. When we employ the transductive kernel classifier (TKC), we obtain even better results. On all domains, the accuracy rates yielded by the transductive classifier are more than 1.5% better than the best baseline. For example, on the Books domain the accuracy of the transductive classifier based on the presence bits kernel (84.1%) is 2.1% above the best baseline (82.0%) represented by the intersection string kernel. Remarkably, the improvements brought by our transductive string kernel approach are statistically significant in all domains.

Results in single-source setting. The results for the single-source cross-domain polarity classification setting are presented in Table 2. We considered all possible combinations of source and target domains in this experiment, and we improve the results in each and every case. Without exception, the accuracy rates reached by the transductive string kernels are significantly better than the best baseline string kernel (Giménez-Pérez et al., 2017), according to the McNemar's test performed at a confidence level of 0.01. The highest improvements (above 2.7%) are obtained when the source domain contains Books reviews and the target domain contains Kitchen reviews. As in the multi-source setting, we obtain much better results when the transductive classifier is employed for the learning task. In all cases, the accuracy rates of the transductive classifier are more than 2% better than the best baseline string kernel. Remarkably, in four cases (E→B, E→D, B→K and D→K) our improvements are greater than 4%. The improvements brought by our transductive classifier based on string kernels are statistically significant in each and every case. In comparison with SFA (Pan et al., 2010), we obtain better results in all but one case (K→D). With respect to KMM (Huang et al., 2007), we also obtain better results in all but one case (B→E). Remarkably, we surpass the

Table 3: Arabic dialect identification accuracy rates (in %) of our adapted string kernels versus the 2017 ADI Shared Task winner (sota) (Ionescu and Butnaru, 2017) and the first runner up (Malmasi and Zampieri, 2017). The best accuracy rates are highlighted in bold. The marker * indicates that the performance is significantly better than (Ionescu and Butnaru, 2017) according to a paired McNemar's test performed at a significance level of 0.01.

other state-of-the-art approaches (Sun et al., 2016; Huang et al., 2017) in all cases.

4 Arabic Dialect Identification

Data set. The Arabic Dialect Identification (ADI) data set (Ali et al., 2016) contains audio recordings and Automatic Speech Recognition (ASR) transcripts of Arabic speech collected from the Broadcast News domain. The classification task is to discriminate between Modern Standard Arabic and four Arabic dialects, namely Egyptian, Gulf, Levantine, and Maghrebi. The training set contains 14000 samples, the development set contains 1524 samples, and the test contains another 1492 samples. The data set was used in the ADI Shared Task of the 2017 VarDial Evaluation Campaign (Zampieri et al., 2017).

Baseline. We choose as baseline the approach of Ionescu and Butnaru (2017), which is based on string kernels and multiple kernel learning. The approach that we consider as baseline is the winner of the 2017 ADI Shared Task (Zampieri et al., 2017). In addition, we also compare with the second-best approach (Meta-classifier) (Malmasi and Zampieri, 2017).

Evaluation procedure and parameters. Ionescu and Butnaru (2017) combined four kernels into a sum, and used Kernel Ridge Regression for training. Three of the kernels are based on character n-grams extracted from ASR transcripts. These are the presence bits string kernel ($K_{0/1}$), the intersection string kernel ($K_{\cap}$), and a kernel based on Local Rank Distance (K_{LRD}) (Ionescu, 2013). The fourth kernel is an RBF kernel (K_{ivec}) based on the i-vectors provided with the ADI data set (Ali et al., 2016). In our experiments, we employ the exact same kernels as Ionescu and Butnaru (2017) to ensure an unbiased comparison with their approach. As in the polarity classification experiments, we select $r = 1000$ unlabeled test samples to be included in the training set for the second round of training the transductive classifier, and we use Kernel Ridge Regression with a regularization of 10^{-5} in all our ADI experiments.

Results. The results for the cross-domain Arabic dialect identification experiments on both the development and the test sets are presented in Table 3. The domain-adapted sum of kernels obtains improvements above 0.8% over the state-of-the-art sum of kernels (Ionescu and Butnaru, 2017). The improvement on the development set (from 64.17% to 65.42%) is statistically significant. Nevertheless, we obtain higher and significant improvements when we employ the transductive classifier. Our best accuracy is 66.73% (2.56% above the baseline) on the development set and 78.35% (2.08% above the baseline) on the test set. The results show that our domain adaptation framework based on string kernels attains the best performance on the ADI Shared Task data set, and the improvements over the state-of-the-art are statistically significant, according to the McNemar's test.

Abstract

We introduce a novel parameterized convolutional neural network for aspect level sentiment classification. Using parameterized filters and parameterized gates, we incorporate aspect information into convolutional neural networks (CNN). Experiments demonstrate that our parameterized filters and parameterized gates effectively capture the aspect-specific features, and our CNN-based models achieve excellent results on SemEval 2014 datasets.

1 Introduction

Continuous growing of user generated text in social media platforms such as Twitter drives sentiment classification increasingly popular. The goal of sentiment classification is to detect whether a piece of text expresses a positive, a negative, or a neutral sentiment (Rosenthal et al., 2017). The majority of the literature focuses on general sentiment analysis (document level), not involving a specific topic or entity. When there are multiple aspects about an entity in a sentence, it is hard to determine the sentiment as a whole.

Differing from general sentiment classification, aspect level sentiment classification identifies opinions from text about specific entities and their aspects (Pontiki et al., 2015). For example, given a sentence "great food but the service was dreadful", the sentiment polarity about aspect "food" is positive while the sentiment polarity about "service" is negative. If we ignore the aspect information, it is hard to determine the sentiment for a target aspect, which accounts for a large portion of sentiment classification error (Jiang et al., 2011).

Recently, machine learning based approaches are becoming popular for this task. Representative approaches in literature include Support Vector Machine (SVM) with manually created features (Jiang et al., 2011; Wagner et al., 2014) and neural network based models (Tang et al., 2016; Wang et al., 2016; Huang et al., 2018). Because of neural networks' capacity of learning representations from data without feature engineering, they are of growing interest for this natural language processing task. The mainstream neural methods are either based on long short-term memory (Hochreiter and Schmidhuber, 1997) or memory networks (Sukhbaatar et al., 2015). None of them are using convolutional neural networks (CNN), which are good at capturing local patterns.

In the present work, we propose two simple yet effective convolutional neural networks with aspect information incorporated. The overall architecture differs significantly from previous work. Specifically, we design two novel neural units that take target aspects into account. One is parameterized filter, the other is parameterized gate. These units both are generated from aspect-specific features and are further applied on the sentence. Our experiments show that our two model variants work surprisingly well on this type of task.

2 Related Work

Aspect level sentiment classification is a branch of sentiment classification (Pang et al., 2002; Wang and Manning, 2012). It aims at identifying the sentiment polarity of one aspect target in a context sentence.

One typical early work tries to identify the aspect level sentiment polarity based on predefined language rules (Nasukawa and Yi, 2003). Nasukawa and Yi first perform dependency parsing on sentences. Then rules are applied to determine the sentiment about aspects. Standard machine learning algorithms like SVM are also widely used on this task. Jiang et al. create several target-dependent features, then they feed these target-dependent features with content features into an

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1091–1096
Brussels, Belgium, October 31 - November 4, 2018.

SVM classifier.

In recent years, aspect level sentiment classification is dominated by neural network based approaches. The majority of published works rely on the architecture of long short-term memory (LSTM) (Tang et al., 2016). Wang et al. (2016) use an attention vector generated from aspect embedding to better capture the important parts in sentences. Tay et al. (2018) introduce a word-aspect fusion operation to learn associative relationships between aspects and sentences. Huang et al. (2018) use an attention-over-attention layer to further improve the performance.

Another type of neural architectures known as memory network (Sukhbaatar et al., 2015) has also been used in this task. Tang et al. (2016) takes an aspect term as a query sent to external memory. Their model consists of multiple computational layers. Each layer is an attention model. One recent work Dyadic MemNN (Tay et al., 2017) places associative layers on top of memory networks to improve the performance.

The overall architecture in this paper differs significantly with all these previous works. To the best of our knowledge, this paper is the first attempt using convolutional neural networks (Kim, 2014; Huang and Carley, 2017) for aspect level sentiment classification.

3 Parameterized Convolutional Neural Networks

In this section, we introduce our method for aspect level sentiment classification, which is based on convolutional neural networks. We first describe CNN for general sentiment classification, then we introduce our two model variants Parameterized Filters for Convolutional Neural Networks (PF-CNN) and Parameterized Gated Convolutional Neural Networks (PG-CNN).

3.1 Problem Definition

In aspect level sentiment classification, we are given a sentence $s = [w_1, w_2, ..., w_i, ..., w_n]$ and an aspect target $t = [w_i, w_{i+1}, ..., w_{i+m-1}]$. The goal is to classify whether the sentiment towards the aspect in the sentence is positive, negative, or neutral.

3.2 Convolutional Neural Networks

We first briefly describe convolutional neural networks (CNN) for general sentiment classification (Kim, 2014). Given a sentence $s = [w_1, w_2, ..., w_i, ..., w_n]$, let $v_i \in R^k$ be the word vector for word w_i. A sentence of length n can be represented as a matrix $\mathbf{s} = [v_1, v_2, ..., v_n] \in R^{n \times k}$. A convolution filter $w \in R^{h \times k}$ with width h is applied to the word matrix to get high-level representative features. Specifically, for a word window $v_{i:i+h-1} \in R^{h \times k}$, a feature c_i is generated by

$$c_i = f(w \odot v_{i:i+h-1} + b) \tag{1}$$

where $\odot$ represents element-wise product, $b \in R$ is a bias term and f is a non-linear function. Sliding the filter window from the beginning of the word matrix till the end, we get a feature map $\mathbf{c} \in R^{n-h+1}$.

$$\mathbf{c} = [c_1, c_2, ..., c_{n-h+1}] \tag{2}$$

After that, a pooling operation is applied over the feature map to get one single general sentiment feature θ_g in each map. We use max pooling in the CNN for sentences.

$$\theta_g = pooling(\mathbf{c}) \tag{3}$$

We denote this process as $\theta_g = CNN_g(\mathbf{s}; w, b)$. Using d such convolutional filters, we can get a general sentiment feature vector $\Theta_g \in R^d$ without information from aspect terms.

3.3 Parameterized Filters

Standard convolutional neural networks do not consider information from aspect terms. Herein, our first model variant overcomes this issue by parameterizing filters using aspect terms. We call it Parameterized Filters for Convolutional Neural Networks (PF-CNN). The overall architecture is shown in the left of Figure 1.

Formally, given the aspect term with length m, $t = [w_i, w_{i+1}, ..., w_{i+m-1}]$ and the corresponding embedding matrix $\mathbf{t} = [v_i, v_{i+1}, ..., v_{i+m-1}] \in R^{m \times k}$, we first use another CNN_t to extract one single feature θ_t from $\mathbf{t}$.

$$\theta_t = CNN_t(\mathbf{t}; w_t, b_t) \tag{4}$$

where $w_t \in R^{h_t \times k}$, b_t are the convolutional filter, bias term for CNN_t. h_t is the width of filters applied on aspect targets. With $h_s \times k$ such filters and bias terms, we can get a feature matrix $\Theta_t \in R^{h_s \times k}$, where h_s is the filter width applied on sentences. We use average pooling in the CNN_t for aspects.

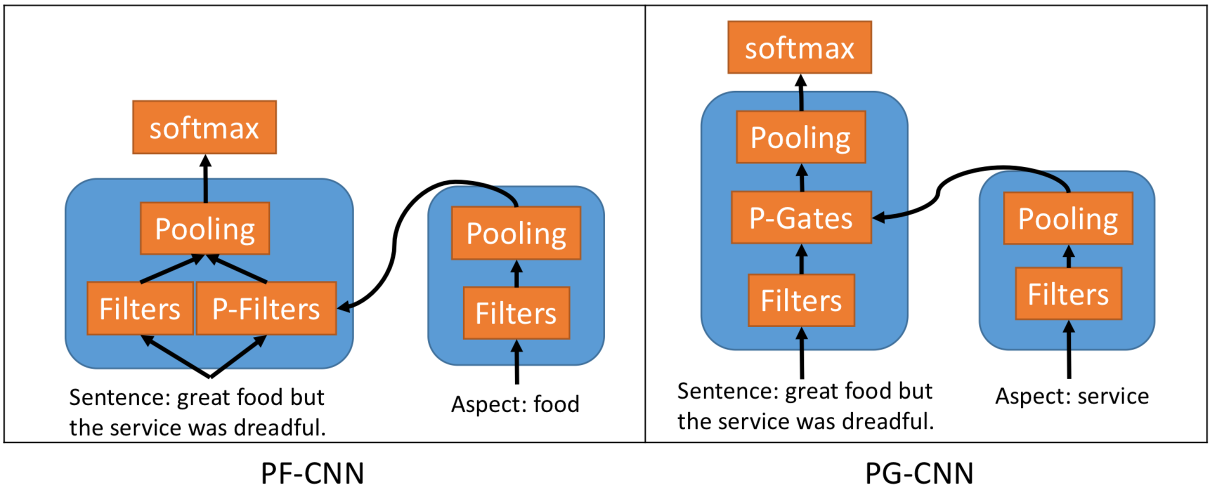

Figure 1: The overall architectures of PF-CNN and PG-CNN.

In the next step, Θ_t is further used as a convolutional filter applied on the sentence.

$$\theta_s = CNN_s(\mathbf{s}; \boldsymbol{\Theta}_t, b_s) \tag{5}$$

Using such d parameterized filters, we get the aspect-specific features $\Theta_s \in R^d$ with target term information. We further concatenate the targeted feature vector with general sentiment features as the final classification features $\Theta = [\Theta_g, \Theta_s]$.

3.4 Parameterized Gates

The second model variant we designed is called Parameterized Gated Convolutional Neural Networks (PG-CNN). The overall architecture is shown in the right of Figure 1.

Similar with PF-CNN, PG-CNN also utilizes a convolutional neural network to extract feature Θ_t from aspect terms, which instead is used as a gate (Dauphin et al., 2017) in the CNN applied on the sentence. The key step of PG-CNN is described in equation (6).

$$c_i = (w \odot v_{i:i+h-1} + b) \cdot \sigma(\Theta_t \odot v_{i:i+h-1} + b) \tag{6}$$

Instead of using a non-linear function f in equation (1), we use a gate $\sigma(\Theta_t \odot v_{i:i+h-1} + b)$ to control how much information passing to the next layer, where $\sigma(\cdot)$ is sigmoid function. For each general filter applied on the sentence, one parameterized gate is generated from the aspect.

After that, we generate the final classification feature Θ in the same way as standard CNN.

3.5 Final Classification

We feed the final classification feature into a linear layer to project Θ into the space of targeted classes:

$$x = W_l \cdot \Theta + b_l \tag{7}$$

where W_l and b_l are the weight matrix and bias. Following the linear layer, we use a softmax layer to compute the probability of class c.

$$P(y = c|x) = \frac{exp(x_c)}{\sum_{i \in C} exp(x_i)} \tag{8}$$

3.6 Model training

We train our model to minimize the cross-entropy loss function with L_2 regularization:

$$loss = -\sum_{(s,t)} \sum_{c \in C} I(y = c) log P(y = c|s, a) + \lambda ||p||^2$$

where $I(\cdot)$ is the indicator function and p is the set of all parameters in the convolutional layers and linear layer.

4 Experiments

4.1 Experiments Setting

Dataset

We adopt one widely used dataset from SemEval 2014 Task 4 (Pontiki et al., 2014). It contains two domain-specific datasets for laptops and restaurants. Each data point is a pair of a sentence and an aspect term. Experienced annotators tagged each pair with sentiment polarity. Following recent work (Tay et al., 2018), we take 500 training instances as development set[1]. Unfortunately, many works have not mentioned the usage of development set (Wang et al., 2016; Ma et al., 2017).

Hyperparameters and Training

We use rectifier as non-linear function f in the CNN_g, CNN_t and sigmoid in the CNN_s, filter window sizes of $1, 2, 3, 4$ with 100 feature maps

each, l_2 regularization term of 0.001 and mini-batch size of 25. Parameterized filters and gates have the same size and number as normal filters. They are generated uniformly by CNN with window sizes of $1, 2, 3, 4$, eg. among 100 parameterized filters with size 3, 25 of them are generated by aspect CNN with filter size 1, 2, 3, 4 respectively. The word embeddings are initialized with 300-dimensional Glove vectors (Pennington et al., 2014) and are fixed during training. For the out of vocabulary words we initialize them randomly from uniform distribution $U(-0.01, 0.01)$. We apply dropout on the final classification features of PG-CNN. The dropout rate is chosen as 0.3.

Training is done through mini-batch stochastic gradient descent with Adam update rule (Kingma and Ba, 2015). The initial learning rate is 0.001. If the training loss does not drop after every three epochs, we decrease the learning rate by half. We adopt early stopping based on the validation loss on development sets.

4.2 Results

We use accuracy metric to measure the performance. To show the effectiveness of our model, we compare it with several baseline methods. We list them as follows:

TD-LSTM uses two LSTM networks to model the preceding and following contexts surrounding the aspect term. The last hidden states of these two LSTM networks are concatenated for predicting the sentiment polarity (Tang et al., 2016).

AT-LSTM combines the sentence hidden states from a LSTM with the aspect term embedding to generate the attention vector. The final sentence representation is the weighted sum of the hidden states (Wang et al., 2016).

ATAE-LSTM further extends AT-LSTM by appending the aspect embedding into each word vector (Wang et al., 2016).

AF-LSTM introduces a word-aspect fusion attention to learn associative relationships between aspect and context words (Tay et al., 2018).

CNN uses the architecture proposed in (Kim, 2014) without explicitly considering aspect. We use filter window sizes of 1,2,3,4 with 100 maps each. Dropout rate is chosen as 0.5. Early stopping based on validation accuracy is applied.

Our two models achieve the best performance when compared to these baselines as shown in Table 2, which shows that our proposed neural units effectively captures the aspect-specific features. Compared to one recently proposed model AF-LSTM, our method achieve 2%-5% improvements. Surprisingly, a vanilla CNN works quite well on this problem. It even beats these well-designed LSTM models, which further proves that using CNN-based methods is a direction worth exploring.

4.3 Case Study & Discussion

Compared to a vanilla CNN, our two model variants could successfully distinguish the describing words for corresponding aspect targets. In the sentence “the appetizers are ok, but the service is slow”, a vanilla CNN outputs the same negative sentiment label for both aspect terms “appetizers” and “service”, while PF-CNN and PG-CNN successfully recognize that “slow” is only used for describing “service” and output neutral and negative labels for aspects “appetizers” and “service” respectively. In another example “the staff members are extremely friendly and even replaced my drink once when i dropped it outside”, our models also find out that positive and neutral sentiment for “staff” and “drink” respectively.

One thing we notice in our experiment is that a vanilla CNN ignoring aspects has comparable performance with some well-designed LSTM models in this aspect-level sentiment classification task.

For a sentence containing multiple aspects, we assume the majority of the aspect-level sentiment label is the sentence-level sentiment label. Using this labeling scheme, in the restaurant data, 1034 out of 1117 test points have the same sentence-level and aspect-level labels. Thus, a sentence-level classifier with accuracy 75% also classifies 70% aspect-labels correctly. A similar observation was made for the laptop dataset as well. Probably this is the reason why a vanilla CNN has comparable performance on these two datasets. For future research, a more balanced dataset would be helpful to overcome this issue.

5 Conclusion

We propose a novel method for aspect level sentiment classification. We introduce two novel neural units called parameterized filter and parameterized gate to incorporate aspect information into the convolutional neural network architecture. Comparisons with baseline methods show our model effectively learns the aspect-specific sentiment expressions. Our experiments demonstrate a significant improvement compared to multiple strong neural baselines.

To the best of our knowledge, our model is the first attempt using convolutional neural networks solving this problem. We hope this work could inspire future research exploring in this direction. It is also interesting to see whether such parameterized CNN architecture could benefit other natural language processing tasks involving text pairs like question answering task.

Abstract

In this paper, we target at improving the performance of multi-label emotion classification with the help of sentiment classification. Specifically, we propose a new transfer learning architecture to divide the sentence representation into two different feature spaces, which are expected to respectively capture the general sentiment words and the other important emotion-specific words via a dual attention mechanism. Extensive experimental results demonstrate that our transfer learning approach can outperform several strong baselines and achieve the state-of-the-art performance on two benchmark datasets.

1 Introduction

In recent years, the number of user-generated comments on social media platforms has grown exponentially. In particular, social platforms such as Twitter allow users to easily share their personal opinions, attitudes and emotions about any topic through short posts. Understanding people's emotions expressed in these short posts can facilitate many important downstream applications such as emotional chatbots (Zhou et al., 2018b), personalized recommendations, stock market prediction, policy studies, etc. Therefore, it is crucial to develop effective emotion detection models to automatically identify emotions from these online posts.

ID	**Tweet**	**Emotion**
T1	AI revolution, soon is possible #fearless #good #goodness	joy, optimism
T2	Shitty is the worst feeling ever #depressed #anxiety	fear, sadness
T3	I am back lol. #revenge	joy, anger

Table 1: Example Tweets from SemEval-18 Task 1.

In the literature, emotion detection is typically modeled as a supervised multi-label classification problem, because each sentence may contain one or more emotions from a standard emotion set containing *anger*, *anticipation*, *disgust*, *fear*, *joy*, *love*, *optimism*, *pessimism*, *sadness*, *surprise* and *trust*. Table 1 shows three example sentences along with their emotion labels. Traditional approaches to emotion detection include lexicon-based methods (Wang and Pal, 2015), graphical model-based methods (Li et al., 2015b) and linear classifier-based methods (Quan et al., 2015; Li et al., 2015a). Given the recent success of deep learning models, various neural network models and advanced attention mechanisms have been proposed for this task and have achieved highly competitive results on several benchmark datasets (Wang et al., 2016; Abdul-Mageed and Ungar, 2017; Felbo et al., 2017; Baziotis et al., 2018; He and Xia, 2018; Kim et al., 2018).

However, these deep models must overcome a heavy reliance on large amounts of annotated data in order to learn a robust feature representation for multi-label emotion classification. In reality, large-scale datasets are usually not readily available and costly to obtain, partly due to the ambiguity of many informal expressions in user-generated comments. Conversely, it is easier to find datasets (especially in English) associated with another closely related task: sentiment classification, which aims to classify the sentiment polarity of a given piece of text (i.e., positive, negative and neutral). We expect that these resources may allow us to improve sentiment-sensitive representations and thus more accurately identify emotions in social media posts. To achieve these goals, we propose an effective transfer learning (TL) approach in this paper.

Most existing TL methods either 1) assume that both the source and the target tasks share the same sentence representation (Mou et al., 2016) or 2) divide the representation of each sentence into a

a. Fully-Shared (FS) b. Private-Shared-Private (PSP) c. Shared-Private (SP) d. Dual Attention Transfer Network

Figure 1: Overview of Different Transfer Learning Models.

shared feature space and two task-specific feature spaces (Liu et al., 2017; Yu et al., 2018), as demonstrated by Fig 1.a and Fig 1.b. However, when applying these TL approaches to our scenario, the former approach may lead the learnt sentence representation to pay more attention to general sentiment words such as *good* but less attention to the other sentiment-ambiguous words like *shock* that are also integral to emotion classification. The latter approach can capture both the sentiment and the emotion-specific words. However, some sentiment words only occur in the source sentiment classification task. These words tend to receive more attention in the source-specific feature space but less attention in the shared feature space, so they will be ignored in our emotion classification task. Intuitively, any sentiment word also indicates emotion and should not be ignored by our emotion classification task.

Therefore, we propose a shared-private (SP) model as shown in Fig 1.c, where we employ a shared LSTM layer to extract shared sentiment features for both sentiment and emotion classification tasks, and a target-specific LSTM layer to extract specific emotion features that are only sensitive to our emotion classification task. However, as pointed out by Liu et al. (2017) and Yu et al. (2018), it is not guaranteed that such a simple model can well differentiate the two feature spaces to extract shared and target-specific features as we expect. Take the sentence **T1** in Table 1 as an example. Both the shared and task-specific layers could assign higher attention weights to *good* and *goodness* due to their high frequencies in the training data but lower attention weights to *fearless* due to its rare occurrences. In this case, this SP model can only predict the *joy* emotion but ignores the *optimism* emotion. Hence, to enforce the orthogonality of the two feature spaces, we further introduce a dual attention mechanism, which feeds the attention weights in one feature space as extra inputs to compute those in the other feature space, and explicitly minimizes the similarity between the two sets of attention weights. Experimental results show that our dual attention transfer architecture can bring consistent performance gains in comparison with several existing transfer learning approaches, achieving the state-of-the-art performance on two benchmark datasets.

2 Methodology

2.1 Base Model for Emotion Classification

Given an input sentence, the goal of emotion analysis is to identify one or multiple emotions contained in it. Formally, let $\mathbf{x} = (\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_n)$ be the input sentence with n words, where $\mathbf{w}_j$ is a d-dimensional word vector for word w_j in the vocabulary $\mathcal{V}$, and is retrieved from a lookup table $\mathbf{E} \in \mathbb{R}^{d \times |\mathcal{V}|}$. Moreover, let $\mathcal{E}$ be a set of pre-defined emotion labels. Accordingly, for each $\mathbf{x}$, our task is to predict whether it contains one or more emotions in $\mathcal{E}$. We denote the output as $\mathbf{e} \in \{0,1\}^K$ where $\mathbf{e}_k \in \{0,1\}$ denotes whether or not $\mathbf{x}$ contains the k-th emotion. We further assume that we have a set of labeled sentences, denoted by $D^{\mathrm{e}} = \{\mathbf{x}^{(i)}, \mathbf{e}^{(i)}\}_{i=1}^{N}$.

Sentence Representation: We use the standard bi-directional Long Short Term Memory (Bi-LSTM) network to sequentially process each word in the input:

$$\overrightarrow{\mathbf{h}_j} = \mathrm{LSTM}(\overrightarrow{\mathbf{h}_{j-1}}, \mathbf{x}_j, \Theta_f),$$
$$\overleftarrow{\mathbf{h}_j} = \mathrm{LSTM}(\overleftarrow{\mathbf{h}_{j+1}}, \mathbf{x}_j, \Theta_b),$$

where Θ_f and Θ_b denotes all the parameters in the forward and backward LSTM. Then, for each word $\mathbf{x}_j$, its hidden state $\mathbf{h}_j \in \mathbb{R}^d$ is generated by concatenating $\overrightarrow{\mathbf{h}_j}$ and $\overleftarrow{\mathbf{h}_j}$ as $\mathbf{h}_j = [\overrightarrow{\mathbf{h}_j}; \overleftarrow{\mathbf{h}_j}]$.

For emotion classification, since emotion words are relatively more important for final predictions, we adopt the widely used attention mechanism (Bahdanau et al., 2014) to select the key words for sentence representation. Specifically, we first take the final hidden state $\mathbf{h}_n$ as a sentence summary vector $\mathbf{z}$, and then obtain the attention weight α_i for each hidden state $\mathbf{h}_j$ as follows:

$$u_j = \mathbf{v}^\top \tanh(\mathbf{W}_h \mathbf{h}_j + \mathbf{W}_z \mathbf{z}), \tag{1}$$

$$\alpha_j = \frac{\exp(u_j)}{\sum_{l=1}^{n} \exp(u_l)}, \tag{2}$$

where $\mathbf{W}_h, \mathbf{W}_z \in \mathbb{R}^{a \times d}$ and $\mathbf{v} \in \mathbb{R}^{a}$ are learnable parameters. The final sentence representation $\mathbf{H}$ is computed as:

$$\mathbf{H} = \sum_{j=1}^{n} \alpha_j \mathbf{h}_j.$$

Output Layer: We first apply a Multilayer Perceptron (MLP) with one hidden layer on top of $\mathbf{H}$, followed by normalizing it to obtain the probability distribution over all of the emotion labels:

$$p(\mathbf{e}^{(i)} \mid \mathbf{H}) = \mathbf{o}^{(i)} = \mathrm{softmax}(\mathrm{MLP}(\mathbf{H})).$$

Then, we propose to minimize the KL divergence between our predicted probability distribution and the normalized ground truth distribution as our objective function:

$$\mathcal{L} = \frac{1}{N} \sum_{i=1}^{N} \sum_{k=1}^{K} \mathbf{e}_k^{(i)} \big(\log(\mathbf{e}_k^{(i)}) - \log(\mathbf{o}_k^{(i)}) \big).$$

During the test stage, we will select a threshold γ on the development set so that the emotion with scores higher than γ will be predicted as 1.

2.2 Transfer Learning Architecture

Due to the limited number of annotated data for multi-label emotion classification, here we resort to sentiment classification to consider a transfer learning scenario. Let $D^s = \{\mathbf{x}^{(m)}, y^{(m)}\}_{m=1}^{M}$ be another set of labeled sentences for sentiment classification, where $y^{(m)}$ is the ground-truth label indicating whether the m-th sentence is *positive*, *negative* or *neutral*.

2.2.1 Shared-Private (SP) Model

Intuitively, sentiment classification is a coarse-grained emotion analysis task, and can be fully leveraged to learn a more robust sentiment-sensitive representation. Therefore, we first use a shared attention-based Bi-LSTM layer to transform the input sentences in both tasks into a shared hidden representation $\mathbf{H_c}$, and also employ another task-specific Bi-LSTM layer to get the target-specific hidden representation $\mathbf{H_t}$. Next, we employ the following operations to map the hidden representations to the sentiment label y and the emotion label $\mathbf{e}$:

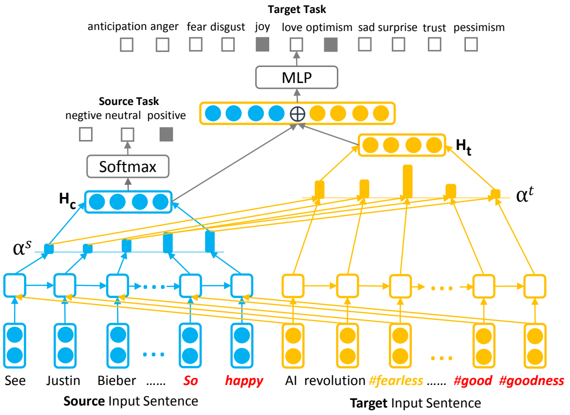

Figure 2: Dual Attention Transfer Network.

$$p(y^{(m)} | \mathbf{H_c}) = \mathrm{softmax}\big(\mathbf{W}^s \mathbf{H_c} + \mathbf{b}^s\big),$$
$$p(\mathbf{e}^{(i)} | \mathbf{H_c}, \mathbf{H_t}) = \mathrm{softmax}\big(\mathrm{MLP}([\mathbf{H_c}; \mathbf{H_t}])\big),$$

where $\mathbf{W}^s \in \mathbb{R}^{d \times 3}$ and $\mathbf{b}^s \in \mathbb{R}^3$ are the parameters for the source sentiment classification task.

2.2.2 Proposed Dual Attention Transfer Network (DATN)

As we introduced before, the shared and target-specific feature spaces in the above SP model are expected to respectively capture the general sentiment words and the task-specific emotion words. However, without any constraints, the two feature spaces may both tend to pay more attention to frequently occurring and important sentiment words like *great* and *happy*, but less to those rarely occurring but crucial emotion words like *anxiety* and *panic*. Therefore, to encourage the two feature spaces to focus on sentiment words and emotion-specific words respectively, we propose using the attention weights computed from the shared layer as extra inputs to compute the attention weights of the target-specific layer. Specifically, as shown in Fig. 2, we first use Eq.1 and Eq.2 to compute the attention weights α^s in the shared layer, and then use the following equation to obtain the attention weights α^t in the target specific layer:

$$u_j^t = \mathbf{v}^{t\top} \tanh(\mathbf{W}_h^t \mathbf{h}_j^t + w_\alpha \alpha_j^s + \mathbf{W}_z^t \mathbf{z}^t),$$
$$\alpha_j^t = \frac{\exp(u_j^t)}{\sum_{l=1}^n \exp(u_l^t)}.$$

In addition, we introduce another similarity loss to explicitly enforce the difference between the two attention weights and minimize the cosine similarity between α^s and α^t.

Finally, our combined objective function is defined as follows:

$$\mathcal{J} = -\frac{1}{M}\sum_{m=1}^{M} \log p(y_m|\mathbf{H_c}) + \mathcal{L}$$
$$+ \lambda \sum_{i=1}^{N} \text{cos\_sim}(\alpha_i^s, \alpha_i^t),$$

where λ is a hyperparameter used to control the effect of the similarity loss.

2.2.3 Model Details

During the training stage, we adopted the widely used alternating optimization strategy, which iteratively samples one mini-batch from D^{s} for only updating the parameters in the left part of our model, followed by sampling another mini-batch from D^{e} for updating all the parameters in our model. It is also worth noting that in Fig. 2, we first obtain the shared attention weights α^s and feed it as extra inputs to compute α^t. In fact, to differentiate the attention weights in the two feature spaces, we can also first compute α^t, followed by computing α^s based on α^t. We refer to these two variants of our model as DATN-1 and DATN-2 respectively.

3 Experiments

3.1 Experiment Settings

Datasets: We conduct experiments on both English and Chinese languages.

For **English**, we employ a widely used Twitter dataset from SemEval 2016 Task 4A (Nakov et al., 2016) as our source sentiment classification task. For our target emotion classification task, we use the Twitter dataset recently released by SemEval 2018 Task 1C (Mohammad et al., 2018), which contains 11 emotions as shown in the top of Fig. 2. To tokenize the tweets in our dataset, we follow (Owoputi et al., 2013) by adopting most of their preprocessing rules except that we split the hashtag into '#' and its subsequent word.

	Dataset	Train	Dev	Test	Words
E1	SemEval-18	6,838	886	3,259	32,557
S1	SemEval-16	28,631	-	-	40439
E2	Ren-CECps-1	13,841	1,972	3,602	40,099
S2	Ren-CECps-2	15,199	-	-	

Table 2: The number of sentences in each dataset.

For **Chinese**, we use a well known Chinese blog dataset Ren-CECps from (Quan and Ren, 2010), which contains 1487 documents with each sentence labeled by a sentiment label and 8 emotion labels: *anger*, *expectation*, *anxiety*, *joy*, *love*, *hate*, *sorrow* and *surprise*. Given the difficulty of finding a large-scale sentiment classification dataset specific to Chinese blogs, we simply divided the original dataset to form our source and target tasks[1]. The basic statistics of our two datasets are summarized in Table 2.

Parameter Settings: The word embedding size d is set to be 300 for E1 and 200 for E2, and the lookup table $\mathbf{E}$ is initialized by pre-trained word embeddings based on Glove[2]. The hidden dimension and the number of LSTM layers in both datasets are set to be 200 and 1. During training, Adam (Kingma and Ba, 2014) is used to schedule the learning rate, where the initial learning rate is set to be 0.001. Also, the dropout rate is set to 0.5. After tuning, λ is set as 0.05 for both datasets, and γ is set as 0.12 for E1 and 0.2 for E2. All the models are implemented with Tensorflow.

Evaluation Metrics: We take the official code from SemEval-18 Task 1C and use accuracy and Macro F1 score as main metrics. For E2, we follow (Zhou et al., 2018a) to use average precision (AP) and one error (OE) as secondary metrics.

3.2 Results

To better evaluate our proposed methods, we employed the following systems for comparison: 1) *Base*, training our base model in Section 2.1 only on D^{e}; 2) *FT* (Fine-Tuning), using D^{s} to pre-train the whole model, followed by using D^{e} to Fine Tune the model parameters; 3) *FS*, the Fully-Shared framework by (Mou et al., 2016) as shown in Fig 1.a; 4) *PSP* and *APSP*, the Private-Shared-Private framework and its extension with Adver-

Table 3: The results of different transfer learning methods by averaging ten runs (top) and the comparison between our best model and the state-of-the-art systems (bottom). DATN-2* indicates the ensemble results of ten runs. Base† and DATN-2† denotes the average results of conducting ten-fold cross validation on the whole dataset for fair comparison, and here for the source and target tasks in DATN-2†, we use the same training data. For E1, Rank1 and Rank2 are the top two systems from the official leadboard; For E2, Rank1 and Rank2 are from (Zhou et al., 2016, 2018a).

sarial losses by (Liu et al., 2017) as shown in Fig 1.b; 5) *SP*, *DATN-1* and *DATN-2*, the Shared-Private model and two variants of our Dual Attention Transfer Network as shown in Fig 1.c and Fig 1.d.

In Table 3, we report the comparison results between our method and the baseline systems. It can be easily observed that 1) for transfer learning, although the performance of *SP* is similar to or even lower than some baseline systems, our proposed dual attention models, i.e., *DATN-1* and *DATN-2*, can generally boost *SP* to achieve the best results. To investigate the significance of the improvements, we combine each model's predictions of all emotion labels followed by treating them as a single label, and then perform McNemar's significance tests (Gillick and Cox, 1989). Finally, we verify that for English, *DATN-1* is significantly better than *Base*, *FT*, *FS* and *SP*, while *DATN-2* is significant better than all the methods except *APSP*; for Chinese, *DATN-1* and *DATN-2* are significantly better than all the compared methods. 2) Even compared with the state-of-the-art systems in E1 which also employ other external resources, including the affective embedding, emotion lexicon and sentiment classification datasets (Baziotis et al., 2018), the ensemble results of *DATN-2* can achieve slightly better performance; in addition, it is clear that our model can obtain the best performance in E2.

Furthermore, to obtain a better understanding of the advantage of our method, we choose one sentence from the test set of E1, and visualize the attention weights obtained by *Base* and *DATN-2* in Fig 3. We can see that *Base* pays more attention to those frequent emotion words while ignoring the less frequent but important emoji, and thus fails to predict the *love* emotion implied by the emoji. In contrast, with the proposed dual attention mechanism, *DATN-2* makes correct predictions since it can respectively capture the general sentiment words and the emotion-specific emojis.

4 Conclusion

In this paper, we proposed a dual attention-based transfer learning approach to leverage sentiment classification to improve the performance of multi-label emotion classification. Using two benchmark datasets, we show the effectiveness of the proposed transfer learning method.

Learning Sentiment Memories for Sentiment Modification without Parallel Data

Yi Zhang, Jingjing Xu, Pengcheng Yang, Xu Sun
MOE Key Lab of Computational Linguistics, School of EECS, Peking University
`{zhangyi16,jingjingxu,yang_pc,xusun}@pku.edu.cn`

Abstract

The task of sentiment modification requires reversing the sentiment of the input and preserving the sentiment-independent content. However, aligned sentences with the same content but different sentiments are usually unavailable. Due to the lack of such parallel data, it is hard to extract sentiment independent content and reverse the sentiment in an unsupervised way. Previous work usually can not reconcile sentiment transformation and content preservation. In this paper, motivated by the fact the non-emotional context (e.g., "staff") provides strong cues for the occurrence of emotional words (e.g., "friendly"), we propose a novel method that automatically extracts appropriate sentiment information from the learned sentiment memories according to the specific context. Experiments show that our method substantially improves the content preservation degree and achieves the state-of-the-art performance. [1]

1 Introduction

Sentiment modification of natural language texts is a special task that connects sentiment analysis and natural language generation. It facilitates many NLP applications, such as news rewriting and automatic conversion of review attitude, which reduce the human effort. Sentiment modification presents two requirements: one is that the sentiment or the attitude of the text needs to be transformed to the opposite; the other is that the transformed text should maintain semantic relevance to the input text as much as possible.

Recently, there have been some researches which focus on the work of editing a sentence to alter specific attributes, like style and sentiment (Shen et al., 2017; Hu et al., 2017). Typically, the parallel data with the same content but different sentiment is not available. This line of work attempts to extract the attribute-independent content from a dense sentence representation by adversarial learning. However, it is hard to extract the attribute-independent content in such implicit ways, which makes these methods tend to generate input-irrelevant texts.

Most existing methods can not reconcile the performance of sentiment transformation and content preservation. Direct replacement of emotional words can keep the context but may lead to low-quality sentences. For example, given an input "*The food is cold like rock*", this method probably outputs "*The food is warm like rock*". State-of-the-art models using neural networks struggle to generate high-quality sentences. However, these models usually lead to poor content preservation. For instance, when the source text is "*This is a wonderful movie*", we expect an output like "*This movie is disappointing*". However, the generated sentence may be "*The waiters are very rude*", which has little relevance to the source text. In general, it is difficult to preserve semantic content and reverse the sentiment at the same time without parallel data.

To address this problem, we propose a novel model which performs well in both sentiment transformation and content preservation. Our model first learns two kinds of sentiment memories by explicitly separating emotional words. Then, according to the specific context, the model extracts appropriate sentiment information from the memory of target sentiment. The decoder takes the extracted memory and the context representation together to perform decoding. The overview of our model is shown in Figure 1. The main architecture of our model is a **S**entiment-**M**emory based **A**uto-**E**ncoder (**SMAE**). The proposed model achieves the state-of-the-art perfor-

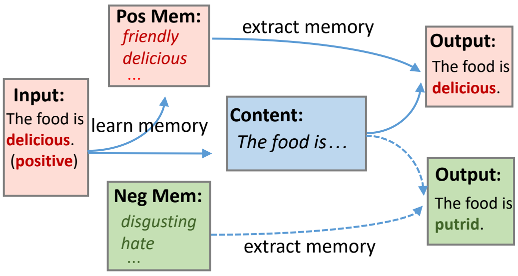

Figure 1: Illustration of the proposed model with a positive input. Solid and dashed lines indicate the training process and the testing process, respectively. The process with a negative input is in a similar way.

mance, especially improves content preservation degree by a large margin.

Our contributions are concluded as follows:

- We propose a method that uses sentiment memories to accomplish sentiment modification without any help of the parallel data.
- The proposed method improves the content preservation degree by a large margin when compared with current systems.

2 Related Work

Recently, there has been some studies for sentiment modification. Shen et al. (2017) learn an encoder that maps a sentence with its original style to a style-independent content representation. This is then passed to a style-dependent decoder for rendering. Fu et al. (2017) implement a multi-decoder auto-encoder (Bengio et al., 2009; Dai and Le, 2015) where the encoder is used to capture the content and the sentiment-specific decoders are used to generate target sentence. Hu et al. (2017) augment the unstructured variables z in vanilla VAE with a set of structured variables c each of which targets a salient and independent semantic feature of sentences, to control sentence sentiment. However, all of these work attempt to implicitly separate the non-emotional content from the emotional information in a dense sentence representation. Xu et al. (2018) explicitly filter out emotional words. They use two sentiment-specific decoders to attach sentiments to non-emotional context. The decoders bear all the burdens to generate sentiments. In our model, we use sentiment memories to assist generating sentiments with only one decoder, which results in fewer parameters.

The proposed sentiment-memory based auto-encoder (Bengio et al., 2009; Ma et al., 2018b) learns the idea of memory network (Weston et al., 2014; Sukhbaatar et al., 2015) but simplifies the process. Our work is also related to the generation tasks (Wang et al., 2017; Liu et al., 2018; Ma et al., 2018a; Lin et al., 2018). These tasks usually generate texts that preserve main information of input texts.

3 Proposed Model

We first use a variant of self-attention(Lin et al., 2017; Kim et al., 2017) mechanism to distinguish the emotional and non-emotional words. Then the positive words and negative words are used to update the corresponding memory modules. Finally, the decoder uses the target sentiment information extracted from the memory and the content representation to perform decoding.

3.1 Emotional Words Detection Model

We first find the emotional words that have the most discriminative power for sentiment polarity. This work is done by training a sentiment classifier with a simple self-attention mechanism. Here the sequence of inputs $\{h_1, ..., h_T\}$ are the hidden states of a LSTM, running over the words in the source sentence $\{x_1, ..., x_T\}$. The context vector can then be computed using a simple sum:

$$\boldsymbol{c} = \sum_{t=1}^{T} a_t \cdot \boldsymbol{h}_t \tag{1}$$

where a_t denotes the attention weight of the t-th word. The sentence vector $\boldsymbol{c}$ is then fed into a fully connected layer to predict the sentiment polarity of the source text. Since the words with obvious emotional tendencies will be given greater weights compared to those non-emotional words during training, a_t can be used to distinguish between emotional and non-emotional words.

The weights of standard attention mechanism sum to 1. When there are several emotional words, the sum 1 is distributed by these words. However, we expect that each emotional word has a weight close to 1 to identify its sentiment attribute. Hence, following (Kim et al., 2017), we modify the calculation of attention weights as follows to get more distinguishable weights:

$$a_t = \mathrm{sigmoid}(\boldsymbol{v}^T \boldsymbol{h}_t) \tag{2}$$

where $\boldsymbol{v}$ is the parameter vector. The sigmoid function follows our intention that giving each input word a distinguishable weight which is close to 1 or 0. However, these weights falls between 0 and 1. They still can not thoroughly distinguish the emotional words from non-emotional words without redundant information. Following Xu et al. (2018), we map attention weights to discrete values, 0 or 1, and we adopt their discrete method. The weights greater than the averaged attention value are assigned to 1 and the weights less than the averaged attention value are assigned to 0. The weight a_t after discretization is denoted as $\hat{a}_t$. Then, $\hat{a}_t$ can be regarded as the emotional word identifier. $1 - \hat{a}_t$ becomes non-emotional word identifier.

3.2 Sentiment-Memory Based Auto-Encoder

After the separation of emotional and non-emotional words, the proposed **SMAE** is used to process these two kinds of information. We employ the seq2seq based auto-encoder. Both the encoder and the decoder are LSTM networks (Hochreiter and Schmidhuber, 1997).

If $\boldsymbol{x}_i$ is a context word, then $\hat{a}_i$ is 0, causing $(1-\hat{a}_i)\boldsymbol{x}_i$ to be $\boldsymbol{x}_i$. Therefore, the sequence $\{(1-\hat{a}_1)\boldsymbol{x}_1, \cdots, (1-\hat{a_T})\boldsymbol{x}_T\}$ can be regarded as non-emotional word embedding sequence. It is fed into the LSTM encoder sequentially. we select $\boldsymbol{h}_T$ in the last state tuple $(\boldsymbol{h}_T, \boldsymbol{c}_T)$ of the encoder as the content representation of the input.

Meanwhile, the embeddings of the emotional words of the source text are used to update the sentiment-memory. Since we have two kinds of sentiments, positive and negative, we use $\boldsymbol{M}^{pos} \in \mathbb{R}^{e \times \gamma}$ and $\boldsymbol{M}^{neg} \in \mathbb{R}^{e \times \gamma}$ to denote the positive memory and the negative memory, respectively. e is the embedding size and γ is a hyper-parameter which controls the size of the memory.

We illustrate the following part by using positive input as an example. We first sum the embedding of the emotional words to get a vector representation of the emotional information, which is denoted as $\boldsymbol{s}^{pos} \in \mathbb{R}^e$. We then use a simple attention mechanism to find the columns in $\boldsymbol{M}^{pos}$ that are most closely related to the emotional information. The outer product of the transposition of emotional information $\boldsymbol{s}^{pos}$ and the attention weights $\boldsymbol{w}$ broadcasts the sentiment vector $\boldsymbol{s}^{pos}$ to a matrix. Then, the matrix is added to the existing memory $\boldsymbol{M}^{pos}$. Due to the attention weight $\boldsymbol{w}$, the columns that are most closely related to the emotional information are updated more with the sentiment information $\boldsymbol{s}^{pos}$. Formally, we have:

$$\boldsymbol{s}^{pos} = \sum_{i=1}^{T} \hat{a}_i \cdot \boldsymbol{x}_i \tag{3}$$

$$\boldsymbol{w} = softmax\left((\boldsymbol{s}^{pos})^T \boldsymbol{M}^{pos}\right) \tag{4}$$

$$\boldsymbol{M}^{pos} = \boldsymbol{M}^{pos} + \boldsymbol{s}^{pos} \otimes \boldsymbol{w} \tag{5}$$

where $\otimes$ denotes the outer product.

Previous work employ two sentiment-specific decoders to generate text based on the supposed non-emotional representation. The decoders bear all the burdens to generate sentiments. In our model, we extract some sentiment information from the sentiment-memories to assist decoding. Intuitively, the context word “staff” is more likely to be associated with the emotional word “friendly”, and “food” is more likely to be associated with “delicious”. So we use the context vector $\boldsymbol{s}^{con}$ to extract the corresponding sentiment memory that is more likely to be used in the future decoding. The context vector $\boldsymbol{s}^{con}$ is represented as the sum of the embedding of non-emotional words. Then $\boldsymbol{s}^{con}$ is used to compute the attention weights $\boldsymbol{u}$ over the columns of sentiment memory matrix. We sum these weighted columns as the extracted memory $\tilde{\boldsymbol{m}}$ and add $\tilde{\boldsymbol{m}}$ to the last cell state $\boldsymbol{c}_T$ of the encoder:

$$\boldsymbol{s}^{con} = \sum_{i=1}^{T} (1 - \hat{a}_i) \cdot \boldsymbol{x}_i \tag{6}$$

$$\boldsymbol{u} = softmax\left((\boldsymbol{s}^{con})^T \boldsymbol{M}^{pos}\right) \tag{7}$$

$$\tilde{\boldsymbol{m}} = \sum_{j=1}^{\gamma} u_j \cdot \boldsymbol{M}_j^{pos} \tag{8}$$

$$\tilde{\boldsymbol{c}}_T = \boldsymbol{c}_T + W \tilde{\boldsymbol{m}} \tag{9}$$

where u_j denotes the j-th value in vector $\boldsymbol{u}$, $\boldsymbol{M}_j^{pos}$ denotes the j-th column of $\boldsymbol{M}^{pos}$ and W is the parameter matrix. The new tuple $(\boldsymbol{h}_T, \tilde{\boldsymbol{c}}_T)$ then acts as the initial state of the decoder.

The negative input is processed in the same way. At the training stage, the decoder is encouraged to restore the source text. Therefore, the cross entropy loss function is optimized.

4 Experiments

4.1 Data Preprocessing

We use the Yelp Review Dataset (Yelp) provided by Yelp Dataset Challenge[2] to conduct experiments. Each item is a sentence from the review

Model	ACC	BLEU
CEA	71.96	2.77
MAE	74.59	5.45
SMAE	**76.64** (+2.05)	**24.00** (+18.55)

Table 1: Performance of the proposed method and state-of-the-art systems.

on Yelp and is labeled as having either negative or positive sentiment. We train a CNN sentence classifier (Kim, 2014) to filter examples with ambiguous sentiment polarities (category probability $<$ 0.8). The processed dataset contains 510K, 20K, and 20K pairs for training, validation, and testing, respectively. The classifier achieves an accuracy of 94% on the processed dataset and is also used to test transformation accuracy.

4.2 Experiment Settings

We tune our hyper-parameters on the development set. The word embeddings are initialized randomly with a size of 128. The hidden size of the sentiment-memory based auto-encoder is 300. We use Adam optimizer (Kingma and Ba, 2014) with an initial learning rate set to 0.001 to train our model and the batch size is set to 64. The hyper-parameter γ which controls the size of memory matrix is 60.

4.3 Baselines

We compare our proposed method with two state-of-the-art systems that have been used for sentiment modification. We run the released code on our dataset.

Cross-aligned Auto-Encoder (CAE): This system, proposed by Shen et al. (2017), uses a shared latent content space across different sentiments and leverages refined alignment of latent representations to perform sentiment modification.

Multi-decoder Auto-Encoder (MAE): This system is proposed by Fu et al. (2017). They use a multi-decoder seq2seq model (Bengio et al., 2009; Dai and Le, 2015) where the encoder captures content information by adversarial learning (Goodfellow et al., 2014) and the sentiment-specific decoders are used to generate target sentences.

4.4 Results and Discussions

We use ACC to denote the transformation accuracy. Following Gan et al. (2017), we also compute BLEU (Papineni et al., 2002) between the output and the source text to evaluate the content preservation degree. A high BLEU score primarily indicates that the system can correctly preserve content by retaining the same words from the source sentence.

Model	Sentiment	Content	Fluency
CAE	6.55	4.46	5.98
MAE	6.64	4.43	5.36
SMAE	6.57	5.98	6.69

Table 2: Results of human evaluation.

Input: *Very helpful and informative staff!*
CAE: *Worst service ever.*
MAE: *Very nice here and poor!*
Proposed: *Very rude and careless staff !*

Input: *I will never go here again.*
CAE: *I love this place here!*
MAE: *I had say this place here.*
Proposed: *I will never go anywhere else.*

Input: *The worst and would never recommend anyone to use them.*
CAE: *The best place I 've been to go here!*
MAE: *The first experience is so happy and nice.*
Proposed: *The best and would definitely recommend anyone to use them.*

Table 3: Examples generated by the proposed method and baselines. In comparison, our model changes the sentiment of inputs with higher semantic relevance.

The experimental results of our proposed model and the baselines are shown in Table 1. Both baseline models have low BLEU score but high accuracy, which indicates that they may be trapped in a situation that they simply output a sentence with the target sentiment regardless of the content. The main reason is that these methods using adversarial learning attempt to implicitly separate the emotional information from the context information in a sentence vector. However, without parallel data, it is difficult to achieve such a goal. Our proposed SMAE model takes advantage of self-attention mechanism and explicitly removes the emotional words, leading to a significant improvement of content preservation and the state-of-the-art performance in terms of both metrics.

We also involve human evaluation to measure the quality of generated text. Each item contains an input and three outputs generated by different systems. Then 200 items are distributed to 2 annotators with linguistic background. The annota-

Models	ACC	BLEU

SMEA (w/o memories)	14.08	26.09

Table 4: Ablation test of memory module.

The staff here is **very rude**.
It really is n't **worth coming** here .
Very pleased with this business.
Been here once and **loved** going **here**.

Table 5: The effectiveness of the memory module with examples. The red words are absent in the input but generated with the help of sentiment memories.

tors have no idea about which system the output is from. They are asked to score the output on three criteria on a scale from 1 to 10: the transformed sentiment degree, the content preservation degree, and the fluency. Table 2 shows the evaluation results. Our model has obvious advantage over the baseline systems in content preservation, and also performs well in other aspects.

Several randomly selected examples generated by different models are shown in Table 3. These examples clearly show our proposed model can generate sentences that are more semantically relevant to the input text compared to the baselines.

4.5 Effectiveness of Sentiment-Memories

To verify the effectiveness of the memory module of our model, we conduct ablation study by excluding the sentiment-memory module. The result is shown in Table 4. According to the result, the complete model achieves an improvement of 62.56% on transformation accuracy over the model that excludes the sentiment memories, which means the sentiment memories are key components to ensure successful sentiment modification. In addition, several examples are shown in Table 5 to visually demonstrate the effectiveness of the memory module. we can find that the proposed model is capable of generating appropriate emotional words (red words in Table 5) to adapt different contexts.

4.6 Error Analysis

To better interpret our model, we also analyze the failure examples whose sentiments are not transformed. We observe that in most cases, these inputs do not have emotional tendencies. Although we have filtered the sentiment-ambiguous examples in preprocessing, there are still a few ambiguous inputs such as “What can I say ?” and “Been here twice.”. Since our model tries to preserve non-emotional content. These words are easily kept and then the decoder barely depends on sentiment-memories. Thus, it is difficult to handle the sentiment transformation with these examples.

5 Conclusion

In this paper, we propose a model that first learns sentiment memories without parallel data and then automatically extracts sentiment information to adapt different contexts when decoding. Experimental results show that our method substantially improves the content preservation degree and achieves the state-of-the-art performance.

Abstract

In this work, we propose a new model for aspect-based sentiment analysis. In contrast to previous approaches, we jointly model the detection of aspects and the classification of their polarity in an end-to-end trainable neural network. We conduct experiments with different neural architectures and word representations on the recent GermEval 2017 dataset. We were able to show considerable performance gains by using the joint modeling approach in all settings compared to pipeline approaches. The combination of a convolutional neural network and fasttext embeddings outperformed the best submission of the shared task in 2017, establishing a new state of the art.

1 Introduction

Sentiment analysis (Pang and Lee, 2008) is the automatic detection of the sentiment expressed in a piece of text. Typically, this is modeled as a classification task with at least two classes (positive, negative), sometimes extended to three (neutral) or more fine-grained categories. Aspect-based sentiment analysis (ABSA) aims at a finer analysis, i.e. it requires that certain aspects of an entity in question be distinguished and the sentiment be classified with regard to each of them. An example can be seen in Figure 1.

German: Alle so “Yeah, Streik beendet” Bahn so “Okay, dafür werden dann natürlich die Tickets teurer” Alle so “Können wir wieder Streik haben?”

Translation: Everybody’s like “Yeah, strike’s over” Bahn goes “Okay, but therefore we’re going to raise the prices” Everybody’s like “Can we have the strike back?”

General sentiment:	neutral
Aspect sentiment:	Ticket purchase:negative General:positive

Figure 1: Example sentence with contained aspects and their polarity.

This introduces several new challenges. First, labeled data, which are needed to train statistical models, are more difficult to obtain. Therefore the amount of available training data is limited. Thus a good model for ABSA has to make the best possible use of the available data. Second, the detection of the subset of aspects that occur in a given piece of text is non-trivial. Errors introduced at this stage severely limit the performance on the overall ABSA task. Third, the general sentiment and the sentiment of each aspect can each be completely different from each other (cf. Figure 1). This means that a model has to be able to distinguish aspects in the text and make independent decisions for each of them.

We want to address each of these challenges by (1) leveraging unlabeled data by modeling word representations and (2) modeling aspect detection and classification of their polarity jointly in an end-to-end trainable system.

We evaluate our approach on the GermEval 2017 data, i.e. customer reviews about *Deutsche Bahn AG* on social media. We particularly address subtask C as the typical setting where two pieces of information have to be detected from raw text:

1. Which aspects are mentioned?
2. For each mentioned aspect, what is the polarity of its sentiment?

From the new state-of-the-art results we obtain, we conclude that modeling of word representations and joint modeling of aspects and polarity have not yet received the attention they deserve.

Brussels, Belgium, October 31 - November 4, 2018.

2 Related Work

Two recent shared tasks address ABSA: SemEval 2016 Task 5 (Pontiki et al., 2016) and GermEval 2017 (Wojatzki et al., 2017). The SemEval dataset is extremely small. The English laptop reviews, e.g., only contain 395 training instances for the prediction of 88 aspect categories and their polarities. Because of this sparsity, top-ranked systems rely on feature engineering and hand-crafted rules. GermEval is a larger dataset (~20K training instances, 20 aspect categories) and thus suited for our goal of evaluating the quality of fully automatic methods for learning aspect and polarity predictions. Furthermore the top systems at SemEval 2016, XRCE (Brun et al., 2016) and IIT-TUDA (Kumar et al., 2016), not only rely heavily on feature engineering but also separate the tasks of aspect detection and aspect polarity classification into two different parts of their pipeline.

The winners of GermEval 2017 rely on neural methods (Lee et al., 2017). They try to link all aspects to a sequence of tokens and model the task as a sequence labeling problem. This leads to problems because some aspects are not assigned to any token but still have to be detected and classified. Our approach always considers the complete document and produces the set of all detected aspects at once. Although Lee et al. (2017) incorporate some aspects of multi-task learning, the prediction of aspect category and polarity remains separated in each of their approaches. In our work, we show that a joint learning of these two tasks achieves better performance. The approach by Lee et al. (2017) also relies more heavily on external sources than ours. While we only collected a corpus of ~113K unlabeled German tweets, Lee et al. (2017) include annotated English data as well as a much larger unlabeled German corpus (Wikipedia, cf. Al-Rfou et al. (2013)) in their setting.

Ruder et al. (2016) propose another neural model for ABSA. Similarly to the approaches mentioned above, they assume that aspects have already been detected by some other system in a pipeline architecture, and they concentrate on polarity classification on the sentence level by unifying information from other sentences on the document level. We compare ourselves to this baseline and show improvements over pipeline approaches.

3 Proposed Model

3.1 Embedding Algorithm

Word2vec skip-gram (Mikolov et al., 2013) is a widely used algorithm to obtain pretrained vector representations for input words. Notably, Lee et al. (2017) use it for their experiments on the GermEval data. FastText (Grave et al., 2017) works in a similar fashion but has the advantage of incorporating subword information in the embedding learning process. So it can not only learn similar embeddings for word forms sharing a common stem but also generate embeddings for unseen words in the test set by combining the learned character ngram embeddings. This can be crucial when dealing with a morphologically rich language such as German. Glove (Pennington et al., 2014) — similar to word2vec — does not incorporate character-level information, but uses global rather than local information to learn its word embeddings.

We have trained each of these embedding learning algorithms on a corpus of ~113K tweets mentioning at least one of `@DB_info` and `@DB_Bahn`, two official accounts of *Deutsche Bahn AG* offering information and replying to questions. We collected these tweets specifically to build a document collection that is closely related to the domain of GermEval 2017. We also included the GermEval training set for the embedding training.

3.2 Pipeline LSTM (baseline)

We compare our proposed approach to the model described in (Ruder et al., 2016). They first encode each sentence with glove word embeddings and a bidirectional LSTM (Hochreiter and Schmidhuber, 1997). Then this output is concatenated with an embedding of the aspect addressed in the current sentence and finally fed in a document-level BiLSTM. As we are dealing with social media texts, our documents are already very short. So we do not split them into shorter units (sentences). Therefore the second hierarchy level of (Ruder et al., 2016), that combines the output of consecutive sentences in a document, is superfluous and omitted in our experiments. In all other aspects — including hyperparameters — we do as (Ruder et al., 2016), i.e. we duplicate a tweet for each aspect detected in it, concatenate an aspect embedding of size 15 to the output of the BiLSTM encoder, use dropout of 0.5 after the embedding layer and after LSTM cells, and apply a gradient clipping norm of 5. As Ruder et al. (2016) rely on the detected aspects to be given at test time, for a realistic comparison, we feed in the aspects as detected by the strong GermEval baseline system based on support vector machines. The so obtained system serves as our first baseline, representing a state-of-the-art pipeline system.

3.3 End-to-end LSTM

We modify the pipeline model described in the last section as follows: the aspect detection is integrated into the neural network architecture permitting an end-to-end optimization of the whole model during training. This is achieved by formatting the classifier output as a vector $\mathbf{z} \in \{0, 1, 2, 3\}^{|A|}$, where A is the set of all 20 aspects (e.g., *General, Ticket purchase, Design, Safety, . . .*). This corresponds to predicting one of the four classes *N/A*, *positive*, *negative* and *neutral* for each aspect. Specifically, we obtain a hidden representation of an input document X in the following manner:

$$\mathbf{v} = DO(BiLSTM(DO(embed(X)))) \tag{1}$$

where $embed \in \{word2vec, glove, fasttext\}$
and DO = dropout (Hinton et al., 2012).
The design choices for the BiLSTM in this step remain the same as in the baseline model.

Then, we transform the feature vector $\mathbf{v}$ extracted from the text X to a score vector $\hat{y}^{(a)}$ for each aspect $a \in A$ and apply softmax normalization:

$$\hat{y}^{(a)} = softmax(W^{(a)}\mathbf{v} + b^{(a)}) \tag{2}$$

where

$$softmax(\mathbf{x})_i = \frac{exp(x_i)}{\sum_{k=0}^{3} exp(x_k)} \quad \text{for } i = 0, \ldots, 3 \tag{3}$$

Thus for each aspect, we predict its presence or absence as well as its polarity in one step:

$$z^{(a)} = \arg\max_i \hat{y}_i^{(a)} \tag{4}$$

The loss is simply the cross entropy summed over all aspects:

$$L(\theta) = \sum_{a \in A} H(y^{(a)}, \hat{y}^{(a)}) \tag{5}$$

with

$$H(y, \hat{y}) = -\sum_i y_i \cdot log(\hat{y}_i) \tag{6}$$

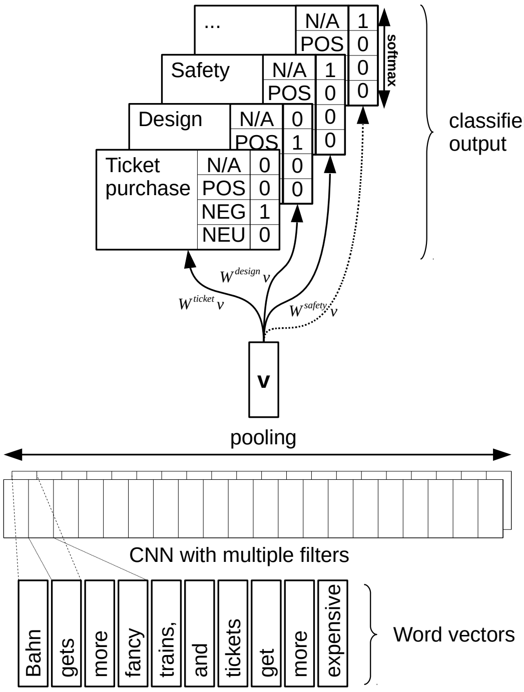

Figure 2: Schematic view of end-to-end CNN architecture.

3.4 End-to-End CNN

Keeping the formalization as an end-to-end task, we replace the BiLSTM by a convolutional neural network (CNN) as described in (Kim, 2014). As in their setting *CNN-non-static*, we use 300-dimensional word embeddings, a max-over-time pooling operation, filter sizes of $3, 4, 5$, and dropout with a rate of 0.5 (as before). We use ReLu ($f(x) = max(0, x)$) as our activation function, and 300 filters of each size, a number also found in related work on sentiment analysis (dos Santos and Gatti, 2014). Following (Kim, 2014), we do not apply dropout after the embedding layer:

$$\mathbf{v} = DO(CNN(embed(X))) \tag{7}$$

With Equation 7 replacing Equation 1, the aspect-wise classification for the end-to-end CNN then follows the same definitions as described in the previous section.

3.5 Pipeline CNN

In order to compare the effects of joint end-to-end and pipeline approaches across neural architectures, we also include an experiment where the CNN model from the previous section replaces the BiLSTM in the pipeline setting described in section 3.2.

4 Experiments

We conduct our experiments on the GermEval 2017 data (Wojatzki et al., 2017), i.e. customer feedback about *Deutsche Bahn AG* on social media, microblogs, news, and Q&A sites. The data were collected over the time of one year and manually annotated, resulting in a main dataset of about 26K documents, divided into a training, development, and test set using a random 80%/10%/10% split. About 1,800 documents from the last 3 months of the data collection period constitute a diachronic test set that can be used to test the robustness of a system over time. We keep the proposed data split and filter out training instances where the same aspect category was assigned two different polarity classes (which affects approximately 4% of the data). The development and test data remain the same.

We choose our hyperparameters based on the development data using the following procedure: we train initial models with a hyperparameter setting based on values we found in the literature, stochastic gradient descent with a learning rate of 0.01 (as in dos Santos and Gatti (2014)) and a mini-batch size of 10 (as in Ruder et al. (2016)). For the best-performing CNN and LSTM architectures (end-to-end + fasttext), we then refine the learning rate and batch size on the development data using random search in the range $\{0.001, 0.003, 0.01, 0.03, 0.1\}$ for learning rate and $\{5, 10, 20\}$ for batch size. For the CNN setting, this results in a learning rate of 0.03 and a batch size of 5 (which we then use for all CNN architectures in the final experiments). For the LSTM setting, this results in a learning rate of 0.01 and a batch size of 10 (which we then use for all LSTM architectures).

Training our models takes between 1-3 minutes per epoch on a GeForce GTX 1080 GPU, the end-to-end CNN being the fastest model to train.

5 Discussion

Aspect polarity Table 1 shows the results of our experiments, as well as the results of our strong baselines. Note that the majority class baseline already provides good results. This is due to highly unbalanced data; the aspect category "*Allgemein*" ("*general*"), e.g., constitutes 61.5% of the cases. This imbalance makes the task even more challenging.

Over all architectures, we observe a comparable or better performance when using fasttext embeddings instead of word2vec or glove. This backs our hypothesis that subword features are important for processing the morphologically rich German language. Leaving everything else unchanged, we can furthermore see an increase in performance for all settings, when switching from the pipeline to an end-to-end approach. The best performance (marked in bold) is achieved by a combination of CNN and FastText embeddings, which outperforms the highly adapted winning system of the shared task.

Aspect category only Even though our architectures are designed for the task of joint prediction of aspect category and polarity, we can also evaluate them on the detection of aspect categories only. Table 2 shows the results for this task. First of all, we can see that the SVM-based GermEval baseline model has very decent performance as it is practically on par with the best submission for the synchronic and even outperforms the best submission on the diachronic test set. It is therefore well-suited to serve as input to the pipeline LSTM model we compare with in our main task.

Comparing our architectures, we see again that fasttext embeddings always lead to equal or better performance. And even though we do not directly optimize our models for this task only, our best model (CNN+fasttext) outperforms all baselines, as well as the GermEval winning system.

Impact of domain-specific corpus We compare the domain-specific FastText embeddings to FastText embeddings trained on Wikipedia[1], which is approximately 100 times the size of our domain-specific corpus. We report the results in Table 3. The embeddings trained on Wikipedia show slightly lower performance on the dev set but slightly higher or equal performance on the test sets. We conclude that the main positive impact of FastText stems from its capability to model subword information and that a large domain-independent corpus or a small domain-specific corpus lead to similar performance gains.

6 Conclusion

We have presented a new approach to ABSA. By solving the two classification problems (aspect

categories + aspect polarity) inherent to ABSA in a joint manner, we observe significant performance gains for both of these tasks on the GermEval 2017 data. Our experiments also showed that word representations leveraging subword information are crucial for a challenging task like ABSA in a morphologically rich language, such as German. Furthermore we observed consistently better performance of CNN architectures in otherwise comparable scenarios, which suggests that CNNs cope better with the irregularities of user-written texts on social media, a research question we leave to future work. By establishing a new state of the art in aspect detection and polarity classification, we provide a new practical baseline for future research in this area.

Representing Social Media Users for Sarcasm Detection

Abstract

We explore two methods for representing authors in the context of textual sarcasm detection: a Bayesian approach that directly represents authors' propensities to be sarcastic, and a dense embedding approach that can learn interactions between the author and the text. Using the SARC dataset of Reddit comments, we show that augmenting a bidirectional RNN with these representations improves performance; the Bayesian approach suffices in homogeneous contexts, whereas the added power of the dense embeddings proves valuable in more diverse ones.

1 Introduction

Irony and sarcasm[1] are extreme examples of context-dependence in language. Given only the text *Great idea!* or *What a hardship!*, we cannot resolve the speaker's intentions unless we have insight into the circumstances of utterance – who is speaking, and to whom, and how the content relates to the preceding discourse (Clark, 1996). While certain texts are biased in favor of sarcastic uses (Kreuz and Caucci, 2007; Wallace et al., 2014), the non-literal nature of this phenomenon ensures that there is an important role for pragmatic inference (Clark and Gerrig, 1984).

The current paper is an in-depth study of one important aspect of the context dependence of sarcasm: the author. Our guiding hypotheses are that authors vary in their propensity for using sarcasm, that this propensity is influenced by more general facts about the context, and that authors have their own particular ways of indicating sarcasm. These hypotheses are well supported by psycholinguistic research (Colston and Lee, 2004; Gibbs, 2000; Dress et al., 2008), but our ability to test them at scale has until recently been limited by available annotated corpora. With the release of the Self-Annotated Reddit Corpus (SARC), Khodak et al. (2017) have helped to address this limitation. SARC is large and diverse, and its distribution of users across comments and forums makes it particularly well suited to modeling authors and their relationship to sarcasm.

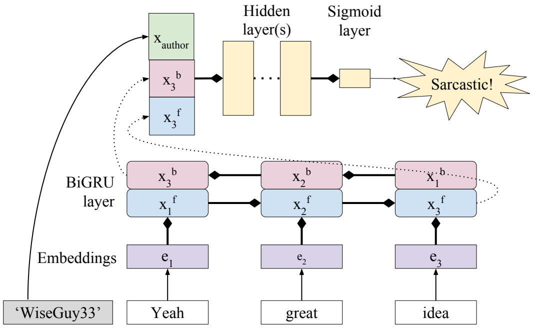

Figure 1: The model architecture. Look-ups are indicated by arrows, dense connections by diamonds. The author embedding can be null (a text-only baseline), a prior reflecting the author's propensity for sarcasm, or a learned embedding. There are potentially multiple layers between the initial example embedding and the output sigmoid layer.

Our core model of comment texts is a bidirectional RNN with GRU cells. To model authors, we propose two strategies for augmenting these RNN representations: a simple Bayesian method that captures only an author's raw propensity for sarcasm, and a dense embedding method that allows for complex interactions between author and text (Figure 1). We find that, on SARC, the simple Bayesian approach does remarkably well, especially in smaller, more focused forums. On the full SARC dataset, author embeddings are able to encode more kinds of variation and interaction with the text, and thus they achieve the highest predictive accuracy. These findings extend and reinforce

---

[1] We use "sarcasm" to include both sarcasm and irony, as the two are generally conflated in the literature we review.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1115–1121
Brussels, Belgium, October 31 - November 4, 2018.

the prior work on user-level modeling for sarcasm (Section 2), and they indicate that simple representation methods are effective here.

2 Previous Work

A substantial literature exists around sarcasm detection. Many of the prior studies focus on the analysis of Twitter posts, which lend themselves well to sarcasm detection with NLP methods because they are available in large quantities, they tend to correspond roughly to a single utterance, and users' hashtags in tweets (e.g., #sarcasm, #not) can provide imperfect but useful labels. A central theme of this literature is that bringing in contextual features helps performance.

González-Ibánez et al. (2011) trained classifiers using a combination of lexical and pragmatic features, including emoticons and whether the user was responding to another tweet (see also Felbo et al. 2017). Bamman and Smith (2015) extend this kind of analysis with additional information about the context. Of special interest here are their contextual features: the author's historical sentiment, topics, and terms; the addressee; and features drawn from historical interactions between the author and addressee. The study finds most features to be useful, but a model trained on the tweet and author features alone achieved essentially the same performance (84.9% accuracy) as a model trained on all features (85.1%).

In a similar vein, Rajadesingan et al. (2015) used a complex combination of features from users' Twitter histories, including sentiment, grammar, and word choice, as inputs into their model, and report a ≈7% gain in classification accuracy upon adding these features to a baseline n-gram classifier.

Recent papers have also applied deep learning methods to detecting sarcastic tweets. Poria et al. (2016) use a combination convolutional–SVM architecture with auxiliary sentiment input features. The architecture of Zhang et al. (2016) includes an RNN, and uses contextual features as well as tweet text for inputs.

Amir et al. (2016) extend the work of Bamman and Smith by generating author embeddings to reflect users' word-usage patterns (but not sarcasm history) in a manner similar to the paragraph vectors introduced by Le and Mikolov (2014). With the inclusion of these embeddings, their convolutional neural network (CNN) achieves a 2% gain in accuracy over that of Bamman and Smith.

Ghosh and Veale (2017) present a combination CNN/LSTM (long short-term memory RNN) architecture that takes as inputs user affect inferred from recent tweets as well as the text of the tweet and that of the parent tweet. When a tweet was addressed to someone by name, the name of the addressee was included in the text representation of the tweet, providing a loose link between interlocutors (West et al., 2014) and a ≈1% gain in performance for some data sets.

There has also been a small amount of previous work on Reddit data for sarcasm (Tay et al., 2018; Ghosh and Muresan, 2018). Wallace et al. (2014) explore a hand-labeled dataset of ≈3K Reddit comments from six subreddits. They report that, when human graders attempted to mark comments as sarcastic or not sarcastic, they needed additional context like subreddit norms and author history roughly 30% of the time, and that the comments which graders found ambiguous were largely the same as those on which a baseline bag-of-words classifier tended to make mistakes. In a follow-up study, Wallace et al. (2015) find that semantic cues for sarcasm differ by subreddit, and they show classifier accuracy gains when modeling subreddit-specific variation.

The work that is closest to our own is that of Hazarika et al. (2018), who also experiment on the SARC dataset. Their model learns author, forum, and text embeddings, and they show that all three kinds of representation contribute positively to the overall performance. We take a much simpler approach to author embeddings and do not include forum embeddings, and we report comparable performance (Section 6). We take this as further indication of the value of author features for modeling sarcasm.

3 The SARC Dataset

The Self-Annotated Reddit Corpus (SARC) was created by Khodak et al. (2017).[2] It includes an unprecedented 533M comments. The corpus is self-annotated in the sense that a comment is considered sarcastic if its author marked it with the "/s" tag. As a result, the positive examples are essentially those which the authors considered ambiguous enough to explicitly tag as sarcastic, meaning that the prediction problem is actually to identify which comments are not only sarcastic but

	Comments	% sarcastic
Entire corpus (bal.)	257,082	50.00
r/politics (bal.)	13,668	50.00
r/politics (unbal.)	309,925	3.06
r/AskReddit (bal.)	11,660	50.00
r/AskReddit (unbal)	1,548,803	0.53

Table 1: Basic statistics for SARC.

both sarcastic and not obviously so.

The dataset is filtered in numerous ways, and has good precision (only ≈1% false positive rate) but poor recall (2% false negatives relative to 0.25% true positives, or ≈11% recall). To alleviate the issues caused by low recall, the dataset also includes a balanced sample, where comments are supplied in pairs, both responding to the same parent comment and with exactly one of the two tagged as sarcastic. All comments are accompanied with ancestor comments from the original conversation, author information, and a score as voted on by Reddit users.

This dataset presents numerous advantages for sarcasm detection. For one, it is vastly larger than past sarcasm datasets, which enables the training of more sophisticated models. In addition, most work in sarcasm detection has focused on tweets, which are very short and tend to use abbreviated and atypical language. Reddit comments are not constrained by length and are therefore more representative of how people typically write. Finally, Reddit is organized into topically-defined communities known as subreddits, each of which has its own community norms and linguistic patterns. By making available large amounts of data from a number of subreddits, SARC facilitates the comparative analysis of subreddits, and more generally provides a view into the differences between communities.

Table 1 provides basic statistics on the entire corpus as well as the subreddits that we focus on in our experiments.

4 Models

Our baseline model is a bidirectional RNN with GRU cells (BiGRU; Cho et al. 2014). We tried variants with LSTM cells and did not observe a significant difference in performance. We therefore chose to use GRU cells as the model with fewer parameters.[3]

The inputs to the BiGRU model are users' comments, which are split into words (and in the case of conjunctions, subwords) and punctuation marks and are converted to word vectors. The final states of the two directions of the BiGRU are concatenated with each other and run through either a single fully-connected linear layer or two fully-connected linear layers with a rectified linear unit in between. The output of the final linear layer is fed through a sigmoid function which outputs the estimated probability of sarcasm. This baseline does not take author information into account: for each comment, only the words of the comment are considered as inputs.

The *Bayesian prior* model extends the BiGRU with the sarcastic and non-sarcastic comment counts for authors seen in the training data, which serves as a prior for sarcasm frequency. This version of the model takes as inputs both a representation of the comment and the author representation $x_{\text{author}} \in \mathbb{Z}^2_{\geq 0}$ to estimate the probability of sarcasm. The model can be interpreted as computing a posterior probability of sarcasm given both the comment and the prior of previous sarcastic and non-sarcastic comment counts – author modeling reduced to a Bernoulli prior. For previously unseen authors, x_{author} is set to $(0, 0)$.

The *author embedding* approach extends the baseline BiGRU in a more sophisticated way. Here, each author seen in the training data is associated with a randomly initialized embedding vector $x_{\text{author}} \in \mathbb{R}^{15}$, which is then provided as an input to the model along with a representation of the words of the comment. A special randomly initialized vector x_{UNK} is used for previously unseen authors. The author embeddings are updated during training, with the goal of learning more sophisticated individualized patterns of sarcasm than the Bayesian prior allows. We experimented with training the x_{UNK} vector on infrequently-seen authors (fewer than 5 comments in the training set) instead of using a random vector, and found some suggestions of improved performance. However, as the differences in performance were not substantial enough to change the relative performance of the different models, we report the results for the simpler random-x_{UNK} model.

---

[3] Our models and associated experiment code are available at `https://github.com/kolchinski/reddit-sarc`

5 Experiments

We conducted three sets of experiments, one for each model, to evaluate the effectiveness of the different approaches to author modeling. Each set of experiments was conducted on five datasets: the balanced version of the entire corpus as well as the balanced and unbalanced versions of the r/politics and r/AskReddit subcorpora (Table 1).

In all cases, the raw comment data was tokenized into words and punctuation marks, with components of contractions treated as individual words. We mapped tokens to FastText embedding vectors which had been trained, using subword infomation, on Wikipedia 2017, the UMBC webbase corpus, and the statmt.org news dataset (Mikolov et al., 2018). While vectors existed for nearly 100% of tokens generated, exceptions were mapped to a randomly initialized UNK vector.

All models were trained with early stopping on a randomly partitioned holdout set of either 5% of the data for balanced subreddit corpora or 1% for the others. The performance of the model, as used for hyperparameter tuning, was evaluated against a second holdout set, generated in the same manner as the first holdout set but disjoint from both it and the portion of the data used for training.

Hyperparameters were tuned to maximize model performance as evaluated in this manner, starting with a randomized search process and fine-tuned manually. The final evaluation was conducted against the test set, with a single randomly partitioned holdout set from the training data again used for early stopping. We applied dropout (Srivastava et al., 2014) during training before and between all linear layers. For additional regularization, we also applied an l2-norm penalty to the linear weights but not to the GRU weights.

We attempted other model variations, including multiple GRU layers and an attention mechanism for GRU outputs, but did not observe any gains in performance from the larger models.

6 Results and Discussion

6.1 Quantitive assessment

Table 2 reports the means of 10 runs to control for variation deriving from randomness in the optimization process (Reimers and Gurevych, 2017).

Where there is overlap between our experiments and those of Hazarika et al. (2018) (CASCADE), our model is highly competitive. We slightly under-perform on the full balanced dataset but come out ahead on r/politics. This is striking because our model makes use of much less information. First, unlike CASCADE, we do not have forum embeddings. Second, CASCADE author embeddings involve extensive feature engineering including “stylometric” and “personality” features. Our author embeddings, on the other hand, are either simple empirical estimates (Bayesian priors) or learned embeddings with random initializations, in both cases allowing simpler model specification and training, and more flexibility on the task for which they are used.

There is also evidence that the BiGRU yields better representations of texts than does Hazarika et al.’s CNN-based model. Our ‘No embed’ model is akin to their CASCADE with no contextual features, which achieves only 0.66 on the full balanced corpus and 0.70 on the r/politics balanced dataset. Both numbers are well behind our ‘No embed’. Unfortunately, we do not have space for a fuller study of the similarities and differences between our model and CASCADE.

Both of our methods for representing authors perform well. This is perhaps especially striking for the unbalanced experiments, where the percentage of sarcastic comments is tiny (Table 1). The two methods perform differently on individual forums than on the full dataset. For the r/politics and r/AskReddit communities, the Bayesian priors give the best results. The situation is reversed for the full dataset, where the high-dimensional embeddings outperform the Bayesian priors. This likely reflects two interacting factors. First, with smaller, more focused forums, it is harder to learn good author embeddings, so the simple prior is more reliable. Second, on the full dataset, there are more examples, and also more complex interactions between authors and their texts, so the added representational power of the embeddings proves justified.

6.2 Qualitative comparisons

Table 3 provides example predictions from the different models. Each example is taken from the holdout set of a run in which all three models were trained on the same training set and evaluation was conducted on the same holdout set.

For both sarcastic and non-sarcastic comments, author modeling can be helpful for disambiguation. For instance, in examples 1 and 2, omitting

		r/politics		r/AskReddit	
	Full balanced	balanced	unbalanced	balanced	unbalanced
No embed	74.8 [74.6, 74.9]	74.3 [74.1, 74.6]	58.7 [58.2, 59.1]	64.3 [63.4, 65.2]	56.9 [56.6, 57.2]
Bayesian prior	74.0 [73.7, 74.3]	77.6 [77.4, 77.9]	64.7 [64.6, 64.8]	69.1 [68.8, 69.4]	57.7 [57.6, 57.7]
15d embed	75.3 [74.8, 75.7]	75.1 [74.4, 75.8]	62.0 [59.9, 63.9]	66.0 [65.1, 66.8]	57.1 [56.6, 57.6]
Khodak et al. (2017)	75.8	76.5	27.0	–	–
CASCADE	77.0	75.0	–	–	–

Table 2: Mean macro-averaged F1 scores with bootstrapped 95% confidence intervals, based on 10 runs. CASCADE is the best system of Hazarika et al. (2018), and we report the strongest baseline numbers established by Khodak et al. (2017).

		Model Predictions of p(sarcastic)		
Reddit comment	Sarcastic?	No user rep.	Bayesian	Multidimensional
1. Good thing Trump is going to bring back all those low education high paying jobs.	Yes	.45	.68	.84
2. lol woops!	No	.78	.36	.25
3. The most ubiquitous undergarments I see these days.	Yes	.15	.17	.79
4. Such a deep confession, and it doesn't sound like the guy who wrote it is an asshole at all.	Yes	.33	.45	.86
5. It's not entirely impossible that there are recipe's that have yet to be discovered.	No	.23	.23	.81

Table 3: Examples selected to highlight differences between the models.

author modeling led to incorrect predictions, but including the frequency of the author's sarcasm use alone was enough to change the prediction from incorrect to correct.

In cases like examples 3 and 4, where the Bayesian prior was insufficient, including a model of the author's individualized patterns of sarcasm was much more powerful. That said, the more complex embedding model can misfire, as in example 5, where the simpler models make a correct prediction but it does not. This appeared to happen more for non-sarcastic examples, where the embedding model would occasionally strongly influence the predicted probability of sarcasm upward. Evidently, authors have more individualized patterns of sarcasm than of non-sarcasm.

Judging by the relative performance of the Bayesian and multidimensional-embedding models (Table 2), the multidimensional model wins more disagreements than it loses with the Bayesian model when there is more training data available. However, when there is not, it overfits to such a degree that its predictions of authors' sarcasm patterns are less useful than the Bayesian approach. This suggests a future direction of exploration: the most useful model of all may be one that expands in complexity for authors with more examples available, and shrinks for those who have fewer.

7 Conclusion

This paper evaluated two data-driven methods for modeling the role of the author in sarcasm detection. Both prove effective. As shown by Hazarika et al. (2018), similar techniques can be extended to other aspects of the context. While our experiments did not support adding these representations, we think listeners rely on them as well, so additional computational modeling work here is likely to prove fruitful.

Abstract

We carry out a syntactic analysis of two state-of-the-art sentiment analyzers, Google Cloud Natural Language and Stanford CoreNLP, to assess their classification accuracy on sentences with negative polarity items. We were motivated by the absence of studies investigating sentiment analyzer performance on sentences with polarity items, a common construct in human language. Our analysis focuses on two sentential structures: downward entailment and non-monotone quantifiers; and demonstrates weaknesses of Google Natural Language and CoreNLP in capturing polarity item information. We describe the particular syntactic phenomenon that these analyzers fail to understand that any ideal sentiment analyzer must. We also provide a set of 150 test sentences that any ideal sentiment analyzer must be able to understand.

1 Introduction

Sentiment analysis of texts, from relatively long product and movie reviews (Pang et al., 2002) to short tweets (Go et al., 2009), is a rich and evolving field. Probabilistic analyzers, such as Google's Natural Language client (Google, 2018) and Stanford's CoreNLP package (Manning et al., 2014), have improved in recent years, but major challenges remain in classifying practical sentences. In this paper, we focus on a particular grammatical phenomena analyzers often misclassify: the presence of specific polarity items.

As one of the fundamental components of natural language, polarity items (e.g. nothing, any, ever) are lexical items that can appear only in specific licensing contexts. Thus, we should be able to identify the grammatical polarity of a sentence by the presence of such polarity items, allowing us to determine its sentiment. However, these licensing contexts are challenging to identify and are generally different for each item (Baker, 1970). We aim to understand how negative polarity items are involved in misclassified sentences and use this knowledge to characterize the syntactic phenomenon an ideal sentiment analyzer must learn.

First, we present a brief background on sentiment analyzers and polarity items. In the next section, we describe our methodology in terms of what kinds of sentences we want to use and how we can best test the sentiment analyzers. Our methodology involves trying sentences with negative polarity items under two different licensing contexts, downward entailment and non-monotone quantifiers. We then evaluate variations of the sentences to show that the sentiment analyzers are not correctly using the polarity items. By exploring these misclassified sentences, we describe the particular syntactic configuration that leads to misclassification, presenting weaknesses in the state-of-the-art sentiment analyzers in understanding and handling polarity items.

2 Background and Previous Work

2.1 Sentiment Analyzers

Most sentiment analyzers (Wang et al., 2012; Pak and Paroubek, 2010; Cambria et al., 2013) are based on a statistical approach, relying on a conglomeration of sentiments of the individual words in a sample. The main assumption behind such statistical approaches is that keywords contain essential information to infer the sentiment of a whole sample. Therefore, this type of statistical approach does not readily consider complex syntactic interactions between individual words; instead, the main focus lies in the system's learning of the relevant knowledge through texts relevant to the sentiment analysis task.

Statistical methods often employ bag-of-words as input features and represent a document by the

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1122–1127
Brussels, Belgium, October 31 - November 4, 2018.

summation of all bag-of-words features in that document. A model, such as a maximum entropy classifier or support vector machine (Mullen and Collier, 2004), can be trained to learn which words or combinations of words are relevant for sentiment analysis (Pang et al., 2002). With bag-of-words as the input of a model, we lose spatial structure for a document, so a classifier is incapable of differentiating "I knew the dog would never bite" from "The dog knew the man would never bite" or "Bite never I knew the dog would."

To overcome such challenges, deep learning models have gained popularity for this task. (Glorot et al., 2011) use domain adaptation to train an adversarial network, where two models are pitted against each other: one classifying sentiment and the other creating input documents. This approach allows the system to learn from data sets across multiple domains, increasing the flexibility of the sentiment classifier. However, the weakness of this approach is that the system uses a bigram bag-of-words as input, making it unable to learn long-distance syntactic phenomena.

Recent methods have proposed learning word embeddings (Tang et al., 2014) or applying deep neural architectures (Dos Santos and Gatti de Bayser, 2014) to extract context and sentiment from short texts, as these contain minimal information. Although these techniques have shown performance improvements, they have not been completely successful in capturing long-distance dependencies, leading to the proposal of memory networks (Weston et al., 2014) and attention-based mechanisms (Wang et al., 2016).

2.2 Polarity Items

In Emergence of Meaning (Crain, 2012), Crain puts forward polarity items, like "some" and "any" that are similar, but are sometimes interpreted differently. He presents the example of (1) "John didn't eat any of the kangaroo." and compares it to (2) "John didn't eat some of the kangaroo." The sentence with "some" implies that John did eat a part of the kangaroo, but there is a part of it that he did not eat. The sentence with "any" implies the stronger statement that John did not eat any of the kangaroos. These two interpretations differ due to the polarity of the two words. "Any" is only accepted in negative contexts, so it has negative polarity, whereas "some" can be accepted in both positive and negative contexts and possesses positive polarity. To observe that "any" only works in negative contexts, consider the sentence (3) "John ate any of the kangaroo." which has positive context, and is incorrect with the word "any".

Further, the words "any" and "some" can sometimes be used interchangeably and have the same interpretation. (4) "You'll never convince me that John didn't eat some/any of the kangaroo." contains (1) and (2). In (4) there is negation (never) in a higher clause; then the latter clause contains negation and "any"/"some". These practical examples demonstrate that word ordering in a sentence matters, and that polarity items can exist in complex statements requiring a fundamental understanding of human language for correct interpretation. Therefore, a model just working with bag-of-words or even n-gram features does not appear to be sufficient for practical sentences that require spatial or syntactic understanding.

Polarity items are permitted only within specific licensing contexts, which means they can only occur in specific sentential structures. Our paper explores two licensing contexts: downward entailment and non-monotone quantifiers. Under downward entailment, the sentence acts as a monotone decreasing function such that when parts of the sentence are removed monotonically, the relative strength of a statement monotonically decreases. For example, "nobody moved into the house" implies "nobody moved into the house quickly", so "nobody moved" is a monotone-decreasing phrase. On the other hand, non-monotone quantifiers lack clear downward or upward entailment (Giannakidou, 2002). For example, the phrase "exactly three men never moved" does not entail "exactly three men never moved quickly" and vice-versa, so it has non-monotone entailment. The linguistic phenomenon of licensing contexts and polarity items are a fundamental part of human language, and the metric to measure the performance of a sentiment analyzer should consider how it handles these polarity items.

3 Related Work

To the best of our knowledge, there are no previous studies investigating the weaknesses of Google Natural Language, CoreNLP, or other probabilistic sentiment analyzers in classifying sentences with polarity items.

	Classification accuracy									
	Downward entailment					Non-monotone quantifier				
	a	b	c	d	e	a’	b’	c’	d’	e’
Google NLP	0%	0%	0%	80%	80%	0%	0%	0%	93.3%	86.7%
Stanford CoreNLP	0%	0%	0%	33.3%	53.3%	0%	0%	0%	33.3%	66.7%

Table 1: Summary of classification accuracy on downward entailment and non-monotone quantifiers. Each category indicates 15 test sentences. a: Bill has never done anything [negative adjective], b: [subject phrase] has never done anything [negative adjective], c: Bill has not done anything [negative adjective], d: Bill has done something [negative adjective], e: [subject phrase] has done something [negative adjective]. a’-e’: instead of Bill, we use a non-monotone quantifier (e.g. exactly half).

4 Experiment

4.1 Methodology

We developed 150 test sentences derived from two base sentences, under two different licensing contexts: downward entailment and non-monotone quantifiers. We first tested on Google Cloud Natural Language (Google, 2018) and then repeated the experiment on the Stanford CoreNLP sentiment analyzer (Socher et al., 2013). Each base sentence consists of a subject phrase, a verb phrase, some polarity item(s), and some modifiers (e.g. painful). The rest of the test sentences consist of variations on the base sentences in the specific phrases, polarity items or modifiers used, allowing us to identify the sentence element responsible for misclassification. We chose 15 sentences with minimal sentiment ambiguity per category, allowing us to demonstrate with statistical confidence the inability of these sentiment analyzers to capture syntactic phenomena.

4.2 Results

For both downward entailment and non-monotone quantifiers, we considered two base sentences:

1. (A) has/have [never or not] done anything (B: negative adjectives). These include categories a, b, c, a’, b’ and c’.

2. (A) has/have done something (B: negative adjectives). These include categories d, e, d’, and e’.

For (A), we used subject phrases such as “I” and “Bill and his friends”, and in the case of non-monotone quantifiers, we used subjects such as “exactly half”, “99% of people”, and “exactly ten students”.

4.2.1 Downward entailment

Sentences in category a (eg: “Bill has never done anything terrible”) should be classified as positive. Both Google Natural Language and CoreNLP achieved 0% accuracy on sentences in this category as shown in Table 1. The sentiment analyzers classified these sentences as either negative or neutral. We consider neutral classification incorrect, as the overall sentence is expressing a positive sentiment towards the subject for possessing good moral character. Our varied adjectives reveals that the adjective used is not the reason for misclassfication.

To investigate misclassification further, we varied the subject phrase (A) with fifteen different subject phrases (category b). We observed that sentences such as “Bill has never done anything terrible” and “Bill in my English class has never done anything terrible.” are classified as negative by Google Natural Language and CoreNLP. The magnitude of the negative sentiment remains the same, indicating that minor variations in the subject phrases do not affect the sentiment of the sentence. However, while CoreNLP classifies “Bill has never done anything grumpy” as neutral, it classifies “Sally has never done anything grumpy” as negative. Google Natural Language classifies both as negative, although the score changes slightly. This example demonstrates another weakness of the sentiment analyzers: they treat subject phrases with the same context (“Bill” vs. “Sally”) differently.

Next, we show that the reason for misclassification is not the presence of “never” by varying the sentences to contain “not” (category c; e.g. “Bill has not done anything terrible”). Both Google Natural Language and CoreNLP classify all 15 sentences as negative and yield the same classification accuracy of 0%. We note that for some sentences there is a minor change in the score, but

          (JJ terrible)))))
  (.)))
```

Figure 2: Parse tree for “Exactly half had never done anything terrible.”

the sentiment of sentences remains the same.

We now consider sentences in category (2) that are semantically opposite to sentences in category (1). For example, “Bill has done something terrible” or other variations (types d and e) should be unambiguously classified as negative. Here, Google Natural Language achieves a classification accuracy of 80% (12 out of 15 test sentences) compared to CoreNLP’s 33.3% (5 out of 15 test sentences). For Google Natural Language, it is evident that the element that causes misclassification is the negative polarity item that the analyzer fails to interpret. The analyzer fails to invert the negative sentiment of negative adjectives (B) and thus classifies the sentence as negative or neutral. CoreNLP, however, does poorly on all categories, although it does significantly better on sentences in category (2).

We now consider the parse tree of the original sentence “Bill has never done anything terrible” (Figure 1) to demonstrate the successful parse of “has never done anything terrible” as a single verb phrase. The failure of the analyzers to correctly determine sentiment implies that despite noting the sentence’s hierarchical structure, they are unable to understand long-term dependencies - they lack an understanding of the c-command relation (Radford, 2004).

4.2.2 Non-monotone quantifiers

We repeated the same analysis for non-monotone quantifiers by including non-monotone quantifiers within the subject phrase. For example, “Exactly half had never done anything terrible” and its sister sentences (e.g. “Ninety percent of parents had never done anything terrible”) should be classified as positive. Similar to our findings on downward entailment, both Google Natural Language and CoreNLP achieve a classification accuracy of 0% on the three classes of sentences within category (1): a total of 45 sentences from class (a’), (b’), and (c’) as shown in Table 1. Analyzers again determine “had never done anything terrible” as a single verb phrase, as shown in a parse tree in Figure 2.

For semantically opposite sentences (class (d’) and (e’)), we get a similar result as in downward entailing sentences, although the classification accuracy slightly increases for both analyzers. Again, we consider neutral classification as a misclassification, as the sentence clearly contains either a positive or negative sentiment towards the subject.

We interpret our experiment with non-monotone quantifiers as follows: (1) both CoreNLP and Google Natural Language lack an understanding of the negative polarity item “anything” and (2) the variation of subject phrases results in a minor change in the sentiment. We note that, as in the case of downward entailment, the failure of the analyzers implies an inability to understand the c-command relation (Radford, 2004). We note a limitation of our experiment: the selection of arbitrary adjectives. However, the 15 adjectives used are commonly used to describe humans, and the result was quite consistent. Further, we found coherent results for both downward entailment and non-monotone quantifiers and were able to highlight the lack of long-distance dependency understanding in state-of-the-art analyzers. Finally, we highlight the importance of assessing performance of sentiment analyzers using practical sentences that involve not only negation as in previous studies (Socher et al., 2013), but also polarity items such as the 150 sentences used in our experiment.

5 Discussion

Our experiment indicates that the Stanford CoreNLP sentiment analyzer (Socher et al., 2013) and Google Cloud Natural Language (Google, 2018) do not understand the c-command relation (Radford, 2004). We now argue that this issue is not a result of the training set used, but rather a fundamental inability of the model class. First, we note that long-term dependencies are a well-known weakness of probabilistic models, even those specifically designed to capture them, such as bidirectional RNNs or LSTMs (Zhang et al., 2018). Next, we note that the sentences that we tested are general sentences whose components could be found in any linguistic corpus; in fact, CoreNLP's treebank does contain annotated sentences containing the "... has never ..." or "... has no ..." constructions, and so the model should correctly analyze such sentences. As a result, we draw the conclusion that these models lack an understanding of long-term dependencies, and based on our experiments, they specifically fail to understand the c-command relation (Radford, 2004). Finally, we remind readers that the c-command relation is associated with Chomskyan grammars; and need not be necessary within other models of syntax. Consequently, learning the c-command relation may lead to better analyzers, but it need not be the only way to improve performance.

6 Conclusions

We evaluated two state-of-the-art sentiment analyzers, Stanford CoreNLP (Socher et al., 2013) and Google Cloud Natural Language (Google, 2018), using sentences with negative polarity items under two different licensing contexts: downward entailment and non-monotone quantifiers. Through such analysis, we noted that current analyzers lack a complete understanding of negative polarity items, and by extension, the c-command relation. We have also produced a set of sentences that can be used to test future analyzers. This work can be extended to validate other analyzers, test non-probabilistic sentiment analyzers or build, new improved sentiment analyzers. We have made the set of misclassified sentences available as supplementary material.

Abstract

Are brand names such as *Nike* female or male? Previous research suggests that the sound of a person's first name is associated with the person's gender, but no research has tried to use this knowledge to assess the gender of brand names. We present a simple computational approach that uses sound symbolism to address this open issue. Consistent with previous research, a model trained on various linguistic features of name endings predicts human gender with high accuracy. Applying this model to a data set of over a thousand commercially-traded brands in 17 product categories, our results reveal an overall bias toward male names, cutting across both male-oriented product categories as well as female-oriented categories. In addition, we find variation within categories, suggesting that firms might be seeking to imbue their brands with differentiating characteristics as part of their competitive strategy.

1 Introduction

When naming humans, clear gender conventions seem to exist in every society. For example, in the English-speaking world, *Jessica*, *Linda*, and *Nancy* are female names, while *John*, *Michael*, and *William* are male names. In turn, decades of gender-stereotyping research suggest that people associate particular genders with particular characteristics. For example, females are viewed as "warm," "expressive," and "emotional," while males are viewed as "assertive," "competent," and "rational" (Broverman et al., 1972; Spence and Helmreich, 1979). We ask whether any of this applies to commercially-traded brands, and is there a gender strategy underlying brand names? If so, what does this strategy say about firms' motivations in making these choices? Is it driven by product category characteristics or is it driven by competitive strategy considerations within each category?

In this paper, we take the first steps toward answering these questions. We start by developing a machine-learning method to predict the gender of human first names. Large labeled data sets of human first names are available from the U.S. and the U.K. to train such an algorithm. Using various linguistic features of such names—for example, "a" ending, sonorant ending (m, n, ng, l, r), etc.—we find that we can predict human gender quite accurately (approximately 80% success rates). We then use this algorithm to predict the masculinity-femininity of brand names (see Figure 1). For this purpose we have identified another data set where a large number of brand names are available, pre-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1128–1132
Brussels, Belgium, October 31 - November 4, 2018.

classified into many different product categories—detergents, analgesics, health and beauty aids, electronics, etc. Finally, having classified brand names by gender, we ask what the variation in brand name gender, within and across product categories, can tell us about the marketing strategy in brand name choices. By using NLP-methods to analyze brand names, we contribute not only a new application domain for such methods, but also, importantly, advance the branding literature by suggesting that brand name gender may be part of a brand's positioning strategy.

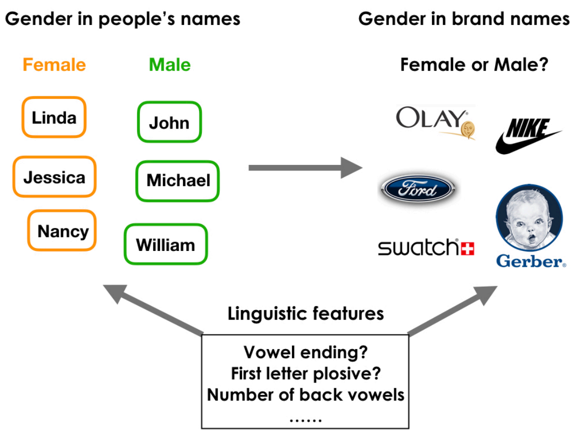

Figure 1: Illustration of our methodology. A gender classifier trained on people's names is applied to brand names.

2 Sound symbolism and gender of names

Existing work from linguistics has suggested that male and female names have different phonological properties. Here we summarize gender-related features of first names identified in the literature: 1) Names ending in the mid-central unstressed vowel sound 'uh' are almost always feminine (Lieberson and Bell, 1992); 2) Names ending in a vowel tend to be feminine (Slater and Feinman, 1985); 3) Names ending in a sonorant (m, n, ng, l, r) may be either masculine or feminine (Barry and Harper, 1995; Lieberson and Bell, 1992; Slater and Feinman, 1985); 4) Names ending in a 'fricative' or 'affricate' produced by restricting airflow through the mouth to create frication (s, z, f, v, h, sh, ch, dj) tend to be masculine (Barry and Harper, 1995); 5) Names ending in a 'plosive' produced by stopping airflow through the mouth (p, b, t, d, k, g) are almost always masculine (Barry and Harper, 1995); 6) Words and names featuring fricatives are more associated with femininity relative to those with plosives, which are associated with masculinity (Folkins and Lenrow, 1966; Guèvremont and Grohmann, 2014; Klink, 2000); 7) The front / back vowel distinction mirrors that of plosives and fricatives. Brand names with front vowels, such as "i," and "ee," seem more feminine than names with back vowels, such as "oh," "oo" (Klink, 2000).

Despite the rich literature on sound symbolism and gender, sparse attempts have been made to systematically examine the contribution of different linguistic features in gender prediction of names at scale (Bird et al., 2009). Although recent work has examined gender issues in web-crawled data (Zhao et al., 2017) and historical corpora (Garg et al., 2018), there has been no study on exploiting linguistic features to predict gender of brand names.

3 Computational methods

Table 1 summarizes the full set of features that we used for modeling. We took orthographic forms of names as a proxy for phonetic forms due to practical scalability. We started by considering names ending in the sound 'uh' as ending with the letter 'a', because 'a' accounts for the vast majority of instances of this sound. After this initial step, we dummy-coded names ending in a vowel with the letters 'a', 'e', 'i', 'o', 'u', and 'y' (i.e., any name ending in a vowel was coded 1 on this feature, whereas all other names were coded 0; see Table 1 for an illustration). We coded names ending in fricatives and plosives with the letters 'p', 'b', 't', 'd', 'k', 'g', 'f', 'v', 's', 'z', 'th', 'sh', 'ch', and 'dge'. We coded sonorant endings based on the letters 'm', 'n', 'ng', 'r', 'and 'l'.

We also considered word-initial occurrences of all the previously mentioned sounds, making symmetric hypotheses that word-initial vowels will predict femininity, word-initial plosives will predict masculinity, and that sonorants and fricatives may be predictive in some way. Coding was based on the same letters with some minor variations (the letters 'w' and 'y' were included with sonorants, and the letter 'j' was included with fricatives).

Finally, we considered the total number of occurrences of all the previously mentioned sounds, hypothesizing that the total number of vowels will predict femininity, total number of plosives will predict masculinity, and total number of sonorants and fricatives may be predictive in some way. Additionally, we consider two distinct categories of vowels: front vowels, represented by the letters 'i', and 'e', which we hypothesize will predict femininity, and back vowels, represented by the letters 'o' and 'u', which we hypothesize will be more predictive of masculinity. We excluded features such as stressed syllable and number of syllables that have been linked with name gender (Slater and Feinman, 1985) because they require manual coding and do not scale. However, we considered total number of letters as a proxy for name length.

Table 1: Features for gender prediction of people's and brand names, with example values for *Linda*.

Linguistic feature	**Value of *Linda***
A ending?	1
Vowel ending (a, e, i, o, u, y)?	1
Fricative ending (f,v,th,s,z,sh,ch,dge)?	0
Sonorant ending (m,n,ng,l,r)?	0
Plosive ending (p,b,t,d,k,g)?	0
1st letter vowel (a, e, i, o, u)?	0
1st letter fricative (f,v,th,s,z,sh,ch,j)?	0
1st letter sonorant (m,n,l,r,w,y)?	1
1st letter plosive (p,b,t,d,k,g)?	0
Number of letters	5
Number of front vowels	1
Number of back vowels	0
Number of vowels (a, e, i, o, u)	2
Number of fricatives (f,v,th,s,z,sh,ch,j)	0
Number of sonorants (m,n,l,r,w,y)	2
Number of plosives (p,b,t,d,k,g)	0

We used three simple models for name gender classification based on the features we have described. For all methods, we considered binary classification (female/male) and excluded "gender-neutral" names that are ambiguous. 1) To examine how each feature contributes to name gender prediction individually, we first considered a single-feature logistic model that determines gender of a name y from one of the features x: $\log \frac{p(y=female)}{p(y=male)} = \beta_0 + \beta_1 x$. 2) To examine how features combine to name gender prediction, we considered a multivariate version of the logistic model. We applied a sparsity constraint with automatic relevance determination (Yamashita et al., 2008) to explore the minimal set of features necessary for gender determination, taking into account the fact that the features are over-complete and not interdependent, e.g. "a ending" entails "vowel ending." We used the default settings on the hyper-parameters in the open-source Python package. [1] 3) We considered random forest as an alternative multivariate classifier, based on decision trees using the Gini impurity criterion and bootstrapped subsamples in ensemble averaging. We used the Python $sklearn$ package for this model.

4 Data

We draw data from three primary sources, two for people's names and one for brand names. For people's names, we relied on databases of U.S. and U.K. names available at `https://github.com/OpenGenderTracking/globalnamedata/tree/master/assets`. The U.S. data come from the yearly birth records maintained by the U.S Social Security Administration from 1880 to 2013; the U.K. data come from the UK Office of National Statistics, the Northern Ireland Statistics and Research Administration, and the Scotland General Register Office. After removing names that are labeled as both male and female, we ended up with 97102 unique English names (60984 female, 36118 male) to work with. For brand names, we relied on Kantar Media's Stradegy database. This database documents U.S. advertising spending by brands in virtually every product category. [2] In this case, after removing multi-word names that are derivative brands (e.g., *Ford Escort*) and a small number (66) of names that are common English words (e.g., *Coach*) based on the $\sim$5000 most frequent words in the British National Corpus, [3] we ended up with 1021 brand names in 17 product categories. We represented each name as a 16-dimensional vector based on the features described, and we made all data available in the supplementary materials.

5 Results

Evaluation. We tested all gender classifiers on the English dataset in a supervised setting. Table 2 summarizes the model performances in a five-fold cross validation with the data initially randomized.

Overall, all models predicted gender of people's names substantially above chance (50%). In particular, the multivariate models performed better than the single-feature model though the difference is small, suggesting that gender information is likely encoded in a restricted set of features. Figure 2 confirms this finding by showing the fitted weights on different features from the sparse logistic classifier. The top four features with the highest weights are "a ending," "plosive ending," "sonorant ending," and "fricative ending," suggesting the dominance of gender information in the ending of names. The same four features also yielded the highest predictive accuracies in the single-feature model except for the feature of "vowel ending" - 75.1%: a end-

ing 65%; plosive ending - 66%; sonorant ending - 72%; fricative ending - 66%.

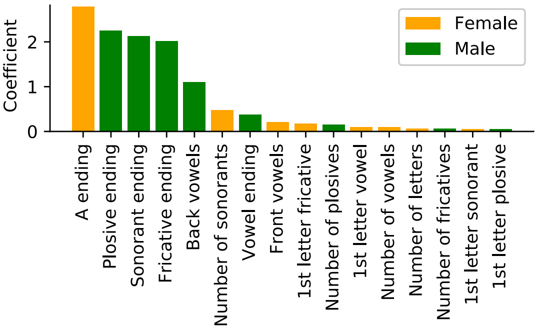

Figure 2: Feature coefficients in logistic regression.

We observed a small difference in predictive accuracy between the random forest model and the sparse logistic model, suggesting the features are relatively robust to classifier variation. We also observed that predictive accuracies on male names tend to be poorer than those on female names, possibly because some male names also end with vowels 27.1%, e.g., *Joshua*), but female names predominantly end with vowels 76.4%).

Table 2: Model accuracies on name gender prediction.

Model	Acc. %	Female %	Male %
Single-feature	75.1	76.4	72.9
Sparse logistic	80.5	83.9	74.9
Random forest	81.8	85.4	75.7

Brand name gender prediction. We applied the three classifiers to the brand name database, by using the weights estimated from the English name database. We used a conservative criterion in determining gender of brand names. In particular, we took majority vote from prediction of the three classifiers for any given brand name as opposed to relying on prediction from a single classifier. [4]

Although it is difficult to fully evaluate the accuracy of our classifiers on brand name gender, we identified "true" gender of a small set of brand names where etymology can be found from the Oxford English Dictionary, summarized in Table 3. We found that our procedure of gender classification yielded an accuracy of 83.3% on this small set, which is consistent with the accuracies we obtained with people's names. We refrained from evaluating our models against human judgments on brand name gender, because people's conceptions might be biased or primed given the products associated with brands (e.g., cosmetic brand names might be perceived as female). Figure 3 visualizes the brand names in the feature space we considered, with predicted gender and annotated example brands.

Table 3: Brand names with gender identified from the OED and model-predicted gender (Male vs. Female).

Brand	Etymology	True	Pred.
Amazon	Female warrior (1398)	F	M
Titan	Helio's father (1413)	M	M
Pandora	Woman (1581)	F	F
Hermes	Zeus' son (1605)	M	M
Nike	Goddess (1846)	F	F
Lincoln	US president (-)	M	M

Brand name gender distribution. We analyzed gender distributions across and within the 17 product categories. Across categories, we observed a strong asymmetry in frequency between male and female brand names. The scatter-plot in Figure 3 illustrates that male and female brand names separate in sound-attribute space. tSNE (Maaten and Hinton, 2008) with 17 feature attributes was used to generate this plot, which shows that male and female names separate along the first dimension, but not in the second dimension. This suggests that these names share commonalities, but they are also different.

We observed that the gross number of male brand names is significantly greater than the number of female brand names (binomial $p < 0.0001$). Several factors could contribute to this bias. For example, many present-day brands originated long before gender equality was valued, and the brand names that emerged from these male-dominated eras tend to skew masculine. It should also be noted that many brands are named after company founders (e.g., *Ford*), and surnames may tend to be more masculine than first names.

A more fine-grained analysis in the individual product categories revealed nuanced patterns in gender distribution (Figure 3). Although the male bias we observed at the broad level applies to 14 of 17 categories (binomial $p < 0.0001$) including some intuitive ones such as "power tools," "military," and "baseball equipment," this bias is surprisingly weak or non-existent in "car / trucks" and "men haircare" where we expect more male as opposed to female consumers. Second, brands where

---

[4] We also considered a more stringent criterion by analyzing only the subset of brand names where all three classifiers agreed on gender prediction ($N = 702$ out of 1021 names), and our results are similar based on that subset of brand names.

we expect more female consumers such as "jewelry," "cosmetics," and "womens underwear" have a relatively high proportion of male-oriented names. These patterns suggest that although male brand names might be an overall preferred convention, gender-polarized brands might have adopted a reversal strategy in naming with the opposite gender.

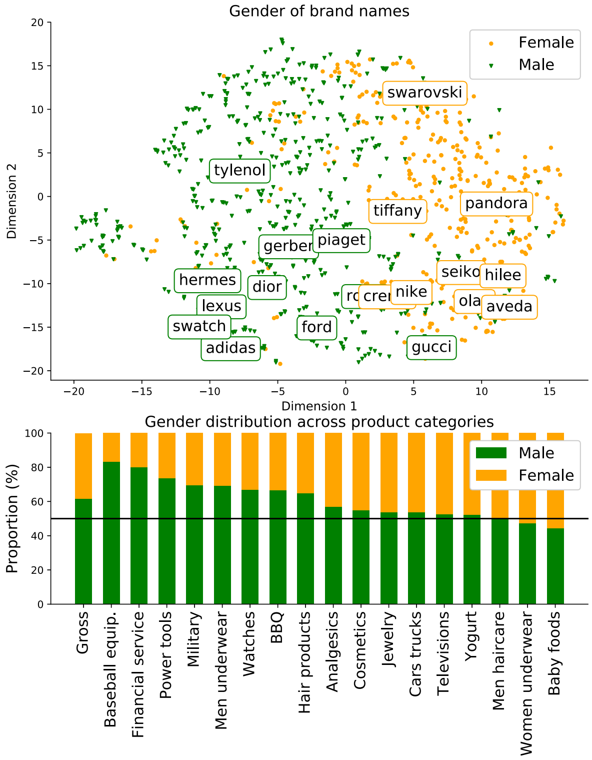

Figure 3: Predicted gender of 1021 brand names given 16 features and mapped a 2D space via tSNE. Bottom panel shows gender proportions in gross and 17 individual product categories.

6 Discussion

While the notion of brand name gender is an intriguing concept in theory, its practical measurement has proved elusive. This paper has shown that NLP-methods can be used fruitfully to get a handle on this problem. Our results suggest that brand names are more male-oriented than female-oriented overall. However, under this broad result, there are several interesting nuances. First, the overall preference for male names applies not only in categories that are primarily male-oriented, but also in some categories that are primarily female-oriented. Second, there is considerable within-category variation in brand name gender. Understanding these nuances is an important topic for future research.

Abstract

Fact-checking of textual sources needs to effectively extract relevant information from large knowledge bases. In this paper, we extend an existing pipeline approach to better tackle this problem. We propose a neural ranker using a decomposable attention model that dynamically selects sentences to achieve promising improvement in evidence retrieval F1 by 38.80%, with (×65) speedup compared to a TF-IDF method. Moreover, we incorporate lexical tagging methods into our pipeline framework to simplify the tasks and render the model more generalizable. As a result, our framework achieves promising performance on a large-scale fact extraction and verification dataset with speedup.

1 Introduction

With the rapid growth of available textual information, automatic extraction and verification, also known as fact-checking, has become important in order to identify relevant and factual information from the ever-growing information pool. The FakeNews Challenge (Pomerleau and Rao) addresses fact-checking as a simple stance detection problem, where the article is verified by checking the stance agreement between an article's title and content. Similar to the FakeNews, (Rashkin et al., 2017; Vlachos and Riedel, 2014) focused on political statements from Politifact.com to verify the degree of truthfulness. However, they assume that the gold standard documents containing the evidence are already known, which overly simplifies the task.

Question Answering (QA) is similar to fact-checking in the sense that a question and its answers can be considered as a claim and evidence respectively, but the answers may come from a large-scale database. Several approaches (Chen et al., 2017a; Ryu et al., 2014; Ahn et al., 2004) proposed QA system utilizing resources such as Wikipedia, which is more comprehensive and incorporates wider world knowledge. However, the main focus is to identify only the "correct" answers that support a given question. Since the ability to refute is as important as to support, it does not fully address the verification problem of fact-checking.

Evidence	**Finding_Dory**: Directed by Andrew Stanton with co-direction by Angus MacLane, the screenplay was *written by Stanton and Victoria Strouse* **Andrew_Stanton**: Andrew Stanton -LRB- born December 3, 1965 -RRB- is an *American film director* , screenwriter, producer and voice actor based at Pixar.
Label	REFUTE

Table 1: Example of verified claim with evidence from multiple Wikipedia pages

Recently, Thorne et al. (2018) proposed a public dataset to explore the complete process of the large-scale fact-checking. It is designed not only to verify claims but also to extract sets of related evidence. Nevertheless, the pipeline solution proposed in that paper suffers from following problems: 1) The overall performance (30.88% accuracy) still needs further improvement to be applicable to the evidence selection and classification, which also highlights the challenging nature of this task. 2) The evidence retrieval using Term Frequency-Inverse Document Frequency (TF-IDF) is time-consuming since the TF-IDF between a claim and set of candidate evidence cannot be computed in advance.

In this paper, we extend the original pipeline solution to achieve faster and better fact-checking results. Our main contributions are: 1) Propose a neural ranker using decomposable attention (DA) model for evidence selection to speed up (×65) and outperform related works. 2) Incorporate several lexical tag information to effectively simplify

the problem and generalize the models. 3) Improve the overall fact extraction F1 by 38.80% and verification accuracy by 2.10% to achieve the state-of-the-art performance on the dataset.

2 Methodology

Our pipeline framework[1] has three main modules: document retrieval (DR), evidence selection (ES), and textual entailment recognition (TER). The goal is to verify a given claim with a set of evidence from Wikipedia (Table 1). The verification labels are support, refute and not enough information (NEI) to verify.

2.1 Lexical Tagging

In our framework, two lexical tags (i.e. part-of-speech (POS) and named entity recognition (NER)) are used to enhance the performance. We compute the tags for claims in advance using the Stanford CoreNLP (Manning et al., 2014) library. Using this information is helpful in the following ways: 1) it helps keyword extraction for each claim. 2) it reduces the out-of-vocabulary (OOV) problems related to name or organization entities, for better generalization. For example, a claim like "Michael Jackson and Justin Timberlake are friends," is replaced as "PERSON-1 and PERSON-2 are friends". In this way, we encourage our model to learn verification without dealing with the real entity values but the delexicalized indexed tokens.

2.2 Document Retrieval (DR)

For document retrieval, we extend the method of DrQA (Chen et al., 2017a), which calculates cosine similarity between query and document, using binned unigram and bigram TF-IDF features. We refer to this method as DR_{tfidf}.

Instead of directly selecting top k document using TF-IDF as in DR_{tfidf}, our document retriever DR_{rerank} use TD-IDF to reduce the search space from 5.4M to 100 documents. Re-ranking is then applied to select the top k documents. For re-rank, we defined a score function f_{rank} that ranks the relevance of the document by considering both the title and the content as follows:

$$r_{claim} = \frac{\text{POS}_{match}}{\text{POS}_{claim}}, r_{title} = \frac{\text{POS}_{match}}{\text{POS}_{title}},$$
$$f_{rank} = r_{claim} \times r_{title} \times tf\text{-}idf$$

To capture the relevance from the title, all the POS tags with high discriminating power (NN, NNS, NNP, NNPS, JJ, CD) of a claim are chosen as keywords. POS_{claim} and POS_{title} are the counts of such POS tags inside the claim and title respectively. POS_{match} is the count of common POS keywords in the claim and the title; r_{claim} is a ratio between POS_{match} and POS_{claim} to reward the documents with higher keyword hits; r_{title} is the ratio between POS_{match} and POS_{title} to penalize those documents with more candidate keywords as it is more likely to have keyword hits with more candidates. We incorporate the TF-IDF score ($tf\text{-}idf$) to ensure that the content information is not neglected. Our experiments show that our re-rank strategy increases the document recall compared to the single-step approach (Table 2). To decide on the optimal value for hyper-parameter k, full-pipeline performance was compared to evaluate the effect of k on final verification accuracy.

2.3 Evidence Selection (ES)

In this module, l sentences are extracted as possible evidence for the claim. Instead of selecting the sentences by recomputing sentence-level TF-IDF features between claim and document text as in Thorne et al. (2018), we propose a neural ranker using decomposable attention (DA) model (Parikh et al., 2016) to perform evidence selection. DA model does not require the input text to be parsed syntactically, nor is an ensemble, and it is faster without any recurrent structure. In general, using neural methods is better for the following reasons: 1) The TF-IDF may have limited ability to capture semantics compared to word representation learning 2) Faster inference time compared to TF-IDF methods that need real-time reconstruction.

The neural ranker DA_{rank} is trained using a fake task, which is to classify whether a given sentence is an evidence of a given claim or not. The

---

Time		3.57s	0.055s					

Table 3: Oracle evidence selection macro-recall in the test set using gold documents (SUPPORT/REFUTE).

output of DA_{rank} is considered as the evidence probability. The training samples are unbalanced since there are more unrelated sentences than evidence sentences. Note that the classifier's accuracy on the fake task is not crucial because the choice of evidence is based on the relative score of relevance compared to other candidates. Therefore, it is not necessary to balance positive and negative samples using up/down-sampling, to the contrary, making it unbalanced actually improved the performance (Table 3).

Unlike the k value which is fixed, the l value is selected dynamically based on the evidence score of DA_{rank}'. It is used as a confidence measure of the given sentence being an evidence. Evidence with the score below fixed threshold value th is eliminated. Hence, each claim will have a different number of l evidence. To decide on th, we also carry out the full-pipeline evaluation. We propose the dynamic selection of l because we hypothesize that any wrong evidence, or noise, from early module could harm the subsequent RTE module.

2.4 Recognizing Textual Entailment (RTE)

Given a claim and l possible evidence, a DA_{rte} classifier is trained to recognize the textual entailment to be support, refute or not enough information to verify (NEI). Same as Thorne et al. (2018), we use the decomposable attention (DA) between the claim and the evidence for RTE. DA model decomposes the RTE problem into subproblems, which can be considered as bi-direction word-level attention features. Note that the DA model is utilized over other models such as as Chen et al. (2017b); Glockner et al. (2018), because it is a simple but effective model.

Our DA_{rte} model must correctly decide whether a claim is NEI, when the evidence retrieved is irrelevant and insufficient. However, NEI claims have no annotated evidence, thus cannot be used to train RTE. To overcome this issue, same as (Thorne et al., 2018), the most probable NEI evidence are simulated by sampling sentences from the nearest page to the claim using the document retrieval module.

	MLP	DA_{rte}	DA_{rte}+NER
Accuracy (%)	63.2	78.4	**79.9**

Table 4: Oracle RTE classification accuracy in the test set using gold evidence.

3 Experimental setup

Dataset: FEVER dataset (Thorne et al., 2018) is a relatively large-scale dataset compared to other previous fact extraction and verification works, with around 5.4M Wikipedia documents and 185k samples. The claims are generated by altering sentences extracted from Wikipedia, with human-annotated evidence sentences and verification labels (e.g. Table 1). The training/validation/test sets of these three datasets are split in advance by the providers. Note that the test-set was equally split into 3 classes: Supported (3333), Refuted (3333), NEI (3333).

Training: We trained our models end-to-end using Adagrad optimizer (Duchi et al., 2011). The embedding size is set to 200 and initialized with GloVe (Pennington et al., 2014). The dropout rate is set to 0.2. In all the datasets, we tuned the hyper-parameters with grid-search over the validation set.

Evaluation: For each module, we independently measure oracle performance, where we assume gold standard documents and set of evidence are provided (oracle evaluation). For the final full-pipeline, we compare to and follow the metric defined in Thorne et al. (2018). NoScoreEv is a simple classification accuracy that only considers the correctness of the verification label. On the other hand, ScoreEv is a stricter measure that also considers the correctness of the retrieved evidence. Hence, it is a more meaningful measure because it considers the classification to be correct only if appropriate evidence is provided to justify the classification.

4 Experimental Results

4.1 Oracle Performance

Document Retrieval: As shown in Table 2, our count-based re-rank strategy outperforms the TF-IDF method.

Take $k = 1$ as an example, we achieve 60.99% recall using only one document, which is $\sim$30% higher than TF-IDF approach. Given that the recall upper-bound of re-rank is 0.8886 (k=100), our method manages to retrieve near the limit by just retrieving a few documents. Note that there is

k	DR results			RTE results

				ScoreEv	NoScoreEv	Precision	Recalll	F1
0.2	**0.653**	0.275	0.353	0.405	0.540	0.337	**0.629**	0.439
0.4	0.607	0.349	**0.406**	0.418	**0.542**	0.481	0.586	0.528
0.6	0.535	**0.368**	**0.406**	**0.424**	0.525	0.618	0.517	**0.563**
0.8	0.413	0.330	0.348	0.416	0.484	**0.772**	0.400	0.527

Table 6: Effect of de-noising ES modules on RTE score

a trade-off between the document recall and the noise ratio (i.e. low precision). As shown in Table 5, $k = 2$ with a low recall but high precision and F1 has the highest accuracy. This means DR that can effectively leverage this trade-off (therefore, high F1) performs the best. Therefore, we select $k = 2$ for our full-pipeline.

Evidence Selection: In Table 3, the trained neural ranker achieves a promising recall of 96.8%. In the case of $l = 5$, our neural ranker can perform 5% better than the TF-IDF method. Here, we use fixed $l = 5$ results for fair comparison with TF-IDF method. The ratios in Table 3 are the ratio of negative samples we tried to train the fake task. For example, 1:4 means that four negative sentences are sampled for each true evidence sentence. The results further give supports to our assumption that using unbalanced up-sampling actually help train our neural ranker. Along with performance gain, we also achieve a drastic gain in inference time by around 65 times from 3.57 seconds to 0.055 seconds for each sample.

The full-pipeline results for different values of th is shown in Table 6. Similar to document retrieval, having a high F1 score is the most important factor in assuring high full-pipeline performance. This is because providing a succinct set of evidence makes the verification task easier for the RTE module. Therefore, we choose DA_{rank}+NER model with $th = 0.6$ for the full-pipeline.

Recognizing Textual Entailment: The oracle classification accuracy for RTE is shown in Table 4. The MLP is a simple multi-layer perceptron using TF and TF-IDF cosine similarity between the claim and evidence as features as shown in Thorne et al. (2018). The highest accuracy achieved is 79.9% using DA_{rte} with NER information, thus, we further evaluate the full-pipeline accuracy on this setting.

4.2 Full pipeline Performance

Combining each of our improved pipeline modules using $k = 2$, $th = 0.6$, the full pipeline results are shown in Table 7. Our proposed framework can achieve 42.43% in ScoreEv and 52.54% in NoScoreEv, which outperforms DR_{tfidf}+DA by 11.55% and 2.10%, respectively. The evidence retrieval F1 in our full framework is 56.3%, which is improved promisingly by 38.80%.

5 Related Work

Prior work (Vlachos and Riedel, 2014; Ciampaglia et al., 2015) have proposed fact-checking through entailment from knowledge bases. Some works have investigated fact verification using PolitiFact data (Wang, 2017; Rashkin et al., 2017) or FakeNews challenge (Pomerleau and Rao). Most closely related to our work, Thorne et al. (2018) addresses large-scale fact extraction and verification task using a pipeline approach. In addition, question answering (Dang et al., 2007; Chen et al., 2017a; Ryu et al., 2014; Ahn et al., 2004) and task-oriented dialog systems (Dhingra et al., 2017;

Model	Label Accuracy (%)		Label			Evidence F1
	ScoreEv	NoScoreEv	Precision	Recall	F1	
DR_{tfidf} + MLP *	21.80	38.75	0.500	0.387	0.310	0.175
DR_{tfidf} + DA *	30.88	50.44	0.530	0.520	0.517	
Proposed	**42.43**	**52.54**	**0.533**	**0.527**	**0.523**	**0.563**

Table 7: Full-pipeline evaluation on the test set using $k = 2$ and $th = 0.6$. The first and the second one (with *) are the baselines from Thorne et al. (2018).

Madotto et al., 2018) also have similar aspects to these works, although aiming at a different goal.

Other fields that are related to the particular individual modules of our system are the following: Document and evidence retrieval for identifying text segments and documents to support a given claim (Salton and Buckley, 1987; Le and Mikolov, 2014; Cartright et al., 2011; Bellot et al., 2013; Rinott et al., 2015). Recognizing textual entailment that aims to determine whether a hypothesis h can justifiably be inferred from a premise (Dang et al., 2007; Bowman et al., 2015; Parikh et al., 2016; Chen et al., 2017b; Glockner et al., 2018). In some of these work (Rinott et al., 2015; Rashkin et al., 2017), the lexical and linguistic features are leveraged to further improve the performance.

6 Conclusion

In this paper, we extend the pipeline framework for fact-checking and propose a neural ranker for evidence selection. Our experiments show that the usage of lexical tagging is helpful in simplifying the task and improving the generalization ability. Moreover, reducing noise in the input of RTE module, by de-noising the DR and SR modules, appears to be crucial for improving the overall performance. As a result, our ranker outperforms the TF-IDF method by 38.8% in evidence retrieval F1, with 65 times faster inference speed, achieving a promising performance in a large-scale fact extraction and verification dataset.

Abstract

We leverage a popularity measure in social media as a distant label for extractive summarization of online conversations. In social media, users can vote, share, or bookmark a post they prefer. The number of these actions is regarded as a measure of popularity. However, popularity is not determined solely by content of a post, e.g., a text or an image it contains, but is highly based on its contexts, e.g., timing, and authority. We propose *Disjunctive model* that computes the contribution of content and context separately. For evaluation, we build a dataset where the informativeness of comments is annotated. We evaluate the results with ranking metrics, and show that our model outperforms the baseline models which directly use popularity as a measure of informativeness.

1 Introduction

Online conversations are increasingly significant for communication, e.g., Slack[1] for work communication and Reddit[2] for general discussion. To organize overwhelming information from these conversations, researchers have been working on summarizing online conversations (Bhatia et al., 2014; Carenini et al., 2007; Mehdad et al., 2013, 2014; Oya et al., 2014). State-of-the-art models in both abstractive (Rush et al., 2015) and extractive (Cheng and Lapata, 2016) summarization tasks are based on neural networks, but these models require large amounts of training data. In previous research, these data were created automatically by retrieving headlines and highlights of news articles edited by news editors. However, these methodologies cannot be applied to the summarization of online conversations because of a lack of summary annotations.

Distant labels have been used to train models, thereby reducing the need for manual labeling; some of these labels were also applied to the summarization task. Categories of news articles (Isonuma et al., 2017) and ratings of online reviews (Xiong and Litman, 2014) were used as distant labels in extractive summarization. However, these have been used as supplementary labels to enhance conventional summarization models, whereas we present labels which a model can solely be trained with.

We leverage a measure of popularity as a distant label. In social media, users can vote, share, or bookmark a post they prefer, and the number of these actions are regarded as indications of popularity. We assume that measures of popularity reflects the *informativeness*, the index required for a summary (Erkan and Radev, 2004), and validate whether popularity can be used as a distant label for extractive summarization. However, popularity is not solely determined by content, e.g., a text or an image, but is highly affected by contexts, e.g., timing, and authority (Cheng et al., 2017; Burghardt et al., 2017; Suh et al., 2010; Hessel et al., 2017; Jaech et al., 2015). Therefore, to utilize popularity as an indicator of informativeness, we need to exclude the effect of context.

To exclude the effect, we propose *Disjunctive model.* This model computes two scalar values; one from a content feature and the other from a context feature. These two values are then multiplied to predict the popularity. The scalar values can be interpreted as the contribution of content and context to the prediction. We assume that the contribution of content to indicate informativeness.

For evaluation, we build a test dataset where comments are annotated for informativeness. We measure informativeness as an index indicative of the best sentences to extract as a summary. We

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1139–1145
Brussels, Belgium, October 31 - November 4, 2018.

select Reddit as a data source, where the *karma score*, a measure of popularity in Reddit, is known to be affected by contexts. Our test task is to extract informative posts. Because informativeness of each post is annotated via crowdsourcing, the extracts can be ranked, but the appropriate number is unknown. Therefore, we employ ranking metrics in the evaluation. Our experiment only use karma scores for training to verify that they reflect informativeness. The results show that our model outperforms baseline models that directly adopt karma scores as an indicator of informativeness. Furthermore, our model focus on a local feature of a single post, whereas conventional centrality-based models (Erkan and Radev, 2004; Mihalcea and Tarau, 2004) use a global context of posts, and the complementary hybrid of the both models outperform both the centrality-based models and our models.

The contributions of this paper are three fold. 1) Propose a model that harnesses a popularity measure as a distant label for extractive summarization. 2) Create a dataset of online conversations in which the informativeness of contents are annotated to verify that popularity does not correlate with informativeness because of the effect of context. 3) Demonstrate that our model, when combined with a centrality-based model, outperforms baseline models in predicting the informativeness of posts.

2 Related Work

Previous research of summarizing online conversations can be categorized into graph-based methods (Mehdad et al., 2013, 2014; Shang et al., 2018), template-based methods (Oya et al., 2014), and methods which use dialogue acts as a feature (Bhatia et al., 2014; Carenini et al., 2007). In previous research, few or no training data was adopted because of a lack of labeled data. Our model harnesses a vast amount of data from social media.

Many researchers used user-contributed labels from social media as distant labels. Xiong (2014) used review scores on a movie-rating site for a summarization task. For a sentiment analysis on Twitter[3], Davidov(2010) used hashtags, and Guibon (2017) used emoji. In our study, we leverage a popularity measure for a summarization task.

Factor analysis quantifies the contribution of each feature to the result, using a linear model. For example, Suh (2010) analyzed factors contributing to popularity in Twitter. Our model assumes a linear relationship between context and content, and thus enables to utilize the contribution of content as an indicator of informativeness.

3 Data

In this study, we work with Reddit threads. A thread is a set of comments, and the first posted comment is called a submission. Comments can be made in response to submissions as well as comments under the submissions, resulting in a thread being tree-structured. Submissions and comments can be upvoted or downvoted by readers, and karma scores are computed as upvotes minus downvotes. Karma scores follow Zipf's law (Cheng et al., 2017). Therefore, we smooth the karma scores as follows:

$$f(k) = \begin{cases} \log(k+1) & (k \geq 0) \\ 0 & (k < 0) \end{cases}$$

where k represents the karma score.

Reddit is organized into subreddits by topic. Posts from the subreddits AskMen, AskWomen, and AskReddit with 420,598, 247,012, and 644,034 comments, respectively, are collected and split into training and validation sets with a 4:1 ratio. The validation sets are used for early-stopping. All comments were posted from June, 1, 2016 through June, 1, 2017.

Manual Annotation We crowdsource the annotation of comments in terms of informativeness to utilize them as test data. Annotators are asked to choose 3 informative comments from 10. We define 10 comments as a *subset*; each comment is a reply to a submission. For submissions with more than 10 replies, posts with the top 10 karma scores are selected. For each subreddit, 130 subsets were annotated, for a total of 1,300 comments. Because 10 annotators vote for 3 different comments each, the number of votes for a comment ranged from 0 to 10. These numbers we refer to as the *annotated score*. The comments in each subset are shuffled to invalidate the effect of the order in which annotators read the comments.

Liu and Liu (2008) observed that the best summary differs among annotators, especially when summarizing conversations, consequently resulting in low Kappa scores. In their study, the Kappa statistics for six different annotators varied from

253	0	Im an English major who wants to go into marketing. Wat do
228	0	Sadly people buy the first thing that the see and this is what is in season.

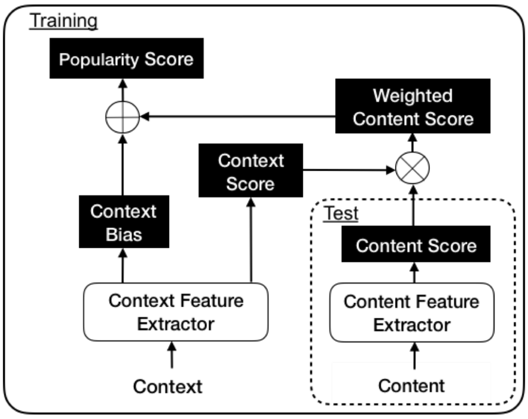

Figure 1: Description of the Disjunctive model. $\oplus$ and $\otimes$ represent addition and multiplication, respectively. The components of each model we use for training and testing are shown. Black and white squares represent scalars and functions, respectively.

0.11 to 0.35. In our study, the Fleiss Kappa coefficients (Fleiss and Cohen, 1973) of the annotated data are 0.252 for AskMen, 0.191 for AskWomen, and 0.213 for AskReddit.

The correlation coefficients of the karma scores versus the annotated scores are low: 0.063 for AskMen, 0.081 for AskReddit, and 0.107 for AskWomen. Table 1 shows some examples of posts with low karma scores and high annotated scores, and vice versa. It shows that there are informative posts with low karma scores, and non-informative posts with high karma scores. This implies that it is necessary to exclude the effect of context to leverage karma scores as distant labels for summarization.

4 Proposed Model

To exclude the effect of context from the popularity, we propose *Disjunctive model* (Figure 1). This model computes two scalar values, a *content score* and a *context score* from a content feature and a context feature, respectively by multiplying parameter vectors. The model is trained to predict popularity by multiplying the two scores and adding a *context bias*, which is also computed from a context feature. After training, the two scores represent the contribution of the content and context to popularity. We assume that the content score indicates informativeness. While training, the *popularity score* is used to predict the popularity, which is represented by the karma scores in our study. During evaluation, the content score is used for prediction of informativeness. The context score is constrained to be positive; otherwise, it can be either positive or negative, making it difficult to assume that a content score represents informativeness.

4.1 Context Feature Extractor

We use a multi-layer perceptron (MLP) to extract the features of the context of comments. Our study discusses six attributes of context: the karma score of a submission, the karma score of the previous comment, the depth in a thread, the relative time since the previous comment, the rank of the relative time among all replies to a previous comment, and the number of replies to a previous comment. The number of layers is set to 3, and the dimensions of each layer are 64.

4.2 Content Feature Extractor

We use two content extractors: long short-term memory (LSTM) as a basic language model, and a factored neural network (FNN) (Cheng et al., 2017) as a model that achieved state-of-the-art results in karma score prediction tasks. FNN, which is a language model, sequentially predicts the next words in a comment and its reply using an attention mechanism. As in the previous research, we pretrain this model using the same data used in the training, and fine-tune its parameters on the karma

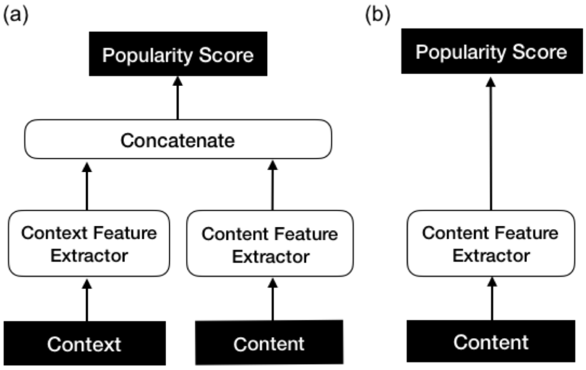

Figure 2: Description of baseline models. (a) Concat model. (b) Text model.

score prediction task. A single-layer LSTM and FNN are used and the last hidden layers are used as the content feature. The dimensions of the hidden layers are set to 64, and the dimensions of the word embedding are set to 256.

5 Experiments

We train the summarization model using karma scores as distant labels and evaluate the prediction of informativeness with the annotated dataset. As explained in Sec 3, the informativeness of each post is annotated via crowdsourcing and it is difficult to determine the appropriate number of posts needed to create a summary. Therefore, we employ ranking metrics for evaluation. In each subset, where subsets were defined in Sec 3, we rank each comment from 1 to 10 in terms of predicted scores and annotated scores. Ranks of tied scores are set randomly. To avoid randomness from affecting the result, we evaluate 100 times and compute an average as a result. We use three metrics: Spearman's Rho ($S\rho$), precision@3 (prec3), and Mean Reciprocal Rank (MRR) (Mcfee and Lanckriet, 2010).

5.1 Experimental Setting

Experiments are conducted by using mean-squared error as the loss function and Adam as the optimizer (Kingma and Ba, 2014). We replace words that appear fewer than five times with <unk>. There are 63,093 unique terms for AskMen, 53,589 for AskWomen, and 80,426 for AskReddit. The maximum length of each comment is clipped to 50. The mini-batch size is 64.

5.2 Baseline Model

We experiment with four baseline models. Two are supervised models as shown in Figure 2: the Concat model concatenates content and context features, and the Text model uses only content features. The other two are centrality-based unsupervised models: LexRank (Erkan and Radev, 2004) and TextRank (Mihalcea and Tarau, 2004). The unsupervised models only use content features. Disjunctive model use different scores for prediction in the training and in the test, as shown in Figure 1; however, Concat and Text models use a popularity score, the predicted value of a karma score, both in the training and in the test. This is because there is no substitute for the content score in these models.

5.3 Hybrid Model

The supervised models in our study, including the Disjunctive models, compute features from a single post only. To also harness the global information encoded in all posts in a subset, we build a Hybrid model which multiplies the scores from the Disjunctive model and the TextRank.

6 Results

The results of the experiments described in Sec 5 are shown in Table 2. The suffixes Disjunctive, Concat, and Text denote the supervised models described in Sec 4 and Sec 5. The prefixes LSTM and FNN indicate the models we use for content feature extractors. Among the supervised models, our Disjunctive models outperform both LSTM and FNN-based baseline models. In contrast, the results of the Concat models are poor. Unsupervised models which use the global feature of posts in a subset perform well. The FNNDisjunctive model combined with TextRank outperforms both the supervised models and the unsupervised models. To confirm that multiplication performs better in our task, we also experimented with Additive models, which simply add the context score and the content score instead of multiplying. Although better performing than the Text model, the performance was not as good as the Disjunctive model (Not shown in Table).

7 Discussion

Here we discuss the comparison of the results shown in Table 2, and how our Disjunctive model separate the effect of content and context.

Text Model vs Concat Model vs Disjunctive Model The Text model performs worse than our model. A possible reason is that karma scores can

Table 2: Result of ranking annotated scores. The best results among the supervised models are underlined, and the best results among all the models are bolded. The names of our models are also bolded.

Content Type	Model	AskMen			AskReddit			AskWomen		
		Sρ	MRR	prec3	Sρ	MRR	prec3	Sρ	MRR	prec3
Super. Local	LSTMConcat	0.021	0.279	0.297	0.028	0.294	0.323	0.146	0.315	0.367

	LSTMDisjunctive	0.046	0.325	0.327	0.137	0.362	0.384	0.302	0.409	0.452
	FNNDisjunctive	0.164	0.375	0.378	0.196	0.411	0.414	0.259	0.402	0.435
Unsup. Global	TextRank	0.300	0.405	0.417	0.301	0.425	0.435	0.291	0.416	0.422
	LexRank	0.043	0.321	0.352	0.137	0.305	0.384	0.122	0.347	0.383
Hybrid	**TextRank+LSTMDisjuntive**	0.095	0.373	0.358	0.199	0.396	0.422	0.340	**0.438**	**0.468**
	TextRank+FNNDisjunctive	**0.319**	**0.436**	**0.452**	**0.336**	**0.452**	**0.448**	**0.345**	0.437	0.460

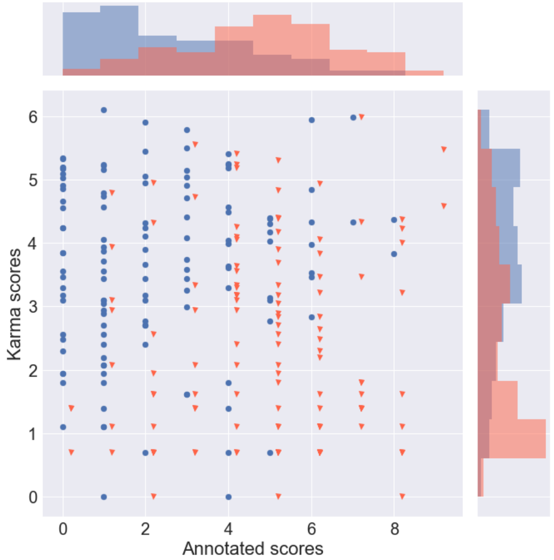

Figure 3: Karma scores and annotated scores of posts extracted by the LSTMConcat model (blue dots on the left) and the LSTMDisjunctive model (red dots shifted to the right for visibility) from the AskWomen dataset. Histograms of the karma scores and the annotated scores are also shown above and on the right.

be different even with similar text content because of different context, and this confuses the models that only use content features. Our model, by contrast, can avoid this problem because it considers the effect of context.

The Text model outperform the Concat model because context is a strong factor in predicting karma scores. If a model can use both content and context (as the Concat model does), it might overfit to context and ignore content. This does not happen in our model because it does not use context in test.

Hybrid Model vs Disjunctive Model The good performance results of the TextRank model indicate that global features of the posts are informative for ranking. While the supervised models just focus on one post at a time in each subset, the unsupervised models look at all the posts together in a subset. The hybrid model of the TextRank and the FNNDisjunctive models takes advantage of the complementary focus of the individual models, and outperforms both the supervised and the unsupervised models.

Separation of Content and Context The visualization in Figure 3 shows that our model can predict informativeness whereas the Concat model cannot. From each subset explained in Sec 3, we extract the post with the highest predicted score by the LSTMConcat and the LSTMDisjunctive. The karma scores and annotated scores of the extracted posts are plotted as blue and red dots, respectively. The karma scores are smoothed by the equation described in Sec 3. There are 130 subsets, for a total of 260 dots plotted. The Concat model extracts posts with low annotated scores but high karma scores, whereas the Disjunctive model extracts posts with high annotated scores regardless of the karma scores.

8 Conclusion

We proposed Disjunctive model that harnesses popularity as distant labels for use in extractive summarization. Our model was shown capable of separating the effects of content and context in a popularity measure and predicting the informativeness of content. To evaluate this, we built a Reddit dataset where informative comments were annotated. Our model, combined with a centrality-based model, outperformed the baseline models on the task of ranking posts to correspond to the rank of the annotated scores in three ranking metrics. Our models currently use only a single post as a feature. In the future, we will develop a model which uses a series of posts as a feature.

Abstract

Individuals express their locus of control, or "control", in their language when they identify whether or not they are in control of their circumstances. Although control is a core concept underlying rhetorical style, it is not clear whether control is expressed by *how* or by *what* authors write. We explore the roles of syntax and semantics in expressing users' sense of control –i.e. being "controlled by" or "in control of" their circumstances– in a corpus of annotated Facebook posts. We present rich insights into these linguistic aspects and find that while the language signaling control is easy to identify, it is more challenging to label it is internally or externally controlled, with lexical features outperforming syntactic features at the task. Our findings could have important implications for studying self-expression in social media.

1 Introduction

Language is a form of action, and written occurrences constitute a performance of power and control (Fairclough, 2001). Research in natural language processing has long focused on distilling the constituents of writing that conveys authority (Danescu-Niculescu-Mizil et al., 2012), dominance (Bradley and Lang, 1999), dogmatism (Fast and Horvitz, 2016), expertise (Levy and Potts, 2015) and politeness (Danescu-Niculescu-Mizil et al., 2012). These studies have shown how authors' use of certain lexical and syntactic patterns achieve specific rhetorical effects. In this study, we contribute to the growing literature with an analysis of how individuals express ***control***, and compare the insights and predictive power obtained from both, lexical and syntactic features.

We operationalize the key aspects of locus of control described by existing psychology theories (Rotter, 1966) to identify an external locus of control when authors express that they feel controlled by other people or the environment. On the other hand, authors communicate an internal locus of control when they ascribe the control of their decisions and circumstances to themselves. This study poses the question: *do writers rely more on content than syntax to convey their control?* Following its psychological underpinnings, we expect that overall lexical choice, self-reference, and certain verb categories would be indicative features for modeling author's locus of control. Our study attempts to validate these assumptions by answering two research questions:

- To what extent can *lexical* and *syntactic* features predict *control relevance* and *internal and external* locus of control?
- Which verb categories are more associated with control relevance and internal vs. external locus of control?

We train a multi-stage predictive model to classify posts on Facebook as (a) control-relevant or not, and (b) internal vs. external control. We find that syntactic and semantic features work well to identify control relevance, with verb categories and pronoun use being the most predictive features. However, determining internal vs. external control is a more challenging task, where lexical features vastly outperform syntax-based features. The best performance is seen by a model that combines lexical and syntactic features along with self-reference ratio. We will be releasing our tools and models along with annotated and anonymized datasets for the benefit of the research community.

2 Background

Locus of control, or "control", reflects the extent to which people ascribe the cause or control of events in their lives to themselves or the external

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1146–1152
Brussels, Belgium, October 31 - November 4, 2018.

factors (Rotter, 1966). The language indicating internal control in a given situation signals intentionality (the author is describing an action that he/she intended) and awareness (the author is aware of the effect of the action). Internal control is often associated with causing a given event or doing something that is clearly a choice. The external control language, on the other hand, is characterized by lack of intention or awareness, or by concrete mention of being controlled by others. It is usually lined to describing an out-of-control event, or something that is not a choice

Organizations and governments are attempting to better understand issues of locus of control and self-efficacy, which are closely related with physical health and job performance (Marmot et al., 1991; Harter et al., 2003). The study by (Jaidka et al., 2018b) offered to explore the relationship between locus of control (measured through surveys) and the Big 5 personality taxonomy (John and Srivastava, 1999), and touched briefly upon the content-related linguistic signals. However, the present study is more interested in comparing the lexical (aka open-vocabulary or bag-of-words) and syntactic signals of control that are embedded in language. If deployed on a large scale with the informed consent of the authors, it may allow unobtrusive, cost-effective estimates of well-being[1].

Signals within the language should provide insight into the cognitive sense of control experienced by an individual; however, to our knowledge, no study has examined whether these signals are stronger in the *way* people express themselves, or *what* they say. Although the discourse and lexical signals that convey status and dominance have been studied in previous work, they involve controlling *other* people (Danescu-Niculescu-Mizil et al., 2012; Fast and Horvitz, 2016), while locus of control is an assessment of the writer's own affairs – perhaps indicated through lexical features that focus on first person pronouns.

Dominance has also been qualitatively measured in terms of the affective context at the level of an utterance (Bradley and Lang, 1999); however, we found that this also did not correspond to our notion of locus of control. With reference to the syntactic features, we will test whether control may be understood through different verb forms, and active versus passive voice. Locus of control is different from semantic role labeling: for internal control, we are mainly interested in *whether* the author is the *agent* (rather than identifying who the agent is, in a sentence), and how much they control their life. External control includes a complex mixture of semantic roles such as *patient, experiencer, theme, recipient*, and *beneficiary*.

3 Locus of control data

Posts on Facebook capture self-expression by a diverse audience about their daily lives, which makes it a natural starting point for exploring the linguistic features of control. For data collection, we deployed a survey on Qualtrics comprising several demographic questions, the Sense of Control facet items from the MIDUS survey (Brim et al., 2004) and a 3-item health inventory measuring poor health, general health and weekly excercise, taken from the CDCs Behavioral Risk Factor Surveillance System (BRFSS) and the European Social Survey (ESS). We invited users to share access to their Facebook status updates and randomly sampled 2000 users who had posted at least 100 words (with 839 status updates on average). We then randomly sampled 2 status updates per user to obtain 4000 statuses. We cleaned up the text by removing URLs, hashtags, user handles, etc. and split each status into sentences using our in-house pattern-based sentence splitter inspired by CMU ARK Twitter Twokenize script (Owoputi et al., 2013). Finally, from each status update, we selected one sentence that has 2 or more words.

3.1 Locus of control annotation

Building a useful computational model requires labeled training data. We labeled the Facebook dataset using three trained annotators pursuing a Master's program in Psychology, to construct the first public corpus annotated with control. We asked the annotators to determine whether the author of the sentence is in control (internal control) or being controlled by others or circumstances (external control). To ensure quality work, we provided examples corresponding to each point on the scale. The examples provided to the annotators are also provided in the annotation scheme described in the Appendix.

In this paper, we focus on Stage 1 and Stage 2 of annotation, which distinguish control-relevant sentences and classify them as either internal or external control. We evaluate the reliability of

---

[1] http://www.pewinternet.org/2016/06/22/social-media-and-the-workplace/

the annotations by computing percent-agreement. The highest pairwise inter-annotator agreement between annotators is 90.2% for Stage 1 and 79% for Stage 2.

4 Methods

To train and test the classifiers for the Stage 1 and 2, we use the Differential Language Analysis ToolKit[2] (DLATK) (Schwartz et al., 2017), a Python package developed for social media text analysis. Lexical features are extracted in DLATK and syntax-based features are separately generated and imported into DLATK feature sets.

4.1 Lexical features

ngrams: Normalized frequency distribution over 1-, 2- and 3-grams

LIWC: Frequency distribution of categories from the Linguistic Inquiry and (LIWC) (Pennebaker et al., 2007).

ANEW: Weighted frequency distribution of the Dominance score in the Affective Norms in English Words (ANEW) (Bradley and Lang, 1999).

Word2Vec Topics: We use word clusters built on top of Word2Vec, by Preoţiuc-Pietro, Lampos and Aletras (2015). They built 200 open-ended word clusters by applying spectral clustering to the word-to-word similarity matrix from the neural embeddings Mikolov et. al (2013).

Pronouns: We clustered all pronouns (except for possessives) into 1st-, 2nd-, and 3rd-person regardless of their syntactic role.

4.2 Syntax-based features

We acquire dependency parses of our corpus by SyntaxNet (Andor et al., 2016) with Parsey McParseface model[3] that produces universal dependencies in *relation, head, dependent* triples in CONLL format. We obtain *subject-verb* tuples (SVs) and *subject-verb-object* triples (SVOs) from the dependency trees. In our in-house evaluation on a random set of 100 Tweets, SyntaxNet with the Parsey McParseface model outperforms the Stanford Parser (Socher et al., 2013) on extracting SVs and SVOs from social media (P=.75, R= 68, TN Rate =.90 for the former; P=.51, R= .55, TN Rate =.80 for the latter). SyntaxNet is also a better tool for our purpose compared to the Tweebo Parser (Kong et al., 2014), that only provides dependency graphs and not the relations.

Verb predicate features: We identify the verb classes using (a) linguistically-driven Levin's Classes (*Lev*) (Levin, 1993), and (b) an in-house manual verb clustering on the most frequent 130 verb into 40 semantic classes (*M*). Inspired by the previous research (Rouhizadeh et al., 2016), we extract five sets of dependency-driven verb predicate features. (1) **Pronouns-SVO**: occurrence of 1st, 2nd, and 3rd person pronouns in the subject/object positions, (2) **VerbCat-1-2-3PP** occurrence of 1st, 2nd, and 3rd person pronouns in the subject/object positions of each verb category (from the Levin's or our own verb classes), (3) **VerbCat-1PP**: occurrence of 1st or non-1st pronouns (i.e. self-reference ratio) in the subject/object positions of each verb category, (4) **VerbCat-SVO**: all words in the subject/object positions of each verb category, and (5) **VerbCat-all** categories of all the verbs in subject-verb and subject-verb-object contexts.

POS-ngrams: We capture shallow syntactic features by constructing Penn Part-of-Speech (POS) unigrams, bigrams and trigrams after tagging every word with their POS information by using the Python NLTK package (Bird et al., 2009).

5 Results

We train multiple classifiers on different sets of lexical and syntactic features after performing feature selection based on univariate regression between each feature and the outcome. We also perform dimensionality reduction by randomized principal component analysis (PCA). After evaluating a number of classification models available in Pythons sklearn package, we report the results from the logistic regression classifier, with L2 penalization, and inverse of regularization strength set to 0.1, which obtain the best results. Although we have experimented with a variety of feature combinations which are included in the Appendix, we discuss selected classifiers (for meaningful comparisons) as well as the best-performing ones.

5.1 Predicting control relevance

We report the results for prediction performance of the main feature in Table 1a. We see that lexical ngrams are moderately effective, whereas LIWC, ANEW, and w2v features are not helpful. On the other hand, pronouns appear to be very

Table 1: Precision, recall and F1-measure for predicting control-relevance and internal/external control (10-fold CV) from lexical and syntactic features.

helpful, despite their linguistic and semantic simplicity. Among the syntax-based features, using the verb categories of SV and SVOs provide the second best F1 score (Levin's classes are better than our classes), and adding self-reference ratio to verb categories generates the best results. Interestingly, POS-ngrams perform on-par with the lexical ngrams, suggesting that the encoded syntactic information in pos-sequences is just as good as lexical information in ngrams with considerably less sparsity and more efficient computation.

5.2 Predicting Internal/External control

The best results for classifying internal vs. external control are in Table 1b. Unlike control relevance, ngrams are the most helpful features here and pronouns and verb category features result in a poor performance. LIWC, ANEW, and w2v do not noticeably improve the results when combined with ngrams, but adding verb categories and self-reference ratio to this combination creates the best result. This suggests that identifying internal/external control benefits from an ensemble of syntactic, semantic and lexical features and simple lexical features are more helpful than word embeddings. Similar to control relevance, POS-ngrams are helpful here although they are not as good as lexical ngrams.

5.3 Linguistic insights

Table 2 shows the most predictive verb categories (with subject or subject-object arguments) based on logistic regression coefficient. We see that not only does the magnitude of the relationship change, but it is possible that the direction can completely change (positive values are control relevance in Table 2a and external control in Table 2b. Interestingly, we see that verbs for audio/visual activities, demand, and start/end of processes, are more frequently used in control-related contexts, whereas using love and like verbs is an informative signal that a given sentence is not related to control. In addition, verbs of cognition, missing, feeling, and hope are positively associated with being controlled by others or the environment, whereas verbs indicating attempt are correlated with author's control of the situation. Although not complete, these semantic categories are intuitively well-associated with the psychological theory of the control concept. In the Appendix, we also identify the POS ngram patterns which are significantly correlated with both, control relevance and internal vs. external control.

6 Error Analysis

In observing the instances of misclassification, we observed the following general patterns:

- **False negatives:**
  – Control-relevant imperative sentences were frequently misclassified as control-irrelevant, e.g. "have a good day everyone"; "Find Jesus."; "Stay focused!"
  – Internal LoC sentences with modals and 'get' were misclassified as external LoC, e.g., "Finally got a best man!"; "Join me and you can save money on all you purchase here."
- **False positives:**
  – Control-irrelevant sentences with emotion verbs ("like", "hate") were often misclassified as control-relevant, e.g., "I Hate SNOW!" ; "I dont like cologne, but it smells nice."
  – External LoC sentences with possessive pronouns and the verb "make" were misclassified as internal LoC, e.g., "It made my day."; "Is your name math because i have a problem with you."

(a) Control Relevance

Hope	.06**	hope, wish
Attempt	-.07**	try, check

Table 2: Logistic regression coefficient between verb categories and control (positive values are control relevance and external control). **: $p < 0.01$ after Benjamini-Hochberg correction. Features with positive coefficients are shaded blue and those with negative coefficients are shaded red.

7 Validation against psychological LoC

An ideal validation of language-based control against psychological LoC would find that users expressing an internal LoC in their social media posts would also be more likely to have an internal psychological LoC as measured by the Sense of Control scale (Brim et al., 2004), and poorer health as reported in previous work (Birnbaum et al., 2010). With only two observations per user, we speculate that our data does not afford us enough power to confirm this relationship. A Spearman correlation between the counts of internal and external-labeled sentences per user and their self-reported LoC and health items, revealed a weak association between authors of a higher number of sentences labeled as external LoC and their psychological LoC as per the survey questionnaire ($\rho = -.06, p < 0.05$, N = 2000), physical and general health (-0.08< ρ < -0.06, $p <$ 0.01, N = 2000). Authors with higher number of sentences labeled as internal LoC did not show a significant association with internal LoC, but were more likely to exercise regularly ($\rho = 0.04, p <$ 0.05, N = 2000). These findings, although weak, correspond in direction to the findings reported in the literature (Birnbaum et al., 2010), suggesting that future work should investigate to what extent the linguistic expressions of control can extrapolate to psychological LoC.

8 Conclusion

We describe a computational linguistic approach to identify the locus of the author's control in their social media writing. Utilizing its psychological underpinnings, we create an annotated dataset of 4000 sentences, labeled with control relevance and of internal and external control. We show that identifying control is largely dependent on syntactic information for control-relevance and lexical information for internal/external control. From the NLP standpoint, this suggests that solely using bag-of-word features may not be sufficient for predicting specific psychological outcomes. We have also distinguished our work against dominance and thematic roles, which may be the closest approximations to LoC; however these concepts do not completely translate into each other.

Differential language analyses identified interesting associations between verbs categories and control. We found that audio/visual verbs tend to occur significantly more in the control-related text, and some emotion verbs such as "miss" or "feel" are correlated with lack of control of the surroundings. A caveat of using language-based models is that their association with traits is correlational, not causal. Furthermore, the differences in platform affordances (Jaidka et al., 2018c) and diachronic drifts in language use over time (Jaidka et al., 2018a) imply that language models to identify control may need domain adaptation before they are applied on other corpora, language from other time periods and other social media platforms, as well as posthoc domain adaptation before they can scale to measure community traits (Rieman et al., 2017).

Existing psychological theories are mainly based on self-expressed and self-perceived locus of control in questionnaires, but they may be susceptible to self-report biases. Instead, we demonstrate that some of these constructs can reliably be extracted from language samples, such as social media posts, which are unsolicited self-expressions of control.

Internal locus of control has been argued to be important for mental and physical health, and to characterize well-run ("empowered") work teams; We hope that the model presented here can be used–with appropriate consent and privacy–for unobtrusive monitoring of LoC in many therapy and work settings.

Somm: Into the Model

Shengli Hu
Cornell University
sh2264@cornell.edu

Abstract

To what extent could the sommelier profession, or wine stewardship, be displaced by machine learning algorithms? There are at least three essential skills that make a qualified sommelier: wine theory, blind tasting, and beverage service, as exemplified in the rigorous certification processes of certified sommeliers and above (advanced and master) with the most authoritative body in the industry, the Court of Master Sommelier (hereafter CMS). We propose and train corresponding machine learning models that match these skills, and compare algorithmic results with real data collected from a large group of certified wine professionals. We find that our machine learning models outperform human sommeliers on most tasks — most notably in the section of blind tasting, where both hierarchically supervised Latent Dirichlet Allocation outperforms sommeliers' judgment calls by over 6% in terms of F1-score; in the section of beverage service — wine and food pairing, a modified Siamese neural networks based on BiLSTM achieves better results than sommeliers by 2%. This demonstrates, contrary to popular opinion in the industry, that the sommelier profession is at least to some extent automatable, barring economic (Kleinberg et al., 2017) and psychological (Dietvorst et al., 2015) complications.

1. Introduction and Related Work

Thanks to the Somm documentaries and a general increase in awareness about wine, sommeliers, and the Court of Master Sommeliers, there is now a certain celebrity status, a glamor associated with becoming a sommelier. When encountered with the question — "is the sommelier profession going to be negatively affected by recent advances in machine learning and artificial intelligence?" during informal interviews conducted by authors in the sommelier community, there appears to be a general consensus among professionals that the high standards of hospitality upheld by qualified sommeliers are well beyond the capabilities of machines.

The current study asks the question, to what extent would the sommelier profession be displaced by machine learning algorithms? What aspects of the sommelier profession could be outperformed, and therefore perhaps displaced by what kinds of applications of machine learning?

What makes a qualified sommelier or wine professional? According to the Court of Master Sommelier[1], one of the two organizations held in the highest esteem in the global industry, there are at least three indispensable components as exemplified in the certification exams leading up to the Master Sommelier diploma: theory, blind tasting, and service.

To satisfy the theoretical requirement, sommelier candidates are required to sit on a timed exam of various questions covering a wide range of wine topics including geography, soil, viticulture, laws, history, language, etc. without any officially structured study guides[2]. We argue that this particular task maps to the stream of research concerning *open-domain* Question Answering (hereafter, OQA), where the model is given a question and access to a large corpus (Chen et al., 2017), combining and therefore leveraging both the Information Retrieval (Weinberger et al., 2009) and Machine Comprehension literature (Hermann et al., 2015; Chen et al., 2016). In Section 3, we train an open-domain QA model building upon Chen et al.

[2] There are indeed a list of recommended references and an unofficial source of study guides popular among candidates: https://www.guildsomm.com, which we use as our training data.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1153–1159
Brussels, Belgium, October 31 - November 4, 2018.

(2017), on a large corpus of wine topics drawn from recommended study resources by CMS. We contrast the machine performance with sommeliers' performance on equivalent test questions.

To satisfy the blind tasting requirement, candidates have to blind taste a flight of wines, precisely describe the wine, and accurately identify the grape varietal, the region (thus the country), the vintage, and the quality level of each. According to wine programs such as CMS or WSET[3], blind tasting consists of two steps — tasting and deduction. Tasting refers to the sensory experience associated with evaluating wines — color, aroma, favor, aftertaste, etc. Proficient candidates are expected be able to detect a wide range of characteristics of the focal wine, and precisely describe the wine with meaningful descriptors accordingly. Deduction is the logical process that leads the candidate to conclude on the identity of the wine given the characteristics he detects in the first step. According to wine educators and master sommeliers such as Geoff Kruth M.S., it is the deduction part of blind tasting that separates great blind tasters from mediocre ones, mostly due to the fact that it requires greater logical thinking and reasoning. We propose that the deduction step maps exactly to the machine learning task of *structured prediction* (Taskar et al., 2005; Belanger and McCallum, 2016; Barutcuoglu et al., 2006; Rousu et al., 2006). In Section 4, we demonstrate that a hierarchical supervised Latent Dirichlet Allocation model (Perotte et al., 2011; Nguyen et al., 2013) trained on a large corpus of textual descriptions of wines of different grape varietals, regions, vintages, and quality levels, outperforms sommeliers in deduction by a large margin.

To satisfy the service requirement, candidates are grilled on questions of wines and spirits, food and wine pairing, salesmanship, and service mechanics in a restaurant setting. In Section 5, we showcase a modified Siamese Neural Network (Yang et al., 2015; Mueller and Thyagarajan, 2016; Neculoiu et al., 2016; Pei et al., 2016; Bertinetto et al., 2016) coupled with Bidirectional Long Short-term Memory Networks (Hochreiter and Schmidhuber, 1997; Schuster and Paliwal, 1997; Zhang et al., 2015) trained on corpora of wine reviews (Hendrickx et al., 2016) and cooking recipes (Tasse and Smith, 2008; Jermsurawong and Habash, 2015) outperforms sommeliers' performance.

2. Data Collection and Preprocessing

Our datasets consist of three parts: (1) *Study Resources*: a large corpus consisting of all the recommended resources for sommelier certification by the CMS, for the Question Answering — Theory Component detailed in Section 3; (2) *Wine Reviews*: a massive repository of expert wine reviews with rich meta-data, based on reviews from Decanter, Vinous, Wine Spectator, and Wine Enthusiast, the four widely recognized media outlets in the industry, for the Structured Prediction — Deduction in Blind Tasting Component detailed in Section 4; (3) *Survey Responses* from $1,305$ certified wine professionals, covering topics on theory, deductive tasting, and wine and food pairing, thus providing experts' performance data with which we compare results from our corresponding machine learning models in Section 3, Section 4, and Section 5.

2.1 Preprocessing

The study resource dataset consists of documents of various categories and topics from the GuildSomm. We treat texts under each sub-category as a document — there are 752 documents in our dataset and the average length of documents is $1,384$ words.

For the wine review dataset, we only consider wines for which we had at least 200 reviews in the training set, leading to $850,119$ reviews combined. When different names were used for the same grape, we normalize these to the same category. For instance, Pinot Bianco (Italy), Pinot Blanc (France), and Weissburgunder (Germany) are mapped together and renamed Pinot Blanc according to the wine grape encyclopedia (Robinson et al., 2013; Robinson and Harding, 2015). We preprocessed all the text data in standard procedures.

2.2 Summary of Datasets

We plot the country and point distributions of our review dataset in Figure 1 , grouped by media outlet. Interestingly, Vinous appears proportionally much more focused on Italian wines and its ratings are more skewed to the right compared to others (a.k.a. greater rating inflation), somehow contrary to the brand image; Wine Spectator is much more focused on Old World whereas Wine Enthusiast is

---

[3] Wine & Spirit Education Trust

more evenly distributed across countries.

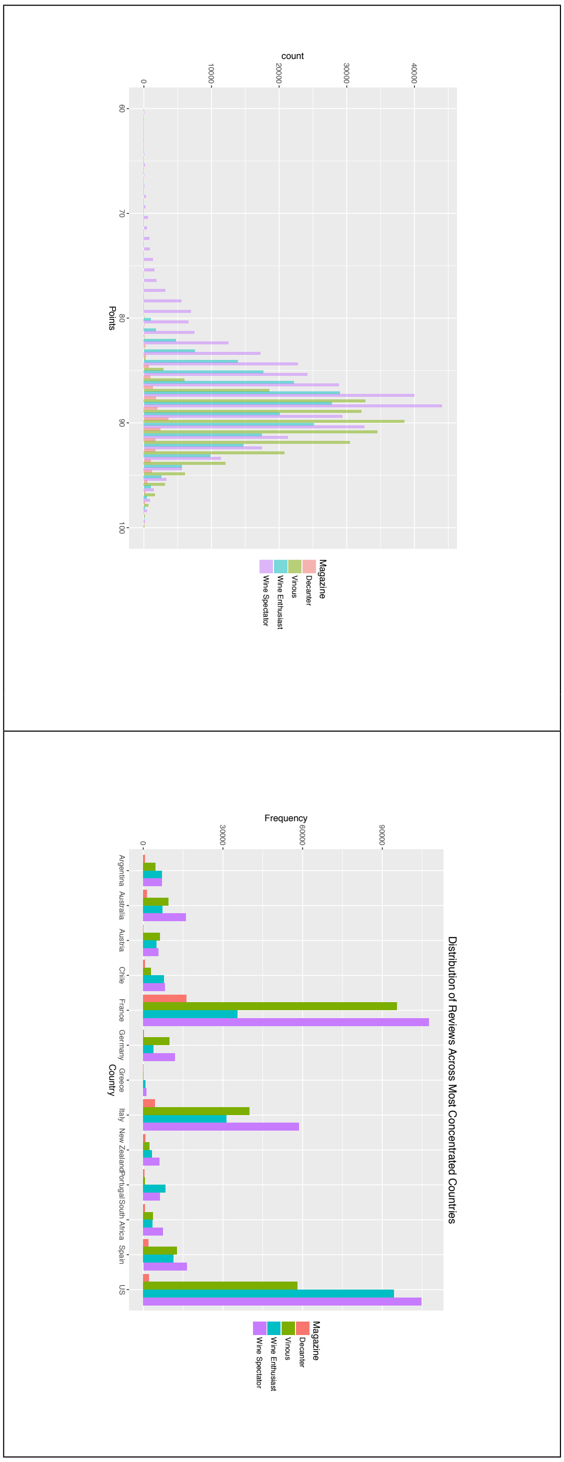

Figure 1: Country and Point Distribution of Wine Reviews

2.3 Survey Details

We administered timed online surveys to wine professionals in several active sommelier communities such as the Guild of Sommeliers, the Society of Wine Educators, etc. Each survey consists of three sections that correspond to the three components respectively — theory, deductive tasting, and pairing. Each section lasts no longer than 15 minutes and consists of 30 questions, randomly drawn from a large pool of practice questions from the Guild of Sommeliers and the Society of Wine Educators.

In the first section, we administered two sets of questions varying difficulty level — one on the level of certified sommelier (CMS level 2), the other on the level of advanced sommelier (CMS level 3). The Question Answering (wine theory) pool consists of $1,400$ questions (700 equivalent to level 2 difficulty, 700 equivalent to level 3 difficulty) from Society of Wine Educators' Certified Specialist of Wine and Certified Specialist of Spirits programs, and $1,480$ questions (740 at level 2 difficulty and 740 at level 3 difficulty) from Guild of Sommelier practice repository. $2,304$ questions were used for training, and the rest for testing. In the second section, we randomly drew 30 textual descriptions from our pool of $850,119$ reviews detailed in Section 2, and asked the subject to deduce the varietal, vintage range, region, and quality level of the wine being described. In the third section, we randomly drew 30 wines (Title and Tasting note) from the repository of wine reviews and 30 recipes from the CMU Recipe Database CURD (Tasse and Smith, 2008), and asked the subject to rate the pairings on a scale from 1 to 5. We circulated our survey to members of the Guild of Sommeliers and Society of Wine Educators communities and received $1,412$ responses. The first section of theory questions serves not only as a dataset compared against QA models, but also as a validation and screening procedure: we removed the responses with fewer than 18[4] correct answers to the 30 questions in section 1, reducing our sample size to $1,305$. Sommelier scores were calculated aggregating all the participants' answers.

3. Wine Theory: open-domain Question Answering

We implemented an open-domain Question Answering system modeled after Chen et al. (2017), consisting of a Document Retriever module and a Document Reader module.

The Document Retriever module finds the three

---

[4] We choose the cutoff rate of 60% because it is the the pass rate in real sommelier exams both for the certified and advanced.

most relevant documents by comparing documents and questions as TF-IDF weighted bag-of-word vectors that include bigrams. We also adopt the hashing of Weinberger et al. (2009) for mapping bigrams with an unsigned murmur3 hash.

The Document Reader module is essentially a bidirectional Long Short-term Memory Network (BiLSTM) (Hochreiter and Schmidhuber, 1997; Zhang et al., 2015) applied to each paragraph in relevant documents, the predicted answers of which are finally aggregated. For detailed procedures of implementation, we refer readers to Chen et al. (2017). The only differences are, our batch size is 25 and we adopted a dropout rate of 0.1. We document the results in Table 1. Surprisingly, our OQA results converge to the high levels of accuracies achievable by machine comprehension models. We argue that it is because our corpus is relatively small and concentrated on wine-related topics, which results in few complications arising from the integration of large-scale information retrieval and machine comprehension, and therefore more germane to single machine comprehension models. Note that we removed survey results below 60% accuracy, stacking the odds against us because now the sommeliers' performance results are inflated, which could provide partial explanations for OQA being behind. The comparison still looks promising, despite the 4.8% disparity in performance.

Data Generation	Training Set		Test Set	
	Exact Match	F1	Exact Match	F1
Sommeliers	NA	NA	67.1	71.7
OQA System	58.1	67.8	55.7	66.9

Table 1: Evaluation results of OQA in comparison with sommeliers' performance.

Comparing the accuracies across regions, we find sommeliers did much better than DrQA in old world regions while DrQA edged out on most new world regions. It might echo the greater emphasis of sommelier training in real life on the old world, and/or reflect the more complications introduced by French, Italian, German, and Spanish terminologies which we didn't correct for when dealing with the old world wine regions.

4. Blind Tasting: HSLDA

We implemented the Hierarchically Supervised Latent Dirichlet Allocation (HSLDA) model (Perotte et al., 2011) for deduction in blind tasting based on textual descriptions of wines, because of the natural fit in-between — the texts describing wines are hierarchically (from top to bottom: grape varietal, country, region, vintage, quality) and multiply (blends vs. monovarietals)) labeled bag-of-word (simple and performant for reviews) data. For model details, we refer readers to Perotte et al. (2011). We use the subset of wine reviews published in Wine Enthusiast and Decanter for this task. It contains $183,660$ wine descriptions for training and $39,150$ for testing. There are 41.1 terms on average in each document, with a 11.6 standard deviation. There are $12,132$ unique (sub-)categories in the form of "Sangiovese, Italy, Tuscany, 2015, Riserva". We use a Gaussian prior over the regression parameters where a range of values for μ, the mean prior parameter for regression coefficients are evaluated ($\mu \in \{-3, -2.5, -2, \ldots, 1\}$). We set the number of topics to 20 based on small sample testing and CMS tasting grid. Prior distributions of hyperparameters are gamma distributed with a shape parameter of 1 and a scale parameter of $1,000$.

Initial results were less satisfying and most errors occurred because mono-varietals were predicted to be blends and vice versa. Therefore we explored two solutions: (1) we separated our data into mono-varietals (Model 1), and blends (Model 2), and trained HSLDAd separately; (2) we created a smaller yet more balanced training set regarding mono-varietals and blends (Model 3).

In Model 1, we simplified "testable" (i.e., included in Court of Master Sommelier tasting exams) blends in our dataset such as "Southern Rhone red blend", "Marsanne Roussanne blend", "Sangiovese blend", and such were treated the same as the mono-varietals. Model 2 and 3 were trained using the exact blending grape varietals. We believe Model 1 is closest to the decision making processes encountered by sommeliers in CMS certification exams, whereas Model 3 is more likely to resemble sommelier challenges such as Top Somm.

We computed precision and recall of all the categories, yielding a $12,132 \times 12,132$ sparse confusion matrix for Model 3, a $11,672 \times 11,672$ sparse confusion matrix for Model 1, and a 386×386 confusion matrix for Model 2. We then averaged them to get a single real number measurement. Table 2 shows the average F1 scores of different models versus sommeliers' performance.

Likewise, the sommeliers' performance measures represent a conservative(ly higher) estimate since scores lower than 60% in section 1 were removed. We find the HSLDA model, especially of monovarietals, outperforms sommeliers by 6.3%, as measured by F1. In aggregate, sommeliers did significantly better in red and sparkling wines, and in French, German, and Californian wines, whereas Model 1 edged out in white wines, south America wines.

F1 Scores	Training Set	Testing Set
HSLDA1 Monovarietal	71.1	68.4
HSLDA2 Blend	62.5	59.1
HSLDA3 Balanced	59.8	56.4
Sommeliers	NA	62.1

Table 2: Evaluation results of HSLDAs in comparison with sommeliers' performance.

5. Food and Wine Pairing: Siamese Neural Networks with LSTM

For food and wine pairing, we trained an untied and modified version of Manhattan LSTM (Mueller and Thyagarajan, 2016), where we preprocessed the texts differently and applied LSTM-Based Importance Weighting in place of the original simple similarity function coupled with LSTM. We retained from the recipes only ingredients, serving ingredients and essential actions, which were passed to the BiLSTM (Zhang et al., 2015). For a given pair of wine and recipe descriptions, we applied a weight compatibility function $g(h_{T_a}^{(a)}, h_{T_b}^{(b)}) = exp(-||a^T h_{T_a}^{(a)} - b^T h_{T_b}^{(b)}||_1)$, where a^T and b^T are shared network weights applied to BiLSTM representations $h_{T_a}^{a}$ and $h_{T_b}^{b}$. For model architecture and other implementation details we refer readers to Mueller and Thyagarajan (2016) and Rücklé and Gurevych (2017).

We obtained our ground-truth labels for wine and recipe pairings on a scale from 1 to 5 using an automated weighting scheme based on wine and food pairing principles (Goldstein and Goldstein, 2006)[5] leveraging the GuildSomm tasting notes of grape varietals and recipe ingredients, under close guidance of a certified sommelier with the CMS. Details of the weighting scheme is included in our online supplementary documents. In the end we simplified our scale to binary — $\{1, 2\}$ converted to 0, $\{3, 4, 5\}$ converted to 1. We document our accuracies in Table 3. Surprisingly, the model edged out by 1.7%.

Accuracy	Training Set	Testing Set
Modified MaLSTM	82.3	79.8
Sommeliers	NA	78.1

Table 3: Evaluation results of Modified MaLSTM in comparison to sommeliers' performance.

6. Conclusion and Future Work

We examine how machine learning can be used to understand, assist, and improve human decision-making, echoing recent studies in computational social sciences (Dietvorst et al., 2015; Kleinberg et al., 2017). We dissect sommelier skills into three parts and train ML models for each. We show with our choices of suitable models, collection of valuable datasets and annotations, that ML algorithms outperform sommeliers in essential skills. Future work could improve on:

1. fine-tuning the Open-domain Question Answering for wine knowledge;
2. connecting our HSLDA or hierarchical multi-label classification to robotic sensors to fully mimic the blind tasting task;
3. exploring other simpler and more efficient ML models for pairing tasks;
4. training a joint multi-task model, since it is accepted in the industry that a solid knowledge of wine theory helps immensely in blind tasting and wine service. It would be interesting to quantify the synergy in the learning process;
5. exploring ML applications to other aspects of the service component.

Abstract

Detecting fine-grained emotions in online health communities provides insightful information about patients' emotional states. However, current computational approaches to emotion detection from health-related posts focus only on identifying messages that contain emotions, with no emphasis on the emotion type, using a set of handcrafted features. In this paper, we take a step further and propose to detect fine-grained emotion types from health-related posts and show how high-level and abstract features derived from deep neural networks combined with lexicon-based features can be employed to detect emotions.

1 Introduction

Emotions are an essential part of our lives and reflect feelings such as joy, sadness, and fear, which affect our overall wellbeing. Emotion detection from text using computational models has been extensively studied from data such as news headlines, social media, blog posts, and song lyrics (Katz et al., 2007; Abdul-Mageed and Ungar, 2017; Mohammad and Turney, 2013; Strapparava and Mihalcea, 2007; Liew and Turtle, 2016).

Recently, emotion detection started to emerge in online health communities (OHCs) (Khanpour et al., 2018; Biyani et al., 2014; Wang et al., 2012). OHCs provide a user-friendly environment for patients, their families and friends to share thoughts and socialize with each other on topics such as therapeutic processes, side effects, and mental and emotional health. Emotion detection in OHCs is substantially different from the general text due to a health-related vocabulary that people use in OHCs. For example, the phrase "hot flashes" may not have a specific meaning in the general domain, but it bears a very negative feeling in patients' posts. Similarly, the post: "Just received notice from my doctor, I have a positive Cologuard result" is associated with a very sad emotion in a health domain, i.e., when a test is positive, it means that the disease is present.

"My doctor's office is very clean, who cares when he has prescribed me a wrong medication for six months!"

Table 1: Example of an emotional message from an OHC that contains a sad emotion.

Despite of emergence of emotion detection in OHCs, most of the recent works have been devoted to high level emotion analysis, i.e., identifying messages that contain emotions, with no emphasis on the unique challenges associated with fine-grained emotion detection. In order to correctly detect the types of emotions present in messages posted in OHCs, a deep understanding of the text and the writer's intention are required. Table 1 shows an example of a message that contains a sad emotion, which is hidden in text. We ran several sentiment tools on this message, including Stanford CoreNLP (Socher et al., 2013), and interestingly, all showed a positive sentiment, while the emotion expressed is clearly one of sadness (mixed with sarcasm). Thus, even an approach to predict the negative sentiment of the message would not suffice.

In this paper, we analyze messages in OHCs to understand the most prominent emotions in health-related posts and propose a computational model that is able to exploit the semantic information from text and coherently combines high-level (abstract) features with surface and lexicon-based features to automatically detect fine-grained emotions. Our contributions are as follows:

1. We study fine-grained emotions and their distribution in messages posted in OHCs by constructing and analyzing two health-related datasets for fine-grained emotion detection.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1160–1166
Brussels, Belgium, October 31 - November 4, 2018.

Identifying emotions in patients' messages augments the capability of OHCs' moderators, caregivers, and doctors to provide high-quality services to OHCs' users and patients. To our knowledge, we are the first to address fine-grained emotion detection in OHCs.

2. We propose a computational model, called ConvLexLSTM, for emotion detection in OHCs. Our model combines the output of a Convolutional Neural Network (CNN) with lexicon-based features, which are all fed into a Long Short-Term Memory (LSTM) network that produces the final output via softmax. We show empirically that ConvLexLSTM significantly outperforms strong baselines and prior works. Moreover, we show that the proposed model continues to perform well even in the absence of lexicon features.
3. Finally, we apply ConvLexLSTM in a large scale experiment to study the correlation between US holidays and users' emotional states, which can help design smarter approaches to improve patients' moods.

2 Related Work

Emotion detection has been extensively studied in computational linguistics for a long time (Mohammad and Turney, 2013; Strapparava et al., 2004). The Ekman's basic emotion set, which includes six emotions: anger, disgust, fear, happiness, sadness, and surprise, is arguably the best well-known emotion categorization (Ekman, 1992). Strapparava and Mihalcea (2008) proposed knowledge-based and corpus-based methods for classifying emotions based on Ekman's basic emotions. Co-occurrence of general words with emotional words has beed used by Katz et al. (2007) for identifying emotion types latent in news headlines. Keyword-based approaches that are based on finding emotional words in text suffer from the inability to classify text that lacks specific keywords. Therefore, Bao et al. (2009) proposed to use topical relations between words and emotion types for emotion classification in online news. Strapparava et al. (2012) studied emotions from song lyrics.

Emotion detection has been studied in social media as well and brings additional challenges due to their informal context in which people do not follow grammatical rules and use many characters that do not occur in formal text (e.g., #, :)). Emotion lexicons derived from social media, e.g., based on *emotion word hashtags*, have been shown to improve models' performance for emotion detection (Mohammad, 2012; Sykora et al., 2013). Abdul-Mageed and Ungar (2017) used distant supervision to construct a large dataset from the general Twitter for fine-grained emotion detection and explored deep learning models to detect emotions. Liew and Turtle (2016) and Liew et al. (2016) also created a dataset of about $15,500$ tweets labeled with 28 emotion types, using the Amazon Mechanical Turk. Some studies combined knowledge-based and keyword-based approaches with linguistic features and used a machine learning algorithm to reasonably classify sentences with no emotional keywords (Yang et al., 2012; Neviarouskaya et al., 2010).

Emotional support is considered as one of the main advantages of using OHCs that brings better feelings (Khanpour et al., 2017; Zhang et al., 2017a,b; Qiu et al., 2011) and fewer mortality odds to patients (Kroenke et al., 2013). Interestingly, to this date, only very few studies have started to analyze emotions in OHCs using computational models (Wang et al., 2012; Biyani et al., 2014; Wang et al., 2014b,a). For example, Wang et al. (2012) used linear regression to identify emotional support from a cancer forum. Their model predicts to what extent each sentence contains either emotional or non-emotional support. Their features include: LIWC features, POS tags, message length, subjectivity intensity, and LDA topical features. Biyani et al. (2014) identified messages that contain emotions in a breast cancer forum using unigrams, POS tags, structural patterns, and five lexicons that contain strong and weak subjective words, cancer drugs, side-effects, and cancer procedures, and showed that lexicons features have a high impact on the results. Khanpour and Caragea (2018) used deep learning to extract therapeutic processes and side effects from patients' posts. Wang et al. (2014b) classified OHCs' messages based on the intention of the participant when writing messages (e.g., seeking or providing information) and used a combination of features from Wang et al. (2012) coupled with lexicon features used in Biyani et al. (2014).

3 Data Collection and Annotation

To study the most prominent emotions and their distribution in OHCs and to evaluate our model for fine-grained emotion detection in OHCs, we constructed two benchmark datasets, since, to our knowledge, no labeled dataset is available for this task. The first dataset is created by using data from Biyani et al. (2014), which contains 1066 sentences from the breast cancer discussion board in the Cancer Survivors' Network (CSN) of the American Cancer Society, denoted as B-DS. Note that Biyani et al. (2014) performed sentence level classification since longer messages often comprise different topics. A sentence level analysis can make a better estimation on the purpose of the commentator in writing that sentence, whether or not expressing his or her emotions. For the second dataset, we randomly selected 225 comments from 21 discussion threads in the lung cancer discussion board of CSN. We denote this second dataset as L-DS. Following Biyani et al. (2014), we extracted all sentences out of comments and chose sentences with a length greater than four words. We ended up with 1041 sentences in L-DS. In total, we have 2107 sentences labeled with emotion types.

For our annotation task, we followed the six emotions suggested by Ekman (1992). Our annotators were allowed to attribute one or more emotions to a single sentence, e.g., a sentence could be annotated as bearing *sadness* or a combination of *sadness* and *fear*. The annotation task was conducted iteratively following prior studies and guidelines, using three training rounds (DMello, 2016; Fort et al., 2016; Shanahan et al., 2006). In each round, 300 sentences drawn from both B-DS and L-DS were assigned to the annotators,[1] and we asked them to meet with the researchers in a group to discuss disagreements and document their discussion before the next 300 instances were assigned. Upon passing the training period, annotators were assigned to annotate the remaining sentences from B-DS and L-DS, and they ended up with 83% Kappa inter-annotator agreement. For the remaining 17%, the annotators expressed their views on each case in the presence of the researchers and finally 100% agreement was achieved during 20 days. All these sentences plus the 900 ones used during the three training rounds became part of the final dataset. Table 2 represents the distribution of emotions in 2107 sentences. Note that some sentences do not contain any emotion. As can be seen from the table, both datasets have a similar distribution of emotions, with joy and sadness being the most prominent.

Emotions	Lung	Breast	Percentage(%)
Anger	59	29	4.0
Disgust	4	1	0.2
Fear	33	39	3.4
Joy	368	470	39.7
Sadness	183	134	15.0
Surprise	8	3	0.5

Table 2: Emotion distributions in B-DS and L-DS with the percentage estimated from both L-DS and B-DS.

4 Model

Given a sentence of n words, we apply CNN to extract high-level (abstract) features that capture the semantic part of the text (Lai et al., 2015). We combine high-level features with surface-level and lexicon-based features. Our proposed model, ConvLexLSTM, is shown graphically in Figure 1. As can be seen from the figure, we use a combination of CNN and LSTM models, where the final feature vectors from CNN augmented with lexicon-based features are fed as input to the LSTM network. The architecture of our proposed classification model is close to the models described in Kim et al. (2016) and Xiao and Cho (2016), in which they applied a character-level CNN to create high-level features, whereas our model works at word-level and uses lexicon features. We use the word-level input to benefit from applying embedding vectors, trained on OHCs. We use the character-level model by Kim et al. (2016), denoted by C-ConvLSTM, as one of our baselines.

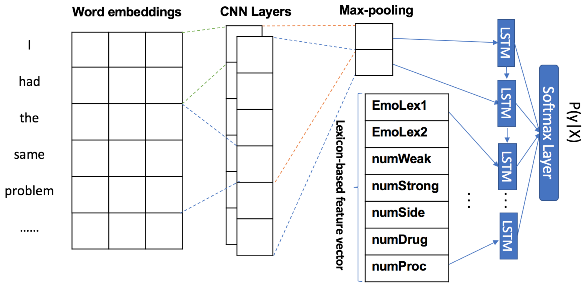

Figure 1: The structure of ConvLexLSTM.

Lexicon-based Features: Lexicon-based approaches for detecting emotions in the text have been the main stream of many models (Strapparava et al., 2004; Strapparava and Mihalcea, 2008; Mohammad, 2012; Liu, 2012).

In our work, we used the same lexicons that were provided by Biyani et al. (2014) such as weak subjective words (**numWeak**), strong subjective words (**numStrong**) (Stoyanov et al., 2005), cancer drugs (**numDrug**), side-effects (**numSide**), and therapeutic procedures (**numProc**). These

---

[1] Annotators were three graduate students.

lexicons address differentiation between emotional versus non-emotional messages. However, we need more granular information for differentiating between a variety of emotion types. Hence, we also used lexicons introduced by Strapparava and Mihalcea (2007), denoted as **EmoLex1**, and by Mohammad and Turney (2013), denoted as **EmoLex2**. We use frequencies of lexicon words to construct the lexicon-based feature vectors. Note that prior work (Biyani et al., 2014) showed that LIWC did not generate high quality features for classification in OHCs, and thus, we did not use it in our study.

5 Experiments and Results

Next, we describe the evaluation of ConvLexLSTM, using the *joy* and *sadness* emotions, which have at least 5% coverage in our labeled data (see Table 2). Also, since binary tasks are considered easier to learn than multi-class tasks (Bishop, 2006), we trained our models in the two-class setting: joy/non-joy (and sad/non-sad), by binarizing the datasets. In all experiments, we used word embeddings as input to the neural networks, which were generated with the W2vector module in Gensim (Řehůřek and Sojka, 2010) on the data (users' comments) from all discussion boards of the Cancer Survivors' Network (CSN) of the American Cancer Society, between June 2000 and June 2012. We also experimented with word embeddings generated using Wikipedia, but these embeddings resulted in lower performance as compared with those generated using CSN data. We estimated hyper-parameters for each deep neural network via a grid search over combinations of important hyper-parameters (e.g., learning rate, decay rate, dropout, number of layers, filter region size, and number of filters). The grid search was done on a development set that consists of removing 20% of instances from the training set in each iteration of 10-fold cross-validation. We report precision, recall and F1-score.

5.1 Performance of ConvLexLSTM

First, we evaluate ConvLexLSTM performance in an ablation experiment to determine the role played by each component for emotion detection. Specifically, we compare ConvLexLSTM with ConvLSTM (a model that has the same architecture as ConvLexLSTM, but does not use any external lexicon), CNN, LSTM, and support vector machine (SVM) with the (concatenated) features from the seven lexicons (described above).

	Method	B-DS			L-DS		
		Pr	**Re**	**F1**	**Pr**	**Re**	**F1**
Joy	ConvLexLSTM	**92.3**	**94.3**	**93.2**	**90.4**	**89.3**	**89.8**
	ConvLSTM	86.6	88.4	87.4	87.0	83.0	85.0
	CNN	85.0	84.0	84.5	82.2	82.8	82.5
	LSTM	86.0	86.6	86.3	85.0	83.0	84.0
	Seven-Lexicon	63.4	87.3	73.45	60.0	85.1	70.37
	C-ConvLSTM	86.2	87.0	86.6	85.0	82.0	83.47
	SWAT	66.0	68.0	67.0	65.5	66.7	66.0
	EmoSVM	81.0	82.0	81.5	82.0	80.0	81.0
Sad	ConvLexLSTM	**93.7**	**91.1**	**92.3**	**88.0**	**90.9**	**89.4**
	ConvLSTM	89.0	87.8	88.4	81.0	87.5	84.0
	CNN	83.2	83.6	83.4	81.7	80.5	81.0
	LSTM	87.4	85.8	86.6	83.2	83.6	83.4
	Seven-Lexicon	61.0	84.9	70.99	61.0	83.3	70.42
	C-ConvLSTM	85.0	83.6	84.3	83.7	82.1	82.9
	SWAT	65.0	66.0	65.5	64.0	65.0	64.5
	EmoSVM	80.5	81.7	81.0	79.0	78.0	78.5

Table 3: Emotion detection results using 10-fold cross validation. The numbers are percentages.

Table 3 shows the results of this comparison. As can be seen from the table, ConvLexLSTM achieves the best results consistently throughout all experiments in terms of all compared measures. This ablation experiment confirms our intuition that all components are contributing to the final emotion detection. For example, removing the seven lexicon features from ConvLexLSTM, which yields ConvLSTM, results in a drop in F1-score by 5.8% on *joy* in B-DS, and by 3.9% on *sadness* in B-DS. Still, ConvLSTM is the second performing model in terms of F1-score. These results show that our model can be successfully applied in a health domain even in the absence of health lexicons, which are often expensive to obtain. Not surprisingly, the SVM with the seven-lexicon based features (denoted as Seven-Lexicon) performs the worst among the compared models, suggesting that capturing the semantic information from text via deep neural networks improves emotion detection.

Second, we compare ConvLexLSTM with three baselines: C-ConvLSTM (i.e., a character-level CNN-LSTM) (Kim et al., 2016), SWAT (Katz et al., 2007) (i.e., an emotion detection model from SemEval-2007), and EmoSVM (i.e., an SVM with a set of handcrafted features: unigrams, bigrams, POS tags, the word-emotions association lexicon by Mohammad (2012), the WordNet-Affect lexicon by Strapparava et al. (2004), and the output of the Stanford sentiment tool by Socher et al. (2013). Table 3 shows the results of this comparison as well. As can be seen, ConvLexLSTM out-

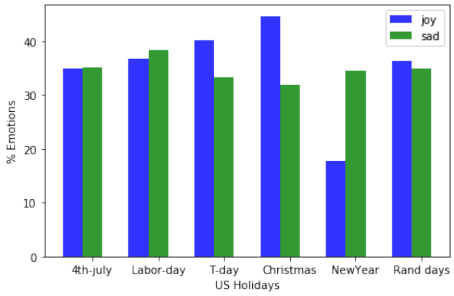

Figure 2: Joy and sadness throughout events.

performs all three baselines on both datasets, and more importantly, the character-level CNN-LSTM by Kim et al. (2016) (i.e., the C-ConvLSTM model). This result confirms our belief that applying word embedding vectors, which are trained directly on data from OHCs yields improvement in performance over character-level models.

It is worth mentioning that all deep neural networks, ConvLexLSTM, ConvLSTM, CNN, LSTM, and C-ConvLSTM, that capture high-level semantic features perform better than the traditional models on emotion detection. The lexicon-based features act as a complement (for the high-level semantic features) by looking into exact words in the text to generate appropriate features in ConvLexLSTM for emotion detection. With a paired T-test, the improvements of ConvLexLSTM over the compared models for F1-score are statistically significant for p-values < 0.05.

5.2 Impact of holidays on emotional states

We further analyzed the impact of several US holidays, i.e., 4th of July, Labor Day, Thanksgiving Day, Christmas Day, and New Year's Eve, on CSN users' emotional states, joy and sadness. For this experiment, we extracted messages from each event day itself and from two days before and two days after each event (holiday) from the entire CSN data. We also collected messages written on five random days (June 15, October 20, March 9, April 3, and January 29), which are not close to any event, to be used as a baseline for comparing the emotional states of participants in different holidays. Consistent with our labeled datasets, we removed messages with less than four tokens. We used our best performing model ConvLexLSTM to classify joy and sadness on these data.

Figure 2 shows the percentage of joy and sad predicted messages for each holiday and for the five random days. As can be seen from the figure, on the random days, the percentage of joy and sad emotions are similar, and so are they for 4th of July and Labor Day, whereas Christmas and Thanksgiving show more joyful spirits, possibly due to family gatherings and other social events around these holidays, in which people feel supported, and hence, feel better. Christmas shows an increase in joy and a slight decrease in sad emotions compared with Thanksgiving. Interestingly, around the New Year's Eve, the percentage of sad messages is almost twice higher compared with the percentage of joy messages, which can be attributed to the end of the holiday season and family gatherings and the beginning of a new challenging year.

6 Conclusion

In this paper, we addressed the problem of fine-grained emotion detection from OHCs messages. To this end, we first annotated a dataset from a cancer forum (i.e., the Cancer Survivors' Network of the American Cancer Society) with the six most common emotions suggested by Ekman (1992) and studied the most prominent emotions and their distribution in OHCs. We found that joy and sadness occur most frequently in the forum, followed by anger and fear. Not surprisingly, disgust and surprise appear the least number of times. We then proposed a computational model that combines the strengths of CNNs, LSTMs and lexicon-based approaches to capture the hidden semantics in OHCs messages and to provide a more insightful understanding of emotional messages by identifying their emotion types.

Our results are promising and show that our proposed model, with or without lexicon-based features, which are often expensive to obtain or maintain in a health domain, provides a better emotion type detection compared with strong baselines and prior works. Given our initial success, in the future, it would be valuable to construct a large health-related dataset to cover other types of emotions, e.g., anger or fear.

Acknowledgments

We are grateful to the American Cancer Society for making the Cancer Survivors' Network available to us. We thank Iulia Bivolaru, Krutarth Patel, and Manoj Panchagnula for their help with data preparation. We would also like to thank our reviewers for their insightful comments and feedback, which helped improve our paper.

Abstract

Nowcasting based on social media text promises to provide unobtrusive and near real-time predictions of community-level outcomes. These outcomes are typically regarding *people*, but the data is often aggregated without regard to users in the Twitter populations of each community. This paper describes a simple yet effective method for building community-level models using Twitter language aggregated by user. Results on four different U.S. county-level tasks, spanning demographic, health, and psychological outcomes show large and consistent improvements in prediction accuracies (e.g. from Pearson $r = .73$ to $.82$ for median income prediction or $r = .37$ to $.47$ for life satisfaction prediction) over the standard approach of aggregating all tweets. We make our aggregated and anonymized community-level data, derived from 37 billion tweets – over 1 billion of which were mapped to counties, available for research.

1 Introduction

Social media is an increasingly popular resource for large-scale population assessment which promises a cheap and non-intrusive complement to standard surveys with finer spatio-temporal scales (Coppersmith et al., 2015; Mowery et al., 2016; Wang et al., 2017). Twitter has been used — among other things — to measure community health (Paul and Dredze, 2011; Mowery et al., 2016; Eichstaedt et al., 2015), well-being (Schwartz et al., 2013), and public opinion on politics (O'Connor et al., 2010; Miranda Filho et al., 2015). By having access to measurements from multiple locations or communities, models trained on text data from social media can be used both to predict future measurements and to provide community estimates where these are lacking or are not robust. Such research is made possible by the massive amount of easily accessible user-generated data from public social media.

However, there has been little research on the way in which such data should be aggregated in order to compute community-level lexical feature estimates. One study explored the benefit of normalizing lexicon word count features as the proportion of users in each county which use at least one word from a given category (Culotta, 2014a). This method lead to a significant improvement but was limited to broad categories of a psychological based dictionary rather than normalizing frequencies of individual lexical features within users before aggregating to the county. Typically, data are aggregated in a "bag of words" style, disregarding tweets and authors (Schwartz et al., 2013; Eichstaedt et al., 2015; Curtis et al., 2018). We find, however, that giving equal weight to each user, rather than to each word or tweet, yields much more accurate community-level predictions.

In this paper, we conduct a series of experiments testing various simple yet intuitive aggregation methods. We show that choice of aggregation methods can result in substantial (one might even say "remarkable") boosts in accuracy when predicting U.S. county level outcomes (e.g. user-to-county aggregation yields a 7% to 27% increase in Pearson correlation). Contributions include (a) validation of aggregation approaches across four outcomes related to health, psychology, and demographics, (b) validation that aggregation has some effect on smaller sample of Twitter data, (c) show the effect of power tweeters (or "super users") and (d) release of resource-intensive community aggregated lexical data.

Related work. This is the first work we know of to explore simple aggregation techniques for population-level prediction tasks from language. Previous work has explored more sophisticated

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1167–1172
Brussels, Belgium, October 31 - November 4, 2018.

adjustments, such as addressing demographic-self selection bias in Twitter community predictions by re-weighting messages, finding small improvements (a 4.5% reduction in symmetric mean absolute percentage error) (Culotta, 2014b). In a political voting intention prediction application, (Lampos et al., 2013) modeled users and words jointly by learning separate regression weights for the two dimensions based on the intuition that each user contributes differently towards the outcome. However, their model was specifically adapted to problems that use time-series outcomes, rather than community-level aggregation. Distributions of lexical features are considered at multiple levels of analysis (message, user and community) in (Almodaresi et al., 2017) though each level considers one type of aggregation. Similar aggregation methods have been used in the context of topic modeling (Latent Dirichlet Allocation (Blei et al., 2003) and Author Topic Model (Rosen-Zvi et al., 2004)) by considering user, hashtag and conversation level aggregations (Alvarez-Melis and Saveski, 2016; Hong and Davison, 2010) but, again, community level aggregation and prediction tasks were not considered.

2 Data

Research was reviewed by an academic institutional review board and deemed exempt.

2.1 Twitter Data Collection

Twitter Sample A random 10% sample of the entire Twitter stream ('GardenHose') was collected between July 2009 and April 2014, which was then supplemented with a random 1% sample from May 2014 to February 2015. The total sample contains approximately 37.6 billion tweets (Preotiuc-Pietro et al., 2012).

County Mapping In order to map each tweet to a location within a county in the United States, we use both self-reported location information in user profiles and latitude/longitude coordinates associated with a tweet. If latitude/longitude coordinates are present then we trivially map the tweet to a county. The self-reported location information is a free text field and we use a cascading set of rules to map this field to a county. The rules are designed to avoid false positives (incorrect mappings) at the expense of fewer mappings. The full details of this process can be found in (Schwartz et al., 2013). Note that the latitude/longitude coordinates are a tweet attribute whereas the self-reported location is a user attribute yet both are used to map tweets to counties. Users are assigned a county by considering their earliest county mapped tweet.

In total, we are able to map 1.78 billion of the 37.6 billion tweets to a US county using the above-mentioned method. The county mapped data set was then filtered to contain only English tweets using the popular langid.py method (Lui and Baldwin, 2012), further reducing our tweet set to 1.64 billion tweets. For experiments with user-level data aggregation, we removed users who made relatively few (less than 30) posts in our data set.

Publicly Available Stream The standard publicly available Twitter stream outputs approximately 1% of the public Tweet volume. Since a 10% sample is not available to most researchers, we replicated a 1% sample by taking a random 10% of our county mapped, English filtered 10% sample. The same process of county mapping, language filtering and user selection was applied to this data resulting in 131 million county mapped English tweets from 1.57 millions users. Table 1 presents the data set statistics.

The County Tweet Lexical Bank The County Tweet Lexical Bank is a U.S. County level data set comprised of two feature sets[1] :

- an aggregated "bag-of-words" count vector across all the county's messages in order to preserve anonymity. The unigrams represent the most frequent words in the data set;[2] ;
- a "bag-of-topics" representation for each county, with 2000 social media-derived topics described in (Schwartz et al., 2013).

Both feature sets will be releases across the 2009-2015 time span as well as individual years. Yearly updates will be included as they become available. As we are only releasing aggregated word-level features, as opposed to raw Tweets, this data release is within Twitter's Terms of Service.

2.2 Outcomes

The following U.S. county demographic, psychological and health variables were used in our prediction tasks. Table 2 gives statistics for each county variable.

---

[1] Available at `https://github.com/wwbp`

[2] While 25,000 features were used in the predictive tasks we removed some features (@-mentions, URLs, etc.) from the data release to preserve anonymity.

	Number of Tweets				Number of Users
	Full Sample	County Mapped	English*	User Level**	
10%	37.6B	1.78B	1.64B	1.53B	5.25M
1%	-	-	199M	131M	1.57M

Table 1: Number of tweets in each section of the resource, including the total number of users. (*) The number of tweets used in the "all" experiments; (**) the number of tweets in the remaining experiments.

	N	Mean	Std Dev	Min	Max	Skew
Income	1750	4.66	0.11	4.33	5.07	0.47
Educat.	1750	21.57	9.46	5.70	70.30	1.20
Life Satis.	1952	3.39	0.03	3.26	3.51	0.02
Heart Dis.	2041	186.66	45.59	54.82	412.32	0.66

Table 2: Descriptives of U.S. County data used in the four prediction tasks.

Income and Education The census data for county median household income (log-transformed to reduce skewness; N=1,750) and percentage of people with a Bachelor's degree (N=1,750) were obtained from the 2010 U.S. Census Bureau's American Community Survey (ACS).

Life Satisfaction To assess subjective well-being we used the average response to the question "In general, how satisfied are you with in your life?" (1 = very dissatisfied and 5 = very satisfied) (Lawless and Lucas, 2011). Estimates are averaged across 2009 and 2010 (N=1,952).

Mortality Rates From the Centers of Disease Control and Prevention (CDC) we collected age-adjusted mortality rates for heart disease (N=2,041). Rates are averaged across 2010-2015.

3 Methods

3.1 Aggregation

Our aim is to use the user-level information based on the assumption that aggregating data first at the user-level would remove biases introduced by non-standard users of the platform. To this end, we explore three types of aggregation: (1) tweet to county, (2) county "bag of words" and (3) user to county.

Tweet to County Here we compute

$$\text{feat}_{i,j} = \frac{1}{N_j} \sum_{k} \mathbb{1}_i(\text{unigram}_k), \qquad (1)$$

where $\mathbb{1}_i$ denotes the indicator function for unigram$_i$. Here the ith feature for the jth unit of analysis (a U.S. county) is equal to the relative frequency of the unigram: the number of times each unigram was mentioned divided by N_j the total number of tweets from county j.

County Next, we use a method which was generally used in past research, which aggregates all messages to a community disregarding any meta-data, including tweet or user information. Previous state-of-the-art results using this method include life satisfaction r = .31 (Schwartz et al., 2013), atheroclerotic heart disease r = .42 (Eichstaedt et al., 2015) and education r = 0.15 (Culotta, 2014b). We therefore consider each county a "bag of words" using (1) with N_j equal to the number of unigrams from county j.

User to County The third method treats the unit of analysis (U.S. county) as a community of users. Therefore, feature weights are extracted at the user level, normalized and then averaged to communities:

$$\text{feat}_{i,j} = \frac{1}{N_j} \sum_{k \in U_j} r_k(\text{unigram}_i), \qquad (2)$$

where U_j is the set of users in county j, N_j is the total number of Twitter users in county j and $r_k(x)$ is the relative frequency of feature x for user k with $i \in \{\text{all unigrams}\}$ and $j \in \{\text{all counties}\}$.

Features

We use as features a list of 2,000 social media-derived topics generated from Latent Dirichlet Allocation (Blei et al., 2003) using the complete MyPersonality Facebook data set consisting of approximately 15 million posts (Schwartz et al., 2013). The topic loadings are computed from the most frequent 25,000 unigrams in our data set. We also use a subset of these unigrams as additional features in our models (25,000 reduced to 10,000).

Experimental setup

For each of the four county level Census and health variables we built three models using 10-fold cross validation with the following features: (1) unigrams, (2) topics and (3) unigrams + topics. For consistency across tasks we only considered counties with 100 or more 30+ tweet users (N=2,041).

	Income	Educat.	Life Satis.	Heart Disease
Tweet to County	.68	.80	.26	.70
County	.73	.80	.37	.70
User to County	**.82**	**.88**	**.47**	**.75**

(a) Unigrams + Topics, Pearson r

	Income	Educat.	Life Satis.	Heart Disease
Tweet to County	.67	.79	.22	.65
County	.72	.78	.37	.64
User to County	**.79**	**.87**	**.44**	**.73**

(b) Unigrams, Pearson r

	Income	Educat.	Life Satis.	Heart Disease
Tweet to County	.65	.77	.31	.71
County	.68	.80	.34	.71
User to County	**.81**	**.87**	**.47**	**.76**

(c) Topics, Pearson r

Table 3: Prediction results (Pearson r) for direct aggregation comparison on the 10% sample.

We used a feature selection pipeline which first removed all low variance features and then features that were not correlated with our census and health data. Principal component analysis was then applied to the reduced feature set for further dimensionality reduction. This preprocessing was used to avoid overfitting, since our model included more independent variables (2000 topic frequencies and/or 10k unigrams) than observations (at most 2,041 counties). For the prediction task we used linear regression with ℓ_2 regularization (Ridge regression) (Eichstaedt et al., 2015). The regression regularization parameter α was set to 1000 using grid search.

Because our initial dataset consisted of 37.6 billion tweets, using distributed IO was crucial for data aggregation and feature extraction. We used a Hadoop-style cluster consisting of 64 disks and 64 CPU cores across 8 physical machines. Over this cluster, we used Hadoop MapReduce for the county mapping step (taking approximately 1 week of wall clock runtime) and Spark for the feature aggregations (taking approximately 1 day of wall clock runtime). The entire pipeline of county mapping, English language filtering, feature extraction and prediction used the DLATK Python package (Schwartz et al., 2017)[3].

	Income	Educat.	Life Satis.	Heart Disease
User to County	**.82**	**.88**	**.47**	**.75**
$N_{user-tweets}$	1.350B	1.350B	1.356B	1.360B
Tweet to County (all)	.72	.81	.36	.71
County (all)	.73	.82	.31	.72
$N_{all-tweets}$	1.621B	1.621B	1.628B	1.634B

Table 4: Prediction results (Pearson r, using unigrams + topics) using full 10% data vs. users with 30+ tweets. The number of tweets used in each task is listed to highlight the fact that the "User to County" tasks use less tweets than the "all" tasks.

Experiments

Using the above setup we perform 3 experiments in order to explore the effects of data aggregation. We 1) directly compare aggregation methods using our 10% data; 2) compare aggregation methods using a 1% sample and, finally, 3) explore the effect of choosing an upper bound on the number of posts per Twitter users, looking at users with less than 50, 500, 1000 posts. This allows us to exclude frequent posters who are potentially organizations or bots.

4 Results and Discussion

Direct aggregation comparison. The results of our predictive experiments on the 10% data can be found in Table 3. Across all four tasks we see that the "User to County" approach outperforms the other aggregation methods, giving a higher Pearson r and obtaining state-of-the-art results for community-level predictions.

We see the largest gains for the "User to County" aggregation for the income outcome, with a 13 point increase in Pearson r for topics alone and a 9 point increase for unigrams + topics.

In Table 4 we remove the 30+ tweet requirement from the "Tweet to County" and "County" methods and compare against the "User to County" method (with the 30+ tweet requirement). Again we see the "User to County" method outperforms all others in spite of the fact that the "User to County" approach uses less data than both "all" approaches, which contains 108 million more tweets.

1% data. In Table 5 we repeat the above experiment on a 1% Twitter sample. Here we see that the "User to County" method outperforms both the "Tweet to County" and "County" methods (with all three tasks using the same number of

	500	.80	.87	.47	.76	611,661
	1000	.81	.87	.47	.76	217,517
	No Max	.81	.87	.48	.76	-

Table 6: Prediction results (Pearson r) using topics + unigrams. Users with more than "Max Tweets" number of tweets are removed from the sample.

tweets). When we compare the "User to County" and "County (all)" methods we see the "User to county" outperforming on two out of four tasks (Income and Life Satisfaction). Again, we note that the "User to County" is using less data than the "County (all)". While, across the board, the performance increase is not as substantial as in the 10% results, we see comparable performance between "User to County" and "County (all)" methods despite the difference in the number of tweets.

Super users. One theory why we see such large gains depending on aggregation technique is that aggregating through users negates the effects of super users – those who post an extraordinary amount (such as organizations or bots). We implemented a maximum tweet requirement in order to remove these users and see if that accounts for the difference. Here we use both the "User to County" and "County (all)" samples and report results in Table 6. These results demonstrate that by keeping only users with less than 500 tweets we get results close to our "User to County (No Max)" method using the user-naive "County (all)" scheme. This shows that relatively few users (in this case 611k) can significantly decrease performance, though still leaves a small gain from the user to county approach. As seen in the lower half of the table, this thresholding does not increase performance when using the "User to County" method, which suggests such users can still be beneficial if they are just treated such that they can't dominate a community. This highlights the benefit of our simple method: we do not need to consider optimizations which may not generalize across data, such as upper-bound thresholds on the number of tweets per user. Further, the user-to-county aggregation seems to provide at least a small benefit beyond removal of super users.

5 Conclusion

This study explored the benefit of aggregation techniques for streaming user-generated data from individual messages to community level data, the typical setting for nowcasting. We showed that by simply aggregating to users first and then taking the mean within a county, we can obtain large gains (remarkably, up to a 13 point increase in Pearson correlation) over typical aggregation methods common in past work. In order to foster nowcasting research utilizing this more ideal aggregation, we will release the County Tweet Lexical Bank – a large aggregated and anonymized county-level data set, and computed on more than 1.6 billion tweets posted over 5 years.

Future work in this area can look at adjusting models to account for other meta-data such as temporal variation and diversity and to adjust for selection biases present in social media, where the user base on social media is not representative of the population of the community (Greenwood et al., 2016).

Abstract

We propose a conditional non-autoregressive neural sequence model based on iterative refinement. The proposed model is designed based on the principles of latent variable models and denoising autoencoders, and is generally applicable to any sequence generation task. We extensively evaluate the proposed model on machine translation (En↔De and En↔Ro) and image caption generation, and observe that it significantly speeds up decoding while maintaining the generation quality comparable to the autoregressive counterpart.

1 Introduction

Conditional neural sequence modeling has become a *de facto* standard in a variety of tasks (see, e.g., Cho et al., 2015, and references therein). Much of this recent success is built on top of autoregressive sequence models in which the probability of a target sequence is factorized as a product of conditional probabilities of next symbols given all the preceding ones. Despite its success, neural autoregressive modeling has its weakness in decoding, i.e., finding the most likely sequence. Because of intractability, we must resort to suboptimal approximate decoding, and due to its sequential nature, decoding cannot be easily parallelized and results in a large latency (see, e.g., Cho, 2016). This has motivated the recent investigation into non-autoregressive neural sequence modeling by Gu et al. (2017) in the context of machine translation and Oord et al. (2017) in the context of speech synthesis.

In this paper, we propose a non-autoregressive neural sequence model based on iterative refinement, which is generally applicable to any sequence generation task beyond machine translation. The proposed model can be viewed as both a latent variable model and a conditional denoising autoencoder. We thus propose a learning algorithm that is hybrid of lowerbound maximization and reconstruction error minimization. We further design an iterative inference strategy with an adaptive number of steps to minimize the generation latency without sacrificing the generation quality.

We extensively evaluate the proposed conditional non-autoregressive sequence model and compare it against the autoregressive counterpart, using the state-of-the-art Transformer (Vaswani et al., 2017), on machine translation and image caption generation. In the case of machine translation, the proposed deterministic non-autoregressive models are able to decode approximately $2-3\times$ faster than beam search from the autoregressive counterparts on both GPU and CPU, while maintaining 90-95% of translation quality on IWSLT'16 En↔De, WMT'16 En↔Ro and WMT'14 En↔De. On image caption generation, we observe approximately $3\times$ and $5\times$ faster decoding on GPU and CPU, respectively, while maintaining 85% of caption quality.[1]

2 Non-Autoregressive Sequence Models

Sequence modeling in deep learning has largely focused on autoregressive modeling. That is, given a sequence $Y = (y_1, \ldots, y_T)$, we use some form of a neural network to parametrize the conditional distribution over each variable y_t given all the preceding variables, i.e.,

$$\log p(y_t | y_{<t}) = f_\theta(y_{<t}),$$

where f_θ is for instance a recurrent neural network. This approach has become a *de facto* standard in language modeling (Mikolov et al.,

Brussels, Belgium, October 31 - November 4, 2018.

2010). When this is conditioned on an extra variable X, it becomes a conditional sequence model $\log p(Y|X)$ which serves as a basis on which many recent advances in, e.g., machine translation (Bahdanau et al., 2014; Sutskever et al., 2014; Kalchbrenner and Blunsom, 2013) and speech recognition (Chorowski et al., 2015; Chiu et al., 2017) have been made.

Despite the recent success, autoregressive sequence modeling has a weakness due to its nature of sequential processing. This weakness shows itself especially when we try to decode the most likely sequence from a trained model, i.e.,

$$\hat{Y} = \arg\max_{Y} \log p(Y|X).$$

There is no known polynomial algorithm for solving it exactly, and practitioners have relied on approximate decoding algorithms (see, e.g., Cho, 2016; Hoang et al., 2017). Among these, beam search has become the method of choice, due to its superior performance over greedy decoding, which however comes with a substantial computational overhead (Cho, 2016).

As a solution to this issue of slow decoding, two recent works have attempted non-autoregressive sequence modeling. Gu et al. (2017) have modified the Transformer (Vaswani et al., 2017) for non-autoregressive machine translation, and Oord et al. (2017) a convolutional network (Oord et al., 2016) for non-autoregressive modeling of waveform. Non-autoregressive modeling factorizes the distribution over a target sequence given a source into a product of conditionally independent per-step distributions:

$$p(Y|X) = \prod_{t=1}^{T} p(y_t|X),$$

breaking the dependency among the target variables across time. This allows us to trivially find the most likely target sequence by taking $\arg\max_{y_t} p(y_t|X)$ for each t, effectively bypassing the computational overhead and sub-optimality of decoding from an autoregressive sequence model.

This desirable property of exact and parallel decoding however comes at the expense of potential performance degradation (Kaiser and Bengio, 2016). The potential modeling gap, which is the gap between the underlying, true model and the neural sequence model, could be larger with the non-autogressive model compared to the autoregressive one due to challenge of modeling the factorized conditional distribution above.

3 Iterative Refinement for Deterministic Non-Autoregressive Sequence Models

3.1 Latent variable model

Similarly to two recent works (Oord et al., 2017; Gu et al., 2017), we introduce latent variables to implicitly capture the dependencies among target variables. We however remove any stochastic behavior by interpreting this latent variable model, introduced immediately below, as a process of iterative refinement.

Our goal is to capture the dependencies among target symbols given a source sentence without auto-regression by introducing L intermediate random variables and marginalizing them out:

$$p(Y|X) = \sum_{Y^0,\ldots,Y^L} \left(\prod_{t=1}^{T} p(y_t|Y^L, X) \right) \qquad (1)$$
$$\left(\prod_{t=1}^{T} p(y_t^L|Y^{L-1}, X) \right) \cdots \left(\prod_{t=1}^{T} p(y_t^0|X) \right).$$

Each product term inside the summation is modelled by a deep neural network that takes as input a source sentence and outputs the conditional distribution over the target vocabulary V for each t.

Deterministic Approximation The marginalization in Eq. (1) is intractable. In order to avoid this issue, we consider two approximation strategies; deterministic and stochastic approximation. Without loss of generality, let us consider the case of single intermediate latent variable, that is $L = 1$. In the *deterministic* case, we set $\hat{y}_t^0$ to the most likely value according to its distribution $p(y_t^0|X)$, that is $\hat{y}_t^0 = \arg\max_{y_t^0} p(y_t^0|X)$. The entire lower bound can then be written as:

$$\log p(Y|X) \geq \left(\sum_{t=1}^{T} \log p(y_t|\hat{Y}^L, X) \right) + \cdots$$
$$+ \left(\sum_{t=1}^{T} \log p(y_t^1|\hat{Y}^0, X) \right) + \left(\sum_{t=1}^{T} \log p(\hat{y}_t^0|X) \right).$$

Stochastic Approximation In the case of *stochastic* approximation, we instead sample $\hat{y}_t^0$ from the distribution $p(y_t^0|X)$. This results in the unbiased estimate of the marginal log-probability $\log p(Y|X)$. Other than the difference in whether most likely values or samples are used, the remaining steps are identical.

Latent Variables Although the intermediate random variables could be anonymous, we constrain them to be of the same type as the output Y is, in order to share an underlying neural network. This constraint allows us to view each conditional $p(Y^l|\hat{Y}^{l-1}, X)$ as a single-step of refinement of a rough target sequence $\hat{Y}^{l-1}$. The entire chain of L conditionals is then the L-step iterative refinement. Furthermore, sharing the parameters across these refinement steps enables us to dynamically adapt the number of iterations per input X. This is important as it substantially reduces the amount of time required for decoding, as we see later in the experiments.

Training For each training pair (X, Y^*), we first approximate the marginal log-probability. We then minimize

$$J_{\text{LVM}}(\theta) = -\sum_{l=0}^{L+1} \left(\sum_{t=1}^{T} \log p_\theta(y_t^*|\hat{Y}^{l-1}, X) \right), \tag{2}$$

where $\hat{Y}^{l-1} = (\hat{y}_1^{l-1}, \ldots, \hat{y}_T^{l-1})$, and θ is a set of parameters. We initialize $\hat{y}_t^0$ (t-th target word in the first iteration) as $x_{t'}$, where $t' = (T'/T) \cdot t$. T' and T are the lengths of the source X and target Y^*, respectively.

3.2 Denoising Autoencoder

The proposed approach could instead be viewed as learning a conditional denoising autoencoder which is known to capture the gradient of the log-density. That is, we implicitly learn to find a direction Δ_Y in the output space that maximizes the underlying true, data-generating distribution $\log P(Y|X)$. Because the output space is discrete, much of the theoretical analysis by Alain and Bengio (2014) are not strictly applicable. We however find this view attractive as it serves as an alternative foundation for designing a learning algorithm.

Training We start with a corruption process $C(Y|Y^*)$, which introduces noise to the correct output Y^*. Given the reference translation Y^*, we sample $\tilde{Y} \sim C(Y|Y^*)$ which becomes as an input to each conditional in Eq. (1). Then, the goal of learning is to maximize the log-probability of the original reference Y^* given the corrupted version. That is, to minimize

$$J_{\text{DAE}}(\theta) = -\sum_{t=1}^{T} \log p_\theta(y_t^*|\tilde{Y}, X). \tag{3}$$

Once this cost J_{DAE} is minimized, we can recursively perform the maximum-a-posterior inference, i.e., $\hat{Y} = \arg\max_Y \log p_\theta(Y|X)$, to find $\hat{Y}$ that (approximately) maximizes $\log p(Y|X)$.

Corruption Process C There is little consensus on the best corruption process for a sequence, especially of discrete tokens. In this work, we use a corruption process proposed by Hill et al. (2016), which has recently become more widely adopted (see, e.g., Artetxe et al., 2017; Lample et al., 2017). Each y_t^* in a reference target $Y^* = (y_1^*, \ldots, y_T^*)$ is corrupted with a probability $\beta \in [0, 1]$. If decided to corrupt, we either (1) replace y_{t+1}^* with this token y_t^*, (2) replace y_t^* with a token uniformly selected from a vocabulary of all unique tokens at random, or (3) swap y_t^* and y_{t+1}^*. This is done sequentially from y_1^* until y_T^*.

3.3 Learning

Cost function Although it is possible to train the proposed non-autoregressive sequence model using either of the cost functions above (J_{LVM} or J_{DAE},) we propose to stochastically mix these two cost functions. We do so by randomly replacing each term $\hat{Y}^{l-1}$ in Eq. (2) with $\tilde{Y}$ in Eq. (3):

$$J(\theta) = -\sum_{l=0}^{L+1} \left(\alpha_l \sum_{t=1}^{T} \log p_\theta(y_t^*|\hat{Y}^{l-1}, X) \right. \tag{4}$$
$$\left. +(1-\alpha_l) \sum_{t=1}^{T} \log p_\theta(y_t^*|\tilde{Y}, X) \right),$$

where $\tilde{Y} \sim C(Y|Y^*)$, and α_l is a sample from a Bernoulli distribution with the probability p_{DAE}. p_{DAE} is a hyperparameter. As the first conditional $p(Y^0|X)$ in Eq. (1) does not take as input any target Y, we set $\alpha_0 = 1$ always.

Distillation Gu et al. (2017), in the context of machine translation, and Oord et al. (2017), in the context of speech generation, have recently discovered that it is important to use knowledge distillation (Hinton et al., 2015; Kim and Rush, 2016) to successfully train a non-autoregressive sequence model. Following Gu et al. (2017), we also use knowledge distillation by replacing the reference target Y^* of each training example

(X, Y^*) with a target Y^{AR} generated from a well-trained autoregressive counterpart. Other than this replacement, the cost function in Eq (4) and the model architecture remain unchanged.

Target Length Prediction One difference between the autoregressive and non-autoregressive models is that the former naturally models the length of a target sequence without any arbitrary upper-bound, while the latter does not. It is hence necessary to separately model $p(T|X)$, where T is the length of a target sequence, although during training, we simply use the length of each reference target sequence.

3.4 Inference: Decoding

Inference in the proposed approach is entirely deterministic. We start from the input X and first predict the length of the target sequence $\hat{T} = \arg\max_T \log p(T|X)$. Then, given X and $\hat{T}$ we generate the initial target sequence by $\hat{y}_t^0 = \arg\max_{y_t} \log p(y_t^0|X)$, for $t = 1, \ldots, T$ We continue refining the target sequence by $\hat{y}_t^l = \arg\max_{y_t} \log p(y_t^l|\hat{Y}^{l-1}, X)$, for $t = 1, \ldots, T$.

Because these conditionals, except for the initial one, are modeled by a single, shared neural network, this refinement can be performed as many iterations as necessary until a predefined stopping criterion is met. A criterion can be based either on the amount of change in a target sequence after each iteration (i.e., $D(\hat{Y}^{l-1}, \hat{Y}^l) \leq \epsilon$), or on the amount of change in the conditional log-probabilities (i.e., $|\log p(\hat{Y}^{l-1}|X) - \log p(\hat{Y}^{l-1}|X)| \leq \epsilon$) or on the computational budget. In our experiments, we use the first criterion and use Jaccard distance as our distance function D.

4 Related Work

Non-Autoregressive Neural Machine Translation Schwenk (2012) proposed a continuous-space translation model to estimate the conditional distribution over a target phrase given a source phrase, while dropping the conditional dependencies among target tokens. The evaluation was however limited to reranking and to short phrase pairs (up to 7 words on each side) only. Kaiser and Bengio (2016) investigated neural GPU (Kaiser and Sutskever, 2015), for machine translation. They evaluated both non-autoregressive and autoregressive approaches, and found that the non-autoregressive approach significantly lags behind the autoregressive variants. It however differs from our approach that each iteration does not output a refined version from the previous iteration. The recent paper by Gu et al. (2017) is most relevant to the proposed work. They similarly introduced a sequence of discrete latent variables. They however use supervised learning for inference, using the word alignment tool (Dyer et al., 2013). To achieve the best result, Gu et al. (2017) stochastically sample the latent variables and rerank the corresponding target sequences with an external, autoregressive model. This is in contrast to the proposed approach which is fully deterministic during decoding and does not rely on any extra reranking mechanism.

Parallel WaveNet Simultaneously with Gu et al. (2017), Oord et al. (2017) presented a non-autoregressive sequence model for speech generation. They use inverse autoregressive flow (IAF, Kingma et al., 2016) to map a sequence of independent random variables to a target sequence. They apply the IAF multiple times, similarly to our iterative refinement strategy. Their approach is however restricted to continuous target variables, while the proposed approach in principle could be applied to both discrete and continuous variables.

Post-Editing for Machine Translation Novak et al. (2016) proposed a convolutional neural network that iteratively predicts and applies token substitutions given a translation from a phase-based translation system. Unlike their system, our approach can edit an intermediate translation with a higher degree of freedom. QuickEdit (Grangier and Auli, 2017) and deliberation network (Xia et al., 2017) incorporate the idea of refinement into neural machine translation. Both systems consist of two autoregressive decoders. The second decoder takes into account the translation generated by the first decoder. We extend these earlier efforts by incorporating more than one refinement steps without necessitating extra annotations.

Infusion Training Bordes et al. (2017) proposed an unconditional generative model for images based on iterative refinement. At each step l of iterative refinement, the model is trained to maximize the log-likelihood of target Y given the weighted mixture of generated samples from the previous iteration $\hat{Y}^{l-1}$ and a corrupted target $\tilde{Y}$. That is, the corrupted version of target is "infused"

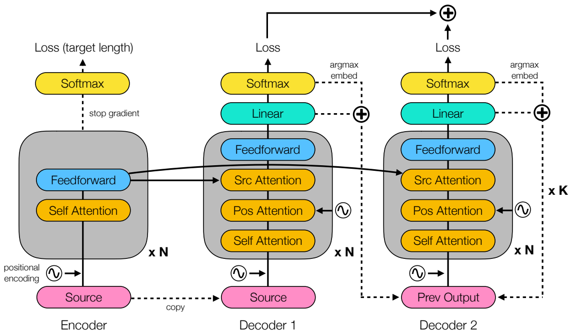

Figure 2: We compose three transformer blocks ("Encoder", "Decoder 1" and "Decoder 2") to implement the proposed non-autoregressive sequence model.

into generated samples during training. In the domain of text, however, computing a weighted mixture of two sequences of discrete tokens is not well defined, and we propose to stochastically mix denoising and lowerbound maximization objectives.

5 Network Architecture

We use three transformer-based network blocks to implement our model. The first block ("Encoder") encodes the input X, the second block ("Decoder 1") models the first conditional $\log p(Y^0|X)$, and the final block ("Decoder 2") is shared across iterative refinement steps, modeling $\log p(Y^l|\hat{Y}^{l-1}, X)$. These blocks are depicted side-by-side in Fig. 2. The encoder is identical to that from the original Transformer (Vaswani et al., 2017). We however use the decoders from Gu et al. (2017) with additional positional attention and use the highway layer (Srivastava et al., 2015) instead of the residual layer (He et al., 2016).

The original input X is padded or shortned to fit the length of the reference target sequence before being fed to Decoder 1. At each refinement step l, Decoder 2 takes as input the predicted target sequence $\hat{Y}^{l-1}$ and the sequence of final activation vectors from the previous step.

6 Experimental Setting

We evaluate the proposed approach on two sequence modeling tasks: machine translation and image caption generation. We compare the proposed non-autoregressive model against the autoregressive counterpart both in terms of generation quality, measured in terms of BLEU (Papineni et al., 2002), and generation efficiency, measured in terms of (source) tokens and images per second for translation and image captioning, respectively.

Machine Translation We choose three tasks of different sizes: IWSLT'16 En↔De (196k pairs), WMT'16 En↔Ro (610k pairs) and WMT'14 En↔De (4.5M pairs). We tokenize each sentence using a script from Moses (Koehn et al., 2007) and segment each word into subword units using BPE (Sennrich et al., 2016). We use 40k tokens from both source and target for all the tasks. For WMT'14 En-De, we use newstest-2013 and newstest-2014 as development and test sets. For WMT'16 En-Ro, we use newsdev-2016 and newstest-2016 as development and test sets. For IWSLT'16 En-De, we use test2013 for validation.

We closely follow the setting by Gu et al. (2017). In the case of IWSLT'16 En-De, we use the small model ($d_{\text{model}} = 278, d_{\text{hidden}} = 507, p_{\text{dropout}} = 0.1, n_{\text{layer}} = 5$ and $n_{\text{head}} = 2$).[2] For WMT'14 En-De and WMT'16 En-Ro, we use the base transformer by Vaswani et al. (2017) ($d_{\text{model}} = 512, d_{\text{hidden}} = 512, p_{\text{dropout}} = 0.1, n_{\text{layer}} = 6$ and $n_{\text{head}} = 8$). We use the warm-up learning rate scheduling (Vaswani et al., 2017) for the WMT tasks, while using linear annealing (from 3×10^{-4} to 10^{-5}) for the IWSLT task. We do not use label smoothing nor average multiple check-pointed models. These decisions were made based on the preliminary experiments. We train each model either on a single

P40 (WMT'14 En-De and WMT'16 En-Ro) or on a single P100 (IWSLT'16 En-De) with each minibatch consisting of approximately 2k tokens. We use four P100's to train non-autoregressive models on WMT'14 En-De.

Image Caption Generation: MS COCO We use MS COCO (Lin et al., 2014). We use the publicly available splits (Karpathy and Li, 2015), consisting of 113,287 training images, 5k validation images and 5k test images. We extract 49 512-dimensional feature vectors for each image, using a ResNet-18 (He et al., 2016) pretrained on ImageNet (Deng et al., 2009). The average of these vectors is copied as many times to match the length of the target sentence (reference during training and predicted during evaluation) to form the initial input to Decoder 1. We use the base transformer (Vaswani et al., 2017) except that n_{layer} is set to 4. We train each model on a single 1080ti with each minibatch consisting of approximately 1,024 tokens.

Target Length Prediction We formulate the target length prediction as classification, predicting the difference between the target and source lengths for translation and the target length for image captioning. All the hidden vectors from the n_{layer} layers of the encoder are summed and fed to a softmax classifier after affine transformation. We however do not tune the encoder's parameters for target length prediction. We use this length predictor only during test time. We find it important to accurately predict the target length for good overall performance. See Appendix A for an analysis on our length prediction model.

Training and Inference We use Adam (Kingma and Ba, 2014) and use $L = 3$ in Eq. (1) during training ($i_{\text{train}} = 4$ from hereon.) We use $p_{\text{DAE}} = 0.5$. We use the deterministic strategy for IWSLT'16 En-De, WMT'16 En-Ro and MS COCO, while the stochastic strategy is used for WMT'14 En-De. These decisions were made based on the validation set performance. After both the non-autogressive sequence model and target length predictor are trained, we decode by first predicting the target length and then running iterative refinement steps until the outputs of consecutive iterations are the same (or Jaccard distance between consecutive decoded sequences is 1). To assess the effectiveness of this adaptive scheme, we also test a fixed number of steps (i_{dec}). In machine translation, we remove any repetition by collapsing multiple consecutive occurrences of a token.

7 Results and Analysis

We make some important observations in Table 1. First, the generation quality improves across all the tasks as we run more refinement steps i_{dec} even beyond that used in training ($i_{\text{train}} = 4$), which supports our interpretation as a conditional denoising autoencoder in Sec. 3.2. To further verify this, we run decoding on WMT'14 (both directions) up to 100 iterations. As shown in Fig. 1 (a), the quality improves well beyond the number of refinement steps used during training.

Second, the generation efficiency decreases as more refinements are made. We plot the average seconds per sentence in Fig. 1 (b), measured on GPU while sequentially decoding one sentence at a time. As expected, decoding from the autoregressive model linearly slows down as the sen-

	i_{train}	p_{DAE}	distill	En→De rep	En→De no rep	De→En rep	De→En no rep

Table 2: Ablation study on the dev set of IWSLT'16.

tence length grows, while decoding from the non-autoregressive model with a fixed number of iterations has the constant complexity. However, the generation efficiency of non-autoregressive model decreases as more refinements are made. To make a smooth trade-off between the quality and speed, the adaptive decoding scheme allows us to achieve near-best generation quality with a significantly lower computational overhead. Moreover, the adaptive decoding scheme automatically increases the number of refinement steps as the sentence length increases, suggesting that this scheme captures the amount of information in the input well. The increase in latency is however less severe than that of the autoregressive model.

We also observe that the speedup in decoding is much clearer on GPU than on CPU. This is a consequence of highly parallel computation of the proposed non-autoregressive model, which is better suited to GPUs, showcasing the potential of using the non-autoregressive model with a specialized hardware for parallel computation, such as Google's TPUs (Jouppi et al., 2017). The results of our model decoded with adaptive decoding scheme are comparable to the results from (Gu et al., 2017), without relying on any external tool. On WMT'14 En-De, the proposed model outperforms the best model from (Gu et al., 2017) by two points.

Lastly, it is encouraging to observe that the proposed non-autoregressive model works well on image caption generation. This result confirms the generality of our approach beyond machine translation, unlike that by Gu et al. (2017) which was for machine translation or by Oord et al. (2017) which was for speech synthesis.

	√	27.11	18.91
√	√	25.39	21.22

Table 3: Deterministic and stochastic approximation

Ablation Study We use IWSLT'16 En-De to investigate the impact of different number of refinement steps during training (denoted as i_{train}) as well as probability of using denoising autoencoder objective during training (denoted as p_{DAE}). The results are presented in Table 2.

First, we observe that it is beneficial to use multiple iterations of refinement during training. By using four iterations (one step of decoder 1, followed by three steps of decoder 2), the BLEU score improved by approximately 1.5 points in both directions. We also notice that it is necessary to use the proposed hybrid learning strategy to maximize the improvement from more iterations during training ($i_{\text{train}} = 4$ vs. $i_{\text{train}} = 4, p_{\text{DAE}} = 1.0$ vs. $i_{\text{train}} = 4, p_{\text{DAE}} = 0.5$.) Knowledge distillation was crucial to close the gap between the proposed deterministic non-autoregressive sequence model and its autoregressive counterpart, echoing the observations by Gu et al. (2017) and Oord et al. (2017). Finally, we see that removing repeating consecutive symbols improves the quality of the best trained models ($i_{\text{train}} = 4, p_{\text{DAE}} = 0.5$) by approximately +1 BLEU. This suggests that the proposed iterative refinement is not enough to remove repetitions on its own. Further investigation is necessary to properly tackle this issue, which we leave as a future work.

We then compare the deterministic and stochastic approximation strategies on IWSLT'16 En→De and WMT'14 En→De. According to the results in Table 3, the stochastic strategy is crucial with a large corpus (WMT'14), while the deterministic strategy works as well or better with a small corpus (IWSLT'16). Both of the strategies benefit from knowledge distillation, but the gap between the two strategies when the dataset is large is much more apparent without knowledge distillation.

7.1 Qualitative Analysis

Machine Translation In Table 4, we present three sample translations and their iterative refinement steps from the development set of IWSLT'16 (De→En). As expected, the sequence generated from the first iteration is a rough version of translation and is iteratively refined over multiple steps. By inspecting the underlined sub-sequences, we see that each iteration does not monotonically improve the translation, but overall modifies the

Table 4: Three sample De→En translations from the non-autoregressive sequence model. Source sentences are from the dev set of IWSLT'16. The first iteration corresponds to Decoder 1, and from thereon, Decoder 2 is repeatedly applied. Sub-sequences with changes across the refinement steps are underlined.

translation towards the reference sentence. Missing words are added, while unnecessary words are dropped. For instance, see the second example. The second iteration removes the unnecessary "were", and the fourth iteration inserts a new word "mostly". The phrase "at the time" is gradually added one word at a time.

Image Caption Generation Table 5 shows two examples of image caption generation. We observe that each iteration captures more and more details of the input image. In the first example (left), the bus was described only as a "yellow bus" in the first iteration, but the subsequent iterations refine it into "yellow and black bus". Similarly, "road" is refined into "lot". We notice this behavior in the second example (right) as well. The first iteration does not specify the place in which "a woman" is "standing on", which is fixed immediately in the second iteration: "standing on a tennis court". In the final and fourth iteration, the proposed model captures the fact that the "woman" is "holding" a racquet.

8 Conclusion

Following on the exciting, recent success of non-autoregressive neural sequence modeling by Gu et al. (2017) and Oord et al. (2017), we proposed a deterministic non-autoregressive neural sequence model based on the idea of iterative refinement. We designed a learning algorithm specialized to the proposed approach by interpreting the entire model as a latent variable model and each refinement step as denoising.

We implemented our approach using the Transformer and evaluated it on two tasks: machine translation and image caption generation. On both tasks, we were able to show that the proposed non-autoregressive model performs closely to the autoregressive counterpart with significant speedup in decoding. Qualitative analysis revealed that the iterative refinement indeed refines a target sequence gradually over multiple steps.

Despite these promising results, we observed that proposed non-autoregressive neural sequence model is outperformed by its autoregressive counterpart in terms of the generation quality. The following directions should be pursued in the future to narrow this gap. First, we should investigate better approximation to the marginal log-probability. Second, the impact of the corruption process on the generation quality must be studied. Lastly, further work on sequence-to-sequence model architectures could yield better results in non-autoregressive sequence modeling.

Abstract

We propose a large margin criterion for training neural language models. Conventionally, neural language models are trained by minimizing perplexity (PPL) on grammatical sentences. However, we demonstrate that PPL may not be the best metric to optimize in some tasks, and further propose a large margin formulation. The proposed method aims to enlarge the *margin* between the "good" and "bad" sentences in a task-specific sense. It is trained end-to-end and can be widely applied to tasks that involve re-scoring of generated text. Compared with minimum-PPL training, our method gains up to 1.1 WER reduction for speech recognition and 1.0 BLEU increase for machine translation.

1 Introduction

Language models (LMs) estimate the likelihood of a symbol sequence $\{x^t\}_{t=0}^T$, based on the joint probability,

$$p(x^0, \ldots, x^T) = p(x^0) \prod_{t=1}^{T} p(x^t | x^0, \ldots, x^{t-1}). \tag{1}$$

To measure the quality of an LM, a commonly adopted metric is perplexity (PPL), defined as

$$\text{PPL} \triangleq \exp\left\{ -\frac{1}{T} \sum_{t=0}^{T} \log p(x^t | x^0, \ldots, x^{t-1}) \right\},$$

A good language model has a small PPL, being able to assign higher likelihoods to sentences that are more likely to appear.

LMs are widely applied in automatic speech recognition (ASR) (Yu and Deng, 2014) and machine translation (MT) (Koehn, 2009). Following Koehn (2009), one may interpret the language model as prior knowledge on the text to be inferred, which provides information complementary to the ASR or MT system itself. In practice, there are several ways to incorporate the language model. The simplest way may be re-scoring an n-best list returned by the ASR or MT system (Mikolov et al., 2010; Sundermeyer et al., 2012). A slightly more sophisticated way is to jointly consider the ASR/MT and language model in a beam search decoder (Amodei et al., 2016). Specifically, at each time step, the decoder appends every symbol in the vocabulary to each sequence in the current candidate set. For every hypothesis, a score is calculated as a linear combination of the log-likelihoods given by both the ASR/MT and language models. Then, only the top K hypotheses with the highest scores are retained, as an updated candidate set. More recently, Gulcehre et al. (2015) and Sriram et al. (2017) propose to predict the next symbol based on a fusion of the hidden states in the ASR/MT and language models. A gating mechanism is jointly trained to determine how much the language model should contribute.

The afore-discussed language models are generative in the sense that they merely model the joint distribution of a symbol sequence (Eq. (1)). While the research community is mostly focused on pushing the limit of PPL (e.g., Jozefowicz et al., 2016), very limited attention has been paid to the discrimination power of language models when they are applied to real tasks, such as ASR and MT (Li and Khudanpur, 2008). By contrast, discriminative language modeling aims at enhancing the performance in downstream applications. For example, existing works (Roark et al., 2004, 2007) often target at improving ASR accuracy. The key motivation underlying them is that the model should be able to discriminate between "good" and "bad" sentences in a task-specific sense, instead

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1183–1191
Brussels, Belgium, October 31 - November 4, 2018.

of just modeling grammatical ones. The common methodology (Dikic et al., 2013) is to build a binary classifier upon hand-crafted features extracted from the sentences. However, it is not obvious how these methods can utilize large unannotated corpus, which is often easily available, and the hand-crafted features are also ad hoc and may result in suboptimal performance.

In this work, we study how to improve the discrimination ability of a recurrent network-based neural language model (RNNLM). The goal is to enlarge the difference between the log-likelihoods of "good" and "bad" sentences. In an contrast to the existing works (Roark et al., 2004, 2007), our method does not rely on hand-crafted features, and is trained in end-to-end manner and able to take advantage of large external text corpus. In fact, it is a general training criterion that is transparent to the network architecture of the RNNLM, and can be applied to various text generation tasks, including ASR and MT. Experiments on state-of-art ASR and MT systems show its significant advantage over an LM trained by minimizing PPL.

2 Background on RNNLM

We first give some background knowledge on RNNLMs. The prototypical RNNLM (Mikolov et al., 2010) has one layer of recurrent cell and works as follows. Denote a sentence as $\mathbf{x} = [x^0, \ldots, x^t, \ldots]$, where the x^t's are words. Let $\vec{x}^t$ be the embedding vector for x^t. The recurrent cell takes in the embedding and produces a hidden state $\vec{h}^t$ by

$$\vec{h}^t = \sigma(U\vec{x}^t + V\vec{h}^{t-1}),$$

where $\sigma(z) = \frac{1}{1+e^{-z}}$ is sigmoid activation function. $\vec{h}^{t-1}$ is the hidden state at the last timestep. U and V are learnable parameters. The $\vec{h}^t$ is then passed into a multi-way classifier to produce a probability distribution over the vocabulary (for the next word),

$$\vec{p} = \mathrm{softmax}(W\vec{h}^t + \vec{b}).$$

The W and $\vec{b}$ are also trainable parameters. The training objective is to maximize the log-likelihood of the next word, and the parameters are learned by back-propagation algorithm.

The vanilla recurrent cell can also be replaced by one or multiple layers of LSTM cells, which produces better results (Zaremba et al., 2014). In a more general form, the RNNLM can be represented as a conditional probability, $p_\theta(x^t|x^0, \ldots, x^{t-1})$, parameterized by θ. In the prototypical case, $\theta = [U, V, W, \vec{b}]$. We could define the *LM-score* of a sentence $\mathbf{x}$ as

$$\begin{aligned}\text{LM-score}(\mathbf{x}) &\triangleq \log p_\theta(\mathbf{x}) \\ &= \sum_t \log p_\theta(x^t|x^0, \ldots, x^{t-1}).\end{aligned}$$

The RNNLM is trained by maximizing the average LM-score over all the $\mathbf{x}$'s in a corpus, or equivalently, minimizing the PPL on the corpus.

3 Problem Formulation

We motivate and formulate a large margin training criterion in this section. Suppose for every reference sentence $\mathbf{x}_i$, we have a collection of hypotheses $\mathbf{x}_{i,j}, j = 1, \ldots, K$, usually obtained as the top-K candidates by a beam search decoder.

3.1 A Motivating Example

An RNNLM trained by minimizing PPL cannot guarantee a higher score on the "gold" reference than the inferior hypothesis, which is undesirable. One example is given in Tab. 1. The reference is taken from the text labels of dev93' set of Wall Street Journal (WSJ) dataset. The hypothesis is generated by a CTC-based (Graves et al., 2006) ASR system trained on WSJ training set. Words in red are mistakes made by the hypothesis. We then train an RNNLM on Common Crawl[1] copora by minimizing PPL. Training follows a typical setup (Jozefowicz et al., 2016) with a vocabulary of 400K the most frequent words. Any out-of-vocabulary word is replaced by an ⟨UNK⟩ token. The RNNLM is then employed to score the sentences. The LM-score of the erroneous hypothesis is higher than that of the reference. In fact, this is reasonable as "a decade as concerns" seems to be a more common phrase. In the training corpus, we find that "a decade as concerns" appears once, but "its defeat is confirmed" does not appear. Moreover, "a decade as" appears 2,280 times, but "its defeat is" appears only 24 times. However, this is undesirable because if there is another hypothesis that happens to be the same as reference, which will not be ranked as the best candidate.

It would be helpful if the LM can also learn from the imperfect hypotheses so that it can tell

---

(a) (b)

Figure 2: Histogram of the margin $\log p(\mathbf{x}_i) - \log p(\mathbf{x}_{i,j})$. The more positive, the more the discrimination. (a) Straightforward formulation; (b) LMLM compared with RNNLM (a minimum-PPL LM trained on Common Crawl)

apart "good" and "bad" candidates. With this motivation, we train to assign larger LM-scores for the $\mathbf{x}_i$'s but smaller ones for the (imperfect) $\mathbf{x}_{i,j}$'s. A quantity of particular interest is $\log p(\mathbf{x}_i) - \log p(\mathbf{x}_{i,j})$, the *margin*/difference between the LM-scores of the references and the (imperfect) hypotheses. The intuition is that the more positive the margin, the better the LM is at discrimination.

3.2 Straightforward but Failed Formulation

Without loss of generality, we assume that all the $\mathbf{x}_{i,j}$'s are imperfect and different from $\mathbf{x}_i$. A straightforward way is to adopt the following objective:

$$\min_{\theta} \frac{1}{N}\sum_{i=1}^{N}\left(-\log p_\theta(\mathbf{x}_i) + \frac{1}{K}\sum_{j=1}^{K}\log p_\theta(\mathbf{x}_{i,j})\right). \tag{2}$$

Similar formulation is also seen in (Tachioka and Watanabe, 2015), where they only utilize one beam candidate, *i.e.*, $K = 1$. Optimization can be carried out by mini-batch stochastic gradient descent (SGD). Each iteration, SGD randomly samples a batch of i's and j's, computes stochastic gradient w.r.t. θ, and takes an update step. However, a potential problem with this formulation is that the second term (corresponding to the inferior hypotheses) may dominate the optimization. Specifically, the training is almost always driven by the $\mathbf{x}_{i,j}$'s, but does not effectively enhance the discrimination. We illustrate this fact in the following experiment.

Using the ASR system in section 3.1, we extract 256 beam candidates for every training example in Wall Street Journal (WSJ) dataset. Warm started from the pre-trained RNNLM in section 3.1, we apply SGD to minimize the loss in Eq. (2), with a mini-batch size of 128. The training loss is shown in Fig. 1a. We observe that the learning dynamic is very unstable, and deceases to be negative. The unbound decreasing is due to the second term in Eq. (2) being negative and dominating the training process. Next, we inspect $\log p_\theta(\mathbf{x}_i) - \log p_\theta(\mathbf{x}_{i,j})$, the *margin* between the scores of a ground-truth and a candidate. In Fig. 2a, we histogram the margins for all the i, j's in a dev set. The distribution appears to be symmetric around zero, which indicates poor discrimination ability. Given these facts, we conclude that the straightforward formulation in Eq. (2) is not effective.

3.3 Large Margin Formulation

To effectively utilize all the imperfect beam candidates, we propose the following objective,

$$\min_{\theta} \sum_{i=1}^{N}\sum_{j=1}^{B} \max\left\{0, \tau - (\log p_\theta(\mathbf{x}_i) - \log p_\theta(\mathbf{x}_{i,j}))\right\}, \tag{3}$$

where $\log p_\theta(\mathbf{x}_i) - \log_\theta(\mathbf{x}_{i,j})$ is the margin between the scores of a ground-truth $\mathbf{x}_i$ and a candidate $\mathbf{x}_{i,j}$. The hinge loss on the margin encourages the log-likelihood of the ground-truth to be at least τ larger than that of the imperfect hypothesis. We call an LM trained by the above formulation as Large Margin Language Model (LMLM).

We repeat the same experiment in section 3.2, but change the objective function to Eq. (3) and set $\tau = 1$. Fig. 1b shows the training loss, which steadily decreases and approaches zero rapidly. Compared with the learning curve of naive formulation (Fig. 1a), the large margin based training is much more stable. In Fig. 2b, we also examine the histogram of $\log p_\theta(\mathbf{x}_i) - \log p_\theta(\mathbf{x}_{i,j})$, where $p_\theta(\cdot)$ is now the LM learned by LMLM. Compared with the histogram by the conventional RNNLM, LMLM significantly moves the distribution to the positive side, indicating more discrimination.

3.4 Ranking Loss Type Formulation

In most cases, all beam candidates are imperfect. It may be beneficial to exploit the information that some candidates are relatively better than the others. We consider ranking them according to some metrics w.r.t. the ground-truth sentences. For ASR, the metric is WER, and for MT, the metric is BLEU score. We define $\mathbf{x}_{i,0} \triangleq \mathbf{x}_i$ and assume that the candidates $\{\mathbf{x}_{i,j}\}_{j=1}^{K}$ are sorted such that

$$\text{WER}(\mathbf{x}_i, \mathbf{x}_{i,j-1}) < \text{WER}(\mathbf{x}_i, \mathbf{x}_{i,j})$$

for ASR, and

$$\text{BLEU}(\mathbf{x}_i, \mathbf{x}_{i,j-1}) > \text{BLEU}(\mathbf{x}_i, \mathbf{x}_{i,j})$$

for MT. In other words, $\mathbf{x}_{i,j-1}$ has better quality than $\mathbf{x}_{i,j}$.

We then enforce the "better" sentences to have a score at least τ larger than those "worse" ones. This leads to the following formulation,

$$\min_\theta \sum_{i=1}^{N} \sum_{j=0}^{B-1} \sum_{k=j+1}^{B} \max \{0, \tau - (\log p_\theta(\mathbf{x}_{i,j}) - \log_\theta(\mathbf{x}_{i,k})), \}. \quad (4)$$

Compared with LMLM formulation Eq. (3), the above introduces more comparisons among the candidates, and hence more computational cost during training. We call this formulation ranking-loss-based LMLM (rLMLM).

To summarize this section, we have proposed LMLM and rLMLM that aim at discriminating between hypotheses in a task-specific (e.g., WER or BLEU) sense, instead of minimizing PPL.

4 Experiments on ASR

We apply the LMs trained under different criteria to rescore the beams in various ASR systems. In particular, we are interested in knowing which of the two training mechanisms is better: minimizing PPL (e.g., the RNNLM in Section 3.1), or fitting to the WER metric by the proposed methods.

Adapting an RNNLM to a specific domain has been of interest, especially to the speech community (Park et al., 2010; Chen et al., 2015; Ma et al., 2017). We adopt Ma et al. (2017) that fine-tune the softmax layer of RNNLM by minimizing the PPL on the text labels of training set. According to Ma et al. (2017), the reason not to fine-tune all the layers is due to the limited text labels in the target domain. Indeed, we also observe overfitting if adapting all layers, but adapting only the softmax layer effectively decreases the PPL on the text labels of dev sets. We refer to this fine-tuning as *RNNLM-adapted* in the following sections.

To make a fair comparison with the adapted model, we also use the RNNLM as an initialization for our LMLM and rLMLM. In total, there are four language models for rescoring the beams. RNNLM and its adapted version that aim at reducing PPL; and the two proposed methods, LMLM and rLMLM that try to fit to WER.

4.1 WSJ Dataset

The WSJ corpora consists of about 80 hours of read speech with texts drawn from a machine-readable corpus of Wall Street Journal news. We use the standard configuration of train si284 dataset for training, dev93 for development and eval92 for testing.

Our ASR model has one convolution layer, followed by 5 bidirectional RNNs and one fully connected layer, with a CTC loss on top. The text labels of the training set are used to train a 4-gram language model, which is employed in the ASR decoder. The beam search decoder has a beam width of 2000. Before beam rescoring, this ASR system achieves a WER of 12.16 on dev93 set and 7.69 on eval92 set. To put this into perspective, we list some previous state-of-the-art system in Tab. 2. Compared with them, our baseline is already very competitive.

4.1.1 WERs and PPLs

The out-of-vocabulary rate of WSJ text is only 0.28%, making the RNNLM reasonable to use.

We apply the RNNLM, RNNLM-adapted (Ma et al., 2017), LMLM and rLMLM to rescore the beams on dev and test set. The final score assigned to a beam is a weighted sum of the ASR and language model scores. The weight is found by minimizing the WER on the dev set.

Tab. 3 reports the WERs on dev93 and eval92 sets. All methods reduce the WER over the baseline without rescoring. However, LMLM and rLMLM are notably better than the other two methods. Moreover, although RNNLM and RNNLM-adapted achieve smaller PPLs on the text labels, the advantage does not transfer to WER.

ASR Models	WER

Table 3: Rescore 2000-best list of WSJ dev93 and eval92 set. Digits in bold are the best and italics are the runner-ups. Lower PPL does not correspond to lower WER.

4.1.2 Correlation between scores and WERs

To better understand the proposed methods, we calculate the correlation coefficients between the hypotheses' WERs and their scores (by different language models). In specific, for every utterance in the test set, we have a set of beam candidates, their word level accuracies (100-WER) and scores given by an LM, from which a Pearson correlation coefficient can be calculated. We calculate the coefficients for all the utterances in the test set, and boxplot these coefficients in Fig. 3. The correlation coefficients by LMLM and rLMLM tend to be higher than RNNLM and RNNLM-adapted. This indicates that LMLM and rLMLM are more aligned with the goal of reducing WER.

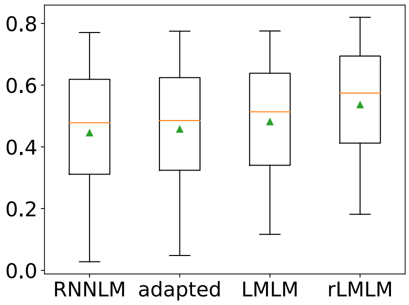

Figure 3: Correlation coefficients between word level accuracy ($1 - \text{WER}/100$) and LM-scores by the different LMs, higher is better. Red horizontal lines are medians. Green dots are means. Whiskers are 5% and 95% quantiles. Lower and upper box boundaries are 25% and 75% quantiles.

4.1.3 Case Study

Tab. 4 posts some examples from the test set. The first column lists the ground-truth labels, and their corresponding best candidates as re-ranked by the four LMs (see notes in the second column). Words in red are mistakes made by the candidate sentences. Scores of these sentences are listed in the last four columns. We have the following observations:

1. LMLM and rLMLM give worse scores on the ground-truth labels than RNNLM and RNNLM-adapted, which explains their higher PPL in Tab. 3.

2. In the first example, RNNLM and RNNLM-adapted assign higher scores to a shorter sentence. This is reasonable (though not necessarily desirable) as LM-score is a summation of log-probabilities, each of which is negative. In contrast, LMLM and rLMLM are able to assign higher scores to longer and better candidates.

3. In the other two examples, LMLM and rLMLM seem to favor more sensible sentences, though they are not more grammatical than those picked by RNNLM and RNNLM-adapted. We conjecture that since LMLM and rLMLM utilize beam candidates in their training, they capture and compensate for

some weakness in the ASR, which is not achieved by RNNLM and RNNLM-adapted.

4.2 10K Speech Dataset

We further validate our methods on a larger noisy dataset collected by Liu et al. (2017). The dataset has about 10K hours of spontaneous speech. The utterances are corrupted by background noise, and a large portion of them are accented. Therefore it is much more challenging than WSJ. We adopt the same training-dev-test split as in Liu et al. (2017). In specific, there are 5.4M utterances for training, 2,066 for development and 2,054 for testing.

Table 5: Rescore 2000-best list of our internal dev and test set. Digits in bold are the best and italics are the runner-ups.

The ASR we build has the same architecture as in Liu et al. (2017), except that its decoder integrates an in-domain 5-gram language model. This system achieves a WER of 19.17 on dev set, better than the reported 19.77 baseline in Liu et al. (2017). Based on the ASR, we repeat the same experiments in section 4.1. Tab. 5 reports WERs and PPLs on dev and test sets. Both LMLM and rLMLM outperform the other methods in WER, although their PPLs are higher. This trend is similar to that in Tab. 3.

5 Experiments on NMT

In this section, we experiment the large-margin criterion trained LM with a competitive Chinese-to-English NMT system. The NMT model is trained from 2M parallel sentence pairs. Following Shen et al. (2016), we use NIST 06 newswire portion (616 sentences) for development and NIST 08 newswire portion (691 sentences) for testing. We use OpenNMT-py[2] package with the default configuration to train the model: batch size is 64; word embedding size is 500; dropout rate is 0.3; target vocabulary size is 50K; number of epochs is 20, after which a minimum dev perplexity of 7.72

---

[2] `https://github.com/OpenNMT/OpenNMT-py`

is achieved.

5.1 BLEUs and PPLs

We use a beam size of 10 for decoding, and report case-insensitive 4-reference BLEU-4 scores (by calling "multi_bleu.perl"[3]). The NMT model achieves 35.18 BLEU score on dev set and 31.52 on test set (see table 6). To put this into perspective, Shen et al. (2016) trains their models on 2.56M pairs of sentences and reports a dev BLEU score of 32.7 (via MOSES) or 30.7 (via RNNsearch, beam size of 10). So our NMT model is already very competitive.

To construct the training data for LMLM and rLMLM, 10 beam candidates are extracted for every sentence in the training set. We then follow the same experimental steps outlined in section 4.1, except that the ASR score is now changed to NMT score. In addition, we also find that normalizing the LM score by sentence length can improve the re-scoring performance substantially. Tab. 6 compares the BLEU score after re-ranking by the different LMs. LMLM and rLMLM both improve upon the baseline significantly, and outperform RNNLM and RNNLM-adapted by a notable margin. We also observe that the PPLs of LMLM and rLMLM are much larger than those of RNNLM and RNNLM-adapted, suggesting that the PPL metric may be very poorly correlated with BLEU.

Interestingly, RNNLM-adapted does not show any gain in BLEU score over RNNLM. To understand this, we recall that NMT is trained by minimizing PPL on target text. Its decoder is implicitly an RNNLM on target language. We conjecture that adapting an LM to the target domain can only duplicate the functionality of the NMT decoder, which does not bring any additional benefit.

rescoring language model	BLEU		PPL	
	dev06	test08	dev06	test08
baseline (no rescore)	35.18	31.52	N/A	N/A
RNNLM	36.17	32.17	129.91	137.25
RNNLM-adapted	36.17	31.97	78.20	89.27
LMLM	*37.79*	*33.11*	7.75e5	3.73e6
rLMLM	**37.82**	**33.13**	2.68e5	1.12e6

Table 6: Rescore 10-best list for dev (nist 06) and test (nist 08) set. Digits in bold are the best and italics are the runner-ups.

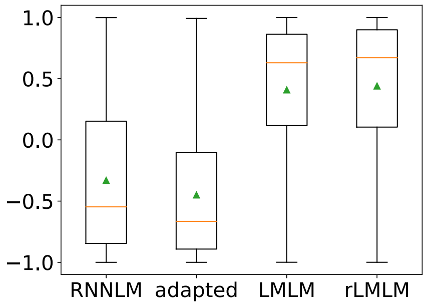

Figure 4: Correlation coefficients between BLEUs and LM-scores by the different LMs, higher is better. Red horizontal lines are medians. Green dots are means. Whiskers are 5% and 95% quantiles. Lower and upper box boundaries are 25% and 75% quantiles.

5.2 Correlation between scores and BLEUs

We measure the correlation between the LM scores and BLUEs. The calculation is done on dev06 set in the same way as Section 4.1.2, but now we change the WERs to BLEUs. The boxplot of the correlation coefficients are shown in Fig. 4. Compared with the boxplot in Fig. 3, now the correlation coefficients by all LMs are more dispersed. Sometimes, they even take negative values. The mean correlation by LMLM and rLMLM, however, is considerably higher than those by RNNLM and RNNLM-adapted.

6 Related Work

"*Language modeling is an art of determining the probability of a sequence of words*" (Goodman, 2001). In the past decades, there has been a trend of increasing the context that an LM can condition on. N-gram models (Chen and Goodman, 1996) assume that each symbol depends on the previous $N-1$ symbols. Feed forward neural network based LMs (Bengio et al., 2003) are not count based but they inherit the restrictive assumption. To model longer-term dependencies, RNNLMs (Mikolov et al., 2010) are proposed. RNNLMs often achieve smaller PPLs than the N-gram counterparts (Sundermeyer et al., 2012; Zaremba et al., 2014; Jozefowicz et al., 2016). This paper focuses on RNNLM-type architectures.

While these works all adopt PPL as the metric

to optimize, sometimes one may optimize a task-specific objective. For example, Kuo et al. (2002); Roark et al. (2007) and Dikic et al. (2013) propose discriminative LMs to improve speech recognition. The common methodology therein is to fit a probabilistic model, e.g., conditional random field (Roark et al., 2004), to the space of text candidates, and maximize the probability at the desired candidate. The problem is often solved by perceptron algorithm. However, these methods all rely on ad-hoc choice of features, e.g., counts of n-grams where n varies in a small range (e.g.,1 to 3). Moreover, it is also not clear how these methods would take advantage of an existing language model (trained on large unsupervised corpus). Nevertheless, the same methodology can be extended to RNNLMs, thus avoiding the aforementioned limitations. For example, Auli and Gao (2014) train an RNNLM by favoring sentences with high BLEU scores and integrate it into a phrase-based MT decoder.

If we cast the problem of picking the best text sequence as a ranking problem, the aforementioned works can be considered as "pointwise" learning-to-rank approaches (Cossock and Zhang, 2008). In contrast, the proposed method is a "pairwise" approach (Liu, 2009), as it learns a neural language model by comparison between pairs of sentences. Earlier works in this fashion may date back to (Collins and Koo, 2005), which improves a semantic parser. Learning "by pairwise comparison" is also seen in several MT literatures. For example, Hopkins and May (2011) propose to train a phrase-based MT system by minimizing a pairwise ranking loss. Wiseman and Rush (2016) optimize the beam search process in a Neural Machine Translation (NMT) system. They enforce the score of a reference to be higher than that of its decoded k-th candidate by at least a unit margin.

Rather than optimizing the MT system itself, this work proposes a general method of training recurrent neural language models, which can benefit various text generation tasks, including speech recognition and machine translation.

7 Conclusions

We have proposed a large margin criterion for training recurrent neural language models. Rather than minimizing PPL, the proposed criterion is based on comparison between pairs of sentences. We have formulated two algorithms that implement the training criterion. One compares between references and imperfect hypotheses (LMLM), the other compares between all pairs of hypotheses (rLMLM). We applied the language models trained by these two algorithms to speech recognition and machine translation. Both of them demonstrate superior performance over their minimum-PPL counterparts. However, the performance gain from LMLM to rLMLM is small, although rLMLM is built on more pairwise comparisons and requires more training efforts. The efficiency with respect to the number of pairs is a future research topic.

Targeted Syntactic Evaluation of Language Models

Abstract

We present a dataset for evaluating the grammaticality of the predictions of a language model. We automatically construct a large number of minimally different pairs of English sentences, each consisting of a grammatical and an ungrammatical sentence. The sentence pairs represent different variations of structure-sensitive phenomena: subject-verb agreement, reflexive anaphora and negative polarity items. We expect a language model to assign a higher probability to the grammatical sentence than the ungrammatical one. In an experiment using this data set, an LSTM language model performed poorly on many of the constructions. Multi-task training with a syntactic objective (CCG supertagging) improved the LSTM's accuracy, but a large gap remained between its performance and the accuracy of human participants recruited online. This suggests that there is considerable room for improvement over LSTMs in capturing syntax in a language model.

1 Introduction

A language model (LM) defines a probability distribution over sequences of words. Recent technological advances have led to an explosion of neural network-based LM architectures. The most popular ones are based on recurrent neural networks (RNNs) (Elman, 1990; Mikolov et al., 2010), in particular Long Short-Term Memory networks (LSTMs) (Hochreiter and Schmidhuber, 1997). While a large number of alternative architectures have been proposed in the past few years, LSTMs are still highly competitive (Melis et al., 2018).

Language models are typically evaluated using perplexity: it is considered desirable for an LM to assign a high probability to held-out data from the same corpus as the training data. This measure conflates multiple sources of success (or failure) in predicting the next word: common collocations, semantics, pragmatics, syntax, and so on. The quality of the **syntactic** predictions made by the LM is arguably particularly difficult to measure using perplexity: since most sentences are grammatically simple and most words can be predicted from their local context, perplexity rewards LMs primarily for collocational and semantic predictions.

We propose to supplement perplexity with a metric that assesses whether the probability distribution defined by the model conforms to the grammar of the language. Following previous work (Lau et al., 2017; Linzen et al., 2016; Gulordava et al., 2018), we suggest that given two sentences that differ minimally from each other, one of which is grammatical and the other which is not, it is desirable for the model to assign a higher probability to the grammatical one.

The value of this approach can be illustrated with a recent study by Tran et al. (2018), where a standard LSTM language model was compared to an attention-only LM without recurrence (Vaswani et al., 2017). Although the attention-only model had somewhat better perplexity on the validation set, when the models were tested specifically on challenging subject-verb agreement dependencies, the attention-only model made three times as many errors as the LSTM. In other words, the LSTM learned more robust syntactic representations, but this advantage was not reflected in its average perplexity on the corpus, since syntactically challenging sentences are relatively infrequent.

Previous work on targeted syntactic evaluation of language models has identified syntactically challenging sentences in corpora (Linzen et al., 2016; Gulordava et al., 2018). While evaluation on naturally occurring examples is appealing, this approach has its limitations (see Section 2). In particular, syntactically challenging examples are sparsely represented in a corpus, their identifica-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1192–1202
Brussels, Belgium, October 31 - November 4, 2018.

tion requires a clean parsed corpus, and naturally occurring sentences are difficult to control for confounds. We contrast the naturalistic approach with a constructed dataset, which allows us to examine a much larger range of specific grammatical phenomena than has been possible before. We use templates to automatically create our test sentences, making it possible to generate a large test set while maintaining experimental control over our materials as well as a balanced number of examples of each phenomenon.

We test three LMs on the data set we develop: an n-gram baseline, an RNN LM trained on an unannotated corpus, and an RNN LM trained on a multitask objective: language modeling and Combinatory Categorial Grammar (CCG) supertagging (Bangalore and Joshi, 1999). We also conduct a human experiment using the same materials. The n-gram baseline largely performed at chance, suggesting that good performance on the task requires syntactic representations. The RNN LMs performed well on simple cases, but struggled on more complex ones. Multi-task training with a supervised syntactic objective improved the performance of the RNN, but it was still much weaker than humans. This suggests that our data set is challenging, especially when explicit syntactic supervision is not available, and can therefore motivate richer language modeling architectures.

2 Overview of the approach

2.1 Grammaticality and LM probability

How should grammaticality be captured in the probability distribution defined by an LM? The most extreme position would be that a language model should assign a probability of zero to ungrammatical sentences. For most applications, some degree of error tolerance is desirable, and it is not practical to assign a sentence a probability of exactly zero.[1] Following Linzen et al. (2016) and Gulordava et al. (2018), our desideratum for the language model is more modest: if two closely matched sentence differ only in their grammaticality, the probability of the grammatical sentence should be higher than the probability of the ungrammatical one. For example, the following minimal pair illustrates the fact that third-person present English verbs agree with the number of their subject:

(1) *Simple agreement*:
  a. The author laughs.
  b. *The author laugh.

We expect the probability of (1a) to be higher than the probability of (1b). Previous work has simplified this setting further by comparing the probability that the LM assigns to a single word that is the locus of ungrammaticality. In (1), for example, the LM would be fed the first two words of the sentence, and would be considered successful on the task if it predicts $P(laughs) > P(laugh)$.

The prediction setting is only applicable when the locus of ungrammaticality is a single word, rather than, say, the interaction between two words; moreover, the information needed to make the grammaticality decision needs to be available in the left context of the locus of grammaticality. These conditions do not always hold. Negative polarity items (NPIs), for example, are words like *any* and *ever* that can only be used in the scope of negation.[2] The grammaticality of placing a particular quantifier in the beginning of the sentences in (2) depends on whether the sentence contains an NPI later on:

(2) *Simple NPI:*
  a. No students have ever lived here.
  b. *Most students have ever lived here.

It would not be possible to compare these two sentences using the prediction task. In the current paper, we use the more general setting and compare the probability of the two complete sentences.

2.2 Data set construction

Previous work has used syntactically complex sentences identified from a parsed corpus. This approach has several limitations. If the corpus is automatically parsed, the risk of a parse error increases with the complexity of the construction (Bender et al., 2011). If the test set is restricted to sentences with gold parses, it can be difficult or impossible to find a sufficient number of examples of syntactically challenging cases. Moreover, using naturally occurring sentences can introduce

---

[1] Nor is it possible to have a threshold ϵ such that all grammatical sentences have probability higher than ϵ and all ungrammatical sentences have probability lower than ϵ, for the simple reason that there is an infinite number of grammatical sentences (Lau et al., 2017).

[2] In practice, the conditions that govern the distribution of NPIs are much more complicated, but this first approximation will suffice for the present purposes. For a review, see Giannakidou (2011).

confounds that may complicate the interpretation of the experiments (Ettinger et al., 2018).

To circumvent these issues, we use templates to automatically construct a large number of English sentence pairs (∼350,000). Our data set includes three phenomena that linguists consider to be sensitive to hierarchical syntactic structure (Everaert et al., 2015; Xiang et al., 2009): subject-verb agreement (described in detail in Sections 4.1 and 4.2), reflexive anaphora (Section 4.3) and negative polarity items (Section 4.4).

The templates can be described using non-recursive context-free grammars. We specify the preterminal symbols that make up a syntactic construction and have different terminal symbols that those preterminals could be mapped to. For example, the template for the simple agreement construction illustrated in (1) consists of the following rules:

(3) a. Simple agreement → D MS MV
 b. D → *the*
 c. MS → {*author*, *pilot*, . . .}
 d. MV → {*laughs*, *smiles*, . . .}

We generate all possible combinations of the terminals. The Supplementary Materials provide a full description of all our templates.[3]

While these examples are somewhat artificial, our goal is to isolate the syntactic capabilities of the model; it is in fact beneficial to minimize the semantic or collocational cues that can be used to identify the grammatical sentence. Gulordava et al. took this approach further and constructed "colorless green ideas" test cases by substituting random content words into sentences from a corpus. We take a more moderate position and avoid combinations that are very implausible or violate selectional restrictions (e.g., *the apple laughs*). We do this by having separate templates for animate and inanimate subjects and verbs so that the resulting sentences are always reasonably plausible.

3 Related work

Targeted evaluation: LM evaluation data sets using challenging prediction tasks have been proposed in the context of semantics and discourse comprehension (Zweig and Burges, 2011; Paperno et al., 2016). Evaluation sets consisting of challenging syntactic constructions have been constructed for parser evaluation (Rimell et al., 2009; Nivre et al., 2010; Bender et al., 2011), and minimal pair approaches have been proposed for evaluating image captioning (Shekhar et al., 2017) and machine translation systems (Sennrich, 2017), but no data sets exist that target a range of syntactic constructions for language model evaluation.

Acceptability judgments: Lau et al. (2017) compared the ability of different LMs to predict graded human acceptability judgments. The forced-choice approach used in the current paper has been shown to be effective in human acceptability judgment experiments (Sprouse and Almeida, 2017). In some early work, neural networks were trained explicitly to predict acceptability judgments (Lawrence et al., 1996; Allen and Seidenberg, 1999); Post (2011) likewise trained a classifier on top of a parser to predict grammaticality. Warstadt et al. (2018) use a transfer learning approach, where an unsupervised model is fine-tuned on acceptability prediction. Our work differs from those studies in that we do not advocate providing any explicit grammaticality signal to the LM at any point ("no negative evidence").

Syntax in LMs: There have been several proposals over the years to incorporate explicit syntax into LMs to overcome the inability of *n*-gram LMs to model long-distance dependencies (Jurafsky et al., 1995; Roark, 2001; Pauls and Klein, 2012). While RNN language models can in principle model longer dependencies (Mikolov et al., 2010; Linzen et al., 2016), in practice it can still be beneficial to inject syntax into the model. This can be done by combining it with a supervised parser (Dyer et al., 2016) or other multi-task learning objectives (Enguehard et al., 2017). Our work is orthogonal to this area of research, but can be seen as providing a potential opportunity to underscore the advantage of such syntax-infused models.

4 Data set composition

This section describes all of the types of sentence pairs included in our data set, which include examples of subject-verb agreement (Sections 4.1 and 4.2), reflexive anaphoras (Section 4.3) and negative polarity items (Section 4.4).

---

[3] The code, the data set and the Supplementary Materials can be found at `https://github.com/BeckyMarvin/LM_syneval`.

4.1 Subject-verb agreement

Determining the correct number of the verb is trivial in examples such as (1) above, in which the sentence only contains a single noun. By contrast, in cases where there are multiple nouns in the sentence, identifying which of them is the subject of a given verb requires understanding the structure of the sentence. In particular, the relevant subject is not necessarily the first noun of the sentence:

(4) *Agreement in a sentential complement:*
 a. The bankers knew the officer smiles.
 b. *The bankers knew the officer smile.

Here the verb *smiles* needs to agree with the embedded subject *officer* rather than the main clause subject *bankers*. The subject is also not necessarily the most recent noun before the verb: when the subject is modified by a phrase, a distracting noun ("attractor") often intervenes in the linear order of the sentence between the head of the subject and the verb. Two examples of such modifiers are prepositional phrases and relative clauses (RCs):

(5) *Agreement across a prepositional phrase:*
 a. The farmer near the parents smiles.
 b. *The farmer near the parents smile.

(6) *Agreement across a subject relative clause:*
 a. The officers that love the skater smile.
 b. *The officers that love the skater smiles.

We include all four possible configurations of noun number for each type of minimal pair; for (5), these would be:[4]

(7) a. The farmer near the parent smiles/*smile.
 b. The farmer near the parents smiles/*smile.
 c. The farmers near the parent smile/*smiles.
 d. The farmers near the parents smile/*smiles.

Sentences where the two nouns conflict in number are expected to be more challenging, but interpretable errors may certainly occur even when they do not. For example, the model may use the heuristic that sentences with multiple nouns are likely to have a plural verb (a heuristic that would be effective for coordination); alternatively, it might prefer singular verbs to plural ones regardless of whether the subject is singular or plural, simply because the singular form of the verb is more frequent.

Next, in verb phrase (VP) coordination, both of the verbs need to agree with the subject:

(8) *Short VP coordination:*
 a. The senator smiles and laughs.
 b. *The senator smiles and laugh.

We had both singular and plural subjects. The number of the verb immediately adjacent to the subject was always grammatical. This problem can in principle be solved with a trigram model (*smiles and laughs* is likely to be a more frequent trigram than *smiles and laugh*); to address this potential concern, we also included a coordination condition with a longer dependency:

(9) *Long VP coordination:*
 The manager writes in a journal every day and likes/*like to watch television shows.

4.2 Agreement and object relative clauses

We go into greater depth in object relative clauses, which most clearly require a hierarchical representation. In (10) and (11), the model needs to be able to distinguish the embedded subject (*parents*) from the main clause subject (*farmer*) when making its predictions:

(10) *Agreement across an object relative clause:*
 a. The farmer that the parents love swims.
 b. *The farmer that the parents love swim.

(11) *Agreement in an object relative clause:*
 a. The farmer that the parents love swims.
 b. *The farmer that the parents loves swims.

In keeping with the minimal pair approach, we never introduce two agreement errors at the same time: either the embedded verb or the main verb is incorrectly inflected, but not both.

We include a number of variations on the pattern in (11). First, we delete the relativizer *that*, with the hypothesis that the absence of an overt cue to structure will make the task more difficult:

(12) The farmer the parents love/*loves swims.

In another condition, we replace the main subject with an inanimate noun and keep the embed-

---

[4] The slash notation indicates the word that differs between the grammatical and ungrammatical sentence; for example, in (7a), the full sentence pair would be:

(i) a. The farmer near the parent smiles.
 b. *The farmer near the parent smile.

ded subject animate. We base this manipulation on human experimental work showing that similar nouns (for example, two animate nouns) are more likely to cause confusion during comprehension than dissimilar nouns, such as an animate and an inanimate noun (Van Dyke, 2007):

(13) The movies that the author likes are/*is good.

For a complete list of all the types of minimal pairs we include, see the Supplementary Materials.

4.3 Reflexive anaphora

A reflexive pronoun such as *himself* needs to have an antecedent from which it derives its interpretation. The pronoun needs to agree in number (and gender) with its antecedent:

(14) *Simple reflexive*:
  a. The senators embarrassed themselves.
  b. *The senators embarrassed herself.

There are structural conditions on the nouns to which a reflexive pronoun can be bound. One of these conditions requires the antecedent to be in the same clause as the reflexive pronoun. For example, (15b) cannot refer to a context in which *the pilot* embarrassed *the bankers*:

(15) *Reflexive in a sentential complement*:
  a. The bankers thought the pilot embarrassed himself.
  b. *The bankers thought the pilot embarrassed themselves.

Likewise, in the following minimal pair, sentence (16b) is ungrammatical, because the reflexive pronoun *themselves*, which is part of the main clause, cannot be bound to the noun phrase *the architects*, which is inside an embedded clause:

(16) *Reflexive across an object relative clause:*
  a. The manager that the architects like doubted himself.
  b. *The manager that the architects like doubted themselves.

4.4 Negative polarity items

Negative polarity items, introduced in example (2) above, are words that (to a first approximation) need to occur in the context of negation. Crucially for the purposes of the present work, the scope of negation is structurally defined. In particular the negative noun phrase needs to c-command the NPI: the syntactic non-terminal node that dominates the negative noun phrase must also dominate the NPI. This is the case in (17a), but not in (17b), where the negative noun phrase is too deep in the tree to c-command the NPI *ever* (Xiang et al., 2009; Everaert et al., 2015).

(17) *NPI across a relative clause:*
  a. No authors that the security guards like have ever been famous.
  b. *The authors that no security guards like have ever been famous.

All of the nouns and verbs in the NPI cases were plural. As in some of the agreement cases, we included a variant of (17) in which the subject was inanimate.

5 Experimental setup

To show how our challenge set can be used to evaluate the syntactic performance of LMs, we trained three LMs with increasing levels of syntactic sophistication. All of the LMs were trained on a 90 million word subset of Wikipedia (Gulordava et al., 2018). Our *n*-gram LM and LSTM LM do not require annotated data. The third model is also an LSTM LM, but it requires syntactically annotated data (CCG supertags).

***N*-gram model:** We trained a 5-gram model on the same 90M word corpus using the SRILM toolkit (Stolcke, 2002) which backs off to smaller *n*-grams using Kneser-Ney smoothing.

Single-task RNN: The RNN LM had two layers of 650 LSTM units, a batch size of 128, a dropout rate of 0.2, and a learning rate of 20.0, and was trained for 40 epochs (following the hyperparameters of Gulordava et al. 2018).

Multi-task RNN: In multi-task learning, the system is trained to optimize an objective function that combines the objective functions of several tasks. We combine language modeling with CCG supertagging, a task that predicts for each word in the sentence its CCG supertag (Bangalore and Joshi, 1999; Lewis et al., 2016). We simply sum the two objective functions with equal weights (Enguehard et al., 2017). Early stopping in this model is based on the combined loss on language modeling and supertagging. Supertags provide a large amount of syntactic information about the word; the sequence of supertags of a sentence strongly constrains the possible parses of the sentence. We use supertagging as a "scaffold" task (Swayamdipta et al., 2017): our goal is not to produce a competitive supertagger, but to induce better syntactic representations, which would then lead to improved language modeling. We used CCG-Bank (Hockenmaier and Steedman, 2007) as our CCG corpus.

Human evaluation: We designed a human experiment on Amazon Mechanical Turk that mirrored the task that was given to the LMs: both versions of a minimal pair were shown on the screen at the same time, and participants were asked to judge which one of them was more acceptable (for details, see the Supplementary Materials). We emphasize that we do not see human performance on complex syntactic dependencies as setting an upper bound on the performance that we should expect from an LM. There is a rich literature showing that humans make mistakes such as subject-verb agreement errors; in fact, most of the phenomena we test were inspired by work in psycholinguistics that studies these errors (Bock and Miller, 1991; Phillips et al., 2011). At the same time, while we do not see a reason not to aspire for 100% accuracy, we are interested in comparing LM and human errors: if the errors are similar, the two systems may be using similar representations.

6 Results

Local agreement: The overall accuracy per condition can be seen in Table 1. The *n*-gram LM's accuracy was only 79% for simple agreement and agreement in a sentential complement, both of which can be solved entirely using local context. This is because not all subject and verb combinations in our materials appeared verbatim in the 90M word training corpus; for those combinations, the model fell back on unigram probabilities, which in this context amounts to selecting the more frequent form of the verb.

Both RNNs performed much better than the *n*-gram model on the simple agreement case (single-task: 94%; multi-task: 100%), reflecting these models' ability to generalize beyond the specific bigrams that occurred in the corpus. Accuracy on agreement in a sentential complement was also very high (single-task: 99%; multi-task: 93%). This indicates that the RNNs do not rely on the heuristic whereby the first noun of the sentence is likely to be its subject. They did slightly worse but still very well on short VP coordination (both 90%); this dependency is also local, albeit across the word *and*.

Non-local agreement: The accuracy of the *n*-gram model on non-local dependencies (long VP coordination and agreement across a phrase or a clause) was very close to 50%. This suggests that local collocational information is not useful in these conditions. The single-task RNN also performed much more poorly on these conditions than on the local agreement conditions, though for the most part its accuracy was better than chance. Humans did worse on these dependencies as well, but their accuracy did not drop as sharply as the RNNs' (human accuracies ranged from 82% to 88%). In most of these cases, multi-task learning was very helpful; for example, accuracy in long VP coordination increased from 61% to 81%. Still, both RNNs performed poorly on agreement across an object RC, especially without *that*, whereas humans performed comparably on all non-local dependencies.

Agreement inside an object RC: This case is particularly interesting, because this dependency is purely local (see (11)), and the interference is from the distant sentence-initial noun. Although this configuration is similar to the sentential complement case, performance was worse both in RNNs and humans. However, RNNs performed *better* than humans, at least when the sentence included the overt relativizer *that*. This suggests that interference is sensitive to proximity in RNNs but to syntactic status in humans — humans appear to be confusing the main clause subject and the embedded subject (Wagers et al., 2009).

Reflexive anaphora: The RNNs' performance was significantly worse on simple reflexives (83%) than on simple agreement (94%), and did not differ between the single-task and multi-task models. By contrast, human performance did not differ between subject-verb agreement and reflexive anaphoras. The surprisingly poor performance for this adjacent dependency seems to be due to an asymmetry in accuracy between *himself* and *themselves* on the one hand (100% accuracy in the multi-task RNN) and *herself* on the other hand (49% accuracy).[5] Accuracy was very low for all

---

[5] This may be because *himself* and *themselves* are significantly more frequent than *herself*, and consequently the num-

	RNN	Multitask	*n*-gram	Humans	# sents
SUBJECT-VERB AGREEMENT:

Table 1: Overall accuracies for the LSTMs, *n*-gram model and humans on each test case.

pronouns in the structurally complex case in which the dependency was across a relative clause (55% compared to 87% in humans).

NPIs: The dependency in simple NPIs spans only four words, so the *n*-gram model could in principle capture it. In practice, the *n*-gram model systematically selected the wrong answer, suggesting that it backed off to comparing the bigrams *no students* and *most students*, the first of which is presumably less frequent. Surprisingly, the *n*-gram model's accuracy was higher than 50% on NPIs across a relative clause, a dependency that spans more than five words. In this case, the bigrams *that the* and *the chef* (for example) happen to be more frequent than the *that no* and *no chef.* This difference was apparently strong enough to make up for the low-frequency bigram at the start of the sentence.

The RNNs did poorly on this task. The accuracy of the single-task model was around 40%. The multi-task did somewhat better on the simple NPIs (48%) and much better on the NPIs across a relative clause (73%). At the same time, an examination of the plot of log probability of each word in a sentence (Figure A.1 in the Supplementary Materials) suggests that the single-task RNN is in fact able to differentiate between the grammatical and ungrammatical sentences when it reaches the NPI, but this difference does not offset the overall probability advantage of the ungrammatical sentence (which is likely due to non-grammatical collocational factors). In any case, the fact that the *n*-gram baseline did not perform at chance suggests that there are non-syntactic cues to this task, complicating the interpretation of the performance of other LMs.

Perplexity: The perplexity of the *n*-gram model on the Wikipedia test data was 157.5, much higher than the perplexity of the single-task RNN (78.65) and the multi-task RNN (61.10). In other words, perplexity tracked accuracy on our syntactic data set – an unsatisfying outcome given our goal of dissociating perplexity and our syntactic evaluation method, but an expected one given that each model was conditioned on richer information than the previous one. In previous work, perplexity and syntactic judgment accuracy have been found to be partly dissociable (Kuncoro et al., 2018; Tran et al., 2018).

Lexical variation and frequency: There was considerable lexical variation in the results; we have mentioned the surprising asymmetry between *himself* and *herself* above. As another case study, we examine variation in the results of the simple agreement condition in the single-

---

ber representation learned for *herself* was not robust. Another possibility is that gender bias reduces the probability of an anaphoric relation between *herself* and words such as *surgeon* (Rudinger et al., 2018).

Main subject	Embedded subject	Single-task	Multi-task	Humans	Example sentence
Across an objective relative clause:					
Singular	Singular	0.83	0.77	0.96	The author that the minister likes laughs/*laugh.
Singular	Plural	0.51	0.30	0.90	The author that the ministers like laughs/*laugh.
Plural	Singular	0.18	0.53	0.77	The authors that the minister likes laugh/*laughs.
Plural	Plural	0.50	0.73	0.80	The authors that the ministers like laugh/*laughs.
Within an objective relative clause:					
Singular	Singular	0.73	0.92	0.94	The author that the minister likes/*like laughs.
Singular	Plural	0.91	0.81	0.72	The author that the ministers like/*likes laugh.
Plural	Singular	0.81	0.97	0.73	The authors that the minister likes/*like laugh.
Plural	Plural	0.87	0.84	0.76	The authors that the ministers like/*likes laugh.

Table 2: Accuracy within and across an object relative clause (only in the cases in which the main subject was animate and the relativizer *that* was present). The subject that the verb is expected to agree with is underlined.

task RNN. Accuracy varied by verb, ranging from *is* and *are*, which had 100% accuracy, to *swims*, where accuracy was only 60% (recall that average accuracy was 94%). This may be a frequency effect: either the LM is learning less robust number representations for infrequent verbs, or the tail of the distribution over the vocabulary is more fragile during word prediction. Pauls and Klein (2012) propose normalizing for unigram frequency when deriving acceptability judgments from an LM. Our preliminary experiments with this method did not significantly improve overall performance; regardless of the effectiveness of this method, such corrections should arguably not be necessary in an LM that adequately captures grammaticality.

7 Case study: agreement and object relative clauses

The overall results in Table 1 were averaged over all of the possible number configurations within each condition. In this section, we take a closer look at agreement in sentences with an object RC (see Table 2). This kind of finer-grained analysis helps explain the cases in which the LMs are failing, and might reveal some of the patterns or heuristics the LMs are using.

Performance in agreement across an object RC was poor. Both RNNs made attraction errors: they often preferred the verb that agreed in number with the irrelevant embedded subject to the verb that agreed with the correct main subject. The multi-task RNN showed greater symmetry between the simpler singular/singular and plural/plural cases, whereas the single-task RNN performed poorly even in these cases, often preferring a singular verb when both subjects were plural. This default preference for singular verbs matches the behavior of younger children (Franck et al., 2004).

Performance in agreement within an object RC was better; still, the single-task RNN made the most errors when both subjects were singular, perhaps due to a heuristic in which a sentence with multiple subjects is likely to have a plural verb (as in coordination sentences). By contrast, the multi-task model seemed to have a general bias towards singular subjects in this condition. Incidentally, the human results with object RCs were also unexpected: while attraction errors when the two subjects differ in number are to be expected (Wagers et al., 2009), our participants made a sizable number of errors even when both subjects were plural.

Despite the generally poor performance in object RCs, Figures A.2 and A.3 in the Supplementary Materials show that the single-task RNN is typically assigning a higher probability to the grammatical word of a minimal pair than to the ungrammatical word.

8 Discussion

We have described a template-based data set for targeted syntactic evaluation of language models. The data set consists of pairs of sentences that are matched except for their grammaticality; we consider a language model to capture the relevant aspects of the grammar of the language if it assigns a higher probability to the grammatical sentence than to the ungrammatical one.

An RNN language model performed very well on local subject-verb agreement dependencies, significantly outperforming an *n*-gram baseline.

This suggests that the task is a viable evaluation strategy. Even on simple cases, however, the RNN's accuracy was sensitive to the particular lexical items that occurred in the sentence; this would not be expected if its syntactic representations were fully abstract. The RNN's performance degraded markedly on non-local dependencies, approaching chance levels on agreement across an object relative clause. Multi-task training with a syntactic objective (CCG supertagging) mitigated this drop in performance for some but not all of the dependencies we tested. We conjecture that the benefits of the inductive bias conferred by multi-task learning will be amplified when the amount of training data is limited.

Our results contrast with the results of Gulordava et al. (2018), who obtained a prediction accuracy of 81% on English sentences from their test corpus and 74% on constructed sentences modeled after sentences from the corpus. It is likely that our sentences are more syntactically challenging than the ones they were able to find in the relatively small manually annotated treebank they used.

One limitation of our approach is that it is not always clear what constitutes a minimal grammaticality contrast. In the subject-verb agreement case, the contrast was clear: the two present-tense forms of the verb, e.g., *laugh* vs. *laughs*. Our NPI manipulations, on the other hand, were less successful: the members of the contrasts differed not only in their syntactic structure but also in low-level *n*-gram probabilities, making the performance on this particular contrast harder to interpret.

We emphasize that the goal of this article was not to advocate for LSTMs in particular as an effective architecture for modeling syntax; indeed, our results show that LSTM language models are far from matching naive annotators' performance on this task, let alone performing at 100% accuracy. We hope that our data set, and future extensions to other phenomena and languages, will make it possible to measure progress in syntactic language modeling and will lead to better understanding of the syntactic generalizations captured by language models.

9 Acknowledgments

We would like to thank Ming Xiang for sharing materials from human experiments that inspired many of our test cases. We also thank Brian Roark and the JHU Computational Psycholinguistics lab for discussion, and Brian Leonard for help conducting the human experiment.

Abstract

Despite the tremendous empirical success of neural models in natural language processing, many of them lack the strong intuitions that accompany classical machine learning approaches. Recently, connections have been shown between convolutional neural networks (CNNs) and weighted finite state automata (WFSAs), leading to new interpretations and insights. In this work, we show that some *recurrent* neural networks also share this connection to WFSAs. We characterize this connection formally, defining **rational recurrences** to be recurrent hidden state update functions that can be written as the Forward calculation of a finite set of WFSAs. We show that several recent neural models use rational recurrences. Our analysis provides a fresh view of these models and facilitates devising new neural architectures that draw inspiration from WFSAs. We present one such model, which performs better than two recent baselines on language modeling and text classification. Our results demonstrate that transferring intuitions from classical models like WFSAs can be an effective approach to designing and understanding neural models.

1 Introduction

Neural models, and in particular gated variants of recurrent neural networks (RNNs, e.g., Hochreiter and Schmidhuber, 1997; Cho et al., 2014), have become a core building block for state-of-the-art approaches in NLP (Goldberg, 2016). While these models empirically outperform classical NLP methods on many tasks (Zaremba et al., 2014; Bahdanau et al., 2015; Dyer et al., 2016; Peng et al., 2017, *inter alia*), they typically lack the intuition offered by classical models, making it hard to understand the roles played by each of their components. In this work we show that many neural models are more interpretable than previously thought, by drawing connections to weighted finite state automata (WFSAs). We study several recently proposed RNN architectures and show that one can use WFSAs to characterize their recurrent updates. We call such models **rational recurrences** (§3).[1] Analyzing recurrences in terms of WFSAs provides a new view of existing models and facilitates the development of new ones.

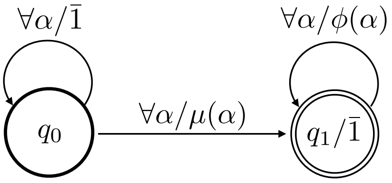

Figure 1: A two-state WFSA $\mathcal{B}$ described in §2. It is closely related to several models studied in this paper (§4.1). Bold circles indicate initial states, and double circles final states, which are associated with final weights. Arrows represent transitions, labeled by the symbols α they consume, and the weights as a function of α. Arcs not drawn are assumed to have weight $\bar{0}$. For brevity, $\forall\alpha$ means $\forall\alpha \in \Sigma$, with Σ being the alphabet.

In recent work, Schwartz et al. (2018) introduced SoPa, an RNN constructed from WFSAs, and thus rational by our definition. They also showed that a single-layer max-pooled CNN (LeCun, 1998) can be simulated by a set of simple WFSAs (one per output dimension), and accordingly are also rational. In this paper we broaden such efforts, and show that rational recurrences are in frequent use (Mikolov et al., 2014; Balduzzi and Ghifary, 2016; Lei et al., 2016, 2017a,b; Bradbury et al., 2017; Foerster et al., 2017). For instance, we will show in §4 that the WFSA diagrammed

---

[1] Where the term *regular* is used with unweighted FSAs (e.g., regular languages, regular expressions), *rational* is the weighted analog (e.g., rational series, Sakarovitch, 2009; rational kernels, Cortes et al., 2004).

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1203–1214
Brussels, Belgium, October 31 - November 4, 2018.

in Figure 1 has strong connections to several of the models mentioned above.

Based on these observations, we then discuss potential approaches to deriving novel neural architectures from WFSAs (§5). As a case study, we present a new model motivated by the interpolation of a two-state WFSA and a three-state one, capturing (soft) unigram and bigram features, respectively. Our experiments show that in two tasks—language modeling and text classification—the proposed model outperforms recently proposed rational models (§6). Further extensions might lead to larger gains, and the rational recurrence view could facilitate easier exploration of such extensions. To promote such exploration, we publicly release our implementation at `https://github.com/Noahs-ARK/rational-recurrences`.

2 Background: Weighted Finite State Automata (WFSAs)

This section reviews weighted finite-state automata and semirings, which underly our analyses in §3. WFSAs extend nondeterministic *unweighted* finite-state automata by assigning weights to transitions, start states, and final states. Instead of simply accepting or rejecting a string, a WFSA returns a score for the string, and this score summarizes the weights along all paths through the WFSA that consume the string. In order for this summary score to be efficiently computable, weights are taken from a **semiring**.

Definition 1 (Kuich and Salomaa, 1986)**.** A **semiring** is a set $\mathbb{K}$ along with two associative binary operations on $\mathbb{K}$, $\oplus$ (addition) and $\otimes$ (multiplication), and two identity elements: $\bar{0}$ for addition, and $\bar{1}$ for multiplication. Semirings also require that addition is commutative, multiplication distributes over addition, and that multiplication by $\bar{0}$ annihilates (i.e., $\bar{0} \otimes a = a \otimes \bar{0} = \bar{0}$).

One common semiring is the **real** (or plus-times) semiring: $\langle \mathbb{R}, +, \cdot, 0, 1\rangle$. The other one used in this work is the **max-plus** semiring $\langle \mathbb{R} \cup \{-\infty\}, \max, +, -\infty, 0\rangle$. We refer the reader to Kuich and Salomaa (1986) for others.

Definition 2. A **weighted finite-state automaton (WFSA)** over a semiring $\mathbb{K}$ is a 5-tuple, $\mathcal{A} = \langle \Sigma, \mathcal{Q}, \tau, \lambda, \rho\rangle$,[2] with:

- a finite input alphabet Σ;
- a finite state set $\mathcal{Q}$;
- transition weights $\tau : \mathcal{Q} \times \mathcal{Q} \times (\Sigma \cup \{\varepsilon\}) \to \mathbb{K}$;
- initial weights $\lambda : \mathcal{Q} \to \mathbb{K}$;
- and final weights $\rho : \mathcal{Q} \to \mathbb{K}$.

$\varepsilon \notin \Sigma$ marks special **ε-transitions** that may be taken without consuming any input. $\mathcal{A}$ assigns a score $\mathcal{A}[\![\mathbf{x}]\!]$ to a string $\mathbf{x} = x_1 \dots x_n \in \Sigma^*$ by summing over the scores of all possible paths deriving $\mathbf{x}$. The score of each individual path is the product of the weights of the transitions it consists of. Formally:

Definition 3 (path score)**.** Let $\boldsymbol{\pi} = \pi_1 \dots \pi_n$ be a sequence of adjacent **transitions** in $\mathcal{A}$, with each transition $\pi_i = (q_i, q_{i+1}, z_i) \in \mathcal{Q} \times \mathcal{Q} \times (\Sigma \cup \{\varepsilon\})$. The path $\boldsymbol{\pi}$ **derives** string $\mathbf{x} \in \Sigma^*$, which is the substring of $\mathbf{z} = z_1 z_2 \dots z_n$ that excludes ε symbols (for example, if $\mathbf{z} = a\varepsilon bc\varepsilon\varepsilon\varepsilon d$, then $\mathbf{x} = abcd$). $\boldsymbol{\pi}$'s score in $\mathcal{A}$ is given by

$$\mathcal{A}[\boldsymbol{\pi}] = \lambda(q_1) \otimes \left(\bigotimes_{i=1}^{n} \tau(\pi_i) \right) \otimes \rho(q_{n+1}). \quad (1)$$

Definition 4 (string score)**.** Let $\Pi(\mathbf{x})$ denote the set of all paths in $\mathcal{A}$ that derive $\mathbf{x}$. Then the score assigned by $\mathcal{A}$ to $\mathbf{x}$ is defined to be

$$\mathcal{A}[\![\mathbf{x}]\!] = \bigoplus_{\boldsymbol{\pi} \in \Pi(\mathbf{x})} \mathcal{A}[\boldsymbol{\pi}]. \quad (2)$$

Because $\mathbb{K}$ is a semiring, $\mathcal{A}[\![\mathbf{x}]\!]$ can be computed in time linear in $|\mathbf{x}|$ by the Forward algorithm (Baum and Petrie, 1966). Here, for simplicity, we describe the Forward algorithm without ε-transitions.[3] Its dynamic program is given by:

$$\Omega_0(q) = \lambda(q), \quad (3a)$$

$$\Omega_{i+1}(q) = \bigoplus_{q' \in \mathcal{Q}} \Omega_i(q') \otimes \tau(q', q, x_i), \quad (3b)$$

$$\mathcal{A}[\![\mathbf{x}]\!] = \bigoplus_{q \in \mathcal{Q}} \Omega_n(q) \otimes \rho(q). \quad (3c)$$

$\Omega_i(q)$ gives the total score of all paths that derive $x_1 \dots x_i$ and end in state q.

Example 5. Figure 1 diagrams a WFSA $\mathcal{B}$, consisting of two states. A path starts from the initial state q_0 (with $\lambda(q_0) = \bar{1}$); it then takes any num-

---

[2] Some authors define τ, λ, and ρ to be partial functions—applying only a subset of transitions, initial states, and final states respectively. Our definition is equivalent, giving the weight functions value $\bar{0}$ wherever they were undefined.

[3] ε-transitions can be handled with a slight modification (Schwartz et al., 2018). Note though that if $\mathcal{A}$ contains a cycle of ε-transitions, then either $\mathbb{K}$ must follow the **star semiring** laws (Kuich and Salomaa, 1986), or the number of consecutive ε-transitions allowed must be capped.

ber of “self-loop” transitions, each consuming an input without changing the path score (since it's weighted by $\bar{1}$); it then consumes an input symbol α and takes a transition weighted by $\mu(\alpha)$, and reaches the final state q_1 (with $\rho(q_1) = \bar{1}$); it may further consume more input by taking self-loops at q_1, updating the path score by multiplying it by $\phi(\alpha)$ for each symbol α. Then from Definition 4, we can calculate that $\mathcal{B}$ gives the empty string score $\bar{0}$, and gives any nonempty string $\mathbf{x} = x_1 \ldots x_n \in \Sigma^+$ score $\mathcal{B}[\![\mathbf{x}]\!] =$

$$\bigoplus_{i=1}^{n-1} \left(\mu(x_i) \otimes \bigotimes_{j=i+1}^{n} \phi(x_j) \right) \oplus \mu(x_n). \tag{4}$$

$\mathcal{B}$ can be seen as capturing soft unigram patterns (Davidov et al., 2010), in the sense that it consumes one input symbol to reach the final state from the initial state. It is straightforward to design WFSAs capturing longer patterns by including more states (Schwartz et al., 2018), as we will discuss later in §4 and §5.

3 Rational Recurrences

Before formally defining rational recurrences in §3.2, we highlight the connection between WFSAs and RNNs using a motivating example (§3.1).

3.1 A Motivating Example

We describe a simplified RNN which strips away details of some recent RNNs, in order to highlight the behaviors of the forget gate and the input.

Example 6. For an input sequence $\mathbf{x} = x_1 \ldots x_n$, let the word embedding vector for x_t be $\mathbf{v}_t$. As in many gated RNN variants (Hochreiter and Schmidhuber, 1997; Cho et al., 2014), we use a forget gate $\mathbf{f}_t$, which is computed with an affine transformation followed by an elementwise sigmoid function $\boldsymbol{\sigma}$. The current input representation $\mathbf{u}_t$ is similarly computed, but with an optional nonlinearity (e.g., tanh) $\boldsymbol{g}$. The hidden state $\mathbf{c}_t$ can be seen as a weighted sum of the previous state and the new input, controlled by the forget gate.

$$\mathbf{f}_t = \boldsymbol{\sigma}\big(\mathbf{W}_f \mathbf{v}_t + \mathbf{b}_f\big), \tag{5a}$$
$$\mathbf{u}_t = (\mathbf{1} - \mathbf{f}_t) \odot \boldsymbol{g}\big(\mathbf{W}_u \mathbf{v}_t + \mathbf{b}_u\big), \tag{5b}$$
$$\mathbf{c}_t = \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{u}_t. \tag{5c}$$

The hidden state $\mathbf{c}_t$ can then be used in downstream computation, e.g., to calculate output state $\mathbf{h}_t = \tanh(\mathbf{c}_t)$, which is then fed to an MLP classifier. We focus only on the recurrent computation.

In Example 6, both $\mathbf{f}_t$ and $\mathbf{u}_t$ depend only on the current input token x_t (through $\mathbf{v}_t$), and not the previous state. Importantly, the interaction with the previous state $\mathbf{c}_{t-1}$ is *not* via affine transformations followed by nonlinearities, as in, e.g., an Elman network (Elman, 1990), where $\mathbf{c}_t = \tanh(\mathbf{W}_c \mathbf{c}_{t-1} + \mathbf{W}_v \mathbf{v}_t + \mathbf{b}_c)$. As we will discuss later, this is important in relating this recurrent update function to WFSAs.

Since the recurrent update in Equation 5c is elementwise, for simplicity we focus on just the ith dimension. Unrolling it in time steps, we get

$$\begin{aligned} [\mathbf{c}_t]_i &= [\mathbf{f}_t]_i \, [\mathbf{c}_{t-1}]_i + [\mathbf{u}_t]_i \\ &= \sum_{j=1}^{t-1} \left([\mathbf{u}_j]_i \prod_{k=j+1}^{t} [\mathbf{f}_k]_i \right) + [\mathbf{u}_t]_i, \end{aligned} \tag{6}$$

where $[\cdot]_i$ denotes the ith dimension of a vector. As noted by Lee et al. (2017), the hidden state at time step t can be seen as a sum of previous input representations, weighted by the forget gate; longer histories typically get a smaller weight, since the forget gate values are between 0 and 1 due to the sigmoid function.

Let's recall the WFSA $\mathcal{B}$ (Figure 1 and Example 5) using the real semiring $\langle \mathbb{R}, +, \cdot, 0, 1 \rangle$. Equation 6 is recovered by parameterizing $\mathcal{B}$'s weight functions μ and ϕ with

$$\mu(x_t) = [\mathbf{u}_t]_i, \quad \phi(x_t) = [\mathbf{f}_t]_i. \tag{7}$$

Denote the resulting WFSA by $\mathcal{B}_i$, and we have:

Proposition 7. *Running a single layer RNN in Example 6 over any nonempty input string $\mathbf{x} \in \Sigma^+$, the ith dimension of its hidden state at time step t equals the score assigned by $\mathcal{B}_i$ to $\mathbf{x}_{:t}$:*

$$[\mathbf{c}_t]_i = \mathcal{B}_i[\![\mathbf{x}_{:t}]\!]. \tag{8}$$

In other words, the ith dimension of the RNN in Example 6 can be seen as a WFSA structurally equivalent to $\mathcal{B}$. Its weight functions are implemented as the ith dimension of Equations 5, and the learned parameters are the ith row of $\mathbf{W}$ and $\mathbf{b}$. Then it is straightforward to recover the full d-dimensional RNN, by collecting d such WFSAs, each of which is parametrized by a row in the $\mathbf{W}$s and $\mathbf{b}$s. Based on this observation, we are now ready to formally define rational recurrences.

3.2 Recurrences and Rationality

For a function $\mathbf{c}\colon \Sigma^* \to \mathbb{K}^d$, its *recurrence* is said to be the dependence of $\mathbf{c}(\mathbf{x}_{:t})$ on $\mathbf{c}(\mathbf{x}_{:t-1})$, for input sequence $\forall \mathbf{x} \in \Sigma^+$. We discuss a class of recurrences that can be characterized by WFSAs. The mathematical counterpart of WFSAs are *rational power series* (Berstel and Reutenauer, 1988), justifying naming such recurrences *rational*:

Definition 8 (rational recurrence)**.** The recurrence of $\mathbf{c}\colon \Sigma^* \to \mathbb{K}^d$ is said to be *rational*, if there exists a set of weighted finite state automata $\{\mathcal{A}_i\}_{i=1}^d$ over alphabet Σ and semiring $\langle \mathbb{K}, \oplus, \otimes, \bar{0}, \bar{1}\rangle$ with both $\oplus$ and $\otimes$ taking constant time and space, such that $\forall \mathbf{x} \in \Sigma^*$,

$$\big[\mathbf{c}(\mathbf{x})\big]_i = \mathcal{A}_i[\![\mathbf{x}]\!],\ \forall i \in \{1, 2, \ldots, d\}.^4 \qquad (9)$$

It directly follows from Proposition 7 that

Corollary 9. *The recurrence in Example 6 is rational.*

4 Relationship to Existing Neural Models

This section studies several recently proposed neural architectures, and relates them to rational recurrences. §4.1 begins by relating some of them to the RNN defined in Example 6, and then to the WFSA $\mathcal{B}$ (Example 5). We then describe a WFSA similar to $\mathcal{B}$, but with one additional state, and discuss how it provides a new view of RNN models motivated by n-gram features (§4.2). In §4.3 we study rational recurrences that are not elementwise, using an existing model.

In the following discussion, we shall assume the real seimiring, unless otherwise noted.

4.1 Neural Architectures Related to $\mathcal{B}$

Despite its simplicity, Example 6 corresponds to several existing neural architectures. For instance, quasi-RNN (QRNN; Bradbury et al., 2017) and simple recurrent unit (SRU; Lei et al., 2017b) aim to speed up the recurrent computation. To do so, they drop the matrix multiplication dependence on the previous hidden state, resulting in similar recurrences to that in Example 6.[5] Other works start from different motivations, but land on similar recurrences, e.g., strongly-typed RNNs (T-RNN; Balduzzi and Ghifary, 2016) and its gated variants (T-LSTM and T-GRU), and structurally constrained RNNs (SCRN; Mikolov et al., 2014).

The analysis in §3.1 directly applies to SRU, T-RNN, and SCRN. In fact, Example 6 presents a slightly more complicated version of them. In these models, input representations are computed without the bias term or any nonlinearity: $\mathbf{u}_t = \mathbf{W}_u \mathbf{v}_t$. By Proposition 7 and Corollary 9:

Corollary 10. *The recurrences of single-layer SRU, T-RNN, and SCRN architectures are rational.*

It is slightly more complicated to analyze the recurrences of the QRNN, T-LSTM, and T-GRU. Although their hidden states $\mathbf{c}_t$ are updated in the same way as Equation 5c, the input representations and gates may depend on *previous inputs*. For example, in T-LSTM and T-GRU, the forget gate is a function of two consecutive inputs:

$$\mathbf{f}_t = \boldsymbol{\sigma}\left(\mathbf{V}_f \mathbf{v}_{t-1} + \mathbf{W}_f \mathbf{v}_t + \mathbf{b}_f\right). \qquad (10)$$

QRNNs are similar, but may depend on up to K tokens, due to the K-window convolutions. Eisner (2002) discuss finite state machines for second (or higher) order probabilistic sequence models. Following the same intuition, we sketch the construction of WFSAs corresponding to QRNNs with 2-window convolutions in Appendix A, and summarize the key results here:

Proposition 11. *The recurrences of single-layer T-GRU, T-LSTM, and QRNN are rational. In particular, a single-layer d-dimensional QRNN using K-window convolutions can be recovered by a set of d WFSAs, each with $O(2\,|\Sigma|^{K-1})$ states.*

The size of WFSAs needed to recover QRNN grows exponentially in the window size. Therefore, at least for QRNNs, Proposition 11 has more conceptual value than practical.

4.2 More than Two States

So far our discussion has centered on $\mathcal{B}$, a two-state WFSA capturing unigram patterns (Example 5). In the same spirit as going from unigram to n-gram features, one can use WFSAs with more states to capture longer patterns (Schwartz et al., 2018). In this section we augment $\mathcal{B}$ by introducing more states, and explore its relationship to some neural architectures motivated by n-gram features. We start with a three-state WFSA as an example, and then discuss more general cases.

Figure 2 diagrams a WFSA $\mathcal{C}$, augmenting $\mathcal{B}$ with another state. To reach the final state q_2, at

---

[4] We restrict that both operations take constant time and space, to exclude the use of arbitrarily complex semirings (§4.3).

[5] The SRU architecture discussed through this work is based on Lei et al. (2017b). In a later updated version, Lei et al. (2018) introduce diagonal matrix multiplication interaction in the hidden state updates, inspired by (Li et al., 2018), which yields a recurrence not obviously rational.

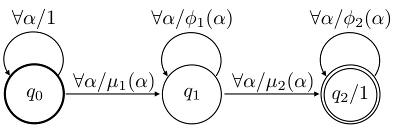

Figure 2: A three-state WFSA $\mathcal{C}$ discussed in §4.2.

least two transitions must be taken, in contrast to one in $\mathcal{B}$. History information is decayed by the self-loop at the final state q_2, assuming ϕ_2 is between 0 and 1. $\mathcal{C}$ has another self-loop over q_1, weighted by $\phi_1 \in (0,1)$. The motivation is to allow (but down-weight) nonconsecutive bigrams, as we will soon show.

The scores assigned by $\mathcal{C}$ can be inductively computed by applying the Forward algorithm (§2). Given input sequence $\mathbf{x}$ longer than one, let $\mathcal{C}[\![\mathbf{x}_{:0}]\!] = 0$, then $\mathcal{C}[\![\mathbf{x}_{:t+1}]\!] =$

$$\mathcal{C}[\![\mathbf{x}_{:t}]\!]\,\phi_2(x_{t+1}) + \beta_t\,\mu_2(x_{t+1}), \tag{11}$$

where

$$\beta_t = \beta_{t-1}\,\phi_1(x_t) + \mu_1(x_t), \tag{12}$$

and $\beta_0 = 0$. Unrolling β_t in time, we get $\beta_t =$

$$\sum_{j=1}^{t-1}\left(\mu_1(x_j)\prod_{k=j+1}^{t}\phi_1(x_k)\right) + \mu_1(x_t). \tag{13}$$

Due to the self-loop over state q_1, β_t can be seen as a weighted sum of the μ_1 terms up to x_t (Equaltion 13). The second product term in Equation 11 then provides multiplicative interactions between μ_2, and the weighted sum of μ_1s. In this sense, it captures nonconsecutive bigram features.

At a first glance, Equations 11 and 12 resemble recurrent convolutional neural networks (RCNN; Lei et al., 2016). RCNN is inspired by nonconsecutive n-gram features and low rank tensor factorization. It is later studied from a string kernel perspective (Lei et al., 2017a). Here we review its nonlinear bigram version:

$$\mathbf{c}_t^{(1)} = \mathbf{c}_{t-1}^{(1)} \odot \boldsymbol{\lambda}_t + \mathbf{u}_t^{(1)}, \tag{14a}$$

$$\mathbf{c}_t^{(2)} = \mathbf{c}_{t-1}^{(2)} \odot \boldsymbol{\lambda}_t + \mathbf{c}_{t-1}^{(1)} \odot \mathbf{u}_t^{(2)}, \tag{14b}$$

where the $\mathbf{u}_t^{(j)}$s are computed similarly to Equation 5b, and $\mathbf{c}_t^{(2)}$ is used as output for onward computation. Different strategies to computing $\boldsymbol{\lambda}_t$ were explored (Lei et al., 2015, 2016). When $\boldsymbol{\lambda}_t$ is a constant, or depends only on x_t, e.g., $\boldsymbol{\lambda}_t = \boldsymbol{\sigma}(\mathbf{W}_\lambda \mathbf{v}_t + \mathbf{b}_\lambda)$, the ith dimension of Equations 14 can be recovered from Equation 11, by letting

$$\mu_j(x_t) = [\mathbf{u}_t^{(j)}]_i,\ \phi_j(x_t) = [\boldsymbol{\lambda}_t]_i,\ j = 1, 2. \tag{15}$$

It is straightforward to generalize the above discussion to higher order cases: n-gram RCNN corresponds to WFSAs with $n+1$ states, constructed similarly to how we build $\mathcal{C}$ from $\mathcal{B}$ (Appendix B).

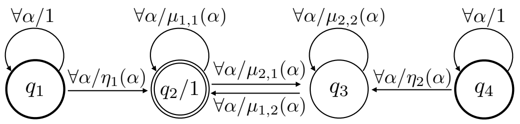

Figure 3: WFSA $\mathcal{D}_1$ discussed in §4.3. Two initial states q_1 and q_4 are used here.

Proposition 12. *For a single-layer RCNN with $\boldsymbol{\lambda}_t$ being a constant or depending only on x_t, the recurrence is rational.*

As noted later in §4.3, its recurrence may not be rational when $\boldsymbol{\lambda}_t = \boldsymbol{\sigma}(\mathbf{W}_c\mathbf{c}_{t-1} + \mathbf{W}_\lambda\mathbf{v}_t + \mathbf{b}_\lambda)$.

4.3 Beyond Elementwise Operations

So far we have discussed rational recurrences for models using elementwise recurrent updates (e.g., Equation 5c). This section uses an existing model as an example, to study a rational recurrence that is not elementwise. We focus on the input switched affine network (ISAN; Foerster et al., 2017). Aiming for efficiency and interpretability, it does not use any explicit nonlinearity; its affine transformation parameters depend only on the input:

$$\mathbf{c}_t = \mathbf{W}_{x_t}\mathbf{c}_{t-1} + \mathbf{b}_{x_t}. \tag{16}$$

Due to the matrix multiplication, the recurrence of a single-layer ISAN is not elementwise. Yet, we argue that it is rational. We will sketch the proof for a 2-dimensional case, and it is straightforward to generalize to higher dimensions (Appendix C).

We define two WFSAs, each recovering one dimension of ISAN's recurrent updates. Figure 3 diagrams one of them, $\mathcal{D}_1$. The other one, $\mathcal{D}_2$, is identical (including shared weights), except using q_3 instead of q_2 as the final state. For any nonempty input sequence $\mathbf{x} \in \Sigma^+$, the scores assigned by $\mathcal{D}_1$ and $\mathcal{D}_2$ can be inductively computed by applying the Forward algorithm. Letting $\mathcal{D}_1[\![\mathbf{x}_{:0}]\!] = \mathcal{D}_2[\![\mathbf{x}_{:0}]\!] = 0$, for $t \geq 1$

$$\begin{bmatrix}\mathcal{D}_1[\![\mathbf{x}_{:t}]\!]\\ \mathcal{D}_2[\![\mathbf{x}_{:t}]\!]\end{bmatrix} = \widetilde{\mathbf{W}}_{x_t}\begin{bmatrix}\mathcal{D}_1[\![\mathbf{x}_{:t-1}]\!]\\ \mathcal{D}_2[\![\mathbf{x}_{:t-1}]\!]\end{bmatrix} + \widetilde{\mathbf{b}}_{x_t}, \tag{17}$$

where

$$\widetilde{\mathbf{W}}_{x_t} = \begin{bmatrix} \mu_{1,1}(x_t) & \mu_{1,2}(x_t) \\ \mu_{2,1}(x_t) & \mu_{2,2}(x_t) \end{bmatrix}, \qquad (18)$$
$$\widetilde{\mathbf{b}}_{x_t} = \begin{bmatrix} \eta_1(x_t) \\ \eta_2(x_t) \end{bmatrix}.$$

Then Equation 16, in the case of hidden size 2, is recovered by letting $\mathbf{W}_{x_t} = \widetilde{\mathbf{W}}_{x_t}$ and $\mathbf{b}_{x_t} = \widetilde{\mathbf{b}}_{x_t}$.

Proposition 13. *The recurrence of a single-layer ISAN is rational.*

Corollary 14. *For a single-layer Elman network, in the absence of any nonlinearity, the recurrence is rational.*

Discussion. It is known that an Elman network can approximate any recursively computable partial function (Siegelmann and Sontag, 1995). On the other hand, in their single-layer cases, WFSAs (and thus models with rational recurrences) are restricted to rational series (Schützenberger, 1961). Therefore, we hypothesize that models like Elman networks, LSTMs, and GRUs, where the recurrences depend on previous states through affine transformations followed by nonlinearities, are not rational.

This work does not intend to propose rational recurrences as a concept general enough to include most existing RNNs. Rather, we wish to study a more constrained class of methods to better understand the connections between WFSAs and RNNs. Therefore in Definition 8, we restrict the semirings to be "simple," in the sense that both operations take constant time and space. Such a restriction aims to exclude the possibility of hiding arbitrarily complex computations inside the semiring, which might allow RNNs to satisfy the definition in a trivial and unilluminating way.

Such theoretical limitations might be less severe than they appear, since it is not yet entirely clear what they correspond to in practice, especially when multiple vertical layers of these models are used (Leshno and Schocken, 1993). We defer to future work the further study of the connections between WFSAs and Elman-style RNNs.

Closing this section, Table 1 summarizes the discussed recurrent neural architectures and their corresponding WFSAs.

5 Deriving Neural Models from WFSAs

Rational recurrences provide a new view of several recently proposed neural models. Based on such observations, this section aims to explore potential approaches to designing neural architectures in a more interpretable and intuitive way: by deriving them from WFSAs. §5.1 studies an interpolation of unigram and bigram features by combining 2-state and 3-state WFSAs (Figures 1 and 2). We then explore alternative semirings (§5.2), an approach orthogonal to what we've discussed so far.

	Models	Recurrence Function	WFSA
§4.1	SRU, SCRN T-RNN, QRNN	$\mathbf{c}_t = \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{u}_t$	$\mathcal{B}$
§4.2	RCNN	$\mathbf{c}_t^{(1)} = \mathbf{c}_{t-1}^{(1)} \odot \boldsymbol{\lambda}_t + \mathbf{u}_t^{(1)}$ $\mathbf{c}_t^{(2)} = \mathbf{c}_{t-1}^{(2)} \odot \boldsymbol{\lambda}_t + \mathbf{c}_{t-1}^{(1)} \odot \mathbf{u}_t^{(2)}$	$\mathcal{C}$
§4.3	ISAN	$\mathbf{c}_t = \mathbf{W}_{x_t}\mathbf{c}_{t-1} + \mathbf{b}_{x_t}$	$\mathcal{D}_1, \mathcal{D}_2$

Table 1: Recurrent neural network architectures discussed in §4 and their corresponding WFSAs. §4.1: SRU (Lei et al., 2017b), SCRN (Mikolov et al., 2014), T-RNN and its gated variants (Balduzzi and Ghifary, 2016), and QRNN (Bradbury et al., 2017); §4.2: RCNN (Lei et al., 2016); §4.3: ISAN (Foerster et al., 2017).

We note that our goal is not to devise new state-of-the-art architectures. Rather, we illustrate a new design process for neural architectures that draws inspiration from WFSAs. That said, in our experiments (§6), one of our new architectures performs as well as or better than strong baselines.

5.1 Aggregating Different Length Patterns

We start by presenting a straightforward extension to 2-state and 3-state rational models: one combining both. It is inspired by many classical NLP models, where unigram features and higher-order ones are interpolated.

Figure 4 diagrams a 4-state WFSA $\mathcal{F}$. Compared to $\mathcal{C}$ (Figure 2), $\mathcal{F}$ uses q_1 as a second final state, aiming to capture both unigram and bigram patterns, since a path is allowed to stop at q_1 after consuming one input. The final states are weighted by ρ_1 and ρ_2 respectively. Another notable modification is the additional state q_3, which is used to create a "shortcut" to reach q_2, together with an ε-transition. Specifically, starting from q_0, a path can now take the ε-transition and reach q_3, and then take a transition with weight μ_2 to reach q_2. Recall from §2, that ε-transitions do not consume any input, yet they can still be weighted by a (parameterized) function γ *not* depending on the inputs. The ε-transition allows for skipping the

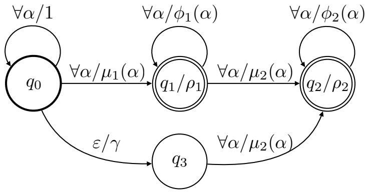

Figure 4: A WFSA $\mathcal{F}$ that combines both unigram and bigram features (§5.1). Two final states q_1 and q_2 are used, with weights ρ_1 and ρ_2, respectively.

first word in a bigram. It can be discouraged by using $\gamma \in (0, 1)$, just as we do in our experiments.

Deriving the neural architecture. As in §3, we relate hidden states of an RNN to the scores assigned by WFSAs to input strings. We then derive the neural architecture with a dynamic program. Here we keep the discussion self-contained by explicitly overviewing the procedure. It is a direct application of the Forward algorithm (§2), though now in a form that deals with the ε-transition. Such an approach applies, of course, to more general cases, as noted by Schwartz et al. (2018).

Given an input string $\mathbf{x} \in \Sigma^+$, let $z_t^{(j)}$ denote the total score of all paths landing in state q_j *just* after consuming x_t. Let $z_0^{(j)} = 0$, then for $t \geq 1$,

$$\begin{aligned}
z_t^{(0)} &= 1\\
z_t^{(1)} &= z_{t-1}^{(1)}\,\phi_1(x_t) + z_{t-1}^{(0)}\,\mu_1(x_t)\\
z_t^{(3)} &= z_t^{(0)}\,\gamma\\
z_t^{(2)} &= z_{t-1}^{(2)}\,\phi_2(x_t) + (z_{t-1}^{(1)} + z_{t-1}^{(3)})\,\mu_2(x_t)\\
\mathcal{F}[\![\mathbf{x}_{:t}]\!] &= \rho_1\, z_t^{(1)} + \rho_2\, z_t^{(2)}.
\end{aligned}$$

We now collect d of these WFSAs to construct an RNN, and we parameterize their weight functions with the technique we've been using:

$$\mathbf{c}_t^{(1)} = \mathbf{c}_{t-1}^{(1)} \odot \mathbf{f}_t^{(1)} + \mathbf{u}_t^{(1)}, \tag{19a}$$

$$\mathbf{c}_t^{(2)} = \mathbf{c}_{t-1}^{(2)} \odot \mathbf{f}_t^{(2)} + (\mathbf{c}_{t-1}^{(1)} + \mathbf{r}) \odot \mathbf{u}_t^{(2)}, \tag{19b}$$

$$\mathbf{c}_t = \mathbf{p}^{(1)} \odot \mathbf{c}_t^{(1)} + \mathbf{p}^{(2)} \odot \mathbf{c}_t^{(2)}, \tag{19c}$$

where

$$\mathbf{f}_t^{(j)} = \boldsymbol{\sigma}\big(\mathbf{W}_f^{(j)}\mathbf{v}_t + \mathbf{b}_f^{(j)}\big), \tag{20a}$$

$$\mathbf{u}_t^{(j)} = (\mathbf{1} - \mathbf{f}_t^{(j)}) \odot \boldsymbol{g}\big(\mathbf{W}_u^{(j)}\mathbf{v}_t + \mathbf{b}_u^{(j)}\big), \tag{20b}$$

$$\mathbf{p}^{(j)} = \boldsymbol{\sigma}(\mathbf{b}_p^{(j)}), \quad \mathbf{r} = \boldsymbol{\sigma}(\mathbf{b}_r). \tag{20c}$$

The $\mathbf{p}$ vectors correspond to the final state weights ρ_1 and ρ_2. Despite the similarities, $\mathbf{p}$ are different from output gates (Bradbury et al., 2017), since the former do not depend on the input, and are parameterized (through a sigmoid) by two leanred vectors $\mathbf{b}_p^{(j)}$. The same applies to $\mathbf{r}$ and $\mathbf{b}_r$, which correspond to the weights for ε-transitions γ.

Model	**Unigram**	**Bigram**	**Semiring**

RRNN($\mathcal{C}$)		✓	real
RRNN($\mathcal{F}$)	✓	✓	real

Table 2: Rational recurrent neural architectures compared in the experiments (§6.1).

5.2 Alternative Semirings

Our new understanding of rational recurrences allows us to consider a different kind of extension: replacing the semiring. We introduce an example, which modifies Example 6 by replacing its real (plus-times) semiring with the max-plus semiring $\langle \mathbb{R} \cup \{-\infty\}, \max, +, -\infty, 0\rangle$:

Example 15.

$$\mathbf{f}_t = \log \boldsymbol{\sigma}\big(\mathbf{W}_f\mathbf{v}_t + \mathbf{b}_f\big), \tag{21a}$$

$$\mathbf{u}_t = \boldsymbol{g}\big(\mathbf{W}_u\mathbf{v}_t + \mathbf{b}_u\big), \tag{21b}$$

$$\mathbf{c}_t = \max\{\mathbf{f}_t + \mathbf{c}_{t-1}, \mathbf{u}_t\}. \tag{21c}$$

Example 15 does not use the forget gate when computing $\mathbf{u}_t$ (Equation 21b), which is different from its plus-times counterpart, where $\mathbf{u}_t = (\mathbf{1} - \mathbf{f}_t) \odot \boldsymbol{g}\big(\mathbf{W}_u\mathbf{v}_t + \mathbf{b}_u\big)$. The reason is that, unlike the real semiring, the max-plus semiring lacks a well-defined negation. Possible alternatives include taking the log of a separate input gate, or using $\log(\mathbf{1} - \mathbf{f}_t)$, which we leave for future work.

Example 15 can be seen as replacing sum-pooling with max-pooling. Both max and sum-pooling have been used successfully in vision and NLP models. Intuitively, max-pooling "detects" the occurrence of a pattern while sum-pooling "counts" the occurrence of a pattern. One advantage of max operator is that the model's decisions can be back-traced and interpreted, as argued by Schwartz et al. (2018). Such a technique is applicable to all the models with rational recurrences.

6 Experiments

This section evaluates four rational RNNs on language modeling (§6.2) and text categorization (§6.3). Our goal is to compare the behaviors of models derived from different WFSAs, showing that our understanding of WFSAs allows us to improve existing rational models.

6.1 Compared Models

Our comparisons focus on the *recurrences* of the models, i.e., how the hidden states $\mathbf{c}_t$ are computed (e.g., Equations 5c and 19c). Therefore we follow Lei et al. (2017b) and use $\mathbf{u}_t^{(j)} = \mathbf{W}_u^{(j)} \mathbf{v}_t^{(j)}$ across all compared models, listed below and as well as in Table 2:

- RRNN($\mathcal{B}$), with real semiring (§4.1);
- RRNN($\mathcal{B}$)$_{\text{m+}}$, with max-plus semiring (§5.2);
- RRNN($\mathcal{C}$), with real semiring (§4.2);
- RRNN($\mathcal{F}$), with real semiring (§5.1).

We also compare to an LSTM baseline. Aiming to control for comfounding factors, we do not use highway connections in any of the models.[6] In the interest of space, the full architectures and hyperparameters are detailed in Appendices D and E.

6.2 Language Modeling

Dataset and implementation. We experiment with the Penn Treebank corpus (PTB; Marcus et al., 1993). We use the preprocessing and splits from Mikolov et al. (2010), resulting in a vocabulary size of 10K and 1M tokens.

Following standard practice, we treat the training data as one long sequence, split into mini batches, and train using BPTT truncated to 35 time steps (Williams and Peng, 1990). The input embeddings and output softmax weights are tied (Press and Wolf, 2017).

Results. Following Collins et al. (2017) and Melis et al. (2018), we compare models controlling for parameter budget. Table 3 summarizes language modeling perplexities on PTB test set. The middle block compares all models with two layers and 10M trainable parameters. RRNN($\mathcal{B}$) and RRNN($\mathcal{C}$) achieve roughly the same performance; interpolating both unigram and bigram features, RRNN($\mathcal{F}$) outperforms others by more than 2.9 test perplexity. For the three-layer and 24M setting (the bottom block), we observe similar trends, except that RRNN($\mathcal{C}$) slightly underperforms RRNN($\mathcal{B}$). Here RRNN($\mathcal{F}$) outperforms others by more than 2.1 perplexity.

Using a max-plus semiring, RRNN($\mathcal{B}$)$_{\text{m+}}$ *underperforms* RRNN($\mathcal{B}$) under both settings. Possible reasons could be the suboptimal design choice for computing input representations in the former (§5.2). Finally, most compared models outperform the LSTM baselines, whose numbers are taken from Lei et al. (2017b).[7]

Model	ℓ	# Params.	Dev.	Test
LSTM	2	24M	73.3	71.4
LSTM	3	24M	78.8	76.2
RRNN($\mathcal{B}$)	2	10M	73.1	69.2
RRNN($\mathcal{B}$)$_{\text{m+}}$	2	10M	75.1	71.7
RRNN($\mathcal{C}$)	2	10M	72.5	69.5
RRNN($\mathcal{F}$)	2	10M	**69.5**	**66.3**
RRNN($\mathcal{B}$)	3	24M	68.7	65.2
RRNN($\mathcal{B}$)$_{\text{m+}}$	3	24M	70.8	66.9
RRNN($\mathcal{C}$)	3	24M	70.0	67.0
RRNN($\mathcal{F}$)	3	24M	**66.0**	**63.1**

Table 3: Language modeling perplexity on PTB test set (lower is better). LSTM numbers are taken from Lei et al. (2017b). ℓ denotes the number of layers. Bold font indicates best performance.

Split	Amazon	SST	subj	CR

Dev.	5K	0.9K	1K	0.4K
Test	25K	1.8K	1K	0.4K

Table 4: Number of instances in the text classification datasets (§6.3).

6.3 Text Classification

Implementation. We use unidirectional 2-layer architectures for all compared models. To build the classifiers, we feed the final RNN hidden states into a 2-layer tanh-MLP. Further implementation details are described in Appendix E.

Datasets. We experiment with four binary text classification datasets, described below.

- **Amazon** (electronic product review corpus; McAuley and Leskovec, 2013).[8] We focus on the positive and negative reviews.
- **SST** (Stanford sentiment treebank; Socher et al., 2013).[9] We focus on the binary classification task. SST provides labels for syntactic phrases; we experiment with a more realistic setup, and

---

[6] Thus RRNN($\mathcal{B}$) is essentially an SRU without highway connections. We denote it differently, to note its differences from the original implementation (Lei et al., 2017b). Similarly, we do not denote RRNN($\mathcal{C}$) as RCNN (Lei et al., 2016).

[7] Melis et al. (2018) point out that carefully tuning LSTMs can achieve much stronger performance, at the cost of exceptionally large amounts of computational resources for tuning.

Model	**Amazon**	**SST**	**subj**	**CR**
LSTM	$91.2_{\pm 0.3}$	$85.1_{\pm 0.6}$	$93.3_{\pm 0.6}$	$82.4_{\pm 1.5}$
RRNN($\mathcal{B}$)	$92.4_{\pm 0.1}$	$85.8_{\pm 0.3}$	$93.9_{\pm 0.4}$	$84.1_{\pm 1.0}$
RRNN($\mathcal{C}$)	$\mathbf{92.8}_{\pm 0.2}$	$84.8_{\pm 0.4}$	$93.8_{\pm 0.6}$	$84.5_{\pm 0.9}$
RRNN($\mathcal{B}$)$_{\text{m+}}$	$89.2_{\pm 3.1}$	$84.9_{\pm 0.4}$	$92.6_{\pm 0.5}$	$84.3_{\pm 0.5}$
RRNN($\mathcal{F}$)	$92.7_{\pm 0.2}$	$\mathbf{86.5}_{\pm 0.6}$	$\mathbf{94.8}_{\pm 0.5}$	$\mathbf{85.1}_{\pm 0.5}$

Table 5: Text classification test accuracy averaged over 5 runs. ± denotes standard deviation, and bold font indicates best averaged performance.

consider only complete sentences at either training or evaluating time.

- **subj** (Subjectivity dataset; Pang and Lee, 2004). As **subj** doesn't come with official splits, we randomly split it to train (80%), development (10%), and test (10%) sets.
- **CR** (customer reviews dataset; Hu and Liu, 2004).[10] As with **subj**, we randomly split this dataset using the same ratio.

Table 4 summarizes the sizes of the datasets.

Results. Table 5 summarizes text classification test accuracy. We report the average performance of 5 trials different only in random seeds. RRNN($\mathcal{F}$) outperforms all other models on 3 out of the 4 datasets. For Amazon, the largest one, we do not observe significant differences between RRNN($\mathcal{F}$) and RRNN($\mathcal{C}$), while both outperform others. This may suggest that the interpolation of unigram and bigram features by RRNN($\mathcal{F}$) is especially useful in small data setups. As in the language modeling experiments, RRNN($\mathcal{B}$)$_{\text{m+}}$ underperforms all other models in most cases, and in particular RRNN($\mathcal{B}$). These results provide evidence that replacing the real semiring in rational models might be challenging. We leave further exploration to future work.

7 Related Work

Weighted finite state automata. WFSAs were once popular among many sequential tasks (Mohri et al., 2002; Kumar and Byrne, 2003; Cortes et al., 2004; Pardo and Birmingham, 2005; Moore et al., 2006, *inter alia*), and are still successful in morphology (Dreyer, 2011; Cotterell et al., 2015; Rastogi et al., 2016, *inter alia*). Compared to neural networks, WFSAs are better understood theoretically and arguably more interpretable. They were recently revisited in combination with the former in, e.g., text generation (Ghazvininejad et al., 2016, 2017; Lin et al., 2017) and automatic music accompaniment (Forsyth, 2016).

Recurrent neural networks. RNNs (Elman, 1990; Jordan, 1989) prove to be strong models for sequential data (Siegelmann and Sontag, 1995). Besides the perhaps most notable gated variants (Hochreiter and Schmidhuber, 1997; Cho et al., 2014), extensive efforts have been devoted to developing alternatives (Balduzzi and Ghifary, 2016; Miao et al., 2016; Zoph and Le, 2017; Lee et al., 2017; Lei et al., 2017a; Vaswani et al., 2017; Gehring et al., 2017, *inter alia*). Departing from the above approaches, this work derives RNN architectures drawing inspiration from WFSAs.

Another line of work studied the connections between WFSAs and RNNs in terms of modeling capacity, both empirically (Kolen, 1993; Giles et al., 1992; Weiss et al., 2018, *inter alia*) and theoretically (Cleeremans et al., 1989; Visser et al., 2001; Chen et al., 2018, *inter alia*).

8 Conclusion

We presented *rational recurrences*, a new construction to study the recurrent updates in RNNs, drawing inspiration from WFSAs. We showed that rational recurrences are in frequent use by several recently proposed recurrent neural architectures, providing new understanding of them. Based on such connections, we discussed approaches to deriving novel neural architectures from WFSAs. Our empirical results demonstrate the potential of doing so. We publicly release our implementation at `https://github.com/Noahs-ARK/rational-recurrences`.

Abstract

Many efforts have been made to facilitate natural language processing tasks with pre-trained language models (LMs), and brought significant improvements to various applications. To fully leverage the nearly unlimited corpora and capture linguistic information of multifarious levels, large-size LMs are required; but for a specific task, only parts of these information are useful. Such large-sized LMs, even in the inference stage, may cause heavy computation workloads, making them too time-consuming for large-scale applications. Here we propose to compress bulky LMs while preserving useful information with regard to a specific task. As different layers of the model keep different information, we develop a *layer selection* method for model pruning using sparsity-inducing regularization. By introducing the dense connectivity, we can detach any layer without affecting others, and stretch shallow and wide LMs to be *deep* and *narrow*. In model training, LMs are learned with *layer-wise dropouts* for better robustness. Experiments on two benchmark datasets demonstrate the effectiveness of our method.

1 Introduction

Benefited from the recent advances in neural networks (NNs) and the access to nearly unlimited corpora, neural language models are able to achieve a good perplexity score and generate high-quality sentences. These LMs automatically capture abundant linguistic information and patterns from large text corpora, and can be applied to facilitate a wide range of NLP applications (Rei, 2017; Liu et al., 2018; Peters et al., 2018).

Recently, efforts have been made on learning contextualized representations with pre-trained language models (LMs) (Peters et al., 2018). These pre-trained layers brought significant improvements to various NLP benchmarks, yielding up to 30% relative error reductions. However, due to high variability of language, gigantic NNs (e.g., LSTMs with 8,192 hidden states) are preferred to construct informative LMs and extract multifarious linguistic information (Peters et al., 2017). Even though these models can be integrated without retraining (using their forward pass only), they still result in heavy computation workloads during inference stage, making them prohibitive for real-world applications.

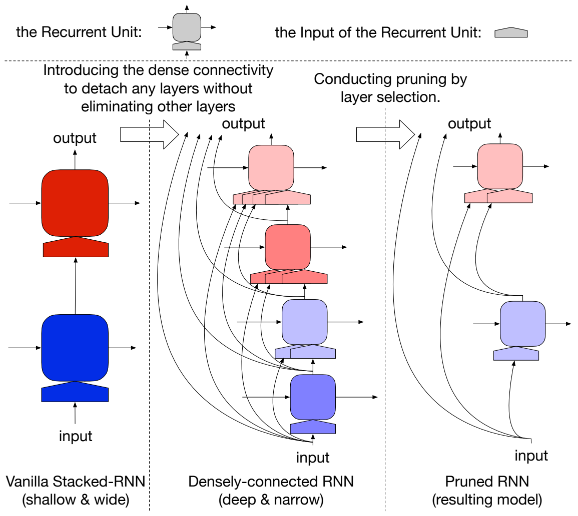

Figure 1: Leverage the dense connectivity to compress models via layer selection, and replace wide and shallow RNNs with deep and narrow ones.

In this paper, we aim to compress LMs for the end task in a plug-in-and-play manner. Typically, NN compression methods require the retraining of the whole model (Mellempudi et al., 2017). However, neural language models are usually composed of RNNs, and their backpropagations require significantly more RAM than their inference. It would become even more cumbersome when the target task equips the coupled LMs to capture information in both directions. Therefore, these methods do not fit our scenario very

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1215–1225
Brussels, Belgium, October 31 - November 4, 2018. ©2018 Association for Computational Linguistics

well. Accordingly, we try to compress LMs while *avoiding costly retraining*.

Intuitively, layers of different depths would capture linguistic information of different levels. Meanwhile, since LMs are trained in a task-agnostic manner, not all layers and their extracted information are relevant to the end task. Hence, we propose to compress the model by layer selection, which retains useful layers for the target task and prunes irrelevant ones. However, for the widely-used stacked-LSTM, directly pruning any layers will eliminate all subsequent ones. To overcome this challenge, we introduce the dense connectivity. As shown in Fig. 1, it allows us to detach any layers while keeping all remaining ones, thus creating the basis to avoid retraining. Moreover, such connectivity can stretch shallow and wide LMs to be deep and narrow (Huang et al., 2017), and enable a more fine-grained layer selection.

Furthermore, we try to retain the effectiveness of the pruned model. Specifically, we modify the L_1 regularization for encouraging the selection weights to be not only sparse but binary, which protects the retained layer connections from shrinkage. Besides, we design a layer-wise dropout to make LMs more robust and better prepared for the layer selection.

We refer to our model as LD-Net, since the *layer selection* and the *dense connectivity* form the basis of our pruning methods. For evaluation, we apply LD-Net on two sequence labeling benchmark datasets, and demonstrated the effectiveness of the proposed method. In the CoNLL03 Named Entity Recognition (NER) task, the F_1 score increases from 90.78±0.24% to 91.86±0.15% by integrating the unpruned LMs. Meanwhile, after pruning over 90% calculation workloads from the best performing model[1] (92.03%), the resulting model still yields 91.84±0.14%. Our implementations and pre-trained models would be released for futher study[2].

2 LD-Net

Given a input sequence of T word-level tokens, $\{x_1, x_2, \cdots, x_T\}$, we use $\mathbf{x}_t$ to denote the embedding of x_t. For a L-layers NN, we mark the input and output of the l^{th} layer at the t^{th} time stamp as $\mathbf{x}_{l,t}$ and $\mathbf{h}_{l,t}$.

2.1 RNN and Dense Connectivity

We represent one RNN layer as a function:

$$\mathbf{h}_{l,t} = F_l(\mathbf{x}_{l,t}, \mathbf{h}_{l,t-1}) \tag{1}$$

where F_l is the recurrent unit of l^{th} layer, it could be any RNNs variants, and the vanilla LSTMs is used in our experiments.

As deeper NNs usually have more representation power, RNN layers are often stacked together to form the final model by setting $\mathbf{x}_{l,t} = \mathbf{h}_{l-1,t}$. These vanilla stacked-RNN models, however, suffer from problems like the vanishing gradient, and it's hard to train very deep models.

Recently, the dense connectivity and residual connectivity have been proposed to handle these problems (He et al., 2016; Huang et al., 2017). Specifically, dense connectivity refers to adding direct connections from any layer to all its subsequent layers. As illustrated in Figure 1, the input of l^{th} layer is composed of the original input and the output of all preceding layers as follows.

$$\mathbf{x}_{l,t} = [\mathbf{x}_t, \mathbf{h}_{1,t}, \cdots, \mathbf{h}_{l-1,t}]$$

Similarly, the final output of the L-layer RNN is $\mathbf{h}_t = [\mathbf{x}_t, \mathbf{h}_{1,t}, \cdots, \mathbf{h}_{L,t}]$. With dense connectivity, we can detach any single layer without eliminating its subsequent layers (as in Fig. 1). Also, existing practices in computer vision demonstrate that such connectivities can lead to deep and narrow NNs and distribute parameters into different layers. Moreover, different layers in LMs usually capture linguistic information of different levels. Hence, we can compress LMs for a specific task by pruning unrelated or unimportant layers.

2.2 Language Modeling

Language modeling aims to describe the sequence generation. Normally, the generation probability of the sequence $\{x_1, \cdots, x_T\}$ is defined in a "forward" manner:

$$p(x_1, \cdots, x_T) = \prod_{t=1}^{T} p(x_t|x_1, \cdots, x_{t-1}) \tag{2}$$

Where $p(x_t|x_1, \cdots, x_{t-1})$ is computed based on the output of RNN, $\mathbf{h}_t$. Due to the dense connectivity, $\mathbf{h}_t$ is composed of outputs from different layers, which are designed to capture linguistic information of different levels. Similar to the bottleneck layers employed in the DenseNet (Huang et al., 2017), we add additional layers to unify such

---

[1] Based on their performance on the development sets

[2] `https://github.com/LiyuanLucasLiu/LD-Net`.

information. Accordingly, we add an projection layer with the ReLU activation function:

$$\mathbf{h}_t^* = \mathrm{ReLU}(W_{proj} \cdot \mathbf{h}_t + \mathbf{b}_{proj}) \tag{3}$$

Based on $\mathbf{h}_t^*$, it's intuitive to calculate $p(x_t|x_1, \cdots, x_{t-1})$ by the softmax function, i.e., $\mathrm{softmax}(W_{out} \cdot \mathbf{h}_t^* + \mathbf{b})$.

Since the training of language models needs nothing but the raw text, it has almost unlimited corpora. However, conducting training on extensive corpora results in a huge dictionary, and makes calculating the vanilla softmax intractable. Several techniques have been proposed to handle this problem, including adaptive softmax (Grave et al., 2017), slim word embedding (Li et al., 2018), the sampled softmax and the noise contrastive estimation (Józefowicz et al., 2016). Since the major focus of our paper does not lie in the language modeling task, we choose the adaptive softmax because of its practical efficiency when accelerated with GPUs.

2.3 Contextualized Representations

As pre-trained LMs can describe the text generation accurately, they can be utilized to extract information and construct features for other tasks. These features, referred as contextualized representations, have been demonstrated to be essentially useful (Peters et al., 2018). To capture information from both directions, we utilized not only forward LMs, but also backward LMs. Backward LMs are based on Eqn. 4 instead of Eqn. 2. Similar to forward LMs, backward LMs approach $p(x_t|x_{t+1}, \cdots, x_T)$ with NNs. For reference, the output of the RNN in backward LMs for x_t is recorded as $\mathbf{h}_t^r$.

$$p(x_1, \cdots, x_n) = \prod_{t=1}^{T} p(x_t|x_{t+1}, \cdots, x_T) \tag{4}$$

Ideally, the final output of LMs (e.g., $\mathbf{h}_t^*$) would be the same as the representation of the target word (e.g., x_{t+1}); therefore, it may not contain much context information. Meanwhile, the output of the densely connected RNN (e.g., $\mathbf{h}_t$) includes outputs from every layer, thus summarizing all extracted features. Since the dimensions of $\mathbf{h}_t$ could be too large for the end task, we add a non-linear transformation to calculate the contextualized representation ($\mathbf{r}_t$):

$$\mathbf{r}_t = \mathrm{ReLU}(W_{cr} \cdot [\mathbf{h}_t, \mathbf{h}_t^r] + \mathbf{b}_{cr}) \tag{5}$$

Our proposed method bears the same intuition as the ELMo (Peters et al., 2018). ELMo is designed for the vanilla stacked-RNN, and tries to calculate a weighted average of different layers' outputs as the contextualized representation. Our method, benefited from the dense connectivity and its narrow structure, can directly combine the outputs of different layers by concatenation. It does not assume the outputs of different layers to be in the same vector space, thus having more potential for transferring the constructed token representations. More discussions are available in Sec. 4.

2.4 Layer Selection

Typical model compression methods require retraining or gradient calculation. For the coupled LMs, these methods require even more computation resources compared to the training of LMs, thus not fitting our scenario very well.

Benefited from the dense connectivity, we are able to train deep and narrow networks. Moreover, we can detach one of its layer without eliminating all subsequent layers (as in Fig. 1). Since different layers in NNs could capture different linguistic information, only a few of them would be relevant or useful for a specific task. As a result, we try to compress these models by the task-guided layer selection. For i-th layer, we introduce a binary mask $z_i \in \{0, 1\}$ and calculate $\mathbf{h}_{l,t}$ with Eqn. 6 instead of Eqn. 1.

$$\mathbf{h}_{l,t} = z_i \cdot F_l(\mathbf{x}_{l,t}, \mathbf{h}_{l,t-1}) \tag{6}$$

With this setting, we can conduct a layer selection by optimizing the regularized empirical risk:

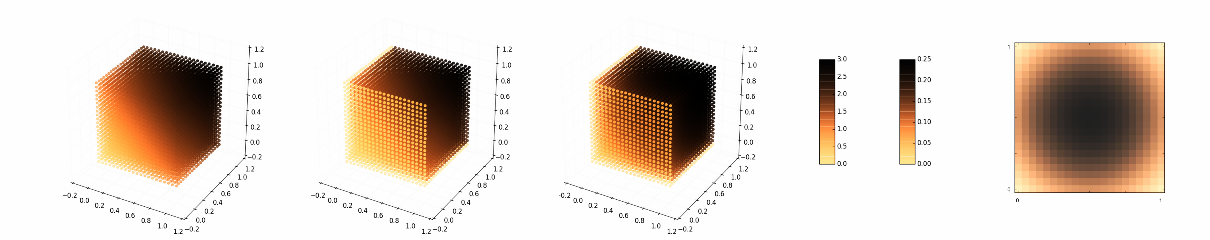
$$\min \mathcal{L} + \lambda_0 \cdot \mathcal{R} \tag{7}$$

where $\mathcal{L}$ is the empirical risk for the sequence labeling task and $\mathcal{R}$ is the sparse regularization.

The ideal choice for $\mathcal{R}$ would be the L_0 regularization of $\mathbf{z}$, i.e., $\mathcal{R}_0(\mathbf{z}) = |\mathbf{z}|_0$. However, it is not continuous and cannot be efficiently optimized. Hence, we relax z_i from binary to a real value (i.e., $0 \leq z_i \leq 1$) and replace $\mathcal{R}_0$ by:

$$\mathcal{R}_1 = |\mathbf{z}|_1$$

Despite the sparsity achieved by $\mathcal{R}_1$, it could hurt the performance by shifting all z_i far away from 1. Such shrinkage introduces additional noise in $\mathbf{h}_{l,t}$ and $\mathbf{x}_{l,t}$, which may result in ineffective pruned LMs. Since our goal is to conduct



$\mathcal{R}_1(\mathbf{z})$ $\mathcal{R}_2(\mathbf{z})$ $\mathcal{R}_3(\mathbf{z})$ $\mathcal{R}_3(\mathbf{z})$ with $z_3 = 0$

Figure 2: Penalty values of various $\mathcal{R}$ for $\mathbf{z}$ with three dimensions. λ_1 has been set to 2 for $\mathcal{R}_2$ and $\mathcal{R}_3$.

pruning without retraining, we further modify the L_1 regularization to achieve sparsity while alleviating its shrinkage effect. As the target of $\mathcal{R}$ is to make $\mathbf{z}$ sparse, it can be "turned-off" after achieving a satisfying sparsity. Therefore, we extend $\mathcal{R}_1$ to a margin-based regularization:

$$\mathcal{R}_2 = \delta(|\mathbf{z}|_0 > \lambda_1)|\mathbf{z}|_1$$

In addition, we also want to make up the relaxation made on $\mathbf{z}$, i.e., relaxing its values from binary to $[0, 1]$. Accordingly, we add the penalty $|\mathbf{z}(1 - \mathbf{z})|_1$ to encourage $\mathbf{z}$ to be binary (Murray and Ng, 2010) and modify $\mathcal{R}_2$ into $\mathcal{R}_3$:

$$\mathcal{R}_3 = \delta(|\mathbf{z}|_0 > \lambda_1)|\mathbf{z}|_1 + |\mathbf{z}(1 - \mathbf{z})|_1$$

To compare $\mathcal{R}_1$, $\mathcal{R}_2$ and $\mathcal{R}_3$, we visualize their penalty values in Fig. 2. The visualization is generated for a 3-dimensional $\mathbf{z}$ while the targeted sparsity, λ_1, is set to 2. Comparing to $\mathcal{R}_1$, we can observe that $\mathcal{R}_2$ enlarges the optimal point set from $\mathbf{0}$ to all $\mathbf{z}$ with a satisfying sparsity, thus avoiding the over-shrinkage. To better demonstrate the effect of $\mathcal{R}_3$, we further visualize its penalties after achieving a satisfying sparsity (w.l.o.g., assuming $z_3 = 0$). One can observe that it penalizes non-binary $\mathbf{z}$ and favors binary values.

2.5 Layer-wise Dropout

So far, we've customized the regularization term for the layer-wise pruning, which protects the retained connections among layers from shrinking. After that, we try to further retain the effectiveness of the compressed model. Specifically, we choose to prepare the LMs for the pruned inputs, thus making them more robust to pruning.

Accordingly, we conduct the training of LMs with a layer-wise dropout. As in Figure 3, a random part of layers in the LMs are randomly dropped during each batch. The outputs of the dropped layers will not be passed to their subsequent recurrent layers, but will be sent to the projection layer (Eqn. 3) for predicting the next word. In other words, this dropout is only applied to the input of recurrent layers, which aims to imitate the pruned input without totally removing any layers.

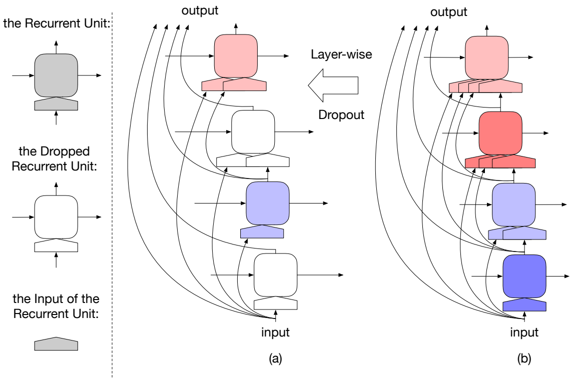


Figure 3: Layer-wise dropout conducted on a 4-layer densely connected RNN. (a) is the remained RNN. (b) is the original densely connected RNN.

3 Sequence Labeling

In this section, we will introduce our sequence labeling architecture, which is augmented with the contextualized representations.

3.1 Neural Architecture

Following the recent studies (Liu et al., 2018; Kuru et al., 2016), we construct the neural architecture as in Fig. 4. Given the input sequence $\{x_1, x_2, \cdots, x_T\}$, for t^{th} token (x_t), we assume its word embedding is $\mathbf{w}_t$, its label is y_t, and its character-level input is $\{c_{i,1}, c_{i,2}, \cdots, c_{i,\_}\}$, where $c_{i,\_}$ is the space character following x_t.

The character-level representations have become the required components for most of the state-of-the-art. Following the recent study (Liu et al., 2018), we employ LSTMs to take the character-level input in a context-aware manner, and mark its output for x_t as $\mathbf{c}_t$. Similar to the contextualized representation, $\mathbf{c}_t$ usually has more dimensions than $\mathbf{w}_t$. To integrate them together, we set the output dimension of Eqn. 5 as the dimension of $\mathbf{w}_t$, and project $\mathbf{c}_t$ to a new space with the same dimension number. We mark the projected character-level representation as $\mathbf{c}^*_t$.

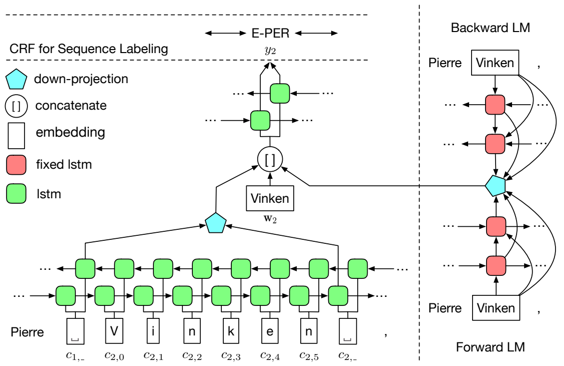

Figure 4: The proposed sequence labeling architecture with contextualized representations.

After projections, these vectors are concatenated as $\mathbf{v}_t = [\mathbf{c}_t^*; \mathbf{r}_t; \mathbf{w}_t], \forall i \in [1, T]$ and further fed into the word-level LSTMs. We refer to their output as $\mathbf{U} = \{\mathbf{u}_1, \cdots, \mathbf{u}_T\}$. To ensure the model to predict valid label sequences, we append a first-order conditional random field (CRF) layer to the model (Lample et al., 2016). Specifically, the model defines the generation probability of $\mathbf{y} = \{y_1, \cdots, y_T\}$ as

$$p(\mathbf{y}|\mathbf{U}) = \frac{\prod_{t=1}^{T} \phi(y_{t-1}, y_t, \mathbf{u}_t)}{\sum_{\hat{\mathbf{y}} \in \mathbf{Y}(\mathbf{U})} \prod_{t=1}^{T} \phi(\hat{y}_{t-1}, \hat{y}_t, \mathbf{u}_t)} \quad (8)$$

where $\hat{\mathbf{y}} = \{\hat{y}_1, \ldots, \hat{y}_T\}$ is a generic label sequence, $\mathbf{Y}(\mathbf{U})$ is the set of all generic label sequences for $\mathbf{U}$ and $\phi(y_{t-1}, y_t, \mathbf{u}_t)$ is the potential function. In our model, $\phi(y_{t-1}, y_t, \mathbf{u}_t)$ is defined as $\exp(W_{y_t}\mathbf{u}_t + b_{y_{t-1},y_t})$, where W_{y_t} and b_{y_{t-1},y_t} are the weight and bias parameters.

3.2 Model Training and Inference

We use the following negative log-likelihood as the empirical risk.

$$\mathcal{L} = -\sum_{\mathbf{U}} \log p(\mathbf{y}|\mathbf{U}) \quad (9)$$

For testing or decoding, we want to find the optimal sequence $\mathbf{y}^*$ that maximizes the likelihood.

$$\mathbf{y}^* = \underset{\mathbf{y} \in \mathbf{Y}(\mathbf{U})}{\text{argmax}}\ p(\mathbf{y}|\mathbf{U}) \quad (10)$$

Although the denominator of Eq. 8 is complicated, we can calculate Eqs. 9 and 10 efficiently by the Viterbi algorithm.

For optimization, we decompose it into two steps, i.e., model training and model pruning.

Model training. We set λ_0 to 0 and optimize the empirical risk without any regularization, i.e., $\min \mathcal{L}$. In this step, we conduct optimization with the stochastic gradient descent with momentum. Following (Peters et al., 2018), dropout would be added to both the coupled LMs and the sequence labeling model.

Model pruning. We conduct the pruning based on the checkpoint which has the best performance on the development set during the model training. We set λ_0 to non-zero values and optimize $\min \mathcal{L} + \lambda_0 \mathcal{R}_3$ by the projected gradient descent with momentum. Any layer i with $z_i = 0$ would be deleted in the final model to complete the pruning. To get a better stability, dropout is only added to the sequence labeling model.

4 Experiments

We will first discuss the capability of the LD-Net as language models, then explore the effectiveness of its contextualized representations.

4.1 Language Modeling

For comparison, we conducted experiments on the one billion word benchmark dataset (Chelba et al., 2013) with both LD-Net (with 1,600 dimensional projection) and the vanilla stacked-LSTM. Both kinds of models use word embedding (random initialized) of 300 dimension as input and use the adaptive softmax (with default setting) as an approximation of the full softmax. Additionally, as preprocessing, we replace all tokens occurring equal or less than 3 times with as UNK, which shrinks the dictionary from 0.79M to 0.64M.

The optimization is performed by the Adam algorithm (Kingma and Ba, 2014), the gradient is clipped at 5.0 and the learning rate is set to start from 0.001. The layer-wise dropout ratio is set to 0.5, the RNNs are unrolled for 20 steps without resetting the LSTM states, and the batch size is set to 128. Their performances are summarized in Table 1, together with several LMs used in our sequence labeling baselines. For models without official reported parameter numbers, we estimate their values (marked with†) by assuming they adopted the vanilla LSTM. Note that, for models 3, 5, 6, 7, 8, and 9, PPL refers to the averaged perplexity of the forward and the backward LMs.

We can observe that, for those models taking word embedding as the input, embedding composes the vast majority of model parameters. However, embedding can be embodied as a "sparse" layer which is computationally efficient. Instead, the intense calculations are conducted in

Network	Ind. #	Hid. #	Layer #	Param.# ($\cdot 10^7$)		PPL
				RNN	Others	
8192-1024 (Józefowicz et al., 2016)	1	8192	2	15.1$^\sharp$	163$^\sharp$	30.6
CNN-8192-1024 (Józefowicz et al., 2016)	2	8192	2	15.1$^\sharp$	89$^\sharp$	30.0
CNN-4096-512 (Peters et al., 2018)	3	4096	2	3.8$^\sharp$	40.6$^\sharp$	39.7
2048-512 (Peters et al., 2017)	4	2048	1	0.9$^\sharp$	40.6$^\sharp$	47.50
2048-Adaptive (Grave et al., 2017)	5	2048	2	5.2†	26.5†	39.8
vanilla LSTM	6	2048	2	5.3†	25.6†	40.27
	7	1600	2	3.2†	24.2†	48.85
LD-Net without Layer-wise Dropout	8	300	10	2.3†	24.2†	45.14
LD-Net with Layer-wise Dropout	9	300	10	2.3†	24.2†	50.06

Table 1: Performance comparison of language models. Models marked with† adopted adaptive softmax and the vanilla LSTMs, which has less softmax parameters. Models marked with$^\sharp$ employed sampled softmax LSTMs w. projection, which results in less RNN parameters w.r.t. the size of hidden states.

RNN layers and softmax layer for language modeling, or RNN layers for contextualized representations. At the same time, comparing the model 8192-1024 and CNN-8192-1024, their only difference is the input method. Instead of taking word embedding as the input, CNN-8192-1024 utilizes CNN to compose word representation from the character-level input. Despite the greatly reduced parameter number, the perplexity of the resulting models remains almost unchanged. Since replacing embedding layer with CNN would make the training slower, we only conduct experiments with models taking word embedding as the input.

Comparing LD-Net with other baselines, we think it achieves satisfactory performance with regard to the size of hidden states. It demonstrates the LD-Net's capability of capturing the underlying structure of natural language. Meanwhile, we find that the layer-wise dropout makes it harder to train LD-Net and its resulting model achieves less competitive results. However, as would be discussed in the next section, layer-wise dropout allows the resulting model to generate better contextualized representations and be more robust to pruning, even with a higher perplexity.

4.2 Sequence Labeling

Following TagLM (Peters et al., 2017), we evaluate our methods in two benchmark datasets, the CoNLL03 NER task (Tjong Kim Sang and De Meulder, 2003) and the CoNLL00 Chunking task (Tjong Kim Sang and Buchholz, 2000).

CoNLL03 NER has four entity types and includes the standard training, development and test sets.

CoNLL00 chunking defines eleven syntactic chunk types (e.g., `NP` and `VP`) in addition to `Other`. Since it only includes training and test sets, we sampled 1000 sentences from training set as a held-out development set (Peters et al., 2017).

In both cases, we use the BIOES labeling scheme (Ratinov and Roth, 2009) and use the micro-averaged F_1 as the evaluation metric. Based on the analysis conducted in the development set, we set $\lambda_0 = 0.05$ for the NER task, and $\lambda_0 = 0.5$ for the Chunking task. As discussed before, we conduct optimization with the stochastic gradient descent with momentum. We set the batch size, the momentum, and the learning rate to 10, 0.9, and $\eta_t = \frac{\eta_0}{1+\rho t}$ respectively. Here, $\eta_0 = 0.015$ is the initial learning rate and $\rho = 0.05$ is the decay ratio. Dropout is applied in our model, and its ratio is set to 0.5. For a better stability, we use gradient clipping of 5.0. Furthermore, we employ the early stopping in the development set and report averaged score across five different runs.

Regarding the network structure, we use the 30-dimension character-level embedding. Both character-level and word-level RNNs are set to one-layer LSTMs with 150-dimension hidden states in each direction. The GloVe 100-dimension pre-trained word embedding[3] is used as the initialization of word embedding $\mathbf{w}_t$, and will be fine-tuned during the training. The layer selection variables z_i are initialized as 1, remained unchanged

during the model training and only be updated during the model pruning. All other variables are randomly initialized (Glorot and Bengio, 2010).

Compared methods. The first baseline, referred as NoLM, is our sequence labeling model without the contextualized representations, i.e., calculating $\mathbf{v}_t$ as $[\mathbf{c}_t^*; \mathbf{w}_t]$ instead of $[\mathbf{c}_t^*; \mathbf{r}_t; \mathbf{w}_t]$. Besides, ELMo (Peters et al., 2018) is the major baseline. To make comparison more fair, we implemented the ELMo model and use it to calculate the $\mathbf{r}_t$ in Eqn. 5 instead of $[\mathbf{h}_t, \mathbf{h}_t^r]$. Results of re-implemented models are referred with R-ELMo (λ is set to the recommended value, 0.1) and the results reported in its original paper are referred with O-ELMo. Additionally, since TagLM (Peters et al., 2017) with one-layer NNs can be viewed as a special case of ELMo, we also include its results.

Sequence labeling results. Table 2 and 3 summarizes the results of LD-Net and baselines. Besides the F_1 score and averaged perplexity, we also estimate FLOPs (i.e., the number of floating-point multiplication-adds) for the efficiency evaluation. Since our model takes both word-level and character-level inputs, we estimated the FLOPs value for a word-level input with 4.39 character-level inputs, while 4.39 is the averaged length of words in the CoNLL03 dataset.

Before the model pruning, LD-Net achieves a 96.05±0.08 F_1 score in the CoNLL00 Chunking task, yielding nearly 30% error reductions over the NoLM baseline. Also, it scores 91.86±0.15 F_1 in the CoNLL03 NER task with over 10% error reductions. Similar to the language modeling, we observe that the most complicated models achieve the best perplexity and provide the most improvements in the target task. Still, considering the number of model parameters and the resulting perplexity, our model demonstrates its effectiveness in generating contextualized representations. For example, comparing to our methods, R-ELMo (7) leverages LMs with the similar perplexity and parameter number, but cannot get the same improvements with our method on both datasets.

Network (LMs Ind.#)	Avg. ppl	#FLOPs $(\cdot 10^6)$	F_1 score (avg±std)
NoLM (/)	/	3	90.78±0.24

Table 3: Performance comparison in the CoNLL03 NER task. Models marked with† employed LSTMs with projection, which is more efficient than the vanilla LSTMs. LD-Net maked with * are trained without pruning (layer selection).

Actually, contextualized representations have strong connections with the skip-thought vectors (Kiros et al., 2015). Skip-thought models try to embed sentences and are trained by predicting the previous and afterwards sentences. Similarly, LMs encode a specific context as the hidden states of RNNs, and use them to predict future contexts. Specifically, we recognize the cell states of LSTMs are more like to be the sentence embedding (Radford et al., 2017), since they are only passed to the next time stamps. At the same time, because the hidden states would be passed to other layers, we think they are more like to be the token representations capturing necessary signals for predicting the next word or updating context representations[4]. Hence, LD-Net should be more

---

[4] We tried to combine the cell states with the hidden states to construct the contextualized representations by concatenation or weighted average, but failed to get better performance.

Network (LMs Ind.#)	FLOPs	Batch size	Peak RAM	Time (s)	Speed	
					10^3words/s	10^3sents/s
R-ELMo (6)	108	200	8Gb	32.88	22	0.4
LD-Net (9, origin)	51	80	8Gb	25.68	26	0.5
LD-Net (9, pruned)	5	80	4Gb	6.90	98	2.0
		500	8Gb	4.86 (**5X**)	166 (**6X**)	2.9 (**5X**)

Table 4: Speed comparison in the CoNLL03 NER task. We can observe that LD-Net (9, pruned) achieved about 5 times speed up on the wall-clock time over LD-Net (9, origin).

effective then ELMo, as concatenating could preserve all extracted signals while weighted average might cause information loss.

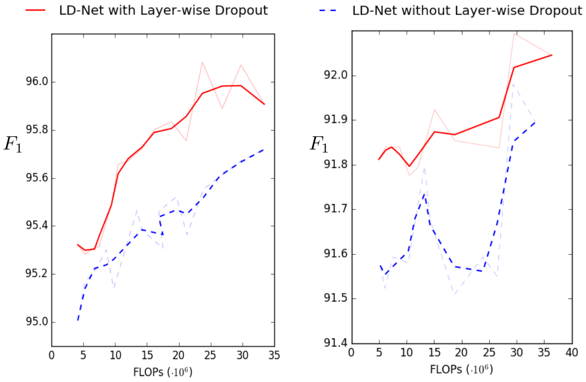
Although the layer-wise dropout makes the model harder to train, their resulting LMs generate better contextualized representations, even without the same perplexity. Also, as discussed in (Peters et al., 2018, 2017), the performance of the contextualized representation can be further improved by training larger models or using the CNN to represent words.

For the pruning, we started from the model with the best performance on the development set (referred with "origin"), and refer the performances of pruned models with "pruned" in Table 2 and 3. Essentially, we can observe the pruned models get rid of the vast majority of calculation while still retaining a significant improvement. We will discuss more on the pruned models in Sec. 4.4.

4.3 Speed Up Measurements

We use FLOPs for measuring the inference efficiency as it reflects the time complexity (Han et al., 2015), and thus is independent of specific implementations. For models with the same structure, improvements in FLOPs would result in monotonically decreasing inference time. However, it may not reflect the actual efficiency of models due to the model differences in parallelism. Accordingly, we also tested wall-clock speeds of our implementations.

Our implementations are based on the PyTorch 0.3.1[5], and all experiments are conducted on the CoNLL03 dataset with the Nvidia GTX 1080 GPU. Specifically, due to the limited size of CoNLL03 test set, we measure such speeds on the training set. As in Table 4, we can observe that, the pruned model achieved about 5 times speed up. Although there is still a large margin between the actual speed-up and the FLOPs speed-up, we think the resulting decode speed (166K words/s) is sufficient for most real-world applications.



(a) ConNLL00 Chunking

(b) ConNLL03 NER

Figure 5: The performance of pruned models in two tasks w.r.t. their efficiency (FLOPs).

4.4 Case Studies

Effect of the pruning ratio. To explore the effect of the pruning ratio, we adjust λ_1 and visualize the performance of pruned models v.s. their FLOPs # in Fig 5. We can observe that LD-Net outperforms its variants and demonstrates its effectiveness.

As the pruning ratio becoming larger, we can observe the performance of LD-Net first increases a little, then starts dropping. Besides, in the CoNLL03 NER task, LMs can be pruned to a relatively small size without much loss of efficiency. As in Table 3, we can observe that, after pruning over 90% calculations, the error of the resulting model only increases about 2%, yielding a competitive performance. As for the CoNLL00 Chunking task, the performance of LD-Net decays in a faster rate than that in the NER task. For example, after pruning over 80% calculations, the error of the resulting model increases about 13%. Considering the fact that this corpus is only half the size of the CoNLL03 NER dataset, we can expect the resulting models have more dependencies on the LMs. Still, the pruned model achieves a 25% error reduction over the NoLM baseline.

We think it implies that ELMo works as token representations instead of sentence representations

[5] `http://pytorch.org/`

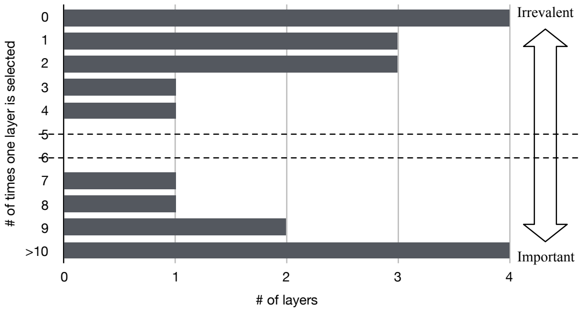


Figure 6: The performance of pruned models in two tasks w.r.t. their efficiency (FLOPs).

Layer selection pattern. We further studied the layer selection patterns. Specifically, we use the same setting of LD-Net (9) in Table 3, conduct model pruning using for 50 times, and summarize the statics in Figure 6. We can observe that network layers formulate two clear clusters, one is likely to be preserved during the selection, and the other is likely to be pruned. This is consistent with our intuition that some layers are more important than others and the layer selection algorithm would pick up layers meaningfully.

However, there is some randomness in the selection result. We conjugate that large networks trained with dropout can be viewed as a ensemble of small sub-networks (Hara et al., 2016), also there would be several sub-networks having the similar function. Accordingly, we think the randomness mainly comes from such redundancy.

Effectiveness of model pruning. Zhu and Gupta (2017) observed pruned large models consistently outperform small models on various tasks (including LM). These observations are consistent with our experiments. For example, LD-Net achieves 91.84 after pruning on the CoNLL03 dataset. It outperforms TagLM (4) and R-ELMo (7), whose performances are 91.62 and 91.54. Besides, we trained small LMs of the same size as the pruned LMs (1-layer densely connected LSTMs). Its perplexity is 69 and its performance on the CoNLL03 dataset is 91.55 ± 0.19.

5 Related Work

Sequence labeling. Linguistic sequence labeling is one of the fundamental tasks in NLP, encompassing various applications including POS tagging, chunking, and NER. Many attempts have been made to conduct end-to-end learning and build reliable models without handcrafted features (Chiu and Nichols, 2016; Lample et al., 2016; Ma and Hovy, 2016).

Language modeling. Language modeling is a core task in NLP. Many attempts have been paid to develop better neural language models (Zilly et al., 2017; Inan et al., 2016; Godin et al., 2017; Melis et al., 2017). Specifically, with extensive corpora, language models can be well trained to generate high-quality sentences from scratch (Józefowicz et al., 2016; Grave et al., 2017; Li et al., 2018; Shazeer et al., 2017). Meanwhile, initial attempts have been made to improve the performance of other tasks with these methods. Some methods treat the language modeling as an additional supervision, and conduct co-training for knowledge transfer (Dai and Le, 2015; Liu et al., 2018; Rei, 2017). Others, including this paper, aim to construct additional features (referred as contextualized representations) with the pre-trained language models (Peters et al., 2017, 2018).

Neural Network Acceleration. There are mainly three kinds of NN acceleration methods, i.e., prune network into smaller sizes (Han et al., 2015; Wen et al., 2016), converting float operation into customized low precision arithmetic (Hubara et al., 2018; Courbariaux et al., 2016), and using shallower networks to mimic the output of deeper ones (Hinton et al., 2015; Romero et al., 2014). However, most of them require costly retraining.

6 Conclusion

Here, we proposed LD-Net, a novel framework for efficient contextualized representation. As demonstrated on two benchmarks, it can conduct the layer-wise pruning for a specific task. Moreover, it requires neither the gradient oracle of LMs nor the costly retraining. In the future, we plan to apply LD-Net to other applications.

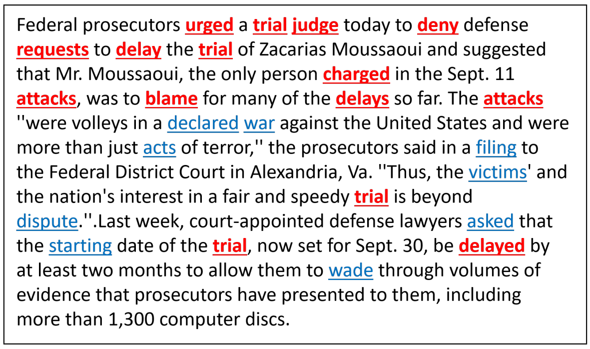
Abstract

Identifying the salience (i.e. importance) of discourse units is an important task in language understanding. While events play important roles in text documents, little research exists on analyzing their saliency status. This paper empirically studies the *Event Salience* task and proposes two salience detection models based on content similarities and discourse relations. The first is a feature based salience model that incorporates similarities among discourse units. The second is a neural model that captures more complex relations between discourse units. Tested on our new large-scale event salience corpus, both methods significantly outperform the strong frequency baseline, while our neural model further improves the feature based one by a large margin. Our analyses demonstrate that our neural model captures interesting connections between salience and discourse unit relations (e.g., scripts and frame structures).

1 Introduction

Automatic extraction of prominent information from text has always been a core problem in language research. While traditional methods mostly concentrate on the word level, researchers start to analyze higher-level discourse units in text, such as entities (Dunietz and Gillick, 2014) and events (Choubey et al., 2018).

Events are important discourse units that form the backbone of our communication. They play various roles in documents. Some are more central in discourse: connecting other entities and events, or providing key information of a story. Others are less relevant, but not easily identifiable by NLP systems. Hence it is important to be able to quantify the "importance" of events. For example, Figure 1 is a news excerpt describing a debate around a jurisdiction process: "*trial*" is central as the main discussing topic, while "*war*" is not.



Federal prosecutors **urged** a **trial** **judge** today to **deny** defense **requests** to **delay** the **trial** of Zacarias Moussaoui and suggested that Mr. Moussaoui, the only person **charged** in the Sept. 11 **attacks**, was to **blame** for many of the **delays** so far. The **attacks** ''were volleys in a declared war against the United States and were more than just acts of terror,'' the prosecutors said in a filing to the Federal District Court in Alexandria, Va. ''Thus, the victims' and the nation's interest in a fair and speedy **trial** is beyond dispute.''.Last week, court-appointed defense lawyers asked that the starting date of the **trial**, now set for Sept. 30, be **delayed** by at least two months to allow them to wade through volumes of evidence that prosecutors have presented to them, including more than 1,300 computer discs.

Figure 1: Examples annotations. Underlying words are annotated event triggers; the red bold ones are annotated as salient.

Researchers are aware of the need to identify central events in applications like detecting salient relations (Zhang et al., 2015), and identifying climax in storyline (Vossen and Caselli, 2015). Generally, the salience of discourse units is important for language understanding tasks, such as document analysis (Barzilay and Lapata, 2008), information retrieval (Xiong et al., 2018), and semantic role labeling (Cheng and Erk, 2018). Thus, proper models for finding important events are desired.

In this work, we study the task of **event salience detection**, to find events that are most relevant to the main content of documents. To build a salience detection model, one core observation is that salient discourse units are forming discourse relations. In Figure 1, the "*trial*" event is connected to many other events: "*charge*" is pressed before "*trial*"; "*trial*" is being "*delayed*".

We present two salience detection systems based on the observations. First is a feature based learning to rank model. Beyond basic features like frequency and discourse location, we design features using cosine similarities among events and entities, to estimate the *content organization* (Grimes, 1975): how lexical meaning of elements relates to each other. Similarities from within-sentence or across the whole document are used to capture

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1226–1236
Brussels, Belgium, October 31 - November 4, 2018.

interactions on both local and global aspects (§4). The model significantly outperforms a strong "Frequency" baseline in our experiments.

However, there are other discourse relations beyond lexical similarity. Figure 1 showcases some: the script relation (Schank and Abelson, 1977)[1] between "*charge*" and "*trial*", and the frame relation (Baker et al., 1998) between "*attacks*" and "*trial*" ("*attacks*" fills the "charges" role of "*trial*"). Since it is unclear which ones contribute more to salience, we design a Kernel based Centrality Estimation (`KCE`) model (§5) to capture salient specific interactions between discourse units automatically.

In `KCE`, discourse units are projected to embeddings, which are trained end-to-end towards the salience task to capture rich semantic information. A set of soft-count kernels are trained to weigh salient specific latent relations between discourse units. With the capacity to model richer relations, `KCE` outperforms the feature-based model by a large margin (§7.1). Our analysis shows that `KCE` is exploiting several relations between discourse units: including script and frames (Table 5). To further understand the nature of `KCE`, we conduct an *intrusion test* (§6.2), which requires a model to identify events from another document. The test shows salient events form tightly related groups with relations captured by `KCE`.

The notion of salience is subjective and may vary from person to person. We follow the empirical approaches used in entity salience research (Dunietz and Gillick, 2014). We consider the *summarization test*: an event is considered salient if a summary written by a human is likely to include it, since events about the main content are more likely to appear in a summary. This approach allows us to create a large-scale corpus (§3).

In this paper, we make three main contributions. First, we present two event salience detection systems, which capture rich relations among discourse units. Second, we observe interesting connections between salience and various discourse relations (§7.1 and Table 5), implying potential research on these areas. Finally, we construct a large scale event salience corpus, providing a testbed for future research. Our code, dataset and models are publicly available[2].

2 Related Work

Events have been studied on many aspects due to their importance in language. To name a few: event detection (Li et al., 2013; Nguyen and Grishman, 2015; Peng et al., 2016), coreference (Liu et al., 2014; Lu and Ng, 2017), temporal analysis (Do et al., 2012; Chambers et al., 2014), sequencing (Araki et al., 2014), script induction (Chambers and Jurafsky, 2008; Balasubramanian et al., 2013; Rudinger et al., 2015; Pichotta and Mooney, 2016).

However, studies on event salience are premature. Some previous work attempts to approximate event salience with word frequency or discourse position (Vossen and Caselli, 2015; Zhang et al., 2015). Parallel to ours, Choubey et al. (2018) propose a task to find the most dominant event in news articles. They draw connections between event coreference and importance, on hundreds of closed-domain documents, using several oracle event attributes. In contrast, our proposed models are fully learned and applied on more general domains and at a larger scale. We also do not restrict to a single most important event per document.

There is a small but growing line of work on entity salience (Dunietz and Gillick, 2014; Dojchinovski et al., 2016; Xiong et al., 2018; Ponza et al., 2018). In this work, we study the case for events.

Text relations have been studied in tasks like text summarization, which mainly focused on cohesion (Halliday and Hasan, 1976). Grammatical cohesion methods make use of document level structures such as anaphora relations (Baldwin and Morton, 1998) and discourse parse trees (Marcu, 1999). Lexical cohesion based methods focus on repetitions and synonyms on the lexical level (Skorochod'ko, 1971; Morris and Hirst, 1991; Erkan and Radev, 2004). Though sharing similar intuitions, our proposed models are designed to learn richer semantic relations in the embedding space.

Comparing to the traditional summarization task, we focus on events, which are at a different granularity. Our experiments also unveil interesting phenomena among events and other discourse units.

3 The Event Salience Corpus

This section introduces our approach to construct a large-scale event salience corpus, including methods for finding event mentions and obtaining saliency labels. The studies are based on the Annotated New York Times corpus (Sandhaus, 2008), a newswire corpus with expert-written abstracts.

---

[1] Scripts are prototypical sequences of events: a *restaurant* script normally contains events like "order", "eat" and "pay".

[2] `https://github.com/hunterhector/EventSalience`

3.1 Automatic Corpus Creation

Event Mention Annotation: Despite many annotation attempts on events (Pustejovsky et al., 2002; Brown et al., 2017), automatic labeling of them in general domain remains an open problem. Most of the previous work follows empirical approaches. For example, Chambers and Jurafsky (2008) consider all verbs together with their subject and object as events. Do et al. (2011) additionally include nominal predicates, using the nominal form of verbs and lexical items under the *Event* frame in FrameNet (Baker et al., 1998).

There are two main challenges in labeling event mentions. First, we need to decide which lexical items are event triggers. Second, we have to disambiguate the word sense to correctly identify events. For example, the word "phone" can refer to an entity (a physical phone) or an event (a phone call event). We use FrameNet to solve these problems. We first use a FrameNet based parser: Semafor (Das and Smith, 2011), to find and disambiguate triggers into frame classes. We then use the FrameNet ontology to select event mentions.

Our frame based selection method follows the Vendler classes (Vendler, 1957), a four way classification of eventuality: *states*, *activities*, *accomplishments* and *achievements*. The last three classes involve state change, and are normally considered as events. Following this, we create an "event-evoking frame" list using the following procedure:

1. We keep frames that are subframes of *Event* and *Process* in the FrameNet ontology.
2. We discard frames that are subframes of state, entity and attribute frames, such as *Entity*, *Attributes*, *Locale*, etc.
3. We manually inspect frames that are not subframes of the above-mentioned ones (around 200) to keep event related ones (including subframes), such as *Arson*, *Delivery*, etc.

This gives us a total of 569 frames. We parse the documents with Semafor and consider predicates that trigger a frame in the list as candidates. We finish the process by removing the light verbs[3] and reporting events[4] from the candidates, similar to previous research (Recasens et al., 2013).

Salience Labeling: For all articles with a human written abstract (around 664,911) in the New York Times Annotated Corpus, we extract event mentions. We then label an event mention as salient if we can find its lemma in the corresponding abstract (Mitamura et al. (2015) showed that lemma matching is a strong baseline for event coreference.). For example, in Figure 1, event mentions in bold and red are found in the abstract, thus labeled as salient. Data split is detailed in Table 1 and §6.

	Train	Dev	Test
# Documents	526126	64000	63589
Avg. # Word	794.12	790.27	798.68
Avg. # Events	61.96	60.65	61.34
Avg. # Entities	197.63	196.95	198.40
Avg. # Salience	8.77	8.79	8.90

Table 1: Dataset Statistics.

3.2 Annotation Quality

While the automatic method enables us to create a dataset at scale, it is important to understand the quality of the dataset. For this purpose, we have conducted two small manual evaluation study.

Our lemma-based salience annotation method is based on the assumption that lemma matching being a strong detector for event coreference. In order to validate this assumption, one of the authors manually examined 10 documents and identified 82 coreferential event mentions pairs between the text body and the abstract. The automatic lemma rule identifies 72 such pairs: 64 of these matches human decision, producing a precision of 88.9% (64/72) and a recall of 78% (64/82). There are 18 coreferential pairs missed by the rule.

The next question is: *is an event really important if it is mentioned in the abstract?* Although prior work (Dunietz and Gillick, 2014) shows that the assumption to be valid for entities, we study the case for events. We asked two annotators to manually annotate 10 documents (around 300 events) using a 5-point Likert scale for salience. We compute the agreement score using Cohen's Kappa (Cohen, 1960). We find the task to be challenging for human: annotators don't agree well on the 5-point scale (Cohens Kappa = 0.29). However, if we collapse the scale to binary decisions, the Kappa between the annotators raises to 0.67. Further, the Kappa between each annotator and automatic labels are 0.49 and 0.42 respectively. These agreement scores are also close to those reported in the entity salience tasks (Dunietz and Gillick, 2014).

---

[3] Light verbs carry little semantic information: "appear", "be", "become", "do", "have", "seem", "do", "get", "give", "go", "have", "keep", "make", "put", "set", "take".

[4] Reporting verbs are normally associated with the narrator: "argue", "claim", "say", "suggest", "tell".

While errors exist in the automatic annotation process inevitably, we find the error rate to be reasonable for a large-scale dataset. Further, our study indicates the difficulties for human to rate on a finer scale of salience. We leave the investigation of continuous salience scores to future work.

4 Feature-Based Event Salience Model

This section presents the feature-based model, including the features and the learning process.

4.1 Features

Our features are summarized in Table 2.

Basic Discourse Features: We first use two basic features similar to Dunietz and Gillick (2014): *Frequency* and *Sentence Location*. *Frequency* is the lemma count of the mention's syntactic head word (Manning et al., 2014). *Sentence Location* is the sentence index of the mention, since the first few sentences are normally more important. These two features are often used to estimate salience (Barzilay and Lapata, 2008; Vossen and Caselli, 2015).

Content Features: We then design several lexical similarity features, to reflect Grimes' content relatedness (Grimes, 1975). In addition to events, the relations between events and entities are also important. For example, Figure 1 shows some related entities in the legal domain, such as "*prosecutors*" and "*court*". Ideally, they should help promote the salience status for event "*trial*".

Lexical relations can be found both within-sentence (local) or across sentence (global) (Halliday and Hasan, 1976). We compute the local part by averaging similarity scores from other units in the same sentence. The global part is computed by averaging similarity scores from other units in the document. All similarity scores are computed using cosine similarities on pre-trained embeddings (Mikolov et al., 2013).

These lead to 3 content features: *Event Voting*, the average similarity to other events in the document; *Entity Voting*, the average similarity to entities in the document; *Local Entity Voting*, the average similarity to entities in the same sentence. Local event voting is not used since a sentence often contains only 1 event.

4.2 Model

A Learning to Rank (LeToR) model (Liu, 2009) is used to combine the features. Let ev_i denote the ith event in a document d. Its salience score is computed as:

$$f(ev_i, d) = W_f \cdot F(ev_i, d) + b \qquad (1)$$

where $F(ev_i, d)$ is the features for ev_i in d (Table 2); W_f and b are the parameters to learn.

The model is trained with pairwise loss:

$$\sum_{ev^+, ev^- \in d} \max(0, 1 - f(ev^+, d) + f(ev^-, d)), \qquad (2)$$
$$\text{w.r.t. } y(ev^+, d) = +1 \ \& \ y(ev^-, d) = -1.$$

$$y(e_i, d) = \begin{cases} +1, & \text{if } e_i \text{ is a salient entity in } d, \\ -1, & \text{otherwise.} \end{cases}$$

where ev^+ and ev^- represent the salient and non-salient events; y is the gold standard function. Learning can be done by standard gradient methods.

5 Neural Event Salience Model

As discussed in §1, the salience of discourse units is reflected by rich relations beyond lexical similarities, for example, script ("*charge*" and "*trial*") and frame (a "*trial*" of "*attacks*"). The relations between these words are specific to the salience task, thus difficult to be captured by raw cosine scores that are optimized for word similarities. In this section, we present a neural model to exploit the embedding space more effectively, in order to capture relations for event salience estimation.

5.1 Kernel-based Centrality Estimation

Inspired by the kernel ranking model (Xiong et al., 2017), we propose Kernel-based Centrality Estimation (KCE), to find and weight semantic relations of interests, in order to better estimate salience.

Formally, given a document d, the set of annotated events $\mathbb{V} = \{ev_1, \ldots ev_i \ldots, ev_n\}$, KCE first embed an event into vector space: $ev_i \xrightarrow{Emb} \overrightarrow{ev_i}$. The embedding function is initialized with pre-trained embeddings. It then extract K features for each ev_i:

$$\Phi_K(ev_i, \mathbb{V}) = \{\phi_1(\overrightarrow{ev_i}, \mathbb{V}), \ldots, \phi_k(\overrightarrow{ev_i}, \mathbb{V}), \ldots, \phi_K(\overrightarrow{ev_i}, \mathbb{V})\}, \qquad (3)$$

$$\phi_k(\overrightarrow{ev_i}, \mathbb{V}) = \sum_{ev_j \in \mathbb{V}} \exp\left(-\frac{(\cos(\overrightarrow{ev_i}, \overrightarrow{ev_j}) - \mu_k)^2}{2\sigma_k^2}\right). \qquad (4)$$

Name	Description
`Frequency`	The frequency of the event lemma in document.
`Sentence Location`	The location of the first sentence that contains the event.
`Event Voting`	Average cosine similarity with other events in document.
`Entity Voting`	Average cosine similarity with other entities in document.
`Local Entity Voting`	Average cosine similarity with entities in the sentence.

Table 2: Event Salience Features.

$\phi_k(\overrightarrow{ev_i}, \mathbb{V})$ is the k-th Gaussian kernel with mean μ_k and variance σ_k^2. It models the interactions between events in its kernel range defined by μ_k and σ_k. $\Phi_K(ev_i, \mathbb{V})$ enforces multi-level interactions among events — relations that contribute similarly to salience are expected to be grouped into the same kernels. Such interactions greatly improve the capacity of the model with negligible increase in the number of parameters. Empirical evidences (Xiong et al., 2017) have shown that kernels in this form are effective to learn weights for task-specific term pairs.

The final salience score is computed as:

$$f(ev_i, d) = W_v \cdot \Phi_K(ev_i, \mathbb{V}) + b, \tag{5}$$

where W_v is learned to weight the contribution of the certain relations captured by each kernel.

We then use the exact same learning objective as in equation (2). The pairwise loss is first backpropagated through the network to update the kernel weights W_v, assigning higher weights to relevant regions. Then the kernels use the gradients to update the embeddings, in order to capture the meaningful discourse relations for salience.

Since the features and `KCE` capture different aspects, combining them may give superior performance. This can be done by combining the two vectors in the final linear layer:

$$f(ev_i, d) = W_v \cdot \Phi_K(ev_i, \mathbb{V}) + W_f \cdot F(ev_i, d) + b \tag{6}$$

5.2 Integrating Entities into KCE

`KCE` is also used to model the relations between events and entities. For example, in Figure 1, the entity "*court*" is a frame element of the event "*trial*"; "*United States*" is a frame element of the event "*war*". It is not clear which pair contributes more to salience. We again let `KCE` to learn it.

Formally, let $\mathbb{E}$ be the list of entities in the document, i.e. $\mathbb{E} = \{en_1, \dots, en_i, \dots, en_n\}$, where en_i is the ith entity in document d. `KCE` extracts the kernel features about entity-event relations as follows:

$$\begin{aligned}\Phi_K(ev_i, \mathbb{E}) = \{&\phi_1(\overrightarrow{ev_i}, \mathbb{E}), \dots, \\ &\phi_k(\overrightarrow{ev_i}, \mathbb{E}), \dots, \phi_K(\overrightarrow{ev_i}, \mathbb{E})\},\end{aligned} \tag{7}$$

$$\phi_k(\overrightarrow{ev_i}, \mathbb{E}) = \sum_{en_j \in \mathbb{E}} \exp\left(-\frac{\left(\cos(\overrightarrow{ev_i}, \overrightarrow{en_j}) - \mu_k\right)^2}{2\sigma_k^2}\right) \tag{8}$$

similarly, en_i is embedded by: $en_i \xrightarrow{Emb} \overrightarrow{en_i}$, which is initialized by pre-trained entity embeddings.

We reach the full `KCE` model by combining all the vectors using a linear layer:

$$\begin{aligned}f(ev_i, d) = &W_e \cdot \Phi_K(ev_i, \mathbb{E}) + W_v \cdot \Phi_K(ev_i, \mathbb{V}) \\ &+ W_f \cdot F(ev_i, d) + b\end{aligned} \tag{9}$$

The model is again trained by equation (2).

6 Experimental Methodology

This section describes our experiment settings.

6.1 Event Salience Detection

Dataset: We conduct our experiments on the salience corpus described in §3. Among the 664,911 articles with abstracts, we sample 10% of the data as the test set and then randomly leave out another 10% documents for development. Overall, there are 4359 distinct event lexical items, at a similar scale with previous work (Chambers and Jurafsky, 2008; Do et al., 2011). The corpus statistics are summarized in Table 1.

Input: The inputs to models are the documents and the extracted events. The models are required to rank the events from the most to least salience.

Baselines: Three methods from previous researches are used as baselines: *Frequency*, *Location* and *PageRank*. The first two are often used to simulate saliency (Barzilay and Lapata, 2008; Vossen and Caselli, 2015). The *Frequency* baseline ranks events based on the count of the headword lemma; the *Location* baseline ranks events using the order of their appearances in discourse. Ties are broken randomly.

Similar to entity salience ranking with PageRank scores (Xiong et al., 2018), our *PageRank* baseline runs PageRank on a fully connected graph whose nodes are the events in documents. The edges are weighted by the embedding similarities between event pairs. We conduct supervised PageRank on this graph, using the same pairwise loss setup as in `KCE`. We report the best performance obtained by linearly combining *Frequency* with the scores obtained after a one-step random walk.

Evaluation Metric: Since the importance of events is on a continuous scale, the boundary between "important" and "not important" is vague. Hence we evaluate it as a ranking problem. The metrics are the precision and recall value at 1, 5 and 10 respectively. It is adequate to stop at 10 since there are less than 9 salient events per document on average (Table 1). We also report Area Under Curve (AUC). Statistical significance values are tested by permutation (randomization) test with $p < 0.05$.

Implementation Details: We pre-trained word embeddings with 128 dimensions on the whole Annotated New York Times corpus using Word2Vec (Mikolov et al., 2013). Entities are extracted using the TagMe entity linking toolkit (Ferragina and Scaiella, 2010). Words or entities that appear only once in training are replaced with special "unknown" tokens.

The hyper-parameters of the `KCE` kernels follow previous literature (Xiong et al., 2017). There is one exact match kernel ($\mu = 1, \sigma = 1e^{-3}$) and ten soft-match kernels evenly distributed between $(-1, 1)$, i.e. $\mu \in \{-0.9, -0.7, \ldots, 0.9\}$, with the same $\sigma = 0.1$.

The parameters of the models are optimized by Adam (Kingma and Ba, 2015), with batch size 128. The vectors of entities are initialized by the pre-trained embeddings. Event embeddings are initialized by their headword embedding.

6.2 The Event Intrusion Test: A Study

`KCE` is designed to estimate salience by modeling relations between discourse units. To better understand its behavior, we design the following **event intrusion test**, following the word intrusion test used to assess topic model quality (Chang et al., 2009).

Event Intrusion Test: The test will present to a model a set of events, including: the **origins**, all events from one document; the **intruders**, some events from another document. Intuitively, if events inside a document are organized around the core content, a model capturing their relations well should easily identify the intruder(s).

Specifically, we take a bag of unordered events $\{O_1, O_2, \ldots, O_p\}$, from a document O, as the origins. We insert into it intruders, events drawn from another document, I: $\{I_1, I_2, \ldots, I_q\}$. We ask a model to rank the mixed event set $M = \{O_1, I_1, O_2, I_2, \ldots\}$. We expect a model to rank the intruders I_i below the origins O_i.

Intrusion Instances: From the development set, we randomly sample 15,000 origin and intruding document pairs. To simplify the analysis, we only take documents with at least 5 salient events. The intruder events, together with the entities in the same sentences, are added to the origin document.

Metrics: AUC is used to quantify ranking quality, where events in O are positive and events in I are negative. To observe the ranking among the salient origins, we compute a separate AUC score between the intruders and the salient origins, denoted as SA-AUC. In other words, SA-AUC is the AUC score on the list with non-salient origins removed.

Experiments Details: We take the full `KCE` model to compute salient scores for events in the mixed event set M, which are directly used for ranking. Frequency is recounted. All other features (Table 2) are set to 0 to emphasize the relational aspects,

We experiment with two settings: 1. adding only the salient intruders. 2. adding only the non-salient intruders. Under both settings, the intruders are added one by one, allowing us to observe the score change regarding the number of intruders added. For comparison, we add a *Frequency* baseline, that directly ranks events by the Frequency feature.

7 Evaluation Results

This section presents the evaluations and analyses.

7.1 Event Salience Performance

We summarize the main results in Table 3.

Baselines: *Frequency* is the best performing baseline. Its precision at 1 and 5 are higher than 40%. *PageRank* performs worse than *Frequency* on all

Method	P@01		P@05		P@10		AUC

Table 3: Event salience performance. (-E) and (-F) marks removing Entity information and Features from the full KCM model. The relative performance differences are computed against `Frequency`. W/T/L are the number of documents a method wins, ties, and loses compared to `Frequency`. † and ‡ mark the statistically significant improvements over `Frequency`†, `LeToR`‡ respectively.

Feature Groups	P@1	P@5	P@10	R@1	R@5	R@10	AUC
`Loc`	0.3548	0.3069	0.2497	0.0807	0.2671	0.3792	0.5226
`Frequency`	0.4536	0.4018	0.3440	0.0792	0.2846	0.4270	0.5732
+ `Loc`	0.4734	0.4097	0.3513	0.0835	0.2976	0.4436	0.6354
+ `Loc` + `Event`	0.4726	0.4101†	0.3516	0.0831	0.2969	0.4431	0.6365†
+ `Loc` + `Entity`	0.4739	0.4100	0.3518	0.0812	0.2955	0.4418	0.6374
+ `Loc` + `Entity` + `Event`	0.4739	0.4100	0.3518†	0.0832	0.2974	0.4452†	0.6374†
+ `Loc` + `Entity` + `Event` + `Local`	0.4754†	0.4100	0.3517†	0.0837	0.2981	0.4454†	0.6373†

Table 4: Feature Ablation Results. + sign indicates the additional features to `Frequency`. `Loc` is the sentence location feature. `Event` is the event voting feature. `Entity` is the entity voting feature. `Local` is the local entity voting feature. † marks the statistically significant improvements over + `Loc`.

the precision and recall metrics. *Location* performs the worst.

Feature Based: `LeToR` outperforms the baselines significantly on all metrics. Particularly, its P@1 value outperforms the *Frequency* baseline the most (4.64%), indicating a much better estimation on the most salient event. In terms of AUC, `LeToR` outperforms *Frequency* by a large margin (11.19% relative gain).

Feature Ablation: To understand the contribution of individual features, we conduct an ablation study of various feature settings in Table 4. We gradually add feature groups to the *Frequency* baseline. The combination of *Location* (sentence location) and *Frequency* almost sets the performance for the whole model. Adding each voting feature individually produces mixed results. However, adding all voting features improves all metrics. Though the margin is small, 4 of them are statistically significant over *Frequency*+*Location*.

Kernel Centrality Estimation: The `KCE` model further beats `LeToR` significantly on all metrics, by around 5% on AUC and precision values, and by around 10% on the recall values. Notably, the P@1 score is much higher, reaching 50%. The large relative gain on all the recall metrics and the high performance on precision show that `KCE` works really well on the top of the rank list.

Kernel Ablation: To understand the source of performance gain of `KCE`, we conduct an ablation study by removing its components: `-E` removes of entity kernels; `-EF` removes the entity kernels and the features. We observe a performance drop in both cases. Without entities and features, the model only using event information still performs similarly to *Frequency*. The drops are also a reflection of the small number of events (≈ 60 per document) comparing to entities (≈ 200 per document).

		Word2Vec	**KCE**
attack	kill	0.69	0.3
arrest	charge	0.53	0.3
USA (E)	war	0.46	0.3
911 attack (E)	attack	0.72	0.3
attack	trade	0.42	0.9
hotel (E)	travel	0.49	0.9
charge	murder	0.49	0.7
business (E)	increase	0.43	0.7
attack	walk	0.44	-0.3
people (E)	work	0.40	-0.3

Table 5: Similarities between event entity pairs. **Word2vec** shows the cosine similarity in pre-trained embeddings. **KCE** lists their closest kernel mean after training. (E) marks entities.

The study indicates that the relational signals and features contain different but both important information.

Discussion: The superior results of `KCE` demonstrate its effectiveness in predicting salience. So what additional information does it capture? We revisit the changes made by `KCE`: 1. it adjusts the embeddings during training. 2. it introduces weighted soft count kernels. However, the *PageRank* baseline also does embedding tuning but produces poor results, thus the second change should be crucial. We plot the learned kernel weights of `KCE` in Figure 2. Surprisingly, the salient decisions are not linearly related, nor even positively correlated to the weights. In fact, besides the "Exact Match" bin, the highest absolute weights actually appear at 0.3 and -0.3. This implies that embedding similarities do not directly imply salience, breaking some assumptions of the feature based model and *PageRank*.

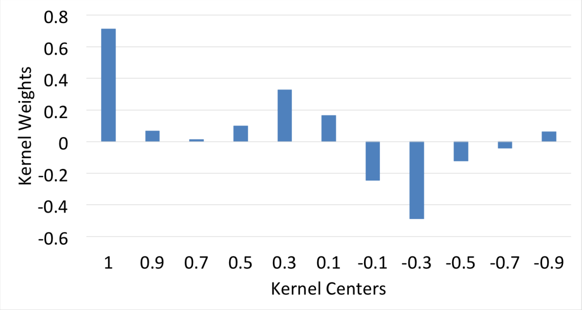

Figure 2: Learned Kernel Weights of `KCE`

Case Study: We inspect some pairs of events and entities in different kernels and list some examples in Table 5. The pre-trained embeddings are changed a lot. Pairs of units with different raw similarity values are now placed in the same bin. The pairs in Table 3 exhibit interesting types of relations: e.g.,"*arrest-charge*" and "*attack-kill*" form script-like chains; "911 attack" forms a quasi-identity relation (Recasens et al., 2010) with "attack"; "business" and "increase" are candidates as frame-argument structure. While these pairs have different raw cosine similarities, they are all useful in predicting salience. `KCE` learns to gather these relations into bins assigned with higher weights, which is not achieved by pure embedding based methods. The `KCE` has changed the embedding space and the scoring functions significantly from the original space after training. This partially explains why the raw voting features and PageRank are not as effective.

7.2 Intrusion Test Results

Figure 3 plots results of the intrusion test . The left figure shows the results of setting 1: adding non-salient intruders. The right one shows the results of setting 2: adding salient intruders. The AUC is 0.493 and the SA-AUC is 0.753 if all intruders are added.

The left figure shows that `KCE` successfully finds the non-salient intruders. The SA-AUC is higher than 0.8. Yet the AUC scores, which include the rankings of non-salience events, are rather close to random. This shows that the salient events in the origin documents form a more cohesive group, making them more robust against the intruders; the non-salient ones are not as cohesive.

In both settings, `KCE` produces higher SA-AUC than *Frequency* at the first 30%. However, in setting 2, `KCE` starts to produce lower SA-AUC than *Frequency* after 30%, then gradually drops to 0.5 (random). This phenomenon is expected since the asymmetry between origins and intruders allow `KCE` to distinguish them at the beginning. When all intruders are added, `KCE` performs worse because it relies heavily on the relations, which can be also formed by the salient intruders. This phenomenon is observed only on the salient intruders, which again confirms the cohesive relations are found among salient events.

In conclusion, we observe that the salient events form tight groups connected by discourse relations while the non-salient events are not as related. The observations imply that the main scripts in documents are mostly anchored by small groups of salient events (such as the "Trial" script in

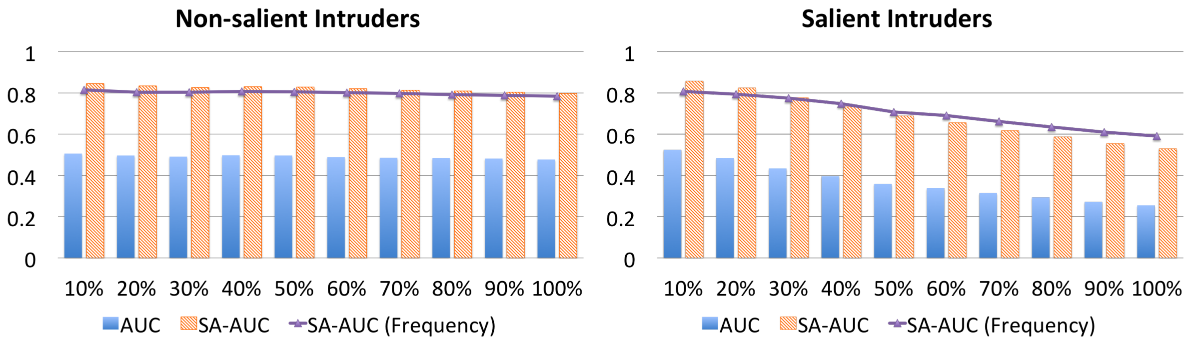

Figure 3: Intruder study results. X-axis shows the percentage of intruders inserted. Y-axis is the AUC score scale. The left and right figures are results from salient and non-salient intruders respectively. The blue bar is AUC. The orange shaded bar is SA-AUC. The line shows the SA-AUC of the frequency baseline.

Example 1). Other events may serve as "backgrounds" (Cheung et al., 2013). Similarly, Choubey et al. (2018) find that relations like event coreference and sequence are important for saliency.

8 Conclusion

We propose two salient detection models, based on lexical relatedness and semantic relations. The feature-based model with lexical similarities is effective, but cannot capture semantic relations like scripts and frames. The `KCE` model uses kernels and embeddings to capture these relations, thus outperforms the baselines and feature-based models significantly. All the results are tested on our newly created large-scale event salience dataset. While the automatic method inevitably introduces noises to the dataset, the scale enables us to study complex event interactions, which is infeasible via costly expert labeling.

Our case study shows that the salience model finds and utilize a variety of discourse relations: script chain (*attack* and *kill*), frame argument relation (*business* and *increase*), quasi-identity (*911 attack* and *attack*). Such complex relations are not as prominent in the raw word embedding space. The core message is that a salience detection module automatically discovers connections between salience and relations. This goes beyond prior centering analysis work that focuses on lexical and syntax and provide a new semantic view from the script and frame perspective.

In the intrusion test, we observe that the small number of salient events are forming tight connected groups. While `KCE` captures these relations quite effectively, it can be confused by salient intrusion events. The phenomenon indicates that the salient events are tightly connected, which form the main scripts of documents.

This paper empirically reveals many interesting connections between discourse phenomena and salience. The results also suggest that core script information may reside mostly in the salient events. Limited by the data acquisition method, this paper only models discourse salience as binary decisions. However, salience value may be continuous and may even have more than one aspects. In the future, we plan to investigate these complex settings. Another direction of study is large-scale semantic relation discovery, for example, frames and scripts, with a focus on salient discourse units.

Temporal Information Extraction by Predicting Relative Time-lines

Artuur Leeuwenberg and **Marie-Francine Moens**
Department of Computer Science
KU Leuven, Belgium
`{tuur.leeuwenberg, sien.moens}@cs.kuleuven.be`

Abstract

The current leading paradigm for temporal information extraction from text consists of three phases: (1) recognition of events and temporal expressions, (2) recognition of temporal relations among them, and (3) time-line construction from the temporal relations. In contrast to the first two phases, the last phase, time-line construction, received little attention and is the focus of this work. In this paper, we propose a new method to construct a linear time-line from a set of (extracted) temporal relations. But more importantly, we propose a novel paradigm in which we directly predict start and end-points for events from the text, constituting a time-line without going through the intermediate step of prediction of temporal relations as in earlier work. Within this paradigm, we propose two models that predict in linear complexity, and a new training loss using TimeML-style annotations, yielding promising results.

1 Introduction

The current leading perspective on temporal information extraction regards three phases: (1) a *temporal entity recognition* phase, extracting events (blue boxes in Fig. 1) and their attributes, and extracting temporal expressions (green boxes), and normalizing their values to dates or durations, (2) a *relation extraction* phase, where temporal links (TLinks) among those entities, and between events and the document-creation time (DCT) are found (arrows in Fig. 1, left). And (3), construction of a time-line (Fig. 1, right) from the extracted temporal links, if they are temporally consistent. Much research concentrated on the first two steps, but very little research looks into step 3, time-line construction, which is the focus of this work.

In this paper, we propose a new time-line construction paradigm that evades phase 2, the relation extraction phase, because in the classical paradigm temporal relation extraction comes with many difficulties in training and prediction that arise from the fact that for a text with n temporal entities (events or temporal expressions) there are n^2 possible entity pairs, which makes it likely for annotators to miss relations, and makes inference slow as n^2 pairs need to be considered. Temporal relation extraction models consistently give lower performance than those in the entity recognition phase (UzZaman et al., 2013; Bethard et al., 2016, 2017), introducing errors in the time-line construction pipe-line.

The ultimate goal of our proposed paradigm is to predict from a text in which entities are already detected, for each entity: (1) a probability distribution on the entity's starting point, and (2) another distribution on the entity's duration. The probabilistic aspect is crucial for time-line based decision making. Constructed time-lines allow for further quantitative reasoning with the temporal information, if this would be needed for certain applications.

As a first approach towards this goal, in this paper, we propose several initial time-line models in this paradigm, that directly predict - in a linear fashion - start points and durations for each entity, using text with annotated temporal entities as input (shown in Fig. 1). The predicted start points and durations constitute a *relative time-line*, i.e. a total order on entity start and end points. The time-line is relative, as start and duration values cannot (yet) be mapped to absolute calender dates or durations expressed in seconds. It represents the relative temporal order and inclusions that temporal entities have with respect to each other by the quantitative start and end values of the entities. Relative time-lines are a first step toward our goal, building models that predict statistical absolute time-lines. To train our relative time-line models, we define novel loss functions that exploit TimeML-style an-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1237–1246
Brussels, Belgium, October 31 - November 4, 2018.

notations, used in most existing temporal corpora.

This work leads to the following contributions:

- A new method to construct a relative time-line from a set of temporal relations (TL2RTL).
- Two new models that, for the first time, directly predict (relative) time-lines - in linear complexity - from entity-annotated texts without doing a form of temporal relation extraction (S-TLM & C-TLM).
- Three new loss functions based on the mapping between Allen's interval algebra and the end-point algebra to train time-line models from TimeML-style annotations.

In the next sections we will further discuss the related work on temporal information extraction. We will describe the models and training losses in detail, and report on conducted experiments.

2 Related Work

2.1 Temporal Information Extraction

The way temporal information is conveyed in language has been studied for a long time. It can be conveyed directly through verb tense, explicit temporal discourse markers (e.g. *during* or *afterwards*) (Derczynski, 2017) or temporal expressions such as dates, times or duration expressions (e.g. *10-05-2010* or *yesterday*). Temporal information is also captured in text implicitly, through background knowledge about, for example, duration of events mentioned in the text (e.g. even without context, *walks* are usually shorter than *journeys*).

Most temporal corpora are annotated with TimeML-style annotations, of which an example is shown in Fig 1, indicating temporal entities, their attributes, and the TLinks among them.

The automatic extraction of TimeML-style temporal information from text using machine learning was first explored by Mani et al. (2006). They proposed a multinomial logistic regression classifier to predict the TLinks between entities. They also noted the problem of missed TLinks by annotators, and experimented with using temporal reasoning (temporal closure) to expand their training data.

Since then, much research focused on further improving the pairwise classification models, by exploring different types of classifiers and features, such as (among others) logistic regression and support vector machines (Bethard, 2013; Lin et al., 2015), and different types of neural network models, such as long short-term memory networks (LSTM) (Tourille et al., 2017; Cheng and Miyao, 2017), and convolutional neural networks (CNN) (Dligach et al., 2017). Moreover, different sieve-based approaches were proposed (Chambers et al., 2014; Mirza and Tonelli, 2016), facilitating mixing of rule-based and machine learning components.

Two major issues shared by these existing approaches are: (1) models classify TLinks in a pair-wise fashion, often resulting in an inference complexity of $O(n^2)$, and (2) the pair-wise predictions are made independently, possibly resulting in prediction of temporally inconsistent graphs. To address the second, additional temporal reasoning can be used at the cost of computation time, during inference (Chambers and Jurafsky, 2008; Denis and Muller, 2011; Do et al., 2012), or during both training and inference (Yoshikawa et al., 2009; Laokulrat et al., 2015; Ning et al., 2017; Leeuwenberg and Moens, 2017). In this work, we circumvent these issues, as we predict time-lines - in linear time complexity - that are temporally consistent by definition.

2.2 Temporal Reasoning

Temporal reasoning plays a central role in temporal information extraction, and there are roughly two approaches: (1) Reasoning directly with Allen's interval relations (shown in Table 1), by constructing rules like: If event X occurs before Y, and event Y before Z then X should happen before Z (Allen, 1990). Or (2), by first mapping the temporal interval expressions to expressions about interval end-points (start and endings of entities) (Vilain et al., 1990). An example of such mapping is that If event X occurs before Y then the end of X should be before the start of Y. Then reasoning can be done with end-points in a point algebra, which has only three point-wise relations $(=, <, >)$, making reasoning much more efficient compared to reasoning with Allen's thirteen interval relations.

Mapping interval relations to point-wise expressions has been exploited for model inference by Denis and Muller (2011), and for evaluation by UzZaman and Allen (2011). In this work, we ex-

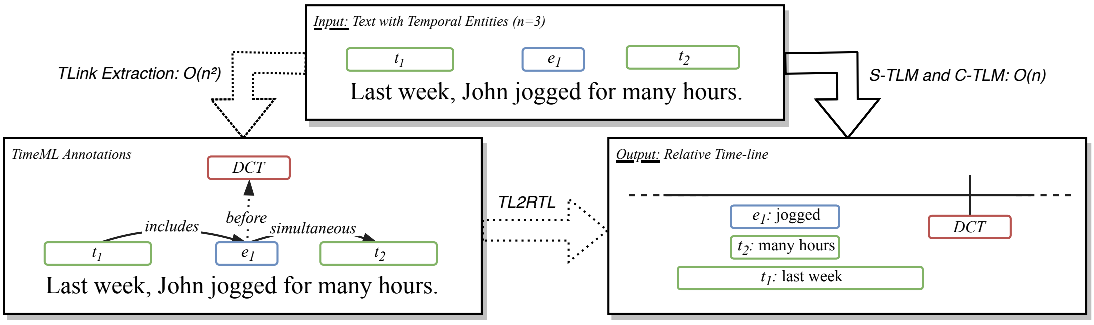

Figure 1: An overview of two paradigms: (1) The indirect approach (dashed arrows), where first TLinks are predicted from which we can build a relative time-line using TL2RTL. And (2), the direct approach (solid arrow), where a relative time-line is predicted directly from the input by S-TLM or C-TLM.

ploit it for the first time for model training, in our loss functions.

3 Models

We propose two model structures for direct time-line construction: (1) a simple context-independent model (S-TLM), and (2) a contextual model (C-TLM). Their structures are shown in Fig. 2. Additionally, we propose a method to construct relative time-lines from a set of (extracted) TLinks (TL2RTL). In this section we first explain the first two direct models S-TLM and C-TLM, and afterwards the indirect method TL2RTL.

3.1 Direct Time-line Models

Word representation

In both S-TLM and C-TLM, words are represented as a concatenation of a word embedding, a POS embedding, and a Boolean feature vector containing entity attributes such as the type, class, aspect, following (Do et al., 2012). Further details on these are given in the experiments section.

Simple Time-line Model (S-TLM)

For the simple context-independent time-line model, each entity is encoded by the word representation of the last word of the entity (generally the most important). From this representation we have a linear projection to the duration d, and the start s. S-TLM is shown by the dotted edges in Fig 2. An advantage of S-TLM is that it has very few parameters, and each entity can be placed on the time-line independently of the others, allowing parallelism during prediction. The downside is that S-TLM is limited in its use of contextual information.

Contextual Time-line Model (C-TLM)

To better exploit the entity context we also propose a contextual time-line model C-TLM (solid edges in Fig 2), that first encodes the full text using two bi-directional recurrent neural networks, one for entity starts (BiRNN$_s$), and one for entity durations (BiRNN$_d$).[1] On top of the encoded text we learn two linear mappings, one from the BiRNN$_d$ output of the last word of the entity mention to its duration d, and similarly for the start time, from the BiRNN$_s$ output to the entity's start s.

Predicting Start, Duration, and End

Both proposed models use linear mappings[2] to predict the start value s_i and duration d_i for the encoded entity i. By summing start s_i and duration d_i we can calculate the entity's end-point e_i.

$$e_i = s_i + \max(d_i, d_{min}) \tag{1}$$

Predicting durations rather than end-points makes it easy to control that the end-point lies after the start-point by constraining the duration d_i by a constant minimum duration value d_{min} above 0, as shown in Eq. 1.

Modeling Document-Creation Time

Although the DCT is often not found explicitly in the text, it is an entity in TimeML, and has TLinks to other entities. We model it by assigning it a text-independent start s_{DCT} and duration d_{DCT}.

Start s_{DCT} is set as a constant (with value 0). This way the model always has the same reference point, and can learn to position the entities w.r.t. the DCT on the time-line.

---

[1] We also experimented with sharing weights among BiRNN$_d$ and BiRNN$_s$. In our experiments, this gave worse performance, so we propose to keep them separate.

[2] Adding more layers did not improve results.

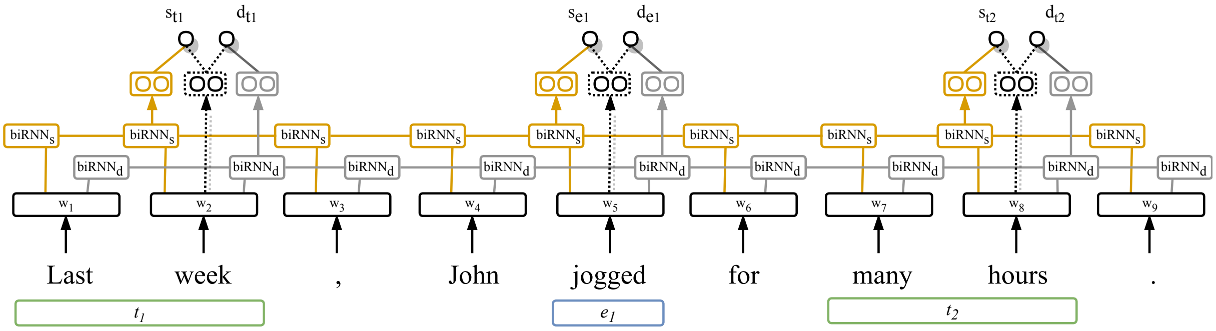

Figure 2: Schematic overview of our two time-line models: C-TLM (solid edges), exploiting entity context, and the simpler S-TLM (dotted edges), which is context independent. The models predict a starting point (s) and duration (d) for each given temporal entity (t_1, e_1, and t_2) in the input.

In contrast, DCT duration d_{DCT} is modeled as a single variable that is learned (initialized with 1). Since multiple entities may be included in the DCT, and entities have a minimum duration d_{min}, a constant d_{DCT} could possibly prevent the model from fitting all entities in the DCT. Modeling d_{DCT} as a variable allows growth of d_{DCT} and averts this issue.[3]

Training Losses

We propose three loss functions to train time-line models from TimeML-style annotations: a regular time-line loss L_τ, and two slightly expanded discriminative time-line losses, $L_{\tau ce}$ and $L_{\tau h}$.

Regular Time-line Loss (L_τ)

Ground-truth TLinks can be seen as constraints on correct positions of entities on a time-line. The regular time-line loss L_τ expresses the degree to which these constraints are met for a predicted time-line. If all TLinks are satisfied in the time-line for a certain text, L_τ will be 0 for that text.

As TLinks relate entities (intervals), we first convert the TLinks to expressions that relate the start and end points of entities. How each TLink is translated to its corresponding point-algebraic constraints is given in Table 1, following Allen (1990).

As can be seen in the last column there are only two point-wise operations in the point-algebraic constraints: an order operation ($<$), and an equality operation ($=$). To model to what degree each point-wise constraint is met, we employ hinge losses, with a margin m_τ, as shown in Eq. 2.

Table 1: Point algebraic interpretation (I_{PA}) of temporal links used to construct the loss function. The start and end points of event X are indicated by s_x and e_x respectively.

Allen Algebra	**Temporal Links**	**Point Algebra**
X precedes Y Y preceded by X	X before Y Y after X	$e_x < s_y$
X starts Y Y started by X	X begins Y Y begun by X	$s_x = s_y$ $e_x < e_y$
X finishes Y Y finished by X	X ends Y Y ended by X	$e_x = e_y$ $s_y < s_x$
X during Y Y includes X	X is included Y Y includes X	$s_y < s_x$ $e_x < e_y$
X meets Y Y met by X	X immediately before Y Y immediately after X	$e_x = s_y$
X overlaps Y Y overlapped by X	absent[4] absent[4]	$s_x < s_y$ $s_y < e_x$ $e_x < e_y$
X equals Y	X simultaneous Y X identity Y	$s_x = s_y$ $e_x = e_y$

To explain the intuition and notation: If we have a point-wise expression ξ of the form $x < y$ (first case of Eq. 2), then the predicted point $\hat{x}$ should be at least a distance m_τ smaller (or earlier on the time-line) than predicted point $\hat{y}$ in order for the loss to be 0. Otherwise, the loss represents the distance $\hat{x}$ or $\hat{y}$ still has to move to make $\hat{x}$ smaller than $\hat{y}$ (and satisfy the constraint). For the second case, if ξ is of the form $x = y$, then point $\hat{x}$ and $\hat{y}$ should lie very close to each other, i.e. at most a distance m_τ away from each other. Any distance further than the margin m_τ is counted as loss. Notice that if we set margin m_τ to 0, the second case becomes an L1 loss $|\hat{x} - \hat{y}|$. However, we use a small margin m_τ to promote some distance between ordered points and prevent con-

---

[3] Other combinations of modeling s_{DCT} and d_{DCT} as variable or constant decreased performance.

[4] No TLink for Allen's overlap relation is present in TimeML, also concluded by UzZaman and Allen (2011).

fusion with equality. Fig. 3 visualizes the loss for three TLinks.

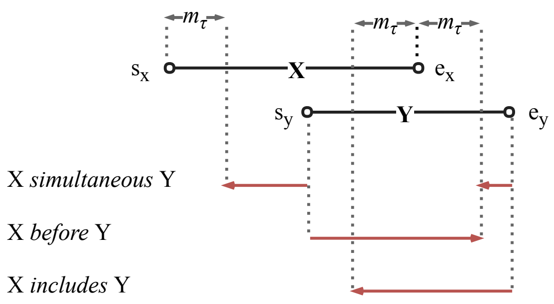

Figure 3: Visualization of the time-line loss L_τ with margin m_τ, for two events X and Y, and TLinks *simultaneous*, *before*, and *includes*. The red arrows' lengths indicate the loss per relation, i.e. how much the points should be shifted to satisfy each relation.

$$L_p(\xi|t,\theta) = \begin{cases} \max(\hat{x} + m_\tau - \hat{y}, 0) & \text{iff } x < y \\ \max(|\hat{x} - \hat{y}| - m_\tau, 0) & \text{iff } x = y \end{cases} \tag{2}$$

The total time-line loss $L_\tau(t|\theta)$ of a model with parameters θ on text t with ground-truth TLinks $R(t)$, is the sum of the TLink-level losses of all TLinks $r \in R(t)$. Each TLink-level loss $L_r(r|t,\theta)$ for TLink r is the sum of the point-wise losses $L_p(\xi|t,\theta)$ of the corresponding point-algebraic constraints $\xi \in I_{PA}(r)$ from Table 1.[5]

$$L_r(r|t,\theta) = \sum_{\xi \in I_{PA}(r)} L_p(\xi|t,\theta) \tag{3}$$

$$L_\tau(t,\theta) = \sum_{r \in R(t)} L_r(r|t,\theta) \tag{4}$$

Discriminative Time-line Losses

To promote a more explicit difference between the relations on the time-line we introduce two discriminative loss functions, $L_{\tau ce}$ and $L_{\tau h}$, which build on top of L_r. Both discriminative loss functions use an intermediate score $S(r|t,\theta)$ for each TLink r based on the predicted time-line. As scoring function, we use the negative L_r loss, as shown in Eq. 5.

$$S(r|t,\theta) = -L_r(r|t,\theta) \tag{5}$$

Then, a lower time-line loss $L_r(r|t,\theta)$ results in a higher score for relation type r. Notice that the maximum score is 0, as this is the minimum L_r.

Probabilistic Loss ($L_{\tau ce}$)

Our first discriminative loss is a cross-entropy based loss. For this the predicted scores are normalized using a soft-max over the possible relation types (TL). The resulting probabilities are used to calculate a cross-entropy loss, shown in Eq. 6. This way, the loss does not just promote the correct relation type but also distantiates from the other relation types.

$$L_{\tau ce}(t|\theta) = \sum_{r \in R(t)} r \cdot \log\left(\frac{e^{S(r|t,\theta)}}{\sum_{r' \in TL} e^{S(r'|t,\theta)}}\right) \tag{6}$$

Ranking Loss ($L_{\tau h}$)

When interested in discriminating relations on the time-line, we want the correct relation type to have the highest score from all possible relation types TL. To represent this perspective, we also define a ranking loss with a score margin m_h in Eq. 7.

$$L_{\tau h}(t|\theta) = \sum_{r \in R(t)} \sum_{r' \in TL \setminus \{r\}} \max(S(r'|t,\theta) - S(r|t,\theta) + m_h, 0) \tag{7}$$

Training Procedure

S-TLM and C-TLM are trained by by iterating through the training texts, sampling mini-batches of 32 annotated TLinks. For each batch we (1) perform a forward pass, (2) calculate the total loss (for one of the loss functions), (3) derive gradients using Adam[6] (Kingma and Ba, 2014), and (4) update the model parameters θ via back-propagation. After each epoch we shuffle the training texts. As stopping criteria we use early stopping (Morgan and Bourlard, 1990), with a patience of 100 epochs and a maximum number of 1000 epochs.

3.2 From TLinks to Time-lines (TL2RTL)

To model the indirect route, we construct a novel method, TL2RTL, that predicts relative time lines from a subset of TLinks, shown in Fig 1. One can choose any method to obtain a set of TLinks $R(t)$ from a text t, serving as input to TL2RTL.

---

[5] The TLink *during* and its inverse are mapped to *simultaneous*, following the evaluation of TempEval-3.

[6] Using the default parameters from the paper.

TL2RTL constructs a relative time-line, by assigning start and end values to each temporal entity, such that the resulting time-line satisfies the extracted TLinks $R(t)$ by minimizing a loss function that is 0 when the extracted TLinks are satisfied. TL2RTL on itself is a method and not a model. The only variables over which it optimizes the loss are the to be assigned starts and duration values.

In detail, for a text t, with annotated entities $E(t)$, we first extract a set of TLinks $R(t)$. In this work, to extract TLinks, we use the current state-of-the-art structured TLink extraction model by Ning et al. (2017). Secondly, we assign a start variable s_i, and duration variable d_i to each entity $i \in E(t)$. Similar to S-TLM and C-TLM, for each $i \in E(t)$, d_i is bounded by a minimum duration d_{min} to ensure start s_i always lies before end e_i. Also, we model the DCT start s_{DCT} as a constant, and its duration d_{DCT} as a variable. Then we minimize one of the loss functions L_τ, $L_{\tau ce}$, or $L_{\tau h}$ on the extracted TLinks $R(t)$, obtaining three TL2RTL variants, one for each loss. If the initially extracted set of TLinks $R(t)$ is consistent, and the loss is minimized sufficiently, all s_i and d_i form a relative time-line that satisfies the TLinks $R(t)$, but from which we can now also derive consistent TLinks for any entity pair, also the pairs that were not in $R(t)$. To minimize the loss we use Adam for 10k epochs until the loss is zero for each document.[7]

4 Experiments

4.1 Evaluation and Data

Because prediction of relative time-lines trained on TimeML-style annotations is new, we cannot compare our model directly to relation extraction or classification models, as the latter do not provide completely temporally consistent TLinks for all possible entity pairs, like the relative time-lines do. Neither can we compare directly to existing absolute time-line prediction models such as Reimers et al. (2018) because they are trained on different data with a very different annotation scheme.

To evaluate the quality of the relative time-line models in a fair way, we use TimeML-style test sets as follows: (1) We predict a time-line for each test-text, and (2) we check for all ground-truth annotated TLinks that are present in the data, what would be the derived relation type based on the predicted time-line, which is the relation type that gives the lowest time-line loss L_r. This results in a TLink assignment for each annotated pair in the TimeML-style reference data, and therefor we can use similar metrics. As evaluation metric we employ the temporal awareness metric, used in TempEval-3, which takes into account temporal closure (UzZaman et al., 2013). Notice that although we use the same metric, comparison against relation classification systems would be unfair, as our model assigns consistent labels to all pairs, whereas relation classification systems do not.

For training and evaluation we use two data splits, TE‡ and TD‡, exactly following Ning et al. (2017). Some statistics about the data are shown in Table 2.[8] The splits are constituted from various smaller datasets: the TimeBank (TB) (Pustejovsky et al., 2002), the AQUANT dataset (AQ), and the platinum dataset (PT) all from TempEval-3 (UzZaman et al., 2013). And, the TimeBank Dense (Cassidy et al., 2014) , and the Verb-Clause dataset (VC) (Bethard et al., 2007).

4.2 Hyper-parameters and Preprocessing

Hyper-parameters shared in all settings can be found in Table 3. The following hyper-parameters are tuned using grid search on a development set (union of TB and AQ): d_{min} is chosen from $\{1, 0.1, 0.01\}$, m_τ from $\{0, 0.025, 0.05, 0.1\}$, α_d from $\{0, 0.1, 0.2, 0.4, 0.8\}$, and α_{rnn} from $\{10, 25, 50\}$. We use LSTM (Hochreiter and Schmidhuber, 1997) as RNN units[9] and employ 50-dimensional GloVe word-embeddings pre-trained[10] on 6B words (Wikipedia and NewsCrawl) to initialize the models' word embeddings.

We use very simple tokenization and consider punctuation[11] or newline tokens as individual tokens, and split on spaces. Additionally, we lowercase the text and use the Stanford POS Tagger (Toutanova et al., 2003) to obtain POS.

---

[7] For some documents the extracted TLinks were temporally inconsistent, resulting in a non-zero loss. Nevertheless, $> 96\%$ of the extracted TLinks were satisfied.

[8] We explicitly excluded all test documents from training as some corpora annotated the same documents.

[9] We also experimented with GRU as RNN type, obtaining similar results.

5 Results

We compared our three proposed models for the three loss functions L_τ, $L_{\tau ce}$, and $L_{\tau h}$, and their linear (unweighted) combination L_*, on TE3‡ and TD‡, for which the results are shown in Table 4.

A trend that can be observed is that overall performance on TD‡ is higher than that of TE3‡, even though less documents are used for training. We inspected why this is the case, and this is caused by a difference in class balance between both test sets. In TE3‡ there are many more TLinks of type *simultaneous* (12% versus 3%), which are very difficult to predict, resulting in lower scores for TE3‡ compared to TD‡. The difference in performance between the datasets is probably also be related to the dense annotation scheme of TD‡ compared to the sparser annotations of TE3‡, as dense annotations give a more complete temporal view of the training texts. For TL2RTL better TLink extraction[12] is also propagated into the final timeline quality.

If we compare loss functions L_τ, $L_{\tau ce}$, and $L_{\tau h}$, and combination L_*, it can be noticed that, although all loss functions seem to give fairly similar performance, L_τ gives the most robust results (never lowest), especially noticeable for the smaller dataset TD‡. This is convenient, because L_τ is fastest to compute during training, as it requires no score calculation for each TLink type. L_τ is also directly interpretable on the timeline. The combination of losses L_* shows mixed results, and has lower performance for S-TLM and C-TLM, but better performance for TL2RTL. However, it is slowest to compute, and less interpretable, as it is a combined loss.

Moreover, we can clearly see that on TE3‡, C-TLM performs better than the indirect models, across all loss functions. This is a very interesting result, as C-TLM is an order of complexity faster in prediction speed compared to the indirect models ($O(n)$ compared to $O(n^2)$ for a text with n entities).[13] We further explore why this is the case through our error analysis in the next section.

On TD‡, the indirect models seem to perform slightly better. We suspect that the reason for this is that C-TLM has more parameters (mostly the LSTM weights), and thus requires more data (TD‡ has much fewer documents than TE3‡) compared to the indirect methods. Another result supporting this hypothesis is the fact that the difference between C-TLM and S-TLM is small on the smaller

---

[12] F1 of 40.3 for TE3‡ and 48.5 for TD‡ (Ning et al., 2017)

[13] We do not directly compare prediction speed, as it would result in unfair evaluation because of implementation differences. However, currently, C-TLM predicts at ∼100 w/s incl. POS tagging, and ∼2000 w/s without. When not using POS, overall performance decreases consistently with 2-4 points.

S	4.3%	4.1%	1.8%	0.6%	0.9%

Figure 4: On the **left**, the confusion matrix of C-TLM (L_τ), and on the **right** of TL2RTL ($L_{\tau ce}$), on TE3‡ for the top-5 most-frequent TLinks (together 95% of data): BEFORE (B), AFTER (A), IS INCLUDED (II), INCLUDES (I), and SIMULTANEOUS (S). Predictions are shown on the x-axis and ground-truth on the y-axis.

TD‡, indicating that C-TLM does not yet utilize contextual information from this dataset, whereas, in contrast, on TE3‡, the larger dataset, C-TLM clearly outperforms S-TLM across all loss functions, showing that when enough data is available C-TLM learns good LSTM weights that exploit context substantially.

6 Error Analysis

We compared predictions of TL2RTL(L_τ) with those of C-TLM (L_τ), the best models of each paradigm. In Table 4, we show the confusion matrices of both systems on TE3‡.

When looking at the overall pattern in errors, both models seem to make similar confusions on both datasets (TD‡ was excluded for space constraints). Overall, we find that *simultaneous* is the most violated TLink for both models. This can be explained by two reasons: (1) It is the least frequent TLink in both datasets. And (2), simultaneous entities are often co-referring events. Event co-reference resolution is a very difficult task on its own.

We also looked at the average token-distance between arguments of correctly satisfied TLinks by the time-lines of each model. For TL2RTL (L_τ) this is 13 tokens, and for C-TLM (L_τ) 15. When looking only at the TLinks that C-TLM (L_τ) satisfied and TL2RTL (L_τ) did not, the average distance is 21. These two observations suggest that the direct C-TLM (L_τ) model is better at positioning entities on the time-line that lie further away from each other in the text. An explanation for this can be error propagation of TLink extraction to the time-line construction, as the pairwise TLink extraction of the indirect paradigm extracts TLinks in a contextual window, to prune the $O(n^2)$ number of possible TLink candidates. This consequently prevents TL2RTL to properly position distant events with respect to each other.

Table 5: Example events from the top-shortest/longest durations and top-earliest/latest start values assigned by the model.

Short d	**Long** d	**Early** s	**Late** s
started	going	destroyed	realize
meet	expects	finished	bring
entered	recession	invaded	able
told	war	pronounced	got
arrived	support	created	work
allow	make	took	change
send	think	appeared	start
asked	created	leaving	reenergize

To get more insight in what the model learns we calculated mean durations and mean starts of C-TLM (L_τ) predictions. Table 5 contains examples from the top-shortest, and top-longest duration assignments and earliest and latest starting points. We observe that events that generally have more events included are assigned longer duration and vice versa. And, events with low start values are in the past tense and events with high start values are generally in the present (or future) tense.

7 Discussion

A characteristic of our model is that it assumes that all events can be placed on a single time-line, and that it does not assume that unlabeled pairs are temporally unrelated. This has big advantages: it results in fast prediction, and missed annotation do not act as noise to the training, as they do for pairwise models. Ning et al. (2018) argue that actual, negated, hypothesized, expected or opinionated events should possibly be annotated on separate time-axis. We believe such multi-axis representations can be inferred from the generated single time-lines if hedging information is recognized.

8 Conclusions

This work leads to the following three main contributions[14]: (1) Three new loss functions that connect the interval-based TimeML-annotations to points on a time-line, (2) A new method, TL2RTL, to predict relative time-lines from a set of predicted temporal relations. And (3), most importantly, two new models, S-TLM and C-TLM, that – to our knowledge for the first time – predict (relative) time-lines in linear complexity from text, by evading the computationally expensive (often $O(n^2)$) intermediate relation extraction phase in earlier work. From our experiments, we conclude that the proposed loss functions can be used effectively to train direct and indirect relative time-line models, and that, when provided enough data, the – much faster – direct model C-TLM outperforms the indirect method TL2RTL.

As a direction for future work, it would be very interesting to extend the current models, diving further into direct time-line models, and learn to predict absolute time-lines, i.e. making the time-lines directly mappable to calender dates and times, e.g. by exploiting complementary data sources such as the EventTimes Corpus (Reimers et al., 2016) and extending the current loss functions accordingly. The proposed models also provide a good starting point for research into probabilistic time-line models, that additionally model the (un)certainty of the predicted positions and durations of the entities.

Abstract

Event extraction is of practical utility in natural language processing. In the real world, it is a common phenomenon that multiple events existing in the same sentence, where extracting them are more difficult than extracting a single event. Previous works on modeling the associations between events by sequential modeling methods suffer a lot from the low efficiency in capturing very long-range dependencies. In this paper, we propose a novel **J**ointly **M**ultiple **E**vents **E**xtraction (JMEE) framework to jointly extract multiple event triggers and arguments by introducing syntactic shortcut arcs to enhance information flow and attention-based graph convolution networks to model graph information. The experiment results demonstrate that our proposed framework achieves competitive results compared with state-of-the-art methods.

1 Introduction

Extracting events from natural language text is an essential yet challenging task for natural language understanding. When given a document, event extraction systems need to recognize event triggers with their specific types and their corresponding arguments with the roles. Technically speaking, as defined by the ACE 2005 dataset[1], a benchmark for event extraction (Grishman et al., 2005), the event extraction task can be divided into two subtasks, i.e., event detection (identifying and classifying event triggers) and argument extraction (identifying arguments of event triggers and labeling their roles).

In event extraction, it is a common phenomenon that multiple events exist in the same sentence. Extracting the correct multiple events from those sentences is much more difficult than in the one-event-one-sentence cases because those various types of events are often associated with each other. For example, in the sentence "He ***left*** the company, and planned to ***go*** home directly.", the trigger word ***left*** may trigger a *Transport* (a person left a place) event or an *End-Position* (a person retired from a company) event. However, if we take the following event triggered by ***go*** into consideration, we are more confident to judge it as a *Transport* event rather than an *End-Position* event. This phenomenon is quite common in our real world, as *Injure* and *Die* events are more likely to co-occur with *Attack* events than others, whereas *Marry* and *Born* events are less likely to co-occur with *Attack* events. As we investigated in ACE 2005 dataset, there are around 26.2% (1042/3978) sentences belong to this category.

Significant efforts have been dedicated to solving this problem. Most of them exploiting various features (Liu et al., 2016b; Yang and Mitchell, 2016; Li et al., 2013; Keith et al., 2017; Liu et al., 2016a; Li et al., 2015), introducing memory vectors and matrices (Nguyen et al., 2016), introducing more transition arcs (Sha et al., 2018), keeping more contextual information (Chen et al., 2015) into sentence-level sequential modeling methods like RNNs and CRFs. Some also seek features in document-level methods (Liao and Grishman, 2010; Ji and Grishman, 2008). However, sentence-level sequential modeling methods suffer a lot from the low efficiency in capturing very long-range dependencies while the feature-based methods require extensive human engineering, which also largely affects model performance. Besides, these methods do not adequately model the associations between events.

An intuitive way to alleviate this phenomenon is to introduce shortcut arcs represented by linguistic resources like dependency parsing trees to

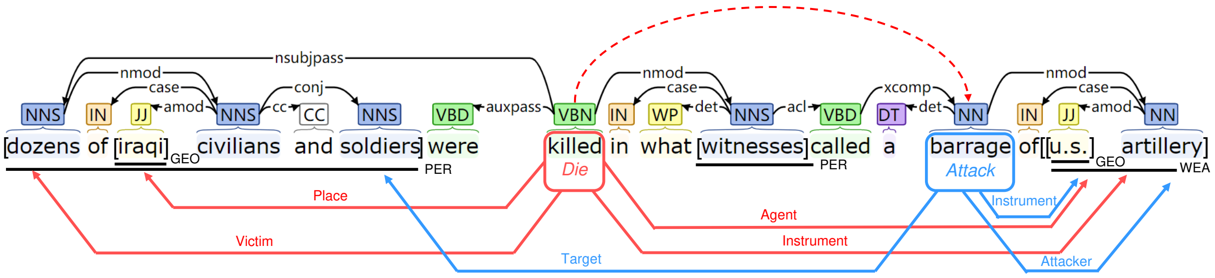

Figure 1: An example of dependency parsing result produced by Stanford CoreNLP. There are two events in the sentence: a *Die* event triggered by the word *killed* with four arguments in red and an *Attack* event triggered by the word *barrage* with three arguments in blue. The red dotted arc is the shortcut path consisting of three directed arcs from trigger *killed* to another trigger *barrage*.

drain the information flow from a point to its target through fewer transitions. Comparing to sequential order, modeling with these arcs often successfully reduce the needed hops from one event trigger to another in the same sentences. In Figure 1, for example, there are two events: a *Die* event triggered by the word *killed* with four arguments in red and an *Attack* event triggered by the word *barrage* with three arguments in blue. We need six hops from *killed* to *barrage* according to sequential order, but only three hops according to the arcs in dependency parsing tree (along the *nmod*-arc from *killed* to *witnesses*, along the *acl*-arc from *witnesses* to *called*, and along the *xcomp*-arc from *called* to *barrage*). These three arcs consist of a shortcut path[2], draining the dependency syntactic information flow from *killed* to *barrage* with fewer hops[3].

In this paper, we propose a novel **J**ointly **M**ultiple **E**vents **E**xtraction (JMEE) framework by introducing syntactic shortcut arcs to enhance information flow and attention-based graphic convolution networks to model the graph information. To implement modeling with the shortcut arcs, we adopt the graph convolutional networks (GCNs) (Kipf and Welling, 2016; Marcheggiani and Titov, 2017; Nguyen and Grishman, 2018) to learn syntactic contextual representations of each node by the representative vectors of its immediate neighbors in the graph. And then we utilize the syntactic contextual representations to extract triggers and arguments jointly by a self-attention mechanism to aggregate information especially keeping the associations between multiple events.

We extensively evaluate the proposed JMEE framework with the widely-used ACE 2005 dataset to demonstrate its benefits in the experiments especially in capturing the associations between events. To summary, our contribution in this work is as follows:

- We propose a novel joint event extraction framework JMEE based on syntactic structures which enhance information flow and alleviate the phenomenon where multiple events are in the same sentence.
- We propose a self-attention mechanism to aggregate information especially keeping the associations between multiple events and prove it is useful in event extraction.
- We achieve the state-of-the-art performance on the widely used datasets for event extraction using the proposed model with GCNs and self-attention mechanism.

2 Approach

Generally, event extraction can be cast as a multi-class classification problem deciding whether each word in the sentence forms a part of event trigger candidate and whether each entity in the sentence plays a particular role in the event triggered by the candidate triggers. There are two main approaches to event extraction: (i) the joint approach that extracts event triggers and arguments simultaneously as a structured prediction problem, and (ii) the pipelined approach that first performs trigger prediction and then identifies arguments in separate stages. We follow the joint approach that can effectively avoid the propagated errors in the pipeline.

Additionally, we extract events in sentence-level mainly for three reasons. Firstly, in our in-

---

[2] In a shortcut path which consists of existing arcs, some arcs may reverse their directions.

[3] The length of the longest path in a tree is always no more than the sequential length consisting of the same number of nodes, which means even in the worst cases, the shortcut path will not perform worse than sequential modeling.

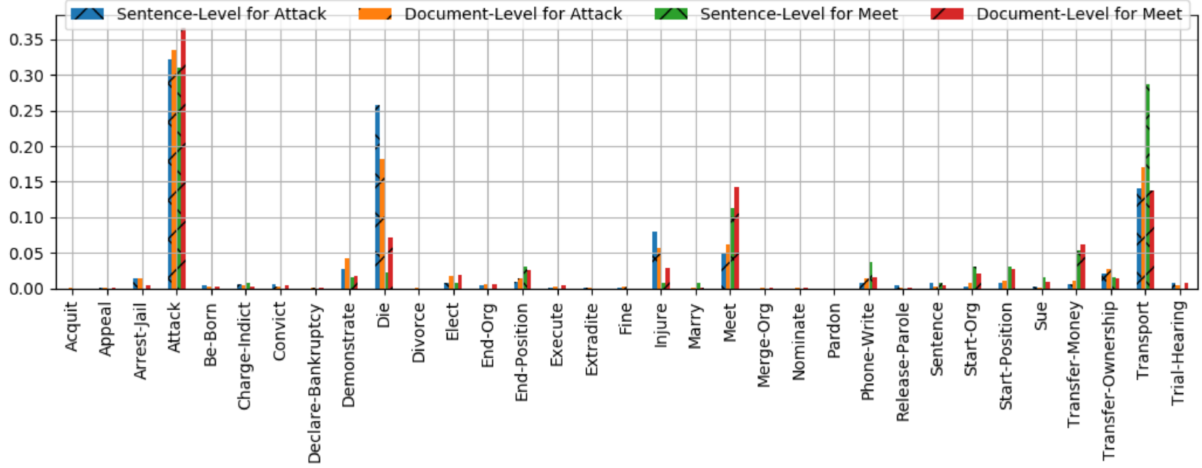

Figure 2: The conditional probability distributions of all the 33 event types in sentences and documents where an *Attack* event or a *Meet* event appears. The label on the top shows which histogram the color stands.

vestigation, we find that the document-level co-occurrence distributions of 33 types of events in the ACE 2005 dataset are relatively similar to the sentence-level co-occurrence distributions. In Figure 2, for example, the blue bars and the orange bars indicate the conditional probability distribution of all the 33 event types in sentences and documents, respectively, where an *Attack* event appears. While the green bars and the red bars indicate the sentence-level and document-level conditional probability distributions respectively. As we can see from this figure, the top three types of *Attack* event in co-occurrence relationships are *Die*, *Transport* and *Injure*, while those of *Meet* event are *Attack*, *Transport*, and *Transfer-Money*. Although different types of events have different co-occurrence relationships, the conditional probability distributions in two levels of the same event type are relatively similar[4]. Secondly, there are many off-the-shelf sentence-level linguistic resources in the NLP community which can offer analytical information about the shortcut paths of some structures, like dependency parsing trees, AMR parsing graphs, and semantic role labeling structures. Last but not least, we also find that events within the same sentences have more explicit relationships with each other than events in different sentences of a document, which means the associations between two events is more accessible to capture.

Let $W = w_1, w_2, ..., w_n$ be a sentence of length n where w_i is the i-th token. Similarly, let $E = e_1, e_2, ..., e_k$ be the entity mentions in the sentence where k is the number of the entity mentions. We apply the BIO annotation schema to assign trigger label t_i to each token w_i, as there are triggers that consist of multiple tokens. If we can get trigger candidates of certain types from trigger labels in BIO annotation schema, we then need to predict the roles (if any) that each entity mention e_j plays in such events.

Our JMEE framework consists of the following four modules: (i) word representation module that represents the sentence with vectors, (ii) syntactic graph convolution network module that performs convolution operations by introducing shortcut arcs from syntactic structures, (iii) self-attention trigger classification module that captures the associations between multiple events in a sentence, and (iv) argument classification that predicts the roles each entity mention e_j plays in the event candidates of specific types, as shown in Figure 3.

2.1 Word Representation

In the word representation module, each token w_i in the sentence is transformed to a real-valued vector x_i by looking up in embedding matrices and concatenating the following vectors:

- The word embedding vector of w_i: This is obtained by looking up a pre-trained word embedding matrix Glove (Pennington et al., 2014).
- The POS-tagging label embedding vector of w_i: This is generated by looking up the randomly initialized POS-tagging label embedding table.

---

[4] We only focus on the top-K co-occurrence relationships because the rest are too sparse for statistic analysis.

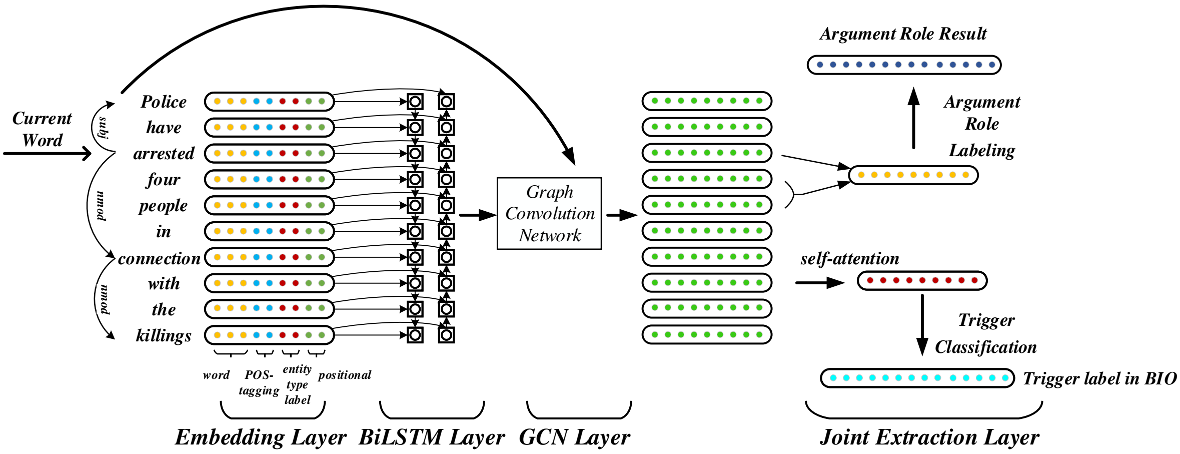

Figure 3: The architecture of our jointly multiple events extraction framework.

- The positional embedding vector of w_i: If w_c is the current word, we encode the relative distance $i - c$ from w_i to w_c as a real-valued vector by looking up the randomly initialized position embedding table (Nguyen et al., 2016; Liu et al., 2017; Nguyen and Grishman, 2018).

- The entity type label embedding vector of w_i: Similarly to the POS-tagging label embedding vector of w_i, we annotate the entity mentions in a sentence using BIO annotation schema and transform the entity type labels to real-valued vectors by looking up the embedding table. It should be noticed that we use the whole entity extent in ACE 2005 dataset which contains overlapping entity mentions and we sum all the possible entity type label embedding vectors for each token.

The transformation from the token w_i to the vector x_i essentially converts the input sentence W into a sequence of real-valued vectors $X = (x_1, x_2, ..., x_n)$, which will be feed into later modules to learn more effective representations for event extraction.

2.2 Syntactic Graph Convolution Network

Considering an undirected graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ as the syntactic parsing tree for sentence W, where $\mathcal{V} = v_1, v_2, ..., v_n (|\mathcal{V}| = n)$ and $\mathcal{E}$ are sets of nodes and edges, respectively. In $\mathcal{V}$, each v_i is the node representing token w_i in W. Each edge $(v_i, v_j) \in \mathcal{E}$ is a directed syntactic arc from token w_i to token w_j, with the type label $K(w_i, w_j)$. Additionally, to allow information to flow against the direction, we also add reversed edge (v_j, v_i) with the type label $K'(w_i, w_j)$. Following Kipf and Welling (2016), we also add all the self-loops, i.e., (v_i, v_i) for any $v_i \in \mathcal{V}$. For example, in the dependency parsing tree shown in Figure 1, there are four arcs in the subgraph with only two nodes *"killed"* and *"witnesses"*: the dependency arc with the type label $K($*"killed"*, *"witnesses"*$) = nmod$, the revresed dependency arc with the additional type label $K($*"witnesses"*, *"killed"*$) = nmod'$, and the two self-loops of *"killed"* and *"witnesses"* with type label $K($*"killed"*, *"killed"*$) = K($*"witnesses"*, *"witnesses"*$) = loop$.

Therefore, in the k-th layer of syntactic graph convolution network module, we can calculate the graph convolution vector $h_v^{(k+1)}$ for node $v \in \mathcal{V}$ by:

$$h_v^{(k+1)} = f\Big(\sum_{u \in \mathcal{N}(v)} (W^{(k)}_{K(u,v)} h_u^{(k)} + b^{(k)}_{K(u,v)})\Big) \quad (1)$$

where $K(u, v)$ indicates the type label of the edge (u, v); $W^{(k)}_{K(u,v)}$ and $b^{(k)}_{K(u,v)}$ are the weight matrix and the bias for the certain type label $K(u, v)$, respectively; $\mathcal{N}(v)$ is the set of neighbors of v including v (because of the self-loop); f is the activation function. Moreover, we use the output of the word representation module x_i to initialize the node representation $h^0_{v_i}$ of the first layer of GCNs.

After applying the above two changes, the number of predefined directed arc type label (let us say, N) will be doubled (to $2N + 1$). It means we will have $2N + 1$ sets of parameter pairs $W_k^{(k)}$ and $b_k^{(k)}$ for a single layer of GCN. In this work, we use Stanford Parser (Klein and Manning, 2003) to generate the arcs in dependency parsing trees for sentences as the shortcut arcs. The current representation contains approximately 50 different grammatical relations, which is too high for the parameter number of a single layer of GCN and not compatible with the existing training data scale. To reduce the parameter numbers, following Marcheggiani and Titov (2017), we modify the definition of type label $K(w_i, w_j)$ to:

$$K(w_i, w_j) = \begin{cases} along, & (v_i, v_j) \in \mathcal{E} \\ rev, & i! = j \& (v_j, v_i) \in \mathcal{E} \\ loop, & i == j \end{cases} \tag{2}$$

where the new $K(w_i, w_j)$ only have three type labels.

As not all types of edges are equally informative for the downstream task, moreover, there are also noises in the generated syntactic parsing structures; we apply gates on the edges to weight their individual importances. Inspired by Dauphin et al. (2017); Marcheggiani and Titov (2017), we calculate a weight $g_{u,v}^{(k)}$ for each edge (u, v) indicating the importance for event extraction by:

$$g_{u,v}^{(k)} = \sigma(h_u^{(k)} V_{K(u,v)}^{(k)} + d_{K(u,v)}^{(k)}) \tag{3}$$

where σ is the logistic sigmoid function, $V_{K(u,v)}^{(k)}$ and $d_{K(u,v)}^{(k)}$ are the weight matrix and the bias of the gate. With this additional gating mechanism, the final syntactic GCN computation is formulated as

$$h_v^{(k+1)} = f\Big(\sum_{u \in \mathcal{N}(v)} g_{u,v}^{(k)} (W_{K(u,v)}^{(k)} h_u^{(k)} + b_{K(u,v)}^{(k)})\Big) \tag{4}$$

As stacking k layers of GCNs can model information in k hops, and sometimes the length of shortcut path between two triggers is less than k, to avoid information over-propagating, we adapt highway units (Srivastava et al., 2015), which allow unimpeded information flowing across stacking GCN layers. Typically, highway layers conduct nonlinear transformation as:

$$t = \sigma(W_T h_v^k + b_T) \tag{5}$$

$$\overline{h}_v^{(k+1)} = h_v^{(k+1)} + t \odot g(W_H h_v^k + b_H) + (1-t) \odot h_v^k \tag{6}$$

where σ is the sigmoid function; $\odot$ is the element-wise product operation; g is a nonlinear activation function; t is called transform gate and $(1-t)$ is called carry gate. Therefore, the input of the k-th GCN layers should be $\overline{h}^{(k)}$ instead of $h^{(k)}$.

The GCNs are designed to capture the dependencies between shortcut arcs, while the layer number of GCNs limits the ability to capture local graph information. However, in this cases, we find that leveraging local sequential context will help to expand the information flow without increasing the layer number of GCNs, which means LSTMs and GCNs maybe complementary. Therefore, instead of feeding the word representation $X = (x_1, x_2, ..., x_n)$ into the first GCN layer, we follow Marcheggiani and Titov (2017), apply Bidirectional LSTM (Bi-LSTM) (Hochreiter and Schmidhuber, 1997) to encode the the word representation X as:

$$\overrightarrow{p}_t = \overrightarrow{LSTM}(\overrightarrow{p}_{t-1}, x_t) \tag{7}$$

$$\overleftarrow{p}_t = \overleftarrow{LSTM}(\overleftarrow{p}_{t-1}, x_t) \tag{8}$$

and the input of t-th token to GCNs is $\overline{x}_t = [\overrightarrow{p}_t, \overleftarrow{p}_t]$, where $[,]$ is the concatenation operation. The Bi-LSTM adaptively accumulates and abstracts the context for each token in the sentence.

2.3 Self-Attention Trigger Classification

When taking each token as the current word, we get the representation D from all tokens calculated by GCNs. Traditional event extraction systems often use max-pooling or its amelioration to aggregate information to each position. However, the max-pooling aggregation mechanisms tend to produce similar results after GCN modules in our framework. For example, if we get the aggregated vector Ag_i at each position i by this max-pooling mechanism $Ag_i = max\_pooling_{j=1}^{n}(H_j)$ with the GCNs output $\{H_j | j = 1, ..., n\}$ in which n is the sentence length, and the vector Ag_i is all the same at each position. Besides, predicting a trigger label for a token should take other possible trigger candidates into consideration. To capture the associations between triggers in a sentence, we design a self-attention mechanism to aggregate information especially keeping the associations between multiple events.

Given the current token w_i, the self-attention score vector and the context vector at position i are calculated as:

$$score = norm(exp(W_2 f(W_1 D + b_1) + b_2)) \tag{9}$$

$$C_i = [\sum_{j=1,j!=i}^{n} score_j * D_j, D_i] \tag{10}$$

where $norm$ means the normalization operation. Then we feed the context vector C_i into a fully-connected network to predict the trigger label in BIO annotation schema as:

$$\overline{C}_i = f(W_c C_i + b_c) \tag{11}$$

$$y_{t_i} = softmax(W_t \overline{C}_i + b_t) \tag{12}$$

where f is a non-linear activation and y_{t_i} is the final output of the i-th trigger label.

2.4 Argument Classification

When we have extracted an entire trigger candidate, which is meeting an *O* label after an *I-Type* label or a *B-Type* label, we use the aggregated context vector $\overline{C}$ to perform argument classification on the entity list in the sentence.

For each entity-trigger pair, as both the entity and the trigger candidate are likely to be a subsequence of tokens, we aggregate the context vectors of subsequences to trigger candidate vector T_i and entity vector E_j by average pooling along the sequence length dimension. Then we concatenate them together and feed into a fully-connected network to predict the argument role as:

$$y_{a_{ij}} = softmax(W_a[T_i, E_j] + b_a) \tag{13}$$

where $y_{a_{ij}}$ is the final output of which role the j-th entity plays in the event triggered by the i-th trigger candidate.

When training our framework, if the trigger candidate that we focus on is not a correct trigger, we set all the golden argument labels concerning the trigger candidate to *OTHER* (not any roles). With this setting, the labels of the trigger candidate will be further adjusted to reach a reasonable probability distribution.

2.5 Biased Loss Function

In order to train the networks, we minimize the joint negative log-likelihood loss function. Due to the data sparsity in the ACE 2005 dataset, we adapt our joint negative log-likelihood loss function by adding a bias item as:

$$\begin{aligned} J(\theta) = -\sum_{p=1}^{N}(\sum_{i=1}^{n_p} I(y_{t_i}) log(p(y_{t_i}|\theta)) \\ +\beta \sum_{i=1}^{t_p}\sum_{j=1}^{e_p} log(p(y_{a_{ij}}|\theta))) \end{aligned} \tag{14}$$

where N is the number of sentences in training corpus; n_p, t_p and e_p are the number of tokens, extracted trigger candidates and entities of the p-th sentence; $I(y_{t_i})$ is an indicating function, if y_{t_i} is not *O*, it outputs a fixed positive floating number α bigger than one, otherwise one; β is also a floating number as a hyper-parameter like α.

3 Experiments

3.1 Experiment Settings

Dataset, Resources and Evaluation Metric

We evaluate our JMEE framework on the ACE 2005 dataset. The ACE 2005 dataset annotate 33 event subtypes and 36 role classes, along with the NONE class and BIO annotation schema, we will classify each token into 67 categories in event detection and 37 categories in argument extraction. To comply with previous work, we use the same data split as the previous work (Ji and Grishman, 2008; Liao and Grishman, 2010; Li et al., 2013; Chen et al., 2015; Liu et al., 2016b; Yang and Mitchell, 2016; Nguyen et al., 2016; Sha et al., 2018). This data split includes 40 newswire articles (881 sentences) for the test set, 30 other documents (1087 sentences) for the development set and 529 remaining documents (21,090 sentences) for the training set.

We deploy the Stanford CoreNLP toolkit[5] to preprocess the data, including tokenizing, sentence splitting, pos-tagging and generating dependency parsing trees.

Also, we follow the criteria of the previous work (Ji and Grishman, 2008; Liao and Grishman, 2010; Li et al., 2013; Chen et al., 2015; Liu et al., 2016b; Yang and Mitchell, 2016; Nguyen et al., 2016; Sha et al., 2018) to judge the correctness of the predicted event mentions.

Hyperparameter Setting

For all the experiments below, in the word representation module, we use 300 dimensions for the embeddings and 50 dimensions for the rest

Table 1: Overall performance comparing to the state-of-the-art methods with golden-standard entities.

three embeddings including pos-tagging embedding, positional embedding and entity type embedding. In the syntactic GCN module, we use a three-layer GCN, a one-layer Bi-LSTM with 220 hidden units, self-attention with 300 hidden units and 200 hidden units for the rest transformation. We also set dropout rate to 0.5 and L2-norm to 1e-8. The batch size in our experiments is 32, and we utilize a maximum length $n = 50$ of sentences in the experiments by padding shorter sentences and cutting off longer ones. These hyperparameters are either randomly searched or chosen by experiences when tuning in the development set.

We use ReLU (Glorot et al., 2011) as our nonlinear activate function. We apply the stochastic gradient descent algorithm with mini-batches and the AdaDelta update rule (Zeiler, 2012). The gradients are computed using back-propagation. During training, besides the weight matrices, we also fine-tune all the embedding tables.

3.2 Overall Performance

We compare our performance with the following state-of-the-art methods:

1 **Cross-Event** is proposed by Liao and Grishman (2010), which uses document level information to improve the performance of event extraction;

2 **JointBeam** is the method proposed by Li et al. (2013), which extracts events based on structure prediction by manually designed features;

3 **DMCNN** is proposed by Chen et al. (2015), which uses dynamic multi-pooling to keep multiple events' information;

4 **PSL** is proposed by Liu et al. (2016b), which uses a probabilistic reasoning model to classify events by using latent and global information to encode the associations between events;

5 **JRNN** is proposed by Nguyen et al. (2016), which uses a bidirectional RNN and manually designed features to jointly extract event triggers and arguments.

6 **dbRNN** is proposed by Sha et al. (2018), which adds dependency bridges over Bi-LSTM for event extraction.

Table 1 shows the overall performance comparing to the above state-of-the-art methods with golden-standard entities. From the table, we can see that our JMEE framework achieves the best F_1 scores for both trigger classification and argument-related subtasks among all the compared methods. There is a significant gain with the trigger classification and argument role labeling performances, which is 2% higher over the best-reported models. These results demonstrate the effectivenesses of our method to incorporate with the graph convolution and syntactic shortcut arcs.

3.3 Effect on Extracting Multiple Events

To evaluate the effect of our framework for alleviating the multiple events phenomenon, we divide the test data into two parts (**1/1** and **1/N**) following Nguyen et al. (2016); Chen et al. (2015) and perform evaluations separately. **1/1** means that one sentence only has one trigger or one argument plays a role in one sentence; otherwise, **1/N** is used.

Table 2 illustrates the performance (F_1 scores) of **JRNN** (Nguyen et al., 2016), **DMCNN** (Chen et al., 2015), the two baseline model **Embedding+T** and **CNN** in Chen et al. (2015) and our framework in trigger classification subtask and argument role labeling subatsk. **Embedding+T** uses word embedding vectors and the traditional sentence-level features in Li et al. (2013), while

Stage	Model	1/1	1/N	all
Trigger	Embedding+T	68.1	25.5	59.8
	CNN	72.5	43.1	66.3
	DMCNN	74.3	50.9	69.1
	JRNN	**75.6**	64.8	69.3
	JMEE	75.2	**72.7**	**73.7**
Argument	Embedding+T	37.4	15.5	32.6
	CNN	51.6	36.6	48.9
	DMCNN	54.6	48.7	53.5
	JRNN	50.0	55.2	55.4
	JMEE	**59.3**	**57.6**	**60.3**

Table 2: System Performance on Single Event Sentences **(1/1)** and Multiple Event Sentences **(1/N)**

CNN is similar to **DMCNN**, except that it applies the standard max-pooling mechanism instead of the dynamic multi-pooling mechanism. We can see that our framework significantly outperforms all the other methods, especially in trigger classification subtask. In the **1/N** data split of triggers, our framework is 7.9% better than the **JRNN**, which demonstrates that our method of leveraging syntactic shortcut arcs and self-attention aggregation mechanism is helpful in alleviating the multiple events phenomenon.

3.4 Analysis of Self-Attention Mechanism

We use a sentence "police have arrested four people in connection with the killing" as an example to illustrate the captures features in our self-attention aggregation mechanism by transforming the attention scores to a row-wise heap map in Figure 4. There are two events in the sentence: an *Arrest-Jail* event triggered by *arrested* and a *Die* event triggered by *killings*. Additionally, the entity *police* plays an *Agent* role and the entity *four people* plays a *Person* role in the *Arrest-Jail* event.

As we can see from the Figure 4, in the row of *arrested*, there are relatively strong connections with *arrested* (self), *four people* (its argument) and *killings* (other event). And in the row of *killings*, there are also relatively strong connections with *killings* (self) and *arrested* (other event). Besides, the words *police*, *four* and *in* also have high scores with *killings*, which may mean be on account of the context information propagation though syntactic shortcut arcs.

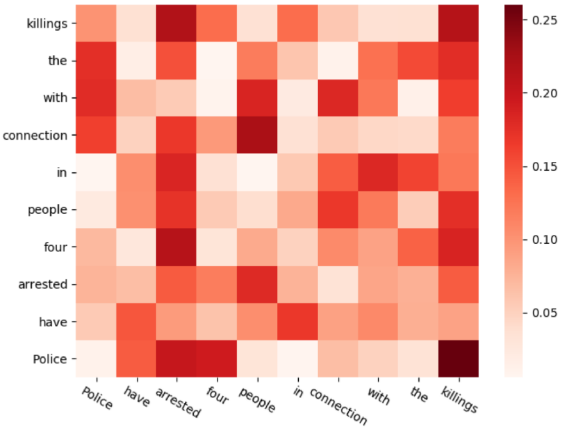

Figure 4: Visualization of the attention scores of a sentence containing two events: an *Arrest-Jail* event triggered by *arrested* and a *Die* event triggered by *killings*. Each row is the group of scores derived by the self-attention aggregation mechanism. Darker red means higher score and stronger interaction.

4 Related Work

There are several existing approaches exploiting the associations between events in the event extraction task. Some of them alleviate this phenomenon by exploiting various sentence-level features, such as ranking dependencies (McClosky et al., 2011), combinational features of triggers and arguments (Li et al., 2013), probabilistic soft logic information (Liu et al., 2016b,a), trigger-specific features and relational features (Yang and Mitchell, 2016; Keith et al., 2017). Others also seek features in document-level methods (Liao and Grishman, 2010; Ji and Grishman, 2008; Hong et al., 2011; Reichart and Barzilay, 2012; Lu and Roth, 2012). The feature-based methods require extensive human engineering, which also essentially affects model performances, and learn them from the unbalanced training data, however, it is difficult for sparse events.

There are also a group of deep learning methods using RNNs (Nguyen et al., 2016; Sha et al., 2018; Liu et al., 2018) and CNNs (Chen et al., 2015; Feng et al., 2016; Nguyen and Grishman, 2016) capturing the associations between events. However, sentence-level sequential modeling methods suffer a lot from the low efficiency in capturing very long-range dependencies. Besides, these methods do not fully model the associations between events.

5 Conclusion and Future Work

This paper presents a novel deep neural jointly multiple events extraction (JMEE) framework for the task of event extraction, especially for alleviating the multiple-event phenomenon. In our framework, we introduce syntactic shortcut arcs to enhance information flow and adapt the graph convolution network to capture the enhanced representation. Then a self-attention aggregation mechanism is applied to aggregate the associations between events. Besides, we jointly extract event triggers and arguments by optimizing a biased loss function due to the imbalances in the dataset. The experiment results demonstrate the effectiveness of our proposed framework. In the future, we plan to exploit the information of one argument which plays different roles in various events to do better in event extraction task.

Abstract

Distantly-supervised Relation Extraction (RE) methods train an extractor by automatically aligning relation instances in a Knowledge Base (KB) with unstructured text. In addition to relation instances, KBs often contain other relevant side information, such as aliases of relations (e.g., *founded* and *co-founded* are aliases for the relation *founderOfCompany*). RE models usually ignore such readily available side information. In this paper, we propose RESIDE, a distantly-supervised neural relation extraction method which utilizes additional side information from KBs for improved relation extraction. It uses entity type and relation alias information for imposing soft constraints while predicting relations. RESIDE employs Graph Convolution Networks (GCN) to encode syntactic information from text and improves performance even when limited side information is available. Through extensive experiments on benchmark datasets, we demonstrate RESIDE's effectiveness. We have made RESIDE's source code available to encourage reproducible research.

1 Introduction

The construction of large-scale Knowledge Bases (KBs) like Freebase (Bollacker et al., 2008) and Wikidata (Vrandečić and Krötzsch, 2014) has proven to be useful in many natural language processing (NLP) tasks like question-answering, web search, etc. However, these KBs are not exhaustive. Relation Extraction (RE) attempts to fill this gap by extracting semantic relationships between entity pairs from plain text. This task can be modeled as a simple classification problem after the entity pairs are specified. Formally, given an entity pair (e_1,e_2) from the KB and an entity annotated sentence (or instance), we aim to predict the relation r, from a predefined relation set, that exists between e_1 and e_2. If no relation exists, we simply label it *NA*.

Most supervised relation extraction methods require large labeled training data which is expensive to construct. Distant Supervision (DS) (Mintz et al., 2009) helps with the construction of this dataset automatically, under the assumption that if two entities have a relationship in a KB, then all sentences mentioning those entities express the same relation. While this approach works well in generating large amounts of training instances, the DS assumption does not hold in all cases. Riedel et al. (2010); Hoffmann et al. (2011); Surdeanu et al. (2012) propose multi-instance based learning to relax this assumption. However, they use NLP tools to extract features, which can be noisy.

Recently, neural models have demonstrated promising performance on RE. Zeng et al. (2014, 2015) employ Convolutional Neural Networks (CNN) to learn representations of instances. For alleviating noise in distant supervised datasets, attention has been utilized by (Lin et al., 2016; Jat et al., 2018). Syntactic information from dependency parses has been used by (Mintz et al., 2009; He et al., 2018) for capturing long-range dependencies between tokens. Recently proposed Graph Convolution Networks (GCN) (Defferrard et al., 2016) have been effectively employed for encoding this information (Marcheggiani and Titov, 2017; Bastings et al., 2017). However, all the above models rely only on the noisy instances from distant supervision for RE.

Relevant side information can be effective for improving RE. For instance, in the sentence, *Microsoft was started by Bill Gates.*, the type information of *Bill Gates (person)* and *Microsoft (organization)* can be helpful in predicting the correct relation *founderOfCompany*. This is because every relation constrains the type of its target en-

Brussels, Belgium, October 31 - November 4, 2018.

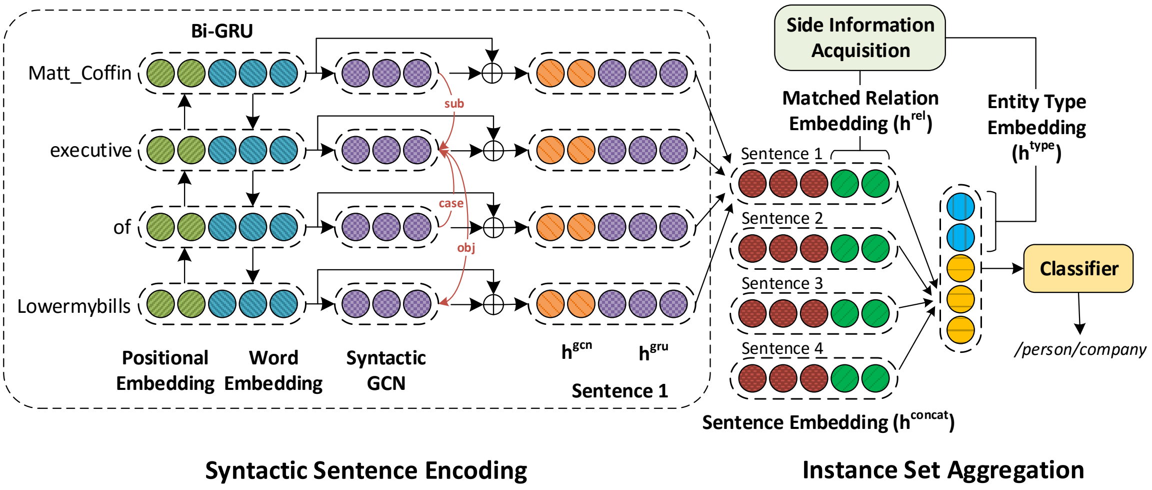

Figure 1: Overview of RESIDE. RESIDE first encodes each sentence in the bag by concatenating embeddings (denoted by ⊕) from Bi-GRU and Syntactic GCN for each token, followed by word attention. Then, sentence embedding is concatenated with relation alias information, which comes from the Side Information Acquisition Section (Figure 2), before computing attention over sentences. Finally, bag representation with entity type information is fed to a softmax classifier. Please see Section 5 for more details.

tities. Similarly, relation phrase *"was started by"* extracted using Open Information Extraction (Open IE) methods can be useful, given that the aliases of relation *founderOfCompany*, e.g., *founded, co-founded, etc.*, are available. KBs used for DS readily provide such information which has not been completely exploited by current models.

In this paper, we propose RESIDE, a novel distant supervised relation extraction method which utilizes additional supervision from KB through its neural network based architecture. RESIDE makes principled use of entity type and relation alias information from KBs, to impose soft constraints while predicting the relation. It uses encoded syntactic information obtained from Graph Convolution Networks (GCN), along with embedded side information, to improve neural relation extraction. Our contributions can be summarized as follows:

- We propose RESIDE, a novel neural method which utilizes additional supervision from KB in a principled manner for improving distant supervised RE.
- RESIDE uses Graph Convolution Networks (GCN) for modeling syntactic information and has been shown to perform competitively even with limited side information.
- Through extensive experiments on benchmark datasets, we demonstrate RESIDE's effectiveness over state-of-the-art baselines.

RESIDE's source code and datasets used in the paper are available at `http://github.com/malllabiisc/RESIDE`.

2 Related Work

Distant supervision: Relation extraction is the task of identifying the relationship between two entity mentions in a sentence. In supervised paradigm, the task is considered as a multi-class classification problem but suffers from lack of large labeled training data. To address this limitation, (Mintz et al., 2009) propose distant supervision (DS) assumption for creating large datasets, by heuristically aligning text to a given Knowledge Base (KB). As this assumption does not always hold true, some of the sentences might be wrongly labeled. To alleviate this shortcoming, Riedel et al. (2010) relax distant supervision for multi-instance single-label learning. Subsequently, for handling overlapping relations between entities (Hoffmann et al., 2011; Surdeanu et al., 2012) propose multi-instance multi-label learning paradigm.

Neural Relation Extraction: The performance of the above methods strongly rely on the quality of hand engineered features. Zeng et al. (2014)

propose an end-to-end CNN based method which could automatically capture relevant lexical and sentence level features. This method is further improved through piecewise max-pooling by (Zeng et al., 2015). Lin et al. (2016); Nagarajan et al. (2017) use attention (Bahdanau et al., 2014) for learning from multiple valid sentences. We also make use of attention for learning sentence and bag representations.

Dependency tree based features have been found to be relevant for relation extraction (Mintz et al., 2009). He et al. (2018) use them for getting promising results through a recursive tree-GRU based model. In RESIDE, we make use of recently proposed Graph Convolution Networks (Defferrard et al., 2016; Kipf and Welling, 2017), which have been found to be quite effective for modelling syntactic information (Marcheggiani and Titov, 2017; Nguyen and Grishman, 2018; Vashishth et al., 2018a).

Side Information in RE: Entity description from KB has been utilized for RE (Ji et al., 2017), but such information is not available for all entities. Type information of entities has been used by Ling and Weld (2012); Liu et al. (2014) as features in their model. Yaghoobzadeh et al. (2017) also attempt to mitigate noise in DS through their joint entity typing and relation extraction model. However, KBs like Freebase readily provide reliable type information which could be directly utilized. In our work, we make principled use of entity type and relation alias information obtained from KB. We also use unsupervised Open Information Extraction (Open IE) methods (Mausam et al., 2012; Angeli et al., 2015), which automatically discover possible relations without the need of any predefined ontology, which is used as a side information as defined in Section 5.2.

3 Background: Graph Convolution Networks (GCN)

In this section, we provide a brief overview of Graph Convolution Networks (GCN) for graphs with directed and labeled edges, as used in (Marcheggiani and Titov, 2017).

3.1 GCN on Labeled Directed Graph

For a directed graph, $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V}$ and $\mathcal{E}$ represent the set of vertices and edges respectively, an edge from node u to node v with label l_{uv} is represented as (u, v, l_{uv}). Since, information in directed edge does not necessarily propagate along its direction, following (Marcheggiani and Titov, 2017) we define an updated edge set $\mathcal{E}'$ which includes inverse edges (v, u, l_{uv}^{-1}) and self-loops $(u, u, \top)$ along with the original edge set $\mathcal{E}$, where $\top$ is a special symbol to denote self-loops. For each node v in $\mathcal{G}$, we have an initial representation $x_v \in \mathbb{R}^d, \forall v \in \mathcal{V}$. On employing GCN, we get an updated d-dimensional hidden representation $h_v \in \mathbb{R}^d, \forall v \in \mathcal{V}$, by considering only its immediate neighbors (Kipf and Welling, 2017). This can be formulated as:

$$h_v = f\left(\sum_{u \in \mathcal{N}(v)} (W_{l_{uv}} x_u + b_{l_{uv}})\right).$$

Here, $W_{l_{uv}} \in \mathbb{R}^{d \times d}$ and $b_{l_{uv}} \in \mathbb{R}^d$ are label dependent model parameters which are trained based on the downstream task. $\mathcal{N}(v)$ refers to the set of neighbors of v based on $\mathcal{E}'$ and f is any non-linear activation function. In order to capture multi-hop neighborhood, multiple GCN layers can be stacked. Hidden representation of node v in this case after k^{th} GCN layer is given as:

$$h_v^{k+1} = f\left(\sum_{u \in \mathcal{N}(v)} \left(W_{l_{uv}}^k h_u^k + b_{l_{uv}}^k\right)\right).$$

3.2 Integrating Edge Importance

In automatically constructed graphs, some edges might be erroneous and hence need to be discarded. Edgewise gating in GCN by (Bastings et al., 2017; Marcheggiani and Titov, 2017) allows us to alleviate this problem by subduing the noisy edges. This is achieved by assigning a relevance score to each edge in the graph. At k^{th} layer, the importance of an edge (u, v, l_{uv}) is computed as:

$$g_{uv}^k = \sigma\left(h_u^k \cdot \hat{w}_{l_{uv}}^k + \hat{b}_{l_{uv}}^k\right), \qquad (1)$$

Here, $\hat{w}_{l_{uv}}^k \in \mathbb{R}^m$ and $\hat{b}_{l_{uv}}^k \in \mathbb{R}$ are parameters which are trained and $\sigma(\cdot)$ is the sigmoid function. With edgewise gating, the final GCN embedding for a node v after k^{th} layer is given as:

$$h_v^{k+1} = f\left(\sum_{u \in \mathcal{N}(v)} g_{uv}^k \times \left(W_{l_{uv}}^k h_u^k + b_{l_{uv}}^k\right)\right). \qquad (2)$$

4 RESIDE Overview

In multi-instance learning paradigm, we are given a bag of sentences (or instances) $\{s_1, s_2, ...s_n\}$ for a given entity pair, the task is to predict the relation between them. RESIDE consists of three components for learning a representation of a given bag, which is fed to a softmax classifier. We briefly present the components of RESIDE below. Each component will be described in detail in the subsequent sections. The overall architecture of RESIDE is shown in Figure 1.

1. **Syntactic Sentence Encoding:** RESIDE uses a Bi-GRU over the concatenated positional and word embedding for encoding the local context of each token. For capturing long-range dependencies, GCN over dependency tree is employed and its encoding is appended to the representation of each token. Finally, attention over tokens is used to subdue irrelevant tokens and get an embedding for the entire sentence. More details in Section 5.1.
2. **Side Information Acquisition:** In this module, we use additional supervision from KBs and utilize Open IE methods for getting relevant side information. This information is later utilized by the model as described in Section 5.2.
3. **Instance Set Aggregation:** In this part, sentence representation from syntactic sentence encoder is concatenated with the *matched relation embedding* obtained from the previous step. Then, using attention over sentences, a representation for the entire bag is learned. This is then concatenated with *entity type embedding* before feeding into the softmax classifier for relation prediction. Please refer to Section 5.3 for more details.

5 RESIDE Details

In this section, we provide the detailed description of the components of RESIDE.

5.1 Syntactic Sentence Encoding

For each sentence in the bag s_i with m tokens $\{w_1, w_2, ...w_m\}$, we first represent each token by k-dimensional GloVe embedding (Pennington et al., 2014). For incorporating relative position of tokens with respect to target entities, we use p-dimensional position embeddings, as used by (Zeng et al., 2014). The combined token embeddings are stacked together to get the sentence representation $\mathcal{H} \in \mathbb{R}^{m \times (k+2p)}$. Then, using Bi-GRU (Cho et al., 2014) over $\mathcal{H}$, we get the new sentence representation $\mathcal{H}^{gru} \in \mathbb{R}^{m \times d_{gru}}$, where d_{gru} is the hidden state dimension. Bi-GRUs have been found to be quite effective in encoding the context of tokens in several tasks (Sutskever et al., 2014; Graves et al., 2013).

Although Bi-GRU is capable of capturing local context, it fails to capture long-range dependencies which can be captured through dependency edges. Prior works (Mintz et al., 2009; He et al., 2018) have exploited features from syntactic dependency trees for improving relation extraction. Motivated by their work, we employ Syntactic Graph Convolution Networks for encoding this information. For a given sentence, we generate its dependency tree using Stanford CoreNLP (Manning et al., 2014). We then run GCN over the dependency graph and use Equation 2 for updating the embeddings, taking $\mathcal{H}^{gru}$ as the input. Since dependency graph has 55 different edge labels, incorporating all of them over-parameterizes the model significantly. Therefore, following (Marcheggiani and Titov, 2017; Nguyen and Grishman, 2018; Vashishth et al., 2018a) we use only three edge labels based on the direction of the edge $\{$*forward* $(\rightarrow)$, *backward* $(\leftarrow)$, *self-loop* $(\top)\}$. We define the new edge label L_{uv} for an edge (u, v, l_{uv}) as follows:

$$L_{uv} = \begin{cases} \rightarrow & \text{if edge exists in dependency parse} \\ \leftarrow & \text{if edge is an inverse edge} \\ \top & \text{if edge is a self-loop} \end{cases}$$

For each token w_i, GCN embedding $h^{gcn}_{i_{k+1}} \in \mathbb{R}^{d_{gcn}}$ after k^{th} layer is defined as:

$$h^{gcn}_{i_{k+1}} = f\left(\sum_{u \in \mathcal{N}(i)} g^k_{iu} \times \left(W^k_{L_{iu}} h^{gcn}_{u_k} + b^k_{L_{iu}} \right) \right).$$

Here, g^k_{iu} denotes edgewise gating as defined in Equation 1 and L_{iu} refers to the edge label defined above. We use ReLU as activation function f, throughout our experiments. The syntactic graph encoding from GCN is appended to Bi-GRU output to get the final token representation, h^{concat}_i as $[h^{gru}_i; h^{gcn}_{i_{k+1}}]$. Since, not all tokens are equally relevant for RE task, we calculate the degree of relevance of each token using attention as used in

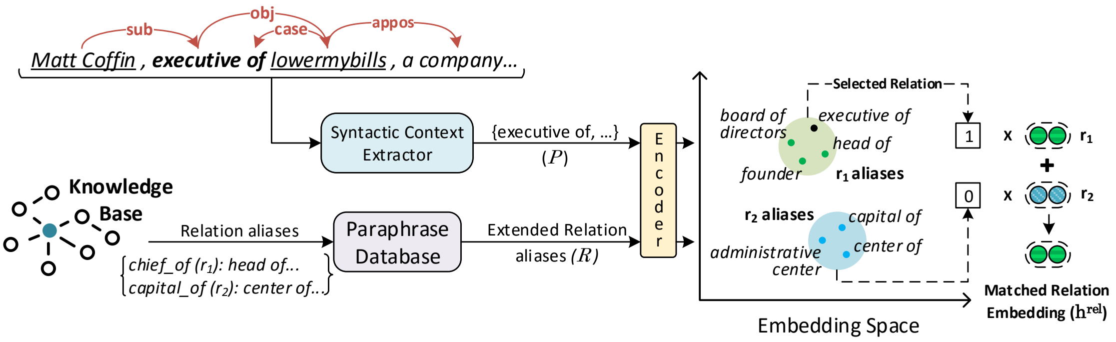

Figure 2: Relation alias side information extraction for a given sentence. First, Syntactic Context Extractor identifies relevant relation phrases $\mathcal{P}$ between target entities. They are then matched in the embedding space with the extended set of relation aliases $\mathcal{R}$ from KB. Finally, the relation embedding corresponding to the closest alias is taken as relation alias information. Please refer Section 5.2.

(Jat et al., 2018). For token w_i in the sentence, attention weight α_i is calculated as:

$$\alpha_i = \frac{\exp(u_i)}{\sum_{j=1}^{m}\exp(u_j)} \quad \text{where, } u_i = h_i^{concat} \cdot r.$$

where r is a random query vector and u_i is the relevance score assigned to each token. Attention values $\{\alpha_i\}$ are calculated by taking softmax over $\{u_i\}$. The representation of a sentence is given as a weighted sum of its tokens, $s = \sum_{j=1}^{m} \alpha_i h_i^{concat}$.

5.2 Side Information Acquisition

Relevant side information has been found to improve performance on several tasks (Ling and Weld, 2012; Vashishth et al., 2018b). In distant supervision based relation extraction, since the entities are from a KB, knowledge about them can be utilized to improve relation extraction. Moreover, several unsupervised relation extraction methods (Open IE) (Angeli et al., 2015; Mausam et al., 2012) allow extracting relation phrases between target entities without any predefined ontology and thus can be used to obtain relevant side information. In RESIDE, we employ Open IE methods and additional supervision from KB for improving neural relation extraction.

Relation Alias Side Information

RESIDE uses Stanford Open IE (Angeli et al., 2015) for extracting relation phrases between target entities, which we denote by $\mathcal{P}$. As shown in Figure 2, for the sentence *Matt Coffin, executive of lowermybills, a company..*, Open IE methods extract *"executive of"* between *Matt Coffin* and *lowermybills*. Further, we extend $\mathcal{P}$ by including tokens at one hop distance in dependency path from target entities. Such features from dependency parse have been exploited in the past by (Mintz et al., 2009; He et al., 2018). The degree of match between the extracted phrases in $\mathcal{P}$ and aliases of a relation can give important clues about the relevance of that relation for the sentence. Several KBs like Wikidata provide such relation aliases, which can be readily exploited. In RESIDE, we further expand the relation alias set using Paraphrase database (PPDB) (Pavlick et al., 2015). We note that even for cases when aliases for relations are not available, providing only the names of relations give competitive performance. We shall explore this point further in Section 7.3.

For matching $\mathcal{P}$ with the PPDB expanded relation alias set $\mathcal{R}$, we project both in a d-dimensional space using GloVe embeddings (Pennington et al., 2014). Projecting phrases using word embeddings helps to further expand these sets, as semantically similar words are closer in embedding space (Mikolov et al., 2013; Pennington et al., 2014). Then, for each phrase $p \in \mathcal{P}$, we calculate its cosine distance from all relation aliases in $\mathcal{R}$ and take the relation corresponding to the closest relation alias as a matched relation for the sentence. We use a threshold on cosine distance to remove noisy aliases. In RESIDE, we define a k_r-dimensional embedding for each relation which we call as *matched relation embedding* (h^{rel}). For a given sentence, h^{rel} is concatenated with its representation s, obtained from syntactic sentence encoder (Section 5.1) as shown in Figure 1. For sentences with $|\mathcal{P}| > 1$, we might get multiple matched relations. In such cases, we take the average of their embeddings. We hypothesize that this helps in improving the performance and find it to be true as shown in Section 7.

Entity Type Side Information

Type information of target entities has been shown to give promising results on relation extraction (Ling and Weld, 2012; Yaghoobzadeh et al., 2017). Every relation puts some constraint on the type of entities which can be its subject and object. For example, the relation *person/place_of_birth* can only occur between a *person* and a *location*. Sentences in distance supervision are based on entities in KBs, where the type information is readily available.

In RESIDE, we use types defined by FIGER (Ling and Weld, 2012) for entities in Freebase. For each type, we define a k_t-dimensional embedding which we call as *entity type embedding* (h^{type}). For cases when an entity has multiple types in different contexts, for instance, *Paris* may have types *government* and *location*, we take the average over the embeddings of each type. We concatenate the *entity type embedding* of target entities to the final bag representation before using it for relation classification. To avoid over-parameterization, instead of using all fine-grained 112 entity types, we use 38 coarse types which form the first hierarchy of FIGER types.

5.3 Instance Set Aggregation

For utilizing all valid sentences, following (Lin et al., 2016; Jat et al., 2018), we use attention over sentences to obtain a representation for the entire bag. Instead of directly using the sentence representation s_i from Section 5.1, we concatenate the embedding of each sentence with *matched relation embedding* h_i^{rel} as obtained from Section 5.2. The attention score α_i for i^{th} sentence is formulated as:

$$\alpha_i = \frac{\exp(\hat{s}_i \cdot q)}{\sum_{j=1}^{n} \exp(\hat{s}_j \cdot q)} \quad \text{where, } \hat{s}_i = [s_i; h_i^{rel}].$$

here q denotes a random query vector. The bag representation $\mathcal{B}$, which is the weighted sum of its sentences, is then concatenated with the *entity type embeddings* of the subject (h_{sub}^{type}) and object (h_{obj}^{type}) from Section 5.2 to obtain $\hat{\mathcal{B}}$.

$$\hat{\mathcal{B}} = [\mathcal{B}; h_{sub}^{type}; h_{obj}^{type}] \quad \text{where, } \mathcal{B} = \sum_{i=1}^{n} \alpha_i \hat{s}_i.$$

Finally, $\hat{\mathcal{B}}$ is fed to a softmax classifier to get the probability distribution over the relations.

$$p(y) = \text{Softmax}(W \cdot \hat{\mathcal{B}} + b).$$

Datasets	Split	# Sentences	# Entity-pairs
Riedel (# Relations: 53)	Train	455,771	233,064
	Valid	114,317	58,635
	Test	172,448	96,678
GIDS (# Relations: 5)	Train	11,297	6,498
	Valid	1,864	1,082
	Test	5,663	3,247

Table 1: Details of datasets used. Please see Section 6.1 for more details.

6 Experimental Setup

6.1 Datasets

In our experiments, we evaluate the models on Riedel and Google Distant Supervision (GIDS) dataset. Statistics of the datasets is summarized in Table 1. Below we described each in detail[1].

1. **Riedel:** The dataset is developed by (Riedel et al., 2010) by aligning Freebase relations with New York Times (NYT) corpus, where sentences from the year 2005-2006 are used for creating the training set and from the year 2007 for the test set. The entity mentions are annotated using Stanford NER (Finkel et al., 2005) and are linked to Freebase. The dataset has been widely used for RE by (Hoffmann et al., 2011; Surdeanu et al., 2012) and more recently by (Lin et al., 2016; Feng et al.; He et al., 2018).
2. **GIDS:** Jat et al. (2018) created Google Distant Supervision (GIDS) dataset by extending the Google relation extraction corpus[2] with additional instances for each entity pair. The dataset assures that the at-least-one assumption of multi-instance learning, holds. This makes automatic evaluation more reliable and thus removes the need for manual verification.

(a) Riedel dataset

(b) GIDS dataset

Figure 3: Comparison of Precision-recall curve. RESIDE achieves higher precision over the entire range of recall than all the baselines on both datasets. Please refer Section 7.1 for more details.

6.2 Baselines

For evaluating RESIDE, we compare against the following baselines:

- **Mintz:** Multi-class logistic regression model proposed by (Mintz et al., 2009) for distant supervision paradigm.
- **MultiR:** Probabilistic graphical model for multi instance learning by (Hoffmann et al., 2011)
- **MIMLRE:** A graphical model which jointly models multiple instances and multiple labels. More details in (Surdeanu et al., 2012).
- **PCNN:** A CNN based relation extraction model by (Zeng et al., 2015) which uses piecewise max-pooling for sentence representation.
- **PCNN+ATT:** A piecewise max-pooling over CNN based model which is used by (Lin et al., 2016) to get sentence representation followed by attention over sentences.
- **BGWA:** Bi-GRU based relation extraction model with word and sentence level attention (Jat et al., 2018).
- **RESIDE:** The method proposed in this paper, please refer Section 5 for more details.

6.3 Evaluation Criteria

Following the prior works (Lin et al., 2016; Feng et al.), we evaluate the models using held-out evaluation scheme. This is done by comparing the relations discovered from test articles with those in Freebase. We evaluate the performance of models with Precision-Recall curve and top-N precision (P@N) metric in our experiments.

7 Results

In this section we attempt to answer the following questions:

Q1. Is RESIDE more effective than existing approaches for distant supervised RE? (7.1)

Q2. What is the effect of ablating different components on RESIDE's performance? (7.2)

Q3. How is the performance affected in the absence of relation alias information? (7.3)

7.1 Performance Comparison

For evaluating the effectiveness of our proposed method, RESIDE, we compare it against the baselines stated in Section 6.2. We use only the neural baselines on GIDS dataset. The Precision-Recall curves on Riedel and GIDS are presented in Figure 3. Overall, we find that RESIDE achieves higher precision over the entire recall range on both the datasets. All the non-neural baselines could not perform well as the features used by them are mostly derived from NLP tools which can be erroneous. RESIDE outperforms PCNN+ATT and BGWA which indicates that incorporating side information helps in improving the performance of the model. The higher performance of BGWA and PCNN+ATT over PCNN shows that attention helps in distant supervised RE. Following (Lin et al., 2016; Liu et al., 2017), we also evaluate our method with different number of sentences. Results summarized in Table 2, show the improved precision of RESIDE in all test settings, as compared to the neural baselines, which demonstrates

	One			Two			All		
	P@100	P@200	P@300	P@100	P@200	P@300	P@100	P@200	P@300
PCNN	73.3	64.8	56.8	70.3	67.2	63.1	72.3	69.7	64.1
PCNN+ATT	73.3	69.2	60.8	77.2	71.6	66.1	76.2	73.1	67.4
BGWA	78.0	71.0	63.3	81.0	73.0	64.0	82.0	75.0	72.0
RESIDE	**80.0**	**75.5**	**69.3**	**83.0**	**73.5**	**70.6**	**84.0**	**78.5**	**75.6**

Table 2: P@N for relation extraction using variable number of sentences in bags (with more than one sentence) in Riedel dataset. Here, One, Two and All represents the number of sentences randomly selected from a bag. RESIDE attains improved precision in all settings. More details in Section 7.1

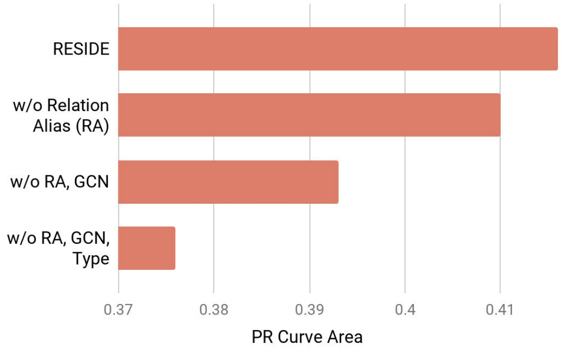

Figure 4: Performance comparison of different ablated version of RESIDE on Riedel dataset. Overall, GCN and side information helps RESIDE improve performance. Refer Section 7.2.

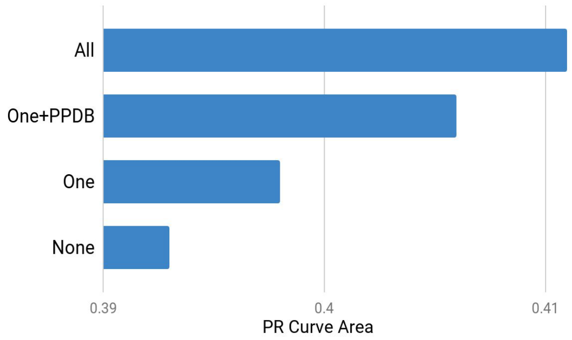

Figure 5: Performance on settings defined in Section 7.3 with respect to the presence of relation alias side information on Riedel dataset. RESIDE performs comparably in the absence of relations from KB.

the efficacy of our model.

7.2 Ablation Results

In this section, we analyze the effect of various components of RESIDE on its performance. For this, we evaluate various versions of our model with cumulatively removed components. The experimental results are presented in Figure 4. We observe that on removing different components from RESIDE, the performance of the model degrades drastically. The results validate that GCNs are effective at encoding syntactic information. Further, the improvement from side information shows that it is complementary to the features extracted from text, thus validating the central thesis of this paper, that inducing side information leads to improved relation extraction.

7.3 Effect of Relation Alias Side Information

In this section, we test the performance of the model in setting where relation alias information is not readily available. For this, we evaluate the performance of the model on four different settings:

- **None:** Relation aliases are not available.
- **One:** The name of relation is used as its alias.
- **One+PPDB:** Relation name extended using Paraphrase Database (PPDB).
- **All:** Relation aliases from Knowledge Base[3]

The overall results are summarized in Figure 5. We find that the model performs best when aliases are provided by the KB itself. Overall, we find that RESIDE gives competitive performance even when very limited amount of relation alias information is available. We observe that performance improves further with the availability of more alias information.

8 Conclusion

In this paper, we propose RESIDE, a novel neural network based model which makes principled use of relevant side information, such as entity type and relation alias, from Knowledge Base, for improving distant supervised relation extraction. RESIDE employs Graph Convolution Networks for

encoding syntactic information of sentences and is robust to limited side information. Through extensive experiments on benchmark datasets, we demonstrate RESIDE's effectiveness over state-of-the-art baselines. We have made RESIDE's source code publicly available to promote reproducible research.

Abstract

Traditional approaches to the task of ACE event detection primarily regard multiple events in one sentence as independent ones and recognize them separately by using sentence-level information. However, events in one sentence are usually interdependent and sentence-level information is often insufficient to resolve ambiguities for some types of events. This paper proposes a novel framework dubbed as **H**ierarchical and **B**ias **T**agging **N**etworks with **G**ated **M**ulti-level **A**ttention Mechanisms (HBTNGMA) to solve the two problems simultaneously. Firstly, we propose a hierarchical and bias tagging networks to detect multiple events in one sentence collectively. Then, we devise a gated multi-level attention to automatically extract and dynamically fuse the sentence-level and document-level information. The experimental results on the widely used ACE 2005 dataset show that our approach significantly outperforms other state-of-the-art methods.

1 Introduction

Event detection (ED) is a crucial subtask of event extraction, which aims to identify event triggers and classify them into specific types from texts. According to the task defined in Automatic Context Extraction[1] (ACE), given the following sentence S1, a robust ED system should be able to recognize two events: a *Die* event triggered by *died* and an *Attack* event triggered by *fired*.

S1: *In Baghdad, a cameraman* ***died*** *when an American tank* ***fired*** *on the Palestine Hotel.*

To this end, most methods (Ahn, 2006; Hong et al., 2011; Chen et al., 2015; Nguyen and Grishman, 2016; Liu et al., 2017) model ED as a multi-classification task and predict every word in the sentence separately to determine whether it triggers a specific type of event by using sentence-level information. However, they face two problems: (1) Neglecting event interdependency by separately predicting each event; (2) Sentence-level information is usually insufficient to resolve ambiguities for some types of events. In the following, we will use examples to illustrate these two problems specifically.

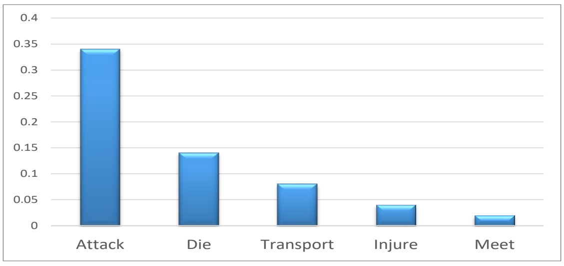

Figure 1: Top 5 event types that co-occur with *Attack* event in the same sentence in ACE 2005.

S2: *The project leader was* ***fired*** *for the* ***bankruptcy*** *of the subsidiary company.*

Event interdependency: In S1, *fired* triggers an *Attack* event, while it triggers an *End-Position* event in S2. Because of the ambiguity, a traditional approach may mislabel *fired* in S1 as a trigger of *End-Position* event. However, if we know *died* triggers a *Die* event in S1, which is easier to disambiguate, we tend to predict that *fired* triggers an *Attack* event. The reason is that the events mentioned in the same sentence tend to be semantically coherent and a *Die* event usually co-occurs with an *Attack* event. The similar phenomenon can be found in S2. We conduct a statistical analysis on ACE 2005 dataset, and find that nearly 30% sentences contain multiple events which is a proportion we can not ignore. To give an intuitive illustration, the top 5 event types that co-occur with *Attack* event in the same sentence are shown in Figure 1. We call such clues as event

Brussels, Belgium, October 31 - November 4, 2018.

interdependency. Some works (Li et al., 2013; Yang and Mitchell, 2016; Liu et al., 2016b) rely on a set of elaborately designed features and complicated natural language processing (NLP) tools to capture event interdependency. However, these methods lack generalization, take a large amount of human effort and are prone to error propagation problem. Though Nguyen et al. (2016) use a Recurrent Neural Networks (RNN) based classification model to capture the event interdependency between current event candidate and the former (left) predicted events, they miss the event interdependency between current event candidate and the later (right) predicted events, and the later events can not change the type of current event. The reason is that they classify the words of the sentence from left to right one by one and only use the former events to predict the later event types. We claim that both of the former and later predicted events are important to predict the event type of current trigger candidate. For example in S1, the former predicted *Die* event can help us to predict that *fired* triggers an *Attack* event, while in S2 the later predicted *bankruptcy* event can help us to predict that *fired* triggers an *End-Position* event. Thus, how to use a neural-based model to capture all event interdependencies (the interdependencies between the current event candidate and its former/later predicted events) in the whole sentence is a challenging problem.

Sentence-level and document-level information: Besides event interdependency, knowing that *American tank* is a weapon can also give us additional evidence to predict that *fired* triggers an *Attack* event in S1. Similarly in S2, knowing that *project leader* is a job title can also help us to predict that *fired* triggers an *End-Position* event. We call such clues as sentence-level information. However, sometimes it is difficult even for people to classify event types from an isolated sentence. We must resort to document-level information. For example, considering the following sentence with an ambiguous word *left*:

S3: *He **left** the company.*

It is hard to tell *left* triggers a *Transport* event which means that he left the place, or an *End-Position* event which means that he resigned from the company. However, if we read the whole document, a clue like "*He planned to go shopping before he went home, because he got off work early today.*" would give us more confidence to believe that *left* triggers a *Transport* event, while a clue like "*They held a party for his retirement.*" would indicate the aforementioned event is an *End-Position* event. We call such clues as document-level information. Moreover, the confidence of sentence-level and document-level information should be taken into consideration when using them together to construct a broader range of contextual information. For example in S3, document-level information will give us more evidence, while in S1 sentence-level information is enough to disambiguate the types of events. There have been some feature-based studies (Ji and Grishman, 2008; Liao and Grishman, 2010; Huang and Riloff, 2012) that construct rules to capture document-level information for improving sentence-level ED. However, they suffer from two problems: (1) The features they used often need to be manually designed and may involve error propagation from existing NLP tools; (2) Sentence-level and document-level information are integrated by a large number of fixed rules, which is complicated to construct and it will be far from complete. Thus, how to use a neural-based model to automatically extract sentence-level and document-level information and dynamically integrate them is another challenging problem.

In this paper, we propose a **H**ierarchical and **B**ias **T**agging **N**etworks with **G**ated **M**ulti-level **A**ttention Mechanisms (HBTNGMA) to address the two problems stated above simultaneously. To capture event interdependency and collectively detect multiple events in one sentence, we propose a hierarchical and bias tagging networks for event detection. In which, we exploit a hierarchical RNN-based tagging layer to capture all event interdependencies in the whole sentence and devise a bias objective function to reinforce the influence of trigger tags on the model[2]. To use a broader range of contextual information of the event candidate, we propose a gated multi-level attention, which can automatically extract sentence-level and document-level information and integrate them dynamically. In summary, the contributions of this paper are as follows:

- We propose a novel framework for event detection, which can automatically extract

---

[2] Compared with the task like Named Entities Recognition, the number of "O" tags is much more than the number of trigger tags in ED task, i.e. if we use the non-bias objective function and tag all words in one sentence as "O", we will gain a low loss. Thus we devise a bias objective function.

and dynamically integrate sentence-level and document-level information and collectively detect multiple events in one sentence.

- To capture event interdependency, we exploit a hierarchical and bias tagging networks to detect multiple events in one sentence collectively. To automatically extract and dynamically integrate contextual information, we devise a gated multi-level attention Mechanisms. To our knowledge, this is the first work to jointly use event interdependency, sentence-level information and document-level information via a neural tagging schema for event detection task.
- We conduct extensive experiments on a widely used ACE 2005 dataset, and the experimental results show that our approach significantly outperforms other state-of-the-art methods [3].

2 Task Description

Event detection (ED) is a crucial subtask of event extraction (EE). In this paper, we focus on ED task defined in ACE evaluation, where an event is defined as a specific occurrence involving one or more participants. Firstly, we introduce some ACE terminology to facilitate the understanding of this task: **Event trigger**: the main word or phrase that most clearly expresses the occurrence of an event. **Event arguments**: the mentions that are involved in an event (viz., participants). **Event mention**: a phrase or sentence within which an event is described, including a trigger and arguments.

Given an English text document, an ED system should identify event triggers and categorize their event types for each sentence. For instance, in the sentence "*He died in the hospital*", an ED system is expected to detect a *Die* event along with the trigger word "*died*". The ACE 2005 evaluation defines 8 event types and 33 subtypes, such as *Attack* or *Die*. Following previous works (Li et al., 2013; Chen et al., 2015; Liu et al., 2017; Nguyen and Grishman, 2016), we categorize triggers into these 33 subtypes.

3 Methodology

In this paper, we formulate event detection as a sequence labelling task. As shown in Figure 2, we label all words in one sentence collectively via a **H**ierarchical and **B**ias **T**agging **N**etworks with **G**ated **M**ulti-level **A**ttention Mechanisms (HBT-NGMA). We assign a tag for each word to indicate whether it triggers a specific type of event. We adopt the "BIO" tags schema, where tag "O" represent the "other" tag which means that the corresponding word does not trigger any event, tags "B-EventType" and "I-EventType" represent the "Begin-EventType" and "Inside-EventType" tag respectively. "EventType" means that the word triggers a specific type of event. "B" and "I" represent the position of the word in a trigger to solve the problem that a trigger word contains multiple words such as "take over", "go off" and so on. Thus, the total number of tags is $N_t = 2 * |N_{eventType}| + 1$, where $|N_{eventType}|$ is the size of the predefined event types and $|N_{eventType}| = 33$ in this paper as stated above.

Figure 2 describes the architecture of HBT-NGMA, which primarily involves the following four components: (i) embedding layer, which transforms each word into a continuous vector; (ii) BiLSTM layer, which uses a Bidirectional Long Short Term Memory (BiLSTM) to encode the semantics of each word considering the forward and backward information; (iii) gated multi-level attention, in which we propose a sentence-level and document-level attention to automatically extract sentence-level and document-level information respectively, and we devise a fusion gate to dynamically integrate them as context information; and (iv) Hierarchical tagging layer, in which we propose two Tagging LSTM (TLSTM1 and TLSTM2) and a tagging attention to automatically capture the event interdependency and tag all the words of the sequence collectively.

3.1 Embedding Layer

This paper uses the learned word embeddings as the source of basic features. Specifically, we use the Skip-gram model (Mikolov et al., 2013) to learn word embeddings on the NYT corpus.

Given a document $d = \{s_1, s_2, ..., s_i, ..., s_{N_s}\}$, where N_s is the number of sentences in the document. The i-th sentence s_i can be represented as token sequence $s_i = \{w_1, w_2, ..., w_t, ..., w_{N_w}\}$, where N_w is length of the sentence and w_t is the t-th token of the sentence. Assume that the word embedding for token w_t is e_t and we use it as the input of the following layer.

---

[3] Our source code, including all hyper-parameter settings and pre-trained word embeddings, is openly available at https://github.com/yubochen/NBTNGMA4ED

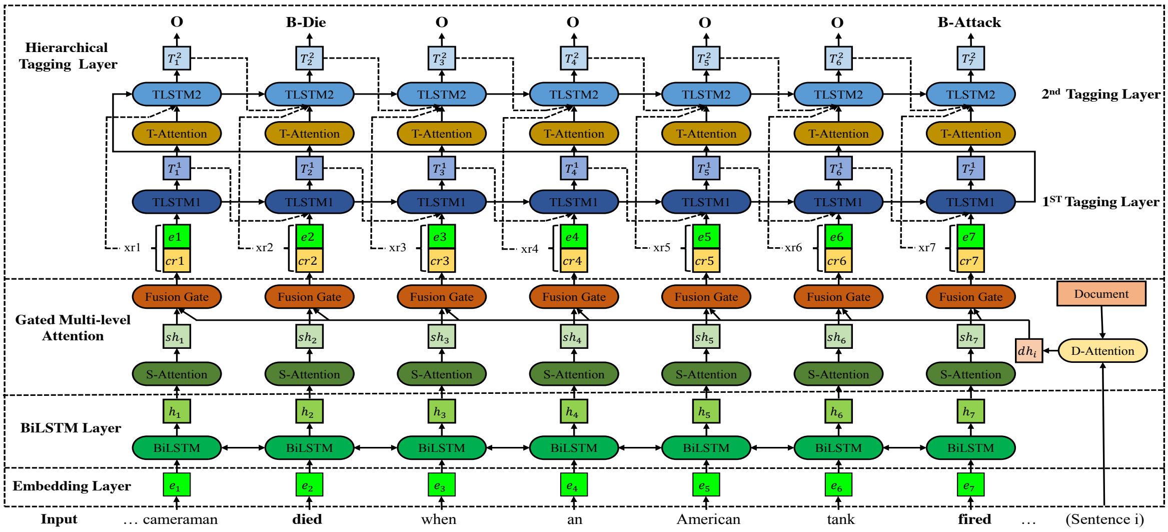

Figure 2: The architecture of our proposed hierarchical and bias tagging networks with gated multi-level attention.

3.2 BiLSTM Layer

In sequence labelling problems, the BiLSTM has been proven effective to capture the semantic information of each word (Lample et al., 2016). In this paper, we use the LSTM unit as described in (Zaremba and Sutskever, 2014). For each word w_t, the forward LSTM encodes w_t by considering the contextual information from word w_1 to w_t, which is marked as $\overrightarrow{h}_t$. Similarly, the backward LSTM encodes w_t based on the contextual information from w_{N_w} to w_t, which is marked as $\overleftarrow{h}_t$. Finally, we concatenate $\overrightarrow{h}_t$ and $\overleftarrow{h}_t$ to represent the information of the word w_t, denoted as $h_t = [\overrightarrow{h}_t, \overleftarrow{h}_t]$, and we concatenate $\overrightarrow{h}_{N_w}$ and $\overleftarrow{h}_1$ to represent the encoding information of the whole sentence s_i, denoted as $h_{s_i} = [\overrightarrow{h}_{N_w}, \overleftarrow{h}_1]$.

3.3 Gated Multi-level Attention

Gated multi-level attention primarily involves the following three components: (i) sentence-level attention layer, which automatically captures important sentence-level information by considering the current word; (ii) document-level attention layer, which automatically captures important document-level information by considering the current sentence; and (iii) fusion gate layer, which use a fusion gate to dynamically integrate sentence-level and document-level information.

Sentence-level Attention Layer

Sentence-level attention layer aims to capture the important clues in sentence level. For each candidate word w_t in the sentence, its sentence-level semantic information sh_t is calculated as follows:

$$sh_t = \sum_{k=1}^{N_w} \alpha_s^k h_k \tag{1}$$

where α_s^k is the weight of each word representation h_k. In this paper, we define α_s^k as following:

$$\alpha_s^k = \frac{exp(z_s^k)}{\sum_{j=1}^{N_w} exp(z_s^j)} \tag{2}$$

where z_s^k is the relatedness between the t-th word representation h_t and the k-th word representation h_k, modeled by bilinear attention as:

$$z_s^k = \tanh(h_t W_{sa} h_k^T + b_{sa}) \tag{3}$$

where W_{sa} is the weight matrix and b_{sa} is the bias term. Following above sentence-level attention mechanism, we can get the sentence-level information for each word w_t by considering the semantic information of the word w_t.

Document-level Attention Layer

Similar to sentence-level attention, document-level attention captures the vital clues in the document level. The document-level semantic information dh_i for i-th sentence calculated as follows:

$$\begin{aligned} dh_i &= \sum_{k=1}^{N_s} \alpha_d^k h_{s_k} \\ \alpha_d^k &= \frac{exp(z_d^k)}{\sum_{j=1}^{N_s} exp(z_d^j)} \\ z_d^k &= \tanh(h_{s_i} W_{da} h_{s_k}^T + b_{da}) \end{aligned} \tag{4}$$

where α_d^k is the weight of each sentence representation h_{s_k}, z_d^k is the relatedness between i-th sentence representation h_{s_i} and the k-th sentence representation h_{s_k}, W_{da} is the weight matrix and b_{da} is the bias term. Compared with sentence-level information, all words in the i-th sentence have the same document-level information dh_i.

Fusion Gate Layer

We devise a fusion gate to dynamically integrate sentence-level information sh_t and document-level information dh_i for the t-th word w_t in the i-th sentence s_i, and calculate the contextual information representation cr_t as follows:

$$cr_t = (G_t \odot sh_t) + ((1 - G_t) \odot dh_i) \tag{5}$$

where G_t is a fusion gate aims to model the confidence of clues provided by sentence-level information sh_t and document-level information dh_i, which is calculated as follows:

$$G = \sigma(W_g[sh_t, dh_i] + b_g) \tag{6}$$

where W_g is the weight matrix and b_g is the bias term, σ is a $sigmoid$ function and $\odot$ denotes element-wise multiplication. Finally, the contextual information cr_t of word w_t and its word embedding e_t are concatenated into a single vector $xr_t = [e_t, cr_t]$ as the feature representation of w_t.

3.4 Hierarchical Tagging Layer

In hierarchical tagging layer, we propose two Tagging LSTMs (TLSTM1 and TLSTM2) and a tagging attention to automatically capture the event interdependency and tag the sequence collectively.

The First Tagging Layer: TLSTM1

When detecting the tag of word w_t in TLSTM1, the inputs are: the feature representation xr_t obtained from embedding layer and gated multi-level attention layer, former predicted tag vector T^1_{t-1}, and former hidden vector h^1_{t-1} in TLSTM1. The detail operations are defined as follows:

$$\begin{aligned}
i^1_t &= \sigma(W^1_{i_x} xr_t + W^1_{i_h} h^1_{t-1} + W^1_{i_T} T^1_{t-1}) \\
f^1_t &= \sigma(W^1_{f_x} xr_t + W^1_{f_h} h^1_{t-1} + W^1_{f_T} T^1_{t-1}) \\
o^1_t &= \sigma(W^1_{o_x} xr_t + W^1_{o_h} h^1_{t-1} + W^1_{o_T} T^1_{t-1}) \\
u^1_t &= \varphi(W^1_{u_x} xr_t + W^1_{u_h} h^1_{t-1} + W^1_{u_T} T^1_{t-1}) \\
c^1_t &= i^1_t \odot u^1_t + f^1_t \odot c^1_{t-1} \\
h^1_t &= o^1_t \odot \varphi(c^1_t) \\
T^1_t &= W^1_T h^1_t + b^1_T
\end{aligned} \tag{7}$$

Where i_t is an input gate, u_t is an input modulation gate, f_t is a forget gate, o_t is an output gate, c_t is a memory cell and T^1_t is a predicted tagging vector.

The Second Tagging Layer: TLSTM2

Though the TLSTM1 can capture the interdependency between current event candidate and the former predicted event tags, it can not capture the interdependency between the current event candidate and the later predicted event tags. Thus, we devise a second tagging layer (TLSTM2) upon the LSTM1 to capture the interdependency between the current event candidate and both of former and later predicted event tags from TLSTM1. When detecting the tag of word w_t in TLSTM2, the inputs are: the feature representation xr_t, former predicted tag vector T^2_{t-1} in TLSTM2, the preliminary predicted information T^a_t calculated from TLSTM1, and former hidden vector h^2_{t-1} in TLSTM2. The detail operations are defined as follows:

$$\begin{aligned}
i^2_t &= \sigma(W^2_{i_x} xr_t + W^2_{i_h} h^2_{t-1} + W^2_{i_T} T^2_{t-1} + W^2_{i_a} T^a_t) \\
f^2_t &= \sigma(W^2_{f_x} xr_t + W^2_{f_h} h^2_{t-1} + W^2_{f_T} T^2_{t-1} + W^2_{f_a} T^a_t) \\
o^2_t &= \sigma(W^2_{o_x} xr_t + W^2_{o_h} h^2_{t-1} + W^2_{o_T} T^2_{t-1} + W^2_{o_a} T^a_t) \\
u^2_t &= \varphi(W^2_{u_x} xr_t + W^2_{u_h} h^2_{t-1} + W^2_{u_T} T^2_{t-1} + W^2_{u_a} T^a_t) \\
c^2_t &= i^2_t \odot u^2_t + f^2_t \odot c^2_{t-1} \\
h^2_t &= o^2_t \odot \varphi(c^2_t) \\
T^2_t &= W^2_T h^2_t + b^2_T
\end{aligned} \tag{8}$$

The unit structure of TLSTM2 is similar to the unit of TLSTM1. The parts need to pay attention are follows: (1) the initial hidden input h^2_0 of the TLSTM2 is the last hidden vector $h^1_{N_w}$ of the TLSTM1. (2) the preliminary predicted information T^a_t is calculated from TLSTM1 by using a tagging attention as follows.

Tagging Attention

Tagging attention aims to automatically encode the preliminary predicted information T^a_t for the word w_t and the details are as follows:

$$\begin{aligned}
T^a_t &= \sum\nolimits_{k=1}^{N_w} \alpha^k_T T^1_k \\
\alpha^k_T &= \frac{exp(z^k_T)}{\sum^{N_w}_{j=1} exp(z^j_T)} \\
z^k_T &= \tanh(T^1_t W_{ta} (T^1_k)^T + b_{ta})
\end{aligned} \tag{9}$$

where α^k_T is the weight of each preliminary predicted tag T^1_k, z^k_T is the relatedness between t-th preliminary predicted tag T^1_t and the k-th preliminary predicted tag T^1_k, W_{ta} is the weight matrix and b_{ta} is the bias term.

The final normalized tag probability for word w_t is based on the predicted tag vector T^2_t from

TLSTM2 and computed as follows:

$$\begin{aligned} O_t &= W_y T_t^2 + b_y \\ p(O_t^i|s_j,\theta) &= \frac{exp(O_t^i)}{\sum_{k=1}^{N_t} exp(O_t^k)} \end{aligned} \tag{10}$$

where $p(O_t^i|s_j,\theta)$ is the probability that assigning the i-th tag to word w_t in sentence s_j when parameters is θ, and N_t is the total number of tags.

3.5 Training with Bias Objective Function

In one sentence, the number of “O” tags is much more than the number of trigger tags. Thus, we devise a bias objective function $J(\theta)$ to reinforce the influence of trigger tags on the model, which is defined as follows:

$$\begin{aligned} J(\theta) = max \sum\nolimits_{j=1}^{N_{ts}} \sum\nolimits_{t=1}^{N_w} (\log p(O_t^{y_t}|s_j,\theta) \cdot I(O) \\ + \alpha \log p(O_t^{y_t}|s_j,\theta) \cdot (1 - I(O))) \end{aligned} \tag{11}$$

where N_{ts} is the number of training sentences, N_w is the length of sentence s_j, $p(O_t^{y_t}|s_j,\theta)$ is the normalized probabilities of tags defined in Formula 10 and y_t is the golden tag of word w_t in sentence s_j, α is the bias weight and the larger α will bring the greater influence of trigger tags on the model. Besides, $I(O)$ is a switching function to distinguish the loss of tag “O” and trigger tags, which is defined as follows:

$$I(O) = \begin{cases} 1, & if \quad tag = \text{“O”} \\ 0, & if \quad tag \neq \text{“O”} \end{cases} \tag{12}$$

To compute the network parameter θ, we maximize the log likelihood $J(\theta)$ through stochastic gradient descent over shuffled mini-batches with the Adadelta (Zeiler, 2012) update rule.

4 Experiments

4.1 Experimental Setting

Dataset and Evaluation Metrics

We conduct experiments on the widely used ACE 2005 dataset. For comparison, as the same as previous works (Liao and Grishman, 2010; Li et al., 2013; Chen et al., 2015; Nguyen et al., 2016; Liu et al., 2017), we used the same test set with 40 documents and the same development set with 30 documents and the rest 529 documents are used for training. Finally, we use *Precision* (P), *Recall* (R) and *F measure* (F_1) as the evaluation metrics as the same as previous work.

Hyper-parameter Setting

Hyper-parameters are tuned on the development dataset by grid search. We train the word embedding using Skip-gram algorithm [4] on the NYT corpus [5]. We set the dimension of word embeddings as 100, the dimension of tag vector as 20, all the size of LSTM in BiLSTM layer, TLSTM1 and TLSTM2 layer as 100, the bias parameter α in Formula 11 as 5, the batch size as 20, the learning rate as 0.001, the dropout rate as 0.5.

4.2 Our Method vs. State-of-the-art Methods

We select the following state-of-the-art methods for comparison, which can be classified as two types: separate and collective methods:

Separate methods: 1) **Li’s MaxEnt**: the method that detects events in one sentence separately by using human-designed features (Li et al., 2013). 2) **Liao’s CrossEvent** : the method that uses cross event information (Liao and Grishman, 2010). 3) **Hong’s CrossEntity**: the method that uses cross entity information (Hong et al., 2011). 4) **Chen’s DMCNN**: the dynamic multi-pooling convolutional neural networks method (Chen et al., 2015). 5) **Chen’s DMCNN+**: the DMCNN method argumented with automatically labeled data (Chen et al., 2017). 6) **Liu’s FrameNet** : the method that leverages FrameNet as extended training data to improve ED (Liu et al., 2016a). 7) **Liu’s ANN-Aug**: the method that use the annotated argument information via a supervised attention to improve ED (Liu et al., 2017).

Collective methods: 1) **Li’s Structure**: the method that collectively detects events by using human-designed features (Li et al., 2013). 2) **Yang’s JointEE**: the method that detects events and entities in one sentence jointly based on human-designed features (Yang and Mitchell, 2016). 3) **Nguyen’s JRNN**: the method that exploits a RNN model to collectively detects events by only using sentence-level information (Nguyen et al., 2016). 4) **Liu’s PSL** : the method that uses a probabilistic soft logic to detect events by using human-designed features (Liu et al., 2016b).

Experimental results are shown in Table 1. From the table, we have the following observations: (1) Among all the methods, our HBT-NGMA achieves the best performance. It can improve the best collective method’s F_1 by

---

[5] https://catalog.ldc.upenn.edu/LDC2008T19

Methods	P	R	F_1
Li's MaxEnt (2013)	74.5	59.1	65.9
Liao's CrossEvent (2010)	68.7	68.9	68.8
Hong's CrossEntity (2011)	72.9	64.3	68.3
Chen's DMCNN (2015)	75.6	63.6	69.1
Chen's DMCNN+ † (2017)	75.7	66.0	70.5
Liu's FrameNet † (2016a)	77.6	65.2	70.7
Liu's ANN-Aug † (2017)	76.8	67.5	71.9
Li's Structure (2013)	73.7	62.3	67.5
Yang's JointEE (2016)	75.1	63.3	68.7
Nguyen's JRNN (2016)	66.0	73.0	69.3
Liu's PSL (2016b)	75.3	64.4	69.4
Ours HBTNGMA	**77.9**	**69.1**	**73.3**

Table 1: Overall performance on blind test data. The upper table illustrates the performance of separate ED systems and the lower illustrates collective ED systems. † means the method that uses external resources.

3.9% (*Liu's PSL*) and improve the best separate method's F_1 by 1.4% (*Liu's ANN-Aug*) although *Liu's ANN-Aug* uses FrameNet as external resources. We also perform a t-test ($p \leqslant 0.05$), which indicates that our method significantly outperforms all of the compared methods. (2) Comparing our HBTNGMA to separate methods, it achieves a better performance. It proves that collectively predicting multiple events in one sentence is effective. (3) Our HBTNGMA outperforms feature-based collective methods (*Li's Structure*, *Yang's JointEE* and *Liu's PSL*), it proves that our automatically learned features can efficiently capture semantic information from plain texts. (4) Compared with Nguyen's JRNN, HBTNGMA gains a 4.0% improvement on F_1 value. The reason is that Nguyen's JRNN only uses sentence-level information while our model exploits multi-level information, and our model can capture the interdependencies between the current event candidate and its former/later predicted events simultaneously.

4.3 Effect of The Hierarchical and Bias Tagging Networks

In this subsection, we prove the effectiveness of hierarchical and bias tagging networks for collective ED. We select following methods as baselines: 1) **LSTM+Softmax**: a simplified version of our HBTNGMA, which directly use a softmax layer to separately detect events after we get the feature representation xr_t of each word w_t. 2) **LSTM+CRF**: the method is similar to our HBTNGMA, which uses a CRF layer to tag words instead of our Hierarchical TLSTM (HTLSTM) tagging layer. 3) **LSTM+TLSTM**: the method is similar to our HBTNGMA, which only use a TLSTM1 and takes all tags have same influence in training loss (i.e. α in is set as 1) . 4) **LSTM+HTLSTM**: the method is similar to our HBTNGMA, which use a HTLSTM (TLSTM1+TLSTM2) and do not use bias objective function. And *LSTM+HTLSTM+Bias* is our proposed HBTNGMA. Moreover, we divide the testing data into two parts according the event number in a sentence (single event and multiple events) and perform evaluations separately.

Method	1/1	1/N	all
LSTM+Softmax	74.7	44.6	66.8
LSTM+CRF	75.1	49.5	68.5
LSTM+TLSTM	76.8	51.2	70.2
LSTM+HTLSTM	77.9	57.3	72.4
LSTM+HTLSTM+Bias	**78.4**	**59.5**	**73.3**

Table 2: Performance of different ED systems. 1/1 means one sentence that only has one event and 1/N means that one sentence has multiple events.

Table 2 shows the results. And we have the following observations: 1) Compared with *LSTM+Softmax*, LSTM-based collective ED methods (*LSTM+CRF*, *LSTM+TLSTM*, *LSTM+HTLSTM*, *LSTM+HTLSTM+Bias*) achieves a better performance. Surprisingly, the *LSTM+HTLSTM+Bias* yields a 14.9% improvement on the sentence contains multiple events over the *LSTM+Softmax*. It proves neural tagging schema is effective for ED task especially for the sentences contain multiple events. 2) The *LSTM+TLSTM* achieve better performances than *LSTM+CRF*. And the *LSTM+HTLSTM* achieve better performances than *LSTM+TLSTM*. The results prove the effectiveness of the TLSTM layer and HTLSTM layer. 3) Compared with *LSTM+HTLSTM*, the *LSTM+HTLSTM+Bias* gains a 0.9% improvement on all sentence. It demonstrates the effectiveness of our proposed bias objective function.

4.4 Effect of The Gated Multi-level Attention

This subsection studies the effectiveness of our gated multi-level attention. We adopt same architecture of our HBTNGMA as shown in Figure 2 with different level clues as baselines: 1) **Word Only** is the method only uses word embedding e_t to identify events. 2) **Word+SA** uses sentence-level attention to capture important sentence-level information as additional clues. 3) **Word+DA** uses document-level attention to capture important document-level information as additional clues. 4) **Word+Average MA** uses both of sentence-level and document-level attention to capture multi-level information and integrate them with a average gate (all the dimension of the fusion gate are set as 0.5), which is a special case of our proposed HBTNGMA. And *Word+Gated MA* is our proposed HBTNGMA model.

Method	P	R	F_1
Word Only	70.1	63.4	66.6
Word+SA	75.6	68.2	71.7
Word+DA	73.1	65.8	69.3
Word+Average MA	76.5	68.7	72.4
Word+Gated MA	**77.9**	69.1	**73.3**

Table 3: Performance of gated multi-level attention.

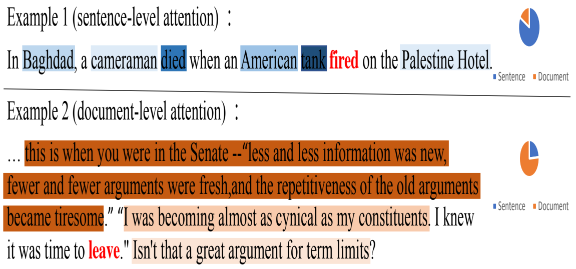
Results are shown in Table 3. From the results, we have the following observations: 1) Compared with *word only*, *Word+SA* achieves a better performance. We can make the same observation when comparing *Word+DA* with *word only*. It proves that both sentence-level and document-level information are helpful for ED task. 2) Compared with *Word+DA*, *Word+SA* achieves a better performance. It proves that in most of cases sentence-level information provides more clues than document-level information. 3) *Word+Gated MA* gains a 0.9% improvement than *Word+Average MA*. It demonstrates that the effectiveness of our fusion gate to dynamically integrate clues from multiple levels.

4.5 Case Study

Interesting Cases: Our neural tagging schema not only can model the interdependency between multiple events in one sentence as proved in Subsection 4.3, but also the "BIO" tagging schema can solve the multiple words trigger inherently. We conduct a statistical analysis on the experimental results, and find that nearly 50% cases with multiple word trigger was solved by our model. Example is shown in Figure 3.

Figure 3: The example of case solved by our model.

Attention Visualization: As limited of space, we take one sentence with high sentence-level gated weight (example 1) and one sentence with high document-level gated weight (example 2) as examples for attention visualization. As shown in Figure 4, in example 1, sentence-level information plays more important role in disambiguating *fired*, and the words (*tank*, *died* and *Baghdad*) give us ample evidence to predict that *fired* triggers an *Attack* event. While document-level information plays a more important role in example 2. The surrounding sentence "*this is ... tiresome*." gives us more confidence to predict that *leave* triggers an *End-Position* event.



Example 1 (sentence-level attention)：

In Baghdad, a cameraman died when an American tank fired on the Palestine Hotel.

Example 2 (document-level attention)：

... this is when you were in the Senate --"less and less information was new, fewer and fewer arguments were fresh,and the repetitiveness of the old arguments became tiresome." "I was becoming almost as cynical as my constituents. I knew it was time to leave." Isn't that a great argument for term limits?

Figure 4: Attention visualization. The heat map indicate the contextual attention. Blue for sentence-level and orange for document-level. The pie chart indicate the fusion gate weight.

5 Related Works

Event detection is an increasingly hot and challenging research topic in NLP. Generally, existing approaches could roughly be divided into two groups: separate and collective methods.

Separate methods: These methods regard multiple events in one sentence as independent ones and recognize them separately. These methods include feature-based methods which exploit a diverse set of strategies to convert classification clues into feature vectors (Ahn, 2006; Ji and Grishman, 2008; Liao and Grishman, 2010; Hong et al., 2011; Huang and Riloff, 2012), and neural-based methods which use neural networks to automatically capture clues from plain texts (Chen et al., 2015; Nguyen and Grishman, 2015; Feng et al., 2016; Nguyen and Grishman, 2016; Chen et al., 2017; Duan et al., 2017; Liu et al., 2017). Though effective these methods, they neglect event interdependency by separately predicting each event.

Collective methods: These methods try to model the event interdependency and detect multiple events in one sentence collectively. However, nearly all of these methods are feature-based methods (McClosky et al., 2011; Li et al., 2013; Yang and Mitchell, 2016; Liu et al., 2016b), which rely on elaborately designed features and suffer error propagation from existing NLP tools. Nguyen et al. (2016) exploits a neural-based method to detect multiple events collectively. However, they only use the sentence-level information and neglect document-level clues, and can only capture the interdependencies between the current event candidate and its former predicted events. Moreover, there method can not handle the multiple words trigger problem.

6 Conclusion

This paper proposes a novel framework for event detection, which can automatically extract and dynamically integrate sentence-level and document-level information and collectively detect multiple events in one sentence. A hierarchical and bias tagging networks is proposed to detect multiple events in one sentence collectively. A gated multi-level attention is devised to automatically extract and dynamically integrate contextual information. The experimental results on the widely used dataset prove the effectiveness of the proposed method.

Valency-Augmented Dependency Parsing

Abstract

We present a complete, automated, and efficient approach for utilizing valency analysis in making dependency parsing decisions. It includes extraction of valency patterns, a probabilistic model for tagging these patterns, and a joint decoding process that explicitly considers the number and types of each token's syntactic dependents. On 53 treebanks representing 41 languages in the Universal Dependencies data, we find that incorporating valency information yields higher precision and F1 scores on the core arguments (subjects and complements) and functional relations (e.g., auxiliaries) that we employ for valency analysis. Precision on core arguments improves from 80.87 to 85.43. We further show that our approach can be applied to an ostensibly different formalism and dataset, Tree Adjoining Grammar as extracted from the Penn Treebank; there, we outperform the previous state-of-the-art labeled attachment score by 0.7. Finally, we explore the potential of extending valency patterns beyond their traditional domain by confirming their helpfulness in improving PP attachment decisions.[1]

1 Introduction

Many dependency parsers treat attachment decisions and syntactic relation labeling as two independent tasks, despite the fact that relation labels carry important subcategorization information. For example, the number and types of the syntactic arguments that a predicate may take is rather restricted for natural languages — it is not common for an English verb to have more than one syntactic subject or more than two objects.

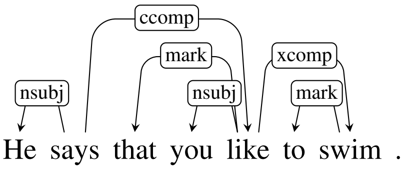

Figure 1: Sample annotation in UD, encoding the core valency pattern nsubj ⋄ ccomp for *says*, nsubj ⋄ xcomp for *like*, and so on (see §2-4)

In this work, we present a parsing approach that explicitly models subcategorization of (some) syntactic dependents as *valency patterns* (see Fig. 1 for examples), and operationalize this notion as extracted supertags. An important distinction from prior work is that our definition of valency-pattern supertags is relativized to a user-specified subset of all possible syntactic relations (see §3). We train supertaggers that assign probabilities of potential valency patterns to each token, and leverages these probabilities during decoding to guide our parsers so that they favor more linguistically plausible output structures.

We mainly focus on two subsets of relations in our analysis, those involving core arguments and those that represent functional relations, and perform experiments over a collection of 53 treebanks in 41 languages from the Universal Dependencies dataset (UD; Nivre et al., 2017). Our valency-aware parsers improve upon strong baseline systems in terms of output linguistic validity, measured as the accuracy of the assigned valency patterns. They also have higher precision and F1 scores on the subsets of relations under analysis, suggesting a potentially controlled way to balance precision-recall trade-offs.

We further show that our approach is not limited to a particular treebank annotation style. We apply our method to parsing another grammar formalism, Tree Adjoining Grammar, where dependency and valency also play an important role in both theory and parser evaluation. Our parser reaches a new state-of-the-art LAS score of 92.59, with more than 0.6 core-argument F1-score improve-

Brussels, Belgium, October 31 - November 4, 2018.

ment over our strong baseline parser.

Finally, we demonstrate the applicability of our valency analysis approach to other syntactic phenomena less associated with valency in its traditional linguistic sense. In a case study of PP attachment, we analyze the patterns of two syntactic relations commonly used in PP attachment, and include them in the joint decoding process. Precision of the parsers improves by an absolute 3.30% on these two relation types.

2 Syntactic Dependencies and Valencies

According to Nivre (2005), the modern dependency grammar can be traced back to Tesnière (1959), with its roots reaching back several centuries before the Common Era. The theory is centered on the notion of *dependency*, an asymmetrical relation between words of a sentence. Tesnière distinguishes three node types when analyzing simple predicates: verb equivalents that describe actions and events, noun equivalents as the arguments of the events, and adverb equivalents for detailing the (temporal, spatial, etc.) circumstances. There are two types of relations: (1) verbs dominate nouns and adverbs through a dependency relation; (2) verbs and nouns are linked through a *valency* relation. Tesnière compares a verb to an atom: a verb can attract a certain number of arguments, just as the valency of an atom determines the number of bonds it can engage in (Ágel and Fischer, 2015). In many descriptive lexicographic works (Helbig and Schenkel, 1959; Herbst et al., 2004), valency is not limited to verbs, but also includes nouns and adjectives. For more on the linguistic theory, see Ágel et al. (2003, 2006).

Strictly following the original notion of valency requires distinguishing between arguments and adjuncts, as well as obligatory and optional dependents. However, there is a lack of consensus as to how these categorizations may be distinguished (Tutunjian and Boland, 2008), and thus we adopt a more practical definition in this paper.

3 Computational Representation

Formally, we fix a set of syntactic relations $\mathcal{R}$, and define the *valency pattern* of a token w_i with respect to $\mathcal{R}$ as the linearly-ordered[2] sequence $a_{-j} \cdots a_{-1} \diamond a_1 \cdots a_k$: the $\diamond$ symbol denotes the center word w_i, and each a_l asserts the existence of a word w dominated by w_i via relation $a_l \in \mathcal{R}$, $w_i \xrightarrow{a_l} w$. For a_l and a_m, when $l < m$, the syntactic dependent for a_l linearly precedes the syntactic dependent for a_m. As an example, consider the UD-annotated sentence in Fig. 1. The token *says* has a core-relation[3] valency pattern nsubj $\diamond$ ccomp, and *like* has the pattern nsubj $\diamond$ xcomp. If we consider only functional relations, both *like* and *swim* have the pattern mark $\diamond$.[4] We sometimes employ the abbreviated notation $\alpha^L \diamond \alpha^R$, where α indicates a sequence and the letters L and R distinguish left dependencies from right dependencies.

Dataset	Subset	Syntactic Relations
UD	Core	nsubj, obj, iobj, csubj, ccomp, xcomp
	Func.	aux, cop, mark, det, clf, case
	PP (§8)	nmod, obl
TAG	Core	0 (subject), 1 (object), 2 (indirect object)
	Co-head	CO

Table 1: Sets of syntactic relations we used for valency analysis. UD subsets come from the official categorization in the annotation guidelines.

We make our definition of valency patterns dependent on choice of $\mathcal{R}$ not only because some dependency relations are more often obligatory and closer to the original theoretical definition of valency, but also because the utility of different types of syntactic relations can depend on the downstream task. For example, purely functional dependency labels are semantically vacuous, so they are often omitted in the semantic representations extracted from dependency trees for question answering (Reddy et al., 2016, 2017). There are also recent proposals for parser evaluation that downplay the importance of functional syntactic relations (Nivre and Fang, 2017).

---

[2] Our approach, whose full description is in §5, can be adapted to cases where linear ordering is de-emphasized. The algorithm merely requires a distinction between left and right dependents. We choose to encode linearity since it appears that most languages empirically exhibit word order *preferences* even if they allow for relatively free word order.

[3] UD core and functional relations are listed in Table 1.

[4] The (possibly counterintuitive) direction for *that* and *to* is a result of UD's choice of a content-word-oriented design.

4 Pilot Study: Sanity Checks

We consider two questions that need to be addressed at the outset:[5]

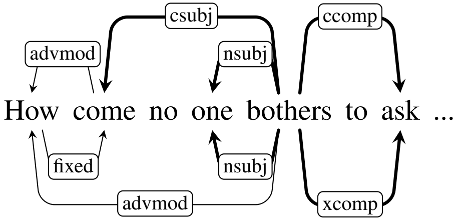
1. How well do the extracted patterns generalize to unseen data?
2. Do state-of-the-art parsers already capture the notion of valency implicitly, though they are not explicitly optimized for it?

The first question checks the feasibility of learning valency patterns from a limited amount of data; the second probes the potential for any valency-informed parsing approach to improve over current state-of-the-art systems.

To answer these questions, we use the UD 2.0 dataset for the CoNLL 2017 shared task (Zeman et al., 2017) and the system outputs[6] of the top five performing submissions (Dozat et al., 2017; Shi et al., 2017b; Björkelund et al., 2017; Che et al., 2017; Lim and Poibeau, 2017). Selection of treebanks is the same as in §6. We extract valency patterns relative to the set of 6 UD core arguments given in Table 1 because they are close to the original notion of valency and we hypothesize that these patterns should exhibit few variations. This is indeed the case: the average number of valency patterns we extract is 110.4 per training treebank, with Turkish (`tr`) having the fewest at 34, and Galician (`gl`) having the most at 298 patterns. We observe that in general, languages with higher degree of flexibility in word order tend to generate more patterns in the data, as our patterns encode linear word order information.

Next, we extract valency patterns from the test set and compare them against those from the training set. On average, out of the 55.4 patterns observed in the gold-standard test sets, only 5.5, or 9.98%, are new and unseen with respect to training. In comparison, 36.2% of the word types appearing in the test sets are not seen during training. This suggests that the valency pattern space is relatively restricted, and the patterns extracted from training sets do generalize well to test sets.

Finally, we consider the average number of valency patterns extracted from the top-performing system outputs and the number of those not observed in training.[7] All 5 systems are remarkably "hallucinatory" in inventing valency relations, introducing 16.8 to 35.5 new valency patterns, significantly larger than the actual number of unseen patterns. Below we show an error committed by the state-of-the-art Dozat et al. (2017) parser (upper half) as compared to the gold-standard annotation (lower half), and we highlight the core argument valency relations of the verb *bothers* in bold. The system incorrectly predicts *how come* to be a clausal subject.



Each such non-existent new pattern implies at least some (potentially small) parsing error that can contribute to the degradation of downstream task performance.

5 Valency-Aware Dependency Parsing

5.1 Overview

Our model is based on the following probability factorization for a given sentence $x = w_1, \ldots, w_n$ and parse tree y for x:

$$P(y|x) = \frac{1}{Z_x} \prod_{i=1}^{n} P(v_i|w_i) P(h_i|w_i) P(r_i|w_i, h_i),$$

where Z_x is the normalization factor, v_i is the valency pattern extracted for w_i from y, h_i is the index of the syntactic governor of w_i, and r_i is the syntactic relation label of the dependency relation between w_{h_i} and w_i. We first assume that we have a feature extractor that associates each token in the sentence w_i with a contextualized feature vector $\mathbf{w}_i$, and explain how to calculate the factored probabilities (§5.2). Then we discuss decoding (§5.3) and training (§5.4). Our decoder can be viewed as a special-case implementation of head-automaton grammars (Alshawi, 1996; Eisner and Satta, 1999). Finally, we return to the issue of feature extraction (§5.5).

---

[5] We actually performed these sanity checks after implementation and experiments of our approach, because we missed this idea and because it requires access to test sets that we abstained from looking at during model development.

[6] Retrieved from `https://lindat.mff.cuni.cz/repository/xmlui/handle/11234/1-2424`.

[7] The CoNLL 2017 shared task is an end-to-end parsing task, so the participating systems do not have access to gold-standard tokenization, which is a potential explanation for the presented analysis. On the other hand, the conclusion still holds even if we restrict to system outputs with perfect or nearly perfect segmentations.

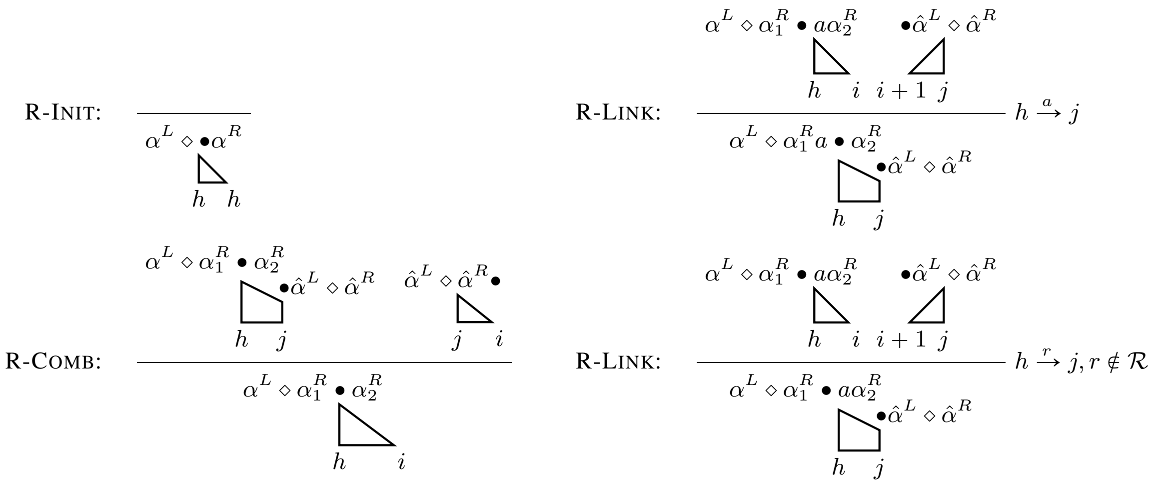


Figure 2: Eisner's (1996)/Eisner and Satta's (1999) algorithm, with valency-pattern annotations, incorporated as state information, shown explicitly. We show only the R-rules; the L-rules are symmetric.

5.2 Parameterization

We parameterize $P(v_i|w_i)$ as a softmax distribution over all candidate valency patterns:

$$P(v_i|w_i) \propto \exp(\text{score}_{v_i}^{\text{VAL}}(\mathbf{w}_i)),$$

where score$^{\text{VAL}}$ is a multi-layer perceptron (MLP).

For each word w_i, we generate a probability distribution over all potential syntactic heads in the sentence (Zhang et al., 2017). After we have selected the head of w_i to be w_{h_i}, we decide on the syntactic relation label based on another probability distribution. We use two softmax functions:

$$P(h_i|w_i) \propto \exp(\text{score}^{\text{HEAD}}(\mathbf{w}_{h_i}, \mathbf{w}_i)),$$
$$P(r_i|w_i, h_i) \propto \exp(\text{score}_{r_i}^{\text{LABEL}}(\mathbf{w}_{h_i}, \mathbf{w}_i)),$$

where both score$^{\text{HEAD}}$ and score$^{\text{LABEL}}$ are parameterized by deep biaffine scoring functions (Dozat and Manning, 2017).

5.3 Decoding

For joint decoding, we adopt the Eisner's (1996) algorithm annotated with valency patterns as the state information in Eisner and Satta (1999). The algorithm is depicted in Fig. 2. For each complete and incomplete span, visualized as triangles and trapezoids respectively, we annotate the head with its valency pattern. We adopt Earley's (1970) notation of $\bullet$ to outward-delimit the portion of a valency pattern, starting from the center word $\diamond$, that has already been collected within the span. INIT generates a minimal complete span with hypothesized valency pattern; the $\bullet$ is put adjacent to $\diamond$. COMB matches an incomplete span to a complete span with compatible valency pattern, yielding a complete analysis on the relevant side of $\diamond$. LINK either advances the $\bullet$ by attaching a syntactic dependent with the corresponding relation label, or attaches a dependent with a relation label irrelevant to the current valency analysis. This algorithm can be easily extended to cases where we analyze multiple subsets of valency relations simultaneously: we just need to annotate each head with multiple layers of valency patterns, one for each subset.[8]

The time complexity of a naïve dynamic programming implementation is $O(|V|^2|\alpha|n^3)$, where $|V|$ is the number of valency patterns and $|\alpha|$ is the maximum length of a valency pattern. In practice, $|V|$ is usually larger than n, making the algorithm prohibitively slow. We thus turn to A* parsing for a more practical solution.

A* parsing We take inspiration from A* CCG parsing (Lewis and Steedman, 2014; Lewis et al., 2016; Yoshikawa et al., 2017). The idea (see Alg. 1) is to estimate the best compatible full parse for every chart item (in our case, complete and incomplete spans), and expand the chart based on the estimated priority scores. Our factorization of probability scores allows the following admissible heuristic: for each span, we can optimistically estimate its best full parse score by assigning to

---

[8] To allow our model to account for unseen patterns in new data, we create a special wildcard valency pattern that allows dependents with arbitrary relations in the decoding process, and during training, treat valency patterns occurring fewer than 5 times as examples of the wildcard pattern.

Algorithm 1 Agenda-based best-first parsing algorithm, adapted from Lewis et al. (2016), Alg. 1.

Helper Functions: $\textsc{Init}(s)$ returns the set of spans generated by $\textsc{Init}$. $C.\textsc{Rules}(p)$ returns the set of spans that can be derived by combining p with existing entries in C through $\textsc{Comb}$ or $\textsc{Link}$.

```
procedure PARSE($s$)
    // Empty priority queue A
    $A \leftarrow \varnothing$
    // Initialize A with minimal complete spans
    for $p \in \textsc{Init}(s)$ do
        $A.\textsc{Insert}(p)$;
    // Empty chart C
    $C \leftarrow \varnothing$
    while $A \neq \varnothing$ do
        $p \leftarrow A.\textsc{PopMax}()$
        // Found the global optimal solution
        if $p$ is a full parse then return $p$
        else if $p \notin C$ then
            $C.\textsc{Add}(p)$
            // Extend the chart
            for $p' \in C.\textsc{Rules}(p)$ do
                $A.\textsc{Insert}(p')$
```

every token outside the span the best possible valency pattern, best possible attachment and best relation label.

5.4 Training

We train all components jointly and optimize for the cross entropy between our model prediction and the gold standard, or, equivalently, the sum of the log-probabilities for the three distributions comprising our factorization from §5.1. This can be thought of as an instance of multi-task learning (MTL; Caruana, 1997), which has been shown to be useful in parsing (Kasai et al., 2018). To further reduce error propagation, instead of using part-of-speech tags as features, we train a tagger jointly with our main parser components (Zhang and Weiss, 2016).

5.5 Feature Extraction

We adopt bi-directional long short-term memory networks (bi-LSTMs; Hochreiter and Schmidhuber, 1997) as our feature extractors, since they have proven successful in a variety of syntactic parsing tasks (Kiperwasser and Goldberg, 2016; Cross and Huang, 2016; Stern et al., 2017; Shi et al., 2017a). As inputs to the bi-LSTMs, we concatenate one pre-trained word embedding, one randomly-initialized word embedding, and the output of character-level LSTMs for capturing sub-token level information (Ballesteros et al., 2015). The bi-LSTM output vectors at each timestep are then assigned to each token as its contextualized representation $\mathbf{w}_i$.

6 Experiments

Data and Evaluation Our main experiments are based on UD version 2.0, which was prepared for the CoNLL 2017 shared task (Zeman et al., 2017). We used 53 of the treebanks[9] across 41 languages that have train and development splits given for the shared task. In contrast to the shared-task setting, where word and sentence segmentation are to be performed by the system, we directly use the test-set gold segmentations in order to focus directly on parsing; but this does mean that the performance of our models cannot be directly compared to the officially-reported shared-task results. For evaluation, we report unlabeled and labeled attachment scores (UAS and LAS respectively). Further, we explicitly evaluate precision, recall and F1 scores (P/R/F) for the syntactic relations from Table 1, as well as valency pattern accuracies (VPA) involving those relations.

Implementation Details We use three-layer bi-LSTMs with 500 hidden units (250 in each direction) for feature extraction. The valency analyzer uses a one-hidden-layer MLP with ReLU activation function (Nair and Hinton, 2010), while the head selector and labeler use 512- and 128-dimensional biaffine scoring functions respectively. Our models are randomly initialized (Glorot and Bengio, 2010) and optimized with AMSgrad (Reddi et al., 2018) with initial learning rate 0.002. We apply dropout (Srivastava et al., 2014) to our MLPs and variational dropout (Gal and Ghahramani, 2016) to our LSTMs with a keep rate of 0.67 during training.

Efficiency Our A* parsers are generally reasonably efficient; for the rare ($< 1\%$) cases where the A* search does not finish within 500,000 chart expansion steps, we back off to a model without valency analysis. When analyzing three or more relation subsets, the initialization steps become pro-

---

[9] We exclude the two large treebanks `cs` and `ru_syntagrus` due to experiment resource constraints. There are other Czech and Russian treebanks in our selected collection.

Table 3: Treebank-specific F1 scores on core argument relations, comparing the baseline models to our Core MTL + joint decoding models, sorted by the error reduction (ER, %) rate. When comparing a model with performance s_2 against baseline score s_1, ER is defined as $(s_2 - s_1)/(1 - s_1)$. For languages with two or three treebanks, we include multiple entries differentiated by the subscripts MAX/MID/MIN, corresponding to the treebanks with the highest/median/lowest ER, respectively. A. Greek = Ancient Greek.

hibitively slow due to the large number of valency pattern combinations. Thus, we limit the number of combinations for each token to the highest-scoring 500.

Results on UD We present our main experimental results on UD in Table 2. The baseline system does not leverage any valency information (we only train the head selectors and labelers, and use the original Eisner decoder). We compare the baseline to settings where we train the parsers jointly with our proposed valency analyzers, distinguishing the effect of using this information only at training (multi-task learning; MTL) vs. both at training and decoding.

Including valency analysis into the training objective already provides a slight improvement in parsing performance, in line with the findings of Kasai et al. (2018). With our proposed joint decoding, there is a mild improvement to the overall UAS and LAS, and a higher boost to VPA. The output parse trees are now more precise in the analyzed valency relations: on core arguments, precision increases by as much as 4.56. As shown by Table 3, the performance gain of joint decoding varies across treebanks, ranging from an error reduction rate of over 30% (Dutch Lassy Small Treebank) on core argument relations to nearly 0% (Japanese). Overall, our approach exhibits a clearly positive impact on most of the treebanks in UD. We do not see performance correlating to language typology, although we do observe smaller error-reduction rates on treebanks with lower baseline performances, that is, on "harder" languages.

7 Parsing Tree Adjoining Grammar

Dependency and valency relations also play an important role in formalisms other than dependency grammar. In this section, we apply our proposed valency analysis to Tree Adjoining Grammar (TAG; Joshi and Schabes, 1997), because TAG derivation trees, representing the process of inserting obligatory arguments and adjoining modifiers, can be treated as a dependency representation (Rambow and Joshi, 1997). We follow prior art and use Chen's (2001) automatic conversion of the Penn Treebank (Marcus et al., 1993) into TAG derivation trees. The dataset annotation has labels 0, 1 and 2, corresponding to subject, direct object, and indirect object; we treat these as our core argument subset in valency analysis.[10] Additionally, we also analyze CO (co-head for phrasal verbs) as a separate singleton subset. We leave out adj (adjuncts) in defining our valency patterns. We strictly follow the experiment protocol of previous work (Bangalore et al., 2009; Chung et al., 2016; Friedman et al., 2017; Kasai et al., 2017, 2018), and report the results in Table 4. The findings are consistent with our main experiments: MTL helps parsing performance, and joint decoding further improves on core argument F1 scores, reaching a new state-of-the-art result of 92.59 LAS. The precision recall trade-off is pronounced for the CO relation subset.

8 Case Study on PP Attachment

Although valency information has traditionally been used to analyze complements or core arguments,[11] in this section, we show the utility of our approach in analyzing other types of syntactic relations. We choose the long-standing problem of prepositional phrase (PP) attachment (Hindle and Rooth, 1993; Brill and Resnik, 1994; Collins and Brooks, 1995; de Kok et al., 2017), which is known to be a major source of parsing mistakes (Kummerfeld et al., 2012; Ng and Curran, 2015). In UD analysis, PPs usually have the labels obl or nmod with respect to their syntactic parents, whereas adpositions are attached via a case relation, which is included in the functional relation subset. Thus, we add another relation subset, obl and nmod, to our valency analysis.

Table 5 presents the results for different combinations of valency relation subsets. We find that PP-attachment decisions are generally harder to make, compared with core and functional relations. Including them during training distracts other parsing objectives (compare Core + PP with only analyzing Core in §6). However, they do permit improvements on precision for PP attachment by 3.30, especially with our proposed joint decoding. This demonstrates the usage of our algorithm outside the traditional notions of valency — it can be a general method for training parsers to focus on specific subsets of syntactic relations.

---

[10] We choose not to use the sparse labels 3 and 4, which encode additional complements.

[11] There are also recent proposals to analyze valency without distinguishing complements and adjuncts (Čech et al., 2010).

9 Further Related Work

Supertagging Supertagging (Bangalore and Joshi, 2010) has been proposed for and used in parsing TAG (Bangalore and Joshi, 1999; Nasr and Rambow, 2004), CCG (Curran and Clark, 2003; Curran et al., 2006), and HPSG (Ninomiya et al., 2006; Blunsom and Baldwin, 2006). Within dependency parsing, supertags have also been explored in the literature, but prior work mostly treats them as additional features. Ambati et al. (2013, 2014) use CCG supertags to improve dependency parsing results, while Ouchi et al. (2014, 2016) leverage dependency-based supertags as features. Faleńska et al. (2015) compare supertagging to parser stacking, where they extract supertags from base parsers to provide additional features for stacked parsers, instead of having a supertagger as a separate component.

Constrained Dependency Grammar Another line of research (Wang and Harper, 2004; Foth et al., 2006; Foth and Menzel, 2006; Bharati et al., 2002, 2009; Husain et al., 2011) utilizes supertags in dependency parsing within the framework of constraint dependency grammar (CDG; Maruyama, 1990; Heinecke et al., 1998). Constraints in CDG may be expressed in very general terms (and are usually hand-crafted for specific languages), so prior work in CDG involves a constraint solver that iteratively or greedily update hypotheses without optimality guarantees. In contrast, our work focuses on a special form of constraints — the valency patterns of syntactic dependents within a subset of relations — and we provide an efficient A*-based exact decoding algorithm.

Valency in Parsing To the best of our knowledge, there have been few attempts to utilize lexical valency information or to improve specifically on core arguments in syntactic parsing apart from CDG. Øvrelid and Nivre (2007) target parsing core relations in Swedish with specifically-designed features such as animacy and definiteness that are useful in argument realization. Jakubıček and Kovář (2013) leverage external lexicons of verb valency frames for reranking. Mirroshandel et al. (2012, 2013) and Mirroshandel and Nasr (2016) extract selectional constraints and subcategorization frames from large unannotated corpora, and enforce them through forest reranking. Our approach does not rely on external resources or lexicons, but directly extracts valency patterns from labeled dependency parse trees. Earlier works in this spirit include Collins (1997).

Semantic Dependency Parsing and Semantic Role Labeling The notion of valency is also used to describe predicate-argument structures that are adopted in semantic dependency parsing and semantic role labeling (Surdeanu et al., 2008; Hajič et al., 2009; Oepen et al., 2014, 2015). While semantic frames clearly have patterns, previous work (Punyakanok et al., 2008; Flanigan et al., 2014; Täckström et al., 2015; Peng et al., 2017; He et al., 2017) incorporates several types of constraints, including uniqueness and determinism constraints that require that certain labels appear as arguments for a particular predicate only once. They perform inference through integer linear programming, which is usually solved approximately, and cannot easily encode linear ordering constraints for the arguments.

A* parsing Best-first search uses a heuristic to expand the parsing chart instead of doing so exhaustively. It was first applied to PCFGs (Ratnaparkhi, 1997; Caraballo and Charniak, 1998; Sagae and Lavie, 2006), and then to dependency parsing (Sagae and Tsujii, 2007; Zhao et al., 2013; Vaswani and Sagae, 2016). Our probability factorization permits a simple yet effective A* heuristic. A* parsing was introduced for parsing PCFGs (Klein and Manning, 2003; Pauls and Klein, 2009), and has been widely used for grammar formalisms and parsers with large search spaces, for example CCG (Auli and Lopez, 2011) and TAG (Waszczuk et al., 2016, 2017). Our decoder is similar to the supertag and dependency factored A* CCG parser (Yoshikawa et al., 2017), which in turn builds upon the work of Lewis and Steedman (2014) and Lewis et al. (2016). Our model additionally adds syntactic relations into the probability factorizations.

10 Conclusions

We have presented a probability factorization and decoding process that integrates valency patterns into the parsing process. The joint decoder favors syntactic analyses with higher valency-pattern supertagging probabilities. Experiments on a large set of languages from UD show that our parsers are more precise in the subset of syntactic relations chosen for valency analysis, in addition to enjoying the benefits gained from jointly training the parsers and supertaggers in a multi-task learning setting.

Our method is not limited to a particular type of treebank annotation or a fixed subset of relations. We draw similar conclusions when we parse TAG derivation trees. Most interestingly, in a case study on PP attachment, we confirm the utility of our parsers in handling syntactic relations beyond the traditional domain of valency.

A key insight of this paper that departs from prior work on automatic extraction of supertags from dependency annotations is that our definition of valency patterns is relativized to a subset of syntactic relations. This definition is closer to the linguistic notion of valency and alleviates the data sparsity problems in that the number of extracted valency patterns is small. At the same time, the patterns generalize well, and empirically, they are effective in our proposed joint decoding process.

Our findings point to a number of directions for future work. First, the choice of subsets of syntactic relations for valency analysis impacts the parsing performance in those categories. This may suggest a controllable way to address precision-recall trade-offs targeting specific relation types. Second, we experimented with a few obvious subsets of relations; characterizing what subsets can be most improved with valency augmentation is an open question. Finally, our decoder builds upon projective dependency-tree decoding algorithms. In the future, we will explore the possibility of removing the projective constraint and the tree requirement, extending the applicability of valency patterns to other tasks such as semantic role labeling.

Acknowledgments

We thank the three anonymous reviewers for their insightful comments, Jungo Kasai for assistance in setting up the TAG parsing experiments, and Xilun Chen, Jason Eisner, Jungo Kasai and Ana Smith for discussion and comments. We also thank CoNLL'17 shared task organizers and participants for publicizing system outputs. TS and LL were supported in part by a Google Focused Research Grant to Cornell University. LL was also supported in part by NSF grant SES-1741441. Unsupervised Learning of Syntactic Structure with Invertible Neural Projections

Junxian He **Graham Neubig** **Taylor Berg-Kirkpatrick**

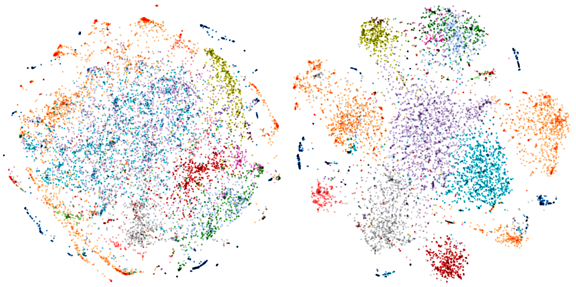
Abstract

Unsupervised learning of syntactic structure is typically performed using generative models with discrete latent variables and multinomial parameters. In most cases, these models have not leveraged continuous word representations. In this work, we propose a novel generative model that jointly learns discrete syntactic structure and continuous word representations in an unsupervised fashion by cascading an *invertible* neural network with a structured generative prior. We show that the invertibility condition allows for efficient exact inference and marginal likelihood computation in our model so long as the prior is well-behaved. In experiments we instantiate our approach with both Markov and tree-structured priors, evaluating on two tasks: part-of-speech (POS) induction, and unsupervised dependency parsing without gold POS annotation. On the Penn Treebank, our Markov-structured model surpasses state-of-the-art results on POS induction. Similarly, we find that our tree-structured model achieves state-of-the-art performance on unsupervised dependency parsing for the difficult training condition where neither gold POS annotation nor punctuation-based constraints are available.[1]

1 Introduction

Data annotation is a major bottleneck for the application of supervised learning approaches to many problems. As a result, unsupervised methods that learn directly from unlabeled data are increasingly important. For tasks related to unsupervised syntactic analysis, discrete generative models have dominated in recent years – for example, for both part-of-speech (POS) induction (Blunsom and Cohn, 2011; Stratos et al., 2016) and unsupervised dependency parsing (Klein and Manning, 2004; Cohen and Smith, 2009; Pate and Johnson, 2016). While similar models have had success on a range of unsupervised tasks, they have mostly ignored the apparent utility of continuous word representations evident from supervised NLP applications (He et al., 2017; Peters et al., 2018). In this work, we focus on leveraging and explicitly representing continuous word embeddings within unsupervised models of syntactic structure.



(a) Traditional pre-trained skip-gram embeddings (b) Learned latent embeddings from our approach

Figure 1: Visualization (t-SNE) of skip-gram embeddings (trained on one billion words with context window size equal to 1) and latent embeddings learned by our approach with a Markov-structured prior. Each node represents a word and is colored according to the most likely gold POS tag from the Penn Treebank (best seen in color).

Pre-trained word embeddings from massive unlabeled corpora offer a compact way of injecting a prior notion of word similarity into models that would otherwise treat words as discrete, isolated categories. However, the specific properties of language captured by any particular embedding scheme can be difficult to control, and, further, may not be ideally suited to the task at hand. For example, pre-trained skip-gram embeddings (Mikolov et al., 2013) with small context window size are found to capture the syntactic properties of language well (Bansal et al., 2014; Lin et al., 2015). However, if our goal is to separate syntactic categories, this embedding space is not ideal – POS categories correspond to overlap-

Brussels, Belgium, October 31 - November 4, 2018.

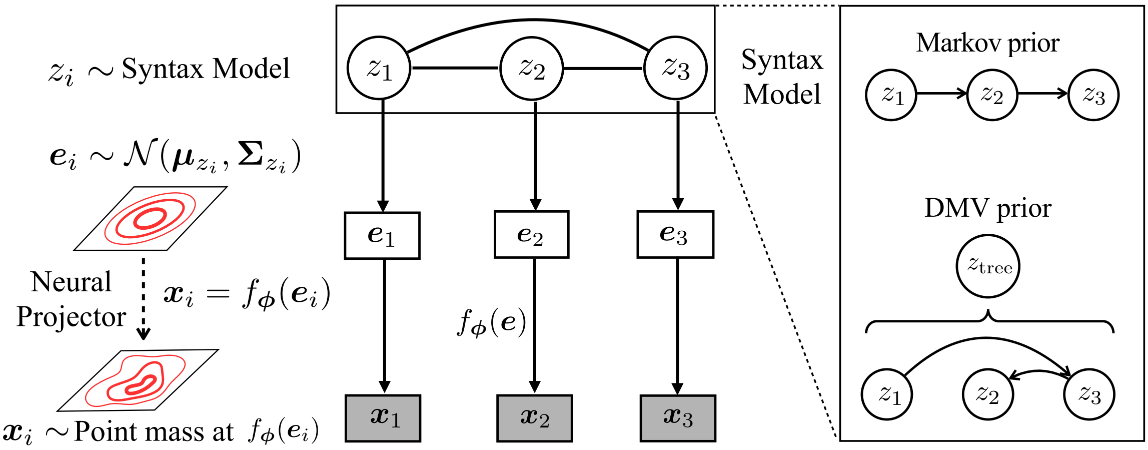

Figure 2: Depiction of proposed generative model. The syntax model is composed of discrete random variables, z_i. Each $\boldsymbol{e}_i$ is a latent continuous embeddings sampled from Gaussian distribution conditioned on z_i, while $\boldsymbol{x}_i$ is the observed embedding, deterministically derived from $\boldsymbol{e}_i$. The left portion depicts how the neural projector maps the simple Gaussian to a more complex distribution in the output space. The right portion depicts two instantiations of the syntax model in our approach: one is Markov-structured and the other is DMV-structured. For DMV, z_{tree} is the latent dependency tree structure.

ping interspersed regions in the embedding space, evident in Figure 1(a).

In our approach, we propose to learn a new latent embedding space as a projection of pre-trained embeddings (depicted in Figure 1(b)), while *jointly* learning latent syntactic structure – for example, POS categories or syntactic dependencies. To this end, we introduce a new generative model (shown in Figure 2) that first generates a latent syntactic representation (e.g. a dependency parse) from a discrete structured prior (which we also call the "syntax model"), then, conditioned on this representation, generates a sequence of latent embedding random variables corresponding to each word, and finally produces the observed (pre-trained) word embeddings by projecting these latent vectors through a parameterized non-linear function. The latent embeddings can be jointly learned with the structured syntax model in a completely unsupervised fashion.

By choosing an invertible neural network as our non-linear projector, and then parameterizing our model in terms of the projection's inverse, we are able to derive tractable exact inference and marginal likelihood computation procedures so long as inference is tractable in the underlying syntax model. In §3.1 we show that this derivation corresponds to an alternate view of our approach whereby we jointly learn a mapping of observed word embeddings to a new embedding space that is more suitable for the syntax model, but include an additional Jacobian regularization term to prevent information loss.

Recent work has sought to take advantage of word embeddings in unsupervised generative models with alternate approaches (Lin et al., 2015; Tran et al., 2016; Jiang et al., 2016; Han et al., 2017). Lin et al. (2015) build an HMM with Gaussian emissions on observed word embeddings, but they do not attempt to learn new embeddings. Tran et al. (2016), Jiang et al. (2016), and Han et al. (2017) extend HMM or dependency model with valence (DMV) (Klein and Manning, 2004) with multinomials that use word (or tag) embeddings in their parameterization. However, they do not represent the embeddings as latent variables.

In experiments, we instantiate our approach using both a Markov-structured syntax model and a tree-structured syntax model – specifically, the DMV. We evaluate on two tasks: part-of-speech (POS) induction and unsupervised dependency parsing without gold POS tags. Experimental results on the Penn Treebank (Marcus et al., 1993) demonstrate that our approach improves the basic HMM and DMV by a large margin, leading to the state-of-the-art results on POS induction, and state-of-the-art results on unsupervised dependency parsing in the difficult training scenario where neither gold POS annotation nor punctuation-based constraints are available.

2 Model

As an illustrative example, we first present a baseline model for Markov syntactic structure (POS induction) that treats a sequence of pre-trained word embeddings as observations. Then, we propose our novel approach, again using Markov structure, that introduces latent word embedding variables and a neural projector. Lastly, we extend our approach to more general syntactic structures.

2.1 Example: Gaussian HMM

We start by describing the Gaussian hidden Markov model introduced by Lin et al. (2015), which is a locally normalized model with multinomial transitions and Gaussian emissions. Given a sentence of length ℓ, we denote the latent POS tags as $\boldsymbol{z} = \{z_i\}_{i=1}^{\ell}$, observed (pre-trained) word embeddings as $\boldsymbol{x} = \{\boldsymbol{x}_i\}_{i=1}^{\ell}$, transition parameters as $\boldsymbol{\theta}$, and Gaussian emission parameters as $\boldsymbol{\eta}$. The joint distribution of data and latent variables factors as:

$$p(\boldsymbol{z}, \boldsymbol{x}; \boldsymbol{\theta}, \boldsymbol{\eta}) = \prod\nolimits_{i=1}^{\ell} p_{\boldsymbol{\theta}}(z_i|z_{i-1}) p_{\boldsymbol{\eta}}(\boldsymbol{x}_i|z_i), \quad (1)$$

where $p_{\boldsymbol{\theta}}(z_i|z_{i-1})$ is the multinomial transition probability and $p_{\boldsymbol{\eta}}(\boldsymbol{x}_i|z_i)$ is the multivariate Gaussian emission probability.

While the observed word embeddings do inform this model with a notion of word similarity – lacking in the basic multinomial HMM – the Gaussian emissions may not be sufficiently flexible to separate some syntactic categories in the complex pre-trained embedding space – for example the skip-gram embedding space as visualized in Figure 1(a) where different POS categories overlap. Next we introduce a new approach that adds flexibility to the emission distribution by incorporating new latent embedding variables.

2.2 Markov Structure with Neural Projector

To flexibly model observed embeddings and yield a new representation space that is more suitable for the syntax model, we propose to cascade a neural network as a projection function, deterministically transforming the simple space defined by the Gaussian HMM to the observed embedding space. We denote the latent embedding of the i^{th} word in a sentence as $\boldsymbol{e}_i \in \mathbb{R}^{d_e}$, and the neural projection function as f, parameterized by $\boldsymbol{\phi}$. In the case of sequential Markov structure, our new model corresponds to the following generative process:

For each time step $i = 1, 2, \cdots, \ell$,

- Draw the latent state $z_i \sim p_{\boldsymbol{\theta}}(z_i|z_{i-1})$
- Draw the latent embedding $\boldsymbol{e}_i \sim \mathcal{N}(\boldsymbol{\mu}_{z_i}, \boldsymbol{\Sigma}_{z_i})$
- Deterministically produce embedding $\boldsymbol{x}_i = f_{\boldsymbol{\phi}}(\boldsymbol{e}_i)$

The graphical model is depicted in Figure 2. The deterministic projection can also be viewed as sampling each observation from a point mass at $f_{\boldsymbol{\phi}}(\boldsymbol{e}_i)$. The joint distribution of our model is:

$$\begin{aligned} &p(\boldsymbol{z}, \boldsymbol{e}, \boldsymbol{x}; \boldsymbol{\theta}, \boldsymbol{\eta}, \boldsymbol{\phi}) \\ &\quad = \prod\nolimits_{i=1}^{\ell} [p_{\boldsymbol{\theta}}(z_i|z_{i-1}) p_{\boldsymbol{\eta}}(\boldsymbol{e}_i|z_i) p_{\boldsymbol{\phi}}(\boldsymbol{x}_i|\boldsymbol{e}_i)], \end{aligned} \quad (2)$$

where $p_{\boldsymbol{\eta}}(\cdot|z_i)$ is a conditional Gaussian distribution, and $p_{\boldsymbol{\phi}}(\boldsymbol{x}_i|\boldsymbol{e}_i)$ is the Dirac delta function centered at $f_{\boldsymbol{\phi}}(\boldsymbol{e}_i)$:

$$p_{\boldsymbol{\phi}}(\boldsymbol{x}_i|\boldsymbol{e}_i) = \delta(\boldsymbol{x}_i - f_{\boldsymbol{\phi}}(\boldsymbol{e}_i)) = \begin{cases} \infty & \boldsymbol{x}_i = f_{\boldsymbol{\phi}}(\boldsymbol{e}_i) \\ 0 & \text{otherwise} \end{cases} \quad (3)$$

2.3 General Structure with Neural Projector

Our approach can be applied to a broad family of structured syntax models. We denote latent embedding variables as $\boldsymbol{e} = \{\boldsymbol{e}_i\}_{i=1}^{\ell}$, discrete latent variables in the syntax model as $\boldsymbol{z} = \{z_k\}_{k=1}^{K}$ ($K \geqslant \ell$), where $z_1, z_2, \ldots, z_\ell$ are conditioned to generate $\boldsymbol{e}_1, \boldsymbol{e}_2, \ldots, \boldsymbol{e}_\ell$. The joint probability of our model factors as:

$$\begin{aligned} p(\boldsymbol{z}, \boldsymbol{e}, \boldsymbol{x}; \boldsymbol{\theta}, \boldsymbol{\eta}, \boldsymbol{\phi}) = &\prod\nolimits_{i=1}^{\ell} \left[p_{\boldsymbol{\eta}}(\boldsymbol{e}_i|z_i) p_{\boldsymbol{\phi}}(\boldsymbol{x}_i|\boldsymbol{e}_i)\right] \\ &\cdot p_{\text{syntax}}(\boldsymbol{z}; \boldsymbol{\theta}), \end{aligned} \quad (4)$$

where $p_{\text{syntax}}(\boldsymbol{z}; \boldsymbol{\theta})$ represents the probability of the syntax model, and can encode any syntactic structure – though, its factorization structure will determine whether inference is tractable in our full model. As shown in Figure 2, we focus on two syntax models for syntactic analysis in this paper. The first is Markov-structured, which we use for POS induction, and the second is DMV-structured, which we use to learn dependency parses without supervision.

The marginal data likelihood of our model is:

$$\begin{aligned} p(\boldsymbol{x}) = &\sum\nolimits_{\boldsymbol{z}} \Big(p_{\text{syntax}}(\boldsymbol{z}; \boldsymbol{\theta}) \\ &\cdot \prod\nolimits_{i=1}^{\ell} \underbrace{\Big[\int_{\boldsymbol{e}_i} p_{\boldsymbol{\eta}}(\boldsymbol{e}_i|z_i) p_{\boldsymbol{\phi}}(\boldsymbol{x}_i|\boldsymbol{e}_i) \mathrm{d}\boldsymbol{e}_i\Big]}_{p(\boldsymbol{x}_i|z_i)}\Big). \end{aligned} \quad (5)$$

While the discrete variables $\boldsymbol{z}$ can be marginalized out with dynamic program in many cases, it is generally intractable to marginalize out the latent continuous variables, $\boldsymbol{e}_i$, for an arbitrary projection f in Eq. (5), which means inference and learning may be difficult. In §3, we address this issue by constraining f to be invertible, and show that this constraint enables tractable exact inference and marginal likelihood computation.

3 Learning & Inference

In this section, we introduce an invertibility condition for our neural projector to tackle the optimization challenge. Specifically, we constrain our neural projector with two requirements: (1) $\dim(\boldsymbol{x}) = \dim(\boldsymbol{e})$ and (2) $f_{\boldsymbol{\phi}}^{-1}$ exists. Invertible transformations have been explored before in independent components analysis (Hyvärinen et al., 2004), gaussianization (Chen and Gopinath, 2001), and deep density models (Dinh et al., 2014, 2016; Kingma and Dhariwal, 2018), for unstructured data. Here, we generalize this style of approach to *structured* learning, and augment it with discrete latent variables (z_i). Under the invertibility condition, we derive a learning algorithm and give another view of our approach revealed by the objective function. Then, we present the architecture of a neural projector we use in experiments: a volume-preserving invertible neural network proposed by Dinh et al. (2014) for independent components estimation.

3.1 Learning with Invertibility

For ease of exposition, we explain the learning algorithm in terms of Markov structure without loss of generality. As shown in Eq. (5), the optimization challenge in our approach comes from the intractability of the marginalized emission factor $p(\boldsymbol{x}_i|z_i)$. If we can marginalize out $\boldsymbol{e}_i$ and compute $p(\boldsymbol{x}_i|z_i)$, then the posterior and marginal likelihood of our Markov-structured model can be computed with the forward-backward algorithm. We can apply Eq. (3) and obtain :

$$p(\boldsymbol{x}_i|z_i;\boldsymbol{\eta},\boldsymbol{\phi}) = \int_{\boldsymbol{e}_i} p_{\boldsymbol{\eta}}(\boldsymbol{e}_i|z_i)\delta(\boldsymbol{x}_i - f_{\boldsymbol{\phi}}(\boldsymbol{e}_i))\mathrm{d}\boldsymbol{e}_i.$$

By using the change of variable rule to the integration, which allows the integration variable $\boldsymbol{e}_i$ to be replaced by $\boldsymbol{x}'_i = f_{\boldsymbol{\phi}}(\boldsymbol{e}_i)$, the marginal emission factor can be computed in closed-form when the invertibility condition is satisfied:

$$\begin{aligned} & p(\boldsymbol{x}_i|\boldsymbol{z}_i;\boldsymbol{\eta},\boldsymbol{\phi}) \\ &= \int_{\boldsymbol{x}'_i} p_{\boldsymbol{\eta}}(f_{\boldsymbol{\phi}}^{-1}(\boldsymbol{x}'_i)|z_i)\delta(\boldsymbol{x}_i - \boldsymbol{x}'_i)\left|\det\frac{\partial f_{\boldsymbol{\phi}}^{-1}}{\partial \boldsymbol{x}'_i}\right|\mathrm{d}\boldsymbol{x}'_i \\ &= p_{\boldsymbol{\eta}}(f_{\boldsymbol{\phi}}^{-1}(\boldsymbol{x}_i)|z_i)\left|\det\frac{\partial f_{\boldsymbol{\phi}}^{-1}}{\partial \boldsymbol{x}_i}\right|, \end{aligned} \tag{6}$$

where $p_{\boldsymbol{\eta}}(\cdot|z)$ is a conditional Gaussian distribution, $\frac{\partial f_{\boldsymbol{\phi}}^{-1}}{\partial \boldsymbol{x}_i}$ is the Jacobian matrix of function $f_{\boldsymbol{\phi}}^{-1}$ at $\boldsymbol{x}_i$, and $\left|\det\frac{\partial f_{\boldsymbol{\phi}}^{-1}}{\partial \boldsymbol{x}_i}\right|$ represents the absolute value of its determinant. This Jacobian term is nonzero and differentiable if and only if $f_{\boldsymbol{\phi}}^{-1}$ exists.

Eq. (6) shows that we can directly calculate the marginal emission distribution $p(\boldsymbol{x}_i|z_i)$. Denote the marginal data likelihood of Gaussian HMM as $p_{\text{HMM}}(\boldsymbol{x})$, then the log marginal data likelihood of our model can be directly written as:

$$\begin{aligned} \log p(\boldsymbol{x}) &= \log p_{\text{HMM}}(f_{\boldsymbol{\phi}}^{-1}(\boldsymbol{x})) \\ &\quad + \sum\nolimits_{i=1}^{\ell} \log\left|\det\frac{\partial f_{\boldsymbol{\phi}}^{-1}}{\partial \boldsymbol{x}_i}\right|, \end{aligned} \tag{7}$$

where $f_{\boldsymbol{\phi}}^{-1}(\boldsymbol{x})$ represents the new sequence of embeddings after applying $f_{\boldsymbol{\phi}}^{-1}$ to each $\boldsymbol{x}_i$. Eq. (7) shows that the training objective of our model is simply the Gaussian HMM log likelihood with an additional Jacobian regularization term. From this view, our approach can be seen as equivalent to reversely projecting the data through $f_{\boldsymbol{\phi}}^{-1}$ to another manifold $\boldsymbol{e}$ that is directly modeled by the Gaussian HMM, with a regularization term. Intuitively, we optimize the reverse projection $f_{\boldsymbol{\phi}}^{-1}$ to modify the $\boldsymbol{e}$ space, making it more appropriate for the syntax model. The Jacobian regularization term accounts for the volume expansion or contraction behavior of the projection. Maximizing it can be thought of as preventing information loss. In the extreme case, the Jacobian determinant is equal to zero, which means the projection is non-invertible and thus information is being lost through the projection. Such "information preserving" regularization is crucial during optimization, otherwise the trivial solution of always projecting data to the same single point to maximize likelihood is viable.[2]

More generally, for an arbitrary syntax model the data likelihood of our approach is:

$$\begin{aligned} p(\boldsymbol{x}) &= \sum\nolimits_{\boldsymbol{z}} \Big(p_{\text{syntax}}(\boldsymbol{z}) \\ &\quad \cdot \prod\nolimits_{i=1}^{\ell} p_{\boldsymbol{\eta}}(f_{\boldsymbol{\phi}}^{-1}(\boldsymbol{x}_i)|z_i)\left|\det\frac{\partial f_{\boldsymbol{\phi}}^{-1}}{\partial \boldsymbol{x}_i}\right|\Big). \end{aligned} \tag{8}$$

If the syntax model itself allows for tractable inference and marginal likelihood computation, the same dynamic program can be used to marginalize out $\boldsymbol{z}$. Therefore, our joint model inherits the tractability of the underlying syntax model.

---

[2] For example, all $\boldsymbol{e}_i$ could learn to be zero vectors, leading to the trivial solution of learning zero mean and zero variance Gaussian emissions achieving infinite data likelihood.

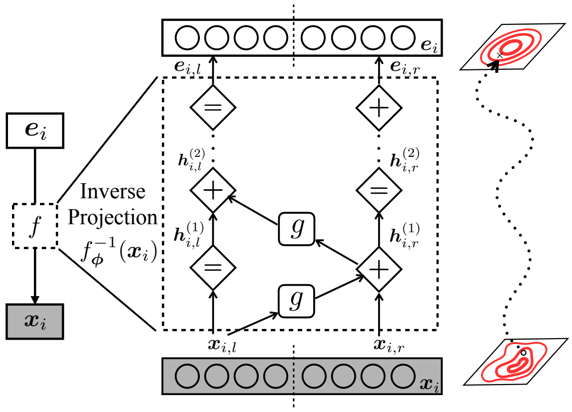

Figure 3: Depiction of the architecture of the inverse projection f_ϕ^{-1} that composes multiple volume-preserving coupling layers, with which we parameterize our model. On the right, we schematically depict how the inverse projection transforms the observed word embedding $\boldsymbol{x}_i$ to a point $\boldsymbol{e}_i$ in a new embedding space.

3.2 Invertible Volume-Preserving Neural Net

For the projection we can use an arbitrary invertible function, and given the representational power of neural networks they seem a natural choice. However, calculating the inverse and Jacobian of an arbitrary neural network can be difficult, as it requires that all component functions be invertible and also requires storage of large Jacobian matrices, which is memory intensive. To address this issue, several recent papers propose specially designed invertible networks that are easily trainable yet still powerful (Dinh et al., 2014, 2016; Jacobsen et al., 2018). Inspired by these works, we use the invertible transformation proposed by Dinh et al. (2014), which consists of a series of "coupling layers". This architecture is specially designed to guarantee a unit Jacobian determinant (and thus the invertibility property).

From Eq. (8) we know that only f_ϕ^{-1} is required for accomplishing learning and inference; we never need to explicitly construct f_ϕ. Thus, we directly define the architecture of f_ϕ^{-1}. As shown in Figure 3, the nonlinear transformation from the observed embedding $\boldsymbol{x}_i$ to $\boldsymbol{h}_i^{(1)}$ represents the first coupling layer. The input in this layer is partitioned into left and right halves of dimensions, $\boldsymbol{x}_{i,l}$ and $\boldsymbol{x}_{i,r}$, respectively. A single coupling layer is defined as:

$$\boldsymbol{h}_{i,l}^{(1)} = \boldsymbol{x}_{i,l}, \qquad \boldsymbol{h}_{i,r}^{(1)} = \boldsymbol{x}_{i,r} + g(\boldsymbol{x}_{i,l}), \qquad (9)$$

where $g : \mathbb{R}^{d_x/2} \rightarrow \mathbb{R}^{d_x/2}$ is the coupling function and can be any nonlinear form. This transformation satisfies $\dim(\boldsymbol{h}^{(1)}) = \dim(\boldsymbol{x})$, and Dinh et al. (2014) show that its Jacobian matrix is triangular with all ones on the main diagonal. Thus the Jacobian determinant is always equal to one (i.e. volume-preserving) and the invertibility condition is naturally satisfied.

To be sufficiently expressive, we compose multiple coupling layers as suggested in Dinh et al. (2014). Specifically, we exchange the role of left and right half vectors at each layer as shown in Figure 3. For instance, from $\boldsymbol{x}_i$ to $\boldsymbol{h}_i^{(1)}$ the left subset $\boldsymbol{x}_{i,l}$ is unchanged, while from $\boldsymbol{h}_i^{(1)}$ to $\boldsymbol{h}_i^{(2)}$ the right subset $\boldsymbol{h}_{i,r}^{(1)}$ remains the same. Also note that composing multiple coupling layers does not change the volume-preserving and invertibility properties. Such a sequence of invertible transformations from the data space $\boldsymbol{x}$ to $\boldsymbol{e}$ is also called normalizing flow (Rezende and Mohamed, 2015).

4 Experiments

In this section, we first describe our datasets and experimental setup. We then instantiate our approach with Markov and DMV-structured syntax models, and report results on POS tagging and dependency grammar induction respectively. Lastly, we analyze the learned latent embeddings.

4.1 Data

For both POS tagging and dependency parsing, we run experiments on the Wall Street Journal (WSJ) portion of the Penn Treebank.[3] To create the observed data embeddings, we train skip-gram word embeddings (Mikolov et al., 2013) that are found to capture syntactic properties well when trained with small context window (Bansal et al., 2014; Lin et al., 2015). Following Lin et al. (2015), the dimensionality d_x is set to 100, and the training context window size is set to 1 to encode more syntactic information. The skip-gram embeddings are trained on the one billion word language modeling benchmark dataset (Chelba et al., 2013) in addition to the WSJ corpus.

4.2 General Experimental Setup

For the neural projector, we employ rectified networks as coupling function g following Dinh et al. (2014). We use a rectified network with an input layer, one hidden layer, and linear output units, the number of hidden units is set to the same as the number of input units. The number of coupling layers are varied as 4, 8, 16 for both tasks.

---

[3] Preprocessing is different for the two tasks, we describe the details in the following subsections.

We optimize marginal data likelihood directly using Adam (Kingma and Ba, 2014). For both tasks in the fully unsupervised setting, we do not tune the hyper-parameters using supervised data.

4.3 Unsupervised POS tagging

For unsupervised POS tagging, we use a Markov-structured syntax model in our approach, which is a popular structure for unsupervised tagging tasks (Lin et al., 2015; Tran et al., 2016).

Setup. Following existing literature, we train and test on the entire WSJ corpus (49208 sentences, 1M tokens). We use 45 tag clusters, the number of POS tags that appear in WSJ corpus. We train the discrete HMM and the Gaussian HMM (Lin et al., 2015) as baselines. For the Gaussian HMM, mean vectors of Gaussian emissions are initialized with the empirical mean of all word vectors with an additive noise. We assume diagonal covariance matrix for $p(\boldsymbol{e}_i|z_i)$ and initialize it with the empirical variance of the word vectors. Following Lin et al. (2015), the covariance matrix is fixed during training. The multinomial probabilities are initialized as $\theta_{kv} \propto \exp(u_{kv})$, where $u_{kv} \sim U[0,1]$. For our approach, we initialize the syntax model and Gaussian parameters with the pre-trained Gaussian HMM. The weights of layers in the rectified network are initialized from a uniform distribution with mean zero and a standard deviation of $\sqrt{1/n_{\text{in}}}$, where n_{in} is the input dimension.[4] We evaluate the performance of POS tagging with both Many-to-One (M-1) accuracy (Johnson, 2007) and V-Measure (VM) (Rosenberg and Hirschberg, 2007). Given a model we found that the tagging performance is well-correlated with the training data likelihood, thus we use training data likelihood as a unsupervised criterion to select the trained model over 10 random restarts after training 50 epochs. We repeat this process 5 times and report the mean and standard deviation of performance.

System	**M-1**	**VM**

(b) Our approach

Figure 4: Normalized Confusion matrix for POS tagging experiments, row label represents the gold tag.

Results. We compare our approach with basic HMM, Gaussian HMM, and several state-of-the-art systems, including sophisticated HMM variants and clustering techniques with hand-engineered features. The results are presented in Table 1. Through the introduced latent embeddings and additional neural projection, our approach improves over the Gaussian HMM by 5.4 points in M-1 and 5.6 points in VM. Neural HMM (NHMM) (Tran et al., 2016) is a baseline that also learns word representation jointly. Both their basic model and extended Conv version does not outperform the Gaussian HMM. Their best model incorporates another LSTM to model long distance dependency and breaks the Markov assumption, yet our approach still achieves substantial improvement over it without considering more context information. Moreover, our method outperforms the best published result that benefits from hand-engineered features (Yatbaz et al., 2012) by 2.0 points on VM.

Confusion Matrix. We found that most tagging errors happen in noun subcategories. Therefore, we do the one-to-one mapping between gold POS tags and induced clusters and plot the normalized confusion matrix of noun subcategories in Figure 4. The Gaussian HMM fails to identify "NN" and "NNS" correctly for most cases, and it often recognizes "NNPS" as "NNP". In contrast, our approach corrects these errors well.

---

[4] This is the default parameter initialization in PyTorch.

4.4 Unsupervised Dependency Parsing without gold POS tags

For the task of unsupervised dependency parse induction, we employ the Dependency Model with Valence (DMV) (Klein and Manning, 2004) as the syntax model in our approach. DMV is a generative model that defines a probability distribution over dependency parse trees and syntactic categories, generating tokens and dependencies in a head-outward fashion. While, traditionally, DMV is trained using gold POS tags as observed syntactic categories, in our approach, we treat each tag as a latent variable, as described in §2.3.

Most existing approaches to this task are not fully unsupervised since they rely on gold POS tags following the original experimental setup for DMV. This is partially because automatically parsing from words is difficult even when using unsupervised syntactic categories (Spitkovsky et al., 2011a). However, inducing dependencies from words alone represents a more realistic experimental condition since gold POS tags are often unavailable in practice. Previous work that has trained from words alone often requires additional linguistic constraints (like sentence internal boundaries) (Spitkovsky et al., 2011a,b, 2012, 2013), acoustic cues (Pate and Goldwater, 2013), additional training data (Pate and Johnson, 2016), or annotated data from related languages (Cohen et al., 2011). Our approach is naturally designed to train on word embeddings directly, thus we attempt to induce dependencies without using gold POS tags or other extra linguistic information.

Setup. Like previous work we use sections 02-21 of WSJ corpus as training data and evaluate on section 23, we remove punctuations and train the models on sentences of length $\leqslant 10$, “head-percolation” rules (Collins, 1999) are applied to obtain gold dependencies for evaluation. We train basic DMV, extended DMV (E-DMV) (Headden III et al., 2009) and Gaussian DMV (which treats POS tag as unknown latent variables and generates observed word embeddings directly conditioned on them following Gaussian distribution) as baselines. Basic DMV and E-DMV are trained with Viterbi EM (Spitkovsky et al., 2010) on unsupervised POS tags induced from our Markov-structured model described in §4.3. Multinomial parameters of the syntax model in both Gaussian DMV and our model are initialized with the pre-trained DMV baseline. Other parameters are initialized in the same way as in the POS tagging experiment. The directed dependency accuracy (DDA) is used for evaluation and we report accuracy on sentences of length $\leqslant 10$ and all lengths. We train the parser until training data likelihood converges, and report the mean and standard deviation over 20 random restarts.

System	$\leqslant 10$	all
w/o gold POS tags

Table 2: Directed dependency accuracy on section 23 of WSJ, evaluating on sentences of length $\leqslant 10$ and all lengths. Starred entries ($*$) denote that the system benefits from additional punctuation-based constraints. Standard deviation is given in parentheses when available.

Comparison with other related work. Our model directly observes word embeddings and does not require gold POS tags during training. Thus, results from related work trained on gold tags are not directly comparable. However, to measure how these systems might perform without gold tags, we run three recent state-of-the-art systems in our experimental setting: UR-A E-DMV (Tu and Honavar, 2012), Neural E-DMV (Jiang et al., 2016), and CRF Autoencoder (CRFAE) (Cai et al., 2017).[5] We use unsupervised POS tags (induced from our Markov-structured model) in place of gold tags.[6] We also train basic DMV on gold tags and include several state-of-the-art results on gold tags as reference points.

Results. As shown in Table 2, our approach is able to improve over the Gaussian DMV by 4.8 points on length $\leqslant 10$ and 4.8 points on all

---

[5] For the three systems, we use implementations from the original papers (via personal correspondence with the authors), and tune their hyperparameters on section 22 of WSJ.

[6] Using words directly is not practical because these systems often require a transition probability matrix between input symbols, which requires too much memory.

System	M-1	VM
Ours (4 layers)	78.2	71.2
Ours (8 layers)	72.5	69.7
Ours (16 layers)	67.2	69.2

Table 3: Unsupervised POS tagging results of our approach on WSJ, with random initialization of syntax model.

lengths, which suggests the additional latent embedding layer and neural projector are helpful. The proposed approach yields, to the best of our knowledge,[7] state-of-the-art performance without gold POS annotation and without sentence-internal boundary information. DMV, UR-A E-DMV, Neural E-DMV, and CRFAE suffer a large decrease in performance when trained on unsupervised tags – an effect also seen in previous work (Spitkovsky et al., 2011a; Cohen et al., 2011). Since our approach induces latent POS tags jointly with dependency trees, it may be able to learn POS clusters that are more amenable to grammar induction than the unsupervised tags. We observe that CRFAE underperforms its gold-tag counterpart substantially. This may largely be a result of the model's reliance on prior linguistic rules that become unavailable when gold POS tag types are unknown. Many extensions to DMV can be considered orthogonal to our approach – they essentially focus on improving the syntax model. It is possible that incorporating these more sophisticated syntax models into our approach may lead to further improvements.

4.5 Sensitivity Analysis

Impact of Initialization. In the above experiments we initialize the structured syntax components with the pre-trained Gaussian or discrete baseline, which is shown as a useful technique to help train our deep models. We further study the results with fully random initialization. In the POS tagging experiment, we report the results in Table 3. While the performance with 4 layers is comparable to the pre-trained Gaussian initialization, deeper projections (8 or 16 layers) result in a dramatic drop in performance. This suggests that the structured syntax model with very deep projections is difficult to train from scratch, and a simpler projection might be a good compromise in the random initialization setting.

Different from the Markov prior in POS tagging experiments, our parsing model seems to be quite sensitive to the initialization. For example, directed accuracy of our approach on sentences of length $\leqslant 10$ is below 40.0 with random initialization. This is consistent with previous work that has noted the importance of careful initialization for DMV-based models such as the commonly used harmonic initializer (Klein and Manning, 2004). However, it is not straightforward to apply the harmonic initializer for DMV directly in our model without using some kind of pre-training since we do not observe gold POS.

System	M-1	VM
Gaussian HMM	72.0	65.0
Ours (4 layers)	76.4	69.3

System	$\leqslant 10$	all
Gaussian DMV	53.6	41.3
Ours (4 layers)	56.9	43.9
Ours (8 layers)	57.1	42.3
Ours (16 layers)	52.9	39.5

Table 5: Directed dependency accuracy on section 23 of WSJ, with fastText vectors as the observed embeddings.

Impact of Observed Embeddings. We investigate the effect of the choice of pre-trained embedding on performance while using our approach. To this end, we additionally include results using fastText embeddings (Bojanowski et al., 2017) – which, in contrast with skip-gram embeddings, include character-level information. We set the context windows size to 1 and the dimension size to 100 as in the skip-gram training, while keeping other parameters set to their defaults. These results are summarized in Table 4 and Table 5. While fastText embeddings lead to reduced performance with our model, our approach still yields an improvement over the Gaussian baseline with the new observed embeddings space.

4.6 Qualitative Analysis of Embeddings

We perform qualitative analysis to understand how the latent embeddings help induce syntactic structures. First we filter out low-frequency words and punctuations in WSJ, and visualize the rest words (10k) with t-SNE (Maaten and Hinton, 2008) under different embeddings. We assign each word with its most likely gold POS tags in WSJ and color them according to the gold POS tags.

---

[7] We tried to be as thorough as possible in evaluation by running top performing systems using our more difficult training setup when this was feasible – but it was not possible to evaluate them all.

Target	Skip-gram	Markov Structure
come	go came follow coming sit	be go do give follow
singing	dancing sing drumming dance dances	dancing drumming marching playing recording
cigars	cigarettes sodas champagne cigar rum	sodas bottles drinks pills cigarettes
newer	flashier fancier conventional low-end new-generation	softer lighter thinner darker smoother
fanciest	priciest up-scale loveliest fancier high-end	liveliest priciest smartest best-run fastest-growing

Table 6: Target words and their 5 nearest neighbors, based on skip-gram embeddings and our learned latent embeddings with Markov-structured syntax model.

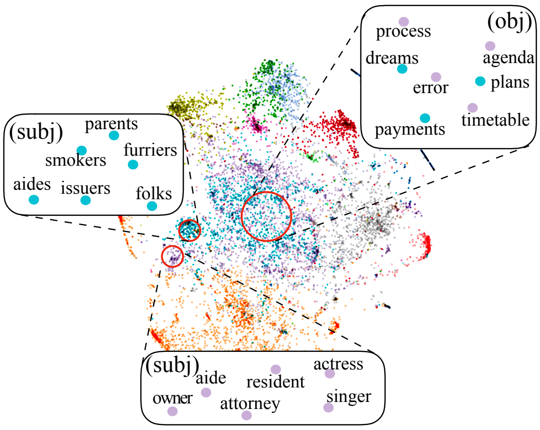

Figure 5: Visualization (t-SNE) of learned latent embeddings with DMV-structured syntax model. Each node represents a word and is colored according to the most likely gold POS tag in the Penn Treebank (best seen in color).

For our Markov-structured model, we have displayed the embedding space in Figure 1(b), where the gold POS clusters are well-formed. Further, we present five example target words and their five nearest neighbors in terms of cosine similarity. As shown in Table 6, the skip-gram embedding captures both semantic and syntactic aspects to some degree, yet our embeddings are able to focus especially on the syntactic aspects of words, in an unsupervised fashion without using any extra morphological information.

In Figure 5 we depict the learned latent embeddings with the DMV-structured syntax model. Unlike the Markov structure, the DMV structure maps a large subset of singular and plural nouns to the same overlapping region. However, two clusters of singular and plural nouns are actually separated. We inspect the two clusters and the overlapping region in Figure 5, it turns out that the nouns in the separated clusters are words that can appear as subjects and, therefore, for which verb agreement is important to model. In contrast, the nouns in the overlapping region are typically objects. This demonstrates that the latent embeddings are focusing on aspects of language that are specifically important for modeling dependency without ever having seen examples of dependency parses.

Some previous work has deliberately created embeddings to capture different notions of similarity (Levy and Goldberg, 2014; Cotterell and Schütze, 2015), while they use extra morphology or dependency annotations to guide the embedding learning, our approach provides a potential alternative to create new embeddings that are guided by structured syntax model, only using unlabeled text corpora.

5 Related Work

Our approach is related to flow-based generative models, which are first described in NICE (Dinh et al., 2014) and have recently received more attention (Dinh et al., 2016; Jacobsen et al., 2018; Kingma and Dhariwal, 2018). This relevant work mostly adopts simple (e.g. Gaussian) and fixed priors and does not attempt to learn interpretable latent structures. Another related generative model class is variational auto-encoders (VAEs) (Kingma and Welling, 2013) that optimize a lower bound on the marginal data likelihood, and can be extended to learn latent structures (Miao and Blunsom, 2016; Yin et al., 2018). Against the flow-based models, VAEs remove the invertibility constraint but sacrifice the merits of exact inference and exact log likelihood computation, which potentially results in optimization challenges (Kingma et al., 2016). Our approach can also be viewed in connection with generative adversarial networks (GANs) (Goodfellow et al., 2014) that is a likelihood-free framework to learn implicit generative models. However, it is non-trivial for a gradient-based method like GANs to propagate gradients through discrete structures.

6 Conclusion

In this work, we define a novel generative approach to leverage continuous word representations for unsupervised learning of syntactic structure. Experiments on both POS induction and unsupervised dependency parsing tasks demonstrate the effectiveness of our proposed approach. Future work might explore more sophisticated invertible projections, or recurrent projections that jointly transform the entire input sequence.

Dynamic Oracles for Top-Down and In-Order Shift-Reduce Constituent Parsing

Daniel Fernández-González and **Carlos Gómez-Rodríguez**

FASTPARSE Lab, LyS Research Group, Departamento de Computación
Campus de Elviña, s/n, 15071 A Coruña, Spain
d.fgonzalez@udc.es, carlos.gomez@udc.es

Abstract

We introduce novel dynamic oracles for training two of the most accurate known shift-reduce algorithms for constituent parsing: the top-down and in-order transition-based parsers. In both cases, the dynamic oracles manage to notably increase their accuracy, in comparison to that obtained by performing classic static training. In addition, by improving the performance of the state-of-the-art in-order shift-reduce parser, we achieve the best accuracy to date (92.0 F1) obtained by a fully-supervised single-model greedy shift-reduce constituent parser on the WSJ benchmark.

1 Introduction

The shift-reduce transition-based framework was initially introduced, and successfully adapted from the dependency formalism, into constituent parsing by Sagae and Lavie (2005), significantly increasing phrase-structure parsing performance.

A shift-reduce algorithm uses a sequence of transitions to modify the content of two main data structures (a buffer and a stack) and create partial phrase-structure trees (or constituents) in the stack to finally produce a complete syntactic analysis for an input sentence, running in linear time. Initially, Sagae and Lavie (2005) suggested that those partial phrase-structure trees be built in a *bottom-up* manner: two adjacent nodes already in the stack are combined under a non-terminal to become a new constituent. This strategy was followed by many researchers (Zhang and Clark, 2009; Zhu et al., 2013; Watanabe and Sumita, 2015; Mi and Huang, 2015; Crabbé, 2015; Cross and Huang, 2016b; Coavoux and Crabbé, 2016; Fernández-González and Gómez-Rodríguez, 2018) who managed to improve the accuracy and speed of the original Sagae and Lavie's bottom-up parser. With this, shift-reduce algorithms have become competitive, and are the fastest alternative to perform phrase-structure parsing to date.

Some of these attempts (Cross and Huang, 2016b; Coavoux and Crabbé, 2016; Fernández-González and Gómez-Rodríguez, 2018) introduced *dynamic oracles* (Goldberg and Nivre, 2012), originally designed for transition-based dependency algorithms, to bottom-up constituent parsing. They propose to use these dynamic oracles to train shift-reduce parsers instead of a traditional *static oracle*. The latter follows the standard procedure that uses a gold sequence of transitions to train a model for parsing new sentences at test time. A shift-reduce parser trained with this approach tends to be prone to suffer from error propagation (i.e. errors made in previous states are propagated to subsequent states, causing further mistakes in the transition sequence). Dynamic oracles (Goldberg and Nivre, 2012) were developed to minimize the effect of error propagation by training parsers under closer conditions to those found at test time, where mistakes are inevitably made. They are designed to guide the parser through any state it might reach during learning time. This makes it possible to introduce error exploration to force the parser to go through non-optimal states, teaching it how to recover from mistakes and lose the minimum number of gold constituents.

Alternatively, some researchers decided to follow a different direction and explore non-bottom-up strategies for producing phrase-structure syntactic analysis.

On the one hand, (Dyer et al., 2016; Kuncoro et al., 2017) proposed a *top-down* transition-based algorithm, which creates a phrase structure tree in the stack by first choosing the non-terminal on the top of the tree, and then considering which should be its child nodes. In contrast to the bottom-up approach, this top-down strategy adds a lookahead

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1303–1313
Brussels, Belgium, October 31 - November 4, 2018.

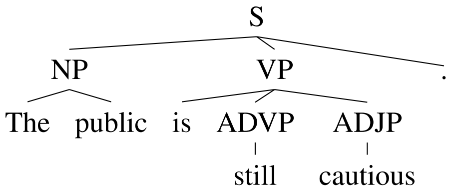

Figure 1: Simplified constituent tree, taken from English WSJ §22.

guidance to the parsing process, while it loses rich local features from partially-built trees.

On the other hand, Liu and Zhang (2017a) recently developed a novel strategy that finds a compromise between the strengths of top-down and bottom-up approaches, resulting in state-of-the-art accuracy. Concretely, this parser builds the tree following an *in-order* traversal: instead of starting the tree from the top, it chooses the non-terminal of the resulting subtree after having the first child node in the stack. In that way each partial constituent tree is created in a bottom-up manner, but the non-terminal node is not chosen when all child nodes are in the stack (as a purely bottom-up parser does), but after the first child is considered.

Liu and Zhang (2017a) report that the top-down approach is on par with the bottom-up strategy in terms of accuracy and the in-order parser yields the best accuracy to date on the WSJ. However, despite being two adequate alternatives to the traditional bottom-up strategy, no further work has been undertaken to improve their performance.[1]

We propose what, to our knowledge, are the first optimal dynamic oracles for both the top-down and in-order shift-reduce parsers, allowing us to train these algorithms with exploration. The resulting parsers outperform the existing versions trained with static oracles on the WSJ Penn Treebank (Marcus et al., 1993) and Chinese Treebank (CTB) benchmarks (Xue et al., 2005). The version of the in-order parser trained with our dynamic oracle achieves the highest accuracy obtained so far by a single fully-supervised greedy shift-reduce system on the WSJ.

2 Preliminaries

The original transition system of Sagae and Lavie (2005) parses a sentence from left to right by reading (moving) words from a *buffer* to a *stack*, where partial subtrees are built. This process is performed by a sequence of Shift (for reading) and Reduce (for building) transitions that will lead the parser through different states or parser configurations until a terminal one is reached. While in the bottom-up strategy the Reduce transition is in charge of labeling the partial subtree with a non-terminal at the same time the tree is built, Dyer et al. (2016) and Liu and Zhang (2017a) introduce a novel transition to choose the non-terminal on top, leaving the Reduce transition just to create the subtree under the previously decided non-terminal. We will now explain more in detail both the top-down and the in-order transition systems.

In both transition systems, parser configurations have the form $c = \langle \Sigma, i, f, \gamma, \alpha \rangle$, where Σ is a stack of constituents, i is the position of the leftmost unprocessed word in the buffer (which is the next to be pushed onto the stack), f is a boolean variable used by the in-order transition system to mark if a configuration is terminal or not and with no value in top-down parser configurations, γ is the set of constituents that have already been built, and α is the set of non-terminal nodes that are currently in the stack.

Each constituent is represented as a tuple (X, l, r), where X is a non-terminal and l and r are integers defining its span. Constituents are composed of one or several words or constituents, and just one non-terminal node on top. Each word w_i is represented as $(w, i, i+1)$. To define our oracles, we will need to represent each non-terminal node of the tree as (X, j), where j has the value of i when X is included in the stack and is used to keep them in order.[2]

For instance, the phrase-structure tree in Figure 1 can be decomposed as the following set of gold constituents: {(S, 0, 6), (NP, 0, 2), (VP, 2, 5), (ADVP, 3, 4), (ADJP, 4, 5)}. In addition, the ordered set of gold non-terminal nodes added to the stack while following a top-down strategy will be {(S, 0), (NP, 0), (VP, 2), (ADVP, 3), (ADJP, 4)} and, according to an in-order approach, {(NP, 1), (S, 2), (VP, 3), (ADVP, 4), (ADJP, 5)}. It is worth mentioning that the index of non-terminal nodes in the top-down method is the same as the leftmost span index of the constituent that it will produce. However, this does not hold in the in-order approach, as the leftmost child is fully processed before the node is added to the stack, so the index

---

[1] In parallel to this work, Fried and Klein (2018) present a non-optimal dynamic oracle for training the top-down parser.

[2] When two or more non-terminals share their labels within the tree, we use a secondary index to make them unique.

for the node will point to the leftmost span index of the second leftmost child.

Note that the information about the span of a constituent, the set of predicted constituents γ and the set α of predicted non-terminal nodes in the stack is not used by the original top-down and in-order parsers. However, we need to include it in parser configurations at learning time to allow an efficient implementation of the proposed dynamic oracles.

Given an input string $w_0 \cdots w_{n-1}$, the in-order parsing process starts at the initial configuration $c_s(w_0 \ldots w_{n-1}) = \langle [\,], 0, \mathit{false}, \{\}, \{\}\rangle$ and, after applying a sequence of transitions, it ends in a terminal configuration $\langle (S, 0, n), n, \mathit{true}, \gamma, \alpha\rangle$, where n is the number of words in the input sentence. The top-down transition system shares the same form for the initial and terminal configurations, except for the fact that variable f has no value in both cases.

Figure 2 shows the available transitions in the top-down algorithm. In particular, the Shift transition moves the first (leftmost) word in the buffer to the stack; the Non-Terminal-X transition pushes onto the stack the non-terminal node X that should be on top of a coming constituent, and the Reduce transition pops the topmost stack nodes until the first non-terminal node appears (which is also popped) and combines them into a constituent with this non-terminal node as their parent, pushing this new constituent into the stack. Note that every reduction action will add a new constituent to γ and remove a non-terminal node from α, and every Non-Terminal transition will include a new non-terminal node in α. Figure 3 shows the top-down transition sequence that produces the phrase-structure tree in Figure 1.

In Figure 4 we describe the available transitions in the in-order algorithm. The Shift, Non-Terminal-X and Reduce transitions have the same behavior as defined for the top-down transition system, except that the Reduce transition not only pops stack nodes until finding a non-terminal node (also removed from the stack), but also the node below this non-terminal node, and combines them into a constituent spanning all the popped nodes with the non-terminal node on top. And, finally, a Finish transition is also available to end the parsing process. Figure 5 shows the in-order transition sequence that outputs the constituent tree in Figure 1.

The standard procedure to train a greedy shift-reduce parser consists of training a classifier to approximate an *oracle*, which chooses optimal transitions with respect to gold parse trees. This classifier will greedily choose which transition sequence the parser should apply at test time.

Depending on the strategy used for training the parser, oracles can be static or dynamic. A static oracle trains the parser only on gold transition sequences, while a dynamic one can guide the parser through any possible transition path, allowing the exploration of non-optimal sequences.

3 Dynamic Oracles

Previous work such as (Cross and Huang, 2016b; Coavoux and Crabbé, 2016; Fernández-González and Gómez-Rodríguez, 2018) has introduced and successfully applied dynamic oracles for bottom-up phrase-structure parsing. We present dynamic oracles for training the top-down and in-order transition-based constituent parsers.

Goldberg and Nivre (2012) show that implementing a dynamic oracle reduces to defining a *loss function* on configurations to measure the distance from the best tree they can produce to the gold parse. This allows us to compute which transitions will lead the parser to configurations where the minimum number of mistakes are made.

3.1 Loss function

According to Fernández-González and Gómez-Rodríguez (2018), we can define a loss function in constituent parsing as follows: given a parser configuration c and a gold tree t_G, a loss function $\ell(c)$ is implemented as the minimum Hamming loss between t and t_G, ($\mathcal{L}(t, t_G)$), where t is the already-built tree of a configuration c' reachable from c (written as $c \rightsquigarrow t$). This Hamming loss is computed as the size of the symmetric difference between the set of constituents γ and γ_G in the trees t and t_G, respectively. Therefore, the loss function is defined as:

$$\ell(c) = \min_{\gamma | c \rightsquigarrow \gamma} \mathcal{L}(\gamma, \gamma_G) = |\gamma_G \setminus \gamma| + |\gamma \setminus \gamma_G|$$

and, according to the authors, it can be efficiently computed for a non-binary bottom-up transition system by counting the individually unreachable arcs from configuration c ($|\mathcal{U}(c, \gamma_G)|$) plus the erroneous constituents created so far ($|\gamma_c \setminus \gamma_G|$):

$$\ell(c) = \min_{\gamma | c \rightsquigarrow \gamma} \mathcal{L}(\gamma, \gamma_G) = |\mathcal{U}(c, \gamma_G)| + |\gamma_c \setminus \gamma_G|$$

$$
\begin{array}{ll}
\text{Shift:} & \langle \Sigma, i, /, \gamma, \alpha \rangle \Rightarrow \langle \Sigma | (w_i, i, i+1), i+1, /, \gamma \cup \{(w_i, i, i+1)\}, \alpha \rangle \\
\text{Non-Terminal-X:} & \langle \Sigma, i, /, \gamma, \alpha \rangle \Rightarrow \langle \Sigma | (X, i), i, /, \gamma, \alpha \cup \{(X, i)\} \rangle \\
\text{Reduce:} & \langle \Sigma | (X, j) | (Y_1, m_0, m_1) | ... | (Y_k, m_{k-1}, m_k), i, /, \gamma, \alpha \rangle \\
 & \qquad \Rightarrow \langle \Sigma | (X, j, m_k), i, /, \gamma \cup \{(X, j, m_k)\}, \alpha \setminus \{(X, j)\} \rangle
\end{array}
$$

Figure 3: Transition sequence for producing the constituent tree in Figure 1 using a top-down parser. SH = Shift, NT_{X} = Non-Terminal-X and RE = Reduce. Already-built constituents are marked in bold.

We adapt the latter to efficiently implement a loss function for the top-down and in-order strategies.

While in bottom-up parsing constituents are created at once by a Reduce transition, in the other two approaches a Non-Terminal transition begins the process by naming the future constituent and a Reduce transition builds it by setting its span and children. Therefore, a Non-Terminal transition that deviates from the non-terminals expected in the gold tree will eventually produce a wrong constituent in future configurations, so it should be penalized. Additionally, a sequence of gold Non-Terminal transitions may also lead to a wrong final parse if they are applied in an incorrect order. Then, the computation of the Hamming loss in top-down and in-order phrase-structure parsing adds two more terms to the bottom-up loss expression: (1) the number of predicted non-terminal nodes that are currently in the stack (α_c),[3] but not included in the set of gold non-terminal nodes (α_G), and (2) the number of gold non-terminal nodes in the stack that are out of order with respect to the order needed in the gold tree:

$$
\ell(c) = \min_{\gamma | c \rightsquigarrow \gamma} \mathcal{L}(\gamma, \gamma_G) = |\mathcal{U}(c, \gamma_G)| + |\gamma_c \setminus \gamma_G|
$$

$$
+ |\alpha_c \setminus \alpha_G| + out\_of\_order(\alpha_c, \alpha_G)
$$

This loss function is used to implement a dynamic oracle that, when given any parser configuration, will return the set of transitions τ that do not increase the overall loss (i.e., $\ell(\tau(c)) - \ell(c) = 0$), leading the system through optimal configurations that minimize Hamming loss with respect to t_G.

As suggested by (Coavoux and Crabbé, 2016; Fernández-González and Gómez-Rodríguez, 2018), *constituent reachability* can be used to efficiently compute the first term of the symmetric difference ($|\gamma_G \setminus \gamma|$), by simply counting the gold constituents that are individually unreachable from configuration c, as we describe in the next subsection.

The second and third terms of the loss ($|\gamma_c \setminus \gamma_G|$ and $|\alpha_c \setminus \alpha_G|$) can be trivially computed and are used to penalize false positives (extra erroneous constituents) so that final F-score is not harmed due to the decrease of precision, as pointed out by (Coavoux and Crabbé, 2016; Fernández-González and Gómez-Rodríguez, 2018). Note that it is crucial that the creation of non-gold Non-Terminal transitions is avoided, since these might not affect the creation of gold constituents, however, they will certainly lead the parser to the creation of extra erroneous constituents in future steps.

Finally, the function out_of_order of the last term can be implemented by computing the *longest increasing subsequence* of gold non-terminal nodes in the stack, where the order relation is given by the order of non-terminals (provided by their associated index) in the transition sequence that builds the gold tree (this order is unique, as none of our two parsers of interest have spurious ambiguity). Obtaining the longest increasing subsequence is a well-known problem solvable in time O(n log n) (Fredman, 1975), where n denotes the length of the input sequence. Once we have the largest possible sub-

---

[3] Note that we only consider predicted non-terminal nodes still in the stack, since wrong non-terminal nodes that have been already reduced are included in the loss as erroneous constituents.

Shift: $\langle \Sigma, i, \mathit{false}, \gamma, \alpha \rangle \Rightarrow \langle \Sigma | (w_i, i, i+1), i+1, \mathit{false}, \gamma \cup \{(w_i, i, i+1)\}, \alpha \rangle$

Non-Terminal-X: $\langle \Sigma, i, \mathit{false}, \gamma, \alpha \rangle \Rightarrow \langle \Sigma | (X, i), i, \mathit{false}, \gamma, \alpha \cup \{(X, i)\} \rangle$

Reduce: $\langle \Sigma | (Y_1, m_0, m_1) | (X, j) | ... | (Y_k, m_{k-1}, m_k), i, \mathit{false}, \gamma, \alpha \rangle$
$\Rightarrow \langle \Sigma | (X, m_0, m_k), i, \mathit{false}, \gamma \cup \{(X, m_0, m_k)\}, \alpha \setminus \{(X, j)\} \rangle$

Finish: $\langle (S, 0, n), n, \mathit{false}, \gamma, \alpha \rangle \Rightarrow \langle (S, 0, n), n, \mathit{true}, \gamma, \alpha \rangle$

sequence of gold non-terminal nodes in our configuration's stack that is compatible with the gold order, the remaining ones give us the number of erroneous constituents that we will unavoidably generate, even in the best case, due to building them in an incorrect order.

We will prove below that this loss formulation returns the exact loss and the resulting dynamic oracle is correct.

3.2 Constituent reachability

We now show how the computation of the set of reachable constituents developed for bottom-up parsing in (Coavoux and Crabbé, 2016; Fernández-González and Gómez-Rodríguez, 2018) can be extended to deal with the top-down and in-order strategies.

Top-down transition system Let γ_G and α_G be the set of gold constituents and the set of gold non-terminal nodes, respectively, for our current input. We say that a gold constituent $(X, l, r) \in \gamma_G$ is reachable from a configuration $c = \langle \Sigma, j, /, \gamma_c, \alpha_c \rangle$ with $\Sigma = [(Y_p, i_p, i_{p-1}) \cdots (Y_2, i_2, i_1) | (Y_1, i_1, j)]$, and it is included in the set of *individually reachable constituents* $\mathcal{R}(c, \gamma_G)$, iff it satisfies one of the following conditions:[4]

(i) $(X, l, r) \in \gamma_c$ (i.e. it has already been created and, therefore, it is reachable by definition).

(ii) $j \leq l < r \wedge (X, l) \notin \alpha_c$ (i.e. the words dominated by the gold constituent are still in the buffer and the non-terminal node that begins its creation has not been added to the stack yet; therefore, it can be still created after pushing the correct non-terminal node and shifting the necessary words).

(iii) $l \in \{i_k \mid 1 \leq k \leq p\} \wedge j \leq r \wedge (X, l) \in \alpha_c$ (i.e. its span is partially or completely in the stack and the corresponding non-terminal node was already added to the stack, then, by shifting more words or/and reducing, the constituent can still be created).

In-order transition system Let γ_G and α_G be the set of gold constituents and the set of gold non-terminal nodes, respectively, for our current input. We say that a gold constituent $(X, l, r) \in \gamma_G$ is reachable from a configuration $c = \langle \Sigma, j, \mathit{false}, \gamma_c, \alpha_c \rangle$ with $\Sigma = [(Y_p, i_p, i_{p-1}) \cdots (Y_2, i_2, i_1) | (Y_1, i_1, j)]$, and it is included in the set of *individually reachable constituents* $\mathcal{R}(c, \gamma_G)$, iff it satisfies one of the following conditions:

(i) $(X, l, r) \in \gamma_c$ (i.e. it has already been created).

(ii) $j \leq l < r$ (i.e. the constituent is entirely in the buffer, then it can be still built).

(iii) $l \in \{i_k \mid 1 \leq k \leq p\} \wedge j \leq r \wedge (X, m) \notin \alpha_c$ (i.e. its first child is still a totally- or partially-built constituent on top of the stack and the non-terminal node has not been created yet;

---

[4] Please note that elements from the stack can be an already-built constituent, a shifted word or a non-terminal node. Therefore, (Y_p, i_p, i_{p-1}), (Y_2, i_2, i_1) and (Y_1, i_1, j) should be represented as (Y_p, i_{p-1}), (Y_2, i_1) and (Y_1, j), respectively, when they are non-terminal nodes. We omit this for simplicity.

therefore, it has to wait till the first child is completed (if it is still pending) and, then, it can be still created by pushing onto the stack the correct non-terminal node and shifting more words if necessary).

(iv) $l \in \{i_k \mid 1 \leq k \leq p\} \wedge j \leq r \wedge (X, m) \in \alpha_c \wedge \exists(Y, l, m) \in \Sigma$ (i.e. its span is partially or completely in the stack, and its first child (which is an alredy-built constituent) and the non-terminal node assigned are adjacent, thus, by shifting more words or/and reducing, the constituent can still be built).

In both transition systems, the set of *individually unreachable constituents* $\mathcal{U}(c, \gamma_G)$ with respect to the set of gold constituents γ_G can be easily computed as $\gamma_G \setminus \mathcal{R}(c, \gamma_G)$ and will contain the gold constituents that can no longer be built.

3.3 Correctness

We will now prove that the above expression of $\ell(c)$ indeed provides the minimum possible Hamming loss to the gold tree among all the trees that are reachable from configuration c. This implies correctness (or optimality) of our oracle.

To do so, we first show that both algorithms are constituent-decomposable. This amounts to saying that if we take a set of m constituents that are tree-compatible (can appear together in a constituent tree, meaning that no pair of constituent spans overlap unless one is a subset of the other) and individually reachable from a configuration c, then the set is also reachable as a whole.

We prove this by induction on m. The base case ($m = 1$) is trivial. Let us suppose that constituent-decomposability holds for any set of m tree-compatible constituents. We will show that it also holds for any set T of $m+1$ tree-compatible constituents.

Let (X, l, r) be one of the constituents in T such that $r = \min\{r' \mid (X', l', r') \in T\}$ and $l = \max\{l' \mid (X', l', r) \in T\}$. Let $T' = T \setminus \{(X, l, r)\}$. Since T' has m constituents, by induction hypothesis, T' is a reachable set from configuration c.

Since (X, l, r) is individually reachable by hypothesis, it must satisfy at least one of the conditions for constituent reachability. As these conditions are different for each particular algorithm, we continue the proof separately for each:

Top-down constituent-decomposability In this case, we enumerated three constituent reachability conditions, so we divide the proof into three cases:

If the first condition holds, then the constituent (X, l, r) has already been created in c. Thus, it will still be present after applying any of the possible transition sequences that build T' starting from c. Hence, $T = T' \cup \{(X, l, r)\}$ is reachable from c.

If the second condition holds, then $j \leq l < r$ and the constituent (X, l, r) can be created by $l - j$ Shift transitions, followed by one Non-Terminal transition, $r - l$ Shift transitions and one Reduce transition. This will leave the parser in a configuration whose value of j is r, and where stack elements with left span index $\leq l$ (apart from those referencing the new non-terminal and its leftmost child) have not changed. Thus, constituents of T' are still individually reachable in this configuration, as their left span index is either $\geq r$ (and then they meet the second reachability condition) or $\leq l$ (and then they meet the third), so T is reachable from c.

Finally, if the third condition holds, then we can create (X, l, r) by applying $r - j$ Shift transitions followed by a sequence of Reduce transitions stopping when we obtain (X, l, r) on the stack (this will always happen after a finite number of such transitions, as the reachability condition guarantees that l is the left span index of some constituent already on the stack, and that (X, l) is on the stack). Following the same reasoning as in the previous case regarding the resulting parser configuration, we conclude that T is reachable from c.

With this we have shown the induction step, and thus constituent decomposability for the top-down parser.

In-order constituent decomposability The in-order parser has four constituent reachability conditions. Analogously to the previous case, we prove the reachability of T by case analysis.

If the first condition holds, then we have a situation where the constituent (X, l, r) has already been created in c, so reachability of T follows from the same reasoning as for the first condition in the top-down case.

If the second condition holds, we have $j \leq l < r$ and the constituent (X, l, r) can be created by $l - j + 1$ Shift transitions (where the last one shifts a word that will be assigned as left child of the new constituent), followed by the relevant Non-Terminal-X transition, $r - l - 1$ more Shift transitions and one Reduce transition. After this, the parser will be in a configuration where j takes the value r, where we can use the same reasoning as in the second condition of the top-down parser to show that all constituents of T' are still reachable, proving reachability of T.

For the third condition, the proof is analogous but the combination of transitions that creates the non-terminal starts with a sequence composed of Reduce transitions (when there is a non-terminal at the top of the stack) or Non-Terminal-Y transitions for arbitrary Y (when the top of the stack is a constituent) until the top node on the stack is a constituent with left span index l (this ensures that the constituent at the top of the stack can serve as leftmost child for our desired constituent), followed by a Non-Terminal-X, $r-j$ Shift transitions and one Reduce transition.

Finally, for the fourth condition, the reasoning is again analogous, but the computation leading to the non-terminal starts with as many Reduce transitions as non-terminal nodes located above (X, m) in the stack (if any). If we call j the index associated to the resulting transition, then it only remains to apply $r - j$ Shift transitions followed by a Reduce transition.

Optimality With this, we have shown constituent decomposability for both parsing algorithms. This means that, for a configuration c, and a set of constituents that are individually reachable from c, there is always some computation that can build them all. This facilitates the proof that the loss function is correct.

To finish the proof, we observe the following:

- Let c' be a final configuration reachable from c. The set $(\gamma_{c'} \setminus \gamma_G)$, representing erroneous constituents that have been built, will always contain at least $|\gamma_c \setminus \gamma_G|$, as the algorithm never deletes constituents.
- In addition, c' will contain one erroneous constituent for each element of $(\alpha_c \setminus \alpha_G)$, as once a non-terminal node is on the stack, there is no way to reach a final configuration without using it to create an erroneous constituent. Note that these erroneous constituents do not overlap those arising from the previous item, as γ_c stores already-built constituents and α_c non-terminals that have still not been used to build a constituent.
- Given a subset $\mathcal{S}$ of $\mathcal{R}(c, \gamma_G)$, the previously shown constituent decomposability property implies that there exists at least one transition sequence starting from c that generates the tree $\mathcal{S} \cup (\gamma_c \setminus \gamma_G) \cup E$, where E is a set of erroneous constituents containing one such constituent per element of $(\alpha_c \setminus \alpha_G)$. This tree has loss $|t_G| - (|\gamma_c \cup \mathcal{S}|) + |\gamma_c \setminus \gamma_G| + |\alpha_c \setminus \alpha_G|$. The term $|t_G| - (|\gamma_c \cup \mathcal{S}|)$ corresponds to missed constituents (gold constituents that have not been already created and are not created as part of $\mathcal{S}$), the other two to erroneous constituents.
- As we have shown that the erroneous constituents arising from $(\gamma_{c'} \setminus \gamma_G)$ and $(\alpha_c \setminus \alpha_G)$ are unavoidable, computations yielding a tree with minimum loss are those that maximize $|\gamma_c \cup \mathcal{S}|$ in the previous term. In general, the largest possible $|\mathcal{S}|$ is for $\mathcal{S} = \mathcal{R}(c, \gamma_G)$. In that case, we would correctly generate every reachable constituent and the loss would be

$$\ell(c) = |\mathcal{U}(c, \gamma_G)| + |\gamma_c \setminus \gamma_G| + |\alpha_c \setminus \alpha_G|$$

However, we additionally want to generate constituents in the correct order, and this may not be possible if we have already shifted some of them into the stack in a wrong order. The function out_of_order gives us the number of reachable constituents that are lost for this cause in the best case. Thus, indeed, the expression

$$\ell(c) = |\mathcal{U}(c, \gamma_G)| + |\gamma_c \setminus \gamma_G| + |\alpha_c \setminus \alpha_G| + out\_of\_order(\alpha_c, \alpha_G)$$

provides the minimum loss from configuration c.

4 Experiments

4.1 Data

We test the two proposed approaches on two widely-used benchmarks for constituent parsers: the Wall Street Journal (WSJ) sections of the English Penn Treebank[5] (Marcus et al., 1993) and version 5.1 of the Penn Chinese Treebank (CTB)[6] (Xue et al., 2005). We use the same predicted POS tags and pre-trained word embeddings as Dyer et al. (2016) and Liu and Zhang (2017a).

---

[5] Sections 2-21 are used as training data, Section 22 for development and Section 23 for testing

[6] Articles 001- 270 and 440-1151 are taken for training, articles 301-325 for system development, and articles 271-300 for final testing

4.2 Neural Model

To perform a fair comparison, we define the novel dynamic oracles on the original implementations of the top-down parser by Dyer et al. (2016) and in-order parser by Liu and Zhang (2017a), where parsers are trained with a traditional static oracle. Both implementations follow a stack-LSTM approach to represent the stack and the buffer, as well as a vanilla LSTM to represent the action history. In addition, they also use a bi-LSTM as a compositional function for representing constituents in the stack. Concretely, this consists in computing the composition representation s_{comp} as:

$$s_{comp} = (LSTM_{fwd}[e_{nt}, s_0, ..., s_m]; \\ LSTM_{bwd}[e_{nt}, s_m, ..., s_0])$$

where e_{nt} is the vector representation of a non-terminal, and s_i, $i \in [0, m]$ is the ith child node.

Finally, the exact same word representation strategy and hyper-parameter values as (Dyer et al., 2016) and (Liu and Zhang, 2017a) are used to conduct the experiments.

4.3 Error exploration

In order to benefit from training a parser by a dynamic oracle, errors should be made during the training process so that the parser can learn to avoid and recover from them. Unlike more complex error-exploration strategies as those studied in (Ballesteros et al., 2016; Cross and Huang, 2016b; Fried and Klein, 2018), we decided to consider a simple one that follows a non-optimal transition when it is the highest-scoring one, but with a certain probability. In that way, we easily simulate test time conditions, when the parser greedily chooses the highest-scoring transition, even when it is not an optimal one, placing the parser in an incorrect state.

In particular, we run experiments on development sets for each benchmark/algorithm with three different error exploration probabilities and choose the one that achieves the best F-score. Table 1 reports all results, including those obtained by the top-down and in-order parsers trained by a dynamic oracle without error exploration (equivalent to a traditional static oracle).

4.4 Results

Table 2 compares our system's accuracy to other state-of-the-art shift-reduce constituent parsers on the WSJ and CTB benchmarks. For comparison,

Table 3: F-score on constituents with a number of children ranging from one to five on WSJ §23.

we also include some recent state-of-the-art parsers with global chart decoding that achieve the highest accuracies to date on WSJ, but are much slower than shift-reduce algorithms.

Top-down and in-order parsers benefit from being trained by these new dynamic oracles in both datasets. The top-down strategy achieves a gain of 0.5 and 0.7 points in F-score on WSJ and CTB benchmarks, respectively. The in-order parser obtains similar improvements on the CTB (0.5 points), but less notable accuracy gain on the WSJ (0.2 points). Although a case of diminishing returns might explain the latter, the in-order parser trained with the proposed dynamic oracle still achieves the highest accuracy to date in greedy transition-based constituent parsing on the WSJ.[7]

While this work was under review, Fried and Klein (2018) proposed to train the top-down and in-order parsers with a policy gradient method instead of custom designed dynamic oracles. They also present a non-optimal dynamic oracle for the top-down parser that, combined with more complex error-exploration strategies and size-10 beam search, significantly outperforms the policy gradient-trained version, confirming that even non-optimal dynamic oracles are a good option.[8]

4.5 Analysis

Dan Bikel's randomized parsing evaluation comparator (Bikel, 2004) was used to perform significance tests on precision and recall metrics on WSJ §23 and CTB §271-300. The top-down parser trained with dynamic oracles achieves statistically significant improvements ($p < 0.05$) in precision both on the WSJ and CTB benchmarks, and in recall on WSJ. The in-order parser trained with the proposed technique obtains significant improvements ($p < 0.05$) in recall in both benchmarks, although not in precision.

We also undertake an analysis to check if dynamic oracles are able to mitigate error propagation. We report in Table 3 the F-score obtained in constituents with different number of children on WSJ §23 by the top-down and in-order algorithms trained with both static and dynamic oracles. Please note that creating a constituent with a great number of children is more prone to suffer from error propagation, since a larger number of transitions is required to build it. The results seem to confirm that, indeed, dynamic oracles manage to alleviate error propagation, since improvements in F-score are more notable for larger constituents.

5 Conclusion

We develop the first optimal dynamic oracles for training the top-down and the state-of-the-art in-order parsers. Apart from improving the systems' accuracies in both cases, we achieve the best result to date in greedy shift-reduce parsing on the WSJ. In addition, these promising techniques could easily benefit from recent studies in error-exploration strategies and yield state-of-the-art accuracies in transition-based parsing in the near future. The parser's source code is freely available at `https://github.com/danifg/Dynamic-InOrderParser`.

---

[7] Note that the proposed dynamic oracles are orthogonal to approaches like beam search, re-ranking or semi-supervision, that can boost accuracy but at a large cost to parsing speed.

[8] Unfortunately, we cannot directly compare our approach to theirs, since they use beam-search decoding with size 10 in all experiments, gaining up to 0.3 points in F-score, while penalizing speed with respect to greedy decoding. However, by extrapolating the results above, we hypothesize that our optimal dynamic oracles (especially the one designed for the in-order algorithm) with their same training and beam-search decoding setup might achieve the best scores to date in shift-reduce parsing.

Abstract

We introduce a method to reduce constituent parsing to sequence labeling. For each word w_t, it generates a label that encodes: (1) the number of ancestors in the tree that the words w_t and w_{t+1} have in common, and (2) the nonterminal symbol at the lowest common ancestor. We first prove that the proposed encoding function is injective for any tree without unary branches. In practice, the approach is made extensible to all constituency trees by collapsing unary branches. We then use the PTB and CTB treebanks as testbeds and propose a set of fast baselines. We achieve 90% F-score on the PTB test set, outperforming the Vinyals et al. (2015) sequence-to-sequence parser. In addition, sacrificing some accuracy, our approach achieves the fastest constituent parsing speeds reported to date on PTB by a wide margin.

1 Introduction

Constituent parsing is a core problem in NLP where the goal is to obtain the syntactic structure of sentences expressed as a phrase structure tree.

Traditionally, constituent-based parsers have been built relying on chart-based, statistical models (Collins, 1997; Charniak, 2000; Petrov et al., 2006), which are accurate but slow, with typical speeds well below 10 sentences per second on modern CPUs (Kummerfeld et al., 2012).

Several authors have proposed more efficient approaches which are helpful to gain speed while preserving (or even improving) accuracy. Sagae and Lavie (2005) present a classifier for constituency parsing that runs in linear time by relying on a shift-reduce stack-based algorithm, instead of a grammar. It is essentially an extension of transition-based dependency parsing (Nivre, 2003). This line of research has been polished through the years (Wang et al., 2006; Zhu et al., 2013; Dyer et al., 2016; Liu and Zhang, 2017; Fernández-González and Gómez-Rodríguez, 2018).

With an aim more related to our work, other authors have reduced constituency parsing to tasks that can be solved faster or in a more generic way. Fernández-González and Martins (2015) reduce phrase structure parsing to dependency parsing. They propose an intermediate representation where dependency labels from a head to its dependents encode the nonterminal symbol and an attachment order that is used to arrange nodes into constituents. Their approach makes it possible to use off-the-shelf dependency parsers for constituency parsing. In a different line, Vinyals et al. (2015) address the problem by relying on a sequence-to-sequence model where trees are linearized in a depth-first traversal order. Their solution can be seen as a machine translation model that maps a sequence of words into a parenthesized version of the tree. Choe and Charniak (2016) recast parsing as language modeling. They train a generative parser that obtains the phrasal structure of sentences by relying on the Vinyals et al. (2015) intuition and on the Zaremba et al. (2014) model to build the basic language modeling architecture.

More recently, Shen et al. (2018) propose an architecture to speed up the current state-of-the-art chart parsers trained with deep neural networks (Stern et al., 2017; Kitaev and Klein, 2018). They introduce the concept of *syntactic distances*, which specify the order in which the splitting points of a sentence will be selected. The model learns to predict such distances, to then recursively partition the input in a top-down fashion.

Contribution We propose a method to transform constituent parsing into sequence labeling. This reduces it to the complexity of tasks such as part-of-speech (PoS) tagging, chunking or named-entity recognition. The contribution is two-fold.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1314–1324
Brussels, Belgium, October 31 - November 4, 2018.

First, we describe a method to linearize a tree into a sequence of labels (§2) of the same length of the sentence minus one.[1] The label generated for each word encodes the number of common ancestors in the constituent tree between that word and the next, and the nonterminal symbol associated with the lowest common ancestor. We prove that the encoding function is injective for any tree without unary branchings. After applying collapsing techniques, the method can parse unary chains.

Second, we use such encoding to present different baselines that can effectively predict the structure of sentences (§3). To do so, we rely on a recurrent sequence labeling model based on BILSTM's (Hochreiter and Schmidhuber, 1997; Yang and Zhang, 2018). We also test other models inspired in classic approaches for other tagging tasks (Schmid, 1994; Sha and Pereira, 2003). We use the Penn Treebank (PTB) and the Penn Chinese Treebank (CTB) as testbeds.

The comparison against Vinyals et al. (2015), the closest work to ours, shows that our method is able to train more accurate parsers. This is in spite of the fact that our approach addresses constituent parsing as a sequence labeling problem, which is simpler than a sequence-to-sequence problem, where the output sequence has variable/unknown length. Despite being the first sequence labeling method for constituent parsing, our baselines achieve decent accuracy results in comparison to models coming from mature lines of research, and their speeds are the fastest reported to our knowledge.

2 Linearization of *n*-ary trees

Notation and Preliminaries In what follows, we use bold style to refer to vectors and matrices (e.g $\mathbf{x}$ and $\mathbf{W}$). Let $\mathbf{w}$=$[w_1, w_2, ..., w_{|w|}]$ be an input sequence of words, where $w_i \in V$. Let $T_{|w|}$ be the set of constituent trees with $|w|$ leaf nodes that have no unary branches. For now, we will assume that the constituent parsing problem consists in mapping each sentence $\mathbf{w}$ to a tree in $T_{|w|}$, i.e., we assume that correct parses have no unary branches. We will deal with unary branches later.

To reduce the problem to a sequence labeling task, we define a set of labels L that allows us to encode each tree in $T_{|w|}$ as a unique sequence of labels in $L^{(|w|-1)}$, via an encoding function $\Phi_{|w|} : T_{|w|} \rightarrow L^{(|w|-1)}$. Then, we can reduce the constituent parsing problem to a sequence labeling task where the goal is to predict a function $F_{|w|,\theta} : V^{|w|} \rightarrow L^{|w|-1}$, where θ are the parameters to be learned. To parse a sentence, we label it and then decode the resulting label sequence into a constituent tree, i.e., we apply $F_{|w|,\theta} \circ \Phi^{-1}_{|w|}$.

For the method to be correct, we need the encoding of trees to be complete (every tree in $T_{|w|}$ must be expressible as a label sequence, i.e., $\Phi_{|w|}$ must be a function, so we have full coverage of constituent trees) and injective (so that the inverse function $\Phi^{-1}_{|w|}$ is well-defined). Surjectivity is also desirable, so that the inverse is a function on $L^{|w|-1}$, and the parser outputs a tree for any sequence of labels that the classifier can generate.

We now define our $\Phi_{|w|}$ and show that it is total and injective. Our encoding is not surjective per se. We handle ill-formed label sequences in §2.3.

2.1 The Encoding

Let w_i be a word located at position i in the sentence, for $1 \leq i \leq |w| - 1$. We will assign it a 2-tuple label $l_i = (n_i, c_i)$, where: n_i is an integer that encodes the number of common ancestors between w_i and w_{i+1}, and c_i is the nonterminal symbol at the lowest common ancestor.

Basic encodings The number of common ancestors may be encoded in several ways.

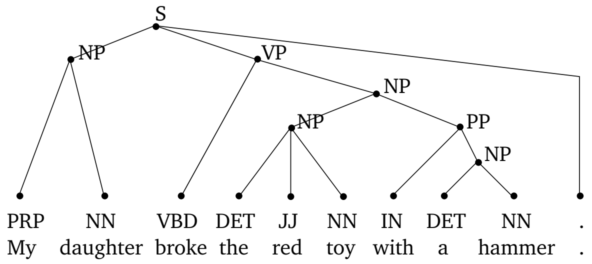
1. Absolute scale: The simplest encoding is to make n_i directly equal to the number of ancestors in common between w_i and w_{i+1}.
2. Relative scale: A second and better variant consists in making n_i represent the difference with respect to the number of ancestors encoded in n_{i-1}. Its main advantage is that the size of the label set is reduced considerably.

Figure 1 shows an example of a tree linearized according to both absolute and relative scales.

Encoding for trees with exactly k children For trees where all branchings have exactly k children, it is possible to obtain a even more efficient linearization in terms of number of labels. To do so, we take the relative scale encoding as our starting point. If we build the tree incrementally in a left-to-right manner from the labels, if we find a negative n_i, we will need to attach the word w_{i+1} (or a new subtree with that word as its leftmost leaf) to the $(-n_i + 2)$th node in the path going from

---

[1] A last dummy label is generated to fulfill the properties of sequence labeling tasks.



Linearized tree (absolute scale):

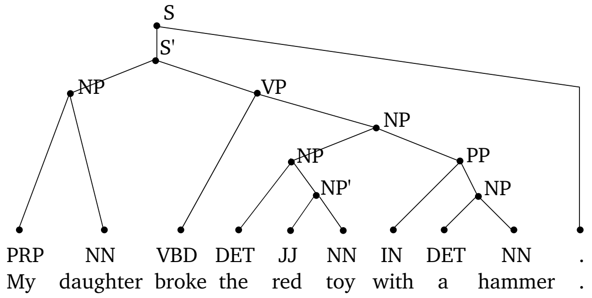
2NP 1S 2VP 4NP 4NP 3NP 4PP 5NP 1S

Linearized tree (relative scale):

2NP -1S 1VP 2NP 0NP -1NP 1PP 1NP -4S

Figure 1: An example of a constituency tree linearized applying both absolute and relative scales.

w_i to the root. If every node must have exactly k children, there is only one valid negative value of n_i: the one pointing to the first node in said path that has not received its kth child yet. Any smaller value would leave this node without enough children (which cannot be fixed later due to the left-to-right order in which we build the tree), and any larger value would create a node with too many children. Thus, we can map negative values to a single label. Figure 2 shows an example for the case of binarized trees ($k = 2$).



Linearized tree (absolute scale):

3NP 2S' 3VP 5NP 6NP' 4NP 5PP 6NP 1S

Linearized tree (relative scale):

3NP -1S' 1VP 2NP 1NP' -2NP 1PP 1NP -5S

Linearized tree (simplified relative scale):

3NP -S' 1VP 2NP 1NP' -NP 1PP 1NP -S

Figure 2: An example of a binarized constituency tree, linearized both applying absolute and relative scales.

Links to root Another variant emerged from the empirical observation that some tokens that are usually linked to the root node (such as the final punctuation in Figure 1) were particularly difficult to learn for the simpler baselines. To successfully deal with these cases in practice, it makes sense to consider a simplified annotation scheme where a node is assigned a special tag (ROOT, c_i) when it is directly linked to the root of the tree.

From now on, unless otherwise specified, we use the relative scale without the simplification for exactly k children. This will be the encoding used in the experiments (§4), because the size of the label set is significantly lower than the one obtained by relying on the absolute one. Also, it works directly with non-binarized trees, in contrast to the encoding that we introduce for trees with exactly k children, which is described only for completeness and possible interest for future work. For the experiments (§4), we also use the special tag (ROOT, c_i) to further reduce the size of the label set and to simplify the classification of tokens connected to the root, where $|n_i|$ is expected to be large.

2.2 Theoretical correctness

We now prove that $\Phi_{|w|}$ is a total function and injective for any tree in $T_{|w|}$. We remind that trees in this set have no unary branches. Later (in §2.3) we describe how we deal with unary branches. To prove correctness, we use the relative scale. Correctness for the other scales follows trivially.

Completeness Every pair of nodes in a rooted tree has at least one common ancestor, and a unique lowest common ancestor. Hence, for any tree in $T_{|w|}$, the label $l_i = (n_i, c_i)$ defined in Section 2.1 is well-defined and unique for each word w_i, $1 \leq i \leq |w| - 1$; and thus $\Phi_{|w|}$ is a total function from $T_{|w|}$ to $L^{(|w|-1)}$.

Injectivity The encoding method must ensure that any given sequence of labels corresponds to exactly one tree. Otherwise, we have to deal with ambiguity, which is not desirable.

For simplicity, we will prove injectivity in two steps. First, we will show that the encoding is injective if we ignore nonterminals (i.e., equivalently, that the encoding is injective for the set of trees resulting from replacing all the nonterminals in trees in $T_{|w|}$ with a generic nonterminal X). Then, we will show that it remains injective when we take nonterminals into account.

For the first part, let $\tau \in T_{|w|}$ be a tree where nonterminals take a generic value X. We represent the label of the ith leaf node as $\bullet_i$. Consider the representation of τ as a bracketed string, where a single-node tree with a node labeled A is represented by (A), and a tree rooted at R

with child subtrees $C_1 \dots C_n$ is represented as $(R(C_1 \dots C_n))$.

Each leaf node will appear in this string as a substring $(\bullet_i)$. Thus, the parenthesized string has the form $\alpha_0(\bullet_1)\alpha_1(\bullet_2)\dots\alpha_{|w|-1}(\bullet_{|w|})\alpha_w$, where the α_is are strings that can only contain brackets and nonterminals, as by construction there can be no leaf nodes between $(\bullet_i)$ and $(\bullet_{i+1})$.

We now observe some properties of this parenthesized string. First, note that each of the substrings α_i must necessarily be composed of zero or more closing parentheses followed by zero or more opening parentheses with their corresponding nonterminal, i.e., it must be of the form $[)]^*[(X]^*$. This is because an opening parenthesis followed by a closing parenthesis would represent a leaf node, and there are no leaf nodes between $(\bullet_i)$ and $(\bullet_{i+1})$ in the tree.

Thus, we can write α_i as $\alpha_{i)}\alpha_{i(}$, where $\alpha_{i)}$ is a string matching the expression $[)]^*$ and $\alpha_{i(}$ a string matching the expression $[(X]^*$. With this, we can write the parenthesized string for τ as

$$\alpha_{0)}\alpha_{0(}(\bullet_1)\alpha_{1)}\alpha_{1(}(\bullet_2)\alpha_{2)}\alpha_{2(}\dots(\bullet_{|w|})\alpha_{|w|)}\alpha_{|w|(}.$$

Let us now denote by β_i the string $\alpha_{i-1(}(\bullet_i)\alpha_{i)}$. Then, and taking into account that $\alpha_{0)}$ and $\alpha_{w(}$ are trivially empty in the previous expression due to bracket balancing, the expression for the tree becomes simply $\beta_1\beta_2\dots\beta_{|w|}$, where we know, by construction, that each β_i is of the form $[(X]^*(\bullet_i)[)]^*$.

Since we have shown that each tree in $T_{|w|}$ uniquely corresponds to a string $\beta_1\beta_2\dots\beta_{|w|}$, to show injectivity of the encoding, it suffices to show that different values for a β_i generate different label sequences.

To show this, we can say more about the form of β_i: it must be either of the form $[(X]^*(\bullet_i)$ or of the form $(\bullet_i)[)]^*$, i.e., it is not possible that β_i contains both opening parenthesis before the leaf node and closing parentheses after the leaf node. This could only happen if the tree had a subtree of the form $(X(\bullet_i))$, but this is not possible since we are forbidding unary branches.

Hence, we can identify each β_i with an integer number $\delta(\beta_i)$: 0 if β_i has neither opening nor closing parentheses outside the leaf node, $+k$ if it has k opening parentheses, and $-k$ if it has k closing parentheses. It is easy to see that $\delta(\beta_1)\delta(\beta_2)\dots\delta(\beta_{|w|-1})$ corresponds to the values n_i in the relative-scale label encoding of the tree τ. To see this, note that the number of unclosed parentheses at the point right after β_i in the string exactly corresponds to the number of common ancestors between the ith and $(i+1)$th leaf nodes. A positive $\delta(\beta_i) = k$ corresponds to opening k parentheses before β_i, so the number of common ancestors of w_i and w_{i+1} will be k more than that of w_{i-1} and w_i. A negative $\delta(\beta_i) = -k$ corresponds to closing k parentheses after β_i, so the number of common ancestors will conversely decrease by k. A value of zero means no opening or closing parentheses, and no change in the number of common ancestors.

Thus, different parenthesized strings $\beta_1\beta_2\dots\beta_{|w|}$ generate different label sequences, which proves injectivity ignoring nonterminals (note that $\delta(\beta_{|w|})$ does not affect injectivity as it is uniquely determined by the other values: it corresponds to closing all the parentheses that remain unclosed at that point).

It remains to show that injectivity still holds when nonterminals are taken into account. Since we have already proven that trees with different structure produce different values of n_i in the labels, it suffices to show that trees with the same structure, but different nonterminals, produce different values of c_i. Essentially, this reduces to showing that every nonterminal in the tree is mapped into a concrete c_i. That said, consider a tree $\tau \in T_{|w|}$, and some nonterminal X in τ. Since trees in T_w do not have unary branches, X has at least two children. Consider the rightmost word in the first child subtree, and call it w_i. Then, w_{i+1} is the leftmost word in the second child subtree, and X is the lowest common ancestor of w_i and w_{i+1}. Thus, $c_i = X$, and a tree with identical structure but a different nonterminal at that position will generate a label sequence with a different value of c_i. This concludes the proof of injectivity.

2.3 Limitations

We have shown that our proposed encoding is a total, injective function from trees without unary branches with yield of length $|w|$ to sequences of $|w| - 1$ labels. This will serve as the basis for our reduction of constituent parsing to sequence labeling. However, to go from theory to practice, we need to overcome two limitations of the theoretical encoding: non-surjectivity and the inability to encode unary branches. Fortunately, both can be overcome with simple techniques.

Handling of unary branches The encoding function $\Phi_{|w|}$ cannot directly assign the nonterminal symbols of unary branches, as there is not any pair of words (w_i, w_{i+1}) that have those in common. Figure 3 illustrates it with an example.

It is worth remarking that this is not a limitation of our encoding, but of any encoding that would facilitate constituent parsing as sequence labeling, as the number of nonterminal nodes in a tree with unary branches is not bounded by any function of $|w|$. The fact that our encoding works for trees without unary branches owes to the fact that such a tree cannot have more than $|w|-1$ non-leaf nodes, and therefore it is always possible to encode all of them in labels associated with $|w|-1$ leaf nodes.

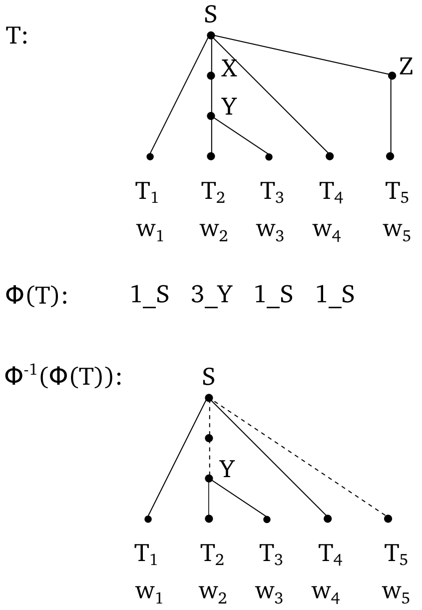


Figure 3: An example of a tree that cannot be directly linearized with our approach. w_i and T_i abstract over words and PoS tags. Dotted lines represent incorrect branches after applying and inverting our encoding naively without any adaptation for unaries. The nonterminal symbol of the second ancestor of w_2 (X) cannot be decoded, as no pair of words have X as their lowest common ancestor. A similar situation can be observed for the closest ancestor of w_5 (Z).

To overcome this issue, we follow a collapsing approach, as is common in parsers that need special treatment of unary chains (Finkel et al., 2008; Narayan and Cohen, 2016; Shen et al., 2018). For clarity, we use the name *intermediate unary chains* to refer to unary chains that end up into a nonterminal symbol (e.g. X → Y in Figure 3) and *leaf unary chains* to name those that yield a PoS tag (e.g. Z → T_5). Intermediate unary chains are collapsed into a chained single symbol, which can be encoded by $\Phi_{|w|}$ as any other nonterminal symbol. On the other hand, leaf unary chains are collapsed together with the PoS tag, but these cannot be encoded and decoded by relying on $\Phi_{|w|}$, as our encoding assumes a fixed sequence of leaf nodes and does not encode them explicitly. To overcome this, we propose two methods:

1. To use an extra function to enrich the PoS tags before applying our main sequence labeling function. This function is of the form $\Psi_{|w|} : V^{|w|} \rightarrow U^{|w|}$, where U is the set of labels of the leaf unary chains (without including the PoS tags) plus a dummy label $\varnothing$. $\Psi_{|w|}$ maps w_i to $\varnothing$ if there is no leaf unary chain at w_i, or to the collapsed label otherwise.

2. To extend our encoding function to predict them as a part of our labels l_i, by transforming them into 3-tuples (n_i, c_i, u_i) where u_i encodes the leaf unary chain collapsed label for w_i, if there is any, or none otherwise. We call this extended encoding function $\Phi'_{|w|}$.

The former requires to run two passes of sequence labeling to deal with leaf unary chains. The latter avoids this, but the number of labels is larger and sparser. In §4 we discuss how these two approaches behave in terms of accuracy and speed.

Non-surjectivity Our encoding, as defined formally in Section 2.1, is injective but not surjective, i.e., not every sequence of $|w|-1$ labels of the form (n_i, c_i) corresponds to a tree in $T_{|w|}$. In particular, there are two situations where a label sequence formally has no tree, and thus $\Phi^{-1}_{|w|}$ is not formally defined and we have to use extra heuristics or processing to define it:

- Sequences with conflicting nonterminals. A nonterminal can be the lowest common ancestor of more than two pairs of contiguous words when branches are non-binary. For example, in the tree in Figure 1, the lowest common ancestor of both “the” and “red” and of “red” and “toy” is the same NP node. This translates into $c_4 = NP$, $c_5 = NP$ in the label sequence. If we take that sequence and set $c_5 = VP$, we obtain a label sequence that does not strictly correspond to the encoding of any tree, as it contains a contradiction: two elements referencing the same node indicate different nonterminal labels. In practice, this problem is trivial to solve: when a label sequence encodes several conflicting nonterminals at a given position in the tree, we compute $\Phi_{|w|}^{-1}$ using the first such nonterminal and ignoring the rest.

- Sequences that produce unary structures. There are sequences of values n_i that do not correspond to a tree in $T_{|w|}$ because the only tree structure satisfying the common ancestor conditions of their values (the one built by generating the string of β_is in the injectivity proof) contains unary branchings, causing the problem described above where we do not have a specification for every nonterminal. An example of this is the sequence $(1, S), (3, Y), (1, S), (1, S)$ in absolute scaling, that was introduced in Figure 3. In practice, as unary chains have been previously collapsed, any generated unary node is considered as not valid and removed.

3 Sequence Labeling

Sequence labeling is an structured prediction task that generates an output label for every token in an input sequence (Rei and Søgaard, 2018). Examples of practical tasks that can be formulated under this framework in natural language processing are PoS tagging, chunking or named-entity recognition, which are in general fast. However, to our knowledge, there is no previous work on sequence labeling methods for constituent parsing, as an encoding allowing it was lacking so far.

In this work, we consider a range of methods ranging from traditional models to state-of-the-art neural models for sequence labeling, to test whether they are valid to train constituency-based parsers following our approach. We give the essential details needed to comprehend the core of each approach, but will mainly treat them as black boxes, referring the reader to the references for a careful and detailed mathematical analysis of each method. Appendix A specifies additional hyperparameters for the tested models.

Preprocessing We add to every sentence both beginning and end tokens.

3.1 Traditional Sequence Labeling Methods

We consider two baselines to train our prediction function $F_{|w|,\theta}$, based on popular sequence labeling methods used in NLP problems, such as PoS tagging or shallow parsing (Schmid, 1994; Sha and Pereira, 2003).

Conditional Random Fields (Lafferty et al., 2001) Let $\text{CRF}_{|w|,\theta}$ be its prediction function, a CRF model computes conditional probability distributions of the form $p(\mathbf{l}, \mathbf{w})$ such that $\text{CRF}_\theta(\mathbf{w}) = \mathbf{l} = \arg\max_{\mathbf{l}'} p(\mathbf{l}', \mathbf{w})$. In our work, the inputs to the CRF are words and PoS tags. To represent a word w_i, we are using information of the word itself and also contextual information from $\mathbf{w}_{[i-1:i+1]}$.[2] In particular:

- We extract the word form (lowercased), the PoS tag and its prefix of length 2, from $\mathbf{w}_{[i-1:i+1]}$. For these words we also include binary features: whether it is the first word, the last word, a number, whether the word is capitalized or uppercased.
- Additionally, for w_i we look at the suffixes of both length 3 and 2 (i.e. $w_{i[-3:]}$ and $w_{i[-2:]}$).

To build our CRF models, we relied on the `sklearn-crfsuite` library[3].

MultiLayer Perceptron (Rosenblatt, 1958) We use one hidden layer. Let $\text{MLP}_{|w|,\theta}$ be its prediction function, it treats sequence labeling as a set of independent predictions, one per word. The prediction for a word is computed as $softmax(\mathbf{W_2} \cdot relu(\mathbf{W_1} \cdot \mathbf{x} + \mathbf{b_1}) + \mathbf{b_2})$, where $\mathbf{x}$ is the input vector and W_i and b_i the weights and biases to be learned at layer i. We consider both a discrete (MLP_d) and an embedded (MLP_e) perceptron. For the former, we use as inputs the same set of features as for the CRF. For the latter, the vector $\mathbf{x}$ for w_i is defined as a concatenation of word and PoS tag embeddings from $\mathbf{w}_{[i-2:i+2]}$.[4]

To build our MLPs, we relied on `keras`.[5]

3.2 Sequence Labeling Neural Models

We are using NCRFPP++[6], a sequence labeling framework based on recurrent neural networks (RNN) (Yang and Zhang, 2018), and more specifically on bidirectional short-term memory networks (Hochreiter and Schmidhuber, 1997),

---

[2] We tried contextual information beyond the immediate previous and next word, but the performance was similar.

[3] https://sklearn-crfsuite.readthedocs.io/en/latest/

[4] In contrast to the discrete input, larger contextual information was useful.

[5] https://keras.io/

[6] https://github.com/jiesutd/NCRFpp, with PyTorch.

which have been successfully applied to problems such as PoS tagging or dependency parsing (Plank et al., 2016; Kiperwasser and Goldberg, 2016). Let $\text{LSTM}(\mathbf{x})$ be an abstraction of a standard long short-term memory network that processes the sequence $\mathbf{x} = [\mathbf{x}_1, ..., \mathbf{x}_{|\mathbf{x}|}]$, then a BILSTM encoding of its ith element, $\text{BILSTM}(\mathbf{x}, i)$ is defined as:

$$\text{BILSTM}(\mathbf{x}, i) = \mathbf{h}_i = \mathbf{h}_i^l \circ \mathbf{h}_i^r = \\ \text{LSTM}^l(\mathbf{x}_{[1:i]}) \circ \text{LSTM}^r(\mathbf{x}_{[|\mathbf{x}|:i]})$$

In the case of multilayer BILSTM'S, the timestep outputs of the BILSTM_m are fed as input to the BILSTM_{m+1}. The output label for each w_i is finally predicted as $softmax(W \cdot \mathbf{h}_i + b)$.

Given a sentence $[w_1, w_2, ..., w_{|w|}]$, the input to the sequence model is a sequence of embeddings $[\mathbf{w_1}, \mathbf{w_2}, ..., \mathbf{w}_{|\mathbf{w}|}]$ where each $\mathbf{w_i} = \mathbf{w}_i \circ \mathbf{p}_i \circ \mathbf{ch}_i$, such that $\mathbf{w}_i$ and $\mathbf{p}_i$ are a word and a PoS tag embedding, and $\mathbf{ch}_i$ is a word embedding obtained from an initial character embedding layer, also based on a BILSTM. Figure 4 shows the architecture of the network.

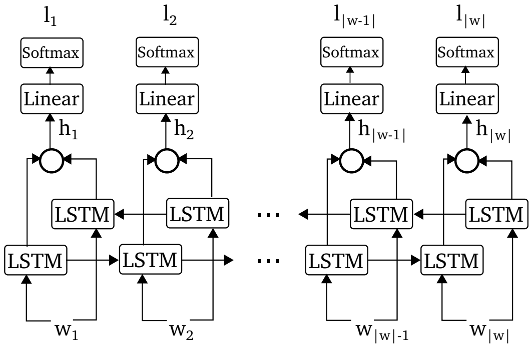

Figure 4: Architecture of the neural model

4 Experiments

We report results on models trained using the relative scale encoding and the special tag (ROOT,c_i). As a reminder, to deal also with leaf unary chains, we proposed two methods in §2.3: to predict them relying both on the encoding functions $\Phi_{|w|}$ and $\Psi_{|w|}$, or to predict them as a part of an enriched label predicted by the function $\Phi'_{|w|}$. For clarity, we are naming these models with the superscripts $^{\Psi,\Phi}$ and $^{\Phi'}$, respectively.

Datasets We use the Penn Treebank (Marcus et al., 1994) and its official splits: Sections 2 to 21 for training, 22 for development and 23 for testing. For the Chinese Penn Treebank (Xue et al., 2005): articles 001- 270 and 440-1151 are used for training, articles 301-325 for development, and articles 271-300 for testing. We use the version of the corpus with the predicted PoS tags of Dyer et al. (2016). We train the Φ models based on the predicted output by the corresponding Ψ model.

Metrics We use the F-score from the EVALB script. Speed is measured in sentences per second. As the problem is reduced to sequence labeling, we briefly comment on the accuracy (percentage of correctly predicted labels) of our baselines.

Source code It can be found at `https://github.com/aghie/tree2labels`

Hardware The models are run on a single thread of a CPU[7] and on a consumer-grade GPU[8]. In sequence-to-sequence work (Vinyals et al., 2015) the authors use a multi-core CPU (the number of threads was not specified), while we provide results on a single core for easier comparability. Parsing sentences on a CPU can be framed as an "embarrassingly parallel" problem (Hall et al., 2014), so speed can be made to scale linearly with the number of cores. We use the same batch size as Vinyals et al. (2015) for testing (128).[9]

4.1 Results

Table 1 shows the performance of our baselines on the PTB development set. It is worth noting that since we are using different libraries to train the models, these might show some differences in terms of performance/speed beyond those expected in theory. For the BILSTM model we test:

- $\text{BILSTM}_{m=1}$: It does not use pretrained word embeddings nor character embeddings. The number of layers m is set to 1.
- $\text{BILSTM}_{m=1,e}$: It adds pretrained word embeddings from GloVe (Pennington et al., 2014) for English and from the Gigaword corpus for Chinese (Liu and Zhang, 2017).
- $\text{BILSTM}_{m=1,e,ch}$: It includes character embeddings processed through a BILSTM.
- $\text{BILSTM}_{m=2,e}$: m is set to 2. No character embeddings.
- $\text{BILSTM}_{m=2,e,ch}$: m is set to 2.

$\text{BILSTM}_{m=1}^{\Psi,\Phi}$	87.2	88.9	144	541
$\text{BILSTM}_{m=1,e}^{\Psi,\Phi}$	88.3	89.8	144	543
$\text{BILSTM}_{m=1,e,ch}^{\Psi,\Phi}$	88.5	90.0	120	456
$\text{BILSTM}_{m=2,e}^{\Psi,\Phi}$	89.7	90.7	72	476
$\text{BILSTM}_{m=2,e,ch}^{\Psi,\Phi}$	89.9	90.9	65	405
$\text{BILSTM}_{m=1}^{\Phi'}$	87.3	89.3	206	941
$\text{BILSTM}_{m=1,e}^{\Phi'}$	88.5	90.1	209	957
$\text{BILSTM}_{m=1,e,ch}^{\Phi'}$	88.0	90.0	180	808
$\text{BILSTM}_{m=2,e}^{\Phi'}$	89.8	90.9	119	842
$\text{BILSTM}_{m=2,e,ch}^{\Phi'}$	89.7	90.9	109	716

Table 1: Performance of the proposed sequence labeling methods on the development set of the PTB. For the CRF models the complexity is quadratic with respect to the number of labels, which causes $\text{CRF}^{\Phi'}$ to be particularly slow.

The Ψ, Φ and the Φ' models obtain similar F-scores. When it comes to speed, the $\text{BILSTMs}^{\Phi'}$ are notably faster than the $\text{BILSTMs}^{\Psi,\Phi}$. Φ' models are expected to be more efficient, as leaf unary chains are handled implicitly. In practice, Φ' is a more expensive function to compute than the original Φ, since the number of output labels is significantly larger, which reduces the expected gains with respect to the Ψ, Φ models. It is worth noting that our encoding is useful to train an MLP_e with a decent sense of phrase structure, while being very fast. Paying attention to the differences between F-score and Accuracy for each baseline, we notice the gap between them is larger for CRFs and MLPs. This shows the difficulties that these methods have, in comparison to the BILSTM approaches, to predict the correct label when a word w_{i+1} has few common ancestors with w_i. For example, let -10X be the right (relative scale) label between w_i and w_{i+1}, and let l_1=-1X and l_2=-9X be two possible wrong labels. In terms of accuracy it is the same that a model predicts $l1$ or $l2$, but in terms of constituent F-score, the first will be much worse, as many closed parentheses will remain unmatched.

Tables 2 and 3 compare our best models against the state of the art on the PTB and CTB test sets. The performance corresponds to models without reranking strategies, unless otherwise specified.

5 Discussion

We are not aware of work that reduces constituency parsing to sequence labeling. The work that can be considered as the closest to ours is that of Vinyals et al. (2015), who address it as a sequence-to-sequence problem, where the output sequence has variable/unknown length. In this context, even a one hidden layer perceptron outperforms their 3-layer LSTM model without attention, while parsing hundreds of sentences per second. Our best models also outperformed their 3-layer LSTM model with attention and even a simple BILSTM model with pretrained GloVe embeddings obtains a similar performance. In terms of F-score, the proposed sequence labeling baselines still lag behind mature shift-reduce and chart parsers. In terms of speed, they are clearly faster than both CPU and GPU chart parsers and are at least on par with the fastest shift-reduce ones. Although with significant loss of accuracy, if phrase-representation is needed in large-scale tasks where the speed of current systems makes parsing infeasible (Gómez-Rodríguez, 2017; Gómez-Rodríguez et al., 2017), we can use the simpler, less accurate models to get speeds well above any parser reported to date.

It is also worth noting that in their recent work, published while this manuscript was under review, Shen et al. (2018) developed a mapping of binary trees with n leaves to sequences of $n-1$ integers (Shen et al., 2018, Algorithm 1). This encoding is different from the ones presented here, as it is based on the height of lowest common ancestors in the tree, rather than their depth. While their purpose is also different from ours, as they use this mapping to generate training data for a parsing algorithm based on recursive partitioning using real-valued distances, their encoding could also be applied with our sequence labeling approach. However, it has the drawback that it only supports binarized trees, and some of its theoretical properties are worse for our goal, as the way to define the inverse of an arbitrary label sequence can be highly ambiguous: for example, a sequence of $n-1$ equal labels in this encoding can represent *any* binary tree with n leaves.

6 Conclusion

We presented a new parsing paradigm, based on a reduction of constituency parsing to sequence labeling. We first described a linearization function

Model	Testbed	CPU Run #Cores	CPU Run Sents/s	GPU Run #GPU	GPU Run Sents/s	F-score
Sequence labeling						
MLP$_e^{\Psi,\Phi}$	WSJ23	1	501	1	669	74.1

to transform a constituent tree (with n leaves) into a sequence of $n-1$ labels that encodes it. We proved that this encoding function is total and injective for any tree without unary branches. We also discussed its limitations: how to deal with unary branches and non-surjectivity, and showed how these can be solved. We finally proposed a set of fast and strong baselines.

Synthetic Data Made to Order: The Case of Parsing

Dingquan Wang and **Jason Eisner**
Department of Computer Science, Johns Hopkins University
{wdd,jason}@cs.jhu.edu

Abstract

To approximately parse an unfamiliar language, it helps to have a treebank of a similar language. But what if the closest available treebank still has the wrong word order? We show how to (stochastically) permute the constituents of an existing dependency treebank so that its surface part-of-speech statistics approximately match those of the target language. The parameters of the permutation model can be evaluated for quality by dynamic programming and tuned by gradient descent (up to a local optimum). This optimization procedure yields trees for a new artificial language that resembles the target language. We show that delexicalized parsers for the target language can be successfully trained using such "made to order" artificial languages.

1 Introduction

Dependency parsing is a core task in natural language processing (NLP). Given a sentence, a dependency parser produces a dependency tree, which specifies the typed head-modifier relations between pairs of words. While *supervised* dependency parsing has been successful (McDonald and Pereira, 2006; Nivre, 2008; Kiperwasser and Goldberg, 2016), unsupervised parsing can hardly produce useful parses (Mareček, 2016). So it is extremely helpful to have some treebank of supervised parses for training purposes.

1.1 Past work: Cross-lingual transfer

Unfortunately, manually constructing a treebank for a new target language is expensive (Böhmová et al., 2003). As an alternative, *cross-lingual transfer* parsing (McDonald et al., 2011) is sometimes possible, thanks to the recent development of multi-lingual treebanks (McDonald et al., 2013; Nivre et al., 2015; Nivre et al., 2017). The idea is to parse the sentences of the target language with a supervised parser trained on the treebanks of one or more source languages. Although the parser cannot be expected to know the words of the target language, it can make do with parts of speech (POS) (McDonald et al., 2011; Täckström et al., 2013; Zhang and Barzilay, 2015) or cross-lingual word embeddings (Duong et al., 2015; Guo et al., 2016; Ammar et al., 2016). A more serious challenge is that the parser may not know how to handle the word *order* of the target language, unless the source treebank comes from a closely related language (e.g., using German to parse Luxembourgish). Training the parser on trees from *multiple* source languages may mitigate this issue (McDonald et al., 2011) because the parser is more likely to have seen target part-of-speech sequences somewhere in the training data. Some authors (Rosa and Žabokrtský, 2015a,b; Wang and Eisner, 2016) have shown additional improvements by preferring source languages that are "close" to the target language, where the closeness is measured by distance between POS language models trained on the source and target corpora.

1.2 This paper: Tailored synthetic data

We will focus on delexicalized dependency parsing, which maps an input POS tag sequence to a dependency tree. We evaluate single-source transfer—train a parser on a single source language, and evaluate it on the target language. This is the setup of Zeman and Resnik (2008) and Søgaard (2011a).

Our novel ingredient is that *rather than seek a close source language that already exists, we create one*. How? Given a dependency treebank of a possibly distant source language, we stochastically permute the children of each node, according to some distribution that *makes the permuted language close to the target language*.

And how do we find this distribution? We adopt the tree-permutation model of Wang and Eisner (2016). We design a dynamic programming algorithm which, for any given distribution p in Wang and Eisner's family, can compute the *expected counts* of all POS bigrams in the permuted source treebank. This allows us to evaluate p by computing the divergence between the bigram POS language model formed by these expected counts,

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1325–1337
Brussels, Belgium, October 31 - November 4, 2018.

and the one formed by the *observed counts* of POS bigrams in the unparsed target language. In order to find a p that locally minimizes this divergence, we adjust the model parameters by stochastic gradient descent (SGD).

1.3 Key limitations in this paper

Better measures of surface closeness between two languages might be devised. However, even counting the expected POS N-grams is moderately expensive, taking time exponential in N if done exactly. So we compute only these local statistics, and only for $N = 2$. We certainly need $N > 1$ because the 1-gram distribution is not affected by permutation at all. $N = 2$ captures useful bigram statistics: for example, to mimic a verb-final language with prenominal modifiers, we would seek constituent permutations that result in matching its relatively high rate of `VERB`–`PUNCT` and `ADJ`–`NOUN` bigrams. While $N > 2$ might have improved the results, it was too slow for our large-scale experimental design. §7 discusses how richer measures could be used in the future.

We caution that throughout this paper, we assume that our corpora are annotated with gold POS tags, even in the target language (which lacks any gold training trees). This is an idealized setting that has often been adopted in work on unsupervised and cross-lingual transfer.§7 discusses a possible avenue for doing without gold tags.

2 Modeling Surface Realization

We begin by motivating the idea of tree permutation. Let us suppose that the dependency tree for a sentence starts as a labeled graph—a tree in which siblings are not yet ordered with respect to their parent or one another. Each language has some systematic way to *realize* its unordered trees as surface strings:[1] it imposes a particular order on the tree's word tokens. More precisely, a language specifies a *distribution* $p(\text{string} \mid \text{unordered tree})$ over a tree's possible realizations.

As an engineering matter, we now make the strong assumption that the unordered dependency trees are similar across languages. That is, we suppose that different languages use similar underlying syntactic/semantic graphs, but differ in how they realize this graph structure on the surface.

Thus, given a gold POS corpus $\mathbf{u}$ of the unknown target language, we may hope to explain its distribution of surface POS bigrams as the result of applying some target-language surface realization model to the distribution of cross-linguistically "typical" unordered trees. To obtain samples of the latter distribution, we use the treebanks of one or more *other* languages. The present paper evaluates our method when only a single source treebank is used. In the future, we could try tuning a mixture of all available source treebanks.

2.1 Realization is systematic

We presume that the target language applies the same stochastic realization model to all trees. All that we can optimize is the parameter vector of this model. Thus, we deny ourselves the freedom to realize each individual tree in an *ad hoc* way. To see why this is important, suppose the target language is French, whose corpus $\mathbf{u}$ contains many `NOUN`–`ADJ` bigrams. We could achieve such a bigram from the unordered source tree 
by ordering it to yield 
. However, that realization is not in fact appropriate for French, so that ordered tree would not be a useful training tree for French. Our approach should disprefer this tempting but incorrect realization, because any model with a high probability of this realization would, if applied *systematically* over the whole corpus, also yield sentences like `He sleepy made Sue`, with unwanted `PRON`–`ADJ` bigrams that would not match the surface statistics of French. We hope our approach will instead choose the realization model that is correct for French, in which the `NOUN`–`ADJ` bigrams arise instead from source trees where the `ADJ` is a dependent of the `NOUN`, yielding (e.g.) 
. This has the same POS sequence as the example above (as it happens), but now assigns the correct tree to it.

2.2 A parametric realization model

As our family of realization distributions, we adopt the log-linear model used for this purpose by Wang and Eisner (2016). The model assumes that the root node a of the unordered dependency tree selects an ordering $\pi(a)$ of the n_a nodes consisting

---

[1] Modeling this process was the topic of the recent Surface Realization Shared Task (Mille et al., 2018). Most relevant is work on *tree linearization* (Filippova and Strube, 2009; Futrell and Gibson, 2015; Puzikov and Gurevych, 2018).

of a and its $n_a - 1$ dependent children. The procedure is repeated recursively at the child nodes. This method can produce only projective trees.

Each node a draws its ordering $\pi(a)$ independently according to

$$p_{\boldsymbol{\theta}}(\pi \mid a) = \frac{1}{Z(a)} \exp \sum_{1 \le i < j \le n_a} \boldsymbol{\theta} \cdot \mathbf{f}(\pi, i, j) \quad (1)$$

which is a distribution over the $n_a!$ possible orderings. $Z(a)$ is a normalizing constant. $\mathbf{f}$ is a feature vector extracted from the ordered pair of nodes π_i, π_j, and $\boldsymbol{\theta}$ is the model's parameter vector of feature weights. See Appendix A for the feature templates, which are a subset of those used by Wang and Eisner (2016). These features are able to examine the tree's node labels (POS tags) and edge labels (dependency relations). Thus, when a is a verb, the model can assign a positive weight to "subject precedes verb" or "subject precedes object," thus preferring orderings with these features.

Following Wang and Eisner (2016, §3.1), we choose new orderings for the noun and verb nodes only,[2] preserving the source treebank's order at all other nodes a.

2.3 Generating training data

Given a source treebank B and some parameters $\boldsymbol{\theta}$, we can use equation (1) to randomly sample realizations of the trees in B. The effect is to reorder dependent phrases within those trees. The resulting permuted treebank B' can be used to train a parser for the target language.

2.4 Choosing parameters $\boldsymbol{\theta}$

So how do we choose $\boldsymbol{\theta}$ that works for the target language? Suppose $\mathbf{u}$ is a corpus of target-language POS sequences, using the same set of POS tags as B. We evaluate parameters $\boldsymbol{\theta}$ according to whether POS tag sequences in B' will be distributed like POS tag sequences in $\mathbf{u}$.

To do this, first we estimate a bigram language model $\hat{q}$ from the actual distribution q of POS sequences observed in $\mathbf{u}$. Second, let $p_{\boldsymbol{\theta}}$ denote the distribution of POS sequences that we expect to see in B', that is, POS sequences obtained by stochastically realizing observed trees in B according to $\boldsymbol{\theta}$. We estimate another bigram model $\hat{p}_{\boldsymbol{\theta}}$ from this distribution $p_{\boldsymbol{\theta}}$.

We then try to set $\boldsymbol{\theta}$, using SGD, to minimize a divergence $D(\hat{p}_{\boldsymbol{\theta}}, \hat{q})$ that we will define below.

2.4.1 Estimation of bigram models

Estimating $\hat{q}$ is straightforward: $\hat{q}(t \mid s) = c_q(st)/c_q(s)$, where $c_q(st)$ is the count of POS bigram st in the average[3] sentence of $\mathbf{u}$ and $c_q(s) = \sum_{t'} c_q(st')$. We estimate $\hat{p}_{\boldsymbol{\theta}}$ in the same way, where $c_p(st)$ denotes the *expected* count of st in a random POS sequence $\mathbf{y} \sim p_{\boldsymbol{\theta}}$. This is equivalent to choosing $\hat{q}, \hat{p}_{\boldsymbol{\theta}}$ to minimize the KL-divergences $\mathrm{KL}(q \mid\mid \hat{q}), \mathrm{KL}(p_{\boldsymbol{\theta}} \mid\mid \hat{p}_{\boldsymbol{\theta}})$. It ensures that each model's expected bigram counts match those in the POS sequences.

However, these maximum-likelihood estimates might overfit on our finite data, $\mathbf{u}$ and B. We therefore smooth both models by first adding $\lambda = 0.1$ to all bigram counts $c_q(st)$ and $c_p(st)$.[4]

2.4.2 Divergence of bigram models

We need a metric to evaluate $\boldsymbol{\theta}$. If p and q are bigram language models over POS sequences $\mathbf{y}$ (sentences), their Kullback-Leibler divergence is

$$\mathrm{KL}(p \mid\mid q) \overset{\text{def}}{=} \mathbb{E}_{\mathbf{y} \sim p}[\log p(\mathbf{y}) - \log q(\mathbf{y})] \quad (2)$$

$$= \sum_{s,t} c_p(st) \cdot (\log p(t \mid s) - \log q(t \mid s)) \quad (3)$$

where $\mathbf{y}$ ranges over POS sequences and st ranges over POS bigrams. These include bigrams where $s = \text{BOS}$ ("beginning of sequence") or $t = \text{EOS}$ ("end of sequence"), which are boundary tags that we take to surround $\mathbf{y}$.

All quantities in equation (3) can be determined directly from the (expected) bigram counts given by c_p and c_q. No other model estimation is needed.

A concern about equation (3) is that a single bigram st that is badly underrepresented in q may contribute an arbitrarily large term $\log \frac{p(t|s)}{q(t|s)}$. To limit this contribution to at most $\log \frac{1}{\alpha}$, for some small $\alpha \in (0, 1)$, we define $\mathrm{KL}_\alpha(p \mid\mid q)$ by a variant of equation (3) in which $q(t \mid s)$ has been replaced by $\tilde{q}(t \mid s) \overset{\text{def}}{=} \alpha p(t \mid s) + (1 - \alpha) q(t \mid s)$.[5]

---

[2] Specifically, the 93% of nodes tagged with `NOUN`, `PROPN`, `PRON` or `VERB` in Universal Dependencies format. In retrospect, this restriction was unnecessary in our setting, but it skipped only 4.4% of nodes on average (from 2% to 11% depending on language). The remaining nodes were nouns, verbs, or childless.

[3] A more familiar definition of c_q would use the *total* count in $\mathbf{u}$. Our definition, which yields the same bigram probabilities, is analogous to our definition of c_p. This c_p is needed for $\mathrm{KL}(p \mid\mid q)$ in (3), and c_q symmetrically for $\mathrm{KL}(q \mid\mid p)$.

[4] Ideally one should tune λ to minimize the language model perplexity on held-out data (e.g., by cross-validation).

[5] This is inspired by the α-skew divergence of Lee (1999,

Our final divergence metric $D(\hat{p}_{\boldsymbol{\theta}}, \hat{q})$ defines D as a linear combination of exclusive and inclusive KL_α divergences, which respectively emphasize $p_{\boldsymbol{\theta}}$'s precision and recall at matching q's bigrams:

$$D(p,q) = (1-\beta)\cdot\frac{\mathrm{KL}_{\alpha_1}(p \,||\, q)}{\mathbb{E}_{\mathbf{y}\sim p}[\,|\mathbf{y}|\,]} + \beta\cdot\frac{\mathrm{KL}_{\alpha_2}(q \,||\, p)}{\mathbb{E}_{\mathbf{y}\sim q}[\,|\mathbf{y}|\,]} \tag{4}$$

where $\beta, \alpha_1, \alpha_2$ are tuned by cross-validation to maximize the downstream parsing performance. The division by average sentence length converts KL from nats per sentence to nats per word,[6] so that the KL values have comparable scale even if B has much longer or shorter sentences than $\mathbf{u}$.

3 Algorithms

3.1 Efficiently computing expected counts

We now present a polynomial-time algorithm for computing the expected bigram counts c_p under $p_{\boldsymbol{\theta}}$ (or equivalently $\hat{p}_{\boldsymbol{\theta}}$), for use above. This averages expected counts from each unordered tree $\mathbf{x} \in B$. Algorithm 1 in the supplement gives pseudocode.

The insight is that rather than sampling a single realization of $\mathbf{x}$ (as B' does), we can use dynamic programming to sum efficiently over all of its exponentially many realizations. This gives an exact answer. It algorithmically resembles tree-to-string machine translation, which likewise considers the possible reorderings of a source tree and incorporates a language model by similarly tracking their surface N-grams (Chiang, 2007, §5.3.2).

For each node a of the tree $\mathbf{x}$, let the POS string $\mathbf{y}_a$ be the realization of the subtree rooted at a. Let $c_a(st)$ be the expected count of bigram st in $\mathbf{y}_a$, whose distribution is governed by equation (1). We allow $s = \textsc{bos}$ or $t = \textsc{eos}$ as defined in §2.4.2.

The c_a function can be represented as a sparse map from POS bigrams to reals. We compute c_a at each node a of $\mathbf{x}$ in a bottom-up order. The final step computes c_{root}, giving the expected bigram counts in $\mathbf{x}$'s realization $\mathbf{y}$ (that is, c_p in §2.4).

We find c_a as follows. Let $n = n_a$ and recall from §2.2 that $\pi(a)$ is an ordering of $a_1, \ldots, a_n$, where $a_1, \ldots, a_{n-1}$ are the child nodes of a, and a_n is a dummy node representing a's head token. Also, let a_0 and a_{n+1} be dummy nodes that always appear at the start and end of any ordering.

For all $0 \leq i \leq n$ and $1 \leq j \leq n+1$, let $p_a(i,j)$ denote the expected count of the $a_i a_j$ node bigram—the probability that $\pi(a)$ places node a_i immediately before node a_j. These *node bigram probabilities* can be obtained by enumerating all possible orderings π, a matter we return to below.

It is now easy to compute c_a:

$$c_a(st) = c_a^{\text{within}}(st) + c_a^{\text{between}}(st) \tag{5}$$

$$c_a^{\text{within}}(st) = \begin{cases} \sum_{i=1}^{n} c_{a_i}(st) & \text{if } s \neq \textsc{bos}, t \neq \textsc{eos} \\ 0 & \text{otherwise} \end{cases}$$

$$c_a^{\text{across}}(st) = \sum_{i=0}^{n}\sum_{j=1}^{n+1} p_a(i,j) c_{a_i}(s\,\textsc{eos}) c_{a_j}(\textsc{bos}\,t)$$

That is, c_a inherits all non-boundary bigrams st that fall within its child constituents (via c_a^{within}). It also counts bigrams st that cross the boundary between consecutive nodes (via c_a^{across}), where nodes a_i and a_j are consecutive with probability $p_a(i,j)$.

When computing c_a via (5), we will have already computed $c_{a_1}, \ldots, c_{a_{n-1}}$ bottom-up. As for the dummy nodes, a_n is realized by the length-1 string h where h is the head token of node a, while a_0 and a_{n+1} are each realized by the empty string. Thus, c_{a_n} simply assigns count 1 to the bigrams $\textsc{bos}\,h$ and $h\,\textsc{eos}$, and c_{a_0} and $c_{a_{n+1}}$ each assign expected count 1 to $\textsc{bos}\ \textsc{eos}$. (Notice that thus, $c_a^{\text{across}}(st)$ counts $\mathbf{y}_a$'s boundary bigrams—the bigrams st where $s = \textsc{bos}$ or $t = \textsc{eos}$—when $i = 0$ or $j = n+1$ respectively.)

3.2 Efficient enumeration over permutations

The main challenge above is computing the node bigram probabilities $p_a(i,j)$. These are marginals of $p(\pi \mid a)$ as defined by (1), which unfortunately is intractable to marginalize: there is no better way than enumerating all $n!$ permutations.

That said, there is a particularly efficient way to enumerate the permutations. The Steinhaus-Johnson-Trotter (SJT) algorithm (Sedgewick, 1977) does so in $O(1)$ time per permutation, obtaining each permutation by applying a single swap to the previous one. Only the features that are affected by this swap need to be recomputed. For our features (Appendix A), this cuts the runtime per permutation from $O(n^2)$ to $O(n)$.

Furthermore, the single swap of adjacent nodes only changes 3 bigrams (possibly including boundary bigrams). As a result, it is possible to

---

2001). Indeed, we may regard $\mathrm{KL}_\alpha(p \,||\, q)$ as the α-skew divergence between the unigram distributions $p(\cdot \mid s)$ and $q(\cdot \mid s)$, averaged over all s in proportion to $c_p(s)$. In principle, we could have used the α-skew divergence between the distributions $p(\cdot)$ and $q(\cdot)$ over POS sequences $\mathbf{y}$, but computing that would have required a sampling-based approximation (§7).

[6] Recall that the units of negated log-probability are called bits for log base 2, but nats for log base e.

obtain the marginal probabilities with $O(1)$ additional work per permutation. When a node bigram is destroyed, we increment its marginal probability by the total probability of permutations encountered since the node bigram was last created. This can be found as a difference of partial sums. The final partial sum is the normalizing constant $Z(a)$, which can be applied at the end. Pseudocode is given in supplementary material as Algorithm 2.

When we train the parameters $\boldsymbol{\theta}$ (§2.4), we must back-propagate through the whole computation of equation (4), which depends on tag bigram counts $c_a(st)$, which depend via (5) on expected node bigram counts $p_a(i, j)$, which depend via Algorithm 2 on the permutation probabilities $p(\pi \mid a)$, which depend via (1) on the feature weights $\boldsymbol{\theta}$.

4 Heuristics

4.1 Pruning high-degree trees

As a further speedup, we only train on trees with number of words < 40 and $\max_a n_a \leq 5$, so $n_a! \leq 120$.[7] We then produce the synthetic treebank B' (§2.3) by drawing a single realization of each tree in B for which $\max_a n_a \leq 7$. This requires sampling from up to $7! = 5040$ candidates per node, again using SJT.[8]

That is, in this paper we run exact algorithms (§3), but only on a subset of B. The subset is not necessarily representative. An improvement would use importance sampling, with a proposal distribution that samples the slower trees less often during SGD but upweights them to compensate.

§7 suggests a future strategy that would run on all trees in B via approximate, sampling-based algorithms. The exact methods would remain useful for calibrating the approximation quality.

4.2 Minibatch estimation of c_p

To minimize (4), we use the Adam variant of SGD (Kingma and Ba, 2014), with learning rate 0.01 chosen by cross-validation (§5.1).

SGD requires a stochastic estimate of the gradient of the training objective. Ordinarily this is done by replacing an expectation over the entire training set with an expectation over a minibatch.

Equation (2) with $p = \hat{p}_{\boldsymbol{\theta}}$ is indeed an expectation over sentences of B. It can be stochastically estimated as (3) where c_p gives the expected bigram counts averaged over only the sentences in a minibatch of B. These are found using §3's algorithms with the current $\boldsymbol{\theta}$. Unfortunately, the term $\log p(t \mid s)$ depends on bigram counts that should be derived from the *entire* corpus B in the same way. Our solution is to simply reuse the *minibatch* estimate of c_p for the latter counts. We use a large minibatch of 500 sentences from B so that this *drop-in estimate* does not introduce too much bias into the stochastic gradient: after all, we only need to estimate bigram statistics on 17 POS types.[9]

By contrast, the c_q values that are used for the expectation in the second term of (4) and in $\log q(t \mid s)$ do not change during optimization, so we simply compute them once from all of $\mathbf{u}$.

4.3 Informed initialization

Unfortunately the objective (4) is not convex, so the optimizer is sensitive to initialization (see §5.3 below for empirical discussion). Initializing $\boldsymbol{\theta} = \mathbf{0}$ (so that $p(\pi \mid a)$ is uniform) gave poor results in pilot experiments. Instead, we initially choose $\boldsymbol{\theta}$ to be the realization parameters of the source language, as estimated from the source treebank B. This is at least a linguistically realistic $\boldsymbol{\theta}$, although it may not be close to the target language.[10]

For this initial estimation, we follow Wang and Eisner (2016) and perform supervised training on B of the log-linear realization model (1), by maximizing the conditional log-likelihood of B, namely $\sum_{(\mathbf{x},\mathbf{t})\in B} \log p_{\boldsymbol{\theta}}(\mathbf{t} \mid \mathbf{x})$, where $(\mathbf{x}, \mathbf{t})$ are an unordered tree and its observed ordering in B. This initial objective is convex.[11]

5 Experiments

We performed a large-scale experiment requiring hundreds of thousands of CPU-hours. To our knowledge, this is the largest study of parsing transfer yet attempted.

---

[7] We found that this threshold worked much better than ≤ 4 and about as well as the much slower ≤ 6.

[8] This pruning heuristic retains 36.1% of the trees (averaging over the 20 development treebanks (§5.1)) for training, and 66.6% for actual realization. The latter restriction follows Wang and Eisner (2016, §4.2): they too discarded trees with nodes having $n_a \geq 8$.

[9] We also used the minibatch to estimate the average sentence length $\mathbb{E}_{\mathbf{y}\sim p}[\,|\mathbf{y}|\,]$ in (4), although here we could have simply used all of B since this value does not change.

[10] As an improvement, one could also try initial realization parameters for B that are estimated from treebanks of *other* languages. Concretely, the optimizer could start by selecting a "galactic" treebank from Wang and Eisner (2016) that is already close to the target language, according to (4), and try to make it even closer. We leave this to future work.

[11] Unfortunately, we did not regularize it, which probably resulted in initializing some parameters too close to $\pm\infty$ for the optimizer to change them meaningfully.

5.1 Data and setup

As our main dataset, we use Universal Dependencies version 1.2 (Nivre et al., 2015)—a set of 37 dependency treebanks for 33 languages, with a unified POS-tag set and relation label set.

Our evaluation metric was unnormalized attachment score (UAS) when parsing a target treebank with a parser trained on a (possibly permuted) source treebank. For both evaluation and training, we used only the training portion of each treebank.

Our parser was Yara (Rasooli and Tetreault, 2015), a fast and accurate transition-based dependency parser that can be rapidly retrained. We modified Yara to ignore the input words and use only the input *gold* POS tags (see §1.3). To train the Yara parser on a (possibly permuted) source treebank, we first train on 80% of the trees and use the remaining 20% to tune Yara's hyperparameters. We then retrain Yara on 100% of the source trees and evaluate it on the target treebank.

Similar to Wang and Eisner (2017), we use 20 treebanks (18 distinct languages) as *development data*, and hold out the remaining 17 treebanks for the final evaluation. We chose the hyperparameters $(\alpha_1, \alpha_2, \beta)$ of (4) to maximize the target-language UAS, averaged over all 376 transfer experiments where the source and target treebanks were development treebanks of different languages.[12] (See Appendix C for details.)

The next few sections perform some exploratory analysis on these 376 experiments. Then, for the final test in §5.4, we will evaluate UAS on all 337 transfer experiments where the source is a development treebank and the target is a test treebank of a different language.[13]

5.2 Exploratory analysis

We have assumed that a smaller divergence between source and target treebanks results in better transfer parsing accuracy. Figure 1 shows that these quantities are indeed correlated, both for the original source treebanks and for their "made to order" permuted versions.

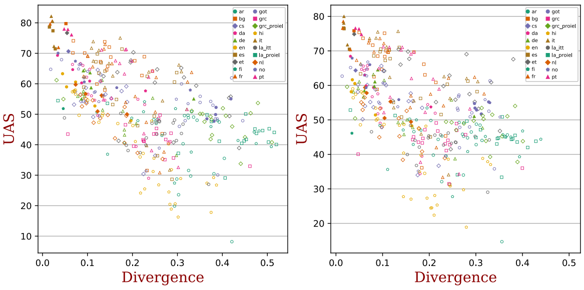

Figure 1: UAS is higher when divergence is lower. Each point represents a pair of source and target languages, whose shape and color identify the treebank of the target language (see legend). The marker is solid if the source and target languages belong to the same language family.[15] The left graph uses the original source treebank (Kendall's $\tau = -0.41$), while the right graph uses its permuted version ($\tau = -0.39$).

Thus, we hope that the optimizer will find a systematic permutation that reduces the divergence. Does it? Yes: Figures 5 and 6 in the supplementary material show that the optimizer almost always manages to reduce the objective on training data, as expected.

One concern is that our divergence metric might misguide us into producing dysfunctional languages whose trees cannot be easily recovered from their surface strings, i.e., they have no good parser. In such a language, the word order might be extremely free (e.g., $\boldsymbol{\theta} = \mathbf{0}$), or common constructions might be syntactically ambiguous. Fortunately, Appendix D shows that our synthetic languages appear natural with respect to their their parsability.

The above findings are promising. So does permuting the source language in fact result in better transfer parsing of the target language? We experiment on the 376 development pairs.

The solid lines in Figure 2 show our improvements on the dev data, with a simpler scatterplot given by in Figure 7 in the supplementary material. The upshot is that the synthetic source treebanks yield a transfer UAS of 52.92 on average. This is not yet a result on held-out test data: recall that 52.92 was the best transfer UAS achieved by any hyperparameter setting. That said, it is 1.00 points better than transferring from the original source treebanks, a significant difference (paired permutation test by language pair, $p < 0.01$).

Figure 2 shows that this average improvement is mainly due to the many cases where the source and target languages come from different families.

---

[12] We have 19*20=380 pairs in total, minus the four excluded pairs (grc, grc_proiel), (grc_proiel, grc), (la_proiel, la_itt) and (la_itt, la_proiel). Unlike Wang and Eisner (2017), we exclude duplicated languages in development and testing.

[13] Specifically, there are 3 duplicated sets: {grc, grc_proiel}, {la, la_proiel, la_itt}, and {fi, fi_ftb}. Whenever one treebank is used as the target language, we exclude the other treebanks in the same set.

[15] According to the family (and sub-family) information at `http://universaldependencies.org`.

Permutation tends to improve source languages that were doing badly to start with. However, it tends to hurt a source language that is already in the target language family.

A hypothetical experiment shows that permuting the source does have good *potential* to help (or at least not hurt) in both cases. The dashed lines in Figure 2—and the scatterplot in Figure 8—show the potential of the method, by showing the improvement we would get from permuting each source treebank using an "oracle" realization policy—the supervised realization parameters $\boldsymbol{\theta}$ that are estimated from the actual target treebank. The usefulness of this oracle-permuted source varies depending on the source language, but it is usually much better than the automatically-permuted version of the same source.

This shows that large improvements would be possible if we could only find the best permutation policy allowed by our model family. The question for future work is whether such gains can be achieved by a more sensitive permutation model than (1), a better divergence objective than (4), or a better search algorithm than §4.2. Identifying the best available source treebank, or the best mixture of all source treebanks, would also help greatly.

5.3 Sensitivity to initializer

Figure 2 makes clear that performance of the synthetic source treebanks is strongly correlated with that of their original versions. Most points in Figure 7 lie near the diagonal (Kendall's $\tau = 0.85$). Even with oracle permutation in Figure 8, the correlation remains strong ($\tau = 0.59$), suggesting that the choice of source treebank is important even beyond its effect on search initialization.

We suspected that when "made to order" source treebanks (more than the oracle versions) have performance close to their original versions, this is in part because the optimizer can get stuck near the initializer (§4.3). To examine this, we experimented with random restarts, as follows. In addition to informed initialization (§4.3), we optimized from 5 other starting points $\boldsymbol{\theta} \sim \mathcal{N}(\mathbf{0}, I)$. From these 6 runs, we selected the final parameters that achieved the best divergence (4). As shown by Figure 9 in the supplement, greater gains appear to be possible with more aggressive search methods of this sort, which we leave to future work. We could also try non-random restarts based on the realization parameters of other languages, as suggested in footnote 10.

5.4 Final evaluation on the test languages

For our final evaluation (§5.1), we use the same hyperparameters (Appendix C) and report on single-source transfer to the 17 held-out treebanks.

The development results hold up in Figure 3. Using the synthetic languages yields 50.36 UAS on average—1.75 points over the baseline, which is significant (paired permutation test, $p < 0.01$).

In the supplementary material (Appendix E), we include some auxiliary experiments on multi-source transfer.

6 Related Work

6.1 Unsupervised parsing

Unsupervised parsing has remained challenging for decades (Mareček, 2016). Classical grammar induction approaches (Lari and Young, 1990; Carroll and Charniak, 1992; Klein and Manning, 2004; Headden III et al., 2009; Naseem et al., 2010) estimate a generative grammar to explain the sentences, for example by the Expectation-Maximization (EM) algorithm, and then use it to parse. Some such approaches try to improve the grammar model. For example, Klein and Manning (2004)'s dependency model with valence was the first to beat a trivial baseline; later improvements considered higher-order effects and punctuation (Headden III et al., 2009; Spitkovsky et al., 2012). Other approaches try to avoid search error, using strategies like convexified objectives (Wang et al., 2008; Gimpel and Smith, 2012), informed initialization (Klein and Manning, 2004; Mareček and Straka, 2013), search bias (Smith and Eisner, 2005, 2006; Naseem et al., 2010; Gillenwater et al., 2010), branch-and-bound search (Gormley and Eisner, 2013), and switching objectives (Spitkovsky et al., 2013).

The alternative of cross-lingual transfer has recently flourished thanks to the development of consistent cross-lingual datasets of POS-tagged (Petrov et al., 2012) and dependency-parsed (McDonald et al., 2013) sentences. McDonald et al. (2011) showed a significant improvement over grammar induction by simply using the delexicalized parser trained on other language(s). Subsequent improvements have come from re-weighting source languages (Søgaard, 2011b; Rosa and Žabokrtský, 2015a,b; Wang and Eisner, 2016), adapting the model to the target language using WALS (Dryer and Haspelmath, 2013) features (Naseem et al., 2012; Täckström et al., 2013;

	All (376)	in-family (46)	cross-family (330)
Original	51.92	**63.90**	50.24
Synthetic	**52.92**	62.85	**51.53**
Oracle	59.45	66.14	58.51

Figure 2: Unlabeled attachment scores (UAS) from 376 pairs of development treebanks. Each column represents a target treebank, and each polyline within that column shows transfer from variants of a different source treebank. The three points on the polyline (from left to right) represent the target UAS for parsers trained on three sources: the original source treebank, the "made to order" permutation that attempts to match surface statistics of the target treebank, and an oracle permutation that uses a realization model trained on the target language. We use solid markers and purple lines if the transfer is *within-family* (source and target treebank from the same language family), and hollow and olive for cross-family transfer. The **black** polyline in each column is the mean of the others. The table in the lower left gives summary results; the number in each column header gives the number of points summarized. For each column, we boldface the better result between the "Synthetic" and "Original", or both if they are not significantly different (paired permutation test, $p < 0.01$). We also show the oracle permutation result in row "Oracle".

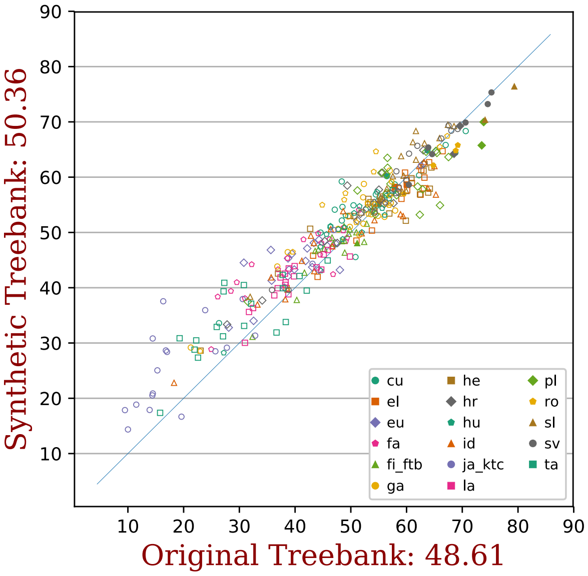

Figure 3: UAS on 337 language pairs from the training languages to the test languages.

Zhang and Barzilay, 2015; Ammar et al., 2016), and improving the lexical representations via multilingual word embeddings (Duong et al., 2015; Guo et al., 2016; Ammar et al., 2016) and synthetic data generation (§6.2).

6.2 Synthetic data generation

Our novel proposal ties into the recent interest in data augmentation in supervised machine learning. In unsupervised parsing, the most widely adopted synthetic data method has been *annotation projection*, which generates synthetic analyses of target-language sentences by "projecting" the analysis from a source-language translation. Of course, this requires bilingual corpora as an additional resource. Annotation projection was proposed by Yarowsky et al. (2001), gained promising results on sequence labelling tasks, and was later developed for unsupervised parsing (Hwa et al., 2005; Ganchev et al., 2009; Smith and Eisner, 2009; Tiedemann, 2014; Ma and Xia, 2014; Tiedemann et al., 2014). Recent work in this vein has mainly focused on improving the synthetic data, including reweighting the training trees (Agić et al., 2016) or pruning those that cannot be aligned well (Rasooli and Collins, 2015, 2017; Lacroix et al., 2016).

On the other hand, Wang and Eisner (2016) proposed to permute source language treebanks using word order realization models trained on other source languages. They generated on the order of 50,000 synthetic languages by "mixing and matching" a few dozen source languages. Their idea was that with a large set of synthetic languages, they could use them as supervised examples to train an unsupervised structure discovery system that could analyze any new language. Systems built with this dataset were competitive in single-source parser transfer (Wang and Eisner, 2016), typology prediction (Wang and Eisner, 2017), and parsing unknown languages (Wang and Eisner, 2018).

Our work in this paper differs in that our synthetic treebanks are "made to order." Rather than combine aspects of different treebanks and hope to get at least one combination that is close to the target language, we "combine" the source treebank with a POS corpus of the target language, which guides our customized permutation of the source.

Beyond unsupervised parsing, synthetic data has been used for several other tasks. In NLP, it has been used for complex tasks such as question-answering (QA) (Serban et al., 2016) and machine reading comprehension (Weston et al., 2016; Hermann et al., 2015; Rajpurkar et al., 2016), where highly expressive neural models are used and not enough real data is available to train them. In the playground of supervised parsing, Gulordava and Merlo (2016) conduct a controlled study on the parsibility of languages by generating treebanks with short dependency length and low variability of word order.

7 Conclusion & Future Work

We have shown how cross-lingual transfer parsing can be improved by permuting the source treebank to better resemble the target language on the surface (in its distribution of gold POS bigrams). The code is available at `https://github.com/wddabc/ordersynthetic`. Our work is grounded in the notion that by trying to explain the POS bigram counts in a target corpus, we can discover a stochastic realization policy for the target language, which correctly "translates" the source trees into appropriate target trees.

We formulated an objective for evaluating such a policy, based on KL-divergence between bigram models. We showed that the objective could be computed efficiently by dynamic programming, thanks to the limitation to bigram statistics.

Experimenting on the Universal Dependencies treebanks v1.2, we showed that the synthetic treebanks were—on average—modestly but significantly better than the corresponding real treebanks for single-source transfer (and in Appendix E, on multi-source transfer).

On the downside, Figure 7 shows that with our current method, permuting the source language to be more like the target language is helpful (on average) only when the source language is from a different language family. This contrast would be even more striking if we had a better optimizer: Figure 9 shows that SGD's initialization bias limits its permutation's benefit for cross-family training, as well as its harm for within-family training.

Several opportunities for future work have already been mentioned throughout the paper. We are also interested in experimenting with richer families of permutation distributions, as well as "conservative" distributions that tend to prefer the original source order. We could use entropy regularization (Grandvalet and Bengio, 2005) to encourage more "deterministic" patterns of realization in the synthetic languages.

We would also like to consider more sensitive divergence measures that go beyond bigrams, for example using recurrent neural network language models (RNNLMs) for $\hat{q}$ and $\hat{p}_{\boldsymbol{\theta}}$. This means abandoning our exact dynamic programming methods; we would also like to abandon exact exhaustive enumeration in order to drop §4.1's bounds on n. Fortunately, there exist powerful MCMC methods (Eisner and Tromble, 2006) that can sample from interesting distributions over the space of $n!$ permutations, even for large n. Thus, we could approximately sample from $p_{\boldsymbol{\theta}}$ by drawing permuted versions of each tree in B.

Given this change, a very interesting direction would be to graduate from POS language models to word language models, using cross-lingual unsupervised word embeddings (Ruder et al., 2017). This would eliminate the need for the gold POS tags that we unrealistically assumed in this paper (which are typically unavailable for a low-resource target language). Furthermore, it would enable us to harness richer lexical information beyond the 17 UD POS tags. After all, even a (gold) POS corpus might not be sufficient to determine the word order of the target language: "`NOUN VERB NOUN`" could be either subject-verb-object or object-verb-subject. However, "`water drink boy`" is presumably object-verb-subject. Thus, using cross-lingual embeddings, we would try to realize the unordered source trees so that their word strings, with few edits, can achieve high probability under a neural language model of the target.

Abstract

In Visual Question Answering, most existing approaches adopt the pipeline of representing an image via pre-trained CNNs, and then using the uninterpretable CNN features in conjunction with the question to predict the answer. Although such end-to-end models might report promising performance, they rarely provide any insight, apart from the answer, into the VQA process. In this work, we propose to break up the end-to-end VQA into two steps: **explaining** and **reasoning**, in an attempt towards a more explainable VQA by shedding light on the intermediate results between these two steps. To that end, we first extract attributes and generate descriptions as explanations for an image. Next, a reasoning module utilizes these explanations in place of the image to infer an answer. The advantages of such a breakdown include: (1) the attributes and captions can reflect what the system extracts from the image, thus can provide some insights for the predicted answer; (2) these intermediate results can help identify the inabilities of the image understanding or the answer inference part when the predicted answer is wrong. We conduct extensive experiments on a popular VQA dataset and our system achieves comparable performance with the baselines, yet with added benefits of explanability and the inherent ability to further improve with higher quality explanations.

1 Introduction

Answering textual questions from images, which is referred to as visual question answering, presents fundamental challenges to both computer vision and natural language processing communities. Significant progress has been made on VQA in recent years (Antol et al., 2015; Zhu et al., 2016; Wu et al., 2016a; Yang et al., 2016; Goyal et al., 2017; Yu et al., 2017; Teney et al., 2017; Wang et al., 2017; Gurari et al., 2018; Anderson et al., 2018; Lu et al., 2018; Li et al., 2018). A widely used pipeline is to first encode an image with Convolutional Neural Networks (CNNs) and represent associated questions with Recurrent Neural Networks (RNNs), and then formulate the vision-to-language task as a classification problem on a list of answer candidates. Although promising performance has been reported, this end-to-end paradigm fails to provide any insight to illuminate the VQA process. In most cases, giving answers without any explanation cannot satisfy hu-

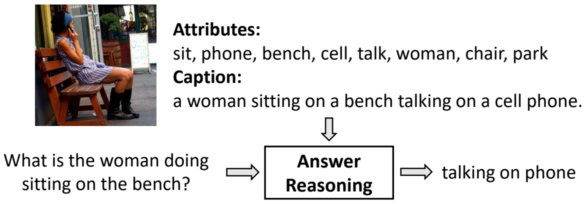

Figure 1: An example of explanation and reasoning in VQA. We first extract attributes in the image such as “sit”, “phone” and “woman.” A caption is also generated to encode the relationship between these attributes, e.g. “woman sitting on a bench.” Then a reasoning module uses these explanations to predict an answer “talking on phone.”

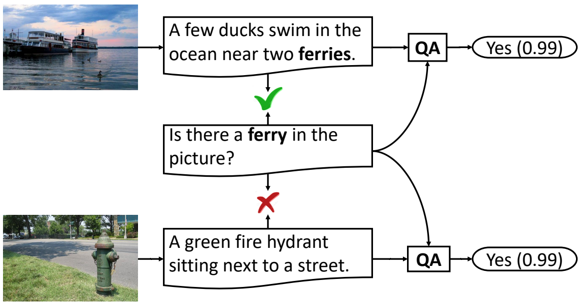

Figure 2: Two contrasting cases that show how the explanations can be used to determine if the system *guesses* the answer.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1338–1346
Brussels, Belgium, October 31 - November 4, 2018. ©2018 Association for Computational Linguistics

man users, especially when the predicted answer is not correct. More frustratingly, the system gives no hint about which part of such systems is the culprit for a wrong answer.

To address the above issues, we propose to break up the popular end-to-end pipeline into two steps: **explaining** and **reasoning**. The philosophy behind such a break-up is to mimic the image question answering process of human beings: first understanding the content of the image and then performing inference about the answer according to the understanding. As is shown in Fig.1, we first generate two-level explanations for an image via pre-trained attribute detectors and image captioning model: 1). word-level: attributes, indicating individual objects and attributes the system learns from the image. 2). sentence-level: captions, representing the relationship between the objects and attributes. Then the generated explanations and question are infused to a reasoning module to predict an answer. The reasoning module is mainly composed of LSTMs.

Our method has three benefits. First, these explanations are interpretable. According to the attributes and captions, we can tell what objects, attributes and their relationship the machine learns from the image as well as what information is lost during the image understanding step. In contrast, the fully-connected layer features of CNNs are usually uninterpretable to humans. When the predicted answer is correct, these attributes and captions can be provided for users as the supplementary explanations to the answer. Second, the separation of explaining and reasoning enables us to localize which step of the VQA process the error comes from when the predicted answer is wrong. If the explanations don't include key information to answer the question, the error is caused by missing information during the explaining step. Otherwise, the reasoning module should be responsible for the wrong answer. Third, the explanations can also indicate whether the system really finds key information from the image to answer the question or merely *guesses* an answer. Fig.2 presents two contrasting cases to illustrate this. In the first case, both the generated caption and the question include the key concept "ferry", so the answer "Yes" with a high probability is reliable. However, although the answer "Yes" has the same high probability in the second case, the caption is irrelevant to the question. The system sticks to a wrong answer even with the correct input from sentence generation. This is due to the training set bias that a large proportion of questions starting with "is there" in the training set have the answer "Yes".

To our knowledge, this is the first effort to break down the previous end-to-end pipeline to shed light on the VQA process. Our main contributions are summarized as follows:

- We propose to formulate VQA into two separate steps: **explaining** and **reasoning**. Our framework generate attributes and captions for images to shed light on why the system predicts any specific answer.
- We adopt several ways to measure the explanation quality and demonstrate strong correlation between explanation quality and VQA accuracy. The current system achieves comparable performance to the baselines and can naturally improve with explanation quality.
- Extensive experiments are conducted on the popular VQA dataset (Antol et al., 2015). We dissect all results according to the measurements of the quality of explanations to present a thorough analysis of the strength and weakness of our framework.

2 Related Work

There is a growing research interest in the task of visual question answering. In this section, we summarize recent advances from two directions.

Attention in VQA. The attention mechanism is firstly used in the machine translation task (Bahdanau et al., 2014) and then is brought into the vision-to-language tasks (Xu et al., 2015; You et al., 2016; Yang et al., 2016; Lu et al., 2016; Nam et al., 2017; Yu et al., 2017; Teney et al., 2017; Anderson et al., 2018; Teney et al., 2018; Liang et al., 2018). The visual attention in the vision-to-language tasks is used to address the problem of "where to look". In VQA, the question is used as a query to search for the relevant regions in the image. Yang *et al.* propose a stacked attention model which queries the image for multiple times to infer the answer progressively. Beyond the visual attention, Lu *et al.* exploit a hierarchical question-image co-attention strategy to attend to both related regions in the image and crucial words in the question. Attention mechanism can find the question-related regions in the image, which accounts for the answer to some extent. But the attended regions still don't explicitly exhibit what the system learns from the image and it is also not explained why these regions should be attended to.

High-level Concepts. In the scenario of vision-to-language, high-level concepts exhibit superior performance than the low-level or middle-level visual features of the image (Fang et al., 2015; Wu et al., 2016a,b). (Fang et al., 2015) first learn independent detectors for visual words based on a multi-instance learning framework and then generate descriptions for images based on the set of visually detected words via a maximum entropy language model. (Wu et al., 2016a,b) presents a thorough study on how much the high-level concepts can benefit the image captioning and visual question answering tasks. These work mainly uses high-level concepts to obtain a better performance. Different from these work, our paper is focused on fully exploiting the readability and understandability of attributes and captions to explain the process of visual question answering and use these explanations to analyze our system.

3 Methodology

In this section, we introduce the proposed framework for the breakdown of VQA. As illustrated in Figure 3, the framework consists of three modules: word prediction, sentence generation, and answer reasoning. Next, we describe the three modules in details.

3.1 Word Prediction

From the work (Wu et al., 2016a), we have learned that explicit high-level attributes can benefit vision-to-language tasks. In fact, besides performance gain, the readability and understandability of attributes also makes them an intuitive way to explain what the model learns from images.

We first build a word list based on MS COCO Captions (Chen et al., 2015). We extract the most N frequent words in all captions and filter them by lemmatization and removing stop words to determine a list of 256 words, which cover over 90% of the word occurrences in the dataset. Our words are not tense or plurality sensitive, for example, "horse" and "horses" are considered as the same word. This significantly decreases the size of our word list. Given the word list, every image is paired with multiple labels (words) according to its captions. Then we formulate word prediction as a multi-label classification task and fine-tune the ResNet-152 (He et al., 2016) on our image-words dataset by minimizing the element-wise sigmoid cross entropy loss:

$$J = \frac{1}{N}\sum_{i=1}^{N}\sum_{j=1}^{V} -y_{ij}\log p_{ij} - (1-y_{ij})\log(1-p_{ij}) \tag{1}$$

where N is batch size, V is the size of word list, $\mathbf{y}_i = [y_{i1}, y_{i2}, ..., y_{iV}], y_{ij} \in \{0, 1\}$ is the label vector of the i^{th} image, $\mathbf{p}_i = [p_{i1}, p_{i2}, ..., p_{iV}]$ is the probability vector.

In the testing phase, instead of using region proposals like (Wu et al., 2016a), we directly feed the whole image into the word prediction CNN in order to keep simple and efficient. As a result, each image is encoded into a fixed-length vector, where each dimension represents the probability of the corresponding word occurring in the image.

Word Quality Evaluation. We adopt two metrics to evaluate the predicted words. The first measures the **accuracy** of the predicted words by computing cosine similarity between the label vector $\mathbf{y}$ and the probability vector $\mathbf{p}$:

$$a = \frac{\mathbf{y}^T\mathbf{p}}{||\mathbf{y}|| \cdot ||\mathbf{p}||} \tag{2}$$

However, this metric disregards the extent to which the predicted words are relevant to the question. Intuitively speaking, question-relevant explanations for images should be more likely to help predict right answers than irrelevant ones. Therefore, we propose another metric to measure the **relevance** between the words and the question. We first encode the question into a 0-1 vector $\mathbf{q}$ in terms of the word list. Then the relevance is computed as:

$$r = \frac{\mathbf{q}^T\mathbf{p}}{||\mathbf{q}|| \cdot ||\mathbf{p}||} \tag{3}$$

3.2 Sentence Generation

This section we talk about generating sentence-level explanations for images by using a pre-trained image captioning model. Similar to (Vinyals et al., 2015), we train an image captioning model by maximizing the probability of the correct caption given an image. Suppose we have an image $\mathcal{I}$ to be described by a caption $\mathcal{S} = \{s_1, s_2, ..., s_L\}, s_t \in \mathcal{V}$, where $\mathcal{V}$ is the vocabulary, L is the caption length. First the image $\mathcal{I}$ is represented by the activations of the first

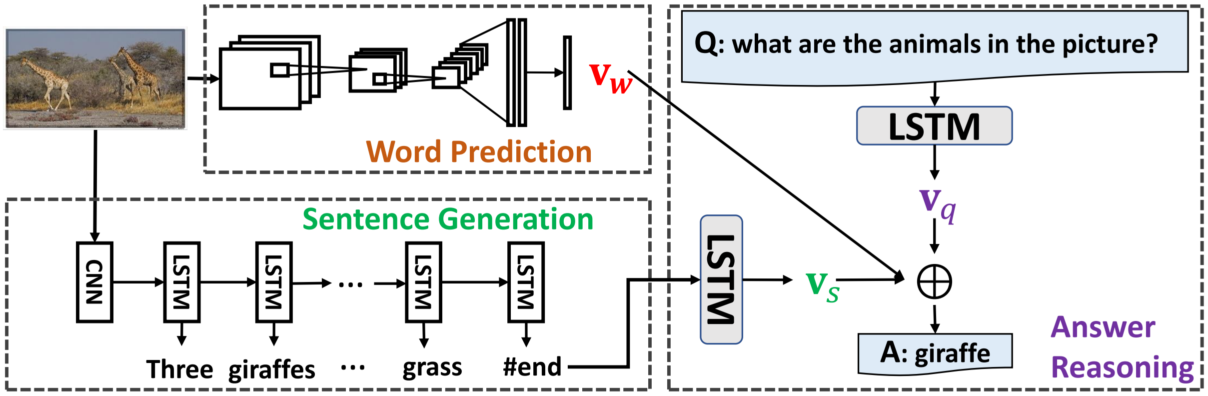

Figure 3: An overview of the proposed framework for VQA with three modules: word prediction (upper left), sentence generation (lower left), answer reasoning (right). **Explaining**: in word prediction, the image is fed into pre-trained visual detectors to extract word-level explanation, which is represented by probability vector $\mathbf{v}_w$; in sentence generation, we input the image to pre-trained captioning model to generate a sentence-level explanation. **Reasoning**: the caption and question are encoded by two different LSTMs into $\mathbf{v}_s$ and $\mathbf{v}_q$, respectively. Then $\mathbf{v}_q, \mathbf{v}_w$ and $\mathbf{v}_s$ are concatenated and fed to a fully connected layer with softmax to predict an answer.

fully connected layer of ResNet-152 pre-trained on ImageNet, denoted as $\mathbf{v}_i$. The caption $\mathcal{S}$ can be represented as a sequence of one-hot vector $\mathbf{S} = \{\mathbf{s}_1, \mathbf{s}_2, ..., \mathbf{s}_L\}$. Then we formulate the caption generation problem as minimizing the cost function:

$$\begin{aligned} J(\mathbf{v}_i, \mathbf{S}) &= -\log P(\mathbf{S}|\mathbf{v}_i) \\ &= -\sum_{t=0}^{L} \log P(\mathbf{s}_t|\mathbf{v}_i, \mathbf{s}_1, ..., \mathbf{s}_{t-1}) \end{aligned} \tag{4}$$

where $P(\mathbf{s}_t|\mathbf{v}_i, \mathbf{s}_1, ..., \mathbf{s}_{t-1})$ is the probability of generating the word $\mathbf{s}_t$ given the image representation $\mathbf{v}_i$ and previous words $\{\mathbf{s}_1, ..., \mathbf{s}_{t-1}\}$. We employ a single-layer LSTM with 512-dimensional hidden states to model this probability. In the testing phase, the image is input to pre-trained image captioning model to generate sentence-level explanation.

Sentence Quality Evaluation. Similar to word quality evaluation, we evaluate the quality of the generated sentence from two perspectives: **accuracy** and **relevance**. The former one is an average fusion of four widely used metrics: BLEU@N, METEOR, ROUGE-L and CIDEr-D (Chen et al., 2015), which try to consider the accuracy of the generated sentence from different perspectives. Note that we normalize all the metrics into $[0, 1]$ before fusion. The latter metric is to measure the relevance between the generated sentence and the question. The binary TF weights are calculated over all words of the sentence to produce an integrated representation of the entire sentence, denoted by $\mathbf{s}$. Likewise, the question can be encoded to $\mathbf{q}$. The relevance is computed as:

$$r = \frac{\mathbf{q}^T \mathbf{s}}{||\mathbf{q}|| \cdot ||\mathbf{s}||} \tag{5}$$

3.3 Answer Reasoning

This section we discuss the reasoning module. Suppose we have an image $\mathcal{I}$ explained by the predicted words $\mathcal{W}$ and the generated sentence $\mathcal{S}$, the question $\mathcal{Q}$ and the answer $\mathcal{A}$. As shown in Fig.3, we denote the representations of the predicted words $\mathcal{W}$ as $\mathbf{v}_s$. The caption $\mathcal{S}$ and question $\mathcal{Q}$ are encoded by two different LSTMs into $\mathbf{v}_s$ and $\mathbf{v}_q$, respectively. What bears mentioning is that these two LSTMs share a common word-embedding matrix, but not other parameters, because the question and caption have different grammar structures and similar vocabularies. At last, the $\mathbf{v}_w$, $\mathbf{v}_s$, and $\mathbf{v}_q$ are concatenated and fed into a fully connected layer with softmax to predict the probability on a set of candidate answers:

$$\mathbf{v} = [\mathbf{v}_w^T \ \mathbf{v}_s^T \ \mathbf{v}_q^T]^T \tag{6}$$

$$\mathbf{p} = softmax(\mathbf{W}\mathbf{v} + \mathbf{b}) \tag{7}$$

where $\mathbf{W}, \mathbf{b}$ are the weight matrix and bias vector of the fully connected layer. The optimizing objective for the reasoning module is to minimize the cross entropy loss as:

$$J(\mathcal{I}, \mathcal{Q}, \mathcal{A}) = J(\mathcal{W}, \mathcal{S}, \mathcal{Q}, \mathcal{A}) = -\log \mathbf{p}(\mathcal{A}) \tag{8}$$

where $\mathbf{p}(\mathcal{A})$ denotes the probability of the ground truth $\mathcal{A}$.

4 Experiments and Analysis

4.1 Experiment Setting

Dataset. We evaluate our framework on VQA-real (Antol et al., 2015) dataset. For each image in VQA-real, 3 questions are annotated by different workers and each question has 10 answers from different annotators. We follow the official split and report our results on the open-ended task.

Metric. We use the accuracy: $\min(\frac{\#\text{humans giving that answer}}{3}, 1)$, i.e., an answer is deemed 100% accurate if at least three workers provided that exact answer.

Ablation Models. To analyze the contribution of word-level and sentence-level explanations, we ablate the full model and evaluate several variants as:

- **Word-based VQA**: use the feature concatenation of the predicted words and question in Eq.6.
- **Sentence-based VQA**: use the feature concatenation of the generated sentence and question in Eq.6.
- **Full VQA**: use the feature concatenation of words, sentence, and question in Eq.6.

4.2 Word-based VQA

Table 1: The relationship between word quality and accuracy (%).

(a) Word accuracy

Word accuracy	VQA accuracy
[0.0, 0.2)	46.30
[0.2, 0.8)	55.84
[0.8, 1.0)	58.52

(b) W-Q Relevance

W-Q Relevance	VQA accuracy
[0.0, 0.2)	54.69
[0.2, 0.8)	60.23
[0.8, 1.0)	76.15

An important characteristics of our framework is that the quality of explanations can influence the final VQA performance. In this section, we analyze the impact of the quality of predicted words on the VQA accuracy. We measure the quality from two sides: word accuracy and word-question relevance. Table 1a shows the relationship between word accuracy and VQA performance. We can learn that the more accurate the predicted words, the better the VQA performance. Similar to word accuracy, the more relevant to the question the predicted words, the better the VQA performance. Particularly, when the word-question relevance exceeds 0.8, the predicted words are highly pertinent to the question, boosting the VQA accuracy to 76.15%. This indicates high-quality word-level explanations can benefit the VQA performance a lot. As shown in Fig.4, word-question relevance has a bigger impact on the final VQA performance than word accuracy.

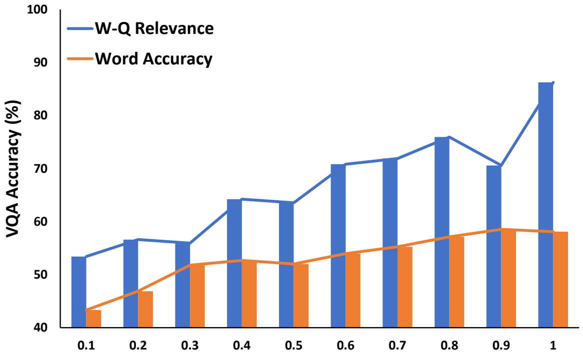

Figure 4: The comparison of the impact of word accuracy and word-question relevance on VQA performance.

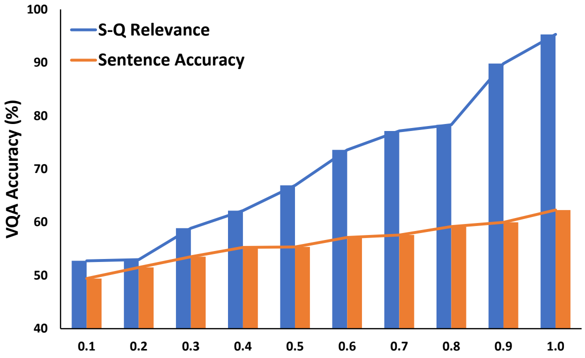

Figure 5: The comparison of the impact of sentence accuracy and sentence-question relevance on VQA performance.

4.3 Sentence-based VQA

Table 2: The relationship between sentence quality and accuracy.

(a) Sentence accuracy

Sentence accuracy	VQA accuracy
[0.0, 0.2)	51.29
[0.2, 0.8)	55.53
[0.8, 1.0)	61.33

(b) S-Q Relevance

S-Q Relevance	VQA accuracy
[0.0, 0.2)	52.79
[0.2, 0.8)	62.34
[0.8, 1.0)	89.81

In this section, we evaluate the sentence-based VQA model and analyze the relationship between the sentence quality and the VQA performance.

Table 3: Performance comparison on the validation split of VQA-real open-ended task when the sentence-based VQA model uses different sources of captions. (accuray in %)

Caption source	validation			
	All	Y/N	Num	Others
null	46.21	73.82	34.98	25.63
sentence generation	54.85	76.31	36.64	42.23
relevant groundtruth	56.05	77.42	41.04	44.34

Similar to the quality measurements of predicted words, we focus on the accuracy of the generated sentence itself and the relevance between sentence and question. As shown in Table 2a, the more accurate the generated sentence, the higher the VQA accuracy. The results suggest that the VQA performance can be further improved by a better image captioning model. From Table 2b, we can see that the more relevant to the question the generated sentence, the better the VQA performance. Once the relevance reaches 0.8, the accuracy can significantly increase to 89.81%. This proves that a question-related sentence is more likely to contain the key information for the VQA module to answer the question. As shown in Fig. 5, sentence-question relevance has greater influence on VQA performance than sentence accuracy does.

To further verify the causal relationship between sentence quality and VQA performance, we conduct the following control experiments. First, we evaluate sentence-based VQA model when feeding different sources of captions with ascending quality: *null* (only including an "#end" token), *sentence generation* and *relevant groundtruth* (selecting from the groundtruth captions the most relevant one to the question). As shown in Table 3, *sentence generation* performs much better than *null*. And using *relevant groundtruth* captions, the accuracy can improve by another 1.2 percent. Figure 6 presents an example to illustrate the effect of the sentence quality on the accuracy. From the above analysis, we can safely reach the conclusion that the VQA performance can be greatly improved by generating sentence-level explanations of high quality, especially of high relevance to the question.

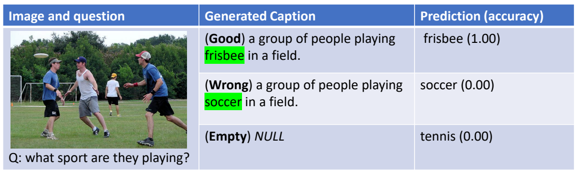

Image and question	Generated Caption	Prediction (accuracy)
Q: what sport are they playing?	(**Good**) a group of people playing frisbee in a field.	frisbee (1.00)
	(**Wrong**) a group of people playing soccer in a field.	soccer (0.00)
	(**Empty**) *NULL*	tennis (0.00)

Figure 6: A control case for comparing the accuracy when inputting captions of different quality. When getting a caption of high quality (the first one), the system can answer the question correctly. If we manually change the "frisbee" to "soccer", a wrong answer is predicted. When using an empty sentence, the system predicts the most popular answer "tennis" for this question.

4.4 Case Study

From the above evaluation of word-based and sentence-based VQA model, we conclude that the relevance between explanations (attributes/caption) and the question has a great impact on the final VQA performance. In this section we illustrate this conclusion by studying four possible types of cases: 1). *high relevance and correct answer*; 2). *low relevance and wrong answer*; 3). *high relevance but wrong answer*; 4). *low relevance but correct answer.*

High relevance and correct answer. From the first case in Fig. 7, we can see that the explanations for the image are highly relevant to the question: both the predicted attributes and the generated sentence contain the words "man" and "racket" occurring in the question. And the explanations also has key information that can predict the answer "tennis court." In this type of case, the system successfully extracts from the image the relevant information that covers the question, facilitating answer generation.

Low relevance and wrong answer. In the second case, although the attributes and caption can reflect part of the image content such as "man" and "food", they neglect the key information about the "glass" that is asked in the question. The absence of "glass" in the explanations produces a low explanation-question relevance score and leads the system to a wrong answer. In this type of case, two lessons can be derived from the low relevance: 1). as the explanations are irrelevant to the question, the system tends to predict the most frequent answer ("beer") for this question type ("what kind of drink ..."), which implies that the answer is actually *guessed* from the dataset bias; 2). the error comes from the image understanding part rather than the question answering module, because the system fails to extract from the image

Image	Explanations, Question and Answer
① **High relevance and correct answer**	
	**Attributes**: tennis, ball, man, racket, hit, court, play, player, swing, hold (0.87, 0.72) **Caption**: a man holding a tennis racket on a tennis court. (0.88, 0.68) **Question**: where is the man swinging the racket? **Answer**: tennis court (tennis court)
② **Low relevance and wrong answer**	
	**Attributes**: bicycle, man, sit, eat, bike, look, outside, food, person, table (0.06, 0.48) **Caption**: a man sitting at a table with a plate of food. (0.00, 0.34) **Question**: what kind of drink is in the glass? **Answer**: beer (water)
③ **High relevance but wrong answer**	
	**Attributes:** street, bus, cow, city, walk, car, drive, stand, road, white (0.51, 0.77) **Caption:** a cow that is walking in the street (0.51, 0.55) **Question:** what is walking next to the bus? **Answer:** car (cow)
④ **Low relevance but correct answer**	
	**Attributes:** woman, bear, teddy, hold, sit, glass, animal, large, lady (0.00, 0.19) **Caption:** a woman holding a sandwich in her hands (0.00, 0.30) **Question:** does the man need a haircut? **Answer:** yes (yes)

Figure 7: Four types of cases in our results: 1). high relevance and correct answer; 2). low relevance and wrong answer; 3). high relevance but wrong answer; 4). low relevance but correct answer. "(*,*)" behind the explanations (attributes/caption) denotes the explanation-question relevance score and explanation accuracy, respectively. Gray denotes groundtruth answers.

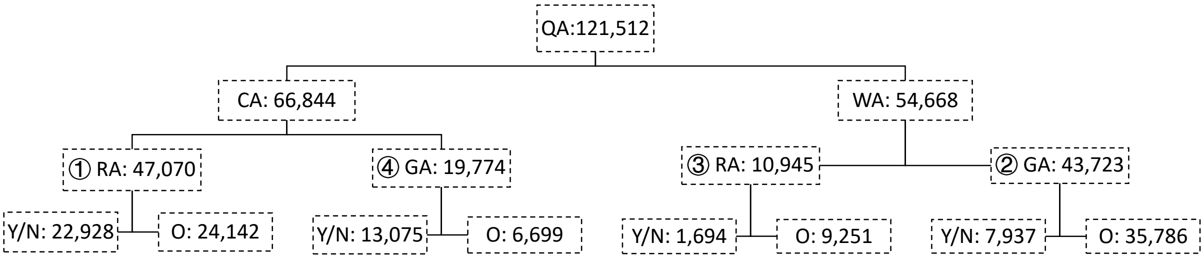

Figure 8: Dataset dissection according to the four types of cases. We define that the answer is guessed when the explanations are irrelevant to the question and otherwise reliable. The case numbers in the third row correspond to these in Fig.7. QA: all questions and answers. CA: questions with correct answers. WA: questions with wrong answers. GA: questions with guessed answers. RA: questions with reliable answers. Y/N: answer type "yes/no". O: answer types other than "yes/no".

enough information to answer the question in the first place. This error suggests that some improvements are needed in word prediction and sentence generation modules to generate more comprehensive explanations for the image.

High relevance but wrong answer. In the third case, we can see that although the system fails to predict the correct answer, the explanations for the image are indeed relevant to the question and the system also recognize the key information "cow." This indicates that the error is caused by the question answering module rather than the explanation generation part. The system can recognize that "a cow is walking in the street" and "a bus is in the street", but it fails to conclude that "the cow is next to the bus." This error may lie in the weakness of LSTM which struggles on such complex spatial relationship inference. In the following analysis, we would show that such cases only occupy a relatively small proportion of the whole dataset.

Low relevance but correct answer. In the last example of Fig. 7, we know from the explanations that the system mistakes the "man" in the image for "woman" and neglects the information about his "hair." The explanations, therefore, have a low relevance score, which indicates that the answer "yes" is guessed by the system. Although the guessed answer is correct, it cannot be credited to the correctness of the system. In fact, for this particular answer type "yes/no", the system has at least 50% chance to hit the right answer.

We dissect all the results in the dataset according to the above four types of cases, as shown in Fig. 8. Among the questions that the system answers correctly, nearly 30% are guessed. This discovery indicates that, buried in the seemingly promising performance, the system actually takes advantage of the dataset bias, rather than truly understands the image content. Over 65% of the answers that are correctly guessed belong to "yes/no", an answer type easier for the system to hit the right answer than other types. As for the questions to which the system predicts wrong answers, a large proportion (around 80%) has a low explanation-question relevance, which means that more efforts need to be put into improving the attributes detectors and image captioning model. Questions with other answer types account for more than 80% of the wrongly-guessed answers. This is not surprising because for these questions the system cannot rely on the dataset bias anymore, considering the great variety of the candidate answers.

4.5 Performance Comparison

Table 4: Performance comparison with the baselines. We show the performance on both test-dev and test-standard splits of VQA-real open-ended task. Human is the human performance for reference.

Method	test-dev				test-standard			
	All	Y/N	Num	Others	All	Y/N	Num	Others
LSTM Q+I (Antol et al., 2015)	53.74	78.94	35.24	36.42	54.06	79.01	35.55	36.80
Concepts (Wu et al., 2016a)	57.46	79.77	36.79	43.10	57.62	79.72	36.04	43.44
ACK (Wu et al., 2016b)	59.17	81.01	38.42	45.23	59.44	81.07	37.12	45.83
MCB w/n attention (Fukui et al., 2016)	60.80	81.20	35.10	49.30	-	-	-	-
Human (Antol et al., 2015)	-	-	-	-	83.30	95.77	83.39	72.67
Word-based VQA	56.76	77.57	35.21	43.85	-	-	-	-
Sentence-based VQA	57.91	78.03	36.73	45.52	-	-	-	-
Full VQA	59.93	79.32	38.41	48.25	60.07	79.09	38.25	48.57

In this section, we present the performance comparison between variants of our framework and the baselines. From Table 4, we can see that sentence-based VQA consistently outperforms word-based VQA, which indicates that sentence-level explanations are superior to word-level ones. The generated captions not only include the objects in the image, but also encode the relationship between these objects, which is important for predicting the correct answer. Furthermore, full VQA model obtains a better performance by combining attributes and captions.

Compared with the baselines, our framework achieves better performance than LSTM Q+I (Antol et al., 2015), Concepts (Wu et al., 2016a), and ACK (Wu et al., 2016b), which use CNN features, high-level concepts, and external knowledge, respectively. MCB without attention (Fukui et al., 2016) achieves better performance than ours and other methods, but it suffers from a high-dimensional feature (16,000 vs 1,280), which poses a limitation on the model's efficiency. The main advantage of our framework over other methods is that it not only predicts an answer to the question, but also generates human-readable attributes and captions to explain the answer. These explanations can help us understand what the system extracts from an image and their relevance to the question. As explanations improve, so would our system.

5 Discussions and Conclusions

In this work, we break up the end-to-end VQA pipeline into **explaining** and **reasoning**, and achieve comparable performance with the baselines. Different from previous work, our method first generates attributes and captions as explanations for an image and then feed these explanations to a question answering module to infer an answer. The merit of our method lies in that these attributes and captions allow a peek into the process of visual question answering. Furthermore, the relevance between these explanations and the question can act as indication whether the system really understands the image content.

It is worth noting although we also use the CNN-RNN combination, we generate words and captions as the explanations of images, thus allowing the VQA system to perform *reasoning on semantics* instead of unexplainable CNN features. Since the effectiveness of CNN for generating attributes and captions is well established, the use of CNN as a component does not contradict our high-level objective for explainable VQA. Our goal is not to immediately make a big gain in performance, but to propose a more powerful framework for VQA. Our current implementation already matches the baselines, but more importantly, provides the ability to explain and to improve.

Learning a Policy for Opportunistic Active Learning

Aishwarya Padmakumar, Peter Stone and Raymond J. Mooney
Department of Computer Science
University of Texas at Austin

Abstract

Active learning identifies data points to label that are expected to be the most useful in improving a supervised model. Opportunistic active learning incorporates active learning into interactive tasks that constrain possible queries during interactions. Prior work has shown that opportunistic active learning can be used to improve grounding of natural language descriptions in an interactive object retrieval task. In this work, we use reinforcement learning for such an object retrieval task, to learn a policy that effectively trades off task completion with model improvement that would benefit future tasks.

1 Introduction

In machine learning tasks where obtaining labeled examples is expensive, active learning is used to lower the cost of annotation without sacrificing model performance. Active learning allows a learner to iteratively query for labels of unlabeled data points that are expected to maximally improve the existing model. It has been used in a number of natural language processing tasks such as text categorization (Lewis and Gale, 1994), semantic parsing (Thompson et al., 1999) and information extraction (Settles and Craven, 2008).

The most commonly used framework for active learning is pool-based active learning, where the learner has access to the entire pool of unlabeled data at once, and can iteratively query for examples. In contrast, sequential active learning is a framework in which unlabeled examples are presented to the learner in a stream (Lewis and Gale, 1994). For every example, the learner can decide whether to query for its label or not. This results in an additional challenge – since the learner cannot compare all unlabeled data points before choosing queries, each query must be chosen based on local information only.

Multilabel active learning is the application of active learning in scenarios where multiple labels, that are not necessarily mutually exclusive, are associated with a data point (Brinker, 2006). These setups often suffer from sparsity, both in the number of labels that are positive for a data point, and in the number of positive data points per label.

Opportunistic active learning incorporates a form of multilabel sequential active learning into an interactive task. It was recently introduced for the task of interpreting natural-language object descriptions, motivated by the task of instructing a robot to retrieve a specific item (Thomason et al., 2017). In this task, a human describes one of a set of objects in unrestricted natural language and the agent must determine which object was described. The agent is allowed to ask questions about other objects in the current environment to obtain labels that allow it to learn classifiers for concepts used in such descriptions. As the questions are restricted to the objects available in the current interaction, the learning process across interactions can be seen as a form of multilabel sequential active learning. Further, the agent can either restrict itself to querying labels relevant to understanding the current description, or be opportunistic and query labels that can only aid future interactions – for example querying whether some object is “round” when trying to understand the description “a red box”.

More generally, in opportunistic active learning, an agent is engaged in a series of sequential decision-making tasks. The agent uses one or more supervised models to complete each task. Each task involves some sampled examples from a given feature space, and the agent is allowed to query for labels of these examples to improve its models for current and future tasks. Queries in this setting have a higher cost than in traditional active learning as the agent may choose to query for la-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1347–1357
Brussels, Belgium, October 31 - November 4, 2018.

bels that are not relevant for the current task, but expected to be of use for future tasks. Such opportunistic queries enable an agent to learn from a greater number of interactions, by allowing it to ask queries that would aid future tasks when it is sufficiently confident of completing the current task. They also allow an agent to focus on concepts that could have more impact than those relevant to the current task – for example by choosing a frequently used concept as opposed to a rare one. Further, identifying which queries are optimal for model improvement is more difficult as the agent does not have access to the entire pool of unlabeled examples at any given time, similar to sequential active learning settings.

Another sample application of opportunistic active learning could be in a task oriented dialog system providing restaurant recommendations to a user. In this case, a possible opportunistic query would be to ask the user for a Chinese restaurant they liked, when the user is searching for an Italian one. The query is not relevant to the immediate task of recommending an Italian restaurant but would improve the underlying recommendation system.

Prior work on using opportunistic active learning in understanding natural-language object descriptions has shown that an agent following an opportunistic policy, that queries for labels not necessarily relevant to the current interaction, learns to perform better at identifying objects correctly over time (Thomason et al., 2017). However, this work only compares static policies that select actions based on manually-engineered heuristics. In this work, we focus on *learning* an optimal policy for this task using reinforcement learning, in the spirit of other recent attempts to learn policies for different types of active learning (Fang et al., 2017; Woodward and Finn, 2017). This allows an agent to choose whether or not to be opportunistic based on the specific interaction as well as the overall statistics of the dataset.

Our learned policy outperforms a static baseline by improving its success rate on object retrieval while asking fewer questions on average. The learned policy also learns to distribute queries more uniformly across concepts than the baseline.

2 Related Work

Active learning methods aim to identify examples that are likely to be the most useful in improving a supervised model. A number of metrics have been proposed to evaluate examples, including uncertainty sampling (Lewis and Gale, 1994), density-weighted methods (Settles and Craven, 2008), expected error reduction (Roy and McCallum, 2001), query by committee (Seung et al., 1992), and the presence of conflicting evidence (Sharma and Bilgic, 2016); as surveyed by Settles (2010). Some of these metrics can be extended to the multilabel setting, by assuming that one-vs-all classifiers are learned for each label, and that all the learned classifiers are comparable (Brinker, 2006; Singh et al., 2009; Li et al.). Label statistics have also been incorporated into heuristics for selecting instances to be queried (Yang et al., 2009; Li and Guo, 2013). There have also been Bayesian approaches that select both an instance and label to be queried (Qi et al., 2009; Vasisht et al., 2014). Our work aims to learn a policy for choosing between queries that can use information from many such indicators, but learns to combine them appropriately for a given task.

Thomason et al. (2017) define the setting of opportunistic active learning, and apply it to an interactive task of grounding natural language descriptions of objects. They compare two static policies to demonstrate that using opportunistic queries improves task performance. We try to learn the optimal policy for this task using reinforcement learning, and compare to a policy similar to theirs.

Recently, there has been interest in using reinforcement learning to learn a policy for active learning. Fang et al. (2017) use deep Q-learning to acquire a policy that sequentially examines unlabeled examples and decides whether or not to query for their labels; using it to improve named entity recognition in low resource languages. Also, Bachman et al. (2017) use meta-learning to jointly learn a data selection heuristic, data representation and prediction function for a distribution of related tasks. They apply this to one shot recognition of characters from different languages, and in recommender systems. In contrast to these works, we learn a policy for a task that contains *both* possible actions that are active learning queries, *and* actions that complete the current task, thus resulting in a greater exploration-exploitation trade-off.

More similar to our setup is that of Woodward and Finn (2017) which uses reinforcement learning with a recurrent-neural-network-based Q-function in a sequential one-shot learning task to decide between predicting a label and acquiring the true label at a cost. This setup also has a higher cost than standard active learning where the test set is separated out. This is a continuous task without clearly separated interactions or episodes. In our setting, each episode or interaction allows for querying and requires completion of an interaction, which further increases the trade-off between model improvement and exploitation. Further, we consider a multilabel setting, which increases the number of actions at each decision step.

There are other works that employ various types of turn-taking interaction to learn models for language grounding. Some of these use a restricted vocabulary (Cakmak et al., 2010; Kulick et al., 2013), or additional knowledge of predicates (for example that "red" is a color) (Mohan et al., 2012). Others do not use active learning (Kollar et al., 2013; Parde et al., 2015; De Vries et al., 2017; Yu et al., 2017), or do not learn a policy that guides the interaction (Vogel et al., 2010; Thomason et al., 2016, 2017).

Also related to our work is the use of reinforcement learning in dialog tasks, such as slot-filling and recommendation (Wen et al., 2015; Pietquin et al., 2011), understanding natural language instructions or commands (Padmakumar et al., 2017; Misra et al., 2017), and open domain conversation (Serban et al., 2016; Das et al., 2017). These typically do not use active learning. In our task, the policy needs to trade-off model improvement against task completion.

3 Opportunistic Active Learning

Opportunistic Active Learning (OAL) is a setting that incorporates active learning queries into interactive tasks. Let $O = \{o_1, o_2, \dots o_n\}$ be a set of examples, and $M = \{m_1, m_2, \dots m_k\}$ be supervised models trained for different concepts, using these examples. For the problem of understanding natural-language object descriptions, O corresponds to the set of objects, M corresponds to the set of possible concepts that can be used to describe the objects, for example their categories (such as *ball* or *bottle*) or perceptual properties (such as *red* or *tall*).

In each interaction, an agent is presented with some subset $O_A \subseteq O$, and must make a decision based on some subset of the models $M_A \subseteq M$. Given a set of objects O_A and a natural language description l, M_A would be the set of classifiers corresponding to perceptual predicates present in l. The decision made by the agent is a guess about which object is being described by l. The agent receives a score or reward based on this decision, and needs to maximize expected reward across a series of such interactions. In the task of object retrieval, this is a 0/1 value indicating whether the guess was correct, and the agent needs to maximize the average guess success rate.

During the interaction, the agent may also query for the label of any of the examples present in the interaction $o \in O_A$, for any model $m \in M$. The agent is said to be opportunistic when it chooses to query for a label $m \notin M_A$, as this label will not affect the decision made in the current interaction, and can only help with future interactions. For example, given a description "*the red box*", asking whether an object is *red*, could help the agent make a better guess, but asking whether an object is *round*, would be an opportunistic query. Queries have a cost, and hence the agent needs to trade-off the number of queries with the success at guessing across interactions.

The agent participates in a sequence of such interactions, and the models improve from labels acquired over multiple interactions. Thus the agent's expected reward per interaction is expected to improve as more interactions are completed.

This setting differs from the traditional application of active learning in the following key ways:

- The agent cannot query for the label of any example from the unlabeled pool. It is restricted to the set of objects available in the current interaction, O_A.
- The agent is evaluated on the reward per interaction, rather than the final accuracy of the models in M.
- The agent may make opportunistic queries (for models $m \notin M_A$) that are not relevant to the current task.

Due to these differences, this setting provides challenges not seen in most active learning scenarios:

- Since the agent never sees the entire pool of unlabeled examples, it can neither choose queries that are globally optimal, nor use variance reduction strategies that still use near-optimal queries (such as sampling from a beam of near globally optimal queries).

- Since the agent is evaluated on task completion, it must learn to trade-off finishing the task with querying to improve the models.
- The agent needs to estimate the usefulness of a model across multiple interactions, to identify good opportunistic queries.

4 Task Setup

We consider an interactive task where an agent tries to learn to ground natural-language object descriptions. Grounded language understanding is the process of mapping natural-language referring expressions to object referents in the world (Thomason et al., 2016). We consider a grounded-language problem based on object retrieval – given a free form natural-language description of an object, the agent needs to identify which of a set of objects is best described by the phrase (Thomason et al., 2016; Guadarrama et al., 2014). In this work, objects are presented as images, but the methods are applicable to any feature representation of objects. We consider a task of interactive object retrieval where the agent is given a natural-language object description, and allowed to interact with the user before it attempts to guess the object being referred to.

In each interaction, the agent is presented with two sets of objects. The first set of objects is called the active training set, and is to be used by the agent to improve its model of object properties. The second set of objects is called the active test set, and the agent will have to retrieve an object from this set. The agent is provided with a natural language description of the object it is expected to retrieve.

Before guessing, the agent is allowed to ask queries of the following two types:

- Label queries - A yes/no question about whether a predicate can be used to describe one of the objects in the active training set, e.g. "Is this object yellow?".
- Example queries - Asking for an object, in the available training set, that can be described by a particular predicate, e.g. "Show me a white object in this set.". This is used for acquiring positive examples since most predicates tend to be sparse. [1]

Figure 1: A sample OAL interaction. Perceptual predicates are marked in bold.

A sample interaction is shown in Figure 1. The agent goes through a series of such interactions, and needs to learn to maximize the number of correct guesses across interactions, without frustrating the user with too many queries. The separate active training set and active test set ensures that the agent needs to learn models for object descriptors. If queries and guessing were performed on the same set of objects, the agent could simply query whether each specific object satisfies each predicate in the description, and use this to guess.

In our experiments, we simulate such dialogs using the Visual Genome dataset (Krishna et al., 2017); which contains images with regions (crops) annotated with natural-language descriptions. Bounding boxes of objects present in the image are also annotated, along with attributes of objects. Region descriptions, objects and attributes are annotated using unrestricted natural language, which leads to a diverse set of predicates. Using the annotations, we can associate a

---

[1] Alternately, we could return all positive examples for the predicate in the active training set, but we chose to return a single example to allow the agent to minimize the amount of supervision obtained

list of objects and attributes relevant to each image region, and use these to answer queries from the agent.

For each interaction, we uniformly sample 4 regions to form the active test set, and 8 regions to form the active training set. [2] One region is then uniformly sampled from the active test set to be the target object. Its description, from annotations in the Visual Genome dataset, is provided to the agent to be grounded. The objects and attributes associated with active training regions are used to answer queries. A predicate is labeled as being applicable to a region if it is present in the list of objects and attributes associated with the region. In the rest of the paper, we use the terms object, image, and region interchangeably.

5 Methodology

5.1 Perceptual Predicates and Classifiers

We assume that the description provided is a conjunction of one-word predicates. Given a description, the agent tokenizes it and removes stopwords. Each remaining word is stemmed and treated as a perceptual predicate. This method allows the agent to learn an open vocabulary of predicates, but unable to handle multi-word predicates or non-compositional phrases.

The agent learns a separate binary classifier for each predicate, and we represent images with a "deep" feature representation obtained from the penultimate layer of the VGG network (Simonyan and Zisserman, 2014) pretrained on ImageNet (Russakovsky et al., 2015). The agent has no initial classifiers for any predicate, and learns these classifiers purely from labels acquired during interactions.

5.2 Grounding Descriptions

The learned perceptual classifiers are used to ground natural language descriptions as follows. Let $p_1, p_2, \ldots p_k$ be the predicates obtained from the natural language description. Let $d(p_i, o) \in \{-1, 1\}$ be the decision from the classifier for predicate p_i for object o, and $C(p_i)$ be the estimated F1 of the classifier for p_i. [3] Then the best guess, from the objects present, is chosen using the weighted sum of the decisions of the classifiers, using their estimated F1 as a weight:

$$o_{guess} = \text{argmax}_{o \in O_A} \sum_{i=1}^{k} d(p_i, o) * C(p_i)$$

5.3 MDP Formulation

We model the task as a Markov Decision Process (MDP). An MDP is a tuple $\langle S, A, T, R, \gamma \rangle$, where S is a set of states, A is a set of actions, T is a transition function, R is a reward function and γ is a discount factor. Each interaction is an episode in the MDP. At any point, the agent is in a state $s \in S$, in our case consisting of the VGG features of the images in the current interaction, the predicates in the current description, and the agent's classifiers. The agent can choose from among actions in A, which include an action for guessing, and an action for each possible query the agent can make, including both label and example queries. The guess action always terminates the episode, and query actions transition the agent to a state $s' \in S$ as one of the classifiers gets updated. The agent gets a reward for each action taken. Query actions have a small negative reward, and guessing results is a large positive reward when the guess is correct, and a large negative reward when the guess is incorrect. In our experiments, we treat the reward values as hyperparameters that can be tuned. The best results were obtained with a reward of 200 for a correct guess, -100 for an incorrect guess and -1 for each query.

5.4 Identifying Candidate Queries

In any interaction, the agent can make label or example queries. In a label query, the agent can ask for the label of any object for a specific predicate. If O_A is the set of objects present in the active training set of the current interaction, and P is the set of predicates that have been seen by the agent in all interactions so far, then the set of possible label queries is $P \times O_A$. Once the agent chooses a predicate p and object o to be queried, it obtains the corresponding label and can update its classifier for p. In an example query, the agent asks for a positive example for any predicate $p \in P$. The agent will either receive a positive label for p for some object $o \in O_A$ or learn that the label is negative $\forall\ o \in O_A$, and can appropriately update the classifier for p.

---

[2] The regions in the dataset are divided into separate pools from which the active training and active test sets are sampled (described as classifier-training and classifier-test sets in section 6.2), to ensure that the agent needs to learn classifiers that generalize across objects.

[3] F1 is estimated by cross-validation on the labels acquired for the predicate.

Since $|P|$ grows across interactions as the agent encounters more predicates in descriptions, the number of candidate actions in a state increases over time, so searching the entire space of possible queries can become intractable. Hence, we identify a beam of promising queries that are then provided as candidate actions for the policy to choose among. Uncertainty sampling is a common method in pool-based active learning to identify the best example to improve a classifier. For a given predicate p, we use this to choose the best label query involving that predicate, picking that object $o \in O_A$ which is closest to the hyperplane of the classifier for p.

However, it is more challenging to narrow down the number of predicates. Thomason et al. (2017) assume that an estimate of classifier accuracy is available, which is comparable across classifiers. They sample predicates with a probability inversely proportional to the estimated accuracy of the classifier. However, if the space of possible predicates is large, then this results in no classifier obtaining a reasonable number of training examples. In this scenario, it is desirable to focus on a small number of predicates, possibly stopping the improvement on a predicate once the classifier for it has been sufficiently improved. We sample queries from a distribution designed to capture this intuition. The probability assigned to a predicate by this distribution increases linearly, for estimated F1 below a threshold, and decreases linearly thereafter. [4] The number of queries sampled is a hyperparameter. We obtain the best results by sampling 3 queries of each type.

5.5 Baseline Static Policy

As a baseline, we use a static policy similar to that used by Thomason et al. (2017). At each state, a single label query and example query are sampled. The agent asks a fixed number of queries before guessing. Thomason et al. (2017) use thresholds that prevent queries from being asked when there are no predicates whose classifiers have sufficiently low estimated accuracy. Since we used a dataset with a much larger number of predicates, these thresholds were always crossed if the agent had even one candidate query.

5.6 Policy Learning

We use the REINFORCE algorithm (Williams, 1992) to learn a policy for the MDP. The agent learns a policy $\pi(a|s;\theta)$, parameterized with weights θ that computes the probability of taking action a in state s. Given a feature representation $f(s,a)$ for a state-action pair (s,a), the policy is of the form:

$$\pi(a|s;\theta) = \frac{e^{\theta^T f(s,a)}}{\sum_{a'} e^{\theta^T f(s,a')}}$$

where the denominator is a sum over all actions possible in state s. The weights are updated using a stochastic gradient ascent rule:

$$\theta \leftarrow \theta + \alpha \nabla_\theta J(\theta)$$

where $J(\theta)$ is the expected return from the policy according to the distribution over trajectories induced by the policy.

The state consists of the predicates in the current description, the candidate objects, and the current classifiers. Since both the number of candidate objects and classifiers varies, and the latter is quite large, it is necessary to identify useful features for the task to obtain a vector representation needed by most learning algorithms. In our problem setting, the number of candidate actions available to the agent in a given state is variable. Hence we need to create features for state-action pairs, rather than just states.

5.7 Features for Policy Learning

The object retrieval task consists of two parts – identifying useful queries to improve classifiers, and correctly guessing the image being referred to by a given description. The current dialog length is also provided to influence the trade-off between guessing and querying.

5.7.1 Guess-success features

Let $P_A = \{p_1, p_2, \dots p_k\}$ be the predicates extracted from the current description. For each predicate $p \in P_A$, we have the estimated F1 of the classifier $C(p)$, and for each object o in the active test set, we have a decision $d(p,o) \in \{-1, 1\}$ from the classifier. We refer to $s(p,o) = d(p,o) * C(p)$ as the score of the classifier of p for object o. The following features are used to predict whether the current best guess is likely to be correct:

- Lowest, highest, second highest, and average estimated F1 among classifiers of predicates

---

[4] The equation for this distribution with some further discussion on its design is included in the supplementary material.

in P_A – learned thresholds on these values can be useful to decide whether to trust the guess.

- Highest score among regions in the active test set, and the differences between this and the second highest, and average scores respectively – a good guess is expected to have a high score to indicate relevance to the description, and substantial differences would indicate that the guess is discriminative. Similar features are also formed using the unweighted sum of decisions.
- An indicator of whether the two most confident classifiers agree on the decision of the top scoring region, which increases the likelihood of its being correct.

We compared directly using these features to training a regressor that uses them to predict the probability of a successful guess, and then using this as a higher-level policy feature. We found no difference between the two methods and the results reported directly use these features in the vector provided to the policy learner.

5.7.2 Query-evaluation features

The following features are expected to be useful in predicting whether it is useful to query for the label of a particular predicate:

- Indicator of whether the predicate is new or already has a classifier – this allows the policy to decide between strengthening existing classifiers or creating classifiers for novel predicates.
- Current estimated F1 of the classifier for the predicate – as there is more to be gained from improving a poor classifier.
- Fraction of previous dialogs in which the predicate has been used, and the agent's success rate in these – as there is more to be gained from improving a frequently used predicate but less if the agent already makes enough correct guesses for it.
- Is the query opportunistic – as these will not help the current guess.

Label queries also have an image region specified, and for these we have additional features that use the VGG feature space in which the region is represented for classification:

- Margin of the image region from the hyperplane of the classifier of the predicate – motivated by uncertainty sampling.
- Average cosine distance of the image region to others in the dataset – motivated by density weighting to avoid outliers.
- Fraction of the k-nearest neighbors of the region that are unlabeled for this predicate – motivated by density weighting to identify a data point that can influence many labels.

6 Experimental Methodology

6.1 Dataset

The Visual Genome dataset contains a total of 108,077 images with 540,6592 annotated regions. Since objects and attributes are annotated with free-form text rather than from a fixed, pre-defined vocabulary, there is considerable diversity in the language used for annotation. There are 80,908 unique objects annotated and 44,235 attributes. We assume that any objects that partially overlap with a region are present in it, as these are usually used in descriptions. Using the annotations, we can associate a list of objects and attributes relevant to each image region. We lower-case all annotations, remove special characters and perform stemming to help normalize terms.

6.2 Sampling dialogs

We want the agent to learn a policy that is independent of the actual predicates present at policy training and policy test time. In order to be able to evaluate this, we divide the set of possible regions into policy training and policy test regions as follows. We select all objects and attributes present in at least 1,000 regions. Half of these were randomly assigned to the policy test set. All regions that contain one of these objects or attributes are assigned to the policy test set, and the rest to the policy training set. Thus regions seen at test time may contain predicates seen during training, but will definitely contain at least one novel predicate. Further, the policy training and policy test sets are respectively partitioned into a classifier training and classifier test set using a uniform 60-40 split.

During policy training, the active training set of each dialog is sampled from the classifier-training subset of the policy-training regions, and the active test set of the dialog is sampled from the classifier-test subset of the policy-training set.

During policy testing, the active training set of each dialog is sampled from the classifier training subset of the policy test regions, and the active test set of the dialog is sampled from the classifier test subset of the policy test set.

6.3 Experiment phases

For efficiency, we run dialogs in batches, and perform classifier and policy updates at the end of each batch. We use batches of 100 dialogs each. Our experiment runs in 3 phases:

- Initialization – Since learning starting with a random policy can be difficult, we first run batches of dialogs on the policy training set using the static policy from section 5.5, and update the RL policy using states, actions and rewards seen in these dialogs. This "supervised" learning phase is used to initialize the RL policy.

- Training – We run batches of dialogs on the policy training set using the RL policy, starting it without any classifiers. In this phase, the policy is updated using its own experience.

- Testing – We fix the parameters of the RL policy, and run batches of dialogs on the policy test set. During this phase, the agent is again reset to start with no classifiers. We do this to ensure that performance improvements seen at test time are purely from learning a strategy for opportunistic active learning, not from acquiring useful classifiers in the process of learning the policy.

7 Experimental Results and Analysis

We initialize the policy with 10 batches of dialogs, and then train on another 10 batches of dialogs, both sampled from the policy training set. Following this, the policy weights are fixed, the agent is reset to start with no classifiers, and we test on 10 batches of dialogs from the policy test set. Table 1 compares the average success rate (fraction of successful dialogs in which the correct object is identified), and average dialog length (average number of system turns) of the best learned policy, and the baseline static policy on the final batch of testing. We also compare the effect of ablating the two main groups of features. The learned agent guesses correctly in a significantly higher fraction of dialogs compared to the static agent, using a significantly lower number of questions per dialog.

Policy	Success rate	Average Dialog Length
Learned	**0.44**	**12.95**
–Guess	0.37	**6.12**
–Query	0.35	**6.16**
Static	0.29	16

Table 1: Results on dialogs sampled from the policy test set after 10 batches of classifier training. *–Guess* and *–Query* are conditions with the guess and query features, respectively, ablated. Boldface indicates that the difference in that metric with respect to the *Static* policy is statistically significant according to an unpaired Welch t-test with $p < 0.05$.

When either the group of guess or query features is ablated, the success rate clearly decreases. While the mean success rate still remains above the baseline, the difference is no longer statistically significant. Further, at the end of the initialization phase, the average dialog length in all three conditions is about the same. In the two ablated conditions, the dialog length does not increase to become close to that of the static policy, which suggests that the agent does not learn that asking more queries improves dialog success. This is expected because the agent is either not able to evaluate the usefulness of queries, or the likelihood of success of a guess. However, in the learned policy with all features, the agent is able to identify a benefit in asking queries, and utilizes them to improve its success rate.

It is important to note that it is non-trivial to decide how to trade-off dialog success with dialog length. This should be decided for any given application by comparing the cost of an error with that of the user time involved in answering queries, and the reward function should be set appropriately based on this. Ideally, we would like to see an increase in dialog success rate *and* a decrease in dialog length, as is the case when comparing the learned and static policies. However, depending on the application, it may also be beneficial to see a smaller increase in success rate with a larger decrease in dialog length, as is the case in the ablated conditions.

We also explored ablating individual features. We found that the effect of ablating most single features is similar to that of ablating a group of features. The mean success rate decreases compared to the full policy with all features. It remains better than that of the static policy, but in most cases the difference stops being statistically significant. Among features for evaluating the guess, the removal of the difference between the two highest scores in the active test set has a fairly large effect, compared with the value of the highest score. This is expected because for retrieval it is sufficient if an object is simply scored higher than the other candidates. Further, since classifiers improve over time, the score threshold that indicates a good guess changes, and hence would be difficult to learn. An interesting result is that removal of features involving the predictions of the second best classifier has more effect than that of the best classifier. This is possibly because when noisy classifiers are in use, support of multiple classifiers is helpful. Among query evaluation features, we find, unsurprisingly, that removal of the feature providing the margin of the object in a label query affects performance much more than removal of features such as density and fraction of labeled neighbors, which merely indicate whether the object is an outlier. The full results of this experiment are included in the supplementary material.

Qualitatively, we found that the dialog success rate was higher for both short, and very long dialogs, with a decrease for dialogs of intermediate length. This suggests that longer dialogs are used to accumulate labels via opportunistic off-topic questions, as opposed to on-topic questions. The learned policy still suffers from high variance in dialog length suggesting that trading off task completion against model improvement is a difficult decision to learn. We find that the labels collected by the learned policy are more equitably distributed across predicates than the static policy, resulting in a tendency to have fewer classifiers of low estimated F1. There is relatively little difference in the number of predicates for which classifiers are learned. This suggests that the policy learns to focus on a few predicates, as the baseline does, but learn all of these equally well, in contrast to the baseline which has much higher variance in the number of labels collected per predicate.

8 Future Work

It would be interesting to examine how a policy learned using a dataset such as Visual Genome generalizes to a different domain such as images captured by a robot operating in an indoor environment, possibly with some fine-tuning using a smaller in-domain dataset. The simulation could also potentially be improved using positive-unlabeled learning methods (Liu et al., 2002; Li and Liu, 2003) instead of assuming that an object or attribute not labeled in an image region is not present in the image. It would also be interesting to compare the effectiveness of the opportunistic active learning framework, as well as the policy learning, across a variety of applications.

9 Conclusion

This paper has shown how to formulate an opportunistic active learning problem as a reinforcement learning problem, and learn a policy that can effectively trade-off opportunistic active learning queries against task completion. We evaluated this approach on the task of grounded object retrieval from natural language descriptions and learn a policy that retrieves the correct object in a larger fraction of dialogs than a previously proposed static baseline, while also lowering average dialog length.

Abstract

Understanding and reasoning about cooking recipes is a fruitful research direction towards enabling machines to interpret procedural text. In this work, we introduce RecipeQA, a dataset for multimodal comprehension of cooking recipes. It comprises of approximately 20K instructional recipes with multiple modalities such as titles, descriptions and aligned set of images. With over 36K automatically generated question-answer pairs, we design a set of comprehension and reasoning tasks that require joint understanding of images and text, capturing the temporal flow of events and making sense of procedural knowledge. Our preliminary results indicate that RecipeQA will serve as a challenging test bed and an ideal benchmark for evaluating machine comprehension systems. The data and leaderboard are available at http://hucvl.github.io/recipeqa.

1 Introduction

There is a rich literature in natural language processing (NLP) and information retrieval on question answering (QA) (Hirschman and Gaizauskas, 2001), but recently deep learning has sparked interest in a special kind of QA, commonly referred to as reading comprehension (RC) (Vanderwende, 2007). The aim in RC research is to build intelligent systems with the abilities to read and understand natural language text and answer questions related to it (Burges, 2013). Such tests are appealing as they require joint understanding of the question and the related passage (*i.e.* context), and moreover, they can analyze many different types of skills in a rather objective way (Sugawara et al., 2017).

Despite the progress made in recent years, there is still a significant performance gap between humans and deep neural models in RC, and researchers are pushing forward our understanding of the limitations and capabilities of these approaches by introducing new datasets. Existing tasks for RC mainly differ in two major respects: the question-answer formats, *e.g.* cloze (fill-in-the-blank), span selection or multiple choice, and the text sources they use, such as news articles (Hermann et al., 2015; Trischler et al., 2017), fictional stories (Hill et al., 2016), Wikipedia articles (Kočiský et al., 2018; Hewlett et al., 2016; Rajpurkar et al., 2016) or other web sources (Joshi et al., 2017). A popular topic in computer vision closely related to RC is Visual Question Answering (VQA) in which context takes the form of an image in the comprehension task, where recent datasets have also been compiled, such as (Antol et al., 2015; Yu et al., 2015; Johnson et al., 2017; Goyal et al., 2017), to name a few.

More recently, research in QA has been extended to focus on the multimodal aspects of the problem where different modalities are being explored. Tapaswi et al. (2016) introduced MovieQA where they concentrate on evaluating automatic story comprehension from both video and text. In COMICS, Iyyer et al. (2017) turned to comic books to test understanding of closure, transitions in the narrative from one panel to the next. In AI2D (Kembhavi et al., 2016) and FigureQA (Kahou et al., 2018), the authors addressed comprehension of scientific diagrams and graphical plots. Last but not least, Kembhavi et al. (2017) has proposed another comprehensive and challenging dataset named TQA, which comprised of middle school science lessons of diagrams and texts.

In this study, we focus on *multimodal machine comprehension of cooking recipes* with images and text. To this end, we introduce a new QA dataset called *RecipeQA* that consists of recipe instructions and related questions (see Fig. 1 for an example text cloze style question). There are a handful of reasons why understanding and reasoning about

Text Cloze Style Question **Context Modalities: Images and Descriptions of Steps**

Recipe: Last-Minute Lasagna

1. Heat oven to 375 degrees F. Spoon a thin layer of sauce over the bottom of a 9-by-13-inch baking dish.
2. Cover with a single layer of ravioli.
3. Top with half the spinach half the mozzarella and a third of the remaining sauce.
4. Repeat with another layer of ravioli and the remaining spinach mozzarella and half the remaining sauce.
5. Top with another layer of ravioli and the remaining sauce not all the ravioli may be needed. Sprinkle with the Parmesan.
6. Cover with foil and bake for 30 minutes. Uncover and bake until bubbly, 5 to 10 minutes.
7. Let cool 5 minutes before spooning onto individual plates.

Question	Choose the best text for the missing blank to correctly complete the recipe Cover. _____________. Bake. Cool, serve.
Answer	**A. Top, sprinkle** B. Finishing touches C. Layer it up D. Ravioli bonus round

Figure 1: An illustrative text cloze style question (context, question and answer triplet). The context is comprised of recipe description and images where the question is generated using the question titles. Each paragraph in the context is taken from another step, as also true for the images. Bold answer is the correct one.

recipes is interesting. Recipes are written with a specific goal in mind, that is to teach others how to prepare a particular food. Hence, they contain immensely rich information about the real world. Recipes consist of instructions, wherein one needs to follow each instruction to successfully complete the recipe. As a classical example in introductory programming classes, each recipe might be seen as a particular way of solving a task and in that regard can also be considered as an algorithm. We believe that recipe comprehension is an elusive challenge and might be seen as important milestone in the long-standing goal of artificial intelligence and machine reasoning (Norvig, 1987; Bottou, 2014).

Among previous efforts towards multimodal machine comprehension (Tapaswi et al., 2016; Kembhavi et al., 2016; Iyyer et al., 2017; Kembhavi et al., 2017; Kahou et al., 2018), our study is closer to what Kembhavi et al. (2017) envisioned in TQA. Our task primarily differs in utilizing substantially larger number of images – the average number of images per recipe in RecipeQA is 12 whereas TQA has only 3 images per question on average. Moreover, in our case, each image is aligned with the text of a particular step in the corresponding recipe. Another important difference is that TQA contains mostly diagrams or textbook images whereas RecipeQA consists of natural images taken by users in unconstrained environments.

Some of the important characteristics of RecipeQA are as follows:

- There are arbitrary numbers of steps in recipes and images in steps, respectively.
- There are different question styles, each requiring a specific comprehension skill.
- There exists high lexical and syntactic divergence between contexts, questions and answers.
- Answers require understanding procedural language, in particular keeping track of entities and/or actions and their state changes.
- Answers may need information coming from multiple steps (*i.e.* multiple images and multiple paragraphs).
- Answers inherently involve multimodal understanding of image(s) and text.

To sum up, we believe RecipeQA is a challenging benchmark dataset which will serve as a test bed for evaluating multimodal comprehension systems. In this paper, we present several statistical analyses on RecipeQA and also obtain baseline performances for a number of multimodal comprehension tasks that we introduce for cooking recipes.

2 RecipeQA Dataset

The Recipe Question Answering (RecipeQA) dataset is a challenging multimodal dataset that evaluates reasoning over real-life cooking recipes. It consists of approximately 20K recipes from 22 food categories, and over 36K questions. Fig. 2 shows an illustrative cooking recipe from our dataset. Each recipe includes an arbitrary number of steps containing both textual and visual elements. In particular, each step of a recipe is accompanied by a 'title', a 'description' and a set of illustrative 'images' that are aligned with the title and the description. Each of these elements can be considered as a different modality of the data. The questions in RecipeQA explore the multimodal aspects of the step-by-step instructions available in the recipes through a number of specific tasks that are described in Sec. 3, namely *textual cloze*, *visual cloze*, *visual coherency* and *visual ordering*.

2.1 Data Collection

We consider cooking recipes as the main data source for our dataset. These recipes were collected from Instructables[1], which is a how-to web site where users share all kinds of instructions including but not limited to recipes.

We employed a set of heuristics that helped us collect high quality data in an automatic manner. For instance, while collecting the recipes, we downloaded only the most popular recipes by considering the popularity as an objective measure for assessing the quality of a recipe. Our assumption is that the mostly viewed recipes contain less noise and include easy-to-understand instructions with high-quality illustrative images.

In total, we collected about 20K unique recipes from the food category of Instructables. We filtered out non-English recipes using a language identification (Lui and Baldwin, 2012), and automatically removed the ones with unreadable contents such as the ones that only contain recipe videos. Finally, as a post processing step, we normalized the description text by removing non-ASCII characters from the text.

2.2 Questions and Answers

For machine comprehension and reasoning, forming the questions and the answers is crucial for evaluating the ability of a model in understanding the content. Prior studies employed natural language questions either collected via crowdsourcing platforms such as SQuAD (Rajpurkar et al., 2016) or generated synthetically as in CNN/Daily Mail (Hermann et al., 2015). Using natural language questions is a good approach in terms of capturing human understanding, but crowdsourcing is often too costly and does not scale well as the size of the dataset grows. Synthetic question generation is a low-cost solution, but the quality of the generated questions is subject to question.

RecipeQA includes structured data about the cooking recipes that consists of step-by-step instructions, which helps us generate questions in a fully automatic manner without compromising the quality. Our questions test the semantics of the instructions of the recipes from different aspects through the tasks described in Sec. 3. In particular, we generate a set of multiple choice questions (the number of choices is fixed as four) by following a simple procedure which apply to all of our tasks with slight modifications.

In order to generate question-answer-context triplets, we first filtered out recipes that contain less than 3 steps or more than 25 steps. We also ignored the initial step of the recipes as our preliminary analysis showed that the first step of the recipes almost always is used by the authors to provide a narrative, *e.g.* why they love making that particular food, or how it makes sense to prepare a food for some occasion, and often is not relevant to the recipe instructions. In addition, we automatically removed some indicators such as step numbers that explicitly emphasize temporal order from the step titles while generating questions.

Given a task, we first randomly select a set of steps from each recipe and construct our questions and answers from these steps according to the task at hand. In particular, we employ the modality that the comprehension task is built upon to generate the candidate answers and use the remaining content as the necessary context for our questions. For instance, if the step titles are used within the candidate answers, the context becomes the descriptions and the images of the steps. As the average number of steps per recipe is larger than four, using this strategy, we can generate multiple context-question-answer triplets from a single recipe.

Candidate answers can be generated by selecting the distractors at random from the steps of other recipes. To make our dataset more challenging, we

Intro

This Creamy Coconut Chickpea Curry is an quick and easy to prepare vegan and gluten free Indian-cuisine-inspired dish, made from fresh ingredients. All it takes is about 5 minutes of prep time and another 20 minutes of cooking time and you have yourself a delicious and healthy dish. Deliciously satisfying!

Step 1: Ingredients

1 can (796mL) of chickpea curry 1 can (400mL) of coconut milk 2 tomatoes 1 lime 2 stalks of coriander 3 cloves of garlic 1 inch knob of ginger 1 large yellow onion 1/4 teaspoon ground black pepper 1/2 teaspoon salt 2 teaspoon curry powder 1/2 teaspoon paprika Flavourless oil like vegetable oil Tools: Cutting board Knife Skillet

Step 2: Prepping the Garlic, Ginger, Onion, and Tomato

Remove the skin from the garlic, ginger, and onion. I found it easiest to use a spoon to scrape the skin from the ginger. Mince the garlic and ginger. Dice the onion Dice the tomatoes. Once done, set aside the garlic and ginger, onions, and tomatoes on separate bowls respectively.

Step 3: Drain the Chickpeas

Drain the water from the can of chickpeas. Then run rinse the chickpeas under cold water, drain very well and leave aside. My chickpeas came with the transparent outer shells of the beans, so I removed those as well, then re-rinsed it before setting it aside.

Step 4: Prepping Lime and Coriander

You can prep the lime and the coriander while the curry is cooking because you will have time, but I find it easier to do all the prepping at once and leave the extra time for washing the dishes. Slice the lime to 6 wedges, these will be served with the curry. Chop the leaves off from the Coriander then roughly chop it to a smaller size as it will be used for garnishing.

Step 5: Cook the Onion, Garlic, and Ginger

Heat the oil in a skillet using medium heat and add in the diced onions. Cook it until the onion softens and becomes a translucent colour. This takes around 2 to 3 minutes. Once the onions are cooked, add your garlic and ginger in and cook for another 90 seconds.

Step 6: Add the Spices

Add in all the spices (curry powder, pepper, salt, and paprika) and stir it for about 30 seconds. This will cook the spices and infuse the flavours of our spices together with the other ingredients.

Step 7: Add the Tomatoes

Add the tomatoes in and stir it around until it is mixed with the spices evenly. Then leave it to cook for another 3 to 5 minutes or until the tomatoes begin break down and harden. The tomatoes add a unique texture as well as a bit of sweetness and tartness to the dish.

Step 8: Add Chickpeas and Coconut Milk

Add the drained chickpeas to the skillet with the can of coconut milk. Stir it in until the curry and the coconut milk becomes uniformly mixed. Bring the heat down to medium-low and cover it for around 15 minutes to bring it to a boil until the sauce thickens up.

Step 9: Garnish and Serve

Garnish the dish with coriander and squeeze in a fresh lime on the curry to complete the dish and further elevate the flavour. Serve with with rice and enjoy!

Figure 2: A recipe of 'Creamy Coconut Chickpea Curry' with 9 steps, taken from Instructables.

employ a different strategy and select the distractors from the relevant modalities (titles, descriptions or images), which are not too far or too close from the correct answer. Specifically, we employ the following simple heuristic. We first find k nearest neighbors ($k = 100$) from other recipes. We then define an adaptive neighborhood by finding the closest distance to the query and remove the candidates that are too close. The remaining candidates are similar enough to be adversarial but not too similar to semantically substitute for the groundtruth. Finally, we randomly sample distractors from that pool. Details of the question generation procedure for each of the tasks are given in Sec. 3.

2.3 Dataset Statistics

RecipeQA dataset contains approximately 20K cooking recipes and over 36K question-answer pairs divided into four major question types reflecting each of the task at hand. The data is split into non-overlapping training, validation and test sets so that one set does not include a recipe and/or questions about that recipe which are available in other sets. There are 22 different food categories across our dataset whose distribution is shown in Fig. 3. While splitting the recipes into sets, we take into account these categories so that all the sets have a similar distribution of recipes across all the categories. In Table 1, we show the detailed statistics about our RecipeQA dataset. Moreover, to visualize the token frequencies, we also provide the word clouds of the titles and the descriptions from the recipes in Fig. 4.

	train	**valid**	**test**
# of recipes	15847	1963	1969
. . . avg. # of steps	5.99	6.01	6.00

Table 1: RecipeQA dataset statistics.

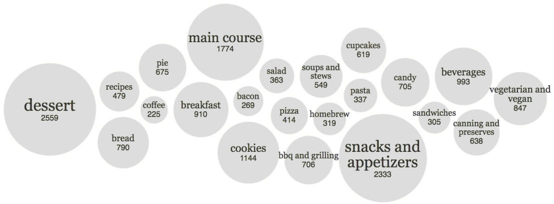

Figure 3: Distribution of the food categories across the RecipeQA.

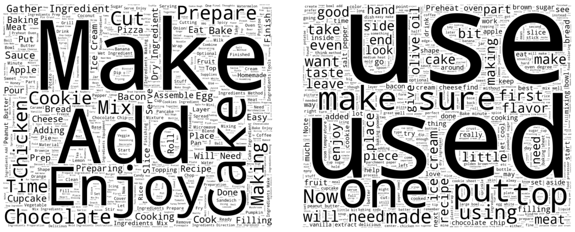
3 Tasks

RecipeQA includes four different types of tasks: (1) Textual cloze, (2) Visual cloze, (3) Visual coherence, and (4) Visual ordering. Each of these tasks requires different reasoning skills as discussed in (Sugawara et al., 2017), and considers different modalities in their contexts and candidate answer sets. By modalities, we refer to the following pieces of information: (i) titles of steps, (ii) descriptions of steps and (iii) illustrative images of steps. While generating the questions for these tasks, we rather employ fixed templates as will be discussed below, which helps us to automatically construct question-answers pairs from the recipes with no human intervention. Using these tasks, we can easily evaluate complex relationships between different steps of a recipe via their titles, their descriptions and/or their illustrative images. Hence, our question-answers pairs are multimodal in nature. In the following, we provide a detailed description of each one of these tasks and discuss our strategies while selecting candidate answers.

3.1 Textual Cloze

Textual cloze style questions test the ability to infer missing text either in the title or in the step description by taking into account the question's context which includes a set of illustrative images besides text. While generating the question-answer pairs for this task, we randomly select a step from the candidate steps of a given recipe, hide its title and description, and ask for identifying this text amongst the multiple choices from the remaining modalities. To construct the distractor answers, we use the strategy in Sec. 2.2 that depends on the WMD (Kusner et al., 2015) distance measure. In Fig. 1, we provide a sample text cloze question from RecipeQA generated automatically in this way.



Step titles

Step descriptions

Figure 4: Word clouds of the tokens for the titles and the descriptions of the recipes from RecipeQA.

3.2 Visual Cloze

Visual cloze style questions test a skill similar to that of textual cloze task with the difference that the missing information in this task reside in the visual domain. Here, just like the textual cloze task, for a recipe we randomly select a step, hide its representative image, and ask to infer this image amongst the multiple choices. The context for this task is all textual and is in the form of a sequence of titles and descriptions. To construct the distractor images, we use Euclidean distances of 2048-d *pool5* features extracted from a ResNet-50 (He et al., 2016) pre-trained on ImageNet classification task. We show a sample visual cloze style question in Fig. 5 (second row).

3.3 Visual Coherence

Visual coherence style questions test the capability to identify an incoherent image in an ordered set of images given the titles and descriptions of the corresponding recipe as the context. Hence, to be successful at this task, a system needs to not only understand the relations between candidate steps, but also align and relate different modalities existing in the context and the answers. While generating the answer candidates for this task, we randomly select a single representative image from a single step and replace this image with a distractor image via employing the distractor selection strategy used for visual cloze task. In Fig. 5 (third row), we provide a sample visual coherence style question from RecipeQA.

3.4 Visual Ordering

Visual ordering questions test the ability of a system in finding a correctly ordered sequence given a jumbled set of representative images of a recipe. As in the previous visual tasks, the context of this task consists of the titles and descriptions of a recipe. To

Context Modalities: Titles and Descriptions of Steps

Recipe: Bacon Sushi

Step 1: **What You'll Need** This recipe makes enough bacon sushi to feed 2 - 4 people. 2 x 500g(1 lb.) packages of bacon (I chose an applewood smoked bacon, but any type would work). 3 tbsp. oil. 1 medium onion, finely diced. 1 1…

Step 2: **Cooking the Bacon** The bacon "nori" will have to be partially cooked before it can be rolled with the risotto filling. Preheat the oven to 350 degrees F. Lay half a package of bacon on the rack of the roasting pan, then bak…

Step 3: **Making the Risotto Filling** I once made risotto with sushi rice, since I had no Arborio rice on hand, and I decided that the starchiness was similar in the two. My experiment was a success, and the resulting dish was just as deli…

Step 4: **Jazzing Up the Risotto** Risotto is a wonderfully customizable dish, and a quick search on the internet will result in a multitude of variations. Here are two of my favorites: Asian mushroom risotto. 1 tbsp. oil. 1 package…

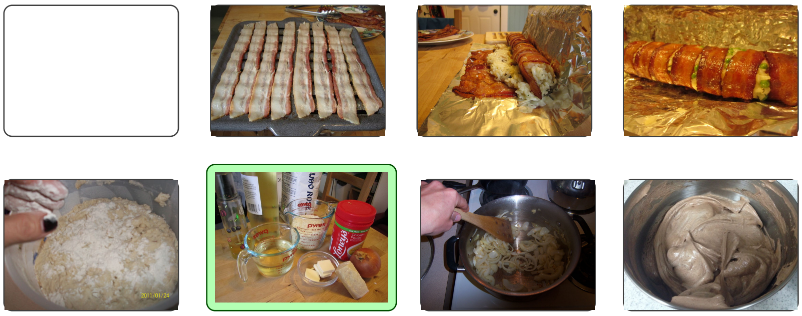
Step 5: **Rolling the Sushi** Cover the sushi rolling mat with a large piece of aluminum foil as protection from the risotto and bacon grease. (You don't want your next sushi dinner tasting like bacon. Or maybe you do...) Lay the stri…

Step 6: **Baking and Slicing** Preheat the oven to 350 degrees F. Place the aluminum foil-covered sushi rolls in the oven and bake for 20 minutes. This will warm all the ingredients and crisp the bacon a little more. It will also melt a…

Step 7: **And You're Done!** Serve the sushi with a light crispy vegetable side dish, such as refreshing cucumber sticks, or a green salad. White wine makes an excellent compliment to the meal, especially if it is the same wine used in …

Visual Cloze Style Question

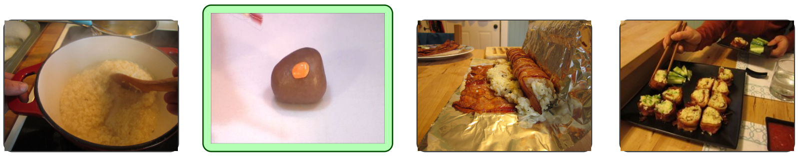
Question Choose the best image for the missing blank to correctly complete the recipe



Answer A. **B.** C. D.

Visual Coherence Style Question

Question Select the incoherent image in the following sequence of images



Answer A. **B.** C. D.

Visual Ordering Style Question

Question Choose the correct order of the images to make a complete recipe

(i) (ii) (iii) (iv)

Answer A. (iv)-(iii)-(ii)-(i) **B. (iv)-(iii)-(i)-(ii)** C. (i)-(ii)-(iii)-(iv) D. (ii)-(iv)-(i)-(iii)

Figure 5: Sample visual cloze, visual coherence and visual ordering style questions (context, question and answer triplet) taken from the RecipeQA training set (Question Ids: 2000-3708-0-1-4-5, 3000-3708-2-3-4-6, 4000-3708-1-2-3-6). Here, the context is comprised of step titles and descriptions where the questions are generated using the images in the recipe. The correct answers are shown with green frames or in bold.

successfully complete this task, the system needs to understand the temporal occurrence of a sequence of recipe steps and infer temporal relations between candidates, *i.e.* boiling the water first, putting the spaghetti next, so that the ordered sequence of images aligns with the given recipe. To generate answer choices, we simply use random permutations of the illustrative images in the recipe steps. In

Fig. 5 (last row), we illustrate this visual ordering task through an example question. Here, we should note that a similar task has been previously investigated by Agrawal et al. (2016) for visual stories where the task is to order a jumbled set of aligned image-description pairs.

4 Experiments

4.1 Data Preparation

Ingredient Detection. We employed the method proposed in (Salvador et al., 2017) to detect recipe ingredients. To learn more effective word embeddings, we transformed the ingredients with compound words such as *olive oil* into single word ingredients with a proper hyphenation as *olive_oil*.

Textual Embeddings. We trained a distributed memory model, namely Doc2Vec (Le and Mikolov, 2014) and used it to learn word level and document level embeddings while encoding the semantic similarity by taking into account the word order within the provided context. In this way, we can represent each word, sentence or paragraph by a fixed sized vector. In our experiments, we employed 100-d vectors to represent all of the textual modalities (titles and descriptions). We made sure that the embeddings encode semantically useful information by exploring nearest neighbors (see Fig. 6 for some examples.)

Query	Nearest Neighbor
Then add the green onion and garlic.	Then add the white onion, red pepper and garlic.
It will thicken some while it cools	Some cornflour to thicken.
Slowly whisk in the milk, scraping the bottom and sides with a heatproof spatula to make sure all the dry ingredients are mixed in.	Stir the dry ingredients in, incrementally, mixing on low speed and scraping with a spatula after each addition.

Figure 6: Sample nearest neighbors from the embeddings by the trained Doc2Vec model.

Visual Features. We used the final activation of the ResNet-50 (He et al., 2016) model trained on the ImageNet dataset (Russakovsky et al., 2015) to extract 2048-d dense visual representations. Then, we further utilized an autoencoder to decrease the dimension of the visual features to 100-d so that they become compatible in size with the text embeddings.

4.2 Baseline Models

Neural Baselines. For our neural baselines, we adapted the Impatient Reader model in (Hermann et al., 2015), which was originally developed only for the cloze style text comprehension questions in the CNN/Daily Mail dataset. In our implementation, we used a uni-directional stacked LSTM architecture with 3 layers, in which we feed the context of the question to the network in a sequential manner. Particularly, we preserve the temporal order of the steps of the recipe while feeding it to the neural model, by mimicking the most common reading strategy – reading from top to bottom. For the multimodal setting, since images are represented with vectors which are of the same size with the text embeddings, we also feed the images to the network in the same order they are presented in the recipe.

In order to account for different question types, we employ a modular architecture, which requires small adjustments to be made for each task. For instance, we place the candidate answers into query for the cloze style questions or remove the candidate answer from the query for the visual coherence type questions. In training our Impatient Reader baseline model, we use a cosine similarity function and employed the *hinge ranking loss* (Collobert et al., 2011) as follows:

$$L = \max\{0, M - cos(q, a_+) + cos(q, a_-)\} \quad (1)$$

where M is a scalar denoting the margin, a_+ represents the ground truth answer, and a_- corresponds to an incorrect answer which is sampled randomly from the whole answer space. For all of our experiments, we select M as 1.5 and employ a simple heuristic to prevent overfitting by following an early stopping scheme with patience set to 10 against the validation set accuracy after the initial epoch. For the optimizer, we use ADAM and set the learning rate to $1e-3$. The training took around 18 to 24 hours on GTX 1080Ti on a single GPU. We did not perform any hyperparameter tuning.

Simple Baselines. We adapt the Hasty Student model described in (Tapaswi et al., 2016), which does not consider the provided context and simply answers questions by only looking at the similarities or the dissimilarities between the elements in questions and the candidate answers.

For the textual close task, each candidate answer is compared against the titles or descriptions of

	Visual Cloze	Textual Cloze	Visual Coherence	Visual Ordering
Hasty Student	27.35	26.89	**65.80**	**40.88**
Impatient Reader (Text only)	–	28.03	–	–
Impatient Reader (Multimodal)	**27.36**	**29.07**	28.08	26.74

Table 2: Results for simple and neural models on the test set of RecipeQA dataset.

the steps by using WMD (Kusner et al., 2015) distance, where such distances are averaged. Then, the choice closest to all of the question steps is selected as the final answer. For the visual cloze task, a similar approach is carried out by considering images instead of text using deep visual features. For the visual coherence task, since the aim is to find the incoherent image among other images, the final answer is chosen as the most dissimilar one to the remaining images on average. Lastly, for the visual ordering task, first, the distances between each consecutive image pair in a candidate ordering of the jumbled image set is estimated. Then, each candidate ordering is scored based on the average of these pairwise distances and the choice with the minimum average distance is set as the final answer. In all these simple baseline models, we use the cosine distance to rank the candidates.

4.3 Baseline Results

We report the performance of the baseline models in Table 2 which indicates the ratio of correct answers against the total questions in the test. For the textual cloze, the comparison between text-only and multimodal Impatient Reader models shows that the additional visual modality helps the model to understand the question better and to provide more accurate answers. While for the cloze style questions, the Impatient Reader outperforms the Hasty student, for the visual coherence and visual ordering style questions Hasty student gives way better results. This demonstrates that better neural models are needed to be able to effectively deal with this kind of questions. Some qualitative examples are provided in the supplementary material.

5 Related Work

Question Answering has been studied extensively in the literature. With the success of deep learning approaches in question answering, comprehension and reasoning aspects of the task has attracted researchers to investigate QA as a medium to measure intelligence. Various datasets and methods have been proposed for measuring different aspects of the comprehension and reasoning problem. Each dataset has its own merits as well as weaknesses. Recently, a thorough analysis by (Chen et al., 2016) revealed that the required reasoning and inference level was quite simple for CNN/Daily Mail dataset (Hermann et al., 2015). To make reasoning task more realistic, new datasets such as SQuAD (Rajpurkar et al., 2016), NewsQA (Trischler et al., 2017), MSMARCO (Nguyen et al., 2016), CLEVR (Johnson et al., 2017), COMICS (Iyyer et al., 2017) and FigureQA (Kahou et al., 2018) have been proposed.

Dataset	#Images	#Questions	Modality
COMICS	1.2M	750K	Image/Text
MovieQA	408	14,944	Image/Video/Text
TQA	3,455	26,260	Image/Text
RecipeQA	250,730	36,786	Image/Text

Table 3: Comparison of the RecipeQA dataset to other multimodal machine comprehension datasets.

In the following, we briefly discuss the publicly available datasets that are closely related to our problem and provide an overview in Table 3.

The closest works to ours are (Iyyer et al., 2017), (Tapaswi et al., 2016) and (Kembhavi et al., 2017) where data multi-modality is the key aspect. COMICS dataset (Iyyer et al., 2017) focus on comic book narratives and explore visual cloze style questions, introducing a dataset consisting of drawings from comic books. The dataset is constructed from 4K Golden Age (1938-1954) comic books from the Digital Comics Museum and contains 1.2M panels with 2.5M textboxes. Three tasks are evaluated in this context, namely text cloze, visual cloze, character coherence. MovieQA dataset (Tapaswi et al., 2016), comprises of 15K crowdsourced questions about 408 movies. It consists of movie clips, subtitles, and snapshots, is about comprehending stories about movies. TQA dataset (Kembhavi et al., 2017), have 26K questions about 1K middle school science lessons with 3.5K images, mostly of diagrams and aims at addressing middle school knowledge acquisition using both images and text. Since the audience is middle school children, it requires limited reasoning.

RecipeQA substantially differentiates from the previous work in the following way. Our dataset consists of natural images that are taken by anonymous users in unconstrained environments, which is a major diversion from COMICS and TQA datasets.

It should also be noted that there has been a long history of research involving cooking recipes. Recent examples include parsing of recipes (Malmaud et al., 2014; Jermsurawong and Habash, 2015), aligning instructional text to videos (Malmaud et al., 2015; Sener et al., 2015), recipe text generation (Kiddon et al., 2016), learning cross-modal embeddings (Salvador et al., 2017), tracking entities and action transformations in recipes (Bosselut et al., 2018).

Finally, to our best knowledge, there is no dataset focusing on "how-to" instructions or recipes; hence, this work will be the first to serve multimodal comprehension of recipes having an arbitrary number of steps aligned with multiple images and multiple sentences.

6 Conclusion

We present RecipeQA, a dataset for multimodal comprehension of cooking recipes, which consists of roughly 20K cooking recipes with over 36K context-question-answer triplets. To our knowledge, RecipeQA is the first machine comprehension dataset that deals with understanding procedural knowledge in a multimodal setting. Each one of the four question styles in our dataset is specifically tailored to evaluate a particular skill and requires connecting the dots between different modalities. Results of our baseline models demonstrate that RecipeQA is a challenging dataset and we plan make it publicly available for other researchers to promote the development of new methods for multimodal machine comprehension. In the future, we also intend to extend the dataset by collecting natural language questions-answer pairs via crowdsourcing. We also hope that RecipeQA will serve other purposes for related research problems on cooking recipes as well.

Acknowledgments

We would like to thank our anonymous reviewers for their insightful comments and suggestions, which helped us improve the paper, Taha Sevim and Kenan Hagverdiyev for their help in building the RecipeQA challenge website, and NVIDIA Corporation for the donation of GPUs used in this research. This work was supported in part by a Hacettepe BAP fellowship (FBB-2016-11653) awarded to Erkut Erdem. Semih Yagcioglu was partly sponsored by STM A.Ş.

Abstract

Recent years have witnessed an increasing interest in image-based question-answering (QA) tasks. However, due to data limitations, there has been much less work on video-based QA. In this paper, we present TVQA, a large-scale video QA dataset based on 6 popular TV shows. TVQA consists of 152,545 QA pairs from 21,793 clips, spanning over 460 hours of video. Questions are designed to be compositional in nature, requiring systems to jointly localize relevant moments within a clip, comprehend subtitle-based dialogue, and recognize relevant visual concepts. We provide analyses of this new dataset as well as several baselines and a multi-stream end-to-end trainable neural network framework for the TVQA task. The dataset is publicly available at `http://tvqa.cs.unc.edu`.

1 Introduction

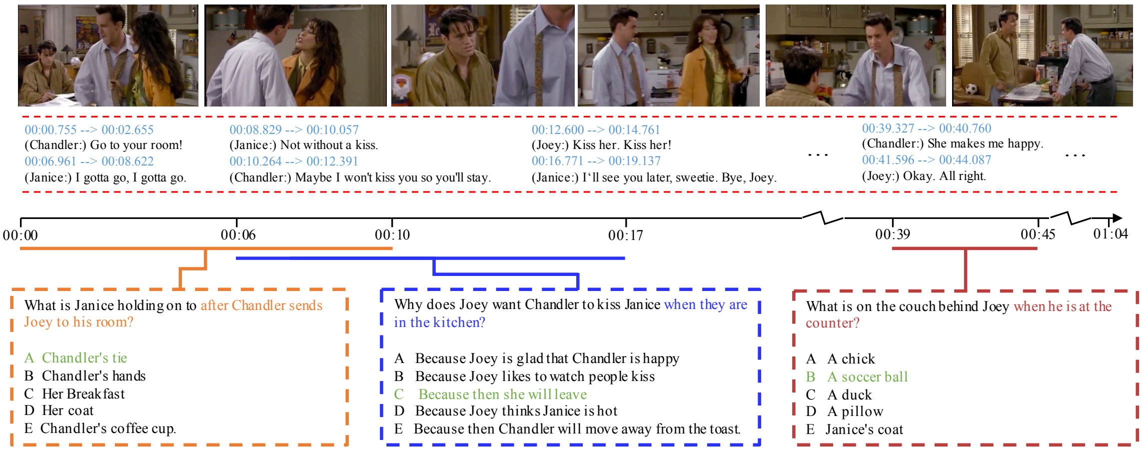
Now that algorithms have started to produce relevant and realistic natural language that can describe images and videos, we would like to understand what these models truly comprehend. The Visual Question Answering (VQA) task provides a nice tool for fine-grained evaluation of such multimodal algorithms. VQA systems take as input an image (or video) along with relevant natural language questions, and produce answers to those questions. By asking algorithms to answer different types of questions, ranging from object identification, counting, or appearance, to more complex questions about interactions, social relationships, or inferences about why or how something is occurring, we can evaluate different aspects of a model's multimodal semantic understanding.

As a result, several popular image-based VQA datasets have been introduced, including DAQUAR (Malinowski and Fritz, 2014), COCO-QA (Ren et al., 2015a), FM-IQA (Gao et al., 2015), Visual Madlibs (Yu et al., 2015), VQA (Antol et al., 2015), Visual7W (Zhu et al., 2016), etc. In addition, multiple video-based QA datasets have also been collected recently, e.g., MovieQA (Tapaswi et al., 2016), MovieFIB (Maharaj et al., 2017a), PororoQA (Kim et al., 2017), TGIF-QA (Jang et al., 2017), etc. However, there exist various shortcomings for each such video QA dataset. For example, MovieFIB's video clips are typically short (∼4 secs), and focused on purely visual concepts (since they were collected from audio descriptions for the visually impaired); MovieQA collected QAs based on text summaries only, making them very plot-focused and less relevant for visual information; PororoQA's video domain is cartoon-based; and TGIF-QA used predefined templates for generation on short GIFs.

With video-QA in particular, as opposed to image-QA, the video itself often comes with associated natural language in the form of (subtitle) dialogue. We argue that this is an important area to study because it reflects the real world, where people interact through language, and where many computational systems like robots or other intelligent agents will ultimately have to operate. As such, systems will need to combine information from what they see with what they hear, to pose and answer questions about what is happening.

We aim to provide a dataset that merges the best qualities from all of the previous datasets as well as focus on multimodal compositionality. In particular, we collect a new large-scale dataset that is built on natural video content with rich dynamics and realistic social interactions, where question-answer pairs are written by people observing both videos and their accompanying dialogues, encouraging the questions to require both vision and language understanding to answer. To further encourage this multimodal-QA quality, we ask people to write compositional questions consisting

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1369–1379
Brussels, Belgium, October 31 - November 4, 2018.



00:00.755 --> 00:02.655
(Chandler:) Go to your room!
00:06.961 --> 00:08.622
(Janice:) I gotta go, I gotta go.

00:08.829 --> 00:10.057
(Janice:) Not without a kiss.
00:10.264 --> 00:12.391
(Chandler:) Maybe I won't kiss you so you'll stay.

00:12.600 --> 00:14.761
(Joey:) Kiss her. Kiss her!
00:16.771 --> 00:19.137
(Janice:) I'll see you later, sweetie. Bye, Joey.

00:39.327 --> 00:40.760
(Chandler:) She makes me happy.
00:41.596 --> 00:44.087
(Joey:) Okay. All right.

What is Janice holding on to after Chandler sends Joey to his room?

A Chandler's tie
B Chandler's hands
C Her Breakfast
D Her coat
E Chandler's coffee cup.

Why does Joey want Chandler to kiss Janice when they are in the kitchen?

A Because Joey is glad that Chandler is happy
B Because Joey likes to watch people kiss
C Because then she will leave
D Because Joey thinks Janice is hot
E Because then Chandler will move away from the toast.

What is on the couch behind Joey when he is at the counter?

A A chick
B A soccer ball
C A duck
D A pillow
E Janice's coat

Figure 1: Examples from the TVQA dataset. All questions and answers are attached to 60-90 seconds long clips. For visualization purposes, we only show a few of the most relevant frames here. As illustrated above, some questions can be answered using subtitles or videos alone, while some require information from both modalities.

of two parts, a main question part, e.g. "What are Leonard and Sheldon arguing about" and a grounding part, e.g. "when they are sitting on the couch". This also leads to an interesting secondary task of QA temporal localization.

Our contribution is the TVQA dataset, built on 6 popular TV shows spanning 3 genres: medical dramas, sitcoms, and crime shows. On this data, we collected 152.5K human-written QA pairs (examples shown in Fig.1). There are 4 salient advantages of our dataset. First, it is large-scale and natural, containing 21,793 video clips from 925 episodes. On average, each show has 7.3 seasons, providing long range character interactions and evolving relationships. Each video clip is associated with 7 questions, with 5 answers (1 correct) for each question. Second, our video clips are relatively long (60-90 seconds), thereby containing more social interactions and activities, making video understanding more challenging. Third, we provide the dialogue (character name + subtitle) for each QA video clip. Understanding the relationship between the provided dialogue and the question-answer pairs is crucial for correctly answering many of the collected questions. Fourth, our questions are compositional, requiring algorithms to localize relevant moments (START and END points are provided for each question).

With the above rich annotation, our dataset supports three tasks: QA on the grounded clip, question-driven moment localization, and QA on the full video clip. We provide baseline experiments on both QA tasks and introduce a state-of-the-art language and vision-based model (leaving moment localization for future work).

2 Related Work

Visual Question Answering: Several image-based VQA datasets have recently been constructed, e.g., DAQUAR (Malinowski and Fritz, 2014), VQA (Antol et al., 2015), COCO-Q (Ren et al., 2015a), FM-IQA (Gao et al., 2015), Visual Madlibs (Yu et al., 2015), Visual7W (Zhu et al., 2016), CLEVR (Johnson et al., 2017), etc. Additionally, several video-based QA datasets have also been proposed, e.g. TGIF-QA (Jang et al., 2017), MovieFIB (Maharaj et al., 2017b), VideoQA (Zhu et al., 2017), LSMDC (Rohrbach et al., 2015), TRECVID (Over et al., 2014), MovieQA (Tapaswi et al., 2016), PororoQA (Kim et al., 2017) and MarioQA (Mun et al., 2017). However, none of these datasets provides a truly realistic, multimodal QA scenario where both visual and language understanding are required to answer a large portion of questions, either due to unrealistic video sources (PororoQA, MarioQA) or data collection strategy being more focused on either visual (MovieFIB, VideoQA, TGIF-QA) or language (MovieQA) sources. In comparison, our TVQA collection strategy takes a directly multimodal approach to construct a large-scale, real-video dataset by letting humans ask and answer questions while watching TV-show videos with associated dialogues.

Text Question Answering: The related task of text-based question answering has been extensively explored (Richardson et al., 2013; Weston et al., 2015; Rajpurkar et al., 2016; Hermann et al., 2015; Hill et al., 2015). Richardson et al. (2013) collected MCTest, a multiple choice QA dataset intended for open-domain reading comprehension.

With the same goal in mind, Rajpurkar et al. (2016) introduced the SQuAD dataset, but their answers are specific spans from long passages. Weston et al. (2015) designed a set of tasks with automatically generated QAs to evaluate the textual reasoning ability of artificial agents and Hermann et al. (2015); Hill et al. (2015) constructed the cloze dataset on top of an existing corpus. While questions in these text QA datasets are specifically designed for language understanding, TVQA questions require both vision understanding and language understanding. Although methods developed for text QA are not directly applicable to TVQA tasks, they can provide inspiration for designing suitable models.

Natural Language Object Retrieval: Language grounding addresses the task of object or moment localization in an image or video from a natural language description. For image-based object grounding, there has been much work on phrase grounding (Plummer et al., 2015; Wang et al., 2016b; Rohrbach et al., 2016) and referring expression comprehension (Hu et al., 2016; Yu et al., 2016; Nagaraja et al., 2016; Yu et al., 2017, 2018b). Recent work (Vasudevan et al., 2018) extends the grounding task to the video domain. Most recently, moment localization was proposed in (Hendricks et al., 2017; Gao et al., 2017), where the goal is to localize a short moment from a long video sequence given a query description. Accurate temporal grounding is a necessary step to answering our compositional questions.

3 TVQA Dataset

3.1 Dataset Collection

We collected our dataset on 6 long-running TV shows from 3 genres: 1) sitcoms: *The Big Bang Theory, How I Met Your Mother, Friends*, 2) medical dramas: *Grey's Anatomy, House*, 3) crime drama: *Castle*. There are in total 925 episodes spanning 461 hours. Each episode was then segmented into short clips. We first created clips every 60/90 seconds, then shifted temporal boudaries to avoid splitting subtitle sentences between clips. Shows that are mainly conversational based, e.g., *The Big Bang Theory*, were segmented into 60 seconds clips, while shows that are less cerebral, e.g. *Castle*, were segmented into 90 seconds clips. In the end, 21,793 clips were prepared for QA collection, accompanied with subtitles and aligned with transcripts to add character names. A sample clip is shown in Fig. 1.

Amazon Mechanical Turk was used for VQA collection on video clips, where workers were presented with both videos and aligned named subtitles, to encourage multimodal questions requiring both vision and language understanding to answer. Workers were asked to create questions using a compositional-question format: [What/How/Where/Why/...] ______ [when/before/after] ______. The second part of each question serves to localize the relevant video moment within a clip, while the first part poses a question about that moment. This compositional format also serves to encourage questions that require both visual and language understanding to answer, since people often naturally use visual signals to ground questions in time, e.g. *What was House saying before he leaned over the bed?* During data collection, we only used prompt words (when/before/after) to encourage workers to propose the desired, complex compositional questions. There were no additional template constraints. Therefore, most of the language in the questions is relatively free-form and complex.

Ultimately, workers pose 7 different questions for each video clip. For each question, we asked workers to annotate the exact video portion required to answer the question by marking the START and END timestamps as in Krishna et al. (2017). In addition, they provide 1 correct and 4 wrong answers for each question. Workers get paid $1.3 for a single video clip annotation. The whole collection process took around 3 months.

To ensure the quality of the questions and answers, we set up an online checker in our collection interface to verify the question format, allowing only questions that reflect our two-step format to be submitted. The collection was done in batches of 500 videos. For each harvested batch, we sampled 3 pairs of submitted QAs from each worker and checked the semantic correctness of the questions, answers, and timestamps.

3.2 Dataset Analysis

Multiple Choice QAs: Our QAs are multiple choice questions with 5 candidate answers for each question, for which only one is correct. Table 1 provides statistics of the QAs based on the first question word. On average, our questions contain 13.5 words, which is fairly long compared to other datasets. In general, correct answers tend

QType	#QA	Q. Len.	CA. Len.	WA. Len.
what	84768	13.3	4.9	4.3
who	17654	13.4	3.1	3.0
where	17777	12.5	5.2	4.8
why	15798	14.5	9.0	7.7
how	13644	14.4	5.7	5.1
others	2904	15.2	4.9	4.7
total	152545	13.5	5.2	4.6

Table 1: Statistics for different question types based on first question word. Q = question, CA = correct answer, WA = wrong answer. Length is defined as the number of words in the sentence.

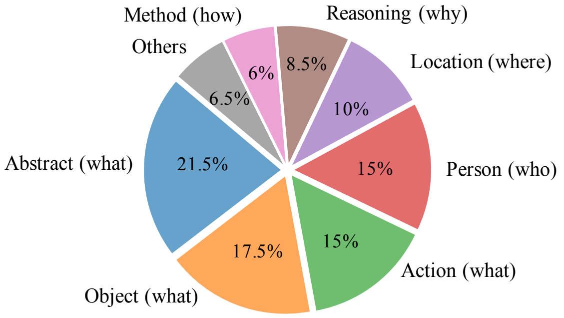


Figure 2: Distribution of question types based on answer types.

to be slightly longer than wrong answers. Fig. 2 shows the distribution of different questions types. Note "what" (Abstract, Object, Action), "who" (Person), "why" (Reasoning) and "where" (Location) questions form a large part of our data.

The negative answers in TVQA are written by human annotators. They are instructed to write false but relevant answers to make the negatives challenging. Alternative methods include sampling negative answers from other questions' correct answers, either based on semantic similarity (Das et al., 2017; Jang et al., 2017) or randomly (Antol et al., 2015; Das et al., 2017). The former is prone to introducing paraphrases of the ground-truth answer (Zhu et al., 2016). The latter avoids the problem of paraphrasing, but generally produces irrelevant negative choices. We show in Table 8 that our human written negatives are more challenging than randomly sampled negatives.

Moment Localization: The second part of our question is used to localize the most relevant video portion to answer the question. The prompt of "when", "after", "before" account for 60.03%, 30.19% and 9.78% respectively of our dataset. TVQA provides the annotated START and END timestamps for each QA. We show the annotated segment lengths in Fig. 3. We found most of the questions rely on relatively short moments (less than 15 secs) within a longer clip (60-90 secs).

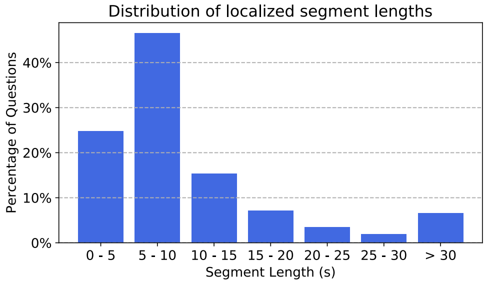

Figure 3: Distribution of localized segment lengths. The majority of our questions have timestamp localized segment with length less than 15 seconds.

Show	Genre	#Sea.	#Epi.	#Clip	#QA
BBT	sitcom	10	220	4,198	29,384
Friends	sitcom	10	226	5,337	37.357
HIMYM	sitcom	5	72	1,512	10,584
Grey	medical	3	58	1,427	9,989
House	medical	8	176	4,621	32,345
Castle	crime	8	173	4,698	32,886
Total	—	44	925	21,793	152,545

Table 2: Data Statistics for each TV show. BBT = *The Big Bang Theory*, HIMYM = *How I Met You Mother*, Grey = *Grey's Anatomy*, House = *House M.D.*, Epi = Episode, Sea. = Season

Show	Top unique nouns
BBT	game, mom, laptop, water, store, dinner, book, stair, computer, food, wine, glass, couch, date
Friends	shop, kiss, hair, sofa, jacket, counter, coffee, everyone, coat, chair, kitchen, baby, apartment
HIMYM	bar, beer, drink, job, dad, sex, restaurant, wedding, party, booth, dog, story, bottle, club, painting
Grey	nurse, side, father, hallway, scrub, chart, wife, window, life, family, chief, locker, head, surgery
House	cane, team, blood, test, brain, pill, office, pain, symptom, diagnosis, hospital, coffee, cancer, drug
Castle	gun, victim, picture, case, photo, body, murder, suspect, scene, crime, money, interrogation

Table 3: Top unique nouns in questions and correct answers.

Differences among our 6 TV Shows: The videos used in our dataset are from 6 different TV shows. Table 2 provides statistics for each show. A good way to demonstrate the difference among questions from TV shows is to show their top unique nouns. In Table 3, we present such an analysis. The top unique nouns in sitcoms (*BBT*, *Friends*, *HIMYM*) are mostly daily objects, scenes and actions, while medical dramas (*Grey, House*) questions contain more medical terms, and crime shows (*Castle*) feature detective terms. Although similar, there are also notable differences among shows in the same genre. For example, *BBT* con-

Dataset	V. Src.	QType	#Clips / #QAs	Avg. Len.(s)	Total Len.(h)	Q. Src.		Timestamp annotation
						text	video	
MovieFIB (Maharaj et al., 2017a)	Movie	OE	118.5k / 349k	4.1	135	✓	-	-
Movie-QA (Tapaswi et al., 2016)	Movie	MC	6.8k / 6.5k	202.7	381	✓	-	✓
TGIF-QA (Jang et al., 2017)	Tumblr	OE&MC	71.7k / 165.2k	3.1	61.8	✓	✓	-
Pororo-QA (Kim et al., 2017)	Cartoon	MC	16.1k / 8.9k	1.4	6.3	✓	✓	-
TVQA (our)	TV show	MC	21.8k / 152.5k	76.2	461.2	✓	✓	✓

Table 5: Comparison of TVQA to various existing video QA datasets. OE = open-ended, MC = multiple-choices. Q. Src. = Question Sources, it indicates where the questions are raised from. TVQA dataset is unique since its questions are based on both text and video, with additional timestamp annotation for each of them. It is also significantly larger than previous datasets in terms of total length of videos.

Character	Top unique nouns
Sheldon	Arthur, train, Kripke, flag, flash, Wil, logo, Barry, superhero, Spock, trek, sword
Leonard	Leslie, helium, robe, Dr, team, Kurt university, key, chess, Stephen
Howard	NASA, trick, van, language, summer, letter, Mike, station, peanut, Missy
Raj	Lucy, Claire, parent, music, nothing, Isabella, bowl, sign, back, India, number
Penny	basket, order, mail, mouth, cheesecake, factory shower, pizza, cream, Alicia, waitress, ice
Amy	Dave, meemaw, tablet, birthday, monkey, coat, brain, ticket, laboratory, theory, lip, candle
Bernadette	song, sweater, wedding, child, husband, everyone, necklace, stripper, weekend, airport

Table 4: Top unique nouns for characters in BBT.

VQA source	Human accuracy on test.
Question	31.84
Video and Question	61.73
Subtitle and Question	72.88
Video, Subtitle, and Question	89.41

Table 5: Human accuracy on test set based on different sources. As expected, humans get the best performance when given both videos and subtitles.

tains "game" and "laptop" while *HIMYM* contains "bar" and "beer", indicating the different major activities and topics in each show. Additionally, questions about different characters also mention different words, as shown in Table 4.

Comparison with Other Datasets: Table 5 presents a comparison of our dataset to some recently proposed video question answering datasets. In terms of total length of videos, TVQA is the largest, with a total of 461.2 hours of videos. MovieQA (Tapaswi et al., 2016) is most similar to our dataset, with both multiple choice questions and timestamp annotation. However, their questions and answers are constructed by people posing questions from a provided plot summary, then later aligned to the video clips, which makes most of their questions text oriented.

Human Evaluation on Usefulness of Video and Subtitle in Dataset: To gain a better understanding of the roles of videos and subtitles in the our dataset, we perform a human study, asking different groups of workers to complete the QA task in settings while observing different sources (subsets) of information:

- Question only.
- Video and Question.
- Subtitle and Question.
- Video, Subtitle, and Question.

We made sure the workers that have written the questions did not participate in this study and that workers see only one of the above settings for answering each question. Human accuracy on our test set under these 4 settings are reported in Table 5. As expected, compared to human accuracy based only on question-answer pairs (Q), adding videos (V+Q), or subtitles (S+Q) significantly improves human performance. Adding both videos and subtitles (V+S+Q) brings the accuracy to 89.41%. This indicates that in order to answer the questions correctly, both visual and textual understanding are essential. We also observe that workers obtain 31.84% accuracy given question-answer pairs only, which is higher than random guessing (20%). We ascribe this to people's prior knowledge about the shows. Note, timestamp annotations are not provided in these experiments.

4 Methods

We introduce a multi-stream end-to-end trainable neural network for Multi-Modal Video Question Answering. Fig. 4 gives an overview of our model. Formally, we define the inputs to the model as: a 60-90 second video clip V, a subtitle S, a question q, and five candidate answers $\{a_i\}_{i=0}^{4}$.

4.1 Video Features

Frames are extracted at 3 fps. We run Faster R-CNN (Ren et al., 2015b) trained on the Visual

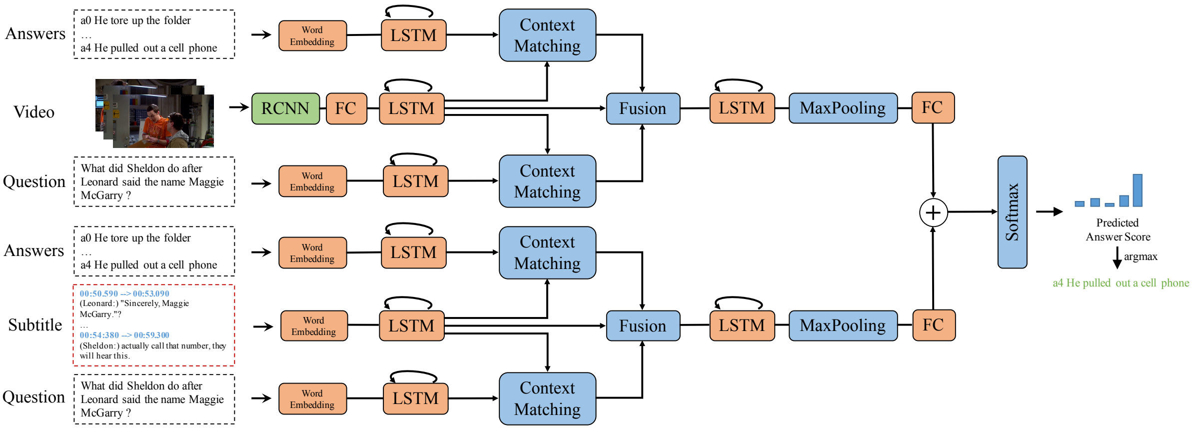

Figure 4: Illustration of our multi-stream model for Multi-Modal Video QA. Our full model takes different contextual sources (regional visual features, visual concept features, and subtitles) along with question-answer pair as inputs to each stream. For brevity, we only show regional visual features (upper) and subtitle (bottom) streams.

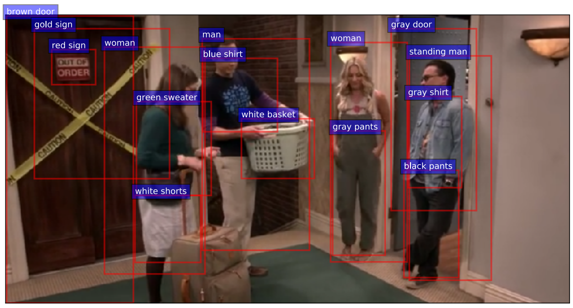

brown door, gold sign, red sign, woman, white shorts,
green sweater, man, blue shirt, white basket, woman,
gray pants, gray door, standing man, gray shirt, black pants

Figure 5: Faster R-CNN detection example. The detected object labels and attributes can be viewed as a description to the frame, which is potentially helpful to answer a visual question.

Genome (Krishna et al., 2017) to detect object and attribute regions in each frame. Both regional features and predicted detection labels can be used as model inputs. We also use ResNet101 (He et al., 2016) trained on ImageNet (Deng et al., 2009) to extract whole image features.

Regional Visual Features: On average, our videos contain 229 frames, with 16 detections per frame. It is not trivial to model such long sequences. For simplicity, we follow (Anderson et al., 2018; Karpathy and Fei-Fei, 2015) selecting the top-K regions[1] from each detected label across all frames. Their regional features are L2-normalized and stacked together to form our visual representation $V^{reg} \in \mathbb{R}^{n_{reg} \times 2048}$. Here n_{reg} is the number of selected regions.

Visual Concept Features: Recent work (Yin and Ordonez, 2017) found that using detected object labels as input to an image captioning system gave comparable performance to using CNN features directly. Inspired by this work, we also experiment with using detected labels as visual inputs. As shown in Fig. 5, we are able to detect rich visual concepts, including both objects and attributes, e.g. "white basket", which could be used to answer "What is Sheldon holding in his hand when everyone is at the door". We first gather detected concepts over all the frames to represent concept presence. After removing duplicate concepts, we use GloVe (Pennington et al., 2014) to embed the words. The resulting video representation is denoted as $V^{cpt} \in \mathbb{R}^{n_{cpt} \times 300}$, where n_{cpt} is the number of unique concepts.

ImageNet Features: We extract the pooled 2048D feature of the last block of ResNet101. Features from the same video clip are L2 normalized and stacked, denoted as $V^{img} \in \mathbb{R}^{n_{img} \times 2048}$, where n_{img} is the number of frames extracted from the video clip.

4.2 LSTM Encoders for Video and Text

We use a bi-directional LSTM (BiLSTM) to encode both textual and visual sequences. A subtitle S, which contains a set of sentences, is flattened into a long sequence of words and GloVe (Pennington et al., 2014) is used to embed the words. We stack the hidden states of the BiLSTM from both directions at each timestep to obtain the subtitle representation $H^S \in \mathbb{R}^{n_S \times 2d}$, where n_S is the number of subtitle words, d is the hidden size of the BiLSTM (set to 150 in our experiments). Similarly, we encode question $H^q \in \mathbb{R}^{n_q \times 2d}$, candidate answers $H^{a_i} \in \mathbb{R}^{n_{a_i} \times 2d}$, and visual con-

---

[1] Based on cross-validation, we find K=6 to perform best.

cepts $H^{cpt} \in \mathbb{R}^{n_{cpt} \times 2d}$. n_q and n_{a_i} are the number of words in question and answer a_i, respectively. Regional features V^{reg} and ImageNet features V^{img} are first projected into word vector space using a non-linear layer with tanh activation, then encoded using the same BiLSTM to obtain the regional representations $H^{reg} \in \mathbb{R}^{n_{reg} \times 2d}$ and $H^{img} \in \mathbb{R}^{n_{img} \times 2d}$, respectively.

4.3 Joint Modeling of Context and Query

We use a context matching module and BiLSTM to jointly model the contextual inputs (subtitle, video) and query (question-answer pair). The context matching module is adopted from the context-query attention layer from previous works (Seo et al., 2017; Yu et al., 2018a). It takes context vectors and query vectors as inputs and produces a set of context-aware query vectors based on the similarity between each context-query pair.

Taking the regional visual feature stream as an example (Fig. 4 upper stream), where H^{reg} is used as context input[2]. The question embedding, H^q, and answer embedding, H^{a_i}, are used as queries. After feeding context-query pairs into the context matching module, we obtain a video-aware-question representation, $G^{reg,q} \in \mathbb{R}^{n_{reg} \times 2d}$, and video-aware-answer representation, $G^{reg,a_i} \in \mathbb{R}^{n_{reg} \times 2d}$, which are then fused with video context:

$$\begin{aligned} M^{reg,a_i} = [&H^{reg}; G^{reg,q}; G^{reg,a_i}; \\ &H^{reg} \odot G^{reg,q}; H^{reg} \odot G^{reg,a_i}], \end{aligned}$$

where $\odot$ is element-wise product. The fused feature, $M^{reg,a_i} \in \mathbb{R}^{n_{reg} \times 10d}$, is fed into another BiLSTM. Its hidden states, $U^{reg,a_i} \in \mathbb{R}^{n_{reg} \times 10d}$, are max-pooled temporally to get the final vector, $u^{reg,a_i} \in \mathbb{R}^{10d}$, for answer a_i. We use a linear layer with softmax to convert $\{u^{reg,a_i}\}_{i=0}^{4}$ into answer probabilities. Similarly, we can compute the answer probabilities given subtitle as context (Fig. 4 bottom stream). When multiple streams are used, we simply sum up the scores from each stream as the final score (Wang et al., 2016a).

5 Experiments

For evaluation, we introduce several baselines and compare them to our proposed model.

In all experiments, setup is as follows. We split the TVQA dataset into 80% training, 10% validation, and 10% testing splits such that videos and their corresponding QA pairs appear in only one split. This results in 122,039 QA pairs for training, 15,253 QA pairs for validation, and 15,253 QA pairs for testing. We evaluate each model using multiple-choice question answering accuracy.

5.1 Baselines

Longest Answer: Table 1 indicates that the average length of the correct answers is longer than the wrong ones; thus, our first baseline simply selects the longest answer for each question.

Nearest Neighbor Search: In this baseline, we use Nearest Neighbor Search (NNS) to compute the closest answer to our question or subtitle. We embed sentences into vectors using TFIDF, SkipThought (Kiros et al., 2015), or averaged GloVe (Pennington et al., 2014) word vectors, then compute the cosine similarity for each question-answer pair or subtitle-answer pair. For TFIDF, we use bag-of-words to represent the sentences, assigning a TFIDF value for each word.

Retrieval: Due to the size of TVQA, there may exist similar questions and answers in the dataset. Thus, we also implement a baseline two-step retrieval approach: given a question and a set of candidate answers, we first retrieve the most relevant question in the training set, then pick the candidate answer that is closest to the retrieved question's correct answer. Similar approaches have also been used in dialogue systems (Jafarpour and Burges, 2010; Leuski and Traum, 2011), picking the appropriate responses to an utterance from a predefined human conversational corpus. Similar to NNS, we use TFIDF, SkipThought, and GloVe vectors with cosine similarity.

5.2 Results

Table 6 shows results from baseline methods and our proposed neural model. Our main results are obtained by using full-length video clips and subtitles, without using timestamps (*w/o ts*). We also run the same experiments using the localized video and subtitle segment specified by the ground truth timestamps (*w/ ts*). If not indicated explicitly, the numbers described below are from the experiments on full-length video clips and subtitles.

Baseline Comparison: Row 1 shows results of the longest answer baseline, achieving 30.41%

---

[2] For visual concept features and ImageNet features, we simply replace H^{reg} with H^{cpt} or H^{img} as the context.

	Method	Video Feature	Test Accuracy	
			w/o ts	w/ ts
0	Random	-	20.00	20.00
1	Longest Answer	-	30.41	30.41
2	Retrieval-Glove	-	22.48	22.48
3	Retrieval-SkipThought	-	24.24	24.24
4	Retrieval-TFIDF	-	20.88	20.88
5	NNS-Glove Q	-	22.40	22.40

17	Our S+V+Q	reg	63.19	67.82
18	Our S+V+Q	cpt	**65.46**	**68.60**

Table 6: Accuracy for different methods on TVQA test set. Q = Question, S = Subtitle, V = Video, img = ImageNet features, reg = regional visual features, cpt = visual concept features, ts = timestamp annotation. Human performance without timestamp annotation is reported in Table 5.

	Q	S+Q	V+Q			S+V+Q		
			img	reg	cpt	img	reg	cpt
what (55.62%)	44.11	62.29	44.96	45.93	47.44	63.88	65.28	66.05
who (11.55%)	36.55	68.33	35.75	34.85	34.68	67.76	67.20	67.99
where (11.67%)	42.58	56.97	47.13	48.43	48.20	61.97	63.71	61.46
how (8.98%)	41.17	71.97	41.17	42.41	40.95	71.17	70.80	71.53
why (10.38%)	45.23	78.65	46.05	45.36	45.48	78.33	77.13	78.77
other (1.80%)	36.50	74.45	37.23	36.50	33.58	73.72	72.63	74.09
all (100%)	42.77	65.15	43.78	44.40	45.03	66.44	67.17	67.70

Table 7: Accuracy of each question type using different models (w/ ts) on TVQA Validation set. Q = Question, S = Subtitle, V = Video, img = ImageNet features, reg = regional visual features, cpt = visual concept features. The percentage of each question type is shown in brackets.

(compared to random chance at 20%). As expected, the retrieval-based methods (row 2-4) and the answer-question similarity based methods (row 5-7) perform rather poorly, since no contexts (video or subtitle) are considered. When using subtitle-answer similarity to choose correct answers, Glove, SkipThought, and TFIDF based approaches (row 8-10) all achieve significant improvement over question-answer similarity. Notably, TFIDF (row 10) answers 49.94% of the questions correctly. Since our questions are raised by people watching the videos, it is natural for them to ask questions about specific and unique objects/locations/etc., mentioned in the subtitle. Thus, it is not surprising that TFIDF based similarity between answer and subtitle performs so well.

Variants of Our Model: Rows 11-18 show results of our model with different contextual inputs and features. The model that only uses question-answer pairs (row 11) achieves 43.34% accuracy. Compared to the subtitle model (row 15), adding video as additional sources (row 16-18) improves performance. Interestingly, adding video to the question only model (row 11) do not work as well (row 12-14). Our hypothesis is that the video feature streams may be struggling to learn models for answering textual questions, which degrades their ability to answer visual questions. Overall, the best performance is achieved by using all the contextual sources, including subtitles and videos (using concept features, row 18).

Comparison with Human Performance: Human performance without timestamp annotation is shown in Table 5. When using only questions (Table 6 row 11), our model outperforms humans (43.34% *vs* 31.84%) as it has access to all statistics of the questions and answers. When using videos or subtitles or both, humans perform significantly better than the models.

Models with Timestamp Annotation: Columns under *w/o ts* and *w/ ts* show a comparison between the same model using full-length videos/subtitles and using timestamp localized videos/subtitles. With timestamp annotation, the models perform consistently better than their counterpart without this information, indicating that localization is helpful for question answering.

Accuracy for Different Question Types: To gain further insight, we examined the accuracy of our models on different question types on the validation set (results in Table 7), all models using timestamp annotation. Compared to S+Q model, S+V+Q models get the most improvements on "what" and "where" questions, indicating these questions require additional visual information. On the other hand, adding video features did not improve S+Q performance on questions relying more on textual reasoning, e.g., "how" questions.

Human-Written Negatives vs. Randomly-Sampled Negatives For comparison, we create a new answer set by replacing the original human written negative answers with randomly sampled negative answers. To produce relevant negative answers, for each question, negatives are sampled (from the other QA pairs) within the same show.

00:00.688 --> 00:03.989
(Raj:)seemed like a chance to show off.
00:06.360 --> 00:08.243
There he is!
00:08.245 --> 00:10.412
(Raj:)There's my happy Hebraic homeboy.

What Raj and Howard are drinking when sat at the table ?

a0 Milk
a1 Beer √
a2 Juice
a3 Vodka
a4 Carrot juice .

(a)

01:04.288 --> 01:07.382
(Professor Jason Byford:)People often call with research questions, so I try to be helpful.
01:07.458 --> 01:09.178
(Professor Jason Byford:)She wanted to know what these symbols meant.

Why does the professor say he met with Susannah when Castle and Beckett are in his office ?
a0 She wanted to work on some research
a1 She wanted to take his class
a2 She discovered a new symbol
a3 She wanted to know the meaning of symbols √
a4 She needed him to translate some languages

Figure 6: Example predictions from our best model. Top row shows correct predictions, bottom row shows failure cases. Ground truth answers are in green, and the model predictions are indicated by ✓. Best viewed in color.

Method	N.A. Src.	Video Feature	Val Accuracy	
			w/o ts	w/ ts
V+Q	Rand	cpt	84.64	85.01
S+Q	Rand	-	90.94	90.72
S+V+Q	Rand	cpt	91.55	92.00
V+Q	Human	cpt	43.03	45.03
S+Q	Human	-	62.99	65.15
S+V+Q	Human	cpt	64.70	67.70

Table 8: Accuracy on TVQA validation set with negative answers collected using different strategies. Negative Answer Source (N.A. Src.) indicates the collection method of the negative answers. Q = Question, S = Subtitle, V = Video, cpt = visual concept features, ts = timestamp annotation. All the experiments are conducted using the proposed multi-stream neural model.

Results are shown in Table 8. Performance on randomly sampled negatives is much higher than that of human written negatives, indicating that human written negatives are more challenging.

Qualitative Analysis: Fig. 6 shows example predictions from our S+V+Q model (row 18) using full-length video and subtitle. Fig. 6a and Fig. 6b demonstrate its ability to solve both grounded visual questions and textual reasoning question. Bottom row shows two incorrect predictions. We found that wrong inferences are mainly due to incorrect language inferences and the model's lack of common sense knowledge. For example, Fig. 6c, the characters are talking about radiology, the model is distracted to believe they are in the radiology department, while Fig. 6d shows a case of questions that need common sense to answer, rather than simply textual or visual cues.

6 Conclusion

We presented the TVQA dataset, a large-scale, localized, compositional video question answering dataset. We also proposed two QA tasks (with/without timestamps) and provided baseline experiments as a benchmark for future comparison. Our experiments show both visual and textual understanding are necessary for TVQA.

There is still a significant gap between the proposed baselines and human performance on the QA accuracy. We hope this novel multimodal dataset and the baselines will encourage the community to develop stronger models in future work. To narrow the gap, one possible direction is to enhance the interactions between videos and subtitles to improve multimodal reasoning ability. Another direction is to exploit human-object relations in the video and subtitle, as we observe that a large number of questions involve such relations. Additionally, temporal reasoning is crucial for answering the TVQA questions. Thus, future work also includes integrating better temporal cues.

Abstract

Localizing moments in a longer video via natural language queries is a new, challenging task at the intersection of language and video understanding. Though moment localization with natural language is similar to other language and vision tasks like natural language object retrieval in images, moment localization offers an interesting opportunity to model temporal dependencies and reasoning in text. We propose a new model that explicitly reasons about different temporal segments in a video, and shows that temporal context is important for localizing phrases which include temporal language. To benchmark whether our model, and other recent video localization models, can effectively reason about temporal language, we collect the novel TEMPOral reasoning in video and language (TEMPO) dataset. Our dataset consists of two parts: a dataset with real videos and template sentences (TEMPO - Template Language) which allows for controlled studies on temporal language, and a human language dataset which consists of temporal sentences annotated by humans (TEMPO - Human Language).

1 Introduction

Consider the video and natural language query in Figure 1 where we seek to localize the desired moment in the video specified by the query. Queries like "the girl bends down" require understanding objects and actions, but do not require reasoning about different video moments. In contrast, queries like "the little girl talks after bending down" require reasoning about the *temporal relationship* between different actions ("talk" and "bend down"). Localizing natural language queries in video is an important challenge, recently studied in Hendricks et al. (2017) and Gao et al. (2017) with applications in areas such as video search and retrieval. We argue that to properly localize queries with temporal language, models must understand and reason about intra-video context.

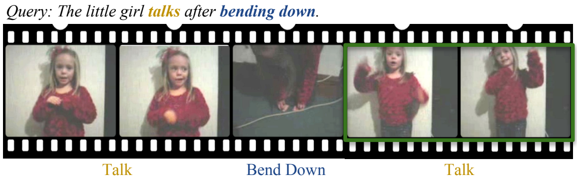

Figure 1: We consider localizing video moments which include *temporal language*. To properly localize "The little girl talks after bending down" localization models must understand how the action "talks" relates to the action "bend down."

Reasoning about intra-video context is difficult as we do not know a priori which moments should be involved in the contextual reasoning and different queries may require reasoning about different contextual moments. For example, in "the little girl talks after bending down", the relevant contextual moment "bending down" occurs just before the target moment "the little girl talks". This is in contrast to the query "the little girl talks *before* bending down" where the relevant contextual moment occurs just after. A limitation of current moment-localization models (Hendricks et al., 2017; Gao et al., 2017) is they consider query-independent video context when localizing moments. For example, when determining whether a proposed temporal region matches a natural language query, Gao et al. (2017) considers the proposed temporal region, as well as video regions just before and after the proposed region. Similarly, Hendricks et al. (2017) considers video context in the form of a global-context feature which represents the entire video. While both may implicitly include the appropriate contextual moment in their context feature, they do not explicitly determine the relevant context for the query.

To address this difficulty, we propose Moment

Localization with Latent Context (MLLC) which models video context as a *latent variable*. The latent variable enables the model to attend to different video contexts conditioned on the specific query/video pair, offering flexibility in the location and length of the contextual moment and overcoming the limitation of query-independent contextual reasoning. We validate the importance of latent context by showing that our model performs well both on simple queries without temporal words and more complex queries requiring temporal reasoning. Moreover, our formulation is generic and unifies approaches in Hendricks et al. (2017) and Gao et al. (2017), allowing us to ablate model component choices, as well as which kind of video context is best for localizing moments described with temporal language.

Though datasets used for moment localization in video (Hendricks et al., 2017; Regneri et al., 2013; Sigurdsson et al., 2016) include temporal language, as we will show, there is not enough temporal language to effectively train and evaluate models. We seek to extensively study this aspect, particularly with respect to temporal prepositions (Pratt-Hartmann, 2004). Thus, we collect the TEMPOral reasoning in video and language (TEMPO) dataset which builds off the recently collected DiDeMo dataset (Hendricks et al., 2017). The dataset consists of two parts: a dataset with real videos and sentences created with a template model (TEMPO - Template Language (TL)), and a dataset with real videos and newly collected user-provided temporal annotations (TEMPO - Human Language (HL)). Considering template sentences allows us to create a large dataset of sentences quickly for study of temporal language in a controlled setting. The human language data then allows us to see these trends transfer to more complex human-language queries. For data collection, we focus on the most common temporal referring words naturally occurring in language-and-video datasets.

Our contributions are twofold. (i) We are the first to study models for temporal language in video moment retrieval with natural language queries. To this end, we introduce TEMPO which includes examples of how humans use temporal language to refer to video moments. (ii) We propose MLLC for moment localization which treats video context as a latent variable and unifies prior approaches for moment localization. Our model outperforms prior work on TEMPO-TL and TEMPO-HL as well as the original DiDeMo dataset.

2 Related Work

Localizing Video Segments with Natural Language. Prior work has considered aligning natural language with video, e.g., instructional videos with transcribed text (Kiddon et al., 2015; Huang et al., 2017; Malmaud et al., 2014, 2015). Our work is most related to recent work in video moment retrieval with natural language (Gao et al., 2017; Hendricks et al., 2017). Both works take a natural language query and candidate video segment as input, and output a score for how well the natural language phrase aligns with the video segment. Gao et al. (2017) includes an additional loss to regress to start and end-points, whereas Hendricks et al. (2017) simplifies the problem by choosing from a discrete set of video segments. Importantly, to represent a proposed video segment, both models consider context features around a moment: Hendricks et al. (2017) uses global context by averaging features over an entire input video, and Gao et al. (2017) incorporates features adjacent to the proposed video segment. We argue that to do proper temporal reasoning, pre-determined, query independent context features may not cover all possible temporal relations. Thus, we propose to model the context as a *latent variable*, allowing our method to learn which context moments to consider as a function of the video and importantly, the query.

Both Gao et al. (2017) and Hendricks et al. (2017) collect data to test their models; Gao et al. (2017) considers the Charades (Sigurdsson et al., 2016) and TACoS (Regneri et al., 2013) datasets. While TACoS includes localized sentences, Charades only has sentences and activity detection localizations, so a semi-automatic method is used to align action detection annotations to visual descriptions in Charades. Hendricks et al. (2017) collected the Distinct Describable Moment (DiDeMo) dataset, which consists of Flickr (Thomee et al., 2016) videos with localized referring expressions. Both Charades and DiDeMo contain a large set of diverse videos (approximately 10,000 videos each). We chose to base TEMPO on DiDeMo because it contains more clip/sentence pairs (40,000 vs. 13,000), and is focused on general videos which we believe is an interesting and useful scenario, rather than being restricted to indoor activities.

Temporal Language. Prior work on temporal language processing has considered building explicit logical frameworks to process temporal prepositions like "during" or "until" (Pratt-Hartmann (2004), Konur (2008)). We do not derive a particular temporal logic, but rather learn to understand temporal language in a data driven fashion. Furthermore, we specifically consider how to understand temporal words commonly used when referring to video content. Other work has modeled dynamics for words which represent a change of state (e.g., "pick up") (Siskind (2001), Yu et al. (2015)) in limited environments. Though we limit the selection of temporal words in our study, the natural language in our data is open-world describing diverse events and how they relate to each other in video. Interpretation of temporal expressions in text ("The game happened on the 19^{th}") is a widely studied task (Angeli et al. (2012), Zhong et al. (2017)). Our work is distinctly different from this line of work as we specifically study temporal prepositions and how they refer to video.

Modeling Visual Relationships. A variety of papers have considered modeling spatial relationships in natural images (Dai et al., 2017; Hu et al., 2017; Peyre et al., 2017; Plummer et al., 2017). Our approach is analogous to this in the temporal domain; we hope to localize moments in videos. CLEVR, a synthetic visual question answering (VQA) dataset (Johnson et al., 2016), was created to allow researchers to systematically study the ability of models to perform complex reasoning. Our dataset is partially motivated by the success of CLEVR to enable researchers to study reasoning abilities of different models in a controlled setting. In contrast to CLEVR we consider a more diverse visual input in the form of real videos.

In the video domain, the TGIF-QA (Jang et al., 2017) and Mario-QA (Mun et al., 2016) datasets provide opportunities to study temporal reasoning for the task of VQA. The TGIF-QA dataset considers three types of temporal questions: before/after questions, repetition count, and determining a repeating action. Each question is accompanied by multiple choice answers. Videos we consider are much longer (25-30s as opposed to an average of 3.1s) which makes the use of temporal reasoning much more important. The MarioQA dataset is an additional VQA dataset designed to gauge temporal reasoning of VQA systems. Both TGIF-QA and MarioQA datasets include template-based natural language queries. In this paper, we consider synthetic queries similar to TGIF-QA and MarioQA, but also include human language queries. In addition, unlike the MarioQA dataset, that consists of synthetic data constructed from gameplay videos, our dataset consists of real visual inputs, and includes temporal grounding of natural language phrases. Finally, neither TGIF-QA nor MarioQA include temporal localization.

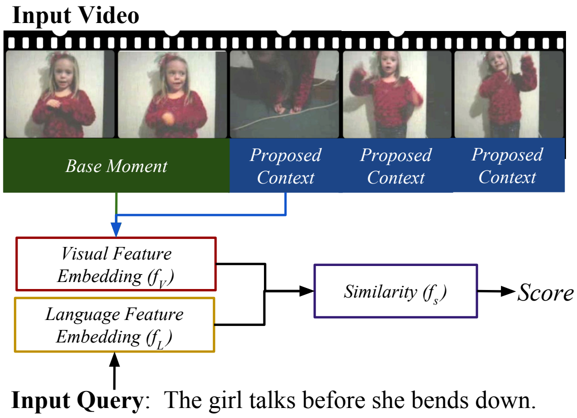

Figure 2: Our model, Moment Localization with Latent Context (MLLC), takes a video and a text query as input and outputs the moment in the video corresponding to the query. MLLC considers many different *context* moments (blue) for a specific *base* moment (green).

3 Moment Localization with Latent Context

Given a video v and natural-language query q describing a moment in the video, our goal is to output the moment $\tau = \left(\tau^{(s)}, \tau^{(e)}\right)$ where $\tau^{(s)}$ and $\tau^{(e)}$ are temporal start and end points in the video, respectively. In the following, we formulate a generic, unified model which encompasses prior approaches (Hendricks et al., 2017; Gao et al., 2017). This allows us to explore and evaluate trade offs for different model components and extensions which then leads to higher performance. Unlike prior work, we consider a latent context variable which enables our model to better reason about temporal language.

Let the moment τ corresponding to the text query be the *base* moment and the set of other video moments T_τ be possible *context* moments for τ. We define a scoring function between the video moment and natural-language query by maximizing over all possible context moments

$\tau' \in \mathrm{T}_\tau$,

$$s_\phi(v, q, \tau) = \max_{\tau' \in \mathrm{T}_\tau} f_\mathcal{S}\left(f_\mathcal{V}\left(v, \tau, \tau'\right), f_\mathcal{L}(q)\right), \tag{1}$$

where $f_\mathcal{V}$ and $f_\mathcal{L}$ are functions computing features over the video and language query, $f_\mathcal{S}$ is a similarity function, and ϕ are model parameters. This formulation is generic and trivially encompasses the MCN and TALL formulations by letting the set of possible context moments T_τ be their respective single-context moment. Figure 2 shows the generic structure of our model.

With this formulation, we seek to answer the following questions: (i) Which combination of model components performs best for the moment-retrieval task? Though our primary goal is localizing moments with temporal language, we believe a good base moment retrieval model is important for localizing moments with temporal language. (ii) How best to incorporate context for moment retrieval with temporal language? We first detail the different terms and outline different model design choices, where design choices marked with ***bold-italic font*** is ablated in Section 5. Components which are used in our final proposed Moment Localization with Latent Context (MLLC) model and prior models are summarized in Table 3.

Video feature $f_\mathcal{V}$. The video feature $f_\mathcal{V} = (g(v, \tau), g(v, \tau'), f_\mathcal{T}(\tau, \tau'))$ is a concatenation of visual features for the base $g(v, \tau)$ and context $g(v, \tau')$ moments and endpoint features $f_\mathcal{T}(\tau, \tau')$. To compute visual features g for a temporal region τ, per-frame features are averaged over the temporal region. Note that if the context moment consists of more than one contiguous temporal region, then the visual features are computed over each contiguous temporal region and then concatenated (c.f., before/after context in TALL, explained below). There are many choices for visual features. TALL (Gao et al., 2017) compares average fc_7 features (extracted from (Simonyan and Zisserman, 2014)) to features extracted with C3D (Tran et al., 2015) and LSTM features (Donahue et al., 2015). Surprisingly, C3D features only outperform average fc_7 features by a small margin. We use the visual features used in the MCN model (Hendricks et al., 2017), which are similar to the fc_7 features from (Gao et al., 2017), but included motion features as well, computed from optical flow (extracted with (Wang et al., 2016)). We then pass the extracted visual features through a MLP. Note that we learn separate embedding functions for RGB and optical flow inputs and combine scores from different input modalities using a late-fusion approach (Hendricks et al., 2017).

Endpoint feature $f_\mathcal{T}$. Modeling temporal context requires understanding how different temporal segments relate in time. Hendricks et al. (2017) suggest including temporal endpoint features (***TEF***) $f_\mathcal{T} = \left(\tau^{(s)}, \tau^{(e)}\right)$ for the base moment which encode when the moment starts and ends to better localize sentences which include words like “first” and “last”. Note that TALL (Gao et al., 2017) does not incorporate TEFs. In order to understand temporal relationships, it is important that models also include features which indicate when a context moment occurs. In addition to providing TEFs for base moments, we also experiment with concatenating TEFs for context moments (***conTEF***) $f_\mathcal{T} = \left(\tau^{(s)}, \tau^{(e)}, \tau'^{(s)}, \tau'^{(e)}\right)$.

Language feature $f_\mathcal{L}$. Text queries are transformed into a fixed-length vector with an LSTM (Hochreiter and Schmidhuber, 1997). Before inputting words into the LSTM, they are embedded in the Glove (Pennington et al., 2014) embedding space. The final layer of the LSTM is projected into the shared video-language embedding space with a fully connected layer. Gao et al. (2017) considers LSTM language features and Skip-thought encoders. Our main goal is to study how context impacts moment localization with temporal language, so we use the LSTM features used on the original DiDeMo dataset.

Similarity $f_\mathcal{S}$. Given video $f_\mathcal{V}$ and language $f_\mathcal{L}$ features, we consider three ways to encode similarity between the features. Like Hendricks et al. (2017), we consider a ***distance-based*** similarity $f_\mathcal{S} = \left(|f_\mathcal{V} - f_\mathcal{L}|^2\right)$. Second, we consider a fused-feature similarity (***mult***) where the Hadamard product $f_\mathcal{V} \odot f_\mathcal{L}$ between the two features are passed to a MLP. We also explore unit normalizing features before the Hadamard product (***normalized mult***). Finally, we consider the similarity (***TALL similarity***) which consists of the concatenation $(f_\mathcal{V}, f_\mathcal{L}, f_\mathcal{V} \odot f_\mathcal{L}, f_\mathcal{V} + f_\mathcal{L})$ and then passed to a MLP.

Context moments T_τ. We consider three sets of context moments. First, we consider the entire video as the context moment (***global***) following Hendricks et al. (2017). Second, we consider using the moments just before and after the base moment (***before/after***). Finally, we consider using the set of all possible moments (***latent*** context) which offers greatest flexibility in contextual reasoning.

Training loss. We consider two training losses. The first loss is the MCN ***ranking loss*** which encourages positive moment/query pairs to have a smaller distance in a shared embedding space than negative moment/query pairs. To sample negative moment/sentence pairs, they consider negative moments *within* a specific video (called intra-video negative moments) and negative moments in different videos (called inter-video negative moments). This sampling strategy leads to a small improvement in performance (approximately one point on all metrics) when compared to just using intra-video negative moments. We also consider the alignment loss used in TALL (***TALL loss***) which is the sum of two log-logistic functions over positive and negative training query/moment pairs (intra-video negatives are used).

Supervising context moments. For the temporal sentences in our newly collected dataset (Section 4), we have access to the ground-truth context moment during training. Thus, we can contrast a ***weakly supervised*** setting in which we optimize over the unknown latent context moments during learning and inference to a ***strongly supervised setting***.

Implementation details. Candidate base and context moments coincide to the pre-segmented five-second segments used when annotating DiDeMo. Moments may consist of any contiguous set of five-second segments. For a 30-second video partitioned into six five-second segments, there are 21 possible moments. All models were implemented in Caffe (Jia et al., 2014) and optimized with SGD. Models were trained for ~ 90 epochs with an initial learning rate of 0.05, which decreases every 30 epochs. Code is publicly released[*].

4 The TEMPO Dataset

We collect the TEMPOral reasoning in video and language (TEMPO) dataset based off the recently released DiDeMo dataset. Our dataset consists of two parts: TEMPO - Template Language (TL) and TEMPO - Human Language (HL). We create TEMPO - TL using language templates to augment the original sentences in DiDeMo with temporal words. The template allows us to generate a large number of sentences with known ground truth base and context moments. However, template language lacks the complexity of human language, so we then collect an additional fully user-constructed dataset, TEMPO - HL, consisting of sentences that contain specific temporal words.

Temporal Words in Current Datasets. We first analyze temporal words which occur in current natural language moment retrieval datasets. We consider temporal adjectives, adverbs, and prepositions found both by closely analyzing moment-localization datasets and consulting lists containing words which belong to different parts of speech. In particular, we rely on the preposition project (Litkowski and Hargraves, 2005)[†] to scrape relevant temporal words. Table 2 shows example temporal words and the number of times they occur in each dataset (TACoS (Regneri et al., 2013), Charades (Gao et al., 2017), DiDeMo (Hendricks et al., 2017)). Though all moment localization datasets use temporal words, they do not contain enough examples to reliably train and evaluate current models. Additionally, we observe that temporal words which are frequently used when describing video segments are different than those commonly used in text without video grounding. For example, in Pratt-Hartmann (2004), "during" is a common example, but we observe that "during" is infrequently used when describing video. Of temporal words, we focus on the four most common words, "before", "after", "then", and "while" when creating our dataset.

TEMPO - Template Language. To construct sentences in TEMPO-TL, we find adjacent moments in the DiDeMo dataset and fill in template sentences for "before", "after", and "then" temporal words. For "before", we use two templates: "X before Y" and "Before Y, X", where X and Y are sentences from the original DiDeMo dataset. Likewise for "after", we consider the templates "X after Y" and "After Y, X". For "then" we only consider one template, "X then Y."

TEMPO - Human Language. Though the template dataset is an interesting testbed for understanding temporal language, it is difficult to replicate the interesting complexities in human language. For example, when writing long sen-

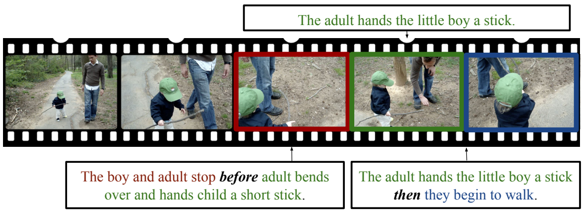

Figure 3: Example sentences in TEMPO - HL. The top sentence corresponds to the reference moment (shown in green). The bottom sentences are newly collected sentences which use temporal language.

tences with temporal prepositions, humans frequently make use of language structure such as coreference to form more cohesive statements.

To collect annotations, we follow the protocol in Hendricks et al. (2017) and segment videos into 5-second temporal segments. After collecting descriptions, we ensure descriptions are localizable by asking other workers to localize each moment. To collect data for "before", "after", and "then", we ask annotators to describe a segment in *relation* to a "reference" moment from the DiDeMo dataset. For example, if the DiDeMo dataset includes a localized phrase like "the cat jumps", annotators write a sentence which refers to the segment "the cat jumps" using a specific temporal word. We provide both the phrase ("the cat jumps") and the reference moment to annotators, and the annotators provide a sentence describing a new moment which references the reference moment.

TEMPO-HL includes unique properties which are hard to replicate with template data. Figure 3 depicts the base moment provided to workers, as well as descriptions from TEMPO-HL. In Figure 3, the description "The adult hands the little boy the stick then they walk away" includes an example of visual coreference ("they"). We note that use of pronouns is much more prevalent in TEMPO-HL, with 28.1% of sentences in TEMPO-HL including pronouns ("he", "she", "it") in contrast to 10.3% of sentences in the original DiDeMo dataset. Additionally, annotators will refer to the base moment with different language than originally used in the base moment (e.g., "the girl waves at the camera" versus the base moment "the girl looks at the camera and waves") in order to make their sentences more fluent.

5 Experiments

Evaluation Method. We follow the evaluation protocol defined for the DiDeMo dataset (Hendricks et al., 2017) over all possible combinations of the five-second video segments. We report rank at one (R@1), rank at five (R@5), and mean intersection over union (mIOU) using their aggregator over three out of the four human annotators. We compare our models on TEMPO-TL, TEMPO-HL, and the DiDeMo dataset. When training our models, we combine the DiDeMo dataset with TEMPO-TL or TEMPO-HL. This enables our model to concurrently learn to localize the simpler DiDeMo sentences with more complex TEMPO sentences.

Baselines. We compare to the two recently proposed approaches for video moment localization: MCN (Hendricks et al., 2017) and TALL (Gao et al., 2017). We adapt the implementation of TALL (Gao et al., 2017) to the DiDeMo dataset in three ways. First, we do not include the temporal localization loss required to regress to specific start and end points as DiDeMo, and thus also TEMPO, is pre-segmented, so the model does not need to compute exact start and end points. Second, the original TALL model uses C3D features.

For a fair comparison we train both models with the same RGB and flow features extracted as was done for the original MCN model. Finally, the MCN model proposes temporal endpoint features (TEF) to indicate when a proposed moment occurs within a video. We train TALL with and without the TEF and show that TEF improves performance on the original DiDeMo dataset.

Ablations. To ablate our proposed latent context, we compare to other models which share the same MLLC base network. We consider the MLLC model with global context and before/after context. We also train a model with weakly supervised (WS) latent context and strongly supervised (SS) latent context. We also train models both with and without context TEF (conTEF).

The MLLC Base Model. We first ablate our MLLC base model (Table 3). We train our models on TEMPO-TL and DiDeMo and evaluate on the original DiDeMo dataset. All models are trained with global context. We find that the ranking loss is preferable on the DiDeMo dataset (compare lines 1 and 2) and that TALL-similarity performs better than the distance based similarity of the MCN model (compare lines 1 and 5). A simpler version of the TALL-similarity, in which the concatenated element wise multiplication, element wise sum, and concatenation is replaced by a single normalized elementwise multiplication, increases R@1 by almost one point and increases mIoU by over two points (compare lines 5-7). We call our best model the MLLC-Base model (line 7). Our MLLC-Base model performs better than previous models (MCN line 1 and TALL line 3).

	Model	Similarity	Training Loss	R@1	R@5	mIoU
1	MCN	Dist.-based	Ranking	26.63	73.38	41.14
2	MCN	Dist.-based	TALL	23.89	76.54	35.69
3	TALL	TALL-sim.	TALL	8.04	36.32	22.68
4	TALL w/TEF	TALL-sim.	TALL	23.56	72.74	35.58
5	MCN	TALL-sim	Ranking	27.52	**79.07**	41.48
6	MCN	Mult	Ranking	28.19	78.97	43.21
7	MLLC-Base	Norm. Mult	Ranking	**28.37**	78.64	**43.65**

Table 3: To select our base network, we consider different variants on the two previously proposed moment retrieval methods, TALL (Gao et al., 2017) and MCN (Hendricks et al., 2017). Results reported on val.

Results: TEMPO - TL. We first compare different moment localization models on TEMPO - TL (Table 4). In particular, our model performs well on "before" and "after" words. Additionally, our MLLC model with global context outperforms both the MCN model (Hendricks et al., 2017) and the TALL (Gao et al., 2017) model when considering all sentence types, verifying the strength of our base MLLC model.

Comparing MLLC with global context and MLLC with before/after context (compare row 4 and 5), we note that before/after context is important for localizing "before" and "after" moments. However, our model with strong supervision (row 9) outperforms the model trained with before and after context, suggesting that learning to reason about which context moment is correct (as opposed to being explicitly provided with the context before and after the moment) is beneficial. We note that strong supervision (SS) outperforms weak supervision (WS) (compare rows 7 and 9) and that the context TEF is important for best performance (compare rows 8 and 9).

We note that though the MLLC-global model outperforms our full model for "then" on TEMPO-TL, our full model performs better on then for the TEMPO-HL (Table 6). One possibility is that the "then" moments in TEMPO-TL do not require context to properly localize the moment. Because TEMPO-TL is constructed from DiDeMo sentences, constituent sentence parts are *referring*. For example, given an example sentence from TEMPO-TL (e.g., "The cross is seen for the first time *then* window is first seen in room"), the model does not need to reason about the ordering of "cross seen for the first time" and "window is seen for the first time" because both moments only happen once in the video. In contrast, when considering the sentence "The adult hands the little boy a stick *then* they begin to walk" (from Figure 3), "begin to walk" could refer to multiple video moments. Consequently, our model must reason about the temporal ordering of reference moments to properly localize the video moment.

On TEMPO - TL, sentences differ from original DiDeMo sentences solely because of the use of temporal words. Thus, we can do a controlled study of how well models understand temporal words. If a model has good temporal reasoning, then if it can localize a reference moment "the dog jumps" it should be easier for the model to localize the moment "the dog sits after the dog jumps". To test whether models are capable of this, we look at only sentences in TEMPO - TL where the model has correctly localized the cor-

Table 4: Comparison of different model performance for different temporal words on TEMPO - TL on our test set. We report scores for the three temporal words in TEMPO - TL as well as on the original DiDeMo dataset. We find that our model performs best when considering all sentence types. B/A indicated before/after context, WS indicates weak context supervision, and SS indicates strong context supervision.

	Before		After		Then	
Context	R@1	mIoU	R@1	mIoU	R@1	mIoU
Global	-1.07	-2.72	-7.59	-6.75	43.30	31.57
Before/After	2.77	2.03	11.47	12.08	42.92	29.09
Latent	7.78	37.55	8.58	10.39	50.09	33.64

Table 5: Difference between performance on full dataset and set on which reference moments are localized properly for different methods on TEMPO-TL.

responding context moment in DiDeMo (Table 5). We report the *difference* in performance when considering only sentences in which temporal context was properly localized and all sentences. On our model, performance on all three temporal word types increases when the context moment can be properly localized. When considering global context, performance on "before" and "after" actually decreases, suggesting global context does not understand temporal reasoning well. Finally, even when the context is correctly localized, there is still ample room for improvement on all three sentence types motivating future work on temporal reasoning for moment retrieval.

Results: TEMPO - HL. Table 6 compares performance on TEMPO - HL. We compare our best-performing model from training on the TEMPO-TL (strongly supervised MLLC and conTEF) to prior work (MCN and TALL) and to MLLC with global and before/after context. Performance on TEMPO-HL is considerably lower than TEMPO-TL suggesting that TEMPO-HL is harder than TEMPO-TL.

On TEMPO - HL, we observe similar trends as on TEMPO-TL. When considering all sentence types, MLLC has the best performance across all metrics. In particular, our model has the strongest performance for all sentence types considering the mIoU metric. In addition to performing better on temporal words, our model also performs better on the original DiDeMo dataset. As was seen in TEMPO-TL, including before/after context performs better than our model trained with global context for both "before" and "after" words.

The final row of Table 6 shows an upper bound in which the ground truth context is used at test time instead of the latent context. We note that results improve for "before", "after", and "then", suggesting that learning to better localize context will improve results for these sentence types.

Localizing Context Fragments. TEMPO-HL sentences can be broken into two parts: a base-sentence fragment (which refers to the base moment), and a context-sentence fragment (which refers to the context moment). For example, for the sentence "The girl holds the ball before throwing it,", "the girl holds the ball" is the base fragment and "throwing it" is the context fragment. A majority of the "before" and "after" sentences in TEMPO-HL are of the form "X before (or after) Y", so we can determine a list of sentence fragments by splitting sentences based on the temporal word. Given "before" and "after" sentences, we determine the ground truth context fragment by considering which reference moment was given to annotators. We can then measure how well models localize context fragments. Table 7 compares two approaches to localizing context fragments: inputting just the context fragment into MLLC

Full Sentence	**27.55**	**35.70**	**32.67**	**40.39**

Table 7: Comparison of different methods to localize context fragments (e.g., the text “she bends down” in the sentence “the girl talks after she bends down”). We compare localizing fragments with the MLLC model to localizing fragments with the latent context considered when localizing the whole query.

Figure 4: Moment localization predictions on TEMPO - HL using our model. In addition to the localized query, we show the selected context segment (blue line) that our model considers when localizing the query.

and reporting the context used by MLLC when inputting the entire query into our model. We find that our model reliably selects the correct context fragments, most likely because it can properly exploit temporal understanding of how the context fragment relates to the base fragment.

Visualizing Context. In addition to a localized query, we can also visualize which context moment the temporal query refers to. Figure 4 shows predicted moments and their corresponding context moments. For the query “The girl with a hat takes a drink before the girl without a hat waves”, the little girl in the hat drinks twice, but our model correctly localizes the time she drinks *before* the other girl waves. Likewise, for the moment “After zooming in to the dog, the dog darts across the grass and into the woods”, the dog darts towards the woods twice (at the beginning of the video and at the end). Our model properly localizes the moment when the dog runs towards the forest the second time as well as the context fragment “zooming in on dog” when localizing the moment.

Discussion. We show promising results on both TEMPO-TL and TEMPO-HL, but there is potential improvement for building better frameworks for understanding temporal language. In Table 6, strongly supervising context at test time improves overall results, suggesting that models which can better localize context text will outperform our current model. Though TEMPO and DiDeMo have over 60,000 sentences combined, visual content is quite diverse. Integrating outside data sources (e.g., image retrieval and captioning) could possibly improve results on moment localization, both with and without temporal language queries. Additionally, in Table 5, even when the MLLC model can properly localize context, it does not always properly localize temporal sentences indicating that improved temporal reasoning can also improve our results. We believe our dataset, analysis, and method are an important step towards better moment retrieval models that effectively reason about temporal language.

CARD-660: Cambridge Rare Word Dataset – a Reliable Benchmark for Infrequent Word Representation Models

Abstract

Rare word representation has recently enjoyed a surge of interest, owing to the crucial role that effective handling of infrequent words can play in accurate semantic understanding. However, there is a paucity of reliable benchmarks for evaluation and comparison of these techniques. We show in this paper that the only existing benchmark (the Stanford Rare Word dataset) suffers from low-confidence annotations and limited vocabulary; hence, it does not constitute a solid comparison framework. In order to fill this evaluation gap, we propose CAmbridge Rare word Dataset (CARD-660), an expert-annotated word similarity dataset which provides a highly reliable, yet challenging, benchmark for rare word representation techniques. Through a set of experiments we show that even the best mainstream word embeddings, with millions of words in their vocabularies, are unable to achieve performances higher than 0.43 (Pearson correlation) on the dataset, compared to a human-level upperbound of 0.90. We release the dataset and the annotation materials at `https://pilehvar.github.io/card-660/`.

1 Introduction

Words in a corpus of natural language utterances approximately follow a Zipfian distribution with their majority, in the "long tail" of frequency distribution, occurring rarely. The prominent distributional approach to semantic representation relies on enormous occurrences for each individual word; therefore, it falls short of learning accurate representations for rare words in the long tail. Moreover, it is unreasonable to expect that all words in the vocabulary of a language are observed in a text corpus, even if it is massive in size. Out-of-vocabulary (OOV) words pose one of the major ongoing challenges for word embedding techniques. Given that effective handling of rare and OOV words is crucial to accurate natural language understanding, several studies have focused on the topic during the past few years, resulting in a wide range of techniques.

However, despite the popularity of rare and subword semantic representation, the field of research has suffered from the lack of high quality generic evaluation benchmarks. A task-based evaluation, i.e., one which directly verifies the impact of representation models in a downstream NLP system, despite being very important, does not provide a solid base for comparing different models, given that small variations in the architecture, parameter setting, or initialisation can lead to performance differences. Moreover, such an evaluation would reflect the "suitability" of representations for that specific configuration and for that particular task, and might not be conclusive for other settings.

As far as generic evaluation is concerned, existing benchmarks generally target frequent words. An exception is the Stanford Rare Word (RW) Similarity dataset (Luong et al., 2013) which has been the standard evaluation benchmark for rare word representation techniques for the past few years. In Section 2.1, we will provide an in-depth analysis of RW and highlight that crowdsourcing the annotations, with no rigorous checkpoints, has compromised the reliability of the dataset. This is mainly reflected by the low inter-annotator agreement (IAA), a performance ceiling which is easily surpassed by many existing models.

To overcome this barrier and to fill the gap for a reliable benchmark for the evaluation of subword and rare word representation techniques, we introduce a new dataset, called CARD-660: Cambridge Rare Word Dataset. Compared to existing benchmarks, CARD-660 provides multiple advantages: (1) thanks to a manual curation by experts, we report IAA of around 0.90 (see Table 3) which is substantially higher than those for exist-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1391–1401
Brussels, Belgium, October 31 - November 4, 2018.

ing datasets; (2) word pairs are selected manually from a wide range of domains and, unlike existing datasets, are not bound to a specific resource; (3) word pairs in the dataset are balanced across the similarity scale; and (4) the huge gap between state of the art and IAA (more than 0.50 in terms of Spearman correlation) promises a challenging dataset with lots of potential for future research.

The paper is structured as follows. The following Section covers the related work, highlighting some of the issues with the RW dataset. Section 3 details the construction procedure for CARD-660. In Section 4, we analyse the dataset from different aspects, showing how it improves existing benchmarks. Section 5 reports our evaluation of mainstream word embeddings and recent word representation techniques on the dataset. Finally, concluding remarks are mentioned in Section 6.

2 Related Work

Word similarity datasets have been one of the oldest, still most prominent, benchmarks for the evaluation and comparison of semantic representation techniques. As a result, several word similarity datasets have been constructed during the past few decades; to name a few: RG-65 (Rubenstein and Goodenough, 1965), WordSim-353 (Finkelstein et al., 2002), YP-130 (Yang and Powers, 2005), MEN-3K (Bruni et al., 2014), SimLex-999 (Hill et al., 2015), and SimVerb-3500 (Gerz et al., 2016). Many of these English word similarity datasets have been translated to other languages to create frameworks for multilingual (Leviant and Reichart, 2015) or crosslingual (Camacho-Collados et al., 2017) semantic representation techniques. However, these datasets mostly target words that occur frequently in generic texts and, as a result, are not suitable for the evaluation of subword or rare word representation models.

One may opt for transforming a frequent-word benchmarks into an artificial rare word dataset by downsampling the dataset's words in the underlying training corpus (Sergienya and Schütze, 2015). However, this benchmark might not properly simulate a real-world rare word representation scenario (cf. Section 3.1).

2.1 Stanford RW Dataset

The Stanford Rare Word Similarity (RW) dataset is an exception as it is dedicated to evaluating infrequent word representations. The dataset has been regarded as the de facto standard evaluation benchmark for subword and rare word representation techniques. However, our analysis shows that RW suffers from multiple issues: (1) skewed distribution of the scores, (2) low-quality and inconsistent scores, and as a consequence, (3) low inter-annotator agreement.

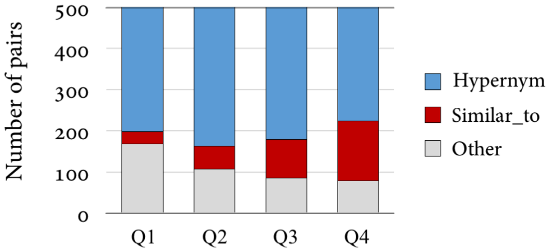

Figure 1: Distribution of relation types ("hypernymy", "similar_to", and others) across four quartiles (sorted by gold similarity scores) of the Stanford Rare Word Similarity dataset. The distribution of pairs with hypernymy relation is almost uniform across the quartiles, whereas one would expect many more pairs in the top quartiles (Q4 and Q3), given the high semantic similarity of hypernym-hyponyms.

The RW dataset comprises 2034 word pairs (i.e., $word_1$ – $word_2$). Candidates for $word_1$ were randomly sampled from Wikipedia documents, distributed across a wide range of frequencies (from 5 to 10,000) to ensure the inclusion of infrequent words. Given this automatic sampling, a measure was required to avoid noisy or junk words. To this end, a sampled word was checked in WordNet (Fellbaum, 1998) and was included only if it appeared in at least one synset. Hence, the vocabulary of the dataset is bound to that of WordNet. Words for $word_2$ were randomly picked from synsets that were directly connected to a synset of $word_1$, through various relations, such as hypernymy, holonymy, and attributes.

2.1.1 Distribution of scores

These word pairs were assigned similarity scores in $[0, 10]$. Given that all word pairs in the dataset are semantically-related according to WordNet, the scores form a skewed distribution biased towards the upper bound (see Figure 2 and Section 4.1 for more details).

2.1.2 Consistency of annotations

The scoring of the pairs has been carried out through crowdsourcing: (Amazon Mechanical) Turkers have provided ten scores for each word pair. The raters were restricted to only US-based workers and they were asked to self-certify themselves by indicating if they "knew" the word; this was used to "discard unreliable pairs." However, our analysis of the dataset clearly indicates that the above measures have not been adequate for guaranteeing quality annotations. For instance, the word *bluejacket* is paired with *submariner* in the dataset. According to WordNet (v3.0), a submariner ("a member of the crew of a submarine") is a bluejacket ("a serviceman in the navy"; a *navy_man*, *sailor*), hence a hypernymy relationship. One would expect a word to have high semantic similarity with its hypernym. However, the gold score for this pair is just 0.43 in the scale $[0, 10]$. Other examples include "untruth" (a false statement) vs. "statement" (again, with a hypernymy relationship) with a low similarity of 1.22. Apart from not being a rigorous evaluation, the self-certification does not verify if the annotator had knowledge of *various* possible meanings of a word. For instance, *decomposition* could refer to the analysis of vectors in algebra; but, when paired with *algebra*, the assigned score is only 0.75. Such examples clearly indicate that the annotators were not aware of specialised senses of some words (e.g., the algebraic meaning of decomposition), despite "knowing" the word.

In fact, there are numerous such pairs in the dataset. According to our estimate, 78% of the 2034 word pairs in the dataset are in a *hypernymy* or *similar_to* relationship. One would expect most of these (semantically similar) pairs to have been assigned high similarity scores which are closer to the upper bound of the similarity scale $[0, 10]$. However, as shown in Figure 1, these pairs are spread across the similarity scale, spanning from complete unrelatedness (lower bound) to identical semantics (synonymy). Having the words in the dataset sorted by their assigned gold scores, respectively, 66%, 79%, 83%, and 85% of the pairs in the first to fourth quartiles contain either "hypernymy" or "similar_to" relations (whereas one would expect most of these semantically-similar pairs to appear in the top quartiles).

Additionally, the dataset suffers from inconsistent annotations. For instance, the two almost identical pairs *tricolour-flag* and *tricolor-flag* were assigned substantially different scores, i.e., 5.80 and 0.71, respectively. This inconsistency is also reflected by high variances across annotators scores (cf. Section 4.3).

2.1.3 Inter-Annotator Agreement (IAA)

This validity metric reflects the homogeneity of the annotators' ratings and it is generally accepted as the upper bound for machine performance. IAA is widely used as a standard evaluation metric for the quality of word similarity datasets. A low IAA indicates a defective similarity scale or unreliable annotations.

In the RW dataset, "up to 10" annotations have been provided for the 2034 word pairs, each with a similarity score in $[0, 10]$ range. More precisely, 214 of the pairs are not provided with 10 scores, with the minimum number of scores for a pair being 7. The authors did not report IAA statistics for this dataset. Given that the annotators are not known for each pair in the released dataset, it is not straightforward to compute IAA.[1] According to a rough calculation, the average pairwise Spearman correlation between annotators' scores is 0.40, which is a significantly low figure compared to other existing word similarity datasets. We report an impressive IAA of 0.89 for our dataset (cf. Section 4.2).

3 The CARD-660 Dataset

3.1 Motivation

Due to a lack of reliable evaluation benchmarks, research in rare word representation has often resorted to artificial experimental setups such as corpus downsampling (Sergienya and Schütze, 2015; Herbelot and Baroni, 2017; Lazaridou et al., 2017). To this end, in order to simulate a rare word scenario, the rare word representation model is provided with only a limited number of occurrences for the target set of words, for instance by means of replacing the dataset's words with some other sequences of characters (e.g., by augmenting "UNK", such as "skyglowUNK" for "skyglow") in the training corpus. The computed representations on the "downsampled" training data are then either evaluated on a standard word similarity dataset (Sergienya and Schütze, 2015), such as RG-65, or compared against reference embeddings computed on a large training corpus (Herbelot and Baroni, 2017; Lazaridou et al., 2017).

However, due to the following three reasons, downsampling does not constitute a reliable

---

[1] The scores are further pruned down to only those that were within one standard deviation of the mean. This results in a further imbalanced set of scores, making the computation of IAA more challenging.

benchmark that can represent the challenging nature of the task: (1) it is unable to control the impact of second-order associations (words that frequently co-occur with the downsampled word) and cannot represent a real-world setting with novel rare usages; (2) given that morphological variations of a word (such as plural forms) are kept intact in this procedure, a subword technique can easily resort to these forms to compute the embedding for downsampled words; and (3) a constrained evaluation configuration in which the task is to estimate the embedding for a (rare) word using one or few occurrences (contexts) of it, limits the benchmark to a subset of corpus-based rare word representation techniques only. Moreover, the evaluation would require the comparison of the computed embeddings for rare words with a set of reference embeddings (computed on the full data). This dependency limits the ability of the benchmark in providing a direct evaluation of the rare word representation technique, independently from the impact of the model used to compute the reference embeddings.

The CARD-660 dataset aims at filling the gap for rigorous generic evaluation of rare word and subword representation models. In what follows in this section, we will detail the construction procedure of the dataset which was carefully planned to guarantee a challenging and reliable dataset.

3.2 Construction Procedure

The following four-phase procedure was used to construct the dataset:

(1) A set of 660 rare words were carefully selected from a wide range of domains;
(2) For each of these initial words, a pairing word was manually selected according to a randomly sampled score from the similarity scale (Section 3.2.2);
(3) All pairs were scored by 8 annotators;
(4) A final adjudication was performed to address disagreements (Section 3.2.3).

3.2.1 Similarity scale

We adopted the five-point Likert scale used for the annotation of the datasets in SemEval-2017 Task 2 (Camacho-Collados et al., 2017). The task reported high IAA scores which reflects the well-definedness and clarity of the scale. We provided annotators with the concise guideline shown in Table 1, along with several examples. Given the continuity of the scale, the annotators were given flexibility to select values in between the five points, whenever appropriate, with a step size of 0.5.

The annotators were asked in the guidelines to make sure they were familiar with *all* common meanings of the word (as defined by WordNet or other online dictionaries). To facilitate the annotation, the annotators were provided with the definitions of some of the words that were defined in WordNet or named entities that had Wikipedia pages. For others, we asked the annotators to check the word in online dictionaries, such as WordNet browser[3] and Wiktionary[4], or encyclopediae, such as Wikipedia.

3.2.2 Word pair selection

Unlike previous work (Luong et al., 2013), we did not rely on random sampling (pruned by frequency) of initial words from a specific dictionary, to prevent the dataset from being restricted to a specific resource or vocabulary. Instead, we carefully hand-picked word pairs from a wide range of domains. To construct the 660 pairs of the dataset (each pair is denoted as $w_1 - w_2$), we first picked 660 w_1 words. Our aim was to have a dataset that can ideally reflect the performance of rare word representation techniques in downstream NLP tasks. To this end, we picked initial words (w_1s) from different common NLP datasets and resources, listed in Table 2. For each text-based resource, a frequency list was obtained and rare words were carefully picked from the long tail of the list, cross-checking the frequency of words in the Google News dataset. For the other resources (such as Wiktionary), we checked a word against a large frequency list to ensure they are not frequent words. The list was computed on the 2.8B token ukWaC+WaCkypedia corpus (Baroni et al., 2009) and comprised 16.5M unique words.

In order to have a balanced distribution of scores in the dataset, we first assigned random integer scores in $[0-4]$ to the 660 initial w_1s. Then, with the corresponding score in mind, a pairing word (w_2) was selected for each w_1. We show in Section 4.1 that this strategy resulted in a uniformly distributed set of scores in the dataset.

The dataset comprises words from a wide range of genres and domains, including slang in so-

cial media (e.g., *2mrw* and *Mnhttn*), named entities (e.g., *Stephen_Hawking* and *Ursa_Major*), and domain specific terms (e.g., *erythroleukemia* and *NetMeeting*). Moreover, to have a rigorous testbed for subword representation techniques that emphasises the importance of semantic (rather than shallow) understanding of the words, the dataset contains several word pairs that have similar surface forms (hence, high string similarity) while being semantically distant, e.g., *infection-inflection* and *currency-concurrency*. There are also many compound words (e.g., *skyglow*, *musclebike*, and *logboat*) which makes the dataset particularly interesting for evaluating compositionality as well as for subword representation techniques.

3.2.3 Scoring and adjudication

Once the 660 word pairs were manually selected (by the first author), the initial scores were discarded and the words were shuffled (vertically and horizontally) to dispense any potential bias from the initial round of creation. Then, the pairs were assigned to 8 annotators (including all but first authors) who independently scored each and every pair according to the annotation guidelines (see Section 3.2.1). All annotators were PhD graduates or students in Computational Linguistics or related fields and were either native or fluent English speakers.

Once all pairs were scored by the annotators, we checked for disagreements. This check was intended to improve the dataset's quality through resolving simple annotation mistakes. For each annotator, we marked the i^{th} pair if for the assigned score s_i: $s_i \geq \mu_i + 1$ or $s_i \leq \mu_i - 1$, where μ_i is the average of the other seven annotators' scores for s_i. The annotator was then asked to (more carefully) re-score the marked pair by checking for its possible meanings. They were asked to keep their initial score if not convinced otherwise. The adjudication revealed that most disagreements were due to an annotator having misread a word or not been familiar with a specific meaning of it, or missing annotations. By average, 13.8% of the pairs were re-scored by each annotator.

4 Analysis

In this section we provide an analysis on the quality of CARD-660 from three different perspectives: distribution of scores, inter-annotator agreement, and consistency among annotators. We benchmark CARD-660 against the Stanford **RW** dataset and two standard word similarity datasets (cf. Section 2): SimVerb-3500 (**SV-3500**) and SimLex-999 (**SL-999**). The latter two datasets do not target rare words; however, given that their construction strategy is similar to that employed for creating RW (based on crowdsourcing), we included them in our analysis experiments to provide better insights. For the purpose of this evaluation, all the datasets were scaled to [0,10] to make them comparable.

4.1 Score Distribution

Figure 2 shows the distribution of pairs across the similarity scale, for CARD-660 and the three other datasets. As discussed in Section 2.1, RW is heavily biased towards the upper bound of the similar-

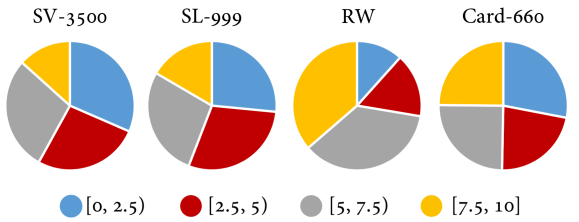

Figure 2: The distribution of word pairs across the four quartiles of the similarity scale for different datasets. A perfectly balanced dataset would have four equally sized slices.

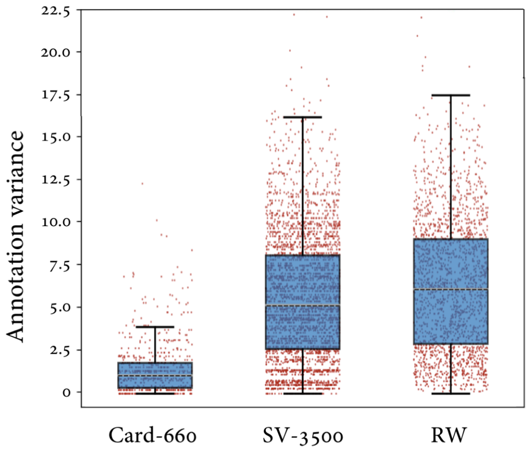

Figure 3: Annotation variance for word pairs across different datasets. Average variance for CARD-660 is 1.47, which is significantly lower than those for SV-3500 and RW: 5.64 and 6.34, respectively.

ity scale (with around 72% of the pairs in the upper half, i.e., $[5, 10]$). The skewed distribution in this dataset can be attributed to the automatic word pair selection from semantically-related words in WordNet (cf. Section 2.1). SV-3500 and SL-999 are skewed towards the lower bound, but to a smaller degree (around 59% of the pairs in $[0, 5)$). Thanks to the manual creation of CARD-660, we have a balanced set of pairs across the similarity scale (50-50% across the two halves).

4.2 Inter-Annotator Agreement

As mentioned in Section 2.1, IAA has been extensively used as a quality metric for word similarity datasets. Following standard practise, we measure two sets of IAA scores: (1) **Pairwise** is the averaged pairwise correlation between all possible rater pairings, and (2) **Mean** is the averaged correlation of each rater against the average of others.

Table 3 reports IAA statistics for CARD-660. Thanks to the manual scoring of the pairs by experts (as opposed to turkers), the IAA values for the dataset are very high, placing it among the best word similarity datasets in the literature. This is particularly interesting considering that, compared to standard word similarity datasets which contain mostly common words, our dataset comprises words that are semantically difficult to annotate due to their rare nature. The pairwise IAA score of 88.9 is significantly higher than the crowdsourced RW, with the estimated pairwise IAA score of around 40.0 (cf. Section 2.1). The same applies to other recent crowdsourced word similarity datasets for common words which usually report pairwise IAA scores below 70.0 (e.g., $\rho = 67.0$ for SL-999)[5].

	Mean		**Pairwise**	
	r	ρ	r	ρ
Initial	88.0±2.3	87.9±1.9	80.2±2.9	80.6±2.6
Final	93.5±1.4	93.1±1.2	88.9±1.7	88.9±1.7

Table 3: Inter-annotator agreement (IAA) scores before (*initial*) and after (*final*) adjudication (± standard deviation). IAA is shown in terms of Pearson r and Spearman ρ percentage correlations. The *final* scores are representative of the dataset's quality.

4.3 Consistency of Annotations

Despite being suitable for measuring linear relationships between scores, correlation cannot fully reflect the consistency between annotators. Two annotators can have perfect correlation, i.e., 1.0, even if they consistently provide different scores for the same pairs (therefore, having different average assigned scores). To check the consistency among annotators, i.e., if they had the same interpretation of the similarity scale, we compute variance across annotators for individual pairs.

The box and whisker (over scatter) plot in Figure 3 shows the distribution of annotator variances for the pairs in different datasets. Clearly, the score variances for CARD-660 are significantly lower than those for the two crowdsourced datasets, i.e., SimVerb-3500 and RW.[6] Specifically, for the majority of pairs in CARD-660 the annotation variance is lower than the other two datasets' first quartile (bottom of the blue square

---

[5] SimVerb-3500 reports a pairwise ρ of 84.0; however, our calculation did not agree with this figure. Personal communication with the authors revealed an issue in the computation of their IAA. The correct figure is instead 61.2.

[6] We are not able to report results for SimLex-999 since individual annotators' scores are not released for this dataset.

Embedding set	$\lvert V \rvert$	**Missed words**		**Missed pairs**		**Pearson r**		**Spearman ρ**

Table 4: Pearson r and Spearman ρ correlation percentage performance of mainstream pre-trained word embeddings on the RW and CARD-660 datasets. Column $|V|$ shows the size of vocabulary for the corresponding embedding set.

which splits the lower 25% of the data from the top 75%). This indicates that our annotators had significantly higher degrees of agreement, reflecting the well-definedness of the similarity scale as well as the reliability of expert-based annotation (as opposed to crowdsourcing).

5 Evaluations

In the remainder of this paper, we provide two sets of experiments to showcase the challenging nature of our dataset. Specifically, in Section 5.1 we report the performance of common pretrained word embeddings on CARD-660, and in Section 5.2 we provide experimental results for state-of-the-art rare word representation techniques. In all experiments, we used the cosine similarity for comparing pairs of word embeddings.

5.1 Pre-trained Embeddings

As was mentioned earlier in the Introduction, it is not possible to enumerate the entire vocabulary of a natural language, even if massive corpora are used. A challenging rare word benchmark should ideally reflect this phenomenon. To verify this in our dataset, we experimented with a set of commonly used word embeddings trained on corpora with billions of tokens.

Table 4 provides correlation performance results for different embedding sets on the RW and CARD-660 datasets. Specifically, we considered different variants of Word2vec[7] (Mikolov et al., 2013) and Glove[8] (Pennington et al., 2014), two commonly-used word embeddings that are trained on massively large text corpora; Dependency-based embeddings[9] (Levy and Goldberg, 2014) which extends the Skip-gram model to handle dependency-based contexts; LexVec[10] (Salle et al., 2016) which improves the Skip-gram model to better handle frequent words; and ConceptNet Numberbatch[11] (Speer et al., 2017) which exploits lexical knowledge from multiple resources, such as Wiktionary and WordNet, and was the best performing system in SemEval 2017 Task 2. In the last two rows of the Table we also report results for two hybrid embeddings constructed by combining the pre-trained Freebase Word2vec, which mostly comprises named entities, with two of the best performing embeddings evaluated on the dataset. Given that the word embeddings are not comparable across two different spaces, we only compute the similarity between a pair only if both words are covered in the same space (with priority given to the non-Freebase embedding).

As can be seen in the Table, many of the embeddings yield high coverage for the RW dataset, with those trained on the Common Crawl (CC) corpus providing near full coverage. This highlights the limited vocabulary of the dataset (which is bound to that of WordNet). Also, many of

[10] https://github.com/alexandres/lexvec

[11] https://github.com/commonsense/conceptnet-numberbatch

the embeddings attain performance around 40.0 on RW, which is higher than the estimated IAA of the dataset. In contrast, CARD-660 proves to be significantly more challenging, with the highest coverage model (Glove CC and Word2vec Freebase hybrid model) missing around 40% of the pairs. Also, the best performance of 42.6 (r) and 32.7 (ρ) are substantially (around 50.0) lower than the IAA for the dataset (see Table 3).

5.2 Rare Word Representation Techniques

Rare and unseen word representation has been an active field of research during the past few years, with many different techniques proposed. In this experiment, we evaluate the performance of some of recent models on our dataset. These techniques can be broadly classified into two categories. The first group exploits the knowledge encoded for a rare word in external lexical resources (Section 5.2.1), whereas the second induces embeddings for rare words by extending the semantics of its subword units (Section 5.2.2).

5.2.1 Resource-based models

The basic assumption here is that a lexical resource, such as dictionary, provides high coverage for words in a language, even if they are rare. Resource-based models usually rely on WordNet as their external resource and estimate the embedding for a rare word by exploiting different types of lexical knowledge encoded for it in the resource. The **definition centroid** model of Lazaridou et al. (2017) takes WordNet word glosses (definitions) as semantic clue. An embedding is induced for an unseen word by averaging the content words' embeddings in its definition.[12] The **definition LSTM** strategy of Bahdanau et al. (2017) extends the centroid model by encoding the definition using an LSTM network (Hochreiter and Schmidhuber, 1997), in order to better capture the semantics and word order in the definition. **SemLand** (Pilehvar and Collier, 2017) also uses WordNet, but takes a different approach which benefits from the graph structure of WordNet. For an unseen word, SemLand extracts the set of its semantically related words from WordNet and induces an embedding for the unseen word by combining pre-trained embeddings for the related words.

5.2.2 Subword models

Resource-based models fall short of inducing embeddings for words that are not covered in the lexical resource. Subword models alleviate this limitation by breaking the word into its subword (Pinter et al., 2017; Bojanowski et al., 2017) or morphological units (Luong et al., 2013; Botha and Blunsom, 2014; Soricut and Och, 2015) and induce an embedding by composing the information available for these. **FastText** (Bojanowski et al., 2017) is one of the popular approaches of this type. The model first splits the unseen word into character ngrams (by default, 3- to 6-grams) and then computes the unseen word's embedding as the centroid of the embeddings of these character n-grams (which are available as a result of a specific training). We also report results for **Mimick** (Pinter et al., 2017), one of the most recent subword models. The technique learns a mapping function from strings to embeddings by training a Bi-LSTM network that encodes character sequences of a word to its pre-trained embedding.

5.3 Experimental Setup

We report results for the five techniques discussed in Sections 5.2.2 and 5.2.1. We used two of the best performing embedding sets, i.e., Glove cased CC and ConceptNet Numberbatch, to train the models (except FastText for which we use the pre-trained WikiNews subword embeddings[13]). In fact, the models were expected to provide improvements over these baseline embeddings by filling their gaps for unseen words.

Mimick was trained with the default parameters,[14] except for the hidden units which we set to 100, instead of the original 50, since the target embeddings in our experiments were larger (300d compared to 128d of the original model). For the Definition LSTM model, the input definitions were represented as sequences of 50d word embeddings, encoded using an LSTM layer of 100 units, and then passed to a dense layer with 300 neurons with linear activation function. The training was carried out with Mean Squared Error loss and the RMSprop optimizer, for 100 epochs with batch size 64.

---

[12] The original model is multimodal (text and images). Given that our focus is on texts, we follow Herbelot and Baroni (2017) and use the text modality only.

Table 5: Correlation performance of different rare and unseen word representation techniques on the Stanford RW and CARD-660 datasets (the best performance in each batch shown in bold; the overall best underlined).

5.4 Experimental Results

Table 5 reports the performance of different rare word representation techniques. Both pre-trained embeddings outperform the IAA of RW, with Glove covering 98% of the pairs. This severely limits the room for further meaningful experiments on the dataset. In contrast, on CARD-660 and similarly to the previous experiment, there are substantial gaps between IAA (cf. Table 3) and the best-performing models: SemLand and Mimick, with the respective figures of 45.5 (r) and 53.3 (ρ). These gaps suggest a difficult dataset which can serve future research in subword and rare word representation as a reliable benchmark.

The definition centroid model proves effective, despite its simplicity, whereas the WordNet-based SemLand provides the best results in most of the settings. Being constrained to the vocabulary of WordNet, the RW dataset does not constitute a challenging benchmark for WordNet-based models, with most of them providing near full coverage. However, these techniques are not as effective on our dataset, with the best WordNet-based model still missing around 33% of the pairs (with Glove pre-trained embeddings).

The CARD-660 dataset also proves a very difficult benchmark for subword models. Despite providing near full coverage, these models are unable to consistently improve the pre-trained word embedding baseline. This would suggest that the simple strategy of backing off to a word's characters might not always provide reliable means of estimating its semantics (e.g., the single-morpheme word *galaxy*, or the exocentric compound *honeymoon*). The results encourage further research on a more semantically-oriented handling of subwords, through learning more effective splitting and composition techniques.

6 Conclusions

Thanks to a carefully designed procedure and an expert-based curation, CARD-660 provides multiple advantages over existing benchmarks, including a very high IAA (average pairwise correlation of around 0.90). A series of experiments was carried out on the dataset, leading to two main conclusions: (1) the dataset proved a very challenging benchmark, with the best pre-trained embedding model still missing around 40% of the word pairs and the best rare word representation model hardly crossing into 40.0s (correlation performance); and (2) knowledge-based models are not enough to provide high coverage whereas subword models, which provide near-full coverage, are not semantically as effective. The significant gap between state of the art and IAA (around 50.0) encourages future research to take this dataset as a challenging, yet reliable, evaluation benchmark.

Acknowledgments

We gratefully acknowledge the funding support of EPSRC (N. Collier and D. Kartsaklis - Grant No. EP/M005089/1) and MRC (M. T. Pilehvar) Grant No. MR/M025160/1 for PheneBank. We would also like to thank Andreas Chatzistergiou, Costanza Conforti, Gamal Crichton, Milan Gritta, and Ehsan Shareghi for their contribution in creating the dataset.

Abstract

The goal of Word Sense Disambiguation (WSD) is to identify the correct meaning of a word in the particular context. Traditional supervised methods only use labeled data (context), while missing rich lexical knowledge such as the gloss which defines the meaning of a word sense. Recent studies have shown that incorporating glosses into neural networks for WSD has made significant improvement. However, the previous models usually build the context representation and gloss representation *separately*. In this paper, we find that the learning for the context and gloss representation can benefit from each other. Gloss can help to highlight the important words in the context, thus building a better context representation. Context can also help to locate the key words in the gloss of the correct word sense. Therefore, we introduce a co-attention mechanism to generate co-dependent representations for the context and gloss. Furthermore, in order to capture both word-level and sentence-level information, we extend the attention mechanism in a hierarchical fashion. Experimental results show that our model achieves the state-of-the-art results on several standard English all-words WSD test datasets.

1 Introduction

Word Sense Disambiguation (WSD) is a crucial task and long-standing problem in Natural Language Processing (NLP). Previous researches mainly exploit two kinds of resources. Knowledge-based methods (Lesk, 1986; Moro et al., 2014; Basile et al., 2014) exploit the lexical knowledge like gloss to infer the correct senses of ambiguous words in the context. However, supervised feature-based methods (Zhi and Ng, 2010; Iacobacci et al., 2016) and neural-based methods (Kågebäck and Salomonsson, 2016; Raganato et al., 2017a) usually use labeled data to train one or more classifiers.

Context	As they often **play** football together, they know each other quite well
Glosses	g_1: participate in games or sports
	g_2: perform music on an instrument
	g_3: behave in a certain way

Table 1: An example of the context and three glosses of different senses according to the target word ***"play"***. It shows that the words *"games/sports"* in the gloss g_1 can help to highlight the important words *"football"* in the context and ignore the words *"know each other"* which are useless for distinguishing the sense of word *"play"*. Meanwhile, the context can potentially help to stress on the words *"games/sports"* of the gloss g_1 which is actually the correct sense for the target word.

Although both lexical knowledge (especially gloss) and labeled data are of great help for WSD, previous supervised methods rarely take the integration of knowledge into consideration. To the best of our knowledge, Luo et al. (2018) are the first to directly incorporate the gloss knowledge from WordNet into a unified neural network for WSD. This model *separately* builds the context representation and the gloss representation as distributed vectors and later calculates their similarity in a memory network. However, we find that the learning of the representations of the context and gloss can contribute to each other. We use an example to illustrate our ideas. Table 1 shows that the red words are more important than the blue words when distinguishing the sense of the target word. In other words, we should pay more attention to the words which can "overlap" between the context and the gloss when generating the representations of context and gloss. Therefore, we introduce a co-attention mechanism to model the mutual influence between the representations of context and gloss.

Moreover, we find that both word-level and sentence-level information are crucial to WSD. As

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1402–1411
Brussels, Belgium, October 31 - November 4, 2018.

shown in Table 1, the local word *"football"* is crucial for distinguishing the sense of word *"play"*. However, in more complex sentences such as *"Investors played it carefully for maximum advantage"* [1], sentence-level information is necessary. Therefore, we extend the co-attention model in a hierarchical fashion to capture both the word-level and sentence-level semantic information.

The main contributions are listed as follows.

- We propose a novel way to integrate gloss knowledge into a neural network for WSD via a co-attention mechanism in order to build better representations of context and gloss. In this way, our model can benefit from both labeled data and lexical knowledge.
- We further extend the attention mechanism into a hierarchical architecture, since both word-level and sentence-level information are crucial to disambiguating the word sense.
- We conduct a series of experiments, which show that our models outperform the state-of-the-art systems on several standard English all-words WSD test datasets.

2 Related work

Lexical knowledge is a fundamental component of Word Sense Disambiguation and provides rich resources which are essential to associate senses with words (Navigli, 2009). Unsupervised knowledge-based methods have shown the effectiveness of textual knowledge such as gloss (Lesk, 1986; Basile et al., 2014) and the structural knowledge (Moro et al., 2014; Agirre et al., 2014) of the lexical databases. However, the prime shortcoming of knowledge-based methods is that they have worse performance than supervised methods, but they have wider coverage for the polysemous words, thanks to the use of large-scale knowledge resources (Navigli, 2009).

There are many other tasks such as Chinese Word Segmentation (Zhang et al., 2018), Language Modeling (Ahn et al., 2016), and LSTMs (Xu et al., 2016; Yang and Mitchell, 2017) show that integrating knowledge and labeled data into a unified system can achieve better performance than other methods which only learn from large scale labeled data. Therefore, it's a promising and challenging study to integrate labeled data and lexical knowledge into a unified system.

A few recent studies of WSD have exploited several ways to incorporate lexical resources into supervised systems. In the field of traditional feature-based methods (Chen et al., 2015; Rothe and Schütze, 2015), they usually utilize knowledge (to train word sense embeddings) as features of the classifier like the support vector machine (SVM). In the field of neural-based methods, Raganato et al. (2017a) regard lexical resource LEX which is extracted from the WordNet as an auxiliary classification task, and propose a multi-task learning framework for WSD and LEX. Luo et al. (2018) integrate the context and glosses of the target word into a unified framework via a memory network. It encodes the context and glosses of the target word *separately*, and then models the semantic relationship between the context vector and gloss vector in the memory module. What's more, Luo et al. (2018) utilize much more knowledge about gloss via its semantic relations such as hypernymy and hyponymy in WordNet. All studies listed above show that integrating lexical resources especially gloss into supervised systems of WSD can significantly improve the performance. Therefore, we follow this direction and seek a new way of better integrating gloss knowledge.

Instead of building representations for context and gloss separately, we use the inner connection between the gloss and the context to promote the representation of each other. The interaction process can be modeled by a co-attention mechanism which has made great progress in the question answering task (Xiong et al., 2016; Seo et al., 2016; Hao et al., 2017; Lu et al., 2016). We are enlightened by this iterative procedure and introduce it into WSD. We then make some adaptations to the output of the original co-attention model to get the score of each word sense.

3 The Co-Attention Model for WSD

In this section, we first give an overview of the **CAN**: co-attention neural network for WSD (Figure 1). And then, we extend it into a hierarchical architecture **HCAN** (Figure 2).

3.1 Overview

The overall architecture of the proposed non-hierarchical co-attention model is shown in Figure 1. It consists of three parts:

---

[1] *Play* in the sentence means *behave in a certain way*.

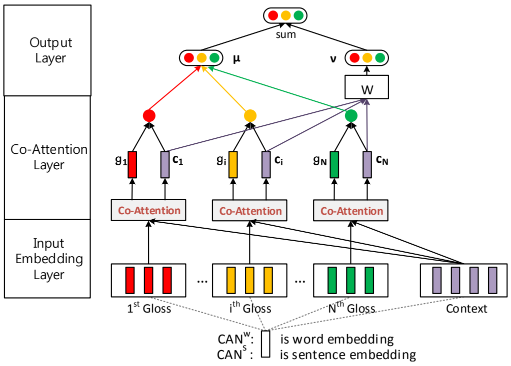

Figure 1: The proposed co-attention neural network.

- **Input Embedding Layer**: First of all, we encode the input context and each gloss [2] into distributed representations C and G, which are also called embeddings in the paper. In Figure 1, if C and G are word embeddings, we call the model CAN^w in the paper. If C and G are sentence embeddings, we call the model CAN^s.
- **Co-Attention Layer**: Then, each co-attention mechanism in this layer generates a context vector and a gloss vector according to the corresponding gloss and context representations. The outputs of the co-attention layer are N pairs of context vector and gloss vector.
- **Output Layer**: Finally, the output layer takes the N pairs of context vector and gloss vector as inputs and calculates the score of each word sense.

Figure 1 shows the non-hierarchical co-attention model which generates either word-level representations (CAN^w) or sentence-level representations (CAN^s). Since both the word-level and sentence-level representations can help to disambiguate the word sense, we extend CAN into a hierarchical model, named as HCAN (Figure 2). The extensions of each layer are listed as follows:

1. The input embedding layer is extended to two sub-layers in the hierarchical architecture which encodes both word-level and sentence-level representations.
2. The co-attention layer is also extended to two attention layers for capturing two different levels' attention.
3. The output layer merges the outputs of the two levels' co-attention layers and generates a sense probability over all word senses.

Since the non-hierarchical model CAN is a subset or a simplified version of the hierarchical model HCAN, the next sections are organized to illustrate the hierarchical co-attention model HCAN [3] shown in Figure 2.

3.2 Input Embedding Layer

We denote each input sentence (context or gloss) as a sequence of words $[x_1, x_2, \ldots, x_{T_x}]$, where T_x is the length of the input sentence.

3.2.1 Word Embedding

After looking up a pre-trained word embedding matrix $E_w \in \mathbb{R}^{d_w \times V}$, we transfer a one-hot vector x_i into a d_w-dimensional vector e_i. We treat $[e_1, e_2, \ldots, e_{T_x}]$ as the word-level representations of the sentence. Specifically, context's word-level representations are denoted as $[e^c_1, e^c_2, \ldots, e^c_n]$ and i-th gloss's word-level representations are denoted as $[e^{g_i}_1, e^{g_i}_2, \ldots, e^{g_i}_m]$, where n and m represent the max length of context and gloss.

3.2.2 Sentence Embedding

We utilize a bi-directional long short-term memory network (Bi-LSTM) to generate the hidden states of the input sentence. Each hidden state h_i is computed by the concatenation of the *forward* hidden state $\overrightarrow{h_i}$, and *backward* hidden state $\overleftarrow{h_i}$. So we treat $[h_1, h_2, \ldots, h_{T_x}]$ as the sentence-level representations. Specifically, context's sentence-level representations are denoted as $[h^c_1, h^c_2, \ldots, h^c_n]$ and i-th gloss's sentence-level representations are denoted as $[h^{g_i}_1, h^{g_i}_2, \ldots, h^{g_i}_m]$.

3.3 Co-Attention Layer

3.3.1 Co-Attention Mechanism

The right part of Figure 2 illustrates the co-attention mechanism which is the most crucial part of the model. The inputs are context representations $C \in \mathbb{R}^{d \times n}$ and gloss representations $G \in \mathbb{R}^{d \times m}$, where d is the dimension of the input representation vector. The outputs are the gloss-aware context vector $c \in \mathbb{R}^d$ and the context-aware gloss vector $g \in \mathbb{R}^d$. Therefore, we can define the co-attention mechanism as a function

$$(c, g) = CoAt(C, G) \tag{1}$$

---

[2] There are N glosses in total, where N is the sense number of the target word in the context.

[3] CAN^w and CAN^s will also be expressed in Section 3.4.

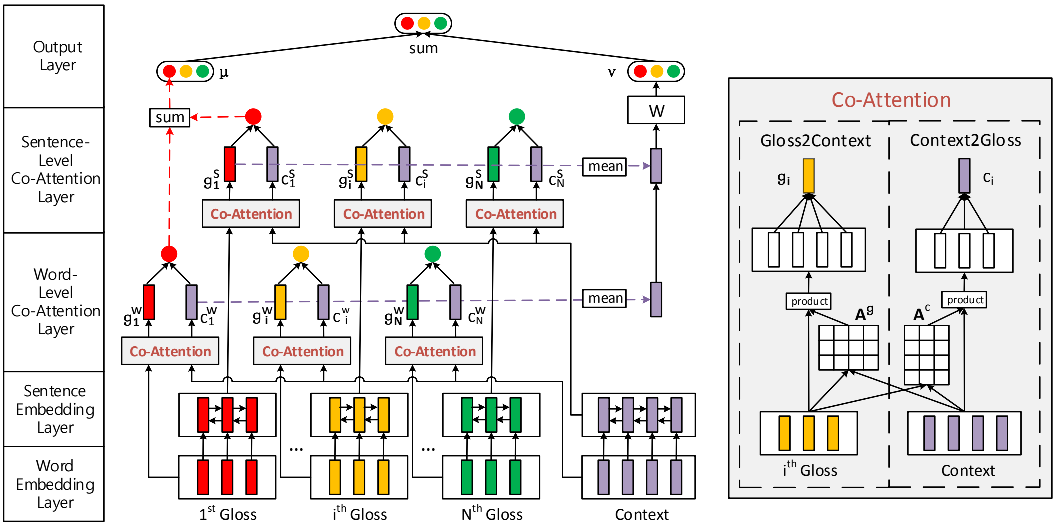

Figure 2: Hierarchical co-attention model for WSD.

Next, we give the detailed definition of the co-attention mechanism function $CoAt$. We begin to compute a similarity matrix A, in which each element A_{ij} indicates the similarity between i-th context word and j-th gloss word. The similarity matrix A is computed by

$$A = C^{\top}UG \in \mathbb{R}^{n\times m} \tag{2}$$

where $U \in \mathbb{R}^{d\times d}$ is a trainable parameter.

Based on the similarity matrix A, we can compute the gloss-to-context attention matrix A^c and context-to-gloss attention matrix A^g.

Gloss-to-Context Attention. Since each gloss word may focus on different context words, we can generate a context representation which is aware of a particular gloss word. Note that each element of A in the j-th column indicates the similarity between j-th gloss word and each context word. Thus, we can get the attention weight for each context word through a softmax function across the column of A:

$$A^c_{:j} = softmax(A_{:j}) \tag{3}$$

where $A_{:j}$ denotes j-th column of A and $A^c_{:j}$ denotes j-th column of $A^c \in \mathbb{R}^{n\times m}$.

Hence we can get the gloss-aware context representations $\hat{C}$ by a product of the initial context representations C and attention weight matrix A^c:

$$\hat{C} = CA^c \in \mathbb{R}^{d\times m} \tag{4}$$

Note that j-th column in $\hat{C}$ means the context representation according to the j-th gloss word. Therefore, we can get the final context vector c by summing across the column of $\hat{C}$:

$$c = \sum_j \hat{C}_{:j} \in \mathbb{R}^d \tag{5}$$

Context-to-Gloss Attention. Conversely, each context word may focus on different gloss words, we can generate a gloss representation which is aware of a particular context word. Since each element of A in the i-th row indicates the similarity between i-th context word and each gloss word, we can get the attention weight of each gloss word through a softmax function across the row of A (or across the column of $A^{\top}$)

$$A^g_{:j} = softmax(B_{:j}) \tag{6}$$

where $B = A^{\top}$, $B_{:j}$ denotes j-th column of B (also j-th row of A) and $A^g_{:j}$ denotes j-th column of $A^g \in \mathbb{R}^{m\times n}$.

Now we can get the context-aware gloss representations in the same way as Equation 4:

$$\hat{G} = GA^g \in \mathbb{R}^{d\times n} \tag{7}$$

Note that j-th column in $\hat{G}$ denotes the gloss representation according to j-th context word. Therefore, we can get the final gloss vector g by summing across the column of $\hat{G}$:

$$g = \sum_j \hat{G}_{:j} \in \mathbb{R}^d \tag{8}$$

3.3.2 Word-Level Co-Attention Layer

Since there are N glosses according to N different word senses, we use N independent co-attention mechanisms in both word-level and sentence-level co-attention layers. And each layer shares a same parameter U in Equation 2. For i-th word-level co-attention mechanism, the inputs are word embeddings of the context and i-th gloss (in Section 3.2.1). Define $C^w = [e_1^c, e_2^c, \dots, e_n^c]$ and $G_i^w = [e_1^{g_i}, e_2^{g_i}, \dots, e_m^{g_i}]$, thus the outputs of i-th word-level co-attention mechanism are computed as

$$(c_i^w, g_i^w) = CoAt(C^w, G_i^w) \tag{9}$$

Inspired by the well-known Lesk algorithm (Lesk, 1986) and its variants (Basile et al., 2014), the score of the i-th word sense can be computed as the similarity of the context vector c_i^w and the gloss vector g_i^w:

$$\beta_i^w = c_i^w \cdot g_i^w \tag{10}$$

The word-level context embedding vector $\hat{c}^w$ can be computed as the average of the N gloss-aware context vectors c_i^w:

$$\hat{c}^w = \frac{1}{N}\sum_{i=1}^{N} c_i^w \tag{11}$$

3.3.3 Sentence-Level Co-Attention Layer

Same to word-level co-attention layer, for the i-th co-attention mechanism, the inputs of sentence-level co-attention layer are Bi-LSTM hidden states of context and the i-th gloss (in Section 3.2.2). Define $C^s = [h_1^c, h_2^c, \dots, h_n^c]$ and $G_i^s = [h_1^{g_i}, h_2^{g_i}, \dots, h_m^{g_i}]$, thus the outputs of i-th sentence-level co-attention mechanism are computed as

$$(c_i^s, g_i^s) = CoAt(C^s, G_i^s) \tag{12}$$

Like Equation 10, we can also calculate a sentence-level score for the i-th word sense by a dot product of the context vector c_i^s and the gloss vector g_i^s:

$$\beta_i^s = c_i^s \cdot g_i^s \tag{13}$$

The sentence-level context embedding vector $\hat{c}^s$ is also computed as the average of N gloss-aware context vectors c_i^s:

$$\hat{c}^s = \frac{1}{N}\sum_{i=1}^{N} c_i^s \tag{14}$$

3.4 Output Layer

The output layer aims to calculate the scores of N senses of the target word x_t and finally outputs a sense probability distribution over the N senses. The final score of each sense is a weighted sum of two values: μ and ν. μ is the similarity score of gloss and context, which reveals the influence of knowledge. ν is generated by the context vector through a linear projection layer, which reveals the influence of labeled data. Finally, the probability distribution $\hat{y}$ over all the senses of the target word is computed as

$$\hat{y} = softmax(\lambda_{x_t}\mu + (1 - \lambda_{x_t})\nu))$$

where $\lambda_{x_t} \in [0, 1]$ is the parameter for word x_t.

For the non-hierarchical model CAN in Figure 1, the final score μ and ν are generated only by the outputs of the one level co-attention layer. Specifically, for the word-level co-attention model CAN^w:

$$\mu = [\beta_1^w, \beta_2^w, \dots, \beta_N^w] \tag{15}$$

$$\nu = W_{x_t}\hat{c}^w + b_{x_t} \tag{16}$$

For the sentence-level co-attention model CAN^s:

$$\mu = [\beta_1^s, \beta_2^s, \dots, \beta_N^s] \tag{17}$$

$$\nu = W_{x_t}\hat{c}^s + b_{x_t} \tag{18}$$

For the hierarchical co-attention model HCAN in Figure 2, the outputs of the word and sentence level layer are merged together to generate the final results. Therefore, the final similarity score between i-th gloss and context is computed as the weighted sum of word-level score β_i^w and sentence-level score β_i^s:

$$\beta_i = \alpha\beta_i^w + (1 - \alpha)\beta_i^s \tag{19}$$

Meanwhile, the final context embedding vector is also generated by a combination of two levels' context embedding vector: $\hat{c}^w$ and $\hat{c}^s$. In order to transfer from word-level encoding space to sentence-level encoding space, we introduce a non-linear projection layer on top of the word-level context vector $\hat{c}^w$. Therefore, the final context embedding vector $\hat{c}$ is generated by

$$\hat{c} = tanh(W\hat{c}^w + b) + \hat{c}^s \tag{20}$$

In total, for the hierarchical co-attention model HCAN:

$$\mu = [\beta_1, \beta_2, \dots, \beta_N] \tag{21}$$

$$\nu = W_{x_t}\hat{c} + b_{x_t} \tag{22}$$

It's noteworthy that in Equation 16, 18 and 22, each ambiguous word x_t has its corresponding weight matrix W_{x_t} and bias b_{x_t}.

During training, all model parameters θ are jointly learned by minimizing a cross-entropy loss between $\hat{y}$ and the true label y.

$$L(\theta) = -\frac{1}{M}\sum_{i=1}^{M}\sum_{j=1}^{N_i} y_{ij}\log\hat{y}_{ij} \tag{23}$$

where M is the number of examples in the dataset, N_i is the word sense number of i-th example, y_{ij} and $\hat{y}_{ij}$ are the true and predict probability of the i-th example belongs to j-th label.

4 Experiments and Evaluation

4.1 Datasets

Validation and Evaluation Datasets: We evaluate our model on several English all-words WSD datasets. For a fair comparison, we use the benchmark datasets proposed by Raganato et al. (2017b) which include five standard all-words fine-grained WSD datasets from the Senseval and SemEval competitions:

- Senseval-2 (Edmonds and Cotton, 2001, **SE2**): It consists of 2282 sense annotations, including nouns, verbs, adverbs and adjectives.

- Senseval-3 task 1 (Snyder and Palmer, 2004, **SE3**): It consists of 1850 sense annotations from three different domains (editorial, news story and fiction), including nouns, verbs, adverbs and adjectives.

- SemEval-07 task 17 (Pradhan et al., 2007, **SE7**): It consists of 455 sense annotations of nouns and verbs, which is the smallest among the five datasets. Like Luo et al. (2018) and Raganato et al. (2017a), we choose SE7 as the validation set.

- SemEval-13 task 12 (Navigli et al., 2013, **SE13**): It consists of 1644 sense annotations from thirteen documents of various domains. SE13 contains nouns only.

- SemEval-15 task 13 (Moro and Navigli, 2015, **SE15**): It's the latest WSD dataset, which consists of 1022 sense annotations from three heterogeneous domains.

Training Dataset: SemCor 3.0 is the largest manually annotated corpus for WSD, which was also used by Luo et al. (2018), Raganato et al. (2017a), Raganato et al. (2017b), Iacobacci et al. (2016), Zhi and Ng (2010), etc. It consists of 226,036 sense annotations from 352 documents, which includes nouns, verbs, adverbs and adjectives.

Knowledge Base: The original WordNet version of sense inventory for SemCor 3.0, SE2, SE3, SE7, SE13, SE15 are 1.4, 1.7, 1.7.1, 2.1, 3.0 and 3.0, respectively. Raganato et al. (2017b) map all the sense annotations in the training and test datasets to WordNet 3.0 via a semi-automatic method. Therefore, We choose WordNet 3.0 as the sense inventory for extracting the gloss.

Data	Noun	Verb	Adj	Adv
SE2	1066	517	445	254

Table 2: Statistics of the different parts of speech annotations in English all-words WSD train and test datasets.

.

4.2 Settings

We use the validation set (SE7) to find the optimal hyper parameters of our models: the word embedding size d_w, the hidden state size d_s of LSTM, the optimizer, etc. However, since there are no adverbs and adjectives in SE7, we randomly sample some adverbs and adjectives from training dataset into SE7 for validation. We use the pre-trained word embeddings [4]. The hidden state size d_s is 256. The mini-batch size is set to 32. The optimizer is Adam (Kingma and Ba, 2014) with 0.001 initial learning rate. In order to avoid over-fitting, we use dropout regularization on the outputs of LSTM and set drop rate to 0.5. Orthogonal initialization is used for initialing weights in LSTM and random uniform initialization with range [-0.1, 0.1] is used for others. Training runs for up to 50 epochs with early stopping if the validation loss doesn't improve within the last 5 epochs.

Table 3: F1-score (%) for fine-grained English all-words WSD on the test sets. **Bold** font indicates best systems. The * represents the systems which don't use any lexical knowledge. The five blocks list the baseline, 2 knowledge-based systems, 2 supervised feature-based systems, 7 neural-based systems and our models, respectively.

4.3 Results and Discussion

4.3.1 English all-words results

Table 3 shows the results on four test datasets and different parts of speech. Note that all the systems in Table 3 are trained on SemCor 3.0.

In the first block, we show the MFS baseline, which simply selects the most frequent sense in the training dataset.

In the second block, we show two latest knowledge-based (unsupervised) systems. Lesk$_{ext+emb}$ is a variant of the well-known Lesk algorithm (Lesk, 1986) which computes the overlap of gloss and context as the score of word sense. Babelfy (Moro et al., 2014) is a graph-based system performed on BabelNet (Navigli and Ponzetto, 2012). We can find that MFS is a strong baseline for knowledge-based systems.

In the third block, we show two traditional supervised systems which only learn from labeled data based on manual designed features. IMS (Zhi and Ng, 2010) is a flexible framework which trains K SVM classifiers for K polysemous words. Its variant IMS$_{+emb}$ (Iacobacci et al., 2016) adds word embedding features into IMS. Both of them train a dedicated classifier for each word individually. In other words, each target word has its own parameters. Therefore, IMS$_{+emb}$ is a hard to beat system for many neural networks which also only uses labeled data but builds a unified system for all the polysemous words.

In the fourth block, we show four latest neural networks. Except for Bi-LSTM (Kågebäck and Salomonsson, 2016), which is a baseline for neural models, the others all utilize not only labeled data but also lexical knowledge. Bi-LSTM$_{+att.+LEX}$ (Raganato et al., 2017a) and its variant Bi-LSTM$_{+att.+LEX+POS}$ are multi-task learning frameworks for WSD, POS tagging and LEX with context self-attention mechanism. GAS (Luo et al., 2018) is a gloss-augmented neural network in an improved memory network paradigm. The best neural network is GAS$_{ext}$ which extends from GAS and uses more gloss knowledge via the semantic relations in WordNet. [5]

In the last block, we give the performance of our proposed co-attention models for WSD. We can see that our best model HCAN improves state-of-the-art result by 0.5% on the concatenation of four datasets. Even though we use less gloss knowledge than the previous best system GAS$_{ext}$, our co-attention models can still get the best results on three test datasets. For non-hierarchical models, CAN^{s} performs much better than the CAN^{w}, which reveals that global sentence-level information is much more useful than local word-level information. Integration of these two levels' information (HCAN) can further boost the performance. What's more, we find that our best model HCAN performs best on all parts of speech, except for *adverbs*. However, there are only 346 examples about adverbs which account for 5% of the four test datasets, thus 1% drop on adverbs means only 4 examples are wrongly classified which will make little influence on the overall score.

Table 4: Ablation study of the proposed model HCAN.

.

4.4 Ablation Study

In this part, we further discuss the impacts of the components of our hierarchical model HCAN. In order to ablate the co-attention mechanism, we replace the co-attention function $CoAt$ in Equation 1 with a function Avg which simply calculates the average of input representation vectors. Specifically, in function Avg, the outputs $c = \sum_j C_{:j}$ and $g = \sum_j G_{:j}$.

We re-train HCAN by ablating certain components:

- *No Attention*: We totally replace the co-attention function $CoAt$ with Avg in both word-level and sentence-level co-attention layers. This is the baseline for comparison.
- *W/O Word-level Attention*: We replace the word-level co-attention function $CoAt$ with Avg. Note that this ablation model is different from CAN^s, for that the word-level representation vector $\hat{c}^w$ is used to calculate the final score in this ablation model.
- *W/O Sentence-level Attention*: We replace the sentence-level co-attention function $CoAt$ with Avg. Note that this ablation model is not same as CAN^w, for the sentence-level representation vector $\hat{c}^s$ is also used to calculate the final score in this ablation model.
- *W/O Context2Gloss Attention*: We remove the attention of generating the context vector, which means all elements in A^g are set to 1.
- *W/O Gloss2Context Attention*: We remove the attention of generating the gloss vector, which means all elements in A^c are set to 1.

Table 4 indicates the effectiveness of different components in the proposed model HCAN. It shows that without any attention mechanism, the overall score declines 2.3%.

Ablated versions without word, sentence level co-attention decline 0.6% and 2.0%, respectively. It reveals that sentence-level co-attention mechanism seems much more important to HCAN, which is consistent with the scores of CAN^s and CAN^w. However, we find that the results of ablated versions without word-level and sentence-level co-attention are worse than CAN^s and CAN^w. We hypothesize that it is because that the context and gloss vector generated from the layer (or level) which doesn't use attention mechanism may bring some noise to the final scores.

Without the context-to-gloss attention, the score declines 1.2% on concatenation of the four test datasets. Conversely, without the gloss-to-context attention, the score declines 0.4%. It is probably due to that the context-to-gloss attention which generates the context-aware gloss vector is more *direct* to find out the correct word sense.

In conclusion, the results in Table 4 show that all components in the proposed hierarchical co-attention model HCAN can contribute to boosting the performance of WSD.

5 Conclusions

In this paper, we investigate the problem of incorporating gloss knowledge into neural network for Word Sense Disambiguation. We find that the gloss can highlight the important words in the context, and later contribute to the representation of the context. Meanwhile, context can also help to focus on the words in gloss of the right word sense. Therefore, we propose a co-attention mechanism to model the gloss-to-context and context-to-gloss attention. Furthermore, in order to capture not only local word-level features but also global sentence-level features, we extend the co-attention model into a hierarchical architecture. The experimental results show that our proposed models achieve the state-of-the-art results on several standard English all-words WSD datasets.
