Full Model	**96.52**	**1.23**

Table 4: Feature ablation comparison of our proposed model on ATIS. slot filling and intent detection result are shown each row after after we exclude each feature from the full architecture

achieves better results than separate learning. It can be interpreted that the two tasks are highly correlated and boost the performance each other. The slot filling task enables the model to learn more meaningful representations which give more supervisory signals for the learning of shared parameters. Similarly, intent is also useful to determine the slot label.

4.6 Ablation Study

The ablation study is performed to evaluate whether and how each part of our model contributes to our full model. To further evaluate the advances of our gating architecture for joint learning, we ablate some techniques used in our model. We ablate three important components and conduct different approaches in this experiment. Note that all the variants are based on joint learning with intent-augmented gate:

- W/O char-embedding, where no character embeddings are added to the embedding layer. The embedding layer is composed of word embeddings only.
- W/O self-attention, where no self-attention is modelled after the embedding layer and in the intent-augmented gating layer. The intent gate is computed by the output of BiLSTM and intent embedding.
- W/O attention-gating, where no self-attention mechanism is performed in the intent-augmented gating layer. The gate is computed by the output of BiLSTM and intent embedding. But we still use the self-attention on top of embedding layer to augment the context information.

Table 4 shows the joint learning performance of our model on ATIS data set by removing one module at a time. We find that all variants of our model perform well based on our gate mechanism. As listed in the table, all features contribute to both slot filling and intent classification task.

If we remove the self-attention from the holistic model or just in the intent-augmented gating layer, the performance drops dramatically. The result can be interpreted that self-attention mechanism computes context representation separately and enhances the interaction of features in the same aspect. We can see that self-attention does improve performance a lot in a large scale, which is consistent with findings of previous work (Vaswani et al., 2017; Lin et al., 2017).

If we remove character-level embeddings and only use word-level embeddings, we see 0.22% drop in terms of F1-score. Though word-level embeddings represent the semantics of each word, character-level embeddings can better handle the out-of-vocabulary (OOV) problem which is essential to determine the slot labels.

5 Conclusion

In this paper, we propose a novel self-attentive model gated with intent for spoken language understanding. We apply joint learning on both intent detection and slot filling tasks. In our model, self-attention mechanism is introduced to better represent the semantic of utterance, and gate mechanism is introduced to make full use of the semantic correlation between slot and intent. Experiment results on ATIS dataset have shown efficiency of our model and outperforms the state-of-the-art approach on both tasks. Besides, our model also shows consistent performance gain over the independent training models. In future works, we plan to improve our model by introducing extra knowledge.

Abstract

In a dialog, there can be multiple valid next utterances at any point. The present end-to-end neural methods for dialog do not take this into account. They learn with the assumption that at any time there is only one correct next utterance. In this work, we focus on this problem in the goal-oriented dialog setting where there are different paths to reach a goal. We propose a new method, that uses a combination of supervised learning and reinforcement learning approaches to address this issue. We also propose a new and more effective testbed, permuted-bAbI dialog tasks [1] by introducing multiple valid next utterances to the original-bAbI dialog tasks, which allows evaluation of goal-oriented dialog systems in a more realistic setting. We show that there is a significant drop in performance of existing end-to-end neural methods from 81.5% per-dialog accuracy on original-bAbI dialog tasks to 30.3% on permuted-bAbI dialog tasks. We also show that our proposed method improves the performance and achieves 47.3% per-dialog accuracy on permuted-bAbI dialog tasks.

1 Introduction

End-to-end, neural conversation models that learn from chatlogs of human-to-human interaction hold the promise of quickly bootstrapping dialog systems and keep evolving them based on new data. Recent work ((Vinyals and Le, 2015; Bordes et al., 2016; Serban et al., 2016)) has shown that dialog models can be trained in an end-to-end manner with satisfactory results.

However, human dialog has some unique properties that many other learning tasks do not. For any given dialog state or input, multiple correct next utterances or answers may be possible; i.e given the dialog so far, there are several different utterances which one can say next that would be valid. However, this property of dialog is not taken into account in the present way of training end-to-end neural dialog systems.

There are two broad ways in which present day neural dialog systems can be trained: Supervised Learning (SL) and Reinforcement Learning (RL). In the RL setting, the dialog system learns through trial and error with reinforcement (rewards at the end or at key dialog points) from a human or a simulator. RL training for dialog is a hard problem to solve. It is difficult to define and award appropriate rewards, and to learn language from scratch through these rewards. RL training also demands a large amount of training interaction. In order to handle these challenges, RL methods are almost always complimented with a SL phase.

In SL setting, a fixed set of dialog data is collected from humans and the dialog system is trained to imitate that data. When a new dialog dataset is curated, the data is extracted from real-world chat logs from human-human conversation, where one human acts as the agent. It is not possible to know all of the valid next utterances for a given dialog state at any single time. A particular dialog in the dataset has access to only one of the valid next utterances given the dialog history and the current utterance. Another valid next utterance could be present in some other dialog in the dataset.

Since for a given dialog only one correct answer is available at any single time, the gradients are calculated based on the assumption that there is only one correct next utterance for the given dialog

state. This results in reducing the probability of other valid next utterances for that dialog. While all this is true for dialog in general, in this work, we focus on the goal-oriented dialog setting.

We propose a novel method which handles the issue of learning multiple possibilities for completing a goal-oriented dialog task. Our presentation is organized as follows: In Sections 2 and 3, we define the multiple-utterance problem and point out the limitations of current learning methodologies.

Section 4 describes our proposed method, which combines Supervised Learning and Reinforcement Learning approaches for handling multiple correct next utterances. In Section 5, we introduce permuted-bAbI dialog tasks, which is our proposed testbed for goal-oriented dialog. Section 6 details our experimental results across all datasets and all models.

2 Multiple-utterance problem in goal-oriented dialog

Goal-oriented dialog tasks are those in which there is an explicit goal that the system tries to achieve through the dialog. These tasks typically involve getting some information from the user, interacting with an external Knowledge Base (KB) and giving back information to the user. Simple examples (form filling) include restaurant reservation, hotel booking etc., whereas complex tasks could involve a combination of informative and form filling tasks (e.g. IT support, customer care etc.).

There could be multiple ways/strategies to achieve a given task. When a dataset is collected from different people performing the task, these different ways of solving the task get reflected in it. These variations could be as simple as difference in the order in which the system asks the information from the user, or as complex as following a completely different line of questions/answers to achieve the task. For example, in an IT support scenario, one may ask a sequence of standard questions or start from common problems and once eliminated, follow the standard set of questions. In the dataset, they turn into multiple valid next utterances for a given dialog so far.

Our objective in this paper is not to mimic all humans from whom the data was collected from or all the possible strategies, but rather to use that knowledge and learn to perform the task better and faster.

3 Issues with the present methods

Consider a goal-oriented dialog dataset for restaurant reservation where the dialog system has to acquire cuisine, location, number of people and price range information from the user before retrieving restaurant options. Consider two dialogs (A and B) in the dataset which have the same first system utterance (`S1a` is same as `S1b`). Let their dialog state vector after encoding the dialog until `S1` be s. This state vector s is what will be used for next utterance generation or retrieval. Their next utterance is different because of the variation in the order in which the information is asked from the user as shown below. i.e `S2a` is different from `S2b`.

Dialog A
U: Hello !
`S1a: Hello, what can I help you with today?`
U: Can you book a table for six people with French food?
`S2a: Where should it be?`
U: In Bombay
`S3a: Which price range are you looking for?`
U: I am looking for a cheap restaurant.
`S4a: Ok, let me look into some options for you.`

Dialog B
U: Hello !
`S1b: Hello, what can I help you with today?`
U: Can you book a table for six people with French food?
`S2b: Which price range are you looking for?`
U: I am looking for a cheap restaurant.
`S3b: Where should it be?`
U: In Bombay
`S4b: Ok, let me look into some options for you.`

These two dialogs might be present in different places in the dataset. When dialog A is part of the batch for which loss is calculated and parameters are updated, the dialog system is asked to produce `S2a` from s. Here, the loss could be negative log-likelihood, squared error or anything that tries to push s towards producing `S2a`. In this process, the probability of the dialog system producing `S2b`, an equally valid answer, is reduced. The

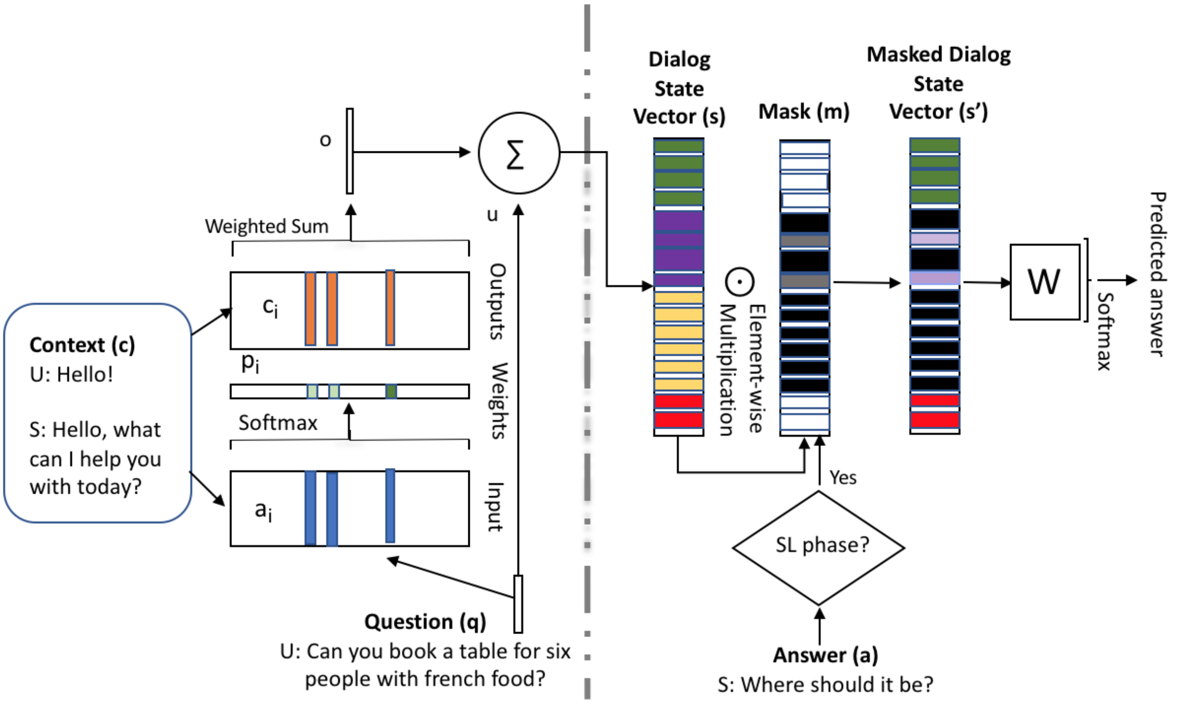

Figure 1: **Mask-memN2N** - *Left*: A single layer version of memN2N. *Right*: Masking

reverse happens when the dialog system encounters a batch with dialog B. This is true whether a softmax or a sigmoid non-linearity for each unit is used in the output layer. In essence, the system is expected to learn a one to many function, but is forced to produce only one of the valid outputs at one time (that is all we have at any one time), while telling that all other outputs are wrong.

Note that this could be a problem even when the dialogs are similar (semantically) in the beginning, but not the same exact dialog. For simplicity, we show an example where two dialogs have the same beginning and only 2 valid next utterances occur.

4 Proposed Method

The proposed method has two phases. In one phase, the dialog system tries to learn how to perform dialog from the dataset by trying to mimic it and in the other it learns through trial and error. The former uses supervised learning and the latter uses reinforcement learning. Consider a dialog state vector s. This has all the information from the dialog so far and is used for next utterance generation or retrieval. Any neural method such as memory network (Weston et al., 2014), HRED (Sordoni et al., 2015) etc. can be used for encoding and producing the dialog state vector s. As discussed earlier for the state vector s, there could be multiple valid next utterances.

During the SL phase, at each data point, the dialog system is trained to produce the one next utterance provided in that data point and is penalized even if it produces one of the other valid next utterances. We avoid this by providing the dialog system, the ability to use only parts of the state vector to produce that particular next utterance. This allows only parts of the network to be affected that were responsible for the prediction of that particular answer. The dialog system can retain other parts of the state vector and values in the network that stored information about other valid next utterances. This is achieved by generating a mask vector m which decides which parts of the state vector s should be used for producing that particular answer. This is achievable, as m is learned as function of s and the actual answer a present in the given dialog data point.

In the RL phase, however, the dialog system is rewarded if it produces an answer that is among any of the set of valid correct answers. While in the SL phase the dialog system had access to the actual answer a at given time to produce the mask, in the RL phase the dialog system produces the mask by only using the dialog state vector s.

$$\text{Supervised Learning phase} \tag{1}$$

$$m = \sigma(W_s s + W_a a + b_{sl})$$

$$s' = m * s$$

$$\text{Reinforcement Learning phase} \tag{2}$$

$$m = \sigma(W_s s + W_r s + b_{rl})$$

$$s' = m * s$$

where W's and b's are the parameters learned, σ is an element wise sigmoid non-linearity and s' is the masked dialog state vector that is used by the dialog system to perform the downstream task such as next utterance generation or retrieval. The parameters of the network that produce s and that follow s' are shared between the two phases. While there are different ways of combining the two phases during training, the RL phase which does not use the answer for its mask is what is used during testing. The masking approach described above is illustrated in Fig 1.

In this work, SL phase is performed first, followed by RL phase. In the SL phase, the dialog system learns different dialog responses and behaviours from the dataset. It has the ability to learn multiple possible next utterances without one contradicting/hindering the learning of the other much. In the RL phase, the dialog system might settle on a unique behaviour that it finds best for it to perform the task and uses that during test time as well.

5 Permuted bAbI dialog tasks

Bordes et al. (2016) proposed bAbI dialog tasks as a testbed to break down the strengths and shortcomings of end-to-end dialog systems in goal-oriented applications. There are five tasks, generated by a simulation set in the context of restaurant reservation, with the final goal of booking a table. The simulation is based on an underlying KB, whose facts contain restaurants and their properties. Tasks 1 (Issuing API calls) and 2 (Updating API calls) test the dialog system to implicitly track dialog state, whereas Task 3 (Displaying options) and 4 (Providing extra information) check if the system can learn to use KB facts in a dialog setting. Task 5 (Conducting full dialogs) combines all tasks.

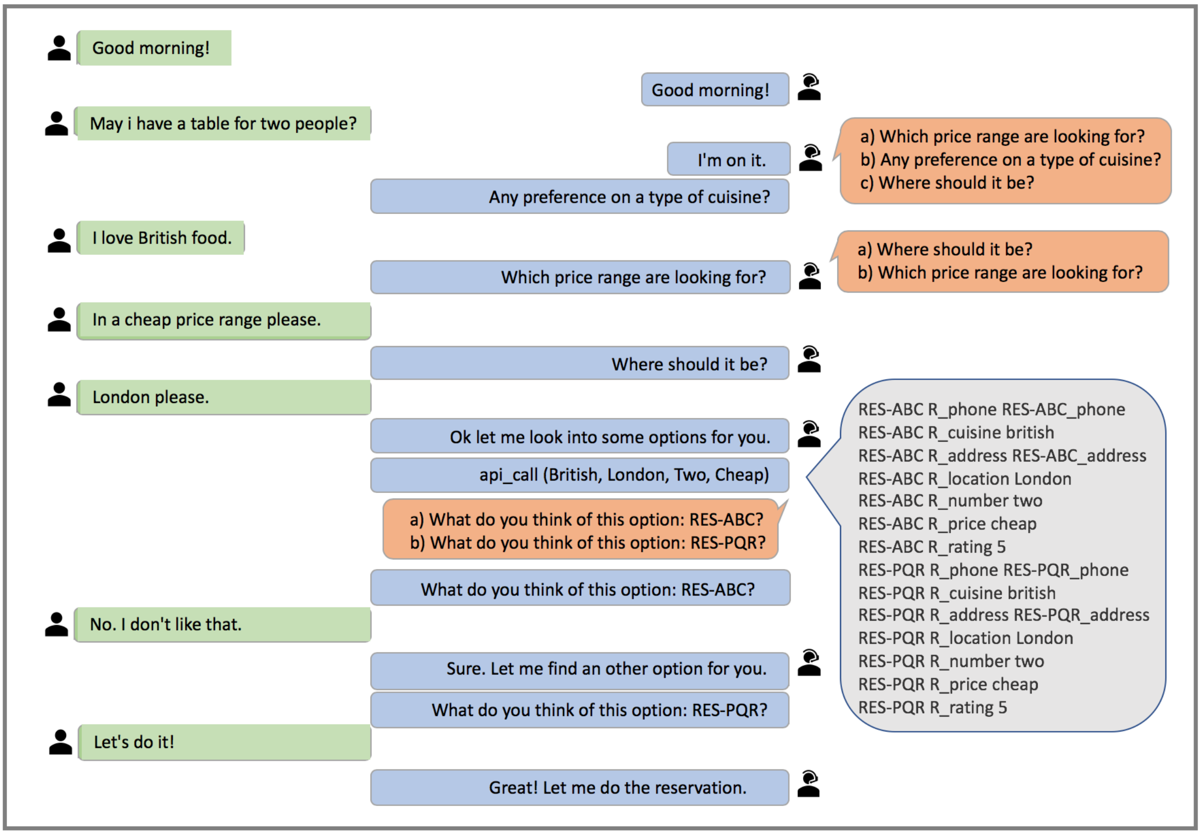
(Bordes et al., 2016) used natural language patterns to create user and system utterances. There are 43 patterns for the user and 20 for the system, which were combined with the KB entities to form thousands of different utterances. However, on a closer analysis of the testbed, we observe that even though there are thousands of different utterances, these utterances always follow a fixed deterministic order (predefined by the simulation), which makes the tasks easier and unsuitable to mimic conversations in the real-world. For example, for Task 1, the system follows a predefined order to ask for missing fields required to complete the dialog state. In Task 3, all restaurants retrieved have a unique and different rating. While this makes evaluation deterministic and easier, these hidden settings in the simulation create conversations, which are simpler compared to real-world conversations for restaurant reservation.

We propose permuted-bAbI dialog tasks, an extension of original-bAbI dialog tasks, which make our proposed testbed more appropriate for evaluating dialog systems in goal-oriented setting. In *original-bAbI dialog tasks* at a given time in the conversation, there is **only one** correct system utterance. *Permuted-bAbI dialog tasks* allow **multiple** correct system utterances at a given point in the conversation.

We propose the following changes to original-bAbI dialog tasks. In Task 1, a user request defines a query that can contain from 0 to 4 of the required fields to make a reservation. The system asks questions to fill the missing fields and eventually generate the correct corresponding API call. However, the system asks for information in a *deterministic* order -
Cuisine → *Location* → *People* → *Price*
to complete the missing fields. In permuted-bAbI dialog tasks, we don't follow a deterministic order and allow the system to ask for the missing fields in any order.

In Task 3, for the API call matching the user request, the facts are retrieved from the KB and provided as part of dialog history. The system must propose options to users by listing the restaurant names sorted by their corresponding rating (from higher to lower) until users accept. However, each restaurant has a different rating. In permuted-bAbI dialog tasks, multiple restaurants can have the same rating but the system must still propose the restaurant names following the decreasing order of rating, which allows multiple valid next utterances.

In Task 5, Tasks 1-4 are combined to generate



Good morning!

Good morning!

May i have a table for two people?

I'm on it.

Any preference on a type of cuisine?

a) Which price range are looking for?
b) Any preference on a type of cuisine?
c) Where should it be?

I love British food.

Which price range are looking for?

a) Where should it be?
b) Which price range are looking for?

In a cheap price range please.

Where should it be?

London please.

Ok let me look into some options for you.

api_call (British, London, Two, Cheap)

RES-ABC R_phone RES-ABC_phone
RES-ABC R_cuisine british
RES-ABC R_address RES-ABC_address
RES-ABC R_location London
RES-ABC R_number two
RES-ABC R_price cheap
RES-ABC R_rating 5
RES-PQR R_phone RES-PQR_phone
RES-PQR R_cuisine british
RES-PQR R_address RES-PQR_address
RES-PQR R_location London
RES-PQR R_number two
RES-PQR R_price cheap
RES-PQR R_rating 5

a) What do you think of this option: RES-ABC?
b) What do you think of this option: RES-PQR?

What do you think of this option: RES-ABC?

No. I don't like that.

Sure. Let me find an other option for you.

What do you think of this option: RES-PQR?

Let's do it!

Great! Let me do the reservation.

Figure 2: **Permuted-bAbI dialog tasks.** A user (in green) chats with a dialog system (in blue) to book a table at a restaurant. At a given point in the dialog, the dialog system has multiple correct next utterances (in orange). The dialog system can choose either of the multiple correct utterances as the next utterance. The list of restaurants are returned from the API_call (in grey) also contain multiple restaurants with the same rating, giving the dialog system more options to propose to the user.

full dialogs. In permuted-bAbI dialog tasks, we incorporate the changes for both Task 1 and Task 3 mentioned above to the final Task 5 (Conducting full dialogs).

Fig 2 shows a dialog sample from permuted-bAbI dialog tasks. Our proposed testbed (We release and show experiments on permuted version of Task 5, i.e. Conducting full dialogs set, as tasks 1-4 are subsets of a full conversation and don't represent a complete meaningful conversation standalone) is more closer to a real-world restaurant reservation conversation, in comparison to the original-bAbI dialog tasks. We release two versions of permuted-bAbI dialog tasks - permuted-bAbI dialog task* (the full dataset with all permutations. There are around 11,000 dialogs in each set and the exact number varies for train, val, test and test-OOV sets), which contains all permutations (the full dataset) and permuted-bAbI dialog task, which contains 1000 dialogs randomly sampled (we used random seed = 599 for sampling) from permuted-bAbI dialog task*. We choose a random 1000 subset from each of train, val, test and test-OOV sets to match the number of dialogs in original-bAbI dialog task. Another key point to choose a small subset and to not include all permutations in the training set is that it allows to mimic real-world data collection. For a real-world use-case, as the number of required fields and user options increase, the cost for gathering data covering all permutations will increase exponentially, and one can't guarantee that enough training examples for all permutations will be present in the collected dataset. Note that, since there are multiple correct next utterances, we also modify the evaluation criteria so that the system is rewarded if it predicts any of the multiple correct next utterances.

6 Experiments and Results

End-to-end memory networks (Sukhbaatar et al., 2015) are an extension of Memory Networks pro-

Dataset	no match-type		+ match-type	
	Per-turn	Per-dialog	Per-turn	Per-dialog
Original-bAbI dialog task	98.5	77.1	98.8	81.5
Permuted-bAbI dialog task*	96.4	58.2	96.9	63.9
Permuted-bAbI dialog task	91.8	22	93.3	30.3
OOV: Original-bAbI dialog task	65.6	0	78.3	0
OOV: Permuted-bAbI dialog task*	63.6	0	78.4	0
OOV: Permuted-bAbI dialog task	63.4	0.5	78.1	0.6

Table 1: **Test results for our baseline end-to-end memory network model across the three datasets.** Results (accuracy %) are given in the standard setup and out-of-vocabulary (OOV) setup. Results are given for both with and without match-type features.

posed by (Weston et al., 2014) which have been successful on various natural language processing tasks. End-to-end memory networks are trained end-to-end and use a memory component to store dialog history and short-term context to predict the required response. They perform well on original-bAbI dialog tasks and have been shown to outperform some other end-to-end architectures based on Recurrent Neural Networks. Hence, we chose them as end-to-end model baseline. We perform experiments on the three datasets mentioned above across all our models. We also perform experiments with match-type features proposed by (Bordes and Weston, 2016b), which allow the model to use type-information for entities like location, cuisine, phone number etc. The results for our baseline model, our proposed model and results on our ablation study are described below. The test results reported are calculated by choosing the model with highest validation per-turn accuracy across multiple runs.

6.1 Baseline model: memN2N

A single layer version of the memN2N model is shown in Fig.1. A given sentence (i) from the context (dialog history) is stored in the memory by it's input representation (a_i). Each sentence (i) also has a corresponding output representation (c_i). To identify the relevance of a memory for the next-utterance prediction, attention of query over memory is computed via dot product, where (p_i) represents the probability for each memory in equation 3. An output vector (o) is computed by a weighted sum of the memory embeddings (c_i) with their corresponding probabilities in equation 4. The output vector (o) represents the overall embedding for the context. The output vector (o) and query (u) added together represent the dialog state vector (s) in equation 5.

$$p_i = \text{Softmax}(u^T(a_i)) \tag{3}$$

$$o = \sum_i p_i c_i \tag{4}$$

$$s = (o + u) \tag{5}$$

Our results for our baseline model across the three datasets are given in Table 1. The hyperparameters used for training the baseline models are provided in Appendix A.1.

The first 3 rows show the results for the three datasets in the standard setup, and rows 4-6 show results in the Out-Of-Vocabulary (OOV) setting. Per-response accuracy counts the percentage of responses that are correct (i.e., the correct candidate is chosen out of all possible candidates). Note that, as mentioned above in Section 5, since there are multiple correct next utterances, a response is considered correct if it predicts any of the multiple correct next utterances. Per-dialog accuracy counts the percentage of dialogs where every response is correct. Therefore, even if only one response is incorrect, this might result in a failed dialog, i.e. failure to achieve the goal of restaurant reservation. We report results both with and without match type features, shown in the last two columns.

From Table 1, we observe that the baseline model performs poorly on permuted-bAbI dialog tasks (both full dataset and 1000 random dialogs). For permuted-bAbI dialog task*, the baseline model achieves 58.2% on per-dialog accuracy, but the number decreases to only 22% for permuted-bAbI dialog task (1000 random dialogs). This implies that only 1 out of every 4 dialogs might be successful in completing the goal. The results improve slightly by using match-type features, but 30% per-dialog accuracy is still

Model	no match-type		+ match-type	
	Per-turn	Per-dialog	Per-turn	Per-dialog
memN2N	91.8	22	93.3	30.3
memN2N + all-answers†	88.5	14.9	92.5	26.4
Mask-memN2N	93.4	**32**	95.2	**47.3**
OOV: memN2N	63.4	0.5	78.1	0.6
OOV: memN2N + all-answers†	60.8	0.5	74.9	0.6
OOV: Mask-memN2N	63.0	0.5	80.1	1

Table 2: **Test results for various models on permuted-bAbI dialog task.** Results (accuracy %) are given in the standard setup and OOV setup; and both with and without match-type features.

very low for real-world use. These results clearly demonstrate that the end-to-end memory network model does not perform well on our proposed testbed, which is more realistic and mimics real-world conversations more closely.

6.2 Mask End-to-End Memory Network: Mask-memN2N

Our model, Mask-memN2N, shown in Fig 1, is built on the baseline memN2N model described above, except for an additional masking performed to the dialog state vector. The SL phase is performed for the first 150 epochs. The best performing model chosen based on validation accuracy is used as a starting point for the RL phase. All parameters except for the network that produces the masks are shared between the two phases. During the SL phase, the mask parameters of the RL phase are pre-trained to match the mask produced in SL phase using an L2 loss. Through this approach, when the model transitions in the RL phase, it does not need to explore the valid masks and hence, the answers from scratch. Instead, its exploration will now be more biased towards relevant answers. For the RL phase, we use REINFORCE (Williams, 1992) for training the system. An additional loss term is added to increase entropy. The hyperparameters used, including the exact reward function are provided in Appendix A.2.

6.3 Model comparison

Our results for our proposed model and comparison with other models for permuted-bAbI dialog task are given in Table 2. Table 2 follows the same format as Table 1, except we show results for different models on permuted-bAbI dialog task. We show results for three models - memN2N, memN2N + all-answers and our proposed model, Mask-memN2N.

In the memN2N + all-answers model, we extend the baseline memN2N model and though not realistic, we provide information on all correct next utterances during training, instead of providing only one correct next utterance. The memN2N + all-answers model has an element-wise sigmoid at the output layer instead of a softmax, allowing it to predict multiple correct answers. This model serves as an important additional baseline, and clearly demonstrates the benefit of our proposed approach.

From Table 2, we observe that the memN2N + all-answers model performs poorly, in comparison to the memN2N baseline model both in standard setup and OOV setting, as well as with and without match-type features. This shows that the existing methods do not improve the accuracy of a dialog system even if all correct next utterances are known and used during training the model. Our proposed model performs better than both the baseline models. In the standard setup, the per-dialog accuracy increases from 22% to 32%. Using match-type features, the per-dialog accuracy increases considerably from 30.3% to 47.3%. In the OOV setting, all models perform poorly and achieve per-dialog accuracy of 0-1% both with and without match-type features. These results are similar to results for original-bAbI dialog Task 5 from Bordes and Weston (2016b) and our results with the baseline model.

Overall, Mask-memN2N is able to handle multiple correct next utterances present in permuted-bAbI dialog task better than the baseline models. This indicates that permuted-bAbI dialog task is a better and effective evaluation proxy compared to original-bAbI dialog task for real-world data. This also shows that we need better neural approaches, similar to our proposed model, Mask-

Model	Per-turn	Per-dialog
Mask-memN2N	93.4	32
Mask-memN2N (w/o entropy)	92.1	24.6
Mask-memN2N (w/o L2 mask pre-training)	85.8	2.2
Mask-memN2N (Reinforcement learning phase only)	16.0	0

Table 3: **Ablation study of our proposed model on permuted-bAbI dialog task.** Results (accuracy %) are given in the standard setup, without match-type features.

memN2N, for goal-oriented dialog in addition to better testbeds for benchmarking goal-oriented dialogs systems.

6.4 Ablation study

Here, we study the different parts of our model for better understanding of how the different parts influence the overall model performance. Our results for ablation study are given in Table 3. We show results for Mask-memN2N in various settings - a) without entropy, b) without pre-training mask c) reinforcement learning phase only.

Adding entropy for the RL phase seems to have improved performance a bit by assisting better exploration in the RL phase. When we remove L2 mask pre-training, there is a huge drop in performance. In the RL phase, the action space is large. In the bAbI dialog task, which is a retrieval task, it is all the candidate answers that can be retrieved which forms the action set. L2 mask pre-training would help the RL phase to try more relevant actions from the very start.

From Table 3 it is clear that the RL phase individually does not perform well; it is the combination of both the phases that gives the best performance. When we do only the RL phase, it might be very tough for the system to learn everything by trial and error, especially because the action space is so large. Preceding it with the SL phase and L2 mask pre-training would have put the system and its parameters at a good spot from which the RL phase can improve performance. Note that it would not be valid to check performance of the SL phase in the test set as the SL phase requires the actual answers for it to create the mask.

7 Related Work

End-to-end dialog systems have been trained to show satisfactory performance in goal-oriented setting, as shown by (Bordes et al., 2016) and (Seo et al., 2016)). The idea of allowing the system to learn to attend to different parts of the state vector at different times depending on the input that the proposed model uses has been used in different settings before. To name a few, Bahdanau et al. (2014) use it for Machine Translation (MT), where the MT system can attend to different words in the input language sentence while producing different words in the output language sentence. Xu et al. (2015) use it for image caption generation where the system attends to different parts of the image while generating different words in the caption. Madotto and Attardi (2017) use it for Question Answering (QA), where the QA system attends and updates different parts of the Recurrent Neural Network story state vector based on the sentence the system is reading in the input story.

In the past, goal-oriented dialog systems would model the conversation as partially observable Markov decision processes (POMDP) (Young et al. (2013)). However, such systems require many hand-crafted features for the state and action space representations, which limited their use only to narrow domains. In recent years, several corpora have been made available for building data-driven dialog systems (Serban et al., 2015). However, there are no good resources to train and test end-to-end models in goal-oriented scenarios.

Some datasets are proprietary (e.g., Chen et al. (2016)) or require participation to a specific challenge and signing a license agreement (e.g., DSTC4 (Kim et al., 2017)). Several datasets have been designed to train or test dialog state tracker components (Henderson et al. (2014), Asri et al. (2017), which are unsuitable for training end-to-end dialog systems, either due to limited number of conversations or due to noise. Recently, some datasets have been designed using crowdsourcing (Hixon et al. (2015), Wen et al. (2015), Su et al. (2015)) e.g., Amazon Mechanical Turk, CrowdFlower etc., but dialog systems built for them are harder to test automatically and involve another set of crowdsource workers for comparing them.

(Bordes et al., 2016) proposed goal-oriented bAbI dialog tasks, a testbed created from a simulation of restaurant reservation setting, which allows easy evaluation and interpretation of end-to-end dialog systems. However, the testbed doesn't mimic real world conversations and conversations are generated around a deterministic set of patterns. Recently, datasets designed using Wizard-of-Oz seting (Eric and Manning (2017), Wen et al. (2016)) show promise, but they are limited in scale, and evaluation metrics are either based around BLEU score and entity F1 scores or require crowdsource workers for evaluation.

8 Conclusion

We propose a method that uses masking to handle the issue of making wrong updates at different times because of the presence of multiple valid next utterances in a dataset, but having access to only one of them at any time. The method has a SL phase where the mask uses the answer as well, and an RL phase, where the system learns to generate the mask solely from its dialog state vector.

We modify the synthetic original-bAbI dialog task to create a more realistic and effective testbed, permuted-bAbI dialog task (which we have made publicly available), that has the issue of multiple next utterances as would be the case with any dataset created from human-human dialogs. Our experiments show that there is a significant drop in performance of the present neural methods in the permuted-bAbI dialog task compared to the original-bAbI dialog task. The experiments also confirm that the proposed method is a step in the right direction for bridging this gap.

A Appendix: Training Details

A.1 Baseline model: memN2N

The hyperparameters used for the baseline model are as follows: hops = 3, embedding_size = 20, batch_size = 32. The entire model is trained using stochastic gradient descent (SGD) (learning rate = 0.01) with annealing (anneal_ratio = 0.5, anneal_period = 25), minimizing a standard cross-entropy loss between $\hat{a}$ and the true label a. We add temporal features to encode information about the speaker for the given utterance (Bordes and Weston, 2016a) and use position encoding for encoding the position of words in the sentence (Sukhbaatar et al., 2015). We learn two embedding matrices A and C for encoding story, separate embedding matrix B for encoding query and weight matrices TA and TC for encoding temporal features. The same weight matrices are used for 3 hops[2].

A.2 Mask End-to-End Memory Network: Mask-memN2N

We use the same hyperparameters as the baseline model mentioned above. The additional hyperparameters are as follows: L2 loss coefficient = 0.1 for pre-training the RL phase mask, entropy with linear decay from 0.00001 to 0, positive reward = 5 for every correct action and negative reward = 0.5 for an incorrect action.

---

[2] We used 599 as the random seed for both tf.set_random_seed and tf.random_normal_initializer for our embedding matrices.

Abstract

Recent progress in dialogue generation has inspired a number of studies on dialogue systems that are capable of accomplishing tasks through natural language interactions. A promising direction among these studies is the use of reinforcement learning techniques, such as self-play, for training dialogue agents. However, current datasets are limited in size, and the environment for training agents and evaluating process is relatively unsophisticated. We present AirDialogue, a large dataset that contains 402,038 goal-oriented conversations. To collect this dataset, we create a context-generator which provides travel and flight restrictions. We then ask human annotators to play the role of a customer or an agent and interact with the goal of successfully booking a trip given the restrictions. Key to our environment is the ease of evaluating the success of the dialogue, which is achieved by using ground-truth states (e.g., the flight being booked) generated by the restrictions. Any dialogue agent that does not generate the correct states is considered to fail. Our experimental results indicate that state-of-the-art dialogue models on the test dataset can only achieve a scaled score of 0.22 and an exact match score of 0.1 while humans can reach a score of 0.94 and 0.93 respectively, which suggests significant opportunities for future improvement.

1 Introduction

Designing machines to talk like a human is one of the most important goals of research in machine learning and natural language generation. (Turing, 1950; Levin et al., 1997, 2000; Banchs and Li, 2012). Rooted in seq2seq models (Sutskever et al., 2014; Cho et al., 2014), recent neural based dialogue models (Shang et al., 2015; Sordoni et al., 2015; Vinyals and Le, 2015; Li et al., 2016a; Wen et al., 2016; Bordes et al., 2017; Lewis et al., 2017; Pieraccini et al., 2009; Serban et al., 2017) have generated promising results. However, building a robust and reliable agent that can hold a conversation with humans while achieving a specific goal remains an open challenge. While a majority of previous work studied *chitchat models* (Ghazvininejad et al., 2018; Sordoni et al., 2015), in this paper we focus on *goal-oriented models* (Li et al., 2017; Liu and Lane, 2017; Liu et al., 2017) for conversations.

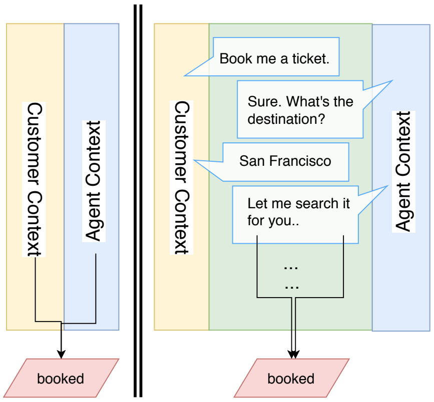

Figure 1: Goal-Oriented Dialogue Environment. (left) Context pairs are mapped to unique states in the environment. (right) Conversation models can only access its own private context and utterance in the public domain. At the end of the conversation, dialogue states are generated from one of the agents using information from the utterance.

We define a goal-driven dialogue to be a conversation that is conditioned on a pair of contexts $c = (u, v)$, with the goal of reaching the target state $s \in \mathcal{S}$. For a dialogue environment E, there exists a mapping f_E that maps from the context pair to the target state (i.e., $s = f_E(c)$). While an environment can access to the full context pair, a dialogue agent, say A_u, can only access its own private context u and the dialogue history $h_t = \{x_1, x_2, ...x_t\}$ with x_t being an utterance generated by one of the agents at time t (i.e., $x_{t+1} \sim A_v(x|v, h_t)$

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3844–3854
Brussels, Belgium, October 31 - November 4, 2018.

or $x_{t+1} \sim A_u(x|u, h_t)$). By forbidding accessing to the context of the other party, goal-driven dialogues will have to be developed so that the dialogue history h_t contains all the information that is necessary for a particular agent, say A_v to reach the target state s of the conversation defined by the environment through a mapping g_v (e.g., $s = g_v(h_t, c_v) = f_E(c)$). When one of u or v is a human, A_u and A_v will have to belong to a class of generators that respond in natural language.

We present AirDialogue, a large-scale corpus with 402,038 dialogues and an environment that makes it easy to simulate and evaluate goal-oriented dialogues. Our setting is centered around the theme of a flight booking session between a customer and a support agent. Since it's easy to find a rule based strategy to book a ticket given all the constraints, a mapping can be easily found in order to generate the ground-truth state (e.g., the ticket that needs to be booked) for each dialogue context so that we can evaluate the generated dialogue. In our environment, a context pair c always comes with a unique s. If the dialogue agent generates a state s' that is different from s, the agent has failed to achieve the goal. We use this as a mechanism to measure the performance of dialogue agents. We consider an additional metric to measure the "natural languageness" of the conversations so that the agents do not just exchange bits.

We have implemented some strong dialogue generation models and experimented with them on our dataset. Experimental results demonstrate that even the most advanced model can only achieve a benchmark score of 0.33. Comparing that to the human score of 0.94, that leaves for significant future improvement.

2 Existing Datasets

A comparison between the AirDialogue and several publicly available ones is shown in Table 1. Existing datasets are usually too small to support deep learning approaches to model dialogues generation. As a comparison, the WMT'15 English-Czech dataset (Luong and Manning, 2016), a benchmark dataset for machine translation, contains 15.8 million translation pairs whereas the current largest goal-oriented dataset has only 20,300 conversations. Synthesized data can also be an option to obtain a large dataset. However, these are often built from templated responses which make it meaningless for dialogue models to learn. Another issue with conversation datasets is the lack of a sophisticated environment that can be used to evaluate a generated dialogue. Some of the recent datasets provide an environment but are generally not representative enough to model real-world settings as illustrated by a narrow context space. As a result, the limited availability of datasets and complex environments have become a bottleneck for research in goal-oriented dialogue.

Our dataset has more than 20 times as many samples as found in the biggest of the existing public datasets. In addition to the number of samples, we have also compared the context complexity and the state complexity. Context complexity measures the unique number of context that a conversaion can be grounded into and state complexity measures the number of states that a conversation can reach. As we can see from the table, AirDialogue has the largest complexity in both context and state, giving it the flexibility to form a diverse selection of goal-oriented conversations. Our dataset also supports a wide range of tasks that can be found in the dialogue community. These include dialogue generation, state tracking and dialogue self-play.

3 Task Environment

We formulate the flight booking problem as a collaborative goal-driven dialogue problem that was defined in the introduction. Two types of agents are present: customers and agents. Dialogues are conditioned on a context pair $c = (c_c, c_a)$, with c_c being the context for the customer and c_a for the context of the agent. Here, the customer context $c_c = (tr, o)$ consists of the goal of the dialogue o (i.e., book, change or cancel) as well as the travel constants tr. Agent context $c_a = (db, r)$ consists of available flights in the database db and a field r indicating whether the customer has an existing reservation in the system. A final dialogue state s is derived at the end of the conversation once the agent has acquired all the information and the customer has confirmed all the changes in their reservation.

Task Logic. One of the main purposes of the flight booking problem is to mix decision making in the context of a dialogue. Figure 2 illustrates the task logic in order to successfully solve our problem. The goal of the conversation is provided as part of the customer's context, which has to be one of the following:

- book: make a new reservation

Dataset	Context complexity	State complexity	Supported tasks	Num. samples
Real Datasets				
AirDialogue	$\geq 4.43 \times 10^{178}$ [a]	750,000 [b]	Dialogue Generation Dialogue Self-play State Tracking	402,038

Task-Completion Dialogue Systems (Li et al., 2016b)	Unknown	3	Dialogue Generation State Tracking	-

[a] Calculated based on all possible combinations of customer and agent context features in Table 2 and Table 3. Assume 365 days a year, 24 airport codes, 8 airlines and 30 flights in the database with each flight having the same departure and arrival date as the intent and is always under the customer's budget. This is a conservative estimate since the actual dataset have flights with different dates and prices.

[b] Calculated based on 30 flights in the database, 5,000 names and 5 dialogue action states.

Table 1: Comparing AirDialogue to Existing Datasets

- change: change an existing reservation
- cancel: cancel an existing reservation.

The agent is then expected to follow the task logic and guide the conversation all the way to one of the five dialogue state actions. For example, when the goal o is "book", the agent will iterate through each of the customer's set of travel restrictions tr and search for available flights in db. If there are available flights, the conversation will be concluded with the status action "booked". Otherwise a status action of "no flight found" will be returned. On the other hand, the task logic for customers with a goal of "change" would be slightly different. Agents are supposed to check for r to determine whether a reservation exists. If it does, the agent will interact with the customer to update the travel constants tr. Otherwise, a status action will be selected with "no reservation". Similarly, the conversation will conclude "no flight found" if none of the flights in db satisfies the customers' need and "changed" if the the new flight is found. Finally, for customers who wish to cancel their ticket, the agents will perform a simple check and cancel if the reservation is found and "no reservation" otherwise.

Agent Context. There are two components in the agent context $c_a = (db, r)$. $db = (f_1, f_2, \ldots, f_m)$ is a list of flights each with 12 features listed in Table 3. Each feature has a prior distribution that we use to generate those settings. For example, 90% of the flights in the database would be economy class

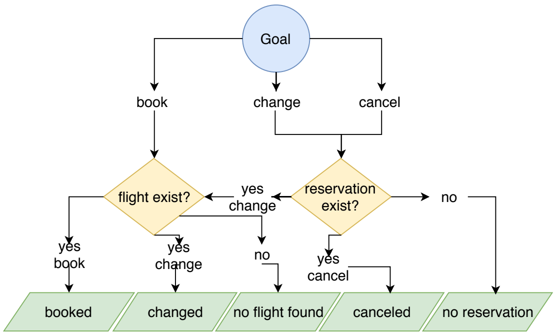

Figure 2: Task Logic of the flight booking problem

while 10% of the flights would be business class. The flight database is unique to each conversation. The price of the flights are drawn from a Gaussian distribution with mean μ and standard deviation $\sigma = \mu * \beta$. μ is 210 for economy class and 650 for business class. β is 0.2 for direct flights, 0.4 for flights with one connection and 0.6 for those with 2 connections. To simplify our setting, we only consider round trip flight tickets with both trips under the same airlines. r is simply a binary variable indicating whether the customer has previously made a reservation.

Customer Context. Customer context $c_c = (tr, o)$ also consists of two pieces. $tr = (tr_1, tr_2, \dots, tr_n)$ is a list of travel restrictions indicated in Table 2. Here we constrain the form of travel restrictions into the ones that are most useful for the flight booking situation, which is illustrated in Table 3. For example, customers may request a flight with either economy class, business class or accepts anything that is available. Some of the restrictions requires certain level of common sense knowledge to "translate" into an actual search query. Take travel time for example, a morning flight would corresponds the flight between 3am to 11am and a standard fare airline would be one of the big brand airline companies. The rest of the airlines are considered low-cost airlines. The probability of each occurrence that will be appeared in the customer context is also listed in the table.

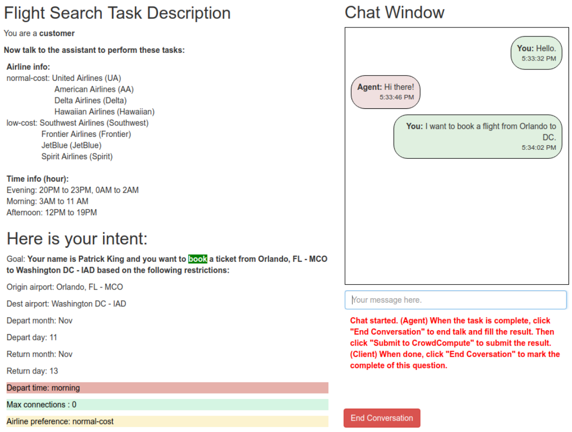
Dialogue States. At the end of the conversation, agent will submit the dialogue states $s = (s_a, s_n, s_f)$, a state action s_a which will be one of the following 5 : "booked", "changed", "no flight found", "no reservation" and "cancel", the name of the customer s_n and the flight being selected for this dialogue s_f. Flights will be identified by a flight number that indicates one of the m flights in the database.

Environment. As we discussed earlier in the introduction, there exists a mapping $f : c \to s$ so that we can acquire the final dialogue state directly from the context pair. This mapping corresponds to our environment and the expected state $s' = f(c)$ generated from the context pair can be used to evaluate the state s generated from our algorithm.

Sentence Level Annotation. In addition to dialogue context and states, some of the sentences in the dialogues are also labeled during the data collection process. The sentence level annotation records the items agent clicked on the web UI when we were collecting the dialogue data. Agents are given the instructions to input all the travel constraints immediately after they receive them from the customers via the chat window.

4 Datasets

In this paper we present the AirDialogue dataset that contains a large collection of human generated dialogues. In addition, we also present the syntherized dataset generated using a templated simulator, along with an out-of-domain dataset that contains context that drawn from a different prior distribution than the previous two. AirDialogue and the synthesized datasets are divided into train, dev and eval sets randomly by applying a ratio of 80%, 10% and 10%. Details of the statistics are shown in Table 5.



Flight Search Task Description

You are a **customer**

Now talk to the assistant to perform these tasks:

Airline info:
normal-cost: United Airlines (UA)
American Airlines (AA)
Delta Airlines (Delta)
Hawaiian Airlines (Hawaiian)
low-cost: Southwest Airlines (Southwest)
Frontier Airlines (Frontier)
JetBlue (JetBlue)
Spirit Airlines (Spirit)

Time info (hour):
Evening: 20PM to 23PM, 0AM to 2AM
Morning: 3AM to 11 AM
Afternoon: 12PM to 19PM

Here is your intent:

Goal: **Your name is Patrick King and you want to book a ticket from Orlando, FL - MCO to Washington DC - IAD based on the following restrictions:**

Origin airport: Orlando, FL - MCO

Dest airport: Washington DC - IAD

Depart month: Nov

Depart day: 11

Return month: Nov

Return day: 13

Depart time: morning

Max connections : 0

Airline preference: normal-cost

Chat Window

You: Hello.
5:33:32 PM

Agent: Hi there!
5:33:46 PM

You: I want to book a flight from Orlando to DC.
5:34:02 PM

Chat started. (Agent) When the task is complete, click "End Conversation" to end talk and fill the result. Then click "Submit to CrowdCompute" to submit the result. (Client) When done, click "End Coversation" to mark the complete of this question.

Figure 3: Customer's Interface

AirDialogue Dataset. To collect human annotated dialogue data, we first generate context pairs based on the prior distributions defined in Table 3

feature	goal	class	max. price	airline	dep./ret. time

final action **(Required)**: --

Figure 4: Agent's Interface

and Table 2. 30 flights are generated for each dialogue. Annotators are then asked to role play the dialogue using the web interface illustrated in Figure 3 and Figure 4. The customer is shown with the goal and any requirements, as well as the chat history. The agent has a similar interface with the addition of a search feature that will search and return the cheapest flights that satisfy the given search constraints. The layouts and colors of the UI were optimized to reduce human errors. Human annotators are highly familiar with the settings of the task as most of them stayed in the project full time for more than 6 month. A human project manager manually examines roughly 5%-6% of the data each day and provide feedbacks to the human annotators to ensure the quality of the data collection. Table 4 shows some of the statistics of the AirDialogue dataset. On average, 88.5% of the dialogues generated by human reaches a perfect state. In the next Section we will analyze the types of human mistakes. In addition to dialogue history, we have also recorded agent search events (e.g. adding a new search constant through the web UI) on each turn, which are sentence level dialogue state annotations. Annotators are given the instructions to put search constraints immediately after they have received them from the natural conversation. 36.1% of the dataset dialogues have access to such information. Tracking search events provides a structured representation of progress of the dialogue.

Synthesized Dataset. In addition to the AirDialogue dataset collected using human annotators, we have also built a dialogue simulator to generate synthesized dialogues. The dialogue simulator relies on the context generator with the same set of priors. Synthesized dialogues are generated by following a set of templates and alternate between them randomly.

Out-of-domain Context Set. We have also generated an out-of-domain context set that does not contain any dialogues. This context set is generated by setting the goal probability from the one showing in Table 2 to a uniform distribution. The reservation probability is also changed from 10% to 70%. The sets of customer name and airport codes have also gone up significantly in those two datasets. This makes it difficult for models with fixed vocabulary size to perform well on those OOD datasets.

5 Data Analysis

5.1 Required Skills

This dataset presents many challenges for existing methods. Table 6 lists some of the skills that are required to accomplish the flight booking task.

Lexical and Syntactic Variations. Human language is diverse and there are many forms of lexical and syntactic variations. Taking the examples in Table 6, the amount of variation that appears in human dialogue poses great challenges for conversational models.

Applying External Knowledge. Another challenge in our data set is the use of external (commonsense) knowledge. Vaguely defined concepts such as morning and afternoon are used comfortably by humans. However, a learning algorithm needs to successfully adapt those concepts when searching for flights. An alternative way to solve this problem is to inject external knowledge into the algorithm, which is ananother important issue in dialogue systems.

Active Information Seeking Conversation. We have observed that human annotators who have high correct rates often have the habit of actively requesting information. They take extra steps to ensure all the flight search conditions are correctly communicated. This is especially important since customers are the only party in the dialogue who have access to the travel restrictions.

Goal-driven Dialogue Development. Another necessary skill to solve the flight booking problem is to develop dialogue that can be used to drive the conversation towards its end goal. Having such a goal in mind distinguishes goal-oriented models from chitchat models and makes the conversation more effective and efficient.

Reasoning over Large Structured Data. Selecting flights relies on effective methods to reason over a large scale structured database. This is a challenge that has practical impact but has rarely been addressed in previous research.

Learning from Multiple Solutions. A final challenge in the problem is the fact that there exists multiple equally optimal flights to the same set of customer restrictions.

5.2 Analysis on Human Mistakes

As we have reported in Table 7, the human error rate on this task is close to 10%. We have analyzed the human errors and grouped them into 6 categories. Here an invalid status indicates that agents have chosen a status that they are not supposed to reach according to Figure 2. For example, a "book" goal should not reach "no reservation" as an action status. "Wrong status", on the other hand, is a possible action status to reach but are not expected given the context of the conversation. Minor mistakes comprise of situations that include when agents misspell the name of the customer but get everything else correct. Those mistakes can be fixed in the dialogue from the ground truth. The majority (85%) of the errors happened when communicating flight search constraints, and entering wrong conditions that lead the search tool to return no results (6.8%).

6 Methods

6.1 Supervised Learning

Model Architecture. Our supervised dialogue model is built based on the seq2seq model(Sutskever et al., 2014). We treat both context from customer and agent as sequences and encode them using RNN. For customer context c_c we encode it using a single RNN. To encode agent context c_a we apply a hierarchical RNN structure by first encoding each flight using an RNN and then encode the outputs of each encoded flights along with the reservation information using another RNN. Utterance of time t is generated using

Skills	Examples
Lexical and Syntactic Variations	Customer: My travelling dates are **Aug 12-14**. Customer: I want to take off on **Sept 18** and please confirm my return ticket on **Sept 20**. Customer: Travelling dates are **12/13** and **12/15**.
Applying External Knowledge	Customer: I am traveling on Oct, 10 and I am returning on Oct, 12 in the **evening**. Customer: I prefer **normal-cost** airlines.
Active Information Seeking	Customer: And **please make sure** that the departure time is at afternoon. Agent: Do you have any **other specifications**? Agent: Can you **mention** Washington airport code for me? Agent: Do you like to travel in a **economy class or business class**?
Goal-driven Dialogue Development	Agent: Sure, please **provide me with your planned travel dates**. Agent: Hello, **how can I help you**? Agent: Thank you for reaching out to us. **Have a great time**.

Table 6: Conversational Skills required to accomplish the AirDialogue task.

invalid status	4.4%	minor mistakes	2.0%
reservation	1.0%	flight constant	85%
wrong condition	6.8%	wrong status	0.8%

Table 7: Human error statistics.

a sequence2sequence model by concatenating the context embedding along with the embeddings of conversation history h_{t-1}. Agent and customer will have their own model $P(x_t|h_{t-1}, c_a; \theta_a)$ and $P(x_t|h_{t-1}, c_c; \theta_c)$. At the end of the conversation the dialogue state will be generated in a sequence using another sequence2sequence model by taking the entire conversation history and the agent context, $P(s_i|s_{i-1}, h_T, c_a; \theta_s)$.

Optimization. During supervised learning, we optimize the model by considering the loss from both the dialogues x and their states s. A token x_t can belong to a either customer utterance ($x_t \in \pi_c$) or an agent utterance ($t \in \pi_a$). The parameters for supervised learning contains all the parameters of the models: $\Theta = \{\theta_a, \theta_c, \theta_s\}$. In supervised learning we optimize the following loss function.

$$\begin{aligned}\ell(\Theta) = -\sum_{(x,c,s)\in\mathcal{D}} \sum_{t=1}^{T} & \mathbb{1}_{\pi_c}(x_t)\log P(x_t|h_{t-1}, c_c; \theta_c) + \\ & \mathbb{1}_{\pi_a}(x_t)\log P(x_t|h_{t-1}, c_a; \theta_a) + \\ \sum_i & \log P(s_i|s_{1:i-1}, h_T, c_a; \theta_s)\end{aligned}$$

6.2 Reinforcement Learning Self-Play

Supervised learning for dialogue generation is known for many issues such as generating templated responses regardless of the inputs (Li et al., 2015). Here we design a reinforcement learning self-play algorithm to enable the model to learn from the environment by chatting with each other. Our self-play model is initialized using a model trained from the supervised learning. Since no conversation data is involved in the self-play, we generate context pairs directly from the context generator during training. Here we consider terminal rewards, which is generated by simulating the dialogue all the way to the end and compare the generated state s with the ground truth state s'. We use the scaled score as rewards introduced in the paragraph of Evaluation Metrics in Section 7.

Value Network. To reduce variance, we build a value network to provide a baseline estimate for returns. Both agent and customer gets their own value network $v_a(h_t|c_a; \theta_{v,a})$ and $v_c(h_t|c_c; \theta_{v,c})$. The value functions are parameterized by a seq2seq model and a linear transform applied on its output. During the training of the value functions, the main model parameters Θ are fixed and the only trainable variables are $\theta_v = \{\theta_{v,a}, \theta_{v,c}\}$.

Policy Network. We use the same structure as in supervised learning to be our policy network. We adopt REINFORCE algorithm (Williams, 1992) to optimize our algorithm using the following gradient.

$$\begin{aligned}&\nabla\ell_{RL}(\Theta) = \\ &\mathop{\mathbb{E}}_{x_t\in\pi_c}(R_t - v_c(h_{t-1}))\nabla\log P(x_t|h_{t-1}, c_c; \theta_c) + \\ &\mathop{\mathbb{E}}_{x_t\in\pi_a}(R_t - v_a(h_{t-1}))\nabla\log P(x_t|h_{t-1}, c_a; \theta_a) + \\ &\mathop{\mathbb{E}}_{s_i}(R_t - v_a(h_T, s_{i-1}))\nabla\log P(s_i|s_{i-1}, h_T, c_a; \theta_s)\end{aligned}$$

Table 10: Performance of Trained Self-play Models on Out-of-domain Context Pairs using AirDialogue Data

7 Experiments

Experiment Setup. We implemented our model using Tensorflow using SGD as the optimizer with a learning rate of 0.1 and a batch size of 64. The seq2seq model was implemented using 4 layers of GRU with a hidden unit 384. Greedy Decoder is used for seq2seq decoding. Inputs are tokenized using NLTK [1]. For AirDialogue dataset, tokens occurred less than 10 times are eliminated but no tokens are removed for the synthesized dataset. As a result, there are 5,547 tokens left the experiments. There are 700 tokens for the synthesized dataset and no tokens are eliminated during the pre-processing. In training we only applied the dialogues that have correct states.

Accelerate Training In the usual seq2seq diagram for dialogue generation, one would treat a single conversation with k turns as k different training samples by feeding conversation before the k^{th} turn into the encoder and use a decoder to generate the k^{th} turn. Such a training strategy would encode the dialogue history repeatedly. We apply a technique to speed up training that is illustrated in Figure 5. Here the encoder is never needed to encode a single dialogue multiple times since its outputs are reused for multiple turn predictions. The decoder generates the output sequence by alternating its states between previous decoder state and the encoder states. If the sentence is within the boundary of the current turn, its hidden state got passed from its previous state. Otherwise, its hidden state will be "reset" into the corresponding state in the encoder. One can easily implement this training strategy and use a pre-processed Boolean array to represent whether a token is within a turn for a specific agent.

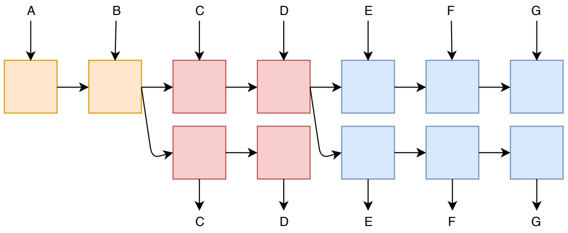

Figure 5: Techniques to speed up training. Here a conversation with 3 turns are annotated using colors. The encoder only needs to pass through the dialogue once for the entire dialouge sample to be trained.

Evaluation Metrics. We use perplexity and BLEU score to evaluate the quality of the language generated by the model. We also compare the dialogue state generated by the model s and the ground truth state s'. Two categories of the metrics are used: exact match scores and scaled scores. In an

---

[1] https://www.nltk.org

exact match metric, dialogue state is given a score of 1 if it matches exactly to the ground truth and 0 otherwise. In a scaled metric, scores are scaled between 0 and 1 to provide information that are of finer granularity. There are three dialogue states: name, flight and action. For name, scaled metric is chosen to be the character-wise F1 score. For flight, scaled metric is chosen to be 1 minus the scaled distance between the selected flight f and the ground truth F_g. Note there might be multiple optimal ground truth flights that have the same price and satisfy the customers' requirements. Therefore F_g should be a set of flights. The distance function $d(f1, f2)$ is a measure of distance on each of the flight features. The scaled score on flight is calculated as the following. Here F is a set of all flights in the datasbase.

$$score(f) = 1 - \frac{\min_{f' \in F_g} d(f, f')}{\max_{f1 \in F, f2 \in F_g} d(f1, f2)}$$

Dialogue action states can only have exact match metrics. Finally, the total score of a dialogue is taken to be a weighed sum scores of name, flight and dialogue status by a factor of 0.2, 0.5 and 0.3 for both scaled and discrete metrics.

Dialogue Generation and State Prediction. We train the models on the train sets and show their performs on the dev and test sets in Table 8. The BLEU score measured by comparing the generated response and the ground truth is around 68.7 for synthesized data and around 23 for AirDialogue. Given the fact that templated dialogues are easier to learn, it is expected that the synthesized dataset gets a high BLEU score. In the state prediction task, the model paper achieved a perfect accuracy across all the dialogue states given the ground truth dialogue and previous states. However, as we will see shortly, the triumph on ground truth hisotry might not be able to be transferred to self-play experiments, which generates dialogues that have different distributions from the ground truth data.

Dialogue Self-play. During the self-play experiments we perform similar predictions on the dialogue states. However, instead of asking the models to predict those states given ground truth history, we now ask the models to predict given the generated dialogues. Table 9 shows the results using both the supervised model and the self-play model. Here we see significantly improvements across all measures for self-play models compare to their supervised learning models. However, the fact that the exact match scores are so low indicates that our models are far from mastering the goal-oriented dialogue problem in the self-play setting as the rewards and accuracies are consistently low. As a comparison, human agents achieved nearly 90% on rewards across all categories, which sets a good target for future work in the field. One possible reason for the low exact match score but relatively high scaled score is because we use the scaled score as rewards in out self-play training. As a result, the metrics are highly tuned toward scaled scores instead of exact match scores. One can apply techniques such as pointer networks (Vinyals et al., 2015) which is possible to optimize exact match scores in a better way. To prevent language from degenerating into binary bits, we mix three supervised training steps on the train data with one reinforcement learning update during self-play training. By doing this, we are able to maintain a BLEU score at similar level compares to the supervised learning.

Out-Of-Domain Self-play. We have also conducted experiments on the out-of-domain context pairs. The results are shown in Table 10. The out-of-domain context pairs contain dialogue contexts with distribution far deviated from the training data. It is not surprised to see here that our model does not perform as good as in the testing data using the data it is familiar with.

8 Conclusions

In this paper, we propose an environment for goal-oriented dialogue research based on the problem of flight bookings. We have collected a dataset that is more than 400,000 conversations. Our environment allows easy generation of new dialogue contexts and allows verification of the generated dialogues, which can be used to support a wide range of research such as dialogue self-play. Although supervised learning seems to perform well in our setting, self-play poses a challenge for goal-oriented dialogue research. The gap between our self-play approach and the human baseline suggests possibilities for significant future improvements.

Abstract

We propose the task of Quantifiable Sequence Editing (QuaSE): editing an input sequence to generate an output sequence that satisfies a given numerical outcome value measuring a certain property of the sequence, with the requirement of keeping the main content of the input sequence. For example, an input sequence could be a word sequence, such as review sentence and advertisement text. For a review sentence, the outcome could be the review rating; for an advertisement, the outcome could be the click-through rate. The major challenge in performing QuaSE is how to perceive the outcome-related wordings, and only edit them to change the outcome. In this paper, the proposed framework contains two latent factors, namely, outcome factor and content factor, disentangled from the input sentence to allow convenient editing to change the outcome and keep the content. Our framework explores the pseudo-parallel sentences by modeling their content similarity and outcome differences to enable a better disentanglement of the latent factors, which allows generating an output to better satisfy the desired outcome and keep the content. The dual reconstruction structure further enhances the capability of generating expected output by exploiting the couplings of latent factors of pseudo-parallel sentences. For evaluation, we prepared a dataset of Yelp review sentences with the ratings as outcome. Extensive experimental results are reported and discussed to elaborate the peculiarities of our framework. [1]

1 Introduction

Typical neural text generation is observed suffering from the problems of repetitions in word n-grams, producing monotonous language, and generating short common sentences (Li et al., 2017). To solve these problems, some researchers branch out into the way of post-editing (could be under some guidance, say sentiment polarity) a given message to generate text of better quality. For example, skeleton-based text generation first outlines a skeleton in the form of phrases/words, and then starts from the skeleton to generate text (Wang et al., 2017; Xiao et al., 2016). Another line of works conduct editing on an existing sentence and expect that the output will serve particular purposes better (Guu et al., 2018). Similarly in conversation, some systems post-edit the retrieval results to generate new sentences as the response (Song et al., 2016). The third type is to perform editing on the input under the guidance of specific style. For example, Shen et al. (2017) take a sentence with negative sentiment as input, and edit it to transfer its sentiment polarity into positive.

In this paper, we generalize the third type of post-editing into a more general scenario, named **Qua**ntifiable **S**equence **E**diting (**QuaSE**). Specifically, in the training stage, each input sentence is associated with a numeric outcome. For example, the outcome of a review sentence is its rating, ranging from 1 to 5; the outcome of each advertisement is its click-through rate. In the test stage, given an input sentence and a specified outcome target, a model needs to edit the input to generate a new sentence that will satisfy the outcome target with high probability. Meanwhile, the output sentence should keep the content described by the input. For example, given the input sentence "The food is terrible", a desired output sentence could be "The food is OK" under the expected outcome

Brussels, Belgium, October 31 - November 4, 2018.

"3.1" (a neutral sentiment), and "The food is delicious" under the expected outcome "4.0". If no outcome target is given, the model could generate "The food is extremely delicious", by defaulting the best outcome, or "The food is extremely terrible", by defaulting the worst outcome.

Our problem setting is more general than previous works in two major aspects: (1) The outcome here is numerical, and it can be regarded as a generalization of the categorical outcome in (Shen et al., 2017; Hu et al., 2017; Gao et al., 2018). With such numerical outcome, it is impossible to construct two corpora as counterpart of each other as done in (Shen et al., 2017; Gao et al., 2018). (2) The editing operation is under a quantifiable guidance, i.e. the specified outcome or the defaulted extrema. For example, we can specify a particular target rating, such as 3.1 or 4.0, as the expected outcome. Although Mueller et al. (2017) also take outcome-associated sentences for training, their model does not perform such outcome-guided editing for sentence generation.

Considering that the goal of the task is to generate an output that satisfies a specified outcome and keeps the content unchanged, QuaSE is challenging in a few aspects. Firstly, a model should be able to perceive the association between an outcome and its relevant wordings. For the previous example "The food is terrible", the model needs to figure out that the low rating is indicated by the word "terrible", instead of "food". Secondly, when performing editing, the model should keep the content, and only edits the outcome-related wordings. Moreover, the model needs to take a specified outcome into account and generate an output that satisfies the specified outcome value with high probability. Continuing the running example, given the expected outcome 3.1, "The food is OK" is an appropriate output, but "The food is extremely delicious" and "The service is OK" are not. Thirdly, we do not have readily available data, such as data points like [input sentence: "The food is terrible", expected outcome: 4.0, output sentence: "The food is delicious"] to show the model what the revised output should look like, that meet our need to train models.

We propose a framework to address this task. The fundamental module of our framework is a Variational Autoencoder (VAE) (Kingma and Welling, 2013) to encode each input sentence into a latent content factor and a latent outcome factor, capturing the content and the outcome related wordings respectively. We propose to leverage pseudo-parallel sentence pairs (i.e, the two sentences in a pair have the same or very similar content, but different outcome values) to enhance our model's capability of disentangling the two factors, which allows attributing the wording difference of the sentences in a pair to the outcome factor, and the wording similarity to the content factor. For sentence reconstruction, we employ a Recurrent Neural Network (RNN) based decoder (Sutskever et al., 2014) that takes as input the combination of a content factor and an outcome factor. To further enhance the capability of generating expected output, we introduce a dual reconstruction structure which exploits the couplings of latent factors of pseudo-parallel sentences. Specifically, it attempts to reconstruct one sentence in a pair from the combination of its outcome factor and the other sentence's content factor, based on the intuition that the wording difference in a pair is outcome-related. In the test stage, taking a sentence and a specified outcome target as input, our model generates a revised sentence which likely satisfies the specified target, and meanwhile the content is preserved as much as possible.

To evaluate the efficacy of our framework, we prepared a dataset of Yelp review sentences with the ratings as outcome. Compared with state-of-the-art methods handling similar tasks, experimental results show that our framework can generate more accurate revisions to satisfy the target outcome and transfer the sentiment polarity, meanwhile it keeps the original content better. Ablation studies illustrate the effectiveness of the designed components for enhancing the performance. We have released the prepared dataset and the code of our model to facilitate other researchers to do further research along this line, refer to Footnote 1.

2 Model Description

2.1 Problem Setting and Model Overview

In the task of Quantifiable Sequence Editing (QuaSE), the aim is to edit an input sentence X_0 under the guidance of an expected outcome value R^* to generate a new sentence X^* that will satisfy R^* with high probability. For training a model, we are given a set of sentence-outcome tuples (X, R).

Our proposed model for training is depicted in Figure 1. The left hand side models individual sentences. Specifically, it employs two encoders,

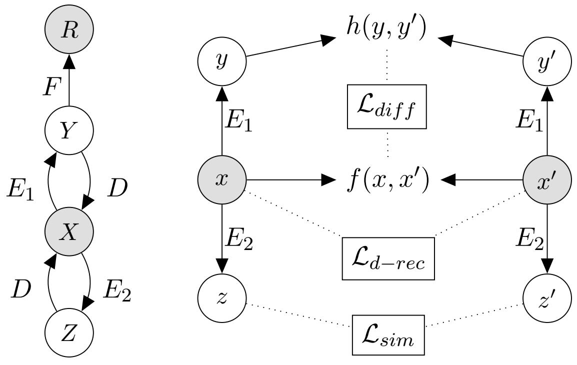

Figure 1: Model Overview.

i.e. E_1 and E_2, to encode a single sentence X into two latent factors Y and Z which capture the outcome and content properties respectively. In contrast, Mueller et al. (2017) employ a single factor for capturing these two properties, which limits the capability of distinguishing one property from the other. As a consequence, when editing a sentence towards a given outcome, the sentence content is likely to be changed, which should be suppressed as much as possible. An RNN-based decoder D takes the concatenation of Y and Z to reconstruct the input X. Moreover, a transformation function F predicts R with Y.

The right hand side models pseudo-parallel sentence pairs (automatically generated from the above tuples), so we first introduce the concept of pseudo-parallel sentences as follows. Let (x, x') denote a pair of pseudo-parallel sentences, x and x' should describe the same or similar content, but their outcomes are different. Note that we use lowercase letters to denote variables related to sentence pairs for better clarity. For two sentences in a pair, the difference of their outcome factors $h(y, y')$ is attributed to their wording difference $f(x, x')$, resulting in the loss $\mathcal{L}_{diff}$; the similar contents of two sentences should result in similar content factors, i.e. minimizing the loss $\mathcal{L}_{sim}$; moreover, a dual reconstruction loss $\mathcal{L}_{d-rec}$ is minimized to enhance the capability of generating expected output.

Overall, the model minimizes the losses from modeling single sentences and sentence pairs. After the model is trained, a separated component is applied for editing an input sentence to output a revision that satisfies a specified outcome target.

2.2 Modeling Single Sentences

In probabilistic theory, we need to maximize the log-likelihood of observing the training sentence-outcome tuples (X,R), denoted as follows:

$$\log \int p(X, R) = \log \int p(X|Y, Z)p(Y, Z)dYdZ + \log \int p(R|Y)p(Y)dY \tag{1}$$

However, the integration in the first term on the right hand side is intractable. Inspired by the idea of VAE (Kingma and Welling, 2013), we alternatively maximize the Evidence Lower Bound (ELBO) (Blei et al., 2016) incorporating variational distributions, i.e. $q(Y|X)$ and $q(Z|X)$. Thus, this term is approximated as follows:

$$\begin{aligned} &\log \int p(X|Y, Z)p(Y, Z)dYdZ \geq -[\mathcal{L}_{rec} + \mathcal{L}_{kl}] \\ &\mathcal{L}_{rec} = -\mathbb{E}_{Y,Z\sim q(Y|X),q(Z|X)}[\log p(X|Y, Z)] \\ &\mathcal{L}_{kl} = KL[q(Y|X)|p(Y)] + KL[q(Z|X)|p(Z)] \end{aligned} \tag{2}$$

where, the term $\mathcal{L}_{rec}$ denotes the error of reconstructing X. As advocated by (Kingma and Welling, 2013) and (Bowman et al., 2016), the variational distributions $q(Y|X)$ and $q(Z|X)$ are modelled as Gaussian distributions, i.e. $q(Y|X) = \mathcal{G}(\mu_{Y|X}, \sigma_{Y|X})$, and $q(Z|X) = \mathcal{G}(\mu_{Z|X}, \sigma_{Z|X})$. The expectation $\mathbb{E}(\cdot)$ can be efficiently approximated using one Monte-Carlo sample, for example, $Y \sim q(Y|X)$ and $Z \sim q(Z|X)$. In practise, we can alternatively employ $Y = \mu_{Y|X}$ and $Z = \mu_{Z|X}$ instead of sampling since they are the means of the Gaussian distributions. We employ two encoder networks E_1 and E_2 to generate $\mu_{Y|X}$ and $\mu_{Z|X}$ respectively from the sentence X, i.e. $\mu_{Y|X} = E_1(X)$ and $\mu_{Z|X} = E_2(X)$. $p(X|Y, Z)$ is the probability of observing the sentence X given Y and Z, which is modelled by a decoder network D. Thus, the reconstruction loss can be rewritten as:

$$\mathcal{L}_{rec} = H(X, D(E_1(X), E_2(X))) \tag{3}$$

where H is the cross entropy loss for the decoder.

The term $\mathcal{L}_{kl}$ in Equation 2 denotes the KL-divergence between the variational posterior distribution and the prior distribution. Following previous works (Mueller et al., 2017), the priors $p(Y)$ and $p(Z)$ are defined as a zero-mean Gaussian distribution, i.e. $p(Y) = p(Z) = \mathcal{G}(\mathbf{0}, \mathbf{I})$. The loss $\mathcal{L}_{kl}$ serves as a regularization term enforcing that the variational posterior distribution resembles the prior distribution, which also avoids overfitting.

The second term in Equation 1 models the log-likelihood of the outcomes. We adopt the usually used Taylor approximation for the calculation, where this term is approximated by an affine transformation from the outcome factor Y to the outcome R, denoted as $F(Y)$. Then, we define the loss as the square error between R and $F(Y)$:

$$\mathcal{L}_{mse} = (R - F(Y))^2 \tag{4}$$

Although Mueller et al. (2017) also model individual sentences and their outcomes, in their model, each sentence is only encoded into one latent factor to capture both outcome and content properties. In contrast, we disentangle two latent factors from a single sentence to model the outcome and the content separately to provide more flexibility. Moreover, such design allows the incorporation of the pseudo-parallel sentences, which will be described in the next subsection.

2.3 Exploiting Pseudo-Parallel Sentences

As mentioned above, pseudo-parallel sentences are similar in terms of the content but different in terms of the outcome. E.g., Table 1 shows a pair of pseudo-parallel sentences, where both talk about "the restaurant", but with different sentiments (i.e. ratings). For the pair (x, x'), let y and y' denote their outcome factors, z and z' denote their content factors. We design three components to leverage pseudo-parallel sentences to enhance our model's capabilities of disentangling the two types of factors and generating the desired output sentences.

x	I will never come back to the restaurant.
x'	I will definitely come back to the restaurant, recommend!

Table 1: A pair of pseudo-parallel sentences.

2.3.1 Modeling Outcome Difference

We exploit the wording difference $f(x, x')$ between x and x'. Note that the preparation (discussed in Section 4.1) determines that a pair of pseudo-parallel sentences are very likely to differ in the outcome factors, denoted as $h(y, y')$. Thus, by aligning the surface wording difference of two sentences in a pair and the difference in their outcome factors, we intend to improve the performance of the encoder E_1 for generating the outcome factor. $f(x, x')$ and $h(y, y')$ are defined as follows:

$$\begin{aligned} f(x,x') &= inc(x,x') \oplus dec(x,x') \\ h(y,y') &= y - y' = E_1(x) - E_1(x') \end{aligned} \tag{5}$$

where $inc(x, x')$ and $dec(x, x')$ are embeddings capturing the wording difference between x and x'. $inc(x, x')$ denotes the "increment" from x to x', i.e. the terms that appear in x' but not in x. $dec(x, x')$ denotes the "decrement". If there are multiple terms in the difference, we sample one term for inc or dec. For the example in Table 1, $dec(x, x')$ is the embedding of "never", and $inc(x, x')$ could be the embedding of "definitely" or "recommend". The effect of outliers during sampling anneals since the training data contain sufficient pairs of sentences. The symbol $\oplus$ denotes concatenation. $h(y, y')$ is defined as the subtraction between the outcome factors.

We employ a regression network U to align $f(x, x')$ and $h(y, y')$, and the loss $\mathcal{L}_{diff}$ is:

$$\mathcal{L}_{diff} = ||h(y, y') - U[f(x, x')]||^2 \tag{6}$$

2.3.2 Modeling Content Similarity

Another property of two pseudo-parallel sentences is that they share similar content. To capture it, we design a loss function minimizing the square error between the content factors.

$$\mathcal{L}_{sim} = ||z - z'||^2 = ||E_2(x) - E_2(x')||^2 \tag{7}$$

Minimizing $\mathcal{L}_{sim}$ helps the encoder E_2 generate the content factor more accurately.

2.3.3 Dual Reconstruction

The decoder D is not only used in Section 2.2 to reconstruct a single training sentence, but also employed for generating output sentences in the test stage (Section 3). To improve the robustness of D, we propose a dual reconstruction component based on the pseudo-parallel sentences. Different from reconstructing an original sentence in Section 2.2, in the dual reconstruction, given a sentence x, we reconstruct its dual sentence x'.

Specifically, we first encode x and x' into their outcome factors y/y' and content factors z/z'. Since x shares similar content with x', its content factor z, when combined with the outcome factor y' of x', should nearly reconstruct x'. For such dual reconstruction, the loss is written as:

$$\begin{aligned} \mathcal{L}^{d-rec}_{x';x} &= H(x', D(E_1(x'), E_2(x))) \\ &= H(x', D(y', z)) \end{aligned} \tag{8}$$

The same dual reconstruction process applies to the counterpart of x', i.e. x. Thus, the whole dual reconstruction loss is as follows:

$$\mathcal{L}_{d-rec} = \mathcal{L}^{d-rec}_{x';x} + \mathcal{L}^{d-rec}_{x;x'} \tag{9}$$

Note that the encoders E_1/E_2 and the decoder D here refer to exactly the same networks (i.e., the parameters are shared) as used in Section 2.2.

The specific design of the networks are as follows. E_1/E_2: RNNs of GRUs with a fully connected neural network appended to the last state to add some noise, which is a reparameterization alternative for sampling. Their outputs are the outcome and content factors, respectively. D: An RNN of GRU cells. The RNN takes the concatenation of an outcome factor and a content factor as the initial state for decoding. F: A fully connected network. It takes an outcome factor as input and outputs an outcome value. U: A fully connected network. It takes $f(x, x')$ as input to predict $h(y, y')$.

2.4 Joint Training

Considering all the aforementioned components, we define a joint loss function as:

$$\begin{aligned}\mathcal{L}_{joint} =& \lambda_{rec}\mathcal{L}_{rec} + \lambda_{kl}\mathcal{L}_{kl} + \lambda_{mse}\mathcal{L}_{mse} + \\ & \lambda_{diff}\mathcal{L}_{diff} + \lambda_{sim}\mathcal{L}_{sim} + \lambda_{d-rec}\mathcal{L}_{d-rec}\end{aligned} \tag{10}$$

in which each component is associated with a weight. Following the sigmoid annealing schedule (Bowman et al., 2016), we design the following strategy to tune the weights: (1) Tune the weights λ_{rec} and λ_{mse} on the validation dataset under the metric MAE (refer to Section 4.3), while fixing the other weights to zeros. We set $\lambda_{rec} + \lambda_{mse} = 1$; (2) Fixed the weights tuned in the first step. For each remaining loss, gradually increase the weight from 0 to 1 during the training, until the reconstruction loss $\mathcal{L}_{rec}$ or the outcome prediction loss $\mathcal{L}_{mse}$ becomes worse. The strategy prioritizes $\mathcal{L}_{rec}$ and $\mathcal{L}_{mse}$, since they are the core components for generating the revised sentences.

3 Editing under Quantifiable Guidance

In the test, the trained model edits an input sentence X_0 and outputs a revision X^* that is likely to satisfy the specified outcome target R^*, and meanwhile preserves the content as much as possible.

We first encode X_0 with E_1 and E_2 to get Y_0 and Z_0 respectively. The next step is to modify Y_0 to get a new outcome factor Y^* that is likely to generate the target outcome R^*. The process to determine a suitable Y^* is as follows. We first assume Y follows the Gaussian distribution $Y \sim \mathcal{G}(Y_0 = E_1(X_0), \sigma)$, the mean of which is Y_0. Then we choose $\mathcal{C} = \{Y : \mathcal{G}(Y|E_1(X_0), \sigma) > \tau\}$ as the feasible range for Y^*, where τ is a threshold. $\mathcal{C}$ will expand if τ is set smaller, and thus allowing more revisions. Finally, Y^* is determined as follows:

$$Y^* = \arg\min_{Y \in \mathcal{C}} (F(Y) - R^*)^2 \tag{11}$$

Note that in (Mueller et al., 2017), Y^* is determined as $\arg\max_{Y \in \mathcal{C}} F(Y)$, which does not consider an outcome target. The revised sentence X^* is generated from X_0 and Y^* via the decoder D:

$$X^* = D(Y^*, Z_0) \tag{12}$$

Thus, the content of X_0 is preserved with Z_0, and the expected outcome is achieved with Y^*.

4 Experiments

4.1 Dataset Preparation

Our dataset contains sentences extracted from Yelp reviews [2], where each review is associated with a rating in {1, 2, 3, 4, 5}. Specifically, we employ the sentences with sentiment polarity (i.e. positive or negative) used in (Shen et al., 2017) as the primary portion of our data. After some cleaning, we obtain about 520K sentences. To add neutral sentences, we randomly select 80K sentences from the original reviews with neutral sentiment (i.e. rating 3). To make sure that the neural sentences added by us are describing the same domain, we only pick neural sentences whose tokens are all in the vocabulary of the primary data. The vocabulary size of the dataset is 9,625. In total, our dataset contains 599K sentences, and we randomly hold 50K for test, 10K for validation, and the remaining for training.

For training, we need each input sentence being associated with a rating value, and for test, we need to measure the rating of a generated sentence to check if the generated sentence satisfies the specified outcome target. Therefore, an automatic method is needed for measuring the rating values of training sentences and generated sentences. We employ the sentiment analyzer in Stanford CoreNLP (Manning et al., 2014) to do so. Specifically, we first invoke CoreNLP to output the probability of each rating in {1, 2, 3, 4, 5} for a sentence, then we take the sum of the probability-multiplied ratings as the sentence rating. Some statistics of the data is given in Table 2. Hereafter, we use "rating" and "outcome" interchangeably.

---

[2] `https://www.yelp.com/dataset/challenge`

Rating interval	$[1,2)$	$[2,3)$	$[3,4)$	$[4,5]$
Sentence#	34273	231740	165159	167803

Table 2: Numbers of sentences in each rating interval.

One may think that would it be possible to use the original rating given by Yelp users as outcome for training? We did not use it for two reasons: (1) We want the ratings of training sentences and generated sentences are measured with a consistent method; (2) In fact, we find that the predicted rating with CoreNLP has a Pearson correlation of 0.85 with the rating given by users. Note that the original Yelp data only has ratings for entire reviews. We derived the sentence ratings by users like this: a sentence takes as its rating the average of the ratings of those reviews where it appears in. Human evaluation in (Shen et al., 2017) shows that a similar method for deriving polarity is basically reasonable as well.

For preparing the pseudo-parallel sentences, we first follow the ideas in (Guu et al., 2018) to generate some initial pairs. Specifically, we first calculate the Jaccard Index (JI) for each pair of sentences, and keep those with JI values no less then 0.5 as the initial pairs. Note that such initial pairs could contain many false positives (roughly 10% as manually evaluated on the Yelp corpus in (Guu et al., 2018)), because the JI calculation does not distinguish content words and outcome words. To solve this problem, we add another constraint: for an initial pair to be regarded as a pseudo-parallel sentence pair, the difference of the two sentences' ratings should be no less than 2. Here, the idea is that given the two sentences are similar enough in wordings (JI $\geq$ 0.5), if their rating scores are dissimilar enough, it looks plausible to conjecture that their wording difference is more likely outcome-related and causes the rating difference. In fact, such wording difference is exactly what we want to capture with pseudo-parallel sentence pairs. In total, we obtain about 604K sentence pairs from the single training sentences. For conducting the joint training with both single sentences and pseudo-parallel pairs, we make each data point composed of a single sentence and a sentence pair. To do so, we couple each sentence pair with a single sentence, thus we can use all pairs for training. Note that because we have more sentence pairs, some single sentences are used twice randomly in composing the data points.

4.2 Comparative Methods

Our model is compared with two state-of-the-art models handling similar tasks.

Sequence to Better Sequence (S2BS) (Mueller et al., 2017): For training, S2BS also requires each sentence is associated with an outcome. For test, S2BS only revises a sentence such that the output is associated with a higher outcome, which is not a specified value. For comparison, we adapt our revision method for S2BS, by which their trained model is able to conduct quantifiable sentence revision. We tune the parameters for S2BS by following the suggestions in their source code.

Text Style Transfer (TST) (Shen et al., 2017): In TST, the sentiment of each sentence is labelled as negative or positive. The model is able to revise a negative sentence into positive, or vice versa. Their task can be treated as a special case of our QuaSE task: we set the outcome target to 1 for the input sentences that are associated with outcomes larger than the neutral rating 3, thus, our task is equal to revising a positive sentence into negative. We follow the suggested parameters reported in (Shen et al., 2017).

4.3 Evaluation Metric and Parameter Setting

Considering that our model's task is to revise a sentence such that its outcome (predicted by Stanford CoreNLP) satisfies a specified target, we define the metric as the mean absolute error (MAE) between the specified target outcome and the outcomes of revised sentences.

$$MAE = \frac{1}{|S|} \sum_{X_i \in S} |R_i - R^*| \qquad (13)$$

where S is the set of revised sentences X_i, R^* is the target outcome, and R_i is the outcome of X_i.

After tuning on the validation set, the determined parameters are: $\lambda_{rec} = 0.75$, $\lambda_{kl} = 0.6$, $\lambda_{mse} = 0.25$, $\lambda_{diff} = 0.2$, $\lambda_{sim} = 0.2$, $\lambda_{d-rec} = 0.1$, and the dimensions of the two factors are both 50. The parameter τ for revision takes $\exp(-100000)$ for both our model and S2BS.

4.4 Automatic Evaluation

We compare our model with S2BS by specifying five target ratings, namely 1, 2, 3, 4, and 5. Both our model and S2BS are fed the sentences in the testing dataset. For each sentence, both models are required to generate five revised sentences, each satisfying one of the target ratings.

	MAE					Edit Distance				
	T=1	T=2	T=3	T=4	T=5	T=1	T=2	T=3	T=4	T=5
Original	2.2182	1.2379	0.8259	0.9279	1.7818	N/A	N/A	N/A	N/A	N/A
S2BS	1.6839	0.9444	0.7567	0.7572	1.3024	6.6439	5.342	4.9390	5.005	6.2290
Our Model	1.4162	0.6298	0.7408	0.5377	0.9408	7.9191	4.7	3.4505	4.13	8.0094

Table 3: MAE and Edit Distance for our proposed model and S2BS. T refers to the target outcome.

We evaluate the MAE between the target outcome and the outcome of the revised sentences. Each model is trained for three times and the average results are reported in Table 3. "Original" refers to the MAE between the targets and the ratings of input sentences. We can observe that the MAE values of both our model and S2BS are smaller than Original. It demonstrates that both models are able to revise the sentences towards the outcome targets. Furthermore, compared with S2BS, our model achieves smaller MAE values. One major reason is that we disentangle a content factor and an outcome factor, and design three components to leverage pseudo-parallel sentences. By modeling the wording difference, our model captures the keywords that cause the difference in the outcome. By enforcing the content factors of pseudo-parallel sentences to be similar, the model is capable to generate the content factor more precisely. Moreover, the dual reconstruction can guide the editing procedure with the hints from the parallel sentences. In contrast, S2BS only disentangles one factor for capturing both content and outcome properties, and thus it cannot perform the same operations on sentence pairs. The MAE for T=5 is smaller than that for T=1. This is partially due to the fact that the outcomes of the test sentences are closer to 5, refer to Table 2. We also report the average Edit Distance between the input sentences and the generated sentences to measure the degree of revisions. For T=1 and T=5, our model conducts more editing than S2BS, which brings in better MAE, while for T={2, 3, 4}, our model generates more accurate sentences (i.e. better MAE) with less editing. This observation coincides with the fact that we need more editing to revise a sentence towards an extreme target (i.e., 1 and 5), such as including degree adverbs "very" and "extremely".

We also compare our model with TST for sentiment polarity transfer. We employ the same evaluation metric as used in (Shen et al., 2017): the sentiment accuracy of the transferred sentences. We define the revised sentences with ratings larger than 3 as positive, smaller than 3 as negative. The results are given in Table 4, where two accuracy values are reported: negative to positive, and the reverse. The results show that our model achieves better accuracy than TST in both transfer directions. One reason is that our method models the associations between each sentence and its outcome, and thus captures the sentiment wordings better. Our model is far better for transferring negative sentences into positive, moreover, both models achieve better performance for this transfer direction. We can probably attribute the reason to the imbalanced training data: 55% positive sentences v.s. 45% negative sentences.

	Neg. to Pos.	Pos. to Neg.
TST	0.7280	0.7097
Our Model	0.8836	0.7862

Table 4: Accuracy comparison with TST.

	Content Preservation (Range: [0, 2])	Fluency (Range: [1, 4])
TST	1.02	2.56
S2BS	0.70	2.53
Our Model	1.38	2.48

Table 5: Manual evaluation.

4.5 Manual Evaluation

We hire five workers to manually evaluate the quality of 500 sentences generated by each of our model and the compared models. The result is shown in Table 5. "Content Preservation" measures whether the generated sentence preserves the content of the input sentence. The score range is {2: fully preserved, 1: partially preserved, 0: not preserved}. "Content Preservation" is an important metric in this task since it is required that the output sentence and the original sentence should describe the same content subject. "Fluency" measures the grammatical quality of a sentence, which

	Generated sentence
E.g. 1	this tire center is amazing .
T=1	this tire center is horrible .
T=3	this tire center is really good .
T=5	this tire center is amazing .
E.g. 2	horrible food !
T=1	horrendous
T=3	their food amazing !
T=5	amazing delicious food ! recommend !
E.g. 3	decent food and wine selection , but nothing i will rush back for .
T=1	decent food and wine selection , but nothing i will rush for no .
T=3	decent food and wine selection , but i will never look back for .
T=5	decent food and wine selection , but excellent service, will return !
E.g. 4	our first time and we had a great meal , wonderful service .
T=1	our first time and we had a terrible meal , stale service .
T=3	our first time and we had a great meal , we have service .
T=5	our first time and we had a great meal , wonderful service .
E.g. 5	food is very addiction tasty !
T=1	food is just horrible here ?
T=3	food is just addiction here !
T=5	food is very yummy addiction !

Table 6: Case study.

ranges from 1 (bad) to 4 (good), by following the definition in TST (Shen et al., 2017).

The result shows that our model achieves the best content preservation score. Our editing procedure explicitly fixes the content factor and only modifies the outcome factor, which helps better preserve the content. In contrast, S2BS and TST include only one shared factor for both the content and the outcome, thus fail to distinguish one from the other. For the "Fluency" metric, S2BS and TST are slightly better than our model. Generally speaking, it is because our model introduces more powerful components for modeling the outcome differences between pseudo-parallel sentences, so as to achieve our goal of editing an input sentence to satisfy the expected outcome. However, these components do not contribute to the language quality of generated sentences.

4.6 Case Study

We show some examples produced by our model in Table 6. For each input, we specify three targets: 1, 3, and 5. For the first and the forth examples, the original sentences are not revised when the target rating is set to 5 (i.e., T=5) since the original sentences are already quite positive. For the first example, when T=3, "amazing" is revised to a relatively less positive phrase "really good". This case demonstrates that our model is able to capture the subtle difference in word sentiments, so that it can revise sentences reasonably according to the quantifiable rating guidance. Moreover, for the second example, we notice that our model revises the original sentence "horrible food !" to "amazing delicious food ! recommend !" for T=5. This case shows that our model not only changes one word with another having different sentiment, e.g. "horrible" to "amazing delicious", but also creatively introduces words from a new perspective, e.g. "recommend".

4.7 Ablation and Tuning Behavior Discussions

Recall that our model is a combination of a revised VAE, which disentangles two factors from a sentence to enable the subsequent design, and a coupling component modeling pseudo-parallel sentence pairs. For the three losses of the coupling component, we show their effects under the MAE metric in Table 7. "None" refers to all three losses are removed, and it is basically worse than S2BS, which implies only using the revised VAE does not work well. As more losses added, the performance is gradually improved. Moreover, the dual reconstruction is more effective than the others.

	T=1	T=3	T=5
S2BS	1.6839	0.7567	1.3024
None	1.6639	0.7684	1.5434
$\mathcal{L}_{sim}$	1.6090	0.8258	1.5233
$\mathcal{L}_{diff}$	1.6793	0.8017	1.3140
$\mathcal{L}_{d-rec}$	1.5191	0.7784	1.1218
$\mathcal{L}_{sim}, \mathcal{L}_{diff}$	1.4991	0.8218	1.3705
$\mathcal{L}_{sim}, \mathcal{L}_{d-rec}$	1.4101	0.8027	1.1246
$\mathcal{L}_{diff}, \mathcal{L}_{d-rec}$	1.3879	0.7786	1.1413
ALL	1.4162	0.7408	0.9408

Table 7: Ablation study.

In the weight tuning, the first step only tunes the weights of $\mathcal{L}_{rec}$ and $\mathcal{L}_{mse}$. We observe that solely minimizing $\mathcal{L}_{rec}$ and $\mathcal{L}_{mse}$ also decreases $\mathcal{L}_{sim}$, because in this process, the encoder E_2 becomes more capable of disentangling the content factor, and thus z and z' become similar as they come from two similar input sentences, i.e. pseudo-parallel sentences. Another observation is that solely minimizing $\mathcal{L}_{rec}$ and $\mathcal{L}_{mse}$ increases $\mathcal{L}_{d-rec}$ after some training epochs. To analyze the reason, let us assume there is a sentence x in the training set. Thus, the loss of reconstructing x from y and z is included in $\mathcal{L}_{rec}$. Assume that x is also included in a pseudo-parallel pair, and thus the loss of reconstructing x from y and z' is included in $\mathcal{L}_{d-rec}$. The only difference between the two losses lies in the content factors z and z'. Given that z and z' are not enforced to resemble each other when $\mathcal{L}_{sim}$ is excluded from this tuning step, $\mathcal{L}_{rec}$ and $\mathcal{L}_{d-rec}$ cannot be minimized simultaneously. Moreover, when we minimize $\mathcal{L}_{sim}$ in the second step with the weights of $\mathcal{L}_{rec}$ and $\mathcal{L}_{mse}$ fixed, we observe that $\mathcal{L}_{d-rec}$ also decreases, which complies with the above analysis.

5 Related Works

Inspired by the task of image style transfer (Gatys et al., 2016; Liu and Tuzel, 2016), researchers proposed the task of text style transfer and obtained some encouraging results (Fu et al., 2018; Hu et al., 2017; Jhamtani et al., 2017; Melnyk et al., 2017; Zhang et al., 2018; Li et al., 2018; Prabhumoye et al., 2018; Niu and Bansal, 2018). Existing studies on text style transfer mainly aim at transferring text from an original style into a target style, e.g., from negative to positive, from male to female, from rude/normal to polite; from modern text to Shakespeare style, etc. In contrast, our proposed task QuaSE assumes each sentence is associated with an outcome pertaining to continues values, and the editing is under the guidance of a specific target.

To transfer the style of a sentence, the paradigm of most works (Shen et al., 2017; Mueller et al., 2017; Prabhumoye et al., 2018) first learns the latent representation of the original sentence and then applies a decoder to generate the transferred sentence. A line of works (Shen et al., 2017; Mueller et al., 2017), including the studied task in this paper, assume that only non-parallel data is available for training. In such settings, VAEs (Kingma and Welling, 2013) are employed to learn the latent representations of sentences. Shen et al. (2017) assume a shared latent content distribution across text corpora belonging to different styles, and leverages the alignment of latent representations from different styles to perform style transfer. Mueller et al. (2017) associate the latent representations with a numerical outcome, which is a measurement of the style. A transferred sentence is generated from a modified latent representation. Different from the aforementioned works based on latent representations, Li et al. (2018) propose a simpler method that achieves attribute transfer by changing a few attribute marker words or phrases in the sentence that are indicative of a particular attribute, while leaving the rest of the sentence largely unchanged. The simple method is able to generate better-quality sentences than the aforementioned works. Besides style transfer, sentence editing models can be developed for other tasks. For example, Schmaltz et al. (2017) propose neural sequence-labelling models for correcting the grammatical errors of sentences.

6 Conclusions

We proposed a new task namely Quantifiable Sequence Editing (QuaSE), where a model needs to edit an input sentences towards the direction of a numerical outcome target. To tackle this task, we proposed a novel framework that simultaneously exploits the single sentences and pseudo-parallel sentence pairs. For evaluation, we prepared a dataset with Yelp sentences and their ratings. Experimental results show that our framework outperforms the compared methods under the measures of sentiment polarity accuracy and target value errors. Case studies show that our framework can generate some interesting sentences.

Abstract

Automatic generation of paraphrases from a given sentence is an important yet challenging task in natural language processing (NLP). In this paper, we present a deep reinforcement learning approach to paraphrase generation. Specifically, we propose a new framework for the task, which consists of a *generator* and an *evaluator*, both of which are learned from data. The generator, built as a sequence-to-sequence learning model, can produce paraphrases given a sentence. The evaluator, constructed as a deep matching model, can judge whether two sentences are paraphrases of each other. The generator is first trained by deep learning and then further fine-tuned by reinforcement learning in which the reward is given by the evaluator. For the learning of the evaluator, we propose two methods based on *supervised learning* and *inverse reinforcement learning* respectively, depending on the type of available training data. Experimental results on two datasets demonstrate the proposed models (the generators) can produce more accurate paraphrases and outperform the state-of-the-art methods in paraphrase generation in both automatic evaluation and human evaluation.

1 Introduction

Paraphrases refer to texts that convey the same meaning but with different expressions. For example, "*how far is Earth from Sun*", "*what is the distance between Sun and Earth*" are paraphrases. Paraphrase generation refers to a task in which given a sentence the system creates paraphrases of it. Paraphrase generation is an important task in NLP, which can be a key technology in many applications such as retrieval based question answering, semantic parsing, query reformulation in web search, data augmentation for dialogue system. However, due to the complexity of natural language, automatically generating accurate and diverse paraphrases is still very challenging. Traditional symbolic approaches to paraphrase generation include rule-based methods (McKeown, 1983), thesaurus-based methods (Bolshakov and Gelbukh, 2004; Kauchak and Barzilay, 2006), grammar-based methods (Narayan et al., 2016), and statistical machine translation (SMT) based methods (Quirk et al., 2004; Zhao et al., 2008, 2009).

Recently, neural network based sequence-to-sequence (Seq2Seq) learning has made remarkable success in various NLP tasks, including machine translation, short-text conversation, text summarization, and question answering (e.g., Cho et al. (2014); Wu et al. (2016); Shang et al. (2015); Vinyals and Le (2015); Rush et al. (2015); Yin et al. (2016)). Paraphrase generation can naturally be formulated as a Seq2Seq problem (Cao et al., 2017; Prakash et al., 2016; Gupta et al., 2018; Su and Yan, 2017). The main challenge in paraphrase generation lies in the definition of the evaluation measure. Ideally the measure is able to calculate the semantic similarity between a generated paraphrase and the given sentence. In a straightforward application of Seq2Seq to paraphrase generation one would make use of cross entropy as evaluation measure, which can only be a loose approximation of semantic similarity. To tackle this problem, Ranzato et al. (2016) propose employing reinforcement learning (RL) to guide the training of Seq2Seq and using lexical-based measures such as BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004) as a reward function. However, these lexical measures may not perfectly represent semantic similarity. It is likely that a correctly generated sequence gets a low ROUGE score due to lexical mismatch. For instance, an input sentence "*how far is Earth from Sun*" can be paraphrased as "*what is the distance between Sun and Earth*", but it will

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3865–3878
Brussels, Belgium, October 31 - November 4, 2018.

get a very low ROUGE score given "*how many miles is it from Earth to Sun*" as a reference.

In this work, we propose taking a data-driven approach to train a model that can conduct evaluation in learning for paraphrasing generation. The framework contains two modules, a generator (for paraphrase generation) and an evaluator (for paraphrase evaluation). The generator is a Seq2Seq learning model with attention and copy mechanism (Bahdanau et al., 2015; See et al., 2017), which is first trained with cross entropy loss and then fine-tuned by using policy gradient with supervisions from the evaluator as rewards. The evaluator is a deep matching model, specifically a decomposable attention model (Parikh et al., 2016), which can be trained by supervised learning (SL) when both positive and negative examples are available as training data, or by inverse reinforcement learning (IRL) with outputs from the generator as supervisions when only positive examples are available. In the latter setting, for the training of evaluator using IRL, we develop a novel algorithm based on max-margin IRL principle (Ratliff et al., 2006). Moreover, the generator can be further trained with non-parallel data, which is particularly effective when the amount of parallel data is small.

We evaluate the effectiveness of our approach using two real-world datasets (Quora question pairs and Twitter URL paraphrase corpus) and we conduct both automatic and human assessments. We find that the evaluator trained by our methods can provide accurate supervisions to the generator, and thus further improve the accuracies of the generator. The experimental results indicate that our models can achieve significantly better performances than the existing neural network based methods.

It should be noted that the proposed approach is not limited to paraphrase generation and can be readily applied into other sequence-to-sequence tasks such as machine translation and generation based single turn dialogue. Our technical contribution in this work is of three-fold:

1. We introduce the generator-evaluator framework for paraphrase generation, or in general, sequence-to-sequence learning.
2. We propose two approaches to train the evaluator, i.e., supervised learning and inverse reinforcement learning.
3. In the above framework, we develop several techniques for learning of the generator and evaluator.

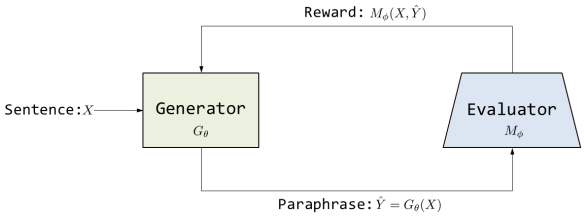

Figure 1: Framework of RbM (Reinforced by Matching).

Section 2 defines the models of generator and evaluator. In section 3, we formalize the problem of learning the models of generator and evaluator. In section 4, we report our experimental results. In section 5, we introduce related work.

2 Models

This section explains our framework for paraphrase generation, containing two models, the generator and evaluator.

2.1 Problem and Framework

Given an input sequence of words $X = [x_1, \ldots, x_S]$ with length S, we aim to generate an output sequence of words $Y = [y_1, \ldots, y_T]$ with length T that has the same meaning as X. We denote the pair of sentences in paraphrasing as (X, Y). We use $Y_{1:t}$ to denote the subsequence of Y ranging from 1 to t and use $\hat{Y}$ to denote the sequence generated by a model.

We propose a framework, which contains a generator and an evaluator, called **RbM** (Reinforced by Matching). Specifically, for the generator we adopt the Seq2Seq architecture with attention and copy mechanism (Bahdanau et al., 2015; See et al., 2017), and for the evaluator we adopt the decomposable attention-based deep matching model (Parikh et al., 2016). We denote the generator as G_θ and the evaluator as M_ϕ, where θ and ϕ represent their parameters respectively. Figure 1 gives an overview of our framework. Basically the generator can generate a paraphrase of a given sentence and the evaluator can judge how semantically similar the two sentences are.

2.2 Generator: Seq2Seq Model

In this work, paraphrase generation is defined as a sequence-to-sequence (Seq2Seq) learning problem. Given input sentence X, the goal is to learn a model G_θ that can generate a sentence

$\hat{Y} = G_\theta(X)$ as its paraphrase. We choose the *pointer-generator* proposed by See et al. (2017) as the generator. The model is built based on the encoder-decoder framework (Cho et al., 2014; Sutskever et al., 2014), both of which are implemented as recurrent neural networks (RNN). The encoder RNN transforms the input sequence X into a sequence of hidden states $H = [h_1, \ldots, h_S]$. The decoder RNN generates an output sentence Y on the basis of the hidden states. Specifically it predicts the next word at each position by sampling from $\hat{y}_t \sim p(y_t|Y_{1:t-1}, X) = g(s_t, c_t, y_{t-1})$, where s_t is the decoder state, c_t is the context vector, y_{t-1} is the previous word, and g is a feed-forward neural network. Attention mechanism (Bahdanau et al., 2015) is introduced to compute the context vector as the weighted sum of encoder states:

$$c_t = \sum_{i=1}^{S} \alpha_{ti} h_i, \quad \alpha_{ti} = \frac{\exp \eta(s_{t-1}, h_i)}{\sum_{j=1}^{S} \exp \eta(s_{t-1}, h_j)},$$

where α_{ti} represents the attention weight and η is the *attention function*, which is a feed-forward neural network.

Paraphrasing often needs copying words from the input sentence, for instance, named entities. The pointer-generator model allows either generating words from a vocabulary or copying words from the input sequence. Specifically the probability of generating the next word is given by a mixture model:

$$p_\theta(y_t|Y_{1:t-1}, X) = q(s_t, c_t, y_{t-1}) g(s_t, c_t, y_{t-1}) + (1 - q(s_t, c_t, y_{t-1})) \sum\nolimits_{i: y_t = x_i} \alpha_{ti},$$

where $q(s_t, c_t, y_{t-1})$ is a binary neural classifier deciding the probability of switching between the generation mode and the copying mode.

2.3 Evaluator: Deep Matching Model

In this work, paraphrase evaluation (identification) is casted as a problem of learning of sentence matching. The goal is to learn a real-valued function $M_\phi(X, Y)$ that can represent the matching degree between the two sentences as paraphrases of each other. A variety of learning techniques have been developed for matching sentences, from linear models (e.g., Wu et al. (2013)) to neural network based models (e.g., Socher et al. (2011); Hu et al. (2014)). We choose a simple yet effective neural network architecture, called the *decomposable-attention* model (Parikh et al., 2016), as the evaluator. The evaluator can calculate the semantic similarity between two sentences:

$$M_\phi(X, Y) = H(\sum_{i=1}^{S} G([e(x_i), \bar{x}_i]), \sum_{j=1}^{T} G([e(y_j), \bar{y}_j])),$$

where $e(\cdot)$ denotes a word embedding, $\bar{x}_i$ and $\bar{y}_j$ denote inter-attended vectors, H and G are feed-forward networks. We refer the reader to Parikh et al. (2016) for details. In addition, we add *positional encodings* to the word embedding vectors to incorporate the order information of the words, following the idea in Vaswani et al. (2017).

3 Learning

This section explains how to learn the generator and evaluator using deep reinforcement learning.

3.1 Learning of Generator

Given training data (X, Y), the generator G_θ is first trained to maximize the conditional log likelihood (negative cross entropy):

$$\mathcal{L}_{\text{Seq2Seq}}(\theta) = \sum\nolimits_{t=1}^{T} \log p_\theta(y_t|Y_{1:t-1}, X). \quad (1)$$

When computing the conditional probability of the next word as above, we choose the previous word y_{t-1} in the ground-truth rather than the word $\hat{y}_{t-1}$ generated by the model. This technique is called *teacher forcing*.

With teacher forcing, the discrepancy between training and prediction (also referred to as *exposure bias*) can quickly accumulate errors along the generated sequence (Bengio et al., 2015; Ranzato et al., 2016). Therefore, the generator G_θ is next fine-tuned using RL, where the reward is given by the evaluator.

In the RL formulation, generation of the next word represents an *action*, the previous words represent a *state*, and the probability of generation $p_\theta(y_t|Y_{1:t-1}, X)$ induces a stochastic *policy*. Let r_t denote the *reward* at position t. The goal of RL is to find a policy (i.e., a generator) that maximizes the expected cumulative reward:

$$\mathcal{L}_{RL}(\theta) = \mathbb{E}_{p_\theta(\hat{Y}|X)} \sum_{t=1}^{T} r_t(X, \hat{Y}_{1:t}). \quad (2)$$

We define a positive reward at the end of sequence ($r_T = R$) and a zero reward at the other positions. The reward R is given by the evaluator M_ϕ. In particular, when a pair of input sentence X and generated paraphrase $\hat{Y} = G_\theta(X)$ is given, the reward is calculated by the evaluator $R = M_\phi(X, \hat{Y})$.

We can then learn the optimal policy by employing policy gradient. According to the policy gradient theorem (Williams, 1992; Sutton et al., 2000), the gradient of the expected cumulative reward can be calculated by

$$\nabla_\theta \mathcal{L}_{RL}(\theta) = \sum_{t=1}^{T} [\nabla_\theta \log p_\theta(\hat{y}_t | \hat{Y}_{1:t-1}, X)] r_t. \tag{3}$$

The generator can thus be learned with stochastic gradient descent methods such as Adam (Kingma and Ba, 2015).

3.2 Learning of Evaluator

The evaluator works as the reward function in RL of the generator and thus is essential for the task. We propose two methods for learning the evaluator in different settings. When there are both positive and negative examples of paraphrases, the evaluator is trained by *supervised learning* (SL). When only positive examples are available (usually the same data as the training data of the generator), the evaluator is trained by *inverse reinforcement learning* (IRL).

Supervised Learning

Given a set of positive and negative examples (paraphrase pairs), we conduct supervised learning of the evaluator with the pointwise cross entropy loss:

$$\mathcal{J}_{\mathrm{SL}}(\phi) = -\log M_\phi(X, Y) - \log(1 - M_\phi(X, Y^-)), \tag{4}$$

where Y^- represents a sentence that is not a paraphrase of X. The evaluator M_ϕ here is defined as a classifier, trained to distinguish negative example (X, Y^-) from positive example (X, Y).

We call this method **RbM-SL** (Reinforced by Matching with Supervised Learning). The evaluator M_ϕ trained by supervised learning can make a judgement on whether two sentences are paraphrases of each other. With a well-trained evaluator M_ϕ, we further train the generator G_θ by reinforcement learning using M_ϕ as a reward function. Figure 2a shows the learning process of RbM-SL. The detailed training procedure is shown in Algorithm 1 in Appendix A.

Inverse Reinforcement Learning

Inverse reinforcement learning (IRL) is a sub-problem of reinforcement learning (RL), about learning of a reward function given *expert demonstrations*, which are sequences of states and actions from an expert (optimal) policy. More specifically, the goal is to find an optimal reward function R^* with which the expert policy $p_{\theta^*}(Y|X)$ really becomes optimal among all possible policies, i.e.,

$$\mathbb{E}_{p_{\theta^*}(Y|X)} R^*(Y) \geq \mathbb{E}_{p_\theta(\hat{Y}|X)} R^*(\hat{Y}), \;\; \forall \theta.$$

In the current problem setting, the problem becomes learning of an optimal reward function (evaluator) given a number of paraphrase pairs given by human experts (expert demonstrations).

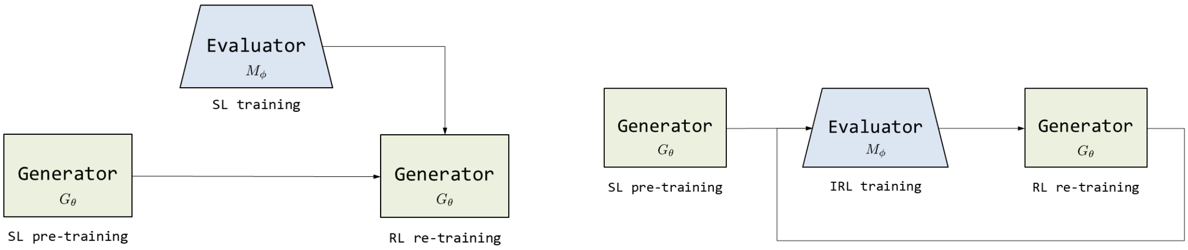
To learn an optimal reward (matching) function is challenging, because the expert demonstrations might not be optimal and the reward function might not be rigorously defined. To deal with the problem, we employ the maximum margin formulation of IRL inspired by Ratliff et al. (2006).

The maximum margin approach ensures the learned reward function has the following two desirable properties in the paraphrase generation task: (a) given the same input sentence, a reference from humans should have a higher reward than the ones generated by the model; (b) the margins between the rewards should become smaller when the paraphrases generated by the model get closer to a reference given by humans. We thus specifically consider the following optimization problem for learning of the evaluator:

$$\mathcal{J}_{\mathrm{IRL}}(\phi) = \max(0, 1 - \zeta + M_\phi(X, \hat{Y}) - M_\phi(X, Y)), \tag{5}$$

where ζ is a slack variable to measure the agreement between $\hat{Y}$ and Y. In practice we set $\zeta = \text{ROUGE-L}(\hat{Y}, Y)$. Different from RbM-SL, the evaluator M_ϕ here is defined as a ranking model that assigns higher rewards to more plausible paraphrases.

Once the reward function (evaluator) is learned, it is then used to improve the policy function (generator) through policy gradient. In fact, the generator G_θ and the evaluator M_ϕ are trained alternatively. We call this method **RbM-IRL** (Reinforced by Matching with Inverse Reinforcement Learning). Figure 2b shows the learning process of RbM-IRL. The detailed training procedure is shown in Algorithm 2 in Appendix A.



(a) RbM-SL

(b) RbM-IRL

Figure 2: Learning Process of RbM models: (a) RbM-SL, (b) RbM-IRL.

We can formalize the whole learning procedure as the following optimization problem:

$$\min_{\phi} \max_{\theta} \mathbb{E}_{p_\theta(\hat{Y}|X)} \mathcal{J}_{\text{IRL}}(\phi). \tag{6}$$

RbM-IRL can make effective use of sequences generated by the generator for training of the evaluator. As the generated sentences become closer to the ground-truth, the evaluator also becomes more discriminative in identifying paraphrases.

It should be also noted that for both RbM-SL and RbM-IRL, once the evaluator is learned, the reinforcement learning of the generator only needs *non-parallel sentences* as input. This makes it possible to further train the generator and enhance the generalization ability of the generator.

3.3 Training Techniques

Reward Shaping

In the original RL of the generator, only a positive reward R is given at the end of sentence. This provides sparse supervision signals and can make the model greatly degenerate. Inspired by the idea of reward shaping (Ng et al., 1999; Bahdanau et al., 2017), we estimate the intermediate cumulative reward (value function) for each position, that is

$$Q_t = \mathbb{E}_{p_\theta(Y_{t+1:T}|\hat{Y}_{1:t},X)} R(X, [\hat{Y}_{1:t}, Y_{t+1:T}]),$$

by Monte-Carlo simulation, in the same way as in Yu et al. (2017):

$$Q_t = \begin{cases} \frac{1}{N}\sum_{n=1}^{n=N} M_\phi(X, [\hat{Y}_{1:t}, \widehat{Y}^n_{t+1:T}]), & t < T \\ M_\phi(X, \hat{Y}), & t = T, \end{cases} \tag{7}$$

where N is the sample size and $\widehat{Y}^n_{t+1:T} \sim p_\theta(Y_{t+1:T}|\hat{Y}_{1:t}, X)$ denotes simulated sub-sequences randomly sampled starting from the $(t+1)$-th word. During training of the generator, the reward r_t in policy gradient (3) is replaced by Q_t estimated in (7).

Reward Rescaling

In practice, RL algorithms often suffer from instability in training. A common approach to reduce the variance is to subtract a baseline reward from the value function. For instance, a simple baseline can be a moving average of historical rewards. While in RbM-IRL, the evaluator keeps updating during training. Thus, keeping track of a baseline reward is unstable and inefficient. Inspired by Guo et al. (2018), we propose an efficient reward rescaling method based on ranking. For a batch of D generated paraphrases $\{\hat{Y}^d\}_{d=1}^D$, each associated with a reward $R^d = M_\phi(X^d, \hat{Y}^d)$, we rescale the rewards by

$$\bar{R}^d = \sigma(\delta_1 \cdot (0.5 - \frac{\text{rank}(d)}{D})) - 0.5, \tag{8}$$

where $\sigma(\cdot)$ is the sigmoid function, $\text{rank}(d)$ is the rank of R^d in $\{R^1, ..., R^D\}$, and δ_1 is a scalar controlling the variance of rewards. A similar strategy is applied into estimation of in-sequence value function for each word, and the final rescaled value function is

$$\bar{Q}^d_t = \sigma(\delta_2 \cdot (0.5 - \frac{\text{rank}(t)}{T})) - 0.5 + \bar{R}^d, \tag{9}$$

where $\text{rank}(t)$ is the rank of Q^d_t in $\{Q^d_1, ..., Q^d_T\}$.

Reward rescaling has two advantages. First, the mean and variance of $\bar{Q}^d_t$ are controlled and hence they make the policy gradient more stable, even with a varying reward function. Second, when the evaluator M_ϕ is trained with the ranking loss as in RbM-IRL, it is better to inform which paraphrase is better, rather than to provide a scalar reward in a range. In our experiment, we find that this method can bring substantial gains for RbM-SL and RbM-IRL, but not for RL with ROUGE as reward.

Curriculum Learning

RbM-IRL may not achieve its best performance if all of the training instances are included in training at the beginning. We employ a curriculum learning strategy (Bengio et al., 2009) for it. During the training of the evaluator M_ϕ, each example k is associated with a weight w^k, i.e.

$$\mathcal{J}^k_{\text{IRL-CL}}(\phi) = w^k \max(0,1 - \zeta^k + M_\phi(X^k, \hat{Y}^k) - M_\phi(X^k, Y^k)) \quad (10)$$

In curriculum learning, w^k is determined by the difficulty of the example. At the beginning, the training procedure concentrates on relatively simple examples, and gradually puts more weights on difficult ones. In our case, we use the edit distance $\mathcal{E}(X, Y)$ between X and Y as the measure of difficulty for paraphrasing. Specifically, w^k is determined by $w^k \sim \text{Binomial}(p^k, 1)$, and $p^k = \sigma(\delta_3 \cdot (0.5 - \frac{\text{rank}(\mathcal{E}(X^k,Y^k))}{K}))$, where K denotes the batch size for training the evaluator. For δ_3, we start with a relatively high value and gradually decrease it. In the end each example will be sampled with a probability around 0.5. In this manner, the evaluator first learns to identify paraphrases with small modifications on the input sentences (e.g. "*what 's*" and "*what is*"). Along with training it gradually learns to handle more complicated paraphrases (e.g. "*how can I*" and "*what is the best way to*").

4 Experiment

4.1 Baselines and Evaluation Measures

To compare our methods (RbM-SL and RbM-IRL) with existing neural network based methods, we choose five baseline models: the attentive Seq2Seq model (Bahdanau et al., 2015), the stacked Residual LSTM networks (Prakash et al., 2016), the variational auto-encoder (VAE-SVG-eq) (Gupta et al., 2018) [1], the pointer-generator (See et al., 2017), and the reinforced pointer-generator with ROUGE-2 as reward (RL-ROUGE) (Ranzato et al., 2016).

We conduct both automatic and manual evaluation on the models. For the automatic evaluation, we adopt four evaluation measures: ROUGE-1, ROUGE-2 (Lin, 2004), BLEU (Papineni et al., 2002) (up to at most bi-grams) and METEOR (Lavie and Agarwal, 2007). As pointed out, ideally it would be better not to merely use a lexical measure like ROUGE or BLEU for evaluation of paraphrasing. We choose to use them for reproducibility of our experimental results by others. For the manual evaluation, we conduct evaluation on the generated paraphrases in terms of relevance and fluency.

4.2 Datasets

We evaluate our methods with the **Quora** question pair dataset [2] and **Twitter** URL paraphrasing corpus (Lan et al., 2017). Both datasets contain positive and negative examples of paraphrases so that we can evaluate the RbM-SL and RbM-IRL methods. We randomly split the Quora dataset in two different ways obtaining two experimental settings: Quora-I and Quora-II. In Quora-I, we partition the dataset by question pairs, while in Quora-II, we partition by question ids such that there is no shared question between the training and test/validation datasets. In addition, we sample a smaller training set in Quora-II to make the task more challenging. Twitter URL paraphrasing corpus contains two subsets, one is labeled by human annotators while the other is labeled automatically by algorithm. We sample the test and validation set from the labeled subset, while using the remaining pairs as training set. For RbM-SL, we use the labeled subset to train the evaluator M_ϕ. Compared to Quora-I, it is more difficult to achieve a high performance with Quora-II. The Twitter corpus is even more challenging since the data contains more noise. The basic statistics of datasets are shown in Table 1.

Table 1: Statistics of datasets.

	Generator			Evaluator (RbM-SL)	
Dataset	#Train	#Test	#Validation	#Positive	#Negative
Quora-I	100K	30K	3K	100K	160K
Quora-II	50K	30K	3K	50K	160K
Twitter	110K	5K	1K	10K	40K

4.3 Implementation Details

Generator We maintain a fixed-size vocabulary of 5K shared by the words in input and output, and truncate all the sentences longer than 20 words. The model architecture, word embedding size and LSTM cell size are as the same as reported in See et al. (2017). We use Adadgrad optimizer (Duchi et al., 2011) in the supervised pre-training and Adam optimizer in the reinforcement learning, with the batch size of 80. We also fine-tune the

Seq2Seq baseline models with Adam optimizer for a fair comparison. In supervised pre-training, we set the learning rate as 0.1 and initial accumulator as 0.1. The maximum norm of gradient is set as 2. During the RL training, the learning rate decreases to 1e-5 and the size of Monte-Carlo sample is 4. To make the training more stable, we use the ground-truth with reward of 0.1.

Evaluator We use the pretrained GoogleNews 300-dimension word vectors [3] in Quora dataset and 200-dimension GloVe word vectors [4] in Twitter corpus. Other model settings are the same as in Parikh et al. (2016). For evaluator in RbM-SL we set the learning rate as 0.05 and the batch size as 32. For the evaluator of M_ϕ in RbM-IRL, the learning rate decreases to 1e-2, and we use the batch size of 80.

We use the technique of reward rescaling as mentioned in section 3.3 in training RbM-SL and RbM-IRL. In RbM-SL, we set δ_1 as 12 and δ_2 as 1. In RbM-IRL, we keep δ_2 as 1 all the time and decrease δ_1 from 12 to 3 and δ_3 from 15 to 8 during curriculum learning. In ROUGE-RL, we take the exponential moving average of historical rewards as baseline reward to stabilize the training:

$$b_m = \lambda \overline{Q}_{m-1} + (1-\lambda) b_{m-1},\ b_1 = 0$$

where b_m is the baseline b at iteration m, $\overline{Q}$ is the mean value of reward, and we set λ as 0.1 by grid search.

4.4 Results and Analysis

Automatic evaluation Table 2 shows the performances of the models on Quora datasets. In both settings, we find that the proposed RbM-SL and RbM-IRL models outperform the baseline models in terms of all the evaluation measures. Particularly in Quora-II, RbM-SL and RbM-IRL make significant improvements over the baselines, which demonstrates their higher ability in learning for paraphrase generation. On Quora dataset, RbM-SL is constantly better than RbM-IRL for all the automatic measures, which is reasonable because RbM-SL makes use of additional labeled data to train the evaluator. Quora datasets contains a large number of high-quality non-paraphrases, i.e., they are literally similar but semantically different, for instance "*are analogue clocks better than digital*" and "*is analogue better than digital*". Trained with the data, the evaluator tends to become more capable in paraphrase identification. With additional evaluation on Quora data, the evaluator used in RbM-SL can achieve an accuracy of 87% on identifying positive and negative pairs of paraphrases.

Table 3 shows the performances on the Twitter corpus. Our models again outperform the baselines in terms of all the evaluation measures. Note that RbM-IRL performs better than RbM-SL in this case. The reason might be that the evaluator

---

[3] `https://code.google.com/archive/p/word2vec/`

[4] `https://nlp.stanford.edu/projects/glove/`

of RbM-SL might not be effectively trained with the relatively small dataset, while RbM-IRL can leverage its advantage in learning of the evaluator with less data.

In our experiments, we find that the training techniques proposed in section 3.3 are all necessary and effective. Reward shaping is by default employed by all the RL based models. Reward rescaling works particularly well for the RbM models, where the reward functions are learned from data. Without reward rescaling, RbM-SL can still outperform the baselines but with smaller margins. For RbM-IRL, curriculum learning is necessary for its best performance. Without curriculum learning, RbM-IRL only has comparable performance with ROUGE-RL.

Human evaluation We randomly select 300 sentences from the test data as input and generate paraphrases using different models. The pairs of paraphrases are then aggregated and partitioned into seven random buckets for seven human assessors to evaluate. The assessors are asked to rate each sentence pair according to the following two criteria: *relevance* (the paraphrase sentence is semantically close to the original sentence) and *fluency* (the paraphrase sentence is fluent as a natural language sentence, and the grammar is correct). Hence each assessor gives two scores to each paraphrase, both ranging from 1 to 5. To reduce the evaluation variance, there is a detailed evaluation guideline for the assessors in Appendix B. Each paraphrase is rated by two assessors, and then averaged as the final judgement. The agreement between assessors is moderate (kappa=0.44).

Table 4 demonstrates the average ratings for each model, including the ground-truth references. Our models of RbM-SL and RbM-IRL get better scores in terms of relevance and fluency than the baseline models, and their differences are statistically significant (paired t-test, p-value < 0.01). We note that in human evaluation, RbM-SL achieves the best relevance score while RbM-IRL achieves the best fluency score.

Case study Figure 3 gives some examples of generated paraphrases by the models on Quora-II for illustration. The first and second examples show the superior performances of RbM-SL and RbM-IRL over the other models. In the third example, both RbM-SL and RbM-IRL capture accurate paraphrasing patterns, while the other models wrongly segment and copy words from the input sentence. Compared to RbM-SL with an error of repeating the word *scripting*, RbM-IRL generates a more fluent paraphrase. The reason is that the evaluator in RbM-IRL is more capable of measuring the fluency of a sentence. In the fourth example, RL-ROUGE generates a totally non-sense sentence, and pointer-generator and RbM-IRL just cover half of the content of the original sentence, while RbM-SL successfully rephrases and preserves all the meaning. All of the models fail in the last example, because the word *ducking* is a rare word that never appears in the training data. Pointer-generator and RL-ROUGE generate totally irrelevant words such as *UNK* token or *victory*, while RbM-SL and RbM-IRL still generate topic-relevant words.

5 Related Work

Neural paraphrase generation recently draws attention in different application scenarios. The task is often formalized as a sequence-to-sequence (Seq2Seq) learning problem. Prakash et al. (2016) employ a stacked residual LSTM network in the Seq2Seq model to enlarge the model capacity. Cao et al. (2017) utilize an additional vocabulary to restrict word candidates during generation. Gupta et al. (2018) use a variational auto-encoder framework to generate more diverse paraphrases. Ma et al. (2018) utilize an attention layer instead of a linear mapping in the decoder to pick up word candidates. Iyyer et al. (2018) harness syntactic information for controllable paraphrase generation. Zhang and Lapata (2017) tackle a similar task of sentence simplification withe Seq2Seq model coupled with deep reinforcement learning, in which the reward function is manually defined for the task. Similar to these works, we also pretrain the paraphrase generator within the Seq2Seq framework. The main difference lies in that we use another trainable neural network, referred to as evaluator, to guide the training of the generator through reinforcement learning.

There is also work on paraphrasing generation in different settings. For example, Mallinson et al. (2017) leverage bilingual data to produce paraphrases by pivoting over a shared translation in another language. Wieting et al. (2017); Wieting and Gimpel (2018) use neural machine translation to generate paraphrases via back-translation of bilingual sentence pairs. Buck et al. (2018) and Dong et al. (2017) tackle the problem of QA-specific paraphrasing with the guidance from an external

QA system and an associated evaluation metric.

Inverse reinforcement learning (IRL) aims to learn a reward function from expert demonstrations. Abbeel and Ng (2004) propose *apprenticeship learning*, which uses a feature based linear reward function and learns to match feature expectations. Ratliff et al. (2006) cast the problem as structured maximum margin prediction. Ziebart et al. (2008) propose max entropy IRL in order to solve the problem of expert suboptimality. Recent work involving deep learning in IRL includes Finn et al. (2016b) and Ho et al. (2016). There does not seem to be much work on IRL for NLP. In Neu and Szepesvári (2009), parsing is formalized as a feature expectation matching problem. Wang et al. (2018) apply adversarial inverse reinforcement learning in visual story telling. To the best of our knowledge, our work is the first that applies deep IRL into a Seq2Seq task.

Generative Adversarial Networks (GAN) (Goodfellow et al., 2014) is a family of unsupervised generative models. GAN contains a generator and a discriminator, respectively for generating examples from random noises and distinguishing generated examples from real examples, and they are trained in an adversarial way. There are applications of GAN on NLP, such as text generation (Yu et al., 2017; Guo et al., 2018) and dialogue generation (Li et al., 2017). RankGAN (Lin et al., 2017) is the one most similar to RbM-IRL that employs a ranking model as the discriminator. However, RankGAN works for text generation rather than sequence-to-sequence learning, and training of generator in RankGAN relies on parallel data while the training of RbM-IRL can use non-parallel data.

There are connections between GAN and IRL as pointed by Finn et al. (2016a); Ho and Ermon (2016). However, there are significant differences between GAN and our RbM-IRL model. GAN employs the discriminator to distinguish generated examples from real examples, while RbM-IRL employs the evaluator as a reward function in RL. The generator in GAN is trained to maximize the loss of the discriminator in an adversarial way, while the generator in RbM-IRL is trained to maximize the expected cumulative reward from the evaluator.

6 Conclusion

In this paper, we have proposed a novel deep reinforcement learning approach to paraphrase generation, with a new framework consisting of a generator and an evaluator, modeled as sequence-to-sequence learning model and deep matching model respectively. The generator, which is for paraphrase generation, is first trained via sequence-to-sequence learning. The evaluator, which is for paraphrase identification, is then trained via supervised learning or inverse reinforcement learning in different settings. With a well-trained evaluator, the generator is further fine-tuned by reinforcement learning to produce more accurate paraphrases. The experiment results demonstrate that the proposed method can significantly improve the quality of paraphrase generation upon the baseline methods. In the future, we plan to apply the framework and training techniques into other tasks, such as machine translation and dialogue.

A Algorithms of RbM-SL and RbM-IRL

Algorithm 1: Training Procedure of RbM-SL

```
Input : A corpus of paraphrase pairs $\{(X, Y)\}$, a corpus of non-paraphrase pairs $\{(X, Y^-)\}$, a corpus of (non-parallel) sentences $\{X\}$.
Output: Generator $G_{\theta'}$
Train the evaluator $M_\phi$ with $\{(X, Y)\}$ and $\{(X, Y^-)\}$;
Pre-train the generator $G_\theta$ with $\{(X, Y)\}$;
Init $G_{\theta'} := G_\theta$;
while not converge do
    Sample a sentence $X = [x_1, \dots, x_S]$ from the paraphrase corpus or the non-parallel corpus;
    Generate a sentence $\hat{Y} = [\hat{y}_1, \dots, \hat{y}_T]$ according to $G_{\theta'}$ given input $X$;
    Set the gradient $g_{\theta'} = 0$;
    for $t = 1$ to $T$ do
        Run $N$ Monte Carlo simulations: $\{\widehat{Y}^1_{t+1:T}, ...\widehat{Y}^N_{t+1:T}\} \sim p_{\theta'}(Y_{t+1:T}|\hat{Y}_{1:t}, X)$;
        Compute the value function by
            $Q_t = \begin{cases} \frac{1}{N}\sum_{n=1}^{N} M_\phi(X, [\hat{Y}_{1:t}, \widehat{Y}^n_{t+1:T}]), & t < T \\ M_\phi(X, \hat{Y}), & t = T. \end{cases}$
        Rescale the reward to $\bar{Q}_t$ by (8);
        Accumulate $\theta'$-gradient: $g_{\theta'} := g_{\theta'} + \nabla_\theta \log p_{\theta'}(\hat{y}_t|\hat{Y}_{1:t-1}, X)\bar{Q}_t$
    end
    Update $G_{\theta'}$ using the gradient $g_{\theta'}$ with learning rate $\gamma_G$: $G_{\theta'} := G_{\theta'} + \gamma_G g_{\theta'}$
end
Return $G_{\theta'}$
```

Algorithm 2: Training Procedure of RbM-IRL

```
Input : A corpus of paraphrase pairs $\{(X, Y)\}$, a corpus of (non-parallel) sentences $\{X\}$.
Output: Generator $G_{\theta'}$, evaluator $M_{\phi'}$
Pre-train the generator $G_\theta$ with $\{(X, Y)\}$;
Init $G_{\theta'} := G_\theta$ and $M_{\phi'}$;
while not converge do
    while not converge do
        Sample a sentence $X = [x_1, \dots, x_S]$ from the paraphrase corpus;
        Generate a sentence $\hat{Y} = [\hat{y}_1, \dots, \hat{y}_T]$ according to $G_{\theta'}$ given input $X$;
        Calculate $\phi'$-gradient: $g_{\phi'} := \nabla_\phi \mathcal{J}_{\text{IRL-CL}}(\phi)$;
        Update $M_{\phi'}$ using the gradient $g_{\phi'}$ with learning rate $\gamma_M$: $M_{\phi'} := M_{\phi'} - \gamma_M g_{\phi'}$
    end
    Train $G_{\theta'}$ with $M_{\phi'}$ as in Algorithm 1;
end
Return $G_{\theta'}$, $M_{\phi'}$
```

B Human Evaluation Guideline

Please judge the paraphrases from the following two criteria:

(1) **Grammar and Fluency**: the paraphrase is acceptable as natural language text, and the grammar is correct;

(2) **Coherent and Consistent**: please view from the perspective of the original poster, to what extent the answer of paraphrase is helpful for you with respect to the original question. Specifically, you can consider following aspects:

- Relatedness: it should be topically relevant to the original question.
- Type of question: the type of the original question remains the same in paraphrase.
- Informative: no information loss in paraphrase.

For each paraphrase, give two separate score ranking from 1 to 5. The meaning of specific score is as following:

- Grammar and Fluency
  - 5: Without any grammatical error;
  - 4: Fluent and has one minor grammatical error that does not affect understanding, e.g. *what is the best ways to learn programming*;
  - 3: Basically fluent and has two or more minor grammatical errors or one serious grammatical error that does not have strong impact on understanding, e.g. *what some good book for read*;
  - 2: Can not understand what it means but it is still in the form of human language, e.g. *what is the best movie of movie*;
  - 1: Non-sense composition of words and not in the form of human language, e.g. *how world war iii world war*.
- Coherent and Consistent
  - 5: Accurate paraphrase with exact the same meaning of the source sentence;
  - 4: Basically the same meaning of the source sentence but does not cover some minor content, e.g. *what are some good places to visit in hong kong during summer → can you suggest some places to visit in hong kong*;
  - 3: Cover part of the content of source sentence and has serious information loss, e.g. *what is the best love movie by wong ka wai → what is the best movie*;
  - 2: Topic relevant but fail to cover most of the content of source sentence, e.g. *what is some tips to learn english → when do you start to learn english*;
  - 1: Topic irrelevant or even can not understand what it means.

There is token *[UNK]* that stands for unknown token in paraphrase. Ones that contains *[UNK]* should have both grammar and coherent score lower than 5. The grammar score should depend on other tokens in the paraphrase. The specific coherent score depends on the impact of *[UNK]* on that certain paraphrase. Here are some paraphrase examples given original question *how can robot have human intelligence ?*:

- *paraphrase:* how can [UNK] be intelligent ?
  coherent score: 1
  This token prevent us from understanding the question and give proper answer. It causes serious information loss here;

- *paraphrase:* how can robot [UNK] intelligent ?
  coherent score: 3
  There is information loss, but the unknown token does not influence our understanding so much;

- *paraphrase:* how can robot be intelligent [UNK] ?
  coherent score: 4
  [UNK] basically does not influence understanding.

NOTED:

- Please decouple *grammar* and *coherent* as possible as you can. For instance, given a sentence *is it true that girls like shopping*, the paraphrase *do girls like go go shopping* can get a *coherent* score of 5 but a *grammar* score of only 3. But for the one you even can not understand, e.g., *how is the go shopping of girls*, you should give both of low *grammar* score and low *coherent* score, even it contains some topic-relevant words.

- Do a Google search when you see any strange entity name such that you can make more appropriate judgement.

Operation-guided Neural Networks for High Fidelity Data-To-Text Generation

Abstract

Recent neural models for data-to-text generation are mostly based on data-driven end-to-end training over encoder-decoder networks. Even though the generated texts are mostly fluent and informative, they often generate descriptions that are not consistent with the input structured data. This is a critical issue especially in domains that require inference or calculations over raw data. In this paper, we attempt to improve the fidelity of neural data-to-text generation by utilizing pre-executed symbolic operations. We propose a framework called **Op**eration-guided **Att**ention-based sequence-to-sequence network (OpAtt), with a specifically designed gating mechanism as well as a quantization module for operation results to utilize information from pre-executed operations. Experiments on two sports datasets show our proposed method clearly improves the fidelity of the generated texts to the input structured data.

1 Introduction

Data-to-text generation is a classic language generation task that takes structured data (e.g., a table of statistics or a set of event records) as input, aiming at automatically producing texts that informatively, correctly and fluently describe the data (Kukich, 1983; Reiter and Dale, 1997; Angeli et al., 2010; Konstas and Lapata, 2012; Perez-Beltrachini and Gardent, 2017). Traditionally, a data-to-text generation system should pay attention to the problem of content selection (i.e., *what to say*) and surface realization (i.e., *how to say*) (Reiter and Dale, 1997; Gatt and Krahmer, 2018). Modern neural generation systems avoid the distinction of these aspects by building over a standard encoder-decoder architecture (Sutskever et al., 2014) with the attention mechanism over input content (Bahdanau et al., 2015) and train the whole system in an end-to-end fashion. As a result, end-to-end neural text generation has drawn increasing attention from the natural language research community (Mei et al., 2016; Lebret et al., 2016; Wiseman et al., 2017; Kiddon et al., 2016).

Input Data				
Row	Team	Points	Rebound	City
1	Heat	94	44	Miami
2	Hawks	95	40	Atlanta
Generated Description				
Hawks edges the Heat with 95 - 94				

Table 1: An example of generated texts from structured data. In this example, the wining team is not indicated explicitly, but can be inferred from the scores for hte two teams. The words with underlining and wave lines are based on the facts from the input data and the results of inferring, respectively.

However, a critical issue for neural text generation has been largely overlooked. In domains such as sports, finance or medical care, language generation should adhere to facts which are supported by or can be derived from the input data through analysis or inference. For instance, the sentence "Hawks edges the Heat with 95-94" describing the result of a basketball game should always conform to the original data in team names and the scoreline. More importantly, the word "edges" in the description is an inferred fact that the scores between the two competing teams are rather close, while "Hawks" is the winner that scores the slightly higher point total of "95". Since current neural models do not have special treatment for such data analytics, they are likely to generate spurious and incorrect statements. This problem has already been pointed out in recent studies (Wiseman et al., 2017). Related studies on neural program induction have shown that cur-

Brussels, Belgium, October 31 - November 4, 2018.

rent neural models have difficulties in learning arithmetic operations such as addition and comparisons (Joulin and Mikolov, 2015; Neelakantan et al., 2016).

A straightforward way to improve the fidelity of neural text generation is to separate symbolic operations out from the neural models. More specifically, it is viable to pre-execute a few symbolic operations before generation, and then use the results of execution to guide the whole generation process. However, there are two major challenges for incorporating pre-defined operations: (1) if we apply operations exhaustively on all fields with compatible value types in the table, it would create a huge search space in which mention worthy results are rare events and (2) it is difficult to establish the correspondences between specific spans of numeric results and lexical choices. For example, the word "edges" corresponds to the slight difference in score, i.e. 1, in Table. 1.

Inspired by recent work that separates neural representations and symbolic operations (Liang et al., 2017), we propose a framework for neural data-to-text generation that is able to utilize information from pre-computed operations on raw data. Based on a standard sequence-to-sequence model with an attention and copying mechanism, we design a gating mechanism for the neural model to decide which part of the execution results should be used for generation. To address the second challenge, we also design a quantization layer to map numerical execution results into bins to guide different lexical choices according to different quantities of values.

To examine the effectiveness of our proposed model, we collect a large dataset of sports headline generation for NBA basketball games[1]. We also evaluate the models on the ROTOWIRE dataset released by Wiseman et al. (2017) which targets at generating short paragraphs. Experiments show that our model outperforms current state-of-the-art neural methods in terms of both fluency and fidelity. In summary, we make the following contributions in this paper:

- We propose a neural data-to-text framework that generate texts by additional processing over input data. Based on a basic sequence-to-sequence model with attention and copying, we design a gating mechanism to enable the model to decide which part of the executed results should be utilized. We also propose a novel quantization layer to map specific numerical values onto different spans to affect lexical choices under different conditions.
- To focus our study on correct text generation, we collect a challenging dataset for NBA headline generation.
- We conduct experiments on the NBA headline dataset as well as the ROTOWIRE dataset from previous work. Results show improvements on both correctness and fluency from our proposed framework over baseline systems.

2 Background: Attention-Based Neural Sequence-to-Sequence Model

In this section, we briefly introduce the architecture of the attention-based sequence-to-sequence (Seq2Seq) (Cho et al., 2014b; Bahdanau et al., 2015) model with a copy mechanism (See et al., 2017), which is the basis of our proposed model.

2.1 RNN Encoder-Decoder

The goal of data-to-text generation is to generate a natural language description for a given set of data records $S = \{r_j\}_{j=1}^{K}$. Usually, a Seq2Seq model consists of an encoder and a decoder with recurrent neural networks (RNN). First, each input record r_j is encoded into a hidden vector $\mathbf{h}_j$ with $j \in \{1, ..., K\}$ using a bidirectional RNN. The decoder generates the description word by word using another RNN.

In the training phase, given a record set and its corresponding natural language description (S, y), the Seq2Seq model maximizes the conditional probability as follows:

$$P(y|S) = \prod_{t=1}^{T} P(y_t|y_{<t}, S) \qquad (1)$$

where y_t is the t-th word in the description and T is the length of the description. The conditional probability $P(y_t|y_{<t}, S)$ is computed as:

$$P(y_t|y_{<t}, S) = \mathrm{softmax}(f(\mathbf{d}_t, y_{t-1}, \mathbf{c}_t)) \qquad (2)$$

where $f(\cdot)$ is a non-linear function and $\mathbf{d}_t$ is the hidden state of the decoder at step t:

$$\mathbf{d}_t = g(\mathbf{d}_{t-1}, y_{t-1}, \mathbf{c}_{t-1}) \qquad (3)$$

---

[1] Available at `https://github.com/janenie/espn-nba-data`

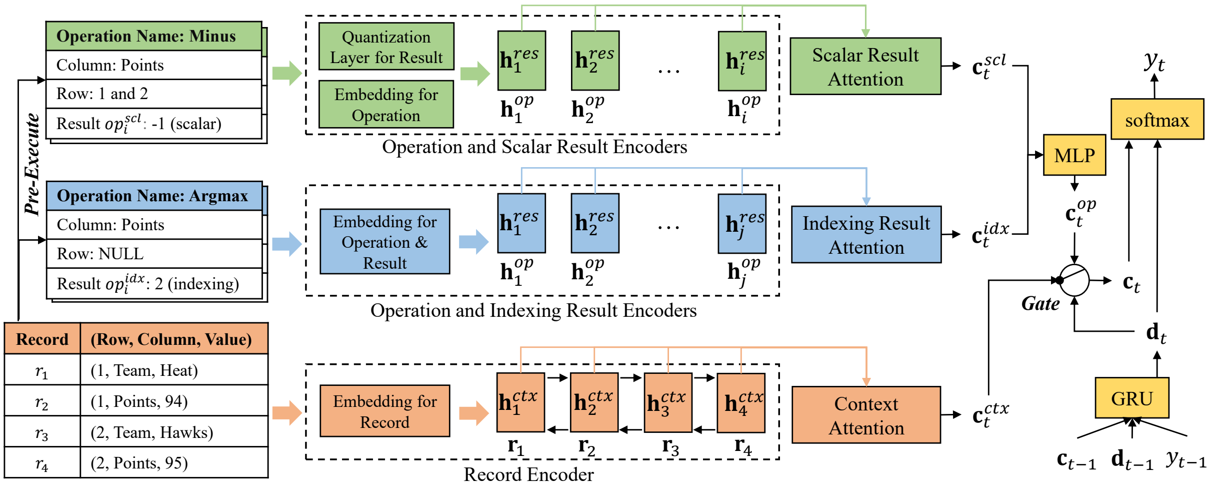

Figure 1: A diagram of the operation guided neural data-to-text generation. The input record table is converted from the first 3 columns of Table1. First, a set of operations are applied to the input records. Then, the records, operations and pre-excuted operation results are encoded. Finally, an attention-equipped GRU decoder with a gating mechanism decides which part of the execution results and context should be used for generation.

where $g(\cdot)$ is a non-linear function. We adopt the Gated Recurrent Unit (GRU) (Cho et al., 2014a) as the recurrent unit for the encoder and decoder. $\mathbf{c}_\mathrm{t}$ in Eq. 2 is the context vector at timestep t, computed as a weighted hidden vectors $\mathbf{h}_j$:

$$\mathbf{c}_t = \sum_{j=1}^{K} \alpha_{t,j} \mathbf{h}_j \tag{4}$$

where $\alpha_{t,j}$ is computed by an attention scheme, typically implemented as a softmax distribution over scores calculated with a multi-layer perceptron (Bahdanau et al., 2015).

2.2 Copy Mechanism

Recent work augments Seq2Seq models to copy words directly from the source information on which they are conditioned (Gu et al., 2016; See et al., 2017). These models usually introduce an additional binary variable z_t into per-timestep target word distribution, which indicates whether the target word y_t is copied from the source or is generated from the recurrent hidden states. We use the pointer-generator network (See et al., 2017) for the copy mechanism. Specifically, the binary variable z_t is calculated from the context vector $\mathbf{c}_t$, the decoder state $\mathbf{d}_t$ and the decoder input y_{t-1}:

$$p_{gen} = \sigma(\mathbf{w}_c^\top \mathbf{c}_t + \mathbf{w}_d^\top \mathbf{d}_t + \mathbf{w}_y^\top y_{t-1} + b_{ptr}) \tag{5}$$

where vectors $\mathbf{w}_c$, $\mathbf{w}_d$, $\mathbf{w}_y$ and the scalar b_{ptr} are learnable parameters, and σ is the sigmoid function. The joint probability for generating y_t is formulated as follows:

$$\begin{aligned} P_{copy}(y_t|y_{<t}, S) &= p_{gen} P(y_t|y_{<t}, S) \\ &+ (1 - p_{gen}) \sum_{i:r_i = y_t} \alpha_{t,i} \end{aligned} \tag{6}$$

3 The Proposed Model

In this paper, we propose to utilize information from pre-executed operations on the input data to guide the generation. As shown in Fig. 1, our model consists of a record encoder, an operation encoder and an operation result encoder, and an attention-equipped GRU decoder with a gating mechanism. First, a set of operations are applied to all valid records in the input data, yielding their corresponding pre-executed results. The pre-executed results act as facts inferred from input data to guide the generation. Then, the records, operation and pre-executed operation results are encoded into corresponding representation. Finally, we design a gating mechanism for the GRU decoder to decide which part of the inferred facts should be used for generation. Moreover, to address the challenge in establishing correspondences between specific numeric results and lexical choices, a quantization layer maps the results into several segmentations to guide the lexical choices.

3.1 Notation

Given the input data and description pair (S, y), where each target description $y = y_1, ..., y_T$ consists of T words, and each input data is stored in a table (e.g., Table 1), where each row is an entity and each column is a field of this entity. The input data can be transferred into K records $S = \{r_i\}_{i=1}^{K}$, where each record r is a triple $(r.idx, r.f, r.v)$. For r_4 in the table of Fig. 1, $r.idx$ $r.f$ and $r.v$ refer to the row index (e.g., row 2), the field name (e.g., column Points) and value (e.g., cell value 95), respectively. We also define a set of operations $\{op_i\}$, and the operations are applied to the input records S to produce corresponding results at the preprocessing stage. The results of operations can be categorized into two types: op_i^{scl} denotes results with a type of scalar value and op_i^{idx} denotes results with a type of indexing value.

3.2 Encoding Records

We map each record $r \in S$ into a vector $\mathbf{r}$ by concatenating the embedding of $r.idx$ (e.g., row 2), $r.f$ (e.g., column Points) and $r.v$ (e.g., cell value 95), denoted as $\mathbf{r} = [\mathbf{e}^{idx}, \mathbf{e}^{f}, \mathbf{e}^{v}]^\top$, where $\mathbf{e}^{idx}$, $\mathbf{e}^{f}$, $\mathbf{e}^{v}$ are trainable word embeddings of $r.idx$, $r.f$ and $r.v$ respectively, similar to (Yang et al., 2017). We feed a set of record vectors $\mathbf{r}_1, ..., \mathbf{r}_K$ to a bidirectional GRU and yield the final record representations $\mathbf{h}_1^{ctx}, ..., \mathbf{h}_K^{ctx}$ as introduced in Section 2. We leave the exploring of different encoding methods as future work, as it would affect the performance.

3.3 Encoding Operations

As shown in Fig. 1, each operation op_i consists of: a) the name of the operation $op_i.t$ (e.g., minus); b) the column $op_i.c$ to which the operation applies (e.g., Points); and c) the row to which the operation applies, denoted as $op_i.arg = \{r_i.idx\}_{i=1}^{A}$, where A is the count of arguments. We then encode each operation op_i by concatenating the representation of these three components and feed them into a nonlinear layer to represent each operation as follows:

$$\mathbf{h}_i^{op} = \tanh(\mathbf{W}_{op}[\mathbf{op}_i^{t}, \mathbf{op}_i^{c}, \mathbf{op}_i^{arg}]^\top{}_i + b_{op}), \quad (7)$$

where $\mathbf{op}_i^{t}$ is the embedding of $op_i.t$; $\mathbf{op}_i^{c}$ is the embedding of column $op_i.c$ which shares the same parameters of embedding with record column $r.f$. For $op_i.arg$, it may contain multiple arguments, so we apply a nonlinear layer to get a fixed length representation as follows:

$$\mathbf{op}_i^{arg} = \tanh(\sum_{k \in arg_i} \mathbf{W}_k^{arg} \mathbf{e}_k^{idx} + b_{arg}), \quad (8)$$

where $\mathbf{e}_k^{idx}$ is the same embedding as used to encode the row index $r.idx$, and $\mathbf{W}_k^{arg}$ and b_{arg} are learnable parameters. For operations which are applied in the entire column (e.g., argmax) without specific rows, the representation of arguments is a special vector which stands for ALL.

3.4 Encoding Operation Results

The operations produce two types of results, one is scalar results (e.g., the minus operation returns -1), the other is indexing results (e.g., the argmax operation returns the row number 2), and two encoders are designed to encode these results respectively.

Scalar Results Representation In Table. 1, the word "edges" is generated based on the fact that the points gap of the two teams is -1. In fact, other value likes -2 or -3 is close to -1, and the word "edges" is also applicable to them. However, directly establishing the lexical choices on various sparse numeric values is not easy (Reiter et al., 2005; Smiley et al., 2016; Zarrieß and Schlangen, 2016). Reiter et al. (2005) use consistent data-to-word rules for time-series weather forecast summary generation. In this paper, we aim to capture the data-to-word mapping automatically by a simple quantization unit. A *quantization layer* is designed to map the scalar values into several bins, namely quantization units. Specifically, we feed each scalar value op_i^{scl} to a softmax layer, and its representation $\mathbf{h}_i^{res}$ is computed as the weighted sum of all quantization embeddings:

$$\mathbf{q}_i = \mathbf{W}_q op_i^{scl} + b_q, \quad (9)$$

$$\mu_{i,l} = \frac{\exp(q_{i,l})}{\sum_{j=1}^{L} \exp(q_{i,j})}, \quad (10)$$

$$\mathbf{h}_i^{res} = \sum_{l=1}^{L} \mu_{i,l}\, \mathbf{e}_l^{scl} \quad (11)$$

where $\mathbf{W}_q$ and b_q are trainable parameters, $\mathbf{e}^{scl}$ is the quantization embedding and L is the size of quantization units. Note that L is much smaller than the unique number of scalar results. We set L to 5 in this paper.

Indexing Results Representation Some operations produce the row number of records (denoted as idx_i) as a result. For instance, the argmax operation in Fig. 1 returns row 2. We then look up the row embedding of the selected record defined in Section 3.2 to represent the result. Defined as $\mathbf{h}_i^{res} = \mathbf{e}_i^{idx}$.

3.5 Decoder

Comparing with the Seq2Seq model described in Section 2 and our model, the main difference is in the context vector $\mathbf{c}_t$. Different from Eq. 4, our model has both records and operations as input. We design two attention layers to summarize information from both parts respectively, the overall context vector $\mathbf{c}_t$ is balanced by a dynamic gate λ_t.

$$\mathbf{c}_t = (1-\lambda_t)\mathbf{c}_t^{op} + \lambda_t \mathbf{c}_t^{ctx}, \quad (12)$$

$$\lambda_t = \sigma(\mathbf{W}_g \mathbf{d}_t + b_g), \quad (13)$$

where $\mathbf{c}_t^{op}$ and $\mathbf{c}_t^{ctx}$ are the context vector of operation results and records, respectively.

As there are two types of operation results which have quite different meanings, their context vectors are calculated separately and then put together by a nonlinear layer. The context vectors $\mathbf{c}_t^{scl}$ of operation results with scalar value at timestep t are constructed as (Luong et al., 2015):

$$\mathbf{c}_t^{scl} = \sum_{j=1}^{N} \alpha_{t,j}^{scl} * \mathbf{h}_j^{res} \quad (14)$$

$$\beta_{t,j}^{scl} = \text{MLP}(\mathbf{d}_{t-1}, \mathbf{h}_j^{op}), \quad (15)$$

$$\alpha_{t,j}^{scl} = \frac{\exp(\beta_{t,j}^{scl})}{\sum_k \exp(\beta_{t,k}^{scl})} \quad (16)$$

where MLP stands for standard 1-layer perceptron (with $\tanh$ nonlinearity), and $\alpha_{t,j}^{scl}$ refers to the importance of j-th operations at the current timestep t. Eq. 14 is based on the attention mechanism which can be treated as mapping a query and a set of key-value pairs to an output. The output $\mathbf{c}_t^{scl}$ is computed as a weighted sum of the values $\mathbf{h}_j^{res}$, where the weight assigned to each value is computed by a compatibility function of the query $\mathbf{d}_{t-1}$ with the corresponding key $\mathbf{h}_j^{op}$. In this way, we also construct $\mathbf{c}_t^{idx}$. Then the context vector of operation results at time step t is computed by putting these two context vectors together:

$$\mathbf{c}_t^{op} = \text{MLP}([\mathbf{c}_t^{scl}, \mathbf{c}_t^{idx}]^\top) \quad (17)$$

The context vector representation $\mathbf{c}_t^{ctx}$ for records is constructed by replacing $\mathbf{h}_j^{res}$ with $\mathbf{h}_j^{ctx}$ in Eq. 14 and replacing $\mathbf{h}_j^{op}$ with $\mathbf{h}_j^{ctx}$ in Eq. 15.

After obtaining $\mathbf{c}_t$, the word distribution for generation can be calculated by substituting the $\mathbf{c}_t$ in Eq. 2. For the copy probability defined in Eq. 6, to copy words based on the information of both operations and records at current time step t, we need to update the attention weights for Eq. 6 based on the newly computed context vector $\mathbf{c}_t$ and decoding state $\mathbf{d}_t$:

$$\beta_{t,j}^{new} = \text{MLP}(\mathbf{h}_j^{ctx}, [\mathbf{d}_{t-1}, \mathbf{c}_t]^\top) \quad (18)$$

$$\alpha_{t,j}^{new} = \frac{\exp(\beta_{t,j}^{new})}{\sum_k \exp(\beta_{t,k}^{new})} \quad (19)$$

3.6 Training

As the results of operations are pre-computed in an offline stage, our proposed model is fully differentiable and can be optimized in an end-to-end manner using back propagation. Given the batches of records $\{S\}_N$ and the standard natural language descriptions $\{Y\}_N$, the objective function is to minimize the negative log-likelihood:

$$L = -\frac{1}{N}\sum_{k=1}^{N}\sum_{t=1}^{T_k} \log p(y_t^k | y_{<t}^k, S^k) \quad (20)$$

where the superscript k indicates the index of the records-description pair, and T_k is the length of the k-th description.

4 Experiments

4.1 Datasets

Several benchmark datasets have been used in recent years for data-to-text generation (Liang et al., 2009; Chen and Mooney, 2008; Lebret et al., 2016). For instance, Lebret et al. (2016) have built a biography generation dataset from Wikipedia. However, a recent study by Perez-Beltrachini and Gardent (2017) shows that existing datasets have a few missing properties such as lacking syntactic and semantic diversity. To check whether the facts mentioned in the descriptions are based on input data, we identify the text spans which contain facts (e.g., in table 1, "Hawks" is a span contain fact) from the descriptions and divide each span into three categories: a) input facts (facts that can be directly found from the input), b) inferred facts (facts that can not be directly found from the input but can be derived), c) unsupported facts (facts that can not be found or derived from input data). Table 2 shows that WikiBio dataset requires inference on only 5.4% of its data. To better demonstrate the effectiveness of our approach, we adopt the following datasets which require substantially more inference based on the input data:

ROTOWIRE We use the dataset and its standard splits released by Wiseman et al. (2017), which consists of 4,853 human written NBA basketball game summaries aligned with their corresponding game statistics. Table 2 shows that 11.7% of facts in the game summaries can be inferred based on the input data. However, this dataset focuses on generating long text and 27.1% of facts are unsupported[2], which brings difficulties to the analysis of fidelity for the generated text.

ESPN We collect 15,054 NBA game result headlines during 2006-2017 from the ESPN website, paired with their corresponding game statistics. These headlines are professional and concise, e.g., the description in Fig. 1. The percentage of inferred facts is 29.1% while unsupportive facts is only 8%, so we can focus on generation for the inferred facts. We split the dataset into 12,043 (80%) for training, 1,505 (10%) for development and 1,506 (10%) for testing respectively.

4.2 Instantiation

In the following experiments, we define two operations, the minus operation which returns the scalar result and the argmax operation which returns a id of a row. These operations are applied to all columns and rows whose record values are numeric numbers. The number of pre-executed results increases with the number of operations, arguments and the size of input data, which will impact the efficiency of our model. The unnecessary operation arguments can be pruned, e.g., only apply operations to the arguments co-mentioned in descriptions on the training set. We will leave this part of research for our future work.

4.3 Experiment Setup

In the main experiments, we compare our model with the following methods: (a) Template: a problem-specific template-based generator which fills structured data into corresponding placeholders to generate texts[3], (b) Seq2Seq+copy: Seq2Seq model with pointer network copy mechanism introduced in Section 2. It is one of the state-of-the-art methods, (c) Seq2Seq+op: Seq2Seq+copy plus the results of operations, where results are directly treated as extra records and fed to the record encoder introduced in Section 3.2 with the original input together, (d) Seq2Seq+op+quanti: We apply the quantization layer Eq. 9-11 to the results of minus operation on the basis of Seq2Seq+op. For completeness, we also report the results of Wiseman et al. (2017) on the ROTOWIRE dataset. The difference between this baseline and Seq2Seq+copy is that the former uses an LSTM rather than GRU for decoding and an additional copying loss. All the experiments use a beam size of 5 in decoding[4].

For model training, we use the stochastic gradient descent algorithm and the AdaDelta optimizer (Zeiler, 2012). The dimension of trainable word embeddings are set to 256 except for the dimension of input record row embedding, which is set to 32; and the dimension of hidden units in GRUs are all set to 512. All the parameters are initialized using a normal distribution with zero mean and a variance of $\sqrt{6/(d_{in}+d_{out})}$, where d_{in} is the dimension of the input layer and d_{out} is the dimension of the output layer (Glorot and Bengio, 2010). Training converges after 40 epochs.

4.4 Main Results

We adopt both automatic evaluation and human evaluation to evaluate the proposed model. **Automatic Evaluation** We employ BLEU-4 as the metric for automatic evaluation. Table 4 gives the automatic evaluation results for generation on two datasets. Our proposed model OpAtt outperforms neural network baselines (See et al., 2017; Wiseman et al., 2017). The results show that our method which incorporates the operations enables generating texts that are fidelity to facts and therefore yields the best performance. Seq2Seq+op+quant outper-

---

[2] e.g., injuries, rankings in the league, team schedule, etc.

[3] For the ROTOWIRE dataset, we adopt Wiseman et al. (2017)'s templates. For the ESPN dataset, we use Dou et al. (2018)'s system to extract templates. The template is constructed by emitting teams and players information in a sentence: `<team1>` beats `<team2>` with `<point1>`-`<point2>`.

[4] The authors have updated the dataset to fix some mistakes recently, so we cannot use the result which is reported in their paper and rerun this baseline with the authors' code.

forms the baseline method Seq2Seq+copy, but is not as good as our method. The result confirms that our proposed method with specialized operation encoder and gating mechanism utilizes the information of operations more effectively. Moreover, Seq2Seq+op+quant outperforms Seq2Seq+op showing the effectiveness of the quantization layer.

Human Evaluation Because of the approximate nature of the automated metric BLEU, we also conduct human evaluation to examine the fidelity of the generated texts. We randomly select some games from testing set, and entrust a professional crowdsourcing company to annotate the generated texts[5]. Specifically, three native English workers who are familiar with NBA games are hired. They are first required to identify the text spans which contain facts from the generated texts, then categorize the text spans into one of three facts listed in Table 2, and finally judge whether the span is supported or contradicted by the input data.

Table 3 shows the annotation results. Our method talks more about the inferred facts in the generated texts while includes less contradictions. In addition, all methods produce some unsupported facts which affect the fidelity of the generated texts. We leave this issue for future work.

Table 6: The generated texts by introducing different operations. The words with underline, wavy line and dot line are input facts, inferred facts and unsupported fact, respectively. And the **bold** words are contradicted facts.

4.5 Analysis

As discussed in Section 4.1, the ESPN dataset is rich in inferred facts. Therefore, the model analysis is based on this dataset, and all case studies are made on the development set.

4.5.1 Effect of Operations

We examine the necessity and the benefit of introducing operations by removing the argmax operation (see "OpAtt w/o argmax op" in Table 5). Comparing to Seq2Seq+copy, the results show that our full model and "OpAtt w/o argmax op" which incorporates results of operations both work well in terms of BLEU, and the improvements increase with the number of operations.

To better illustrate that our model can generate factually correct text, we show the texts generated by different models in Table 6. The game

---

[5] The Fleiss' kappa score of the annotation is 0.782 for ESPN and 0.761 for ROTOWIRE respectively. For the ESPN dataset, we select 50 games and each with one generated sentence. For ROTOWIRE, by following (Wiseman et al., 2017), we select 15 games and each with 3 randomly selected sentences.

results mentioned in the text generated by the Seq2Seq+copy model are wrong, which shows the inability for existing neural models on inferring facts from the structured data. After adding the minus operation, “OpAtt w/o argmax op” is able to infer the game result by applying the minus operation on the points of the two competing teams, therefore its generated text conforms to the game results. The results confirm the necessity of introducing operations to ensure factually correct generation. Furthermore, our full model generates text with the correct point leader and game result based on the results of operation argmax and operation minus respectively.

4.5.2 Effect of Quantization

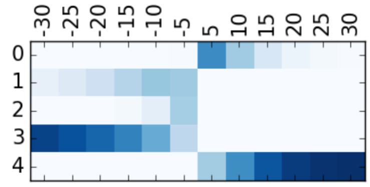

Figure 2: Weights of the quantization softmax layer when mapping the points gap of two competing teams to five bins. X-axis is points gap and Y-axis is quantization bin.

The quantization layer maps the numerical execution results into several bins to enable different lexical choices according to different quantities of values. Compared to our full model, “OpAtt w/o quantization” in Table 5 which removes the quantization layer decreases the BLEU performance, which shows the effectiveness of the quantization layer in the lexical choices during generation.

In Fig. 2, we visualize the weights of quantization softmax layer $\mu_{i,l}$ produced by Eq. 10 when mapping the points gap of two competing teams to five bins. We can see that the points gaps with close numerical values are mapped to the same bin, so the decoder can choose similar words for them in generation. When the absolute value of the points gap is small, the weights distribution over the points gap is dispersive. At this time, the decoder tends to generate general words. This distribution becomes more centralized with the increase of the absolute value of the points gap, to generate more unique words. Moreover, we show the distribution of words that describes the winning relationship of games over different intervals of game points gap. As shown in Table 7, we can clearly see that apart from three most common word “beat”, “past”, “win over”, our proposed quantization layer can choose specific words according to the points gap. The word “edge” and “hold off” will only be chosen when the points gap is small, while the word “rout” and “blow out” will appear when the points gap is larger than 10.

Points Gap	Words describes winning relationship
[0, 5)	beat, past, win over, edge, hold off, survive
[5, 10)	beat, past, win over, out last, hold off
[10, 20)	beat, past, win over, blow out, top, pull away, rout
>= 20	beat, past, win over, power, rout, easy win over, roll past

Table 7: The words that describing the winning relationship of games over different intervals of game points gap.

4.5.3 Effect of Gating Mechanism

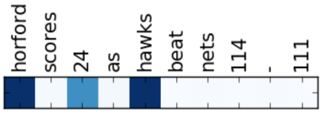

Figure 3: The gating weights at different time steps.

We design a gating mechanism to decide when to incorporate the results of operations to guide the process of generation. From Table 5, “OpAtt w/o gate” stands for the method which replaces the balancing weight λ in Eq. 12 to 0.5, which is a special case of our proposed gating mechanism. The performance of this ablation is worse than our full model, which demonstrates that the gating mechanism is an essential component. Fig. 3 shows an example of the gating weights at each time step in generation, where a darker cell means the incorporation of more information from operation results for decoding corresponding word. We can see that the gate weights are reasonable, as the gate values are large when deciding the team leader “horford” and the winner of the game “hawks”.

5 Related Work

Data-to-text generation is a task of natural language generation (NLG) (Gatt and Krahmer, 2018). Previous research has focused on individual content selection (Kukich, 1983; Reiter and Dale, 1997; Duboué and McKeown, 2003; Barzilay and Lapata, 2005) and surface realization (Goldberg et al., 1994; Soricut and Marcu, 2006; Wong and Mooney, 2007).

Recent work avoids the distinction of the content selection and sentence realization. Chen and Mooney (2008) use an SMT based approach to learn alignments between comments and their corresponding event records. Angeli et al. (2010) transform the problem into a sequence of local decisions using a log-linear model. Konstas and Lapata (2012) employ a PCFG to simultaneously optimize the content selection and surface realization problem.

In the field of neural text generation, Mei et al. (2016) uses a neural encoder-decoder approach for end-to-end training. Some have focused on conditional language generation based on tables (Yang et al., 2017), short biographies generation from Wikipedia tables (Lebret et al., 2016; Chisholm et al., 2017) and comments generation based on stock prices (Murakami et al., 2017). However, none of these methods consider incorporating the facts that can be inferred from the input data to guide the process of generation. Murakami et al. (2017) post-process the price by extending the copy mechanism and replacing numerical values with defined arithmetic operations after generation. While our model, OpAtt utilizes information from pre-computed operations on raw data to guide the generation.

Our work is related to research areas on deep learning models for program induction and question answering from a knowledge base (Neelakantan et al., 2016; Liang et al., 2017; Ling et al., 2017). Neelakantan et al. (2016) solve the problem of semantic parsing from structured data and generate programs using pre-defined arithmetic operations. Liang et al. (2017) design a set of executable operators and obtain the answers by the generated logic forms. Ling et al. (2017) design a set of operators to generate the latent program for math problem solving. However, data-to-text is a different task. The operations for these methods are designed to find the answers, while we use the operations to guide the process of generation.

6 Conclusion and Future Work

In this work, we address the problem of generating consistent text from structured data in a neural data-to-text generation framework, where we extract facts that can be inferred in the given data by applying several executable symbolic operations to guide the generation. Moreover, we design a special quantization layer to operations whose result type is numeric value and establish the correspondence between the numeric values and lexical choice in generation. Experiments show that our method, OpAtt, outperforms existing state-of-the-art neural methods, in both fluency and fidelity evaluations.

As applying operations on a large number of records greatly increases the search space for the attention mechanism, we will extend our model to automatically detect the relevant operations to reduce computing complexity. We will also extend the set of operations to accommodate historical data, graph data and detect the unsupported facts in the generation within the single framework.

Abstract

It is a challenging task to automatically compose poems with not only fluent expressions but also aesthetic wording. Although much attention has been paid to this task and promising progress is made, there exist notable gaps between automatically generated ones with those created by humans, especially on the aspects of term novelty and thematic consistency. Towards filling the gap, in this paper, we propose a conditional variational autoencoder with adversarial training for classical Chinese poem generation, where the autoencoder part generates poems with novel terms and a discriminator is applied to adversarially learn their thematic consistency with their titles. Experimental results on a large poetry corpus confirm the validity and effectiveness of our model, where its automatic and human evaluation scores outperform existing models.

1 Introduction

In mastering concise, elegant wordings with aesthetic rhythms in fixed patterns, classical Chinese poem is a special cultural heritage to record personal emotions and political views, as well as document daily or historical events. Being a fascinating art, writing poems is an attractive task that researchers of artificial intelligence are interested in (Tosa et al., 2008; Wu et al., 2009; Netzer et al., 2009; Oliveira, 2012; Yan et al., 2013, 2016a; Ghazvininejad et al., 2016, 2017; Singh et al., 2017; Xu et al., 2018), partially for the reason that poem generation and its related research could benefit other constrained natural language generation tasks. Conventionally, rule-based models (Zhou et al., 2010) and statistical machine translation (SMT) models (He et al., 2012) are proposed for this task. Recently, deep neural models are employed to generate fluent and natural poems (Wang et al., 2016a; Yan, 2016; Zhang et al., 2017a). Although these models look promising, they are limited in many aspects, e.g., previous studies generally fail to keep thematic consistency (Wang et al., 2016c; Yang et al., 2017) and improve term[1] novelty (Zhang et al., 2017a), which are important characteristics of poems.

In classical Chinese poem composing, thematic consistency and term novelty are usually mutually exclusive conditions to each other, i.e., consistent lines may bring duplicated terms while intriguing choices of characters could result in thematic diversities. On one hand, thematic consistency is essential for poems; it is preferred that all lines concentrate on the same theme throughout a poem. Previous work mainly focused on using keywords (Wang et al., 2016c; Hopkins and Kiela, 2017) to plan a poem so as to generate each line with a specific keyword. Such strategy is risky for the reason that the keywords are not guaranteed consistent in a topic, especially when they are generated or extracted from an inventory (Wang et al., 2016c). On the other hand, Chinese poems are generally short in length, with every character carefully chosen to be concise and elegant. Yet, prior poem generation models with recurrent neural networks (RNN) are likely to generate high-frequency characters (Zhang et al., 2017a), and the resulted poems are trivial and boring. The reason is that RNN tends to be entrapped within local word co-occurrences, they normally fail to capture global characteristic such as topic or hierarchical semantic properties (Bowman et al., 2016).

To address the aforementioned shortcomings, RNN is extended to autoencoder (Dai and Le, 2015) for improving sequence learning, which has

[1] We use term and character interchangeably in this paper.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3890–3900
Brussels, Belgium, October 31 - November 4, 2018.

been proven to be appealing in explicitly modeling global properties such as syntactic, semantic, and discourse coherence (Li et al., 2015). Moreover, boosting autoencoder with variational inference (Kingma and Welling, 2014), known as variational autoencoder (VAE), can generate not only consistent but also novel and fluent term sequences (Bowman et al., 2016). To generalize VAE for versatile scenarios, conditional variational autoencoders (CVAE) are proposed to supervise a generation process with certain attributes while maintaining the advantages of VAE. It is verified in supervised dialogue generation (Serban et al., 2017; Shen et al., 2017; Zhao et al., 2017) that CVAE can generate better responses with given dialogue contexts. Given the above background and to align it with our expectations for poem generation, it is worth trying to apply CVAE to create poems. In the meantime, consider that modeling thematic consistency with adversarial training is proven to be promising in controlled text generation (Hu et al., 2017), models for semantic matching can be potentially improved with an explicit discriminator (Wu et al., 2017), so does poem generation.

In this paper, we propose a novel poem generation model (CVAE-D) using CVAE to generate novel terms and a discriminator (D) to explicitly control thematic consistency with adversarial training. To the best of our knowledge, this is the first work of generating poems with the combination of CVAE and adversarial training. Experiments on a large classical Chinese poetry corpus confirm that, through encoding inputs with latent variables and explicit measurement of thematic information, the proposed model outperforms existing ones in various evaluations. Quantitative and qualitative analysis indicate that our model can generate poems with not only distinctive terms, but also consistent themes to their titles.

2 Preliminaries

2.1 VAE and CVAE

In general, VAE consists of an encoder and a decoder, which correspond to the encoding process where input x is mapped to a latent variable z, i.e., $x \mapsto z$, and the decoding process where the latent variable z is reconstructed to the input x, i.e., $z \mapsto x$. In detail, the encoding process computes a posterior distribution $q_\theta(z \mid x)$ given the input x. Similarly, the decoding process can be formulated as $p_\theta(x \mid z)$, representing the probability distribution of generating input x conditioned on z, where z has a regularized prior distribution $p_\theta(z)$, i.e. a standard Gaussian distribution. Herein θ represents the parameters of both encoder and decoder. Importantly, presented by Kingma and Welling (2014), on the condition of large datasets and intractable integral of the marginal likelihood $p_\theta(x)$, the true posterior $q_\theta(z \mid x)$ is simulated by a variational approximation $q_\phi(z \mid x)$ in modeling the encoding process, where ϕ is the parameters for q.

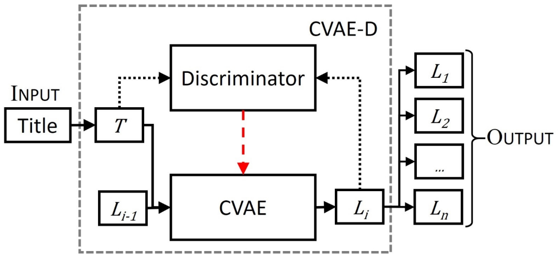

Figure 1: The overall framework of our poem generation model. Solid arrows present the generation process of each line L_i on the condition of the previous line L_{i-1} and title T. Black dotted arrows represent the adversarial learning for thematic consistency. The red dashed arrow refers to the back-propagation of the discriminator to the CVAE.

In learning a VAE, its objective is to maximize the log-likelihood $\log p_\theta(x)$ over input x. To facilitate learning, one can target on pushing up the variational lower bound of $\log p_\theta(x)$:

$$\begin{aligned}\mathbb{L}(\theta, \phi; x) = &- \mathrm{KL}(q_\phi(z|x) \parallel p_\theta(z)) \\ &+ \mathbf{E}_{q_\phi(z|x)}[\log p_\theta(x|z)]\end{aligned} \tag{1}$$

such that the original $\log p_\theta(x)$ is also optimized. Herein the KL-divergence term $\mathrm{KL}(\cdot)$ can be viewed as the regularization for encouraging the approximated posterior $q_\phi(z|x)$ to be close to the prior $p_\theta(z)$, e.g. standard Gaussian distribution. $\mathrm{E}[\cdot]$ is the reconstruction loss conditioned on the approximation posterior $q_\phi(z|x)$, which reflects how well the decoding process goes.

CVAE extends VAE with an extra condition c to supervise the generation process by modifying the. The objective of CVAE is thus to maximize the reconstruction log-likelihood of the input x under the condition of c. Following the operation for VAE, we have the corresponding variational lower bound of $p_\theta(x|c)$ formulated as

$$\begin{aligned}\mathbb{L}(\theta, \phi; x, c) = &- \mathrm{KL}(q_\phi(z|x, c) \parallel p_\theta(z|c)) \\ &+ \mathbf{E}_{q_\phi(z|x,c)}[\log p_\theta(x|z, c)]\end{aligned} \tag{2}$$

which is similar to Eq.1 except that all items are introduced with c, such as $q_\phi(z|x, c)$ and $p_\theta(z|c)$, referring to the conditioned approximate posterior and the conditioned prior, respectively.

2.2 Problem Formulation

Following the text-to-text generation paradigm (Ranzato et al., 2015; Kiddon et al., 2016; Hu et al., 2017; Ghosh et al., 2017), our task has a similar problem setting with conventional studies (Zhang and Lapata, 2014; Wang et al., 2016c), where a poem is generated in a line-by-line manner that each line serves as the input for the next one, as illustrated in Figure 1. To formulate this task, we separate its input and output with necessary notations as follows.

The **INPUT** of the entire model is a title, $T = (e_1, e_2, \ldots, e_N)$, functionalized as the theme of the target poem[2], where e_i refers to i-the character's embedding and N is the length of the title. The first line L_1 is generated only conditioned on the title T, once this step is done, the model takes the input of the previous generated line as well as the title at each subsequent step, until the entire poem is completed.

The overall **OUTPUT** is an n-line poem, formulated as $(L_1, L_2, \ldots, L_n)$, where $L_i = (e_{i,1}, e_{i,2}, \ldots, e_{i,m})$ denotes each line in the poem, with $e_{i,j}$ referring to the embedding of a character at i-th line on j-th position, $\forall\ 1 \leq i \leq n$, $1 \leq j \leq m$. Particularly for classic Chinese poems, there are strict patterns, which require $m = 5$ or $m = 7$, and $n = 4$[3] or $n = 8$[4]. Once a template is chosen, m and n are fixed. In this paper, we mainly focus on $n = 4$.

3 The Model

As illustrated in Figure 1, our CVAE-D consists of two parts, CVAE and a discriminator, where their details are elaborated in the following subsections.

3.1 The CVAE

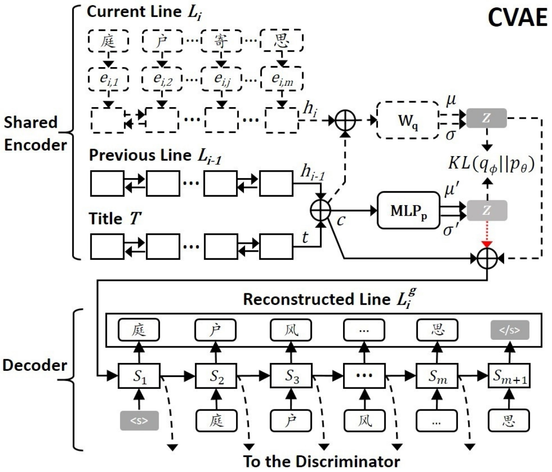

Figure 2: The CVAE for poem generation. $\oplus$ denotes the vector concatenation operation. Only the part with solid lines and the red dotted arrow is applied in prediction, while the entire CVAE is used in training process except the red dotted arrow part.

The CVAE includes an encoder and a decoder, plays as the core part in our model that generates classic Chinese poems. The encoder encodes both the title and lines with shared parameters by a bidirectional RNN (Schuster and Paliwal, 1997) with gated recurrent units (GRU) (Chung et al., 2014). Through the encoder, at each step, the previous line L_{i-1}, current line L_i and title T are represented as concatenated forward and backward[5] vectors $h_{i-1} = [\overrightarrow{h}_{i-1}, \overleftarrow{h}_{i-1}]$, $h_i = [\overrightarrow{h}_i, \overleftarrow{h}_i]$ and $t = [\overrightarrow{t}, \overleftarrow{t}]$, respectively. Note that h_i corresponds to x, while the concatenation of h_{i-1} and t functionalized as c in Eq. 2, i.e., $c = [h_{i-1}, t]$. Following previous work (Kingma and Welling, 2014; Zhao et al., 2017; Yang et al., 2017), we assume that the variational approximate posterior is a multivariate Gaussian $\mathcal{N}$ with a diagonal covariance structure $q_\phi(z|x, c) = \mathcal{N}(\mu, \sigma^2 \boldsymbol{I})$. Thus μ and σ are the key parameters[6] to be learned, and they are computed by

$$\begin{bmatrix} \mu \\ \log\left(\sigma^2\right) \end{bmatrix} = W_q \begin{bmatrix} x \\ c \end{bmatrix} + b_q \tag{3}$$

where W_q and b_q are trainable parameters. Similarly, the prior $p_\theta(z|c)$ can be formulated as another multivariate Gaussian $\mathcal{N}(\mu', \sigma'^2 \boldsymbol{I})$; its parameters are then calculated by a single-layer fully-connected neural network (denoted as MLP) with the $tanh(\cdot)$ activation function,

$$\begin{bmatrix} \mu' \\ \log\left(\sigma'^2\right) \end{bmatrix} = \mathrm{MLP}_p\left(c\right) \tag{4}$$

The decoder uses a one-layer RNN with GRU that takes $[z, c]$ as the input to predict each line L_i. The hidden states of the GRU, $(s_1, s_2, \ldots, s_m)$[7],

---

[2] We directly treat the title as the theme for each poem in this paper instead of transferring it to a few keywords as that was done in Yang et al. (2017).

[3] The quatrain.

[4] The eight-line regulated verse.

[5] $\rightarrow$ and $\leftarrow$ refer to forward and backward, respectively.

[6] μ and σ^2 represent the mean and variance of $\mathcal{N}(\mu, \sigma^2 \boldsymbol{I})$.

[7] Note that s_{m+1} is not passed to the discriminator.

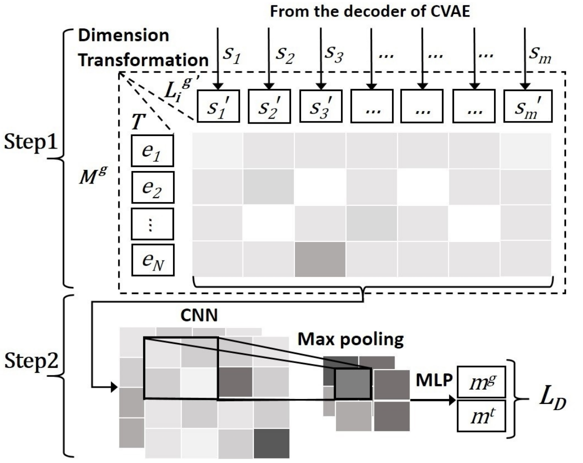

Figure 3: The Discriminator.

are not only used to generate the reconstructed lines, but also passed to the discriminator for learning thematic consistency.

The entire encoder and the decoder are used throughout the training process, with only part of the encoder (objects with solid lines in Figure 2) and the decoder applied in prediction. It is worth noting that, θ and ϕ mentioned in §2.1 are not explicitly corresponded to any particular neural networks described in this section. Instead, the probability process denoted by θ corresponds to the decoding and part of the encoding process, so does ϕ, i.e., $\phi = \{W_q, b_q\}$.

3.2 The Discriminator

The discriminator is introduced in our model to evaluate thematic consistency between the input title and the generated poem lines. The loss from this discriminator is then back-propagated to the decoder of the CVAE to enhance its training. In this paper, we employ a procedure that consists of two steps. First, we compute an interaction (or matching) matrix according to a generated line ${L_i}^g$ and the title T, where ${L_i}^g$ is the reconstructed result of L_i. Then, we utilize a convolutional neural network (CNN) to learn the matching score between ${L_i}^g$ and T, where the score is interpreted as the degree of thematic consistency. Specifically, in the discriminator, we treat ${L_i}^g$ and L_i as the negative and positive instance, referring to thematically inconsistent and consistent case, respectively.

In detail, for the first step, we use the state sequence[8] of the decoder to represent ${L_i}^g$, i.e., ${L_i}^g = (s_1, s_2, \ldots, s_m)$. A dimension transformation is then conducted on ${L_i}^g$, to align ${L_i}^g$ and T:

$$s_i^{'} = ReLU(W_d s_i + b_d) \tag{5}$$

where $ReLU$ is the rectified linear units activation function (Nair and Hinton, 2010), with trainable parameters W_d and b_d. In doing so, the dimension of $s_i^{'}$ is identical to character embeddings. The transformed line is then denoted as ${L_i}^{g'} = (s_1^{'}, s_2^{'}, \ldots, s_m^{'})$. Thus the interaction matrix between ${L_i}^{g'}$ and T is then formulated as

$$M^g = {L_i}^{g'} \cdot T \tag{6}$$

where $M^g \in \mathbb{R}^{N \times m}$; "$\cdot$" denotes the matrix multiplication.

In the second step, a CNN is used to extract features from the interaction matrix. The resulted feature matrix is calculated by $\mathcal{F} = CNN(M^g)$. Then, we apply a max-overtime pooling (Collobert et al., 2011) over $\mathcal{F}$ to capture the most salient information. After this operation, an MLP with one hidden layer is used to flatten the feature matrix and generate the final matching score $m^g \in (0, 1)$ via a $sigmoid$ activation function.

In addition to m^g, the matching score m^t between the positive sample L_i and T is computed in a process similar to the above procedure, except the dimension transformation because character embeddings in both title T and L_i share the same dimension.[9]

Finally, following the routine of generative adversarial networks (GAN) (Goodfellow et al., 2014), the discriminator is trained to measure the thematic consistency of generated lines and the ground truth lines according to the matching scores m^g and m^t, with the objective function

$$\mathcal{L}_D = \log(m^g) + \log(1 - m^t) \tag{7}$$

minimized. Note that the discriminator is only applied during the training process, where the parameters of the encoder and decoder are enhanced by the feedback of the discriminator.

---

[8] Following previous work (Goyal et al., 2016; Hu et al., 2017) using adversarial training, using state sequence instead of the outputs is because the discrete nature of the outputs hinders gradient calculation.

[9] Different from ${L_i}^g$, L_i is represented directly by its sequence of character embeddings, for the reason that the discriminator is only connected with the decoder while L_i does not go through it. Otherwise, if the encoder states are passed to the discriminator, the loss would be back-propagated to the encoder and disturb CVAE training accordingly.

	Poem #	Line #	Vocab #	Token #
PTD	56,549	371,754	7,685	2,093,740
PSD	253,237	1,497,348	9,959	9,008,418
Total	309,786	1,869,102	10,306	11,102,158

Table 1: Corpus statistics of PTD and PSD. **Vocab #** and **Token #** refer to vocabulary size and total number of tokens, respectively, in terms of character.

3.3 Training the Model

The overall objective of CVAE-D is to minimize

$$\mathcal{L}_{\text{CVAE-D}} = \mathcal{L}_{CVAE} - \lambda \mathcal{L}_D \tag{8}$$

with respect to parameters of the CVAE, where $\mathcal{L}_{CVAE}$ is the loss of CVAE, corresponding to $-\mathbb{L}(\theta, \phi; x, c)$. In doing so, $\mathcal{L}_D$ is maximized with regard to parameters of the discriminator, referring to that the generated poems are thematic consistent and able to confuse the discriminator. Herein λ is a balancing parameter. We train the CVAE and the discriminator alternatively in a two-step adversarial fashion similar to that was done in Zhang et al. (2017c). This training strategy is repeated until the $\mathcal{L}_{\text{CVAE-D}}$ is converged.

4 Experiment Setup

4.1 Datasets

To learn our poem generation model, we collect two corpora for experiments: a collection of classic Chinese poems from Tang dynasty (PTD), and the other from Song dynasty (PSD). Statistics of the two corpora are reported in Table 1. Note that for classical Chinese poem, the dominant genres are quatrain and eight-line regulated verse with either 5 or 7 characters in each line. As a result, our model is targeted to generate poems within these two genres, especially the quatrain. All titles of poems are treated as their themes. We randomly choose 1,000 and 2,000 poems for validation and test, respectively, with the rest poems for training.

4.2 Baselines

In addition to our CVAE-D, several highly related and strong methods are conducted as baselines in our experiments, including:

S2S, the conventional sequence-to-sequence model (Sutskever et al., 2014), which has proven to be successful in neural machine translation (NMT) and other text generation tasks.

AS2S and its extension **Key-AS2S** and **Mem-AS2S**, where AS2S is the S2S model integrated with attention mechanism (Bahdanau et al., 2014). Key-AS2S and Mem-AS2S are AS2S with keywords planning (Wang et al., 2016c) and a memory module (Zhang et al., 2017a), respectively. Particularly, they are dedicated models designed for Chinese poem generation.

Criterion	Description
Consistency	Whether a poem displays a consistent theme.
Fluency	Whether a poem is grammatically satisfied.
Meaning	How meaningful the content of a poem is.
Poeticness	Whether a poem has the attributes of poetry.
Overall	Average scores of the above four criteria.

Table 2: Human evaluation criteria.

GAN, a basic implementation of generative adversarial networks (Goodfellow et al., 2014) for this task on top of S2S. This baseline is added to investigate the performance of introducing a discriminator to simple structures other than CVAE.

CVAE[10] and its extension **CVAE-Key**, where the former is the conventional CVAE model and the latter refers to the combination of CVAE and keywords planning (Yang et al., 2017). The CVAE baseline is used for investigating how poem generation can be done with only CVAE, while CVAE-Key aims to provide a comparison to our model with a different technique for thematic control.

4.3 Model Settings

All baselines and the CVAE-D are trained with the following hyper-parameters. The dimension of character embedding is set to 300 for the most frequent 10,000 characters in our vocabulary. The hidden state sizes of the GRU encoder and decoder are set to 500. All trainable parameters, e.g., W_q and W_d, are initialized from a uniform distribution $[-0.08, 0.08]$. We set the mini-batch size to 80 and employ the Adam (Kingma and Ba, 2014) for optimization. We utilize the gradient clipping strategy (Pascanu et al., 2013) to avoid gradient explosion, with the gradient clipping value set to 5.

In addition to the shared hyper-parameters, we have particular settings for CVAE-D. The layer size of MLP_p is set to 400. The dimension of latent variable z is set to 300. For the CNN used in the discriminator, its kernel size is set to $(5, 5)$, with the stride size k to 2. We follow the conventional setting (Hu et al., 2017; Creswell et al.,

---

[10] We do not include VAE as our baseline since VAE cannot perform a supervised generation process.

2017) to set the balancing parameter λ to 0.1.[11]

4.4 Evaluation Metrics

To comprehensively evaluate the generated poems, we employ the following metrics:

BLEU: The BLEU score (Papineni et al., 2002) is an effective metric, widely used in machine translation, for measuring word overlapping between ground truth and generated sentences. In poem generation, BLEU is also utilized as a metric in previous studies (Zhang and Lapata, 2014; Wang et al., 2016a; Yan, 2016; Wang et al., 2016b). We follow their settings in this paper.

Similarity: For thematic consistency, it is challenging to automatically evaluate different models. We adopt the embedding average metric to score sentence-level similarity as that was applied in Wieting et al. (2015). In this paper, we accumulate the embeddings of all characters from the generated poems and that from the given title, and use $cosine$ to compute the similarity between the two accumulated embeddings.

Distinctness: As an important characteristic, poems use novel and unique characters to maintain their elegance and delicacy. Similar to that proposed for dialogue systems (Li et al., 2016), this evaluation is employed to measure character diversity by calculating the proportion of distinctive [1,4]-grams[12] in the generated poems, where final distinctness values are normalized to [0,100].

Human Evaluation: Since writing poems is a complicated task, there always exist incoordinations between automatic metrics and human experiences. Hence, we conduct human evaluation to assess the performance of different models. In doing so, each poem is assessed by five annotators who are well educated and have expertise in Chinese poetry. The evaluation is conducted in a blind review manner, where each annotator has no information about the generation method that each poem belongs to. Following previous work (He et al., 2012; Zhang and Lapata, 2014; Wang et al., 2016c; Zhang et al., 2017a), we evaluate generated poems by four criteria, namely, consistency, fluency, meaning, and poeticness. Each criterion is rated from 1 to 3, representing bad, normal, good, respectively. The details are illustrated in Table 2.

5 Experimental Results

5.1 Quantitative Analysis

Table 3 reports the results of both automatic and human evaluations. We analyze the results from the following aspects.

5.1.1 The effect of CVAE

This study is to investigate whether using latent variable and variational inference can improve the diversity and novelty of terms in generated poems. There are two main observations.

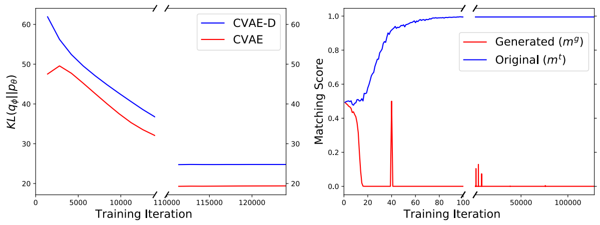
CVAE significantly improves term novelty. As illustrated in Table 3, CVAE outperforms all baselines significantly in terms of distinctness. With diversified terms, the aesthetics scores also confirm that CVAE can generate poems that correspond to better user experiences. Although Mem-AS2S can generate a rather high distinctness score, it requires a more complicated structure in learning and generating poems. The results confirm the effectiveness of CVAE in addressing the issue of term duplications that occurred in RNN.

CVAE cannot control thematic consistency of generated poems. Recall that thematic consistency and term diversity are usually mutually ex-

---

[11] We tried different values for λ, varying from 0.001 to 1, which result in similar performance of the CVAE-D.

[12] Defined as the number of distinctive n-grams divided by the total number of n-grams, shown as Dist-1, Dist-2, Dist-3, Dist-4 in Table 3.



(a) KL divergence (b) Matching score

Figure 4: KL divergences of CVAE and CVAE-D (a) and matching scores of the generated and original lines from the discriminator (b). All curves are drawn against training iterations.

clusive, CVAE produces the worst result in thematic consistency, which is confirmed in Table 3 by the similarity score in automatic evaluation and the consistency score in human evaluation.

5.1.2 The Influence of the Discriminator

As previously stated, introducing a discriminator with adversarial training is expected to bring positive effect on thematic consistency. We investigate the influence of discriminator with two groups of comparison, i.e., CVAE-D v.s. CVAE, GAN v.s. S2S. Following observations are made in this investigation, which confirm that adversarial learning is an effective add-on to existing models for thematics control, without affecting other aspects.

The discriminator effectively enhances poem generation with thematic information. When the discriminator is introduced, CVAE and S2S model are capable of generating thematically consistent poems, as illustrated by the similarity and meaning scores in Table 3. The BLEU results also confirm that the discriminator can improve the overlapping between generated poems and the ground truth, which serves as thematic consistent cases.

The extra discriminator does not affect base models on irrelevant merits. For any base model, e.g., S2S and CVAE, when adding a discriminator, it is expected that it can bring help on thematic consistency while limiting any inferior effects on other evaluations. This is confirmed in the results, e.g., for distinctness, CVAE-D and GAN are comparable to CVAE and S2S.

5.1.3 The Performance of CVAE-D

Overall, the CVAE-D model substantially outperforms all other models in all metrics. Especially for term novelty and thematic consistency, CVAE-D illustrates an extraordinary balance between them, with observable improvements on both sides. This balance is mainly contributed from the proposed framework that seamlessly integrates CVAE and the discriminator. Except for the automatic and human evaluation scores, the fact is also supported by the training loss of $\mathrm{KL}(q_\phi(z|x,c) \parallel p_\theta(z|c))$ and $\mathcal{L}_\mathcal{D}$ as shown in Figure 4, where 1) the KL-divergence of CVAE-D has an analogous trend with CVAE, referring to that the CVAE part in CVAE-D is trained as good as an independent CVAE; 2) the discriminator captures the distinctness of thematic consistency between the generated lines and the ground truth lines at the very early stage of training.

书窗碧桃 Daydream in my garden
庭户风光寄所思， The view in the garden brings up the fantasy, 伊人重过惜残枝。 As if my love dances in the scenery. 窗前花开不知味， Hence blossom can never arouse my curiosity, 唯有落红入我诗。 With only fading memory in the poetry.

Figure 5: An example poem generated by the CVAE-D model. Note that the translation is performed in delivering the meaning instead of the verbatim manner.

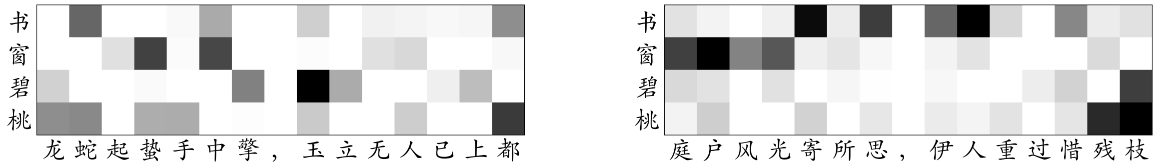
5.2 Qualitative Analysis

In addition to evaluating CVAE-D with quantitative results, we also conduct case studies to illustrate its superiority. Figure 5 gives an example of the CVAE-D generated poems, which well demonstrates the capability of our model. The entire poem elegantly expresses a strong theme of "missing my love".[13] It is clearly shown that the choices of the characters, such as 庭 (yard), 枝 (branch), 花 (flower), 红 (red), etc., match with the given title to a certain extent with no one repetitively used. To further investigate how different models perform on thematic consistency, we visualize the correspondence between generated poems (the first two lines) and the given title with heatmaps in Figure 6, where Figure 6(a) and Figure 6(b) illustrate the results yielded by CVAE and CVAE-D, respectively.[14] Obviously, the overall color in Figure 6(a) is lighter than that in Figure 6(b), which

---

[13] "Seeing an object makes one miss someone" is a popular theme in Classical Chinese poems.

[14] Grids in the heatmap represent the correlations between the fine-tuned embeddings of the characters in the title and the generated lines. Since the embeddings are updated in the training process, a better model leads to higher correlations among the embeddings of related characters.



(a) CVAE

(b) CVAE-D

Figure 6: Heatmaps derived from CVAE (a) and CVAE-D (b), in illustrating the correlation between the characters in lines and the title. The horizontal axis refers to characters of the first two lines generated by different models; the vertical axis corresponds to characters in the title. Darker color indicates higher thematic consistency.

may indicate that most of the characters generated by CVAE are not addressed with thematic attentions over the given title. On the opposite, CVAE-D presents darker color in the grids on all related characters, which further reveals the effectiveness of CVAE-D in improving thematic consistency of a poem with respect to its title.

It is observed that there are also inferior cases generated by our model. A notable example pattern is that some fine-grained attributes, e.g., sentiment, emotion, are not well aligned across lines, where some lines may deliver different mood from others. Since our model does not explicitly control such attributes, thus one potential solution to address this issue is to introduce other features to model such information, which requires a special design to adjust the current model. We also notice there exists a few extraordinary bad cases where their basic characteristics, such as wording, fluency, etc., are unacceptable. This phenomenon is randomly observed with no patterns, which could be explained by the complexity of the model and the fragile natural of adversarial training (Goodfellow et al., 2014; Li et al., 2017). Careful parameter setting and considerate module assemble could mitigate this problem, thus lead to potential future work of designing more robust frameworks.

6 Related Work

Deep Generative Models. This work can be seen as an extension of research on deep generative models (Salakhutdinov and Hinton, 2009; Bengio et al., 2014), where most of the previous work, including VAE and CVAE, focused on image generation (Sohn et al., 2015; Yan et al., 2016b). Since GAN (Goodfellow et al., 2014) is also a successful generative model, there are studies tried to integrate VAE and GAN (Larsen et al., 2016). In natural language processing, many recent deep generative models are applied to dialogue systems Serban et al. (2017); Shen et al. (2017); Zhao et al. (2017) and text generation with (Hu et al., 2017; Yu et al., 2017; Lin et al., 2017; Zhang et al., 2017b; Guo et al., 2018). To the best of our knowledge, this work is the first one integrating CVAE and adversarial training with a discriminator for text generation, especially in a particular text genre, poetry.

Automatic Poem Generation. According to methodology, previous approaches can be roughly classified into three categories: 1) rule and template based methods (Tosa et al., 2008; Wu et al., 2009; Netzer et al., 2009; Zhou et al., 2010; Oliveira, 2012; Yan et al., 2013); 2) SMT approaches (Jiang and Zhou, 2008; Greene et al., 2010; He et al., 2012); 3) deep neural models (Zhang and Lapata, 2014; Wang et al., 2016b; Yan, 2016). Compared to rule-based and SMT models, neural models are able to learn more complicated representations and generate smooth poems. Most recent studies followed this paradigm. For example, Wang et al. (2016c) proposed a modified encoder-decoder model with keyword planning; Zhang et al. (2017a) adopted memory-augmented RNNs to dynamically choose each term from RNN output or a reserved inventory. To improve thematic consistency, Yang et al. (2017) combined CVAE and keywords planning. Compared to them, our approach offers an alternative way for poem generation that can produce novel terms and consistent themes via an integrated framework, without requiring special designed modules or post-processing steps.

7 Conclusions

In this paper, we proposed an effective approach that integrates CVAE and adversarial training for classical Chinese poem generation. Specifically, we used CVAE to generate each line of a poem with novel and diverse terms. A discriminator was then applied with adversarial training to explicitly control thematic consistency. Experiments conducted on a large Chinese poem corpus illustrated that through the proposed architecture with CVAE and the discriminator, substantial improvement was observed on the results from our generated poems over those from the existing models. Further qualitative study on given examples and some brief error analyses also confirmed the validity and effectiveness of our proposed approach.

Abstract

Question generation, the task of automatically creating questions that can be answered by a certain span of text within a given passage, is important for question-answering and conversational systems in digital assistants such as Alexa, Cortana, Google Assistant and Siri. Recent sequence to sequence neural models have outperformed previous rule-based systems. Existing models mainly focused on using one or two sentences as the input. Long text has posed challenges for sequence to sequence neural models in question generation – worse performances were reported if using the whole paragraph (with multiple sentences) as the input. In reality, however, it often requires the whole paragraph as context in order to generate high quality questions. In this paper, we propose a maxout pointer mechanism with gated self-attention encoder to address the challenges of processing long text inputs for question generation. With sentence-level inputs, our model outperforms previous approaches with either sentence-level or paragraph-level inputs. Furthermore, our model can effectively utilize paragraphs as inputs, pushing the state-of-the-art result from 13.9 to 16.3 (BLEU_4).

1 Introduction

Question generation (QG), aiming at creating questions from natural language text, e.g. a sentence or paragraph, is an important area in natural language processing (NLP). It is receiving increasing interests in recent years from both industrial and academic communities, due to the booming of Question-and-Answer (QnA) and conversation systems, including Alexa, Cortana, Google Assistant and Siri, the advancement of QnA or machine comprehension technologies together with the releases of datasets like SQuAD (Rajpurkar et al., 2016) and MS MARCO (Nguyen et al., 2016), and the success of language generation technologies for tasks like machine translation (Wu et al., 2016) and text summarization (See et al., 2017) in NLP. A conversational system can be proactive by asking the user questions (Shum et al., 2018), while a QnA system can benefit from a large scale question-answering corpus which can be created by an automated QG system (Duan et al., 2017). Education is another key application where QG can help with reading comprehension (Heilman and Smith, 2010).

In NLP, QG has been mainly tackled by two approaches: 1) rule-based approach, e.g. (Heilman and Smith, 2010; Mazidi and Nielsen, 2014; Labutov et al., 2015) 2) neural QG approach: end-to-end training a neural network using the sequence to sequence (also called encoder-decoder) framework, e.g. (Du et al., 2017; Yuan et al., 2017; Song et al., 2017; Zhou et al., 2017). In this paper, we adopt the second approach.

More specifically, we focus on an answer-aware QG problem, which takes a passage and an answer as inputs, and generates a question that targets the given answer. It is also assumed the answer is comprised of certain spans of the text from the given passage. This is the exact setting of SQuAD, and similar problems have been addressed in, e.g. (Zhou et al., 2017; Yuan et al., 2017; Wang et al., 2017a).

A paragraph often contains much richer context than a sentence, as shown in Figure 1. (Du et al., 2017) pointed out that about 20% questions in SQuAD require paragraph-level information to be asked and using the whole paragraph can improve QG performance on those questions. However, a paragraph can contain irrelevant information w.r.t. the answer for generating the question. The challenge is thus how to effectively utilize relevant information at paragraph-level for QG. Existing neural QG works conducted on SQuAD use

Brussels, Belgium, October 31 - November 4, 2018.

1 **Paragraph**: carolina suffered a major setback when thomas davis , an 11-year veteran who had already overcome three acl tears in his career , went down with a broken arm in the nfc championship game . *despite this , he insisted he would still find a way to play in the super bowl* . his prediction turned out to be accurate
Human generated: what game did thomas davis say he would play in , despite breaking a bone earlier on ?
Sentence-level QG: what sports game did spielberg decide to play in ?
Paragraph-level QG: what competition did thomas davis think he would play in ?

2 **Paragraph**: walt disney and his brother roy contacted goldenson at the end of 1953 for abc to agree to finance part of the disneyland project in exchange for producing a television program for the network . *walt wanted abc to invest $ 500,000 and accrued a guarantee of $ 4.5 million in additional loans , a third of the budget intended for the park .* around 1954 , abc agreed to finance disneyland in exchange for the right to broadcast a new sunday night program , disneyland , which debuted on the network on october 27 , 1954 as the first of many anthology television programs that disney would broadcast over the course of the next 50 years
Human generated: how much did walt disney want abc to invest in disneyland ?
Sentence-level QG: how much money did walt wanted to invest ?
Paragraph-level QG: how much money did walt wanted to invest in 1953 ?

3 **Paragraph**: following the peterloo massacre of 1819 , poet percy shelley wrote the political poem the mask of anarchy later that year , that begins with the images of what he thought to be the unjust forms of authority of his timeand then imagines the stirrings of a new form of social action . *it is perhaps the first modern [vague] statement of the principle of nonviolent protest .* a version was taken up by the author henry david thoreau in his essay civil disobedience , and later by gandhi in his doctrine of satyagraha . gandhi 's satyagraha was partially influenced and inspired by shelley 's nonviolence in protest and political action . in particular , it is known that gandhi would often quote shelley 's masque of anarchy to vast audiences during the campaign for a free india
Human generated: his poem is considered the first kind of what type of protest ?
Sentence-level QG: what is the principle of the protest ?
Paragraph-level QG: what type of protest did percy shelley write ?

4 **Paragraph**: the victoria and albert museum (often abbreviated as the v & a) , london , is the world 's largest museum of decorative arts and design , housing a permanent collection of over 4.5 million objects *. it was founded in 1852 and named after queen victoria and prince albert.* the v & a is located in the brompton district of the royal borough of kensington and chelsea , in an area that has become known as " albertopolis " because of its association with prince albert , the albert memorial and the major cultural institutions with which he was associated . these include the natural history museum , the science museum and the royal albert hall . the museum is a non-departmental public body sponsored by the department for culture , media and sport . like other national british museums , entrance to the museum has been free since 2001
Human generated: when was the victoria and albert museum founded ?
Sentence-level QG: when was prince albert and prince albert founded ?
Paragraph-level QG: when was the victoria and albert museum founded ?

Figure 1: Examples where paragraph-level information is required to ask right questions. *Sentences* contain *answers* are in *italic* font, while *answers* are underscored. QG results are generated by model *s2s-a-ct-mp-gsa*.

only a sentence as context, e.g. (Du et al., 2017; Song et al., 2017; Zhou et al., 2017); when applied to paragraph-level context (Yuan et al., 2017) we observed large gaps compared to state-of-the-art results achieved by using sentence-level context.

In this paper, we extend previous sequence to sequence attention model with a maxout pointer mechanism and a gated self-attention encoder which outperforms existing neural QG approaches with either sentence or paragraph as inputs. Furthermore, with paragraph-level inputs, it outperforms the results of previous approaches with sentence-level inputs, improving state-of-the-art result from 13.9 to 16.3 (BLEU_4). This is the first model that demonstrates large improvement with paragraph as input over sentence as input. In addition, our model is more concise compared to most of existing ones, e.g. (Yuan et al., 2017; Song et al., 2017). Techniques like incorporating rich features (Zhou et al., 2017) and policy gradient (Song et al., 2017; Yuan et al., 2017) are orthogonal to ours and can be leveraged for further performance improvement in the future.

2 Our Model

2.1 Problem Definition

We use P and A to represent input passage and answer respectively, and use Q to represent the generated question. ”Passage” in this section can represent either a sentence or a paragraph. The task is to find $\bar{Q}$ that:

$$\bar{Q} = \underset{Q}{\operatorname{argmax}}\, Prob(Q|P, A)$$

where passage is comprised of sequence of words:$P = \{x_t\}_{t=1}^{M}$, answer A must be sub spans of the passage. Words generated in $Q = \{y_t\}_{t=1}^{K}$ are either from the input passage, $\{x_t\}_{t=1}^{M}$, or from a vocabulary V.

Figure 2 illustrates the end-to-end structure of our model proposed in this paper.

2.2 Passage and Answer Encoding

Different types of encoders are designed for various domains (Chung et al., 2014; Hochreiter and Schmidhuber, 1997). We are agnostic to the form of the encoder and simply use recurrent neural network (RNN) to present the encoding process:

$$\mathbf{u}_t = RNN^E(\mathbf{u}_{t-1}, [\mathbf{e}_t, \mathbf{m}_t]) \qquad (1)$$

Answer Tagging. In Eq. 1, $\mathbf{u}_t$ represents the RNN hidden state at time step t, $\mathbf{e}_t$ is the word embedding representation of word x_t in passage P. $\mathbf{m}_t$ is the meta-word representation of whether word x_t is in or outside the answer. $[\mathbf{a}, \mathbf{b}]$ represents the concatenation of vector $\mathbf{a}$ and $\mathbf{b}$. We call this approach answer tagging which is similar to the techniques in (Zhou et al., 2017; Yuan et al., 2017). For applications, it is essential to be able to generate question that is coherent to an answer.

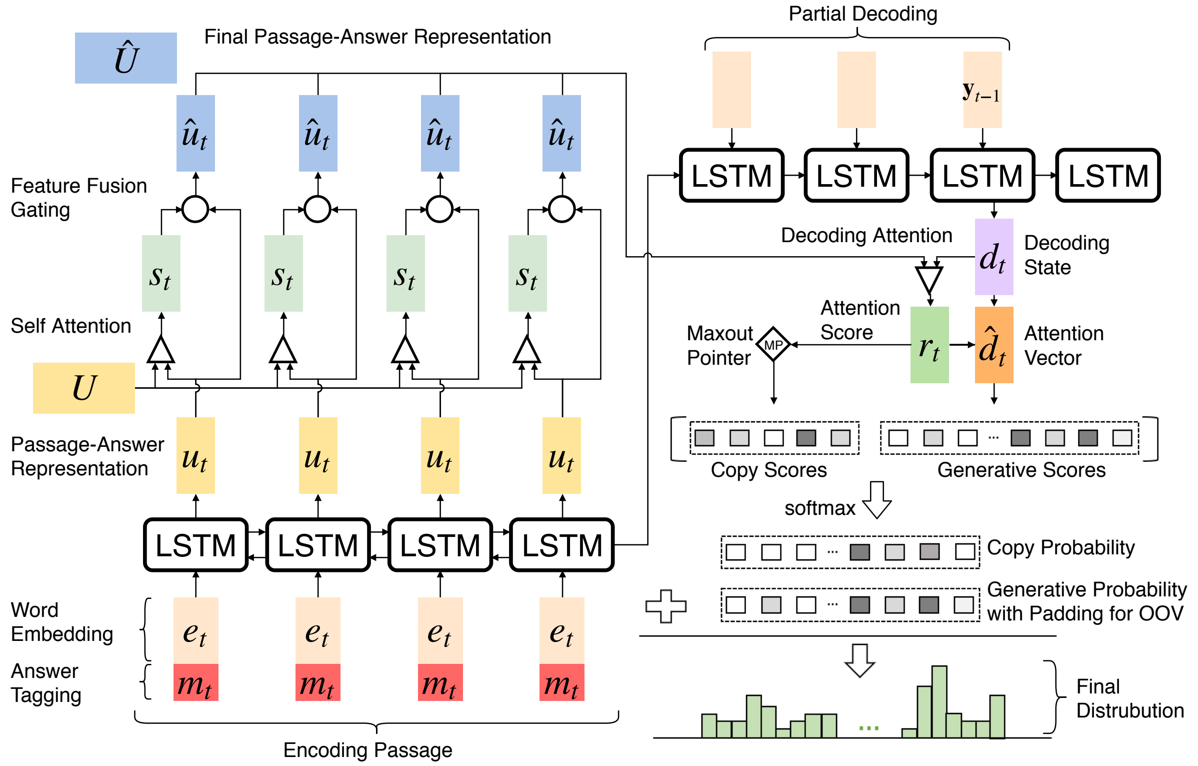

Figure 2: End-to-end diagram for the model with answer tagging, gated self-attention and maxout pointer mechanism.

If RNN^E is bi-directional, $\mathbf{u}$ is the concatenated representation of the forward and backward passes: $\mathbf{U} = \{[\overrightarrow{\mathbf{u}_t}, \overleftarrow{\mathbf{u}_t}]\}_{t=1}^{M}$.

Gated Self-attention. Our gated self-attention mechanism is designed to aggregate information from the whole passage and embed intra-passage dependency to refine the encoded passage-answer representation at every time step. It has two steps: 1) taking encoded passage-answer representation $\mathbf{u}$ as input and conducting matching against itself to compute self matching representation; (Wang et al., 2017b) 2) combining the input with self matching representation using a feature fusion gate (Gong and Bowman, 2017).

$$\mathbf{a^s}_t = softmax(\mathbf{U}^\mathsf{T}\mathbf{W}^s\mathbf{u}_t) \tag{2}$$

$$\mathbf{s}_t = \mathbf{U} \cdot \mathbf{a^s}_t \tag{3}$$

Step 1. In Eq. 2, $\mathbf{W}^s$ is a trainable weight matrix. In Eq. 3, $\mathbf{s}_t$ is the weighted sum of all words' encoded representation in passage based on their corresponding matching strength to current word at t. $\mathbf{s} = \{\mathbf{s}_t\}_{t=1}^{M}$ is the final self matching representation.

$$\mathbf{f}_t = tanh(\mathbf{W}^f[\mathbf{u}_t, \mathbf{s}_t]) \tag{4}$$

$$\mathbf{g}_t = sigmoid(\mathbf{W}^g[\mathbf{u}_t, \mathbf{s}_t]) \tag{5}$$

$$\hat{\mathbf{u}}_t = \mathbf{g}_t \odot \mathbf{f}_t + (1 - \mathbf{g}_t) \odot \mathbf{u}_t \tag{6}$$

Step 2. The self matching representation $\mathbf{s}_t$ is combined with original passage-answer representation $\mathbf{u}_t$ as the new self matching enhanced representation $\mathbf{f}_t$, Eq. 4. A learnable gate vector $\mathbf{g}_t$, Eq. 5, chooses the information between the original passage-answer representation and the new self matching enhanced representation to form the final encoded passage-answer representation $\hat{\mathbf{u}}_t$, Eq. 6, where $\odot$ is the element-wise multiplication.

2.3 Decoding with Attention and Maxout Pointer

In the decoding stage, the decoder is another RNN that generates words sequentially conditioned on the encoded input representation and the previously decoded words.

$$\mathbf{d}_t = RNN^D(\mathbf{d}_{t-1}, \mathbf{y}_{t-1}) \tag{7}$$

$$p(y_t|\{y_{<t}\}) = softmax(\mathbf{W}^V\mathbf{d}_t) \tag{8}$$

In Eq. 7, $\mathbf{d}_t$ represents the hidden state of the RNN at time t where $\mathbf{d}_0$ is passed from the final hidden state of the encoder. y_t stands for the word generated at time t. The bold font $\mathbf{y}_t$ is used to represent y_t's corresponding word embedding representation. In Eq. 8, first an affine layer projects $\mathbf{d}_t$ to a space with vocabulary-size dimensions, then a $softmax$ layer computes a probability distribution over all words in a fixed vocabulary V . $\mathbf{W}^V$ is a trainable weight matrix.

Attention. Attention mechanism (Bahdanau et al., 2014; Luong et al., 2015) has been used to improve sequence to sequence models' performance and has became a default setting for many applications.

We use Luong attention mechanism to compute raw attention scores $\mathbf{r}_t$, Eq. 9. An attention layer, Eq. 12 is applied above the concatenation of decoder state $\mathbf{d}_t$ and the attention context vector $\mathbf{c}_t$ and its output is used as the new decoder state.

$$\mathbf{r}_t = \hat{\mathbf{U}}^\mathsf{T} \mathbf{W}^a \mathbf{d_t} \tag{9}$$

$$\mathbf{a^d}_t = softmax(\mathbf{r}_t) \tag{10}$$

$$\mathbf{c}_t = \hat{\mathbf{U}} \cdot \mathbf{a^d}_t \tag{11}$$

$$\hat{\mathbf{d}}_t = tanh(\mathbf{W}^b[\mathbf{d}_t, \mathbf{c}_t]) \tag{12}$$

Copy/Pointer. Copy mechanism (Gu et al., 2016) or pointer network (See et al., 2017; Vinyals et al., 2015) was introduced to allow both copying words from input via pointing, and generating words from a predefined vocabulary during decoding.

Similar to (Gu et al., 2016), our pointer mechanism directly leverages raw attention scores $\mathbf{r}_t = \{r_{t,k}\}_{k=1}^{M}$ over the input sequence which has a vocabulary of χ. Words at every time step (a pointer) are treated as unique copy targets and the final score on one word is calculated as the sum of all scores pointing to the same word, Eq. 13, where x_k and y_t stand for word vocabulary indices of the kth word in input and the tth word in decoded sequence respectively. The scores of the nonoccurence words are set to negative infinity which will be masked out by the downstream $softmax$ function.

$$\mathbf{sc}^{copy}(y_t) = \begin{cases} \sum\limits_{k, where\ x_k = y_t} r_{t,k}, & y_t \in \chi \\ -inf, & otherwise \end{cases} \tag{13}$$

We then concatenate $\mathbf{sc}_t^{copy}$ with the generative scores (from Eq. 8 before $softmax$), $[\mathbf{sc}_t^{gen}, \mathbf{sc}_t^{copy}]$, which has dimension: $|V| + |\chi|$. Then we perform $softmax$ on the concatenated vectors and sum up the probabilities pointing to same words. Taking $softmax$ on the concatenated score vector enforces copy and generative modes to compete with each other due to the shared normalization denominator. Another popular solution is to do $softmax$ independently to the scores from each mode, and then combine their output probabilities with a dynamic weight which is generated by a trainable network (See et al., 2017). We have tested both and didn't find significant difference in terms of accuracy on our QG task. We choose the former copy approach mainly because it doesn't add extra trainable parameters.

Maxout Pointer. Despite the outstanding performance of existing copy/pointer mechanisms, we observed that repeated occurrence of words in the input sequence tends to cause repetitions in output sequence, especially when the input sequence is long, e.g. a paragraph. This issue exacerbates the repetition problem which has already been commonly observed in sequence to sequence models (Tu et al., 2016; See et al., 2017). In this paper, we propose a new maxout pointer mechanism to address this issue and improve the metrics for QG task. Related works (Goodfellow et al., 2013) have explored MLP maxout with dropout.

Instead of combining all the scores to calculate the probability, We limit the magnitude of scores of repeated words to their maximum value, as shown in Eq. 14. The rest remains the same as in the previous copy mechanism.

$$\mathbf{sc}^{copy}(y_t) = \begin{cases} \max\limits_{k, where\ x_k = y_t} r_{t,k}, & y_t \in \chi \\ -inf, & otherwise \end{cases} \tag{14}$$

3 Experiments

In our experiments, we study the proposed model on the QG task on SQuAD (Rajpurkar et al., 2016) and MS MARCO (Nguyen et al., 2016) dataset, demonstrate the performance of proposed components on both sentence and paragraph inputs, and compare the model with existing approaches.

3.1 Dataset

SQuAD

The SQuAD dataset contains 536 Wikipedia articles and more than 100K questions posed about the articles by crowd-workers. Answers are also

Table 1: Performance of our models on **Split1** with both sentence-level input and paragraph-level input. **Sen.** means sentence, while **Par.** means paragraph.

provided to the questions, which are spans of tokens in the articles.

Following (Du et al., 2017; Zhou et al., 2017; Song et al., 2017), our experiments are conducted using the accessible part of SQuAD: train and development (dev*) sets. To be able to directly compare with their works, we adopt two types of data split: 1) **Split1**: similar to (Du et al., 2017), we use dev* set as test set, and split train set into train and dev sets randomly with ratio 90%-10%. The split is done at article level. However, we keep all samples instead of only keeping the sentence-question pairs that have at least one non-stop-word in common (with 6.7% pairs dropped) as in (Du et al., 2017). This makes our dataset harder for training and evaluation. 2) **Split2**: similar to (Zhou et al., 2017), we split dev* set into dev and test sets randomly with ratio 50%-50%. The split is done at sentence level.

MS MARCO

MS MARCO datasets contains 100,000 queries with corresponding answers and passages. All questions are sampled from real anonymized user queries and context passages are extracted from real web documents. We picked a subset of MS MARCO data where answers are sub-spans within the passages, and use dev set as test set (7k), and split train set with ratio 90%-10% into train (51k) and dev (6k) sets.

3.2 Implementation Details

We used 2 layers LSTM as the RNN cell for both encoding and decoding. For encoding, bi-directional LSTM was used. The cell hidden size was 600. Dropout with probability 0.3 was applied between vertical LSTM stacks. For word embedding, we used pre-trained GloVe word vectors with 300 dimensions (Pennington et al., 2014), and froze them during training. Dimension of answer tagging meta-word embedding was 3. Both encoder and decoder shared the same vocabulary of the most frequent 45k GloVe words. For optimization, we used SGD with momentum (Qian, 1999; Nesterov, 1983). Learning rate was initially set to 0.1 and halved since epoch 8 at every 2 epochs afterwards. Models were totally trained with 20 epochs. The mini-batch size for parameter update was 64. After training, we looked at the 4 models with lowest perplexities and selected the one which used the most number of epochs as final model. During decoding for prediction, we used beam search with the beam size of 10, and stopped decoding when every beam in the stack generates the EOS token.

3.3 Evaluation

We conduct automatic evaluation with metrics: BLEU_1, BLEU_2, BLEU_3, BLEU_4 (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2014) and ROUGE-L (Lin, 2004), and use evaluation package released by (Sharma et al., 2017) to compute them.

4 Results and Analysis

4.1 Comparison of Techniques

Table 1 shows evaluation results for different models on SQuAD Split1. Results with both sentence-level and paragraph-level inputs are included. Similar results also have been observed on SQuAD Split2. The definitions of the models under comparison are:

s2s: basic sequence to sequence model
s2s-a: *s2s* + attention mechanism
s2s-a-at: *s2s-a* + answer tagging
s2s-a-at-cp: *s2s-a-at* + copy mechanism

s2s-a-at-mp: *s2s-a-at* + maxout pointer mechanism
s2s-a-at-mp-gsa: *s2s-a-at-mp* + gated self-attention

Attention Mechanism

s2s-a vs. *s2s*: we can see attention brings in large improvement on both sentence and paragraph inputs. The lower performance on paragraph indicates the challenge of encoding paragraph-level information.

Answer Tagging

s2s-a-at vs. *s2s-a*: answer tagging dramatically boosts the performance, which confirms the importance of answer-aware QG: to generate good question, we need to control/learn which part of the context the generated question is asking about. More importantly, answer tagging clearly reduces the gap between sentence and paragraph inputs, which could be explained with: by providing guidance on answer words, we can make the model learn to neglect noise when processing a long context.

Copy Mechanism

s2s-a-at-cp vs. *s2s-a-at*: as expected, copy mechanism further improves the performance on the QG task. (Du et al., 2017) pointed out most of the sentence-question pairs in SQuAD have over 50% overlaps in non-stop-words. Our results prove that sequence to sequence models with copy mechanism can very well learn when to generate a word and when to copy one from input on such QG task. More interestingly, the performance is lower when paragraph is given as input than sentence as input. The gap, again, reveals the challenge of leveraging longer context. We found that, when paragraph is given, the model tends to generate more repetitive words, and those words (often entities/concepts) usually appear multiple times in the context, Figure 3. The repetition issue can also be seen for sentence input, but it is more severe for paragraph.

Maxout Pointer

s2s-a-at-mp vs. *s2s-a-at-cp*: Maxout pointer is designed to resolve the repetition issue brought by the basic copy mechanism, for example Figure 3. The maxout pointer mechanism outperforms the basic copy mechanism in all metrics. Moreover, the effectiveness of maxout pointer is more significant when paragraph is given as the model input, as it reverses the performance gap between models trained with sentence and paragraph inputs, Table 1.

Paragraph: a problem is regarded as inherently difficult if its solution requires significant resources , whatever the algorithm used . the theory formalizes this intuition , by introducing mathematical models of computation to study these problems and quantifying the amount of resources needed to solve them , such as time and storage . *other complexity measures are also used , such as the amount of communication (used in communication complexity) , the number of gates in a circuit (used in circuit complexity) and the number of processors (used in parallel computing) .* one of the roles of computational complexity theory is to determine the practical limits on what computers can and can not do
Human generated: what unit is measured to determine circuit complexity ?
Basic copy QG: what is an example of a circuit complexity in complexity complexity ?
Maxout Pointer QG: what is another name for circuit complexity ?

Figure 3: Example for maxout pointer vs. basic copy/pointer.

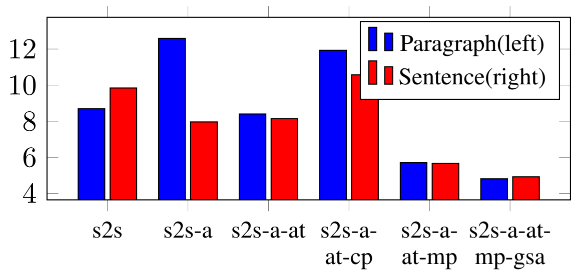

Figure 4: Word duplication rates of QG on Split1, duplication rate on human generated question is **3.53**.

To demonstrate that maxout pointer reduces repetitions in generated questions, we present the word duplication rates in generated questions for various models in Figure 4. Word duplication rate was computed by counting the number of words which appear more than once, and then taking a ratio of them over the total word counts. As shown in Figure 4, both the attention mechanism and the basic copy mechanism introduce more repetitions, although they improve overall accuracy according to Table 1. For models trained with paragraph inputs, where the duplication rates are much higher, maxout pointer reduces the duplication rates to half of their values in the basic copy and to the same level as model trained with sentence inputs.

Such repetition issue was also observed in other sequence to sequence applications, e.g. (See et al., 2017) who proposed a coverage model and coverage loss to resolve this issue. We implemented and tested their approach on our QG task. Even though the duplication ratio dropped as expected, we observed a slight decline in the accuracy when coverage loss was added.

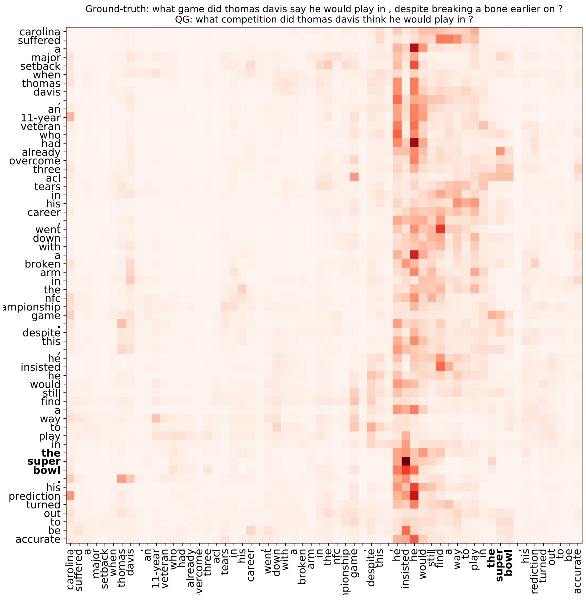

Figure 5: Self-attention alignments map: each row represents an alignment vector of self-attention.

Gated Self-attention

s2s-a-at-mp-gsa vs. *s2s-a-at-mp*: the results demonstrate the effectiveness of gated self-attention, in particular, when working with paragraph inputs. This is the first time, as we know, taking paragraph as input is better than sentence for neural QG tasks. The observation is consistent across all metrics. Gated self-attention helps refine encoded context by fusing important information with the context's self representation properly, especially when the context is long.

To better understand how gated self-attention works, we visualize the self alignment vectors at each time step of the encoded sequence for one example, in Figure 5. This example corresponds to the example 1 in Figure 1. We can see the alignments distribution concentrates near the answer sequence and the most relevant context: "thomas davis" in this example. Such alignments in turn would help to promote the most valuable information for decoding.

Beam Search

Beam search is commonly used for decoding for predictions. Existing neural QG works, e.g. (Du et al., 2017; Zhou et al., 2017), evaluated their models with beam search decoding. However, so far, none of them have reported the comparison between beam search decoding with greedy decoding. In this paper, we give such comparison for our best model: *s2s-a-at-mp-gsa* with both sentence and paragraph inputs in Table 2. We can clearly see beam search decoding boosts all metrics for both sentence and paragraph inputs. The effectiveness of beam search has also been demonstrated for other tasks, like neural machine translation in (Wu et al., 2016).

	Beam_Search		**Greedy**	
Metric	**Sen.**	**Par.**	**Sen.**	**Par.**
BLEU_1	43.47	45.07	42.25	43.48
BLEU_2	28.23	29.58	26.36	27.67
BLEU_3	20.40	21.60	18.35	19.64
BLEU_4	15.32	16.38	13.28	14.50
METEOR	19.29	20.25	18.25	19.17
ROUGE-L	43.91	44.48	42.58	43.62

Table 2: Comparison of beam search and greedy decodings for model **s2s-a-ct-mp-gsa** on Split1.

4.2 Comparison with Existing Neural Question Generation Works

On SQuAD dataset, we compare the BLEU, METEOR, ROUGE-L scores of our best model, *s2s-a-at-mp-gsa*, with the numbers in the existing works in Table 3. Comparison with (Du et al., 2017) and (Song et al., 2017) is conducted on SQuAD data Split1, while comparison with (Zhou et al., 2017) and (Song et al., 2017) is conducted on data SQuAD split2. Because (Song et al., 2017) had results on both splits, we compare with both of them.

On MS MARCO dataset, we compare the BLEU_4 scores reported by (Duan et al., 2017) in Table 4.

Our model with maxout pointer and gated self-attention achieves the state-of-the-art results in QG. Note that all those existing works in SQuAD encoded only sentence-level information, the results from our model surpass them on the same sentence input while achieving much higher numbers when working with paragraph.

4.3 Case Study

In Figure 1, we present some examples for which paragraph-level information is needed to ask good/correct questions. Generated questions from model *s2s-a-ct-mp-gsa* are also presented for both sentence and paragraph inputs. Those examples demonstrate that generated questions contain richer information when paragraphs are provided

	Model	BLEU_1	BLEU_2	BLEU_3	BLEU_4	METEOR	ROUGE-L
Split1	(Du et al., 2017)	43.09	25.96	17.50	12.28	16.62	39.75
	(Song et al., 2017)	x	x	x	13.98	18.77	42.72
	ours, sentence	43.47	28.23	20.40	15.32	19.29	43.91
	ours, paragraph	**45.07**	**29.58**	**21.60**	**16.38**	**20.25**	**44.48**
Split2	(Zhou et al., 2017)	x	x	x	13.27	x	x
	(Song et al., 2017)	x	x	x	13.91	x	x
	ours, sentence	44.51	29.07	21.06	15.82	19.67	44.24
	ours, paragraph	**45.69**	**30.25**	**22.16**	**16.85**	**20.62**	**44.99**

Table 3: Comparison of results on SQuAD dataset.

	Model	BLEU_4
MSMARCO	(Du et al., 2017)	10.46
	(Duan et al., 2017)	11.46
	ours, sentence	16.02
	ours, paragraph	**17.24**

Table 4: Comparison of results on MSMARCO dataset.

instead of sentences.

In example 1 and 3, name ”thomas davis” and ”percy shelley” appear in the paragraphs not the sentences contain the answers.

In example 2, paragraph-level QG can generate richer description ”in 1953” from the paragraph, although human generated is ”disneyland”. Both generated questions lack one relative important piece of information ”want **abc** to invest”.

In example 4, paragraph-level QG correctly identifies ”it” is referring to the museum which is out of the sentence.

5 Related Work

QG has been mainly tackled with two types of approaches. One is built on top of heuristic rules that creates questions with manually constructed template and ranks the generated results, e.g. (Heilman and Smith, 2010; Mazidi and Nielsen, 2014; Labutov et al., 2015). Those approaches heavily depend on human effort, which makes them hard to scale up to many domains. The other one, which is becoming increasingly popular, is to train an end-to-end neural network from scratch by using sequence to sequence or encoder-decoder framework, e.g. (Du et al., 2017; Yuan et al., 2017; Song et al., 2017; Zhou et al., 2017). The second one is more related to us, so we will focus on describing those approaches.

(Du et al., 2017) pioneered the work of automatic QG using an end-to-end trainable sequence to sequence neural model. Automatic and human evaluation results showed that their system outperformed the previous rule-based systems (Heilman and Smith, 2010; Rus et al., 2010). However, in their study, there was no control about which part of the passage the generated question was asking about.

Answer-aware sequence to sequence neural QG systems (Zhou et al., 2017; Subramanian et al., 2017; Yuan et al., 2017) encoded answer location information using an annotation vector corresponding to the answer word positions. (Zhou et al., 2017) utilized rich features of the passage including answer positions. (Subramanian et al., 2017) deployed a two-stage neural model that detects key phrases and subsequently generates questions conditioned on them. (Yuan et al., 2017) combined supervised and reinforcement learning in the training of their model using policy gradient techniques to maximize several rewards that measure question quality. Instead of using an annotation vector to tag the answer locations, (Song et al., 2017) proposed a unified framework for QG and question answering by encoding both the answer and the passage with a multi-perspective matching mechanism.

(Tang et al., 2017; Wang et al., 2017a) proposed joint models to address QG and question answering together. (Duan et al., 2017) conducted QG for improving question answering. Due to the mixed objectives including question answering, their approaches’ performance on QG were lower than the state-of-the-art results.

6 Conclusion and Future Work

In this paper, we proposed a new sequence to sequence network which contains a gated self-attention encoder and a maxout pointer decoder to address the answer-aware QG problem for long text input. We demonstrated the model can effectively utilize paragraph-level context, and outperformed the results with sentence-level context. The new model exceeded state-of-the-art approaches with either paragraph or sentence inputs.

We would like to discuss some potential challenges when applying the QG model in practice. 1) Answer spans aren't provided as input. One straight-forward method is to extract entities or noun phrases and use them as potential answer spans. A neural entity selection model can also be leveraged to extract good answer candidates to improve the precision as proposed in (Subramanian et al., 2017). 2) An input passage does not contain any eligible answers. In such case, we do not expect the model to output valid questions. We could remove questions with low generation probability, while a better approach could be running entity selection or quality detection model before question generation step to eliminate ineligible passages. 3) An answer could be shared by different questions. We could output multiple questions using beam search. However, beam search does not guarantee to output diversified candidates. We would need to explicitly model diversity among candidates during generation, for example, leveraging the approach described in (Li and Jurafsky, 2016).

Our future work lands in the following directions: incorporate rich features, such as POS and entity, in input passages; directly optimize sequence-level metrics with policy gradient; relax the constraint on answer to accept abstractive answers; jointly model question generation and question answering; ask multiple questions simultaneously with diverse perspectives.

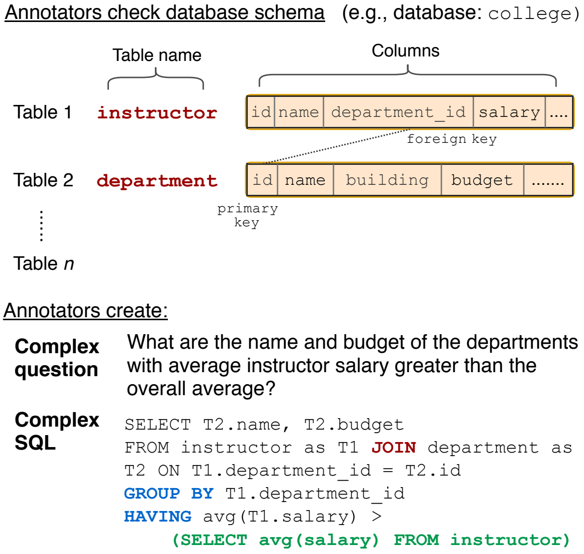
Abstract

We present *Spider*, a large-scale complex and cross-domain semantic parsing and text-to-SQL dataset annotated by 11 college students. It consists of 10,181 questions and 5,693 unique complex SQL queries on 200 databases with multiple tables covering 138 different domains. We define a new complex and cross-domain semantic parsing and text-to-SQL task so that different complicated SQL queries and databases appear in train and test sets. In this way, the task requires the model to generalize well to both new SQL queries and new database schemas. Therefore, Spider is distinct from most of the previous semantic parsing tasks because they all use a single database and have the exact same program in the train set and the test set. We experiment with various state-of-the-art models and the best model achieves only 9.7% exact matching accuracy on a database split setting. This shows that Spider presents a strong challenge for future research. Our dataset and task with the most recent updates are publicly available at `https://yale-lily.github.io/seq2sql/spider`.

1 Introduction

Semantic parsing (SP) is one of the most important tasks in natural language processing (NLP). It requires both understanding the meaning of natural language sentences and mapping them to meaningful executable queries such as logical forms, SQL queries, and Python code.

Recently, some state-of-the-art methods with Seq2Seq architectures are able to achieve over 80% exact matching accuracy even on some complex benchmarks such as ATIS and GeoQuery. These models seem to have already solved most problems in this field.



Complex question What are the name and budget of the departments with average instructor salary greater than the overall average?

Complex SQL

```
SELECT T2.name, T2.budget
FROM instructor as T1 JOIN department as
T2 ON T1.department_id = T2.id
GROUP BY T1.department_id
HAVING avg(T1.salary) >
    (SELECT avg(salary) FROM instructor)
```

Figure 1: Our corpus annotates complex questions and SQLs. The example contains joining of multiple tables, a `GROUP BY` component, and a nested query.

However, previous tasks in this field have a simple but problematic task definition because most of these results are predicted by semantic "matching" rather than semantic parsing. Existing datasets for SP have two shortcomings. First, those that have complex programs (Zelle and Mooney, 1996; Li and Jagadish, 2014; Yaghmazadeh et al., 2017a; Iyer et al., 2017) are too small in terms of number of programs for training modern data-intensive models and have only a single dataset, meaning that the same database is used for both training and testing the model. More importantly, the number of logic forms or SQL labels is small and each program has about 4-10 paraphrases of natural language problem to expand the size of the dataset. Therefore, the exact same target programs appear in both the train and test sets. The models can achieve decent performances even on very complex programs by memorizing the patterns of question and program pairs during training and decoding the programs exactly the same way as it saw in the training set during testing. Finegan-Dollak et al. (2018) split the dataset by programs

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3911–3921
Brussels, Belgium, October 31 - November 4, 2018. ©2018 Association for Computational Linguistics

so that no two identical program would be in both the train and test sets. They show that the models built on this question-splitting data setting fail to generalize to unseen programs. Second, existing datasets that are large in terms of the number of programs and databases such as WikiSQL (Zhong et al., 2017) contain only simple SQL queries and single tables. In order to test a model's real semantic parsing performance on unseen complex programs and its ability to generalize to new domains, an SP dataset that includes a large amount of complex programs and databases with multiple tables is a must.

However, compared to other large, realistic datasets such as ImageNet for object recognition (Deng et al., 2009) and SQuAD for reading comprehension (Rajpurkar et al., 2016), creating such SP dataset is even more time-consuming and challenging in some aspects due to the following reasons. First, it is hard to find many databases with multiple tables online. Second, given a database, annotators have to understand the complex database schema to create a set of questions such that their corresponding SQL queries cover all SQL patterns. Moreover, it is even more challenging to write different complex SQL queries. Additionally, reviewing and quality-checking of question and SQL pairs takes a significant amount of time. All of these processes require very specific knowledge in databases.

To address the need for a large and high-quality dataset for a new complex and cross-domain semantic parsing task, we introduce *Spider*, which consists of 200 databases with multiple tables, 10,181 questions, and 5,693 corresponding complex SQL queries, all written by 11 college students spending a total of 1,000 man-hours. As Figure 1 illustrates, given a database with multiple tables including foreign keys, our corpus creates and annotates complex questions and SQL queries including different SQL clauses such as joining and nested query. In order to generate the SQL query given the input question, models need to understand both the natural language question and relationships between tables and columns in the database schema.

In addition, we also propose a new task for text-to-SQL problem. Since Spider contains 200 databases with foreign keys, we can split the dataset with complex SQL queries in a way that no database overlaps in train and test, which overcomes the two shortcomings of prior datasets, and defines a new semantic parsing task in which the model needs to generalize not only to new programs but also to new databases. Models have to take questions and database schemas as inputs and predict unseen queries on new databases.

To assess the task difficulty, we experiment with several state-of-the-art semantic parsing models. All of them struggle on this task. The best model achieves only 9.7% exact matching accuracy in the database split setting. This suggests that there is a large room for improvement.

2 Related Work and Existing Datasets

Several semantic parsing datasets with different queries have been created. The output can be in many formats, e.g., logic forms. These datasets include ATIS (Price, 1990; Dahl et al., 1994), GeoQuery (Zelle and Mooney, 1996), and JOBS (Tang and Mooney, 2001a). They have been studied extensively (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Wong and Mooney, 2007; Das et al., 2010; Liang et al., 2011; Banarescu et al., 2013; Artzi and Zettlemoyer, 2013; Reddy et al., 2014; Berant and Liang, 2014; Dong and Lapata, 2016). However, they are domain specific and there is no standard label guidance for multiple SQL queries.

Recently, more semantic parsing datasets using SQL as programs have been created. Iyer et al. (2017) and Popescu et al. (2003a) labeled SQL queries for ATIS and GeoQuery datasets. Other existing text-to-SQL datasets also include Restaurants (Tang and Mooney, 2001b; Popescu et al., 2003a), Scholar (Iyer et al., 2017), Academic (Li and Jagadish, 2014), Yelp and IMDB (Yaghmazadeh et al., 2017b), Advising (Finegan-Dollak et al., 2018), and WikiSQL (Zhong et al., 2017). These datasets have been studied for decades in both the NLP community (Warren and Pereira, 1982; Popescu et al., 2003b, 2004; Li et al., 2006; Giordani and Moschitti, 2012; Wang et al., 2017; Iyer et al., 2017; Zhong et al., 2017; Xu et al., 2017; Yu et al., 2018; Huang et al., 2018; Wang et al., 2018; Dong and Lapata, 2018; McCann et al., 2018) and the Database community (Li and Jagadish, 2014; Yaghmazadeh et al., 2017b). We provide detailed statistics on these datasets in Table 1.

Most of the previous work train their models without schemas as inputs because they use a single database for both training and testing. Thus, they do not need to generalize to new domains. Most importantly, these datasets have a limited number of labeled logic forms or SQL queries. In order to expand the size of these datasets and apply neural network approaches, each logic form or SQL query has about 4-10 paraphrases for the natural language input. Most previous studies follow the standard question-based train and test split (Zettlemoyer and Collins, 2005). This way, the exact same target queries (with similar paraphrases) in the test appear in training set as well. Utilizing this assumption, existing models can achieve decent performances even on complex programs by memorizing database-specific SQL templates. However, this accuracy is artificially inflated because the model merely needs to decide which template to use during testing. Finegan-Dollak et al. (2018) show that template-based approaches can get even higher results. To avoid getting this inflated result, Finegan-Dollak et al. (2018) propose a new, program-based splitting evaluation, where the exact same queries do not appear in both training and testing. They show that under this framework, the performance of all the current state-of-the-art semantic parsing systems drops dramatically even on the same database, indicating that these models fail to generalize to unseen queries. This indicates that current studies in semantic parsing have limitations.

We also want the model to generalize not only to unseen queries but also to unseen databases. Zhong et al. (2017) published the WikiSQL dataset. In their problem definition, the databases in the test set do not appear in the train or development sets. Also, the task needs to take different table schemas as inputs. Therefore, the model has to generalize to new databases. However, in order to generate about 90,000 questions and SQL pairs for about 26,000 databases, Zhong et al. (2017) made simplified assumptions about the SQL queries and databases. Their SQL labels only cover single `SELECT` column and aggregation, and `WHERE` conditions. Moreover, all the databases only contain single tables. No `JOIN`, `GROUP BY`, and `ORDER BY`, etc. are included.

Recently, researchers have constructed some datasets for code generation including IFTTT (Quirk et al., 2015), DJANGO (Oda et al., 2015), HEARTHSTONE (Ling et al., 2016), NL2Bash (Lin et al., 2018), and CoNaLa (Yin et al., 2018).

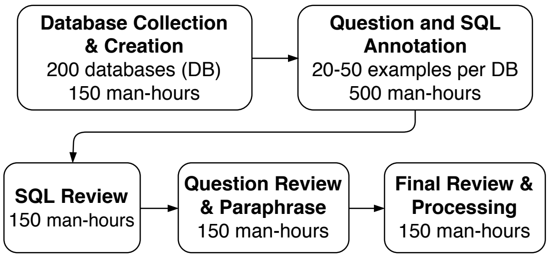


Figure 2: The annotation process of our Spider corpus.

These tasks parse natural language descriptions into a more general-purpose programming language such as Python (Allamanis et al., 2015; Ling et al., 2016; Rabinovich et al., 2017; Yin and Neubig, 2017).

3 Corpus Construction

All questions and SQL queries were written and reviewed by 11 computer science students who were native English speakers.As illustrated in Figure 2, we develop our dataset in five steps, spending around 1,000 hours of human labor in total: §3.1 Database Collection and Creation, §3.2 Question and SQL Annotation, §3.3 SQL Review, §3.4 Question Review and Paraphrase, §3.5 Final Question and SQL Review.

3.1 Database Collection and Creation

Collecting databases with complex schemas is hard. Although relational databases are widely used in industry and academia, most of them are not publicly available. Only a few databases with multiple tables are easily accessible online.

Our 200 databases covering 138 different domains are collected from three resources. First, we collected about 70 complex databases from different college database courses, SQL tutorial websites, online csv files, and textbook examples. Second, we collected about 40 databases from the DatabaseAnswers[1] where contains over 1,000 data models across different domains. These data models contain only database schemas. We converted them into SQLite, populated them using an online database population tool[2], and then manually corrected some important fields so that the table contents looked natural. Finally, we created the remaining 90 databases based on WikiSQL. To ensure the domain diversity, we select about 500 tables in about 90 different domains to create these 90 databases. To create each database,

---

[1] `http://www.databaseanswers.org/`

[2] `http://filldb.info/`

we chose several related tables from WikiSQL dev or test splits, and then created a relational database schema with foreign keys based on the tables we selected. We had to create some intersection tables in order to link several tables together. For most other cases, we did not need to populate these databases since tables in WikiSQL are from Wikipedia, which already had real world data stored.

We manually corrected some database schemas if they had some column names that did not make sense or missed some foreign keys. For table and column names, it is common to use abbreviations in databases. For example, 'student_id' might be represented by 'stu_id'. For our task definition, we manually changed each column name back to regular words so that the system only handled semantic parsing issues.

3.2 Question and SQL Annotation

For each database, we ask eight computer science students proficient in SQL to create 20-50 natural questions and their SQL labels. To make our questions diverse, natural, and reflective of how humans actually use databases, we did not use any template or script to generate question and SQL queries. Our annotation procedure ensures the following three aspects.

A) SQL pattern coverage. We ensure that our corpus contains enough examples for all common SQL patterns. For each database, we ask annotators to write SQL queries that cover all the following SQL components: `SELECT` with multiple columns and aggregations, `WHERE`, `GROUP BY`, `HAVING`, `ORDER BY`, `LIMIT`, `JOIN`, `INTERSECT`, `EXCEPT`, `UNION`, `NOT IN`, `OR`, `AND`, `EXISTS`, `LIKE` as well as nested queries. The annotators made sure that each table in the database appears in at least one query.

B) SQL consistency. Some questions have multiple acceptable SQL queries with the same result. However, giving totally different SQL labels to similar questions can hinder the training of semantic parsing models. To avoid this issue, we designed the annotation protocol so that all annotators choose the same SQL query pattern if multiple equivalent queries are possible. More detail is explained in our appendix.

C) Question clarity. We did not create questions that are (1) vague or too ambiguous, or (2) require knowledge outside the database to answer.

First, ambiguous questions refer to the questions that do not have enough clues to infer which columns to return and which conditions to consider. For example, we would not ask "What is the most popular class at University X?" because the definition of "popular" is not clear: it could mean the rating of the class or the number of students taking the course. Instead, we choose to ask "What is the name of the class which the largest number of students are taking at University X?". Here, "popular" refers to the size of student enrollment. Thus, the "student_enrollment" column can be used in condition to answer this question. We recognize that ambiguous questions appear in real-world natural language database interfaces.

We agree that future work needs to address this issue by having multi-turn interactions between the system and users for clarification. However, our main aim here is to develop a corpus to tackle the problem of handling complex queries and generalizing across databases, which no existing semantic parsing datasets could do. Moreover, the low performances of current state-of-the-art models already show that our task is challenging enough, without ambiguous questions. In addition, questions are required to contain the specific information to return. Otherwise, we don't know if class id is also acceptable in the previous case. Most of questions in the existing semantic parsing datasets are ambiguous. This is not a big problem if we use one single dataset because we have enough data domain specific examples to know which columns are default. However, it would be a serious problem in cross domain tasks since the default return values differ cross domain and people.

Second, humans sometimes ask questions that require common sense knowledge outside the given database. For instance, when people ask "Display the employee id for the employees who report to John", the correct SQL is

```
SELECT employee_id
FROM employees
WHERE manager_id = (
SELECT employee_id
FROM employees
WHERE first_name = 'John')
```

which requires the common knowledge that "X reports to Y" corresponds to an "employee-manager" relation. we do not include such questions and leave them as a future research direction.

Annotation tools We open each database on a web-based interface powered by the sqlite_web[3] tool. It allows the annotators to see the schema and content of each table, execute SQL queries, and check the returned results. This tool was extremely helpful for the annotators to write executable SQL queries that reflect the true meaning of the given questions and return correct answers.

3.3 SQL Review

Once the database is labeled with question-query pairs, we ask a different annotator to check if the questions are clear and contain enough information to answer the query. For a question with multiple possible SQL translations, the reviewers double check whether the SQL label is correctly chosen under our protocol. Finally, the reviewers check if all the SQL labels in the current database cover all the common SQL clauses.

3.4 Question Review and Paraphrase

After SQL labels are reviewed, native English speakers review and correct each question. They first check if the question is grammatically correct and natural. Next, they make sure that the question reflects the meaning of its corresponding SQL label. Finally, to improve the diversity in questions, we ask annotators to add a paraphrased version to some questions.

3.5 Final Review

Finally, we ask the most experienced annotator to conduct the final question and SQL review. This annotator makes the final decision if multiple reviewers are not sure about some annotation issues. Also, we run a script to execute and parse all SQL labels to make sure they are correct.

4 Dataset Statistics and Comparison

We summarize the statistics of Spider and other text-to-SQL datasets in Table 1. Compared with other datasets, Spider contains databases with multiple tables and contains SQL queries including many complex SQL components. For example, Spider contains about twice more nested queries and 10 times more `ORDER BY (LIMIT)` and `GROUP BY (HAVING)` components than the total of previous text-to-SQL datasets. Spider has 200 distinct databases covering 138 different domains such as college, club, TV show, government, etc. Most domains have one database, thus containing 20-50 questions, and a few domains such as flight information have multiple databases with more than 100 questions in total. On average, each database in Spider has 28 columns and 9 foreign keys. The average question length and SQL length are about 13 and 21 respectively. Our task uses different databases for training and testing, evaluating the cross-domain performance. Therefore, Spider is the *only one* text-to-SQL dataset that contains both databases with multiple tables in different domains and complex SQL queries It tests the ability of a system to generalize to not only new SQL queries and database schemas but also new domains.

5 Task Definition

On top of the proposed dataset, we define a text-to-SQL task that is more realistic than prior work. Unlike most of the previous semantic parsing or text-to-SQL tasks, models will be tested on *both different complex SQL queries and different complex databases in different domains* in our task. It aims to ensure that models can only make the correct prediction when they truly understand the semantic meaning of the questions, rather than just memorization. Also, because our databases contain different domains, our corpus tests model's ability to generalize to new databases. In this way, model performance on this task can reflect the real semantic parsing ability.

In order to make the task feasible and to focus on the more fundamental part of semantic parsing, we make the following assumptions:

- In our current task, we do not evaluate model performance on generating values. Predicting correct SQL structures and columns is more realistic and critical at this stage based on the low performances of various current state-of-the-art models on our task. In a real world situation, people need to double check what condition values are and finalize them after multiple times. It is unrealistic to predict condition values without interacting with users. In reality, most people know what values to ask but do not know the SQL logic. A more reasonable way is to ask users to use an interface searching the

Table 1: Comparisons of text-to-SQL datasets. **Spider** is the *only one* text-to-SQL dataset that contains both databases with multiple tables in different domains and complex SQL queries. It was designed to test the ability of a system to generalize to not only new SQL queries and database schemas but also new domains.

values, then ask more specific questions. Also, other previous work with value prediction uses one single database in both train and test which makes it possible to overfit. However, in our task, we have different databases of different domains in train and test.

- As mentioned in the previous sections, we exclude some queries that require outside knowledge such as common sense inference and math calculation. For example, imagine a table with birth and death year columns. To answer the questions like "How long is X's life length?", we use `SELECT death_year - birth_year`. Even though this example is easy for humans, it requires some common knowledge of the life length definition and the use of a math operation, which is not the focus of our dataset.

- We assume all table and column names in the database are clear and self-contained. For example, some databases use database specific short-cut names for table and column names such as "stu_id", which we manually converted to "student id" in our corpus.

6 Evaluation Metrics

Our evaluation metrics include Component Matching, Exact Matching, and Execution Accuracy. In addition, we measure the system's accuracy as a function of the difficulty of a query. Since our task definition does not predict value string, our evaluation metrics do not take value strings into account.

We will release the official evaluation script along with our corpus so that the research community can share the same evaluation platform.

Component Matching To conduct a detailed analysis of model performance, we measure the average exact match between the prediction and ground truth on different SQL components. For each of the following components:

- `SELECT`
- `WHERE`
- `GROUP BY`
- `ORDER BY`
- `KEYWORDS` (including all SQL keywords without column names and operators)

we decompose each component in the prediction and the ground truth as bags of several subcomponents, and check whether or not these two sets of components match exactly. To evaluate each `SELECT` component, for example, consider `SELECT avg(col1), max(col2), min(col1)`, we first parse and decompose into a set `(avg, min, col1), (max, col2)`, and see if the gold and predicted sets are the same. Previous work directly compared decoded SQL with gold SQL. However, some SQL components do not have order constraints. In our evaluation, we treat each component as a set so that for example, `SELECT avg(col1), min(col1), max(col2)` and `SELECT avg(col1), max(col2), min(col1)` would be treated as the same query. To report a model's overall performance on each component, we compute F1 score on exact set matching.

Exact Matching We measure whether the predicted query as a whole is equivalent to the gold query. We first evaluate on the SQL clauses as described in the last section. The predicted query is correct only if all of the components are correct. Because we conduct set comparison in each clause, this exact matching metric can handle the "ordering issue" (Xu et al., 2017).

Execution Accuracy[4] Since Exact Matching can create false negative evaluation when the semantic parser generates novel and correct syntax structures, we also consider Execution Accuracy. All our databases have executable SQLite files, so we can measure execution accuracy as well. However, it is also important to note that Execution Accuracy can create false positive evaluation as a predicted SQL could return the same result (for example, 'NULL') as the gold SQL when they are semantically different. So we can use both to complement each other.

Finally, our evaluation also considers multiple acceptable keys if `JOIN` and `GROUP` are in the query. For example, suppose "stu_id" in one table refers to "stu_id" in another table, `GROUP BY` either is acceptable.

SQL Hardness Criteria To better understand the model performance on different queries, we divide SQL queries into 4 levels: easy, medium, hard, extra hard. We define the difficulty based on the number of SQL components, selections, and conditions, so that queries that contain more SQL keywords (`GROUP BY`, `ORDER BY`, `INTERSECT`, nested subqueries, column selections and aggregators, etc) are considered to be harder. For example, a query is considered as hard if it includes more than two `SELECT` columns, more than two `WHERE` conditions, and `GROUP BY` two columns, or contains `EXCEPT` or nested queries. A SQL with more additions on top of that is considered as extra hard. Figure 3 shows examples of SQL queries in 4 hardness levels.

Easy

What is the number of cars with more than 4 cylinders?

```
SELECT COUNT(*)
FROM cars_data
WHERE cylinders > 4
```

Meidum

For each stadium, how many concerts are there?

```
SELECT T2.name, COUNT(*)
FROM concert AS T1 JOIN stadium AS T2
ON T1.stadium_id = T2.stadium_id
GROUP BY T1.stadium_id
```

Hard

Which countries in Europe have at least 3 car manufacturers?

```
SELECT T1.country_name
FROM countries AS T1 JOIN continents
AS T2 ON T1.continent = T2.cont_id
JOIN car_makers AS T3 ON
T1.country_id = T3.country
WHERE T2.continent = 'Europe'
GROUP BY T1.country_name
HAVING COUNT(*) >= 3
```

Extra Hard

What is the average life expectancy in the countries where English is not the official language?

```
SELECT AVG(life_expectancy)
FROM country
WHERE name NOT IN
    (SELECT T1.name
     FROM country AS T1 JOIN
     country_language AS T2
     ON T1.code = T2.country_code
     WHERE T2.language = "English"
       AND T2.is_official = "T")
```

Figure 3: SQL query examples in 4 hardness levels.

7 Methods

In order to analyze the difficulty and demonstrate the purpose of our corpus, we experiment with several state-of-the-art semantic parsing models. As our dataset is fundamentally different from the prior datasets such as Geoquery and WikiSQL, we adapted these models to our task as follows. We created a 'big' column list by concatenating columns in all tables of the database together as a input to all models. Also, for each model, we limit the column selection space for each question example to all column of the database which the question is asking instead of all column names in the whole corpus.

Seq2Seq Inspired by neural machine translation (Sutskever et al., 2014), we first apply a basic sequence-to-sequence model, **Seq2Seq**. Then, we also explore **Seq2Seq+Attention** from (Dong and Lapata, 2016) by adding an attention mechanism (Bahdanau et al., 2015). In addition, we include **Seq2Seq+Copying** by adding an attention-based copying operation similar to (Jia and Liang, 2016).

The original model does not take the schema into account because it has the same schema in both train and test. We modify the model so that it

---

[4] We will provide the results in the later version. Please check our website for the latest updates on the task at https://yale-lily.github.io/seq2sql/spider

Method	Easy	Medium	Hard	Extra Hard	All
Example Split

Table 3: F1 scores of Component Matching on all SQL queries.

considers the table schema information by passing a vocabulary mask that limits the model to decode the words from SQL key words, table and column names in current database.

(Iyer et al., 2017) Iyer et al. (2017) apply an attention based sequence-to-sequence model similar to (Luong et al., 2015) to SQL datasets with automatic dataset expansion through paraphrasing and SQL templates. In addition, they show how user interactions improve results consistently. In our case, we did not consider the user interaction part.

SQLNet introduced by (Xu et al., 2017) uses column attention and employs a sketch-based method and generates SQL as a slot-filling task. This fundamentally avoids the sequence-to-sequence structure when ordering does not matter in SQL query conditions. Because it is originally designed for WikiSQL, we also extend its `SELECT` and `WHERE` modules to other components.

TypeSQL is the state-of-the-art model on the WikiSQL task (Yu et al., 2018). It improves upon SQLNet by proposing a different training procedure and utilizing types extracted from either knowledge graph or table content to help model better understand entities and numbers in the question. In our experiment, we use the question type info extracted from database content. Also, we extend their modules to other components.

8 Experimental Results and Discussion

We summarize the performance of all models on our test set including accuracy of exact matching in Table 2 and F1 scores of component matching in Table 3. For the final training dataset, we also select and include 752 queries and 1659 questions that follow our annotation protocol from six existing datasets: Restaurants, GeoQuery, Scholar, Academic, IMDB, and Yelp. We report results on two different settings for all models: (1) Example split where examples are randomly split into 7862 train, 1831 dev, 2147 test. Questions for the same database can appear in both train and test. (2) Database split where 206 databases are randomly split into 130 train, 36 dev, and 40 test. All questions for the same database are in the same split.

Overall Performance The performances of the Seq2Seq-based models including Seq2Seq, Seq2Seq+Attention, Seq2Seq+Copying, and Iyer et al. (2017) are very low. However, they are able to generate nested and complex queries. Thus, they can get a few hard and extra hard examples correct. But in the vast majority of cases, they predict invalid SQL queries with grammatical errors. The attention and copying mechanisms do not help much either. In contrast, SQLNet and TypeSQL that utilize SQL structure information to guide the SQL generation process significantly outperform other Seq2Seq model. While they can produce valid queries, however, they are unable to generate nested queries or queries with keywords such as `EXCEPT` and `INTERSECT`.

In general, the overall performances of all models are low, indicating that our task is challenging and there is still a large room for improvement.

Example Split vs Database Split As discussed in Section 5, another challenge of the dataset is to generalize to new databases. To study this, in Table 2 and Table 3 we compare model performances under the two settings. For all models, the performance under database split is much lower than that under example split. In addition, we observe that all models perform poorly on column selection. This shows that our dataset presents a challenge for the model to generalize to new databases.

Complexity of Database Schema In order to show how the complexity of the database schema affects model performance, Figure 4 plots the exact matching accuracy as a function of the number of foreign keys in a database. The performance decreases as the database has more foreign keys. The first reason is because the model has to choose column and table names from many candidates in a complex database schema. Second, a complex database schema presents a great challenge for the model to capture the relationship between different tables with foreign keys. It indicates that this task requires more effective methods to encode the relation of tables with foreign keys.

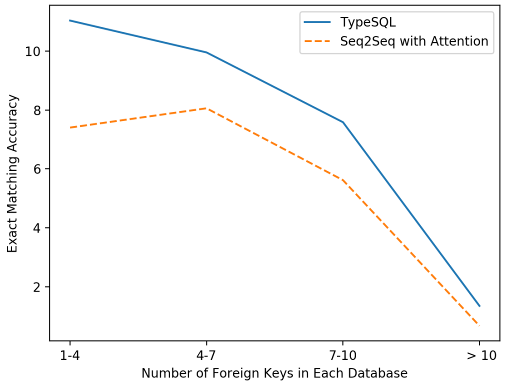

Figure 4: Exact matching accuracy as a function of the number of foreign keys.

9 Conclusion

In this paper we introduce Spider, a large, complex and cross-domain semantic parsing and text-to-SQL dataset, which directly benefits both NLP and DB communities. Based on Spider, we define a new challenging and realistic semantic parsing task. Experimental results on several state-of-the-art models on this task suggests plenty space of improvement.

Unsupervised Natural Language Generation with Denoising Autoencoders

Markus Freitag and **Scott Roy**
Google AI
`{freitag,hsr}@google.com`

Abstract

Generating text from structured data is important for various tasks such as question answering and dialog systems. We show that in at least one domain, without any supervision and only based on unlabeled text, we are able to build a Natural Language Generation (NLG) system with higher performance than supervised approaches. In our approach, we interpret the structured data as a corrupt representation of the desired output and use a denoising auto-encoder to reconstruct the sentence. We show how to introduce noise into training examples that do not contain structured data, and that the resulting denoising auto-encoder generalizes to generate correct sentences when given structured data.

1 Introduction

Natural Language Generation (NLG) is the task of generating text from structured data. Recent success in Deep Learning motivated researchers to use neural networks instead of human designed rules and templates to generate meaningful sentences from structured information. However, these supervised models work well only when provided either massive amounts of labeled data or when restricted to a limited domain. Unfortunately, labeled examples are costly to obtain and are non-existent for many domains. Conversely, large amount of unlabeled data are often freely available in many languages.

A labeled example is given in Table 1. One labeled example consists of a set of slot pairs and at least one golden target sequence. Each slot pair has a slot name (e.g. ”name”) and a slot value (e.g. ”Loch Fyne”). In this work, we present an unsupervised NLG approach that learns its parameters without the slot pairs on target sequences only. We use the approach of a denoising auto-encoder (DAE) (Vincent et al., 2008) to train our model. During training, we use corrupt versions of each target sequence as input and learn to reconstruct the correct sequence using a sequence-to-sequence network (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015). We show how to introduce noise into the training data in such a way that the resulting DAE is capable of generating sentences out of a set of slot pairs. Taking advantage of using unlabeled data only, we also incorporate out-of-domain data into the training process to improve the quality of the generated text.

name	type	food	family friendly
Loch Fyne	restaurant	Indian	yes

Table 1: Three possible correct target sequences for the structured data above: (a) There is an Indian restaurant that is kids friendly. It is Loch Fyne. (b) Loch Fyne is a well-received restaurant with a wide range of delicious Indian food. It also delivers a fantastic service to young children. (c) Loch Fyne is a family friendly restaurant providing Indian food.

2 Network

In all our experiments, we use our in-house attention-based sequence-to-sequence (seq2seq) implementation which is similar to Bahdanau et al. (2015). The approach is based on an encoder-decoder network. The encoder employs a bi-directional RNN to encode the input words $\mathbf{x} = (x_1, ..., x_l)$ into a sequence of hidden states $\mathbf{h} = (h_1, ..., h_l)$, where l is the length of the input sequence. Each h_i is a concatenation of a left-to-right $\overrightarrow{h_i}$ and a right-to-left $\overleftarrow{h_i}$ RNN:

$$h_i = \begin{bmatrix} \overleftarrow{h}_i \\ \overrightarrow{h}_i \end{bmatrix} = \begin{bmatrix} \overleftarrow{f}(x_i, \overleftarrow{h}_{i+1}) \\ \overrightarrow{f}(x_i, \overrightarrow{h}_{i-1}) \end{bmatrix}$$

where $\overleftarrow{f}$ and $\overrightarrow{f}$ are two gated recurrent units (GRU) proposed by Cho et al. (2014).

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3922–3929
Brussels, Belgium, October 31 - November 4, 2018.

Given the encoded $\mathbf{h}$, the decoder predicts the target sentence by maximizing the conditional log-probability of the correct output $\mathbf{y}^* = (y_1^*, ...y_m^*)$, where m is the length of the target. At each time t, the probability of each word y_t from a target vocabulary V_y is:

$$p(y_t|\mathbf{h}, y_{t-1}^*..y_1^*) = g(s_t, y_{t-1}^*, H_t), \qquad (1)$$

where g is a two layer feed-forward neural network over the embedding of the previous target word y_{t-1}^*, the hidden state s_t, and the weighted sum of $\mathbf{h}$ (H_t).

Before we compute s_t and H_t, we first covert s_{t-1} and the embedding of y_{t-1}^* into an intermediate state s_t' with a GRU u as:

$$s_t' = u(s_{t-1}, y_{t-1}^*). \qquad (2)$$

Then we have s_t as:

$$s_t = q(s_t', H_t) \qquad (3)$$

where q is a GRU, and the H_t is computed as:

$$H_t = \begin{bmatrix} \sum_{i=1}^{l} (\alpha_{t,i} \cdot \overleftarrow{h}_i) \\ \sum_{i=1}^{l} (\alpha_{t,i} \cdot \overrightarrow{h}_i) \end{bmatrix}, \qquad (4)$$

The attention weights, α in H_t, are computed with a two layer feed-forward neural network r:

$$\alpha_{t,i} = \frac{\exp\{r(s_t', h_i)\}}{\sum_{j=1}^{l} \exp\{r(s_t', h_j)\}} \qquad (5)$$

3 Unsupervised Approach

Our unsupervised model is based on the same training idea as a denoising auto-encoder (DAE) similar to Vincent et al. (2008). The original DAEs were feedforward nets applied to (image) data. In our experiments, the model architecture is a seq2seq model similar to Bahdanau et al. (2015). The idea of a DAE is to train a model that is able to reconstruct each training example from a partially destroyed input. This is done by first corrupting each training sequence x_i to get a partially destroyed version $\tilde{x_i}$.

In our unsupervised experiments, we generate the training data with the following corrupting process, parameterized by the desired percentage p of deletion: for each target sequence x_i, a fixed percentage p of words are removed at random, while the others are left untouched. We sample a new corrupt version $\tilde{x_i}$ in each training epoch. Instead of always removing a fixed percentage of words, we sample p for each sequence separately from a Gaussian distribution with mean $p = 0.6$ and variance 0.1. We chose $p = 0.6$ based on the average length ratio between the slot values and the target sequences in our labeled training data.

This corruption approach is motivated by the fact that many NLG problems are facing a similar task to the one the DAE is solving. Given some structured information, the task is to generate a target sequence that includes all the information. If we map the structured information to phrases that should be in the desired output, then the structured data problem resembles the DAE problem. For instance, if we have the following structured example: *name: Aromi - family friendly: yes → Aromi has a family friendly atmosphere.* , we convert it into the input *Aromi family friendly* that we can feed to the DAE. To preprocess the structured data, we convert the boolean feature *family friendly* into a meaningful phrase (”family friendly”) by using the slot name. For all non boolean slot pairs, we just use the slot values as meaningful phrases. Please keep in mind this transformation is only needed during inference as the training data has no slot pairs and only consists of pairs of corrupt and correct target sequences.

Nevertheless, there are two major differences between the training procedure of a DAE and an inference instance in NLG: First, we do not need to predict any content information in NLG as all of the content information is already provided by the structured data. On the other hand, a DAE training instance can also remove content words from the sentence. To align the two much closer, we restrict the words which the DAE is allowed to remove and apply the following heuristic to the corruption process of the DAE: Given the absolute counts $N(v_i)$ for each word v_i in our vocabulary, we only allow v_i to be removed when its count $N(v_i)$ is larger than a threshold. This heuristic is motivated by the fact that the corpus frequency of content words like a restaurant name is most likely low and the corpus frequency of non-content words like ”the” is most likely high. The corpus frequencies can be either calculated on the training data itself or on a different corpora. The latter one has the advantage that domain specific content words that are frequent in the training data will have a low frequency in an out-of-domain corpora.

The second difference is that in a DAE training

	original	Loch Fyne is a family friendly restaurant providing Indian food .
(a)	remove random 60%	Fyne is restaurant food .
(b)	remove only words w_i with $N(w_i) > 100$	Loch Fyne family friendly Indian
(c)	shuffle words	family friendly Indian Loch Fyne

Table 2: Training data generation heuristics. (a): random 60% of the words are removed. (b): 60% of the words are removed, but only words that occur more than 100 times in the training data. Our assumption is that these are the non-content words. (c): On top of (b), all words are shuffled while keeping all word pairs (e.g. Loch Fyne) together that also occur in the original sentence.

instance, the words in a corrupt input occur in the same order as in the desired target. For an NLG inference instance, the order of the structured input does not need to match the order of the words in the output. To overcome this issue, we shuffle the words within the corrupt sentence while not splitting bigrams that also exist in the original sentence. An example of all three heuristics is given In Table 2.

4 Supervised Approach

For comparison, we train a supervised baseline based on the vanilla seq2seq model as described in Section 2. To make better use of the structured data, we found that the input word embeddings (wemb) of the seq2seq network should be represented together by the slot name and value. We split the word embedding vector into two parts and use the upper half for a word embedding of the slot name and the lower half for the word embedding of the slot value. If a slot value has multiple words, we build separate word embeddings for each word, but all having the same upper part (slot name). An example for the slot pairs of Table 1 is given in Figure 1.

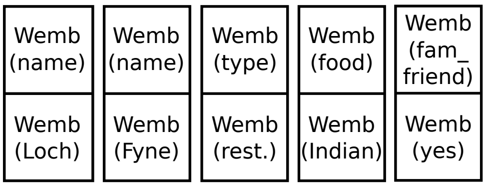

Figure 1: Example input word embeddings for our supervised baseline (Section 4) from the training Example of Table 1. The upper half of the word embedding is used for the slot names; the lower half for the slot values.

5 Data Sets

The **E2E data set** (Novikova et al., 2017) contains reviews in the restaurant domain. Given up to 8 different pieces of information about a restaurant, the task is to generate an English sentence that includes all of the provided structured information. The dataset comes with 42061 training examples. We split the provided dev set (547 examples) into validation (tail 268 examples) and test (head 279 examples), each having between 3 and 42 (on average 8) reference sentences. An example of an E2E training instance is given in Table 1.

The **news-commentary** data set is a parallel corpus of news provided by the WMT conference (Bojar et al., 2017) for training machine translation (MT) systems. For our unsupervised experiments, we use the English **news-commentary** part of the corpora only which contains 256,715 sentences.

All corpora are tokenized and we remove sentences that are longer than 60 tokens. In addition to tokenization, we also apply byte-pair encoding (Sennrich et al., 2016) when **news-commentary** is included in the setup.

dataset	task	# examples
E2E	NLG	42,061
news-commentary	MT (De-En)	256,715

Table 3: Training data statistics. Each training instance in NLG contains structured information and one reference sequence. Each training instance in MT contains one sentence written in both German and English.

6 Experiments

6.1 Model Parameters

For all of our experiments we utilize the seq2seq implementation as described in Section 2. We run inference with a beam size of 5. We use a hidden layer size of 1024 and a word embedding size of 620 and use SGD with an initial learning rate of 0.5. We halve the learning rate every other epoch starting from the 5th epoch. We evaluate the generated text with BLEU (Papineni et al., 2002), ROUGE-L (Lin, 2004), and NIST (Doddington, 2002) and use the evaluation tool provided by the E2E organizers to calculate the scores.

6.2 Automatic Scores

Our experimental results are summarized in Table 4. We list two supervised baselines: The first one is from the organizers of the E2E challenge, the second one is from our supervised setup (Section 4). Our baseline yields better performance on BLEU and ROUGE-L while reaching similar performance in NIST. Our third (unsupervised) *baseline copy input* just runs the evaluation metrics on the input (slot values of the structured data). This system performs much worse, but serves as a lower bound for our unsupervised experiments.

We report results on different unsupervised setups as described in Section 3. The system *randomly drop* just randomly drops 60% of the words, but still yields 57.3 BLEU, 65.9 ROUGE-L and 7.3 NIST points. You can easily detect a lot of extra information in the output that can not be explained by the structured input. Further, the output sounds very machine generated as the output depends on the order of the structured data. The heuristics + *only words w/ count >100 (on ind data)* and + *only words w/ count >100 (on ood data)* forbid removing words in the corruption phase that appear less than 100 times in the in-domain data or out-of-domain (ood) data, respectively. The latter setup uses the out-of-domain data for generating the word counts only and yields an improvement of 5.2 BLEU, 1.3 ROUGE-L and 0.2 NIST points compared to just randomly dropping words. The output still sounds very machine generated, but stops hallucinating additional information. We further improve the performance by 3.5 BLEU, 3.9 ROUGE-L, and 0.2 NIST points when shuffling the words in the corrupted input and using the out-of-domain data also as training examples. We use the English side of the 256,715 sentences from the news-commentary dataset as out-of-domain data only. We did not see any further improvements by adding more out-of-domain training data.

Finally, we build a semi supervised system that in addition to the unlabeled data includes the labeled information for some of the training examples. For these, we remove the slot names from the structured data and use a concatenation of all slot values as input to learn the correct output. By jointly using both unlabeled and labeled data, we yield an additional improvement of 1.0 BLEU points compared to our best fully unsupervised system. In our semi supervised setup, we only use the slot values as input even for the labeled examples. This explains the drop in performance when comparing to the supervised setups. All supervised setups also include the slot names in their input representation.

6.3 Human Evaluation

In addition to automatic scores, we ran human assessment of the generated text as none of the automatic metrics correlates well with human judgment (Belz and Reiter, 2006).

To collect human rankings, we presented 3 outputs generated by 3 different systems side-by-side to crowd-workers, who were asked to score each sentence on a 6-point scale for:

- **fluency**: How do you judge the overall naturalness of the utterance in terms of its grammatical correctness and fluency?

For the next questions, we presented in addition to the 3 different system outputs, the structured representations of each example. We asked the crowd-worker to score the following two questions on a 5-point scale:

- **all information**: How much of the given information is mentioned in the text?
- **bad/ false information**: How much false or extra information is mentioned in the text?

Each task has been given to three different raters. Consequently, each output has a separate score for each question that is the average of 3 different ratings. The human evaluation results are summarized in Table 5. We included the two supervised baselines and our best unsupervised setup in the human evaluation. The unsupervised setup outperforms the supervised setups in fluency. One explanation is that our unsupervised system includes additional unlabeled data that can not be included in a supervised setup. Due to our unsupervised learning approach that all words in the structured data need to be included in the final output, the unsupervised system did not miss any information. Further, all three outputs included little false or wrong information that was not included in the structured data. All in all the output of the

setup	model	BLEU	ROUGE-L	NIST
supervised	baseline E2E challenge (Dušek and Jurcıcek, 2016)	70.2	72.4	8.3
	baseline vanilla seq2seq (Section 4)	72.7	75.1	8.3
unsupervised	baseline copy input	27.7	56.4	3.2
	randomly drop	57.3	65.9	7.3
	+ only words w/ count $>$100 (on ind data)	59.5	66.4	7.3
	+ only words w/ count $>$100 (on ood data)	62.5	67.2	7.5
	+ shuffle pos	64.8	69.4	7.6
	+ ood data	66.0	71.1	7.7
semi-supervised	+ labeled ind data	67.0	72.1	7.8

Table 4: Results on the E2E dataset. The terms ood and ind are abbreviations for out-of-domain and in-domain respectively. The baseline systems as well as the unsupervised systems that are not labeled with + *ood data* are trained on the E2E in-domain training data only.

system	fluency	all information	extra/ false information
baseline E2E challenge (Dušek and Jurcıcek, 2016)	4.01	4.89	0.05
baseline vanilla seq2seq (Section 4)	4.46	4.91	0.08
unsupervised (random drop + words w/ count $>$100 (ood data) + shuffle pos + ood data)	4.70†	5.00†	0.05

Table 5: Human evaluation results: We generated 279 output sequences for each of the 3 listed systems. Each sequence has been evaluated by 3 different raters and the score is the average of 837 ratings per system. For each task and sequence, the raters where asked to give a score between 0 and 5. A score of 5 for *fluency* means that the text is fluent and grammatical correct. A score of 5 for *all information* means that all information from the structured data is mentioned. A score of 0 for *extra/ false information* means that no information besides the structured data is mentioned in the sequence. Scores labeled with † are significant better than all other systems ($p < 0.0001$).

unsupervised system is better than the two supervised systems.

We used approximate randomization (AR) as our significance test, as recommended by (Riezler and Maxwell, 2005). Pairwise tests between results in Table 5 showed that our novel unsupervised approach is significantly better than both baselines regarding fluency and mentioning all information with the likelihood of incorrectly rejecting the null hypothesis of $p < 0.0001$.

7 Limitations

Our unsupervised approach has two limitations and is therefore not easily applicable to all NLG problems or datasets. First, we can only run our approach for datasets where the input meaning representation either overlaps with target texts or we need to generate rules that map the structured data to target words. Unfortunately, the needed pattern can be very complicated and the effort of writing rules can be similar to the one of building a template based system.

Second, to be able to generate text from structured data during inference, the original structured input is converted to an unstructured one by discarding the slot names. This can be problematic in scenarios where the slot name itself contributes to the meaning representation, but the slot name should not be in the target text. For instances the structured data of a WEBNLG (Gardent et al., 2017) training example consists of several subject-predicate-object tuple features. Many of the features for one example have the same subject, but different predicates and objects. But yet in the final output, we prefer to have the subject only once.

8 Related Work

8.1 Neural Language Generation

Due to the recent success in Deep Learning, researchers started to use end-to-end systems to jointly model the traditional separated tasks of content selection, sentence planning and surface realization in one system. Recently, RNNs (Wen et al., 2015b), attention-based methods (Mei et al.,

2016) or LSTMs (Wen et al., 2015a) were successfully applied for the task of NLG. Liu et al. (2018) introduced a modified LSTM that adds a field gate into the LSTM to incorporate the structured data. Further, they used a dual attention mechanism that combines attention of both the slot names and the actual slot content. Sha et al. (2017) extended this approach and integrated a linked matrix in their model that learns the desired order of the slots in the target text. Further, Dušek and Jurcıcek (2016) reranked the n-best output from a seq2seq model to penalize sentences that miss required information or add irrelevant ones. Instead of RNNs, Lebret et al. (2016) introduced a neural feed-forward language model conditioned on both the full structured data and the structured information of the previous generated words. In addition, the authors introduced a copy mechanism for boosting the words given by the structured data.

In contrast to the above mentioned related work, we train our model in a fully unsupervised fashion. Although, all our experiments have been conducted with the seq2seq model, our unsupervised approach can be applied on top of all of the different network architectures that are introduced by the above mentioned papers.

8.2 DAE and Unsupervised Learning

Denoising auto-encoders and unsupervised training have been applied to various other NLP tasks. Vincent et al. (2008) introduced denoising one-layer auto-encoders that are optimized to reconstruct input data from random corruption. The outputs of the intermediate layers of these denoisers are then used as input features for subsequent learning tasks such as supervised classification (Lee et al., 2009; Glorot et al., 2011). They showed that transforming data into DAE representations (as a pre-training or initialization step) gives more robust (supervised) classification performance. Lample et al. (2018) used a denoising auto-encoder to build an unsupervised Machine Translation model. Hill et al. (2016) trained a denoising auto-encoder on a seq2seq network architecture for training sentence and paragraph representations from the output of the intermediate layers. They showed that using noise in the encoder step is helpful to learn a better sentence representation.

In contrast to the above mentioned related work, we train a DAE directly on a task and do not take the intermediate hidden states of a DAE as sentence representation to help learning a different task. Further, none of the related work applied DAEs on the task of generating sentences out of structured data. In addition, we modify the original DAE corruption process by introducing heuristics that remove non-content words only to match the input representation of a supervised NLG training instance.

9 Conclusion

We showed how to train a denoising auto-encoder that is able to generate correct English sentences from structured data. By applying several heuristics to the corruption phase of the auto-encoder, we reach better performance compared to two fully supervised systems. As no labeled data is needed in our approach, we further successfully improve the quality by incorporating out-of-domain data into the training phase. We run a human evaluation for the two supervised baselines and our best unsupervised setup. We see that the output of our unsupervised setup not only includes 100% of the structured information, but also outperforms both supervised baselines in terms of fluency and grammatical correctness.

The unsupervised training scheme gives us the option to incorporate any unlabeled data. One possible addition to our approach would be to incorporate text in different languages into our system, so that we can generate the output in any language from the same structured data.

Our approach is appropriate only for NLG problems where the goal is to include all the information from the structured data in the output. In future work, we will focus on the semi-supervised approach to make the DAE also suitable for problems where instead of all, only a subset of the structured information should be included in the output.

Abstract

In this paper, we focus on the problem of question generation (QG). Recent neural network-based approaches employ the sequence-to-sequence model which takes an answer and its context as input and generates a relevant question as output. However, we observe two major issues with these approaches: (1) The generated interrogative words (or question words) do not match the answer type. (2) The model copies the context words that are far from and irrelevant to the answer, instead of the words that are close and relevant to the answer. To address these two issues, we propose an answer-focused and position-aware neural question generation model. (1) By answer-focused, we mean that we explicitly model question word generation by incorporating the answer embedding, which can help generate an interrogative word matching the answer type. (2) By position-aware, we mean that we model the relative distance between the context words and the answer. Hence the model can be aware of the position of the context words when copying them to generate a question. We conduct extensive experiments to examine the effectiveness of our model. The experimental results show that our model significantly improves the baseline and outperforms the state-of-the-art system.

1 Introduction

The task of question generation (QG) aims to generate questions for a given text, and it can benefit several real applications: (1) In the area of education, QG can help generate questions for reading comprehension materials (Du et al., 2017). (2) QG can enable the machine to actively ask questions in a dialogue system. (3) QG can also aid in the development of question answering datasets (Duan et al., 2017). Typically, QG includes two subtasks: (1) what to say, i.e. determining the targets (e.g. sentences, phrases or words) that should be asked; (2) how to say, i.e. producing the surface-form of the question. In this paper, we focus on the sub-task of surface-form realization of questions by assuming the targets are given.

Previous work of QG can be classified into two categories: rule-based and neural network-based. Compared to the rule-based approach, the neural network-based approach does not rely on hand-crafted rules, and it is instead data-driven and trainable in an end-to-end fashion. The recent release of large-scale machine reading comprehension datasets, e.g. SQuAD (Rajpurkar et al., 2016) and MARCO (Nguyen et al., 2016), also drives the development of neural question generation.

Recent neural question generation approaches (Du et al., 2017; Zhou et al., 2017) employ sequence-to-sequence model that takes an answer and its context as input and outputs a relevant question. Zhou et al. (2017) further enrich the sequence-to-sequence model with rich features (e.g. answer position and lexical features) to generate answer focused questions, and incorporate copy mechanism that allows to copy words from the context when generating questions. To the best of our knowledge, it achieve the best results on SQuAD dataset so far (Zhou et al., 2017). In this paper, we implement this approach and carefully study its generation results. Specifically, we randomly sample 130 questions generated by the approach, and manually judge their quality by comparing them with the references. We find 54 out of 130 questions are ill generated, and we observe two major issues with the 54 questions: (1) 20 (37.04% errors) questions contain the question words that do not match the answer type, though the answer position feature has been incorporated. Because the model does not pay much attention to the answer that is a key to question word generation. Table 1 gives an example. A when-question

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3930–3939
Brussels, Belgium, October 31 - November 4, 2018.

Context: The tax collector who arrested him rose to higher political office , and Thoreau 's essay was not published until after **the end of the Mexican War**.
Answer: the end of the Mexican War
Question generated by the baseline: **Why** was Thoreau's essay published ?
Reference: **When** was Thoreau's essay published ?

Table 1: A bad case where the generated question word does not match the answer type. A when-question should be triggered for answer "the end of the Mexican War", while a why-question is generated by the baseline.

Context: This mechanism is still the **leading theory** today; however, a **second theory** suggests that most cpdna is actually linear and replicates through **homologous recombination**.
Answer: homologous recombination
Question generated by the baseline: What is the **leading theory** today ?
Reference: How does the **second theory** say most cpdna replicates ?

Table 2: A bad case where the model copies the context words far away from and irrelevant to the answer. The baseline copies "leading theory" that is far away from and unrelated to the answer "homologous recombination", but neglects the phrase "second theory" that is close and relevant to the answer.

should be triggered for answer "the end of the Mexican War" while a why-question is generated by the model. (2) 11 (20.37% errors) questions copies the context words that are far from and irrelevant to the answer, instead of the words that are close and relevant to the answer. Because the model is not aware of the positions of context words. Table 2 gives an example. The baseline model copies "leading theory" that is far away from and unrelated to the answer "homologous recombination", but neglects the phrase "second theory" that is close and relevant to the answer.

To address these two issues, we propose an answer-focused and position-aware neural question generation model. (1) By answer-focused, we mean that we explicitly model question word generation by incorporating the answer embedding, which can help generate a question word matching the answer type. (2) By position-aware, we mean that we model the relative distance between the context words and the answer. The relative distance is encoded as position embedding, on which a position-aware attention is generated. The position-aware attention help the model copy the context words that are relatively close and relevant to the answer. We further conduct extensive experiments on SQuAD and MARCO dataset to examine the effectiveness of the answer-focused model and position-aware model, respectively. The experimental results show that the combination of our proposed answer-focused model and position-aware model significantly improves the baseline and outperforms the state-of-the-art system.

The contributions of this paper can be summarized as follows:

- We analyze the generation results by the state-of-the-art neural model, and find two major issues with the model: (a) the generated question words do not match the answer type; (b) the model copies the context words that are far from and irrelevant to the answer.
- To deal with these two issues, we propose an answer-focused and position-aware neural question generation model.
- We conduct extensive experiments to examine the effectiveness of our proposed model.

2 Related Work

Question Generation Previous work of QG can be classified into two categories: rule-based and neural network-based. Regardless of the approach taken, QG usually includes two sub-tasks: (1) what to say, i.e. selecting the targets that should be asked. (2) how to say, i.e. formulating the structure of the question and producing the surface realization. This is similar to other natural language generation tasks. In this paper, we focus on the second sub-task, i.e. surface-form realization of questions by assuming the targets are given.

The rule-based approaches usually include the following steps: (1) Preprocess the given text by applying natural language processing techniques, including syntactic parsing, sentence simplification and semantic role labeling. (2) Identify the targets that should be asked by using rules or semantic roles. (3) Generate questions using transformation rules or templates. (4) Rank the over generated questions by well-designed features (Heilman and Smith, 2009, 2010; Chali and Hasan, 2015). The major drawbacks of rule-based approaches include: (1) they rely on rules or templates that are expensive to manually create; (2) the rules or templates lack diversity; (3) the targets that they can deal with are limited.

To tackle the issues of rule-based approaches, the neural network-based approaches are applied to the task of QG. The neural network-based approaches do not rely on hand-crafted rules, and they are instead data driven and trainable in an end-to-end fashion. Serban et al. (2016) firstly introduce an encoder-decoder framework with attention mechanism to generate factoid questions for the facts (i.e. each fact is a triple composed of a subject, a predicate and an object) from FreeBase. Du et al. (2017) introduce sequence-to-sequence model with attention mechanism to generate questions for the text from SQuAD dataset, which contains large-scale manually annotated triples composed of question, answer and the context (i.e. the passage). Zhou et al. (2017) enrich the sequence-to-sequence model with rich features, e.g. answer position and lexical features, and incorporate copy mechanism that allows it to copy words from the context when generating a question. Their experiments show the effectiveness of the rich features and the copy mechanism. Duan et al. (2017) propose to combine templates and sequence-to-sequence model. Specifically, they mine question patterns from a question answering community and apply sequence-to-sequence to generate question patterns for a given text. Tang et al. (2017) model question answering and question generation as dual tasks. It helps generate better questions when training these two tasks together.

In this paper, we observe two major issues with the exiting neural models: (1) The generated question words do not match the answer type, since the models do not pay much attention to the answers that are critical to generate question words. (2) The model copies the context words that are far from and irrelevant to the answer, instead of the words that are close and relevant to the answer, since the models are not aware the positions of the context words. To address these two issues, we propose an answer-focused and position-aware neural question generation model. As to position-aware models, Zeng et al. (2014); Zhang et al. (2017) introduce position feature in the task of relation extraction. They apply this feature to encode the relative distance to the target noun pairs. In the task of QG, Zhou et al. (2017) apply BIO scheme to label answer position, which is a weak representation of relative distance between answer and its context words.

Sequence-to-sequence In recent years, the sequence-to-sequence model has been widely used in the area of natural language generation, including the tasks of abstractive text summarization, response generation in dialogue, poetry generation, etc. Sutskever et al. (2014) propose a sequence-to-sequence model and apply it to the task of machine translation. Bahdanau et al. (2014) introduce attention mechanism to the sequence-to-sequence model and it greatly improves the model performance on the task of machine translation. To deal with the out of vocabulary issue, several variants of the sequence-to-sequence model have been proposed to copy words from source text (Gu et al., 2016; Gulcehre et al., 2016; Cao et al., 2017; See et al., 2017).

3 Our Models

In this section, we describe the details of our models. We first describe the baseline model, a feature-enriched pointer-generator model. Then, we elaborate the proposed answer-focused model and position-aware model to deal with the two issues discussed in previous section. Finally, a hybrid model is introduced to combine these two models.

3.1 Baseline (Feature-enriched Pointer-generator Model)

Our baseline model is an attention-based pointer-generator model (See et al., 2017) enhanced with various rich features proposed by (Zhou et al., 2017). These features include: named entity (NE), part-of-speech (POS) and answer position in the embedding layer of the encoder.

The encoder in our baseline is a bidirectional LSTM, which takes the joint embedding of word, answer position and lexical features

(NE, POS) as input $(w_1, w_2, ..., w_{T_x})\ with\ w_i \in \mathbb{R}^{d_w+d_a+d_n+d_p}$, where T_x is the input length and d_w, d_a, d_n, d_p is the dimensionality of word embedding, answer position embedding, NE embedding and POS embedding respectively. It produces a sequence of hidden states $(h_1, h_2, ..., h_{T_x})$ to represent its input, each of which is a concatenation of a forward and a backward LSTM representation:

$$\begin{aligned} h_i &= [\overleftarrow{h}_i; \overrightarrow{h}_i], \\ \overleftarrow{h}_i &= \text{LSTM}(w_i, \overleftarrow{h}_{i+1}), \\ \overrightarrow{h}_i &= \text{LSTM}(w_i, \overrightarrow{h}_{i-1}) \end{aligned} \tag{1}$$

where $\overleftarrow{h}_i$, $\overrightarrow{h}_i$ are all d_h-dimensional vectors.

The decoder is a unidirectional LSTM conditioned on all encoded hidden states. At decoding step t, the decoder reads an input word embedding w_t, previous attentional context vector c_{t-1} and its previous hidden state s_{t-1} to update its current hidden state $s_t \in \mathbb{R}^{d_h}$:

$$s_t = \text{LSTM}([w_t; c_{t-1}], s_{t-1}) \tag{2}$$

The context vector c_t together with an attention distribution α_t are generated via attention mechanism (Bahdanau et al., 2014). Attention can be regarded as a semantic match between encoder hidden states and the decoder hidden state. It describes how the model spread out the amount it cares about different encoder hidden states during decoding. At step t, the context vector c_t and the attention distribution α_t are calculated as follows:

$$c_t = \sum_{i=1}^{T_x} \alpha_{ti} h_i \tag{3}$$

$$\alpha_{ti} = \text{softmax}(e_{ti}) \tag{4}$$

$$e_{ti} = v^T \tanh(W_h^T h_i + W_s^T s_t + b) \tag{5}$$

where $W_h, W_s, b\ and\ v$ are all trainable parameters.

Our baseline is based on a pointer-generator framework, which includes two complementary modes: a generation mode and a copy mode. The former mode generates words from a given vocabulary as the vanilla sequence-to-sequence model:

$$P_{vocab} = \text{softmax}\,(g(s_t, c_t)) \tag{6}$$

where $g(\cdot)$ is a two-layer feed-forward network with a maxout internal activation. $P_{vocab} \in \mathbb{R}^{|V|}$ denotes the vocabulary distribution with a vocabulary size of $|V|$.

The latter mode copies words directly from the source sequence. As the attention weights already measure the relevance of each input word to the partial decoding state, we treat α_t as the copy probability i.e. $P_{copy}(w) = \alpha_t$. Both modes are switched via a generation probability p_{gen} as follows:

$$P(w) = p_{gen} P_{vocab}(w) + (1 - p_{gen}) P_{copy}(w) \tag{7}$$

where p_{gen} is computed from the context vector c_t, decoder hidden state s_t and the decoder input w_t:

$$p_{gen} = \sigma(f(c_t, s_t, w_t)) \tag{8}$$

$f(\cdot)$ indicates a simple feed-forward neural network that emits a single scalar value. The whole network is thus trained end-to-end according to the negative log likelihood loss of target word probability $P(w^*)$. In the baseline, we apply BIO scheme to label answer position, where B,I,O denote the begin of an answer, the non-begin of the answer and the non-answer context words respectively. Besides, we introduce dropout (Srivastava et al., 2014) with maxout (Goodfellow et al., 2013) to tackle over-fitting problem and pre-trained global vectors (Glove) for word representation (Pennington et al., 2014). All these techniques have been verified in their effectiveness in our model.

3.2 Answer-focused Model

The mismatch between generated question words and answer type is a major issue in neural question generation (NQG). Even though answer is a key to question word generation, most NQG models do not focus on answer or weakly emphasis on it when generating question words. As Table 1 shows, a when-question should be triggered for the answer “the end of the Mexican War”, but an answer-irrelevant why-question is generated by the baseline. According to our analysis in Section 1, we discover that nearly 37% bad cases from our baseline fall into this category. To deal with this issue, we develop an answer-focused model.

We observe that the generation of question words is mainly related to the answer and its surrounding words. For example in Table 1, the answer and its context “until after the end of the Mexican War” already involve the essential information to generate a question word “when”. This

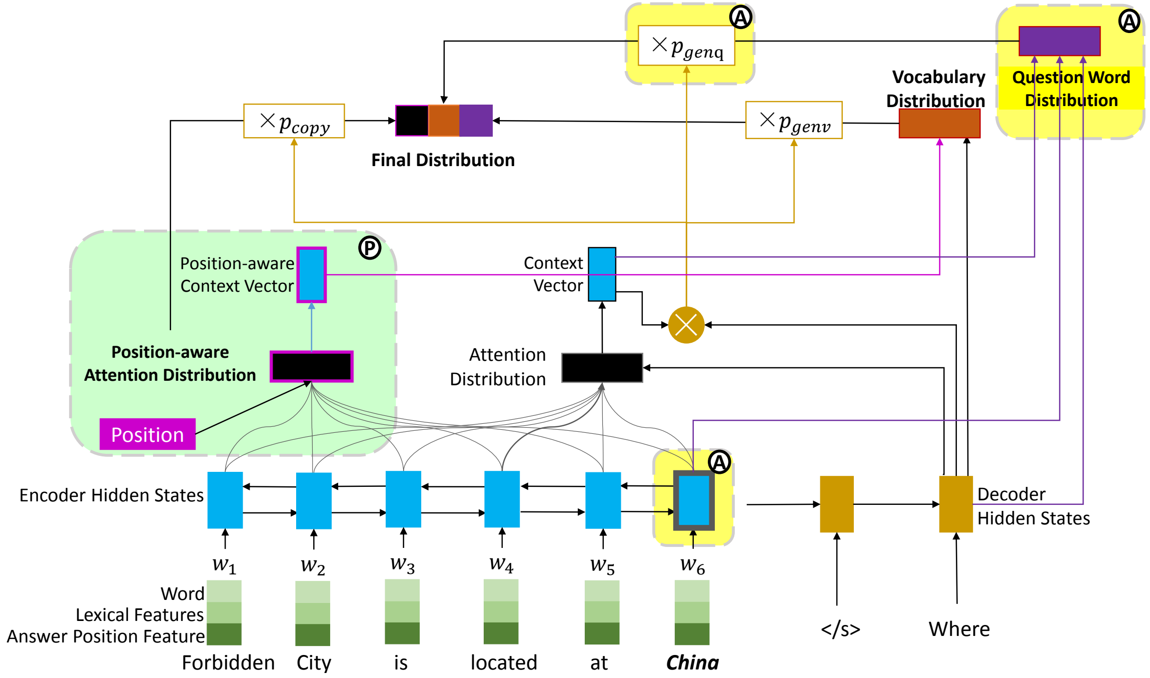

Figure 1: The modules marked with Ⓐ and colored yellow describe the answer-focused model, while the ones marked with Ⓟ and colored green describe the position-aware model. In answer-focused model, comparing to pointer-generator model, we introduce a question word generation mode and generate question words in a restricted vocabulary of question words. In position-aware model, we incorporate word position embeddings to gain a position-aware attention for further generation. The hybrid model has two types of attention distribution: position-aware and non-position-aware attention distribution and two types of context vector accordingly. Question word distribution is generated from non-position-aware context vector while vocabulary distribution is calculated from position-aware one.

suggests that the answer and its context can benefit the generation of question words. We also observe that the number of question words is limited. Therefore, we introduce a specific vocabulary of question words to directly and explicitly model the generation of question words.

As depicted in Figure 1, comparing to pointer-generator model, we introduce an additional question word generation mode to generate question words based on a restricted vocabulary of question words. This mode produces a question word distribution based on an answer embedding v_{ans}, the decoder state s_t and the context vector c_t:

$$P_{question\_word} = \text{softmax}\left(g(v_{ans}, s_t, c_t)\right) \qquad (9)$$

where $P_{question\_word}$ is a $|V_{qw}|$-dimensional probability distribution, and $|V_{qw}|$ is the size of vocabulary of question words. We employ the encoded hidden state at the answer start position as the answer embedding, i.e. $v_{ans} = h_{answer\_start}$. We argue that under bidirectional encoding, this answer embedding has already memorized both the left and the right contexts around the answer region, making it a desired choice. To control the balance among different modes, we introduce a 3-dimensional switch probability:

$$p_{genv}, p_{genq}, p_{copy} = \text{softmax}(f(c_t, s_t, w_t)) \qquad (10)$$

The final probability distribution is calculated via a weighted sum of the three mode probability distributions:

$$\begin{aligned} P(w) = {} & p_{genv}P_{vocab}(w) + p_{copy}P_{copy}(w) \\ & + p_{genq}P_{question\_word}(w) \end{aligned} \qquad (11)$$

3.3 Position-aware Model

Another main issue of NQG is that the generated question copies the context words that are distant from and irrelevant to the answer, instead of the words that are close and relevant to the answer. In other words, attention is distracted by irrelevant words far away from the answer. As shown in Table 2, the baseline model copies "leading theory" that are far away from and unrelated to the answer "homologous recombination", but neglects the words "second theory" and "linear and replicates through" that are closer to the answer. In

Section 1, we analyze the bad cases of our baseline, and find that about 20% suffer from this phenomenon. Further analysis on these cases indicates that the closer a word is to the answer, the more likely it should be copied.

Based on these evidences, we believe that an important reason for the above phenomenon lies in the lack of word position information inside the NQG model. Following this direction, we propose a position-aware model. The model aims at enforcing local attention, and adapting the attention weights so as to put more emphasis on answer-surrounded context words by incorporating word position embeddings.

A straightforward solution to inject position information is to directly incorporate relative word position embeddings. This can inform the model where the answer is and what context words are close to it. As depicted in Figure 1, we achieve this by feeding position embeddings $(d_{p_1}, d_{p_2}, ..., d_{p_{T_x}})$ into the computation of attention distribution through a single layer network:

$$e_{ti} = v^T \tanh(W_d d_{p_i} + W_h h_i + W_s s_t + b) \quad (12)$$

$$\alpha_{ti} = \text{softmax}(e_{ti}) \quad (13)$$

where p_i is the relative distance between the i-th word and the answer, d_{p_i} is the embedding of p_i, which we call word position embedding. By optimizing the attention parameters, our model is expected to discover the correlation between target words and their relative distance from the answer. As a result, distracted attention on irrelevant input words can be avoided.

3.4 A Hybrid Model (Answer-focused and Position-aware)

In Section 3.2 and 3.3, we describe the answer-focused model and position-aware model respectively. In this section, we combine these two models to get a both answer-focused and position-aware hybrid model. As depicted in Figure 1, the hybrid model generates two types of attention distribution: position-aware and non-position-aware distribution. Accordingly, the model has two types of context vector: position-aware and non-position-aware context vector. At time step t, we calculate position-aware attention distribution α'_t as equation (12), (13), and non-position-aware one α_t as equation (4), (5). And we use c_t, c'_t to represent non-position-aware and position-aware context vector calculated as equation (3) respectively.

The hybrid model has three modes as in the answer-focused model. The question word distribution is computed from non-position-aware attention distribution as equation (9), while vocabulary distribution is calculated from position-aware one. The final distribution is weighted sum of the three mode probability distributions:

$$P_{vocab} = \text{softmax}\left(g(s_t, c'_t)\right) \quad (14)$$

$$\begin{aligned} P(w) = {} & p_{genv} P_{vocab}(w) + p_{copy} P_{copy}(w) \\ & + p_{genq} P_{question\_word}(w) \end{aligned} \quad (15)$$

where $P_{copy}(w)$ is the position-aware attention distribution α'_t.

4 Experiments

4.1 Experiment Settings

Dataset In this paper, we conduct the experiments on SQuAD and MARCO. Since the test sets of both data sets are not publicly available, we follow Zhou et al. (2017) to randomly split the development set into two parts and use them as the development set and test set for the task of question generation. In SQuAD, there are $86,635$, $8,965$ and $8,964$ question-answer pairs in our training set, development set and test set, respectively. We directly use the extracted features [1] shared by Zhou et al. (2017). In MARCO, there are $74,097$, $4,539$ and $4,539$ question-answer pairs in our training set, development set and test set, respectively. We use Stanford CoreNLP [2] to extract lexical features. We attach all the processed data sets in the supplemental materials.

Implementation Details In this paper, we set the cutoff length of the input sequence as 100 words. The vocabulary contains the most frequent $20,000$ words in each training set. The vocabulary of question words contains 20 words. We use the pre-trained Glove word vectors [3] with 300 dimensions to initialize the word embeddings that will be further fine-tuned in the training stage. The representations of answer position feature and lexical features at the embedding layer of the encoder

Table 3: The main experimental results of baselines, answer-focused model, position-aware model and a hybrid model on SQuAD and MARCO.

are randomly initialized as 32 dimensional vectors that are trainable during training stage. The hidden size of both the encoder and decoder is 512. We use dropout only in the encoder with a dropout rate 0.5. The size of answer embedding in answer-focused model is 512. The position, that indicates the relative distance between the context words and the answer, ranges from 0 to 80 and its embedding size in position-aware model is 16. We use the optimization algorithm Adagrad (Duchi et al., 2011) with learning rate 0.15, an initial accumulator value of 0.1 and batch size as 64. We use gradient clipping with a maximum gradient norm of 2. During training, we select the best model on development set.

Evaluation Metrics We report BLEU (Papineni et al., 2002) as the main evaluation metric of the question generation systems.

Baselines In the experiments, we have three baselines for comparisons:

- **NQG++ (Zhou et al., 2017)** It is the state-of-the-art neural question generation system on SQuAD that incorporates rich features to the embedding layer of a sequence-to-sequence model and introduces copy mechanism proposed by Gulcehre et al. (2016).
- **Pointer-generator model (See et al., 2017)** It is a sequence-to-sequence model with copy mechanism that has different architecture from the one proposed by Gulcehre et al. (2016). We choose this model since its copy mechanism shows better performance (See et al., 2017). Note that we do not enable the coverage mechanism in this model to have a fair comparison.
- **Feature-enriched pointer-generator model** We add the features to the embedding layer of the pointer-generator model as described in Section 3.1.

4.2 Main Results

Table 3 shows the main results, and we have the following observations:

- The feature-enriched pointer-generator model outperforms NQG++. Both of the two models employ the sequence-to-sequence model with copy mechanism and the same features. The major difference between them is that their copy mechanism has different architecture, and pointer-generator shows better performance.
- The pointer-generator model without the features does not perform well. This verifies the effectiveness of the features extracted by Zhou et al. (2017).
- Both answer-focused model and position-aware model outperform the feature-enriched pointer-generator model and NQG++. We will analyze the effectiveness of these two models in the following two sections, respectively.
- The hybrid model shows the best performance and it outperforms the two single models, answer-focused model and position-aware model.

4.3 Answer-focused Model Analysis

As we discussed in Section 1, one major issue with the neural question generation model is that the generated question word does not match the answer type. The design of answer-focused model is explicitly modeling question word generation by incorporating answer embedding. It is expected that the answer-focused model can reduce such errors. Recall the example shown in Table 1 (Section 1). The answer-focused model correctly predicts the question word, though it copies wrong context words that can be further corrected by the hybrid model. The outputs of the answer-focused model and the hybrid model for the case in Table 1 are as follows:

- **Answer-focused model:** ***When*** did Thoreau's essay come to higher political office ?
- **Answer-focused + Position-aware model:** ***When*** was Thoreau's essay published ?

We further evaluate different systems in terms of the same question word ratio (SQWR). This metric measures the ratio of the generated questions that have the same question words as the reference. Table 4 shows the SQWR of different systems on SQuAD. We can see that answer-focused model outperforms the strong baseline, feature-enriched pointer-generator model.

Model	SQWR
Pointer-generator model (See et al., 2017)	53.17%
Feature-enriched pointer-generator model	71.58%
Answer-focused model	**73.91%**

Table 4: The answer-focused model has the highest same question word ratio.

We re-analyze the 20 (37% of errors) questions (discussed in Section 1) that have the answer type mismatching problem. Our answer-focused model can correct 7 out of the 20 bad cases. All the resolved cases have a commonality that we can easily figure out the answer type from the answer itself, as the case shown in Table 1. We also analyze the remaining 13 of the 20 unresolved cases. (1) 4 cases show that the answer type is closely related to the context words other than the answer. But these context words are far from the answer, and the encoding of the answer by LSTM has little memory of them. As shown in Table 5, the answer "an attempt to avoid responsibility for her actions" is useless to generate a question word "why", while the useful context word "because" is far from the answer. (2) 3 cases show that the answer itself has ambiguity to generate the right question words. (3) 3 cases contain the answers with the wrong named entity labels. (4) 2 cases contain answers which are out of vocabulary. (5) 1 case is hard even for human.

4.4 Position-aware Model Analysis

As discussed in Section 1, another major issue with the neural question generation model is that the model copies the context words that are far from and irrelevant to the answer. The design of position-aware model is tackling this issue by modeling the relative distance between context words and the answer, so that the attention distribution for copy mechanism will be biased towards the context words that are close and relevant to the answer. Recall the example in Table 2 (Section 1). The question generated by the baseline copies the wrong context words "leading theory" instead of "second theory" and "linear and replicates through". The outputs of our position-aware and hybrid model for this case are as follows.

Context: This action was upheld because , according to the U.S. court of appeals for the first circuit , her statement suggested a lack of remorse , **an attempt to avoid responsibility for her actions** , and even a likelihood of repeating her illegal actions .

Answer: an attempt to avoid responsibility for her actions

Reference: Why is giving a defiant speech sometimes more harmful for the individual ?

Question generated by the answer-focused model: What did the court of appeals reject ?

Table 5: A bad case of baseline remains unresolved by applying answer-focused model because answer type is closely related to the context word "because" instead of the answer itself, but "because" is far from the answer. Thus, the encoding of answer has little memory of "because".

- **Position-aware model:** The ***second theory*** suggests that most cpdna is actually ***linear and replicates through*** what ?
- **Position-aware + Answer-focused model:** Most cpdna is actually ***linear and replicates through*** what ?

We can observe that the model can copy the correct context words after introducing the position embedding to the attention distribution. Figure 2 illustrates the attention distributions for copy mechanism before and after introducing position embedding of context words. We can see that "second" has much higher probability in the position-aware attention distribution.

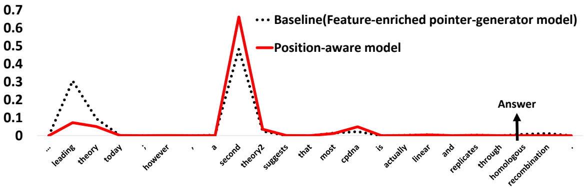

Figure 2: The two attention distributions for copy mechanism when generating questions for the case in Table 2. The position-aware model emphasizes more on the "second" that is close to the answer.

The design of position-aware model aims to help copy the context words close and relevant to the answer. We analyze the effects of position-aware model on copying out of vocabulary (OOV) words from the source sequence. We measure the effects from two perspectives: average precision and average recall. For one generated sequence, the precision is defined as the ratio of the number of OOV words appearing in both the generated question and the reference, and the number of OOV words in the generated question. The recall is defined as the ratio of the number of OOV words appearing in both the generated question and the reference, and the number of OOV words in the reference. The average precision (AP) is the mean of precision of all generated questions, and the average recall (AR) is the mean of recall of all generated questions. As Table 6 shows, our position-aware model can significantly improve the AP and AR, which indicates our position-aware model can help on copying OOV.

Model	AP	AR
Feature-enriched pointer-generator model	21.22%	18.87%
Position-aware model	**22.79%**	**20.62%**

Table 6: Our position-aware model can significantly improve the average precision and recall of copied OOV.

5 Conclusion

In this paper, we find two major issues with the existing neural question generation model. To tackle the two issues, we propose an answer-focused and position-aware model. We further conduct extensive experiments on SQuAD and MARCO dataset. The experimental results show that the combination of our proposed answer-focused model and position-aware model significantly improves the baseline and outperforms the state-of-the-art system.

Diversity-Promoting GAN: A Cross-Entropy Based Generative Adversarial Network for Diversified Text Generation

Jingjing Xu, Xuancheng Ren, Junyang Lin, Xu Sun
MOE Key Lab of Computational Linguistics, School of EECS, Peking University
`{jingjingxu,renxc,linjunyang,xusun}@pku.edu.cn`

Abstract

Existing text generation methods tend to produce repeated and “boring” expressions. To tackle this problem, we propose a new text generation model, called Diversity-Promoting Generative Adversarial Network (DP-GAN). The proposed model assigns low reward for repeatedly generated text and high reward for “novel” and fluent text, encouraging the generator to produce diverse and informative text. Moreover, we propose a novel language-model based discriminator, which can better distinguish novel text from repeated text without the saturation problem compared with existing classifier-based discriminators. The experimental results on review generation and dialogue generation tasks demonstrate that our model can generate substantially more diverse and informative text than existing baselines.[1]

1 Introduction

Text generation is an important task in Natural Language Processing (NLP) as it lays the foundation for many applications, such as dialogue generation, machine translation (Ma et al., 2018b; Xu et al., 2018a), text summarization (Ma et al., 2018a), and table summarization (Liu et al., 2017). In these tasks, most of the systems are built upon the sequence-to-sequence paradigm (Sutskever et al., 2014), which is an end-to-end model that encodes a source sentence to a dense vector and then decodes the vector to a target sentence. The standard training method is based on Maximum Likelihood Estimation (MLE).

Although being widely applied, the conventional MLE training causes systems to repeatedly generate “boring” sentences, which usually are expressions with high frequency (e.g., “I am sorry” in dialogue generation (Li et al., 2016)). The major reason is that MLE encourages the model to overproduce high-frequency words.[2] The overestimation of high-frequency words discourages the model from generating low-frequency but meaningful words in real data, which makes generated text tend to be repeated and “boring”.

To tackle this problem, we propose a new model for diversified text generation, called DP-GAN. The key idea is to build a discriminator that is responsible for giving reward to the generator based on the novelty of generated text. We consider the text that is frequently generated by the generator as the low-novelty text and the text that is uncommon in the generated data as the high-novelty text. Considering most of the real-world sentences are novel and fluent, we treat the real-world text as the positive example and the generated text as the negative example to train the discriminator. Such training mechanism encourages the discriminator to give higher reward for the text that looks like real-world data. The reward is fed back to the generator, which promotes the generator to generate diverse and fluent text via policy gradient. In this framework, a good discriminator that can assign reasonable reward for the generator is a critical component.

However, directly applying a classifier as the discriminator like most existing GAN models (e.g., SeqGAN (Yu et al., 2017)) cannot achieve satisfactory performance. The main problem is that the reward given by the classifier cannot reflect the novelty of text accurately. First, most existing classifier-based discriminators take the probability of a sequence being true as the reward. When a sentence fits the distribution of real-world

---

[1] The code is available at `https://github.com/lancopku/DPGAN`

[2] For example, the frequency ratios of “the”, “and”, “was” are 4.2%, 3.2%, 1.5% in real data, and they go up to 7.1%, 4.6%, 5.3% in the MLE generated data on our review generation task.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3940–3949
Brussels, Belgium, October 31 - November 4, 2018.

text and is far from the generated data, the reward saturates and scarcely distinguishes the difference between these novel sentences. For example, for a sentence A with mildly high novelty and a sentence B with extremely high novelty, the classifier cannot tell the difference and gives them saturated reward: 0.997 and 0.998. Second, in our tasks, we find that a simple classifier can reach very high accuracy (almost 99%), which makes most generated text receive reward around zero because the discriminator can identify them with high confidence. It shows that the classifier also cannot distinguish the difference between low-novelty text. The reason for this problem is that the training objective of the classifier-based GAN is in fact minimizing the Jensen-Shannon Divergence (JSD) between the distributions of the real data and the generated data (Nowozin et al., 2016). If the accuracy of classifier is too high, JSD fails to measure the distance between the two distributions, and cannot give reasonable reward to the model for generating real and diverse text (Arjovsky et al., 2017).

Instead of using a classifier, we propose a novel language-model based discriminator and use the output of the language model, cross-entropy, as the reward. The main advantage of our model lies in that the cross-entropy based reward for novel text is high and does not saturate, while the reward for text with low novelty is small but discriminative. The analysis of the experimental results shows that our discriminator can better distinguish novel text compared with traditional classifier-based discriminators.

Our contributions are listed as follows:

- We propose a new model, called DP-GAN, for diversified text generation, which assigns low reward for repeated text and high reward for novel and fluent text.
- We propose a novel language-model based discriminator that can better distinguish novel text from repeated text without the saturation problem.
- The experimental results on review generation and dialogue generation tasks show that our method can generate substantially more diverse and informative text than existing methods.

2 Related Work

A great deal of attention has been paid to developing data-driven methods for natural language dialogue generation. Conventional statistical approaches tend to rely extensively on hand-crafted rules and templates, require interaction with humans or simulated users to optimize parameters, or produce conversation responses in an information retrieval fashion. Such properties prevent training on the large corpora that are becoming increasingly available, or fail to produce novel natural language responses.

Currently, a popular model for text generation is the sequence-to-sequence model (Sutskever et al., 2014; Cho et al., 2014). However, the sequence-to-sequence model tends to generate short, repetitive (Lin et al., 2018), and dull text (Luo et al., 2018). Recent researches have focused on developing methods to generate informative (Xu et al., 2018b) and diverse text (Li et al., 2017, 2016; Guu et al., 2017; Shao et al., 2017). Reinforcement learning is incorporated into the model of conversation generation to generate more human-like speeches (Li et al., 2017). Moreover, there are also other methods to improve the diversity of the generated text by using mutual-information, prototype editing, and self attention (Li et al., 2016; Guu et al., 2017; Shao et al., 2017).

In this paper, to handle this problem, we propose to use adversarial training (Goodfellow et al., 2014; Denton et al., 2015; Li et al., 2017), which has achieved success in image generation (Radford et al., 2015; Chen et al., 2016; Gulrajani et al., 2017; Berthelot et al., 2017). However, training GAN is a non-trivial task and there are some previous researches that investigate methods to improve training performance, such as Wasserstein GAN (WGAN) (Arjovsky et al., 2017) and Energy-based GAN (EGAN) (Salimans et al., 2016; Gulrajani et al., 2017; Zhao et al., 2017; Berthelot et al., 2017). GAN in text generation has not shown significant improvement as it has in computer vision. This is partially because text generation is a process of sampling in discrete space where the normal gradient descent solution is not available, which makes it difficult to train. There are some researches that focus on tackling this problem. SeqGAN (Yu et al., 2017) incorporates the policy gradient into the model by treating the procedure of generation as a stochastic policy in reinforcement learning. Ranzato et al. (2016)

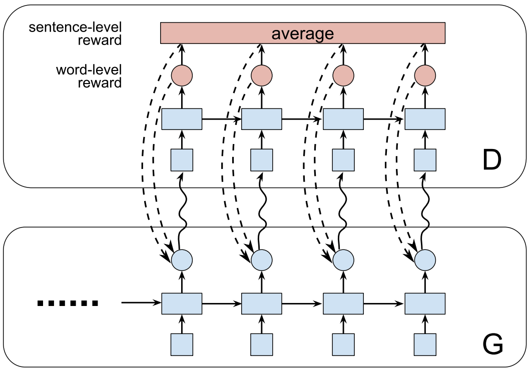

Figure 1: Illustration of DP-GAN. Lower: The generator is trained by policy gradient where the reward is provided by the discriminator. Upper: The discriminator is based on the language model trained over the real text and the generated text.

trains the sequence-to-sequence model with policy gradient for neural machine translation. Bahdanau et al. (2017) applies the actor-critic model on the same task.

3 Diversity-Promoting GAN

The basic structure of our DP-GAN contains a generator that is responsible for generating text and a discriminator that discriminates between the generated text and the real text. The sketch of DP-GAN is shown in Figure 1.

3.1 Overview

The generator G_θ is based on a sequence-to-sequence structure. Given a sentence as input, the generator is capable of generating long text, which contains multiple sentences of various lengths. To put it formally, given the input sentence $x_{1:m} = (x_1, x_2, x_3, ..., x_m)$ of m words from Γ, the vocabulary of words, the model generates the text of T sentences $Y_{1:T} = (y_1, ..., y_t, ..., y_T)$, where y_t from Λ, the set of candidate sentence. The term $y_t = (y_{t,1}, ..., y_{t,K})$ is the t^{th} sentence, where $y_{t,K}$ is the K^{th} word.

The discriminator D_ϕ is a language model. The output of the language model, cross entropy, is defined as the reward to train the generator. Our reward consists of two parts, the reward at the sentence level and that at the word level. With the discriminator and the reward function, we train the generator by reinforcement learning. A sketch of training DP-GAN is shown in Algorithm 1. The details are described as follows.

Algorithm 1 The adversarial reinforcement learning algorithm for training the generator G_θ and the discriminator D_ϕ.

```
Initialize $G_\theta$, $D_\phi$ with random weights $\theta$, $\phi$
Pre-train $G_\theta$ using MLE on a sequence dataset $\mathcal{D} = (X, Y)$
Generate samples using $G_\theta$ for training $D_\phi$
Pre-train $D_\phi$ by Eq. (1)
$N$ = number of training iterations
$M$ = number of training generator
$K$ = number of training discriminator
for each $i = 1, 2, ..., N$ do
    for each $j = 1, 2, ..., M$ do
        Generate a sequence $Y_{1:T} \sim G_\theta$
        Compute rewards by Eq. (2) and Eq. (3)
        Update generator via policy gradient Eq. (5)
        Sample a sequence $Y_{1:T} \sim \mathcal{D}$
        Compute rewards by Eq. (2) and Eq. (3)
        Update generator parameters via Eq. (5)
    end for
    for each $j = 1, 2, ..., K$ do
        Generate samples using $G_\theta$
        Train discriminator $D_\phi$ by Eq. (1)
    end for
end for
```

3.2 Generator

For the concern of real-world applications, this paper assumes that the output of the model can be long text made up of multiple sentences. In order to generate multiple sentences, we build a standard hierarchical LSTM decoder (Li et al., 2015). The two layers of the LSTM are structured hierarchically. The bottom layer decodes the sentence representation and the top layer decodes each word based on the output of the bottom layer. The attention mechanism is used for word decoding (Bahdanau et al., 2014; Luong et al., 2015).

3.3 Discriminator

Most existing GAN models use a binary classifier as the discriminator. The probability of being true is regarded as the reward (Li et al., 2016; Yu et al., 2017). Different from that, we propose a language-model based discriminator D_ϕ that builds on a unidirectional LSTM. We use the output of the language model, cross-entropy, as the reward. Specifically, given a sentence y_t, the cross-entropy based reward for the k^{th} word is calculated as

$$R(y_{t,k}) = -\log D_\phi(y_{t,k}|y_{t,<k})$$

We maximize the reward of real-world text and minimize the reward of generated text to train the discriminator. The reason of minimizing the reward of generated text is that, we expect the text that is repeatedly generated by the generator can be identified by the discriminator and get lower reward. The motivation of maximizing the reward of real-world data lies in that, we expect not only the uncommon text in the generated data can get high reward, but also low-quality text can be punished to some extend. Considering the real-world text is diverse and fluent, we maximize the reward of real-world text to encourage the discriminator to give high reward for the text that looks like the real-world data. Therefore, such training mechanism avoids the problem of novel but low-quality text getting high reward. The loss function of the discriminator is formulated as follows:

$$\begin{aligned} J(\phi) = \\ -\left(E_{Y\sim p_{data}}[R(Y)] - E_{Y\sim G_\theta}[R(Y)]\right) \end{aligned} \tag{1}$$

where $R(Y)$ stands for the averaged reward of Y.

3.4 Reward

Our reward function consists of two parts, the sentence-level reward and the word-level reward, which are illustrated as follows.

3.4.1 Sentence-Level Reward

For a sentence y_t of K words, the reward at the sentence level is the averaged reward of each word:

$$R(y_t) = -\frac{1}{K}\sum_{k=1}^{K} \log D_\phi(y_{t,k}|y_{t,<k}) \tag{2}$$

In contrast, the reward of the existing classifier-based discriminators (Li et al., 2016; Yu et al., 2017) is calculated as follows:

$$R(y_t) = D_\phi(true|y_t)$$

where D_ϕ is a binary classifier judging how likely y_t is from the real-world data.

The major problem of the classifier-based discriminator is that the reward cannot reflect the novelty of text accurately. First, the reward for high-novelty text is easy to saturate, which scarcely distinguishes the difference between novel text. Second, we find that the discriminator can easily achieve very high accuracy on identifying the generated text, which makes most of them get reward around zero. It shows that the classifier still cannot tell the difference between the text with low novelty.

On the contrary, the analysis of experimental result shows that our proposed discriminator can better distinguish high-novelty text from low-novelty text without the saturation problem. The reward for high-novelty text is high and does not saturate while the reward for low-novelty text is small but discriminative.

3.4.2 Word-Level Reward

Considering that the reward for different words in a sentence y_t should be different, we further propose to use the reward at the word level as follows:

$$R(y_{t,k}|y_{t,<k}) = -\log D_\phi(y_{t,k}|y_{t,<k}) \tag{3}$$

It can be found that the classifier-based discriminator only provides reward for the finished sequence. Thus, for a sequence of length T, to evaluate the action-value for a word at the time step t, Monte Carlo Search (MCS) with a roll-out policy G_θ is usually applied to sample the unknown last $T-t$ tokens (Yu et al., 2017). However, this could be computationally expensive because the time complexity is $O(T^2)$. On the contrary, our discriminator can calculate the reward of all words with the time complexity of $O(T)$, which is more computationally efficient.

3.5 Policy Gradient Training

The loss function of the generator (policy) is to maximize the reward from the start state s_0 to the end state (Sutton et al., 1999):

$$\begin{aligned} J(\theta) &= \sum_{t=1}^{T} E[R_{t,K}|s_{t-1},\theta] \\ &= \sum_{t=1}^{T}\sum_{y_{t,1}} G_\theta(y_{t,1}|s_{t-1}) Q_{D_\phi}^{G_\theta}(s_{t-1},y_{t,1}) \end{aligned} \tag{4}$$

where $R_{t,K} = \sum_{k=1}^{K}\gamma^{k-1}R(y_t)R(y_{t,k})$ is the total reward for a complete sentence, including both the sentence-level and the word-level rewards. The term $Q_{D_\phi}^{G_\theta}(s_{t-1},y_{t,1})$ is estimated by $R_{t,1}$. The term γ is the discount rate and s_t is the initial state.

In this paper, we use the policy gradient method (Williams, 1992). The gradient of Eq. (4) is approximated as follows:

$$\begin{aligned} &\nabla_\theta J(\theta) \simeq \\ &\sum_{t=1}^{T}\sum_{k=1}^{K}\gamma^{k-1}R_{t,k}\nabla_\theta \log G_\theta(y_{t,k}|y_{t,<k}) \end{aligned} \tag{5}$$

where $R_{t,k} = \sum_{i=k}^{K} \gamma^{i-1} R(y_t) R(y_{t,i})$ is the total reward starting from step k.

Following previous work (Li et al., 2017), we also use teacher forcing (Bengio et al., 2015) to train the generator. In teacher forcing, the decoder receives the real-world text as input at each time step. The loss function of teacher forcing is the same with that of policy gradient training. The only difference is that the text is generated from G_θ in policy gradient training but from the real data in teacher forcing.

4 Experiment

We evaluate DP-GAN on two real-world natural language generation tasks, review generation and dialogue generation. We first introduce the dataset, the training details, the baselines, and the evaluation metrics. Then, we compare our model with the state-of-the-art models. Finally, we show the experimental results and provide the detailed analysis.

4.1 Datasets

Yelp Review Generation Dataset (Yelp): This dataset is provided by Yelp Dataset Challenge.[3] In our version of review generation, the model should generate a paragraph based on a given sentence. We build a new dataset for this task by splitting the data into two parts. In each review, we take the first sentence as the input text, and the following sentences as the target text. The processed Yelp dataset contains 1,400K, 400K, and 12K pairs for training, validation, and testing, respectively.

Amazon Review Generation Dataset (Amazon): This dataset is provided by McAuley and Leskovec (2013). It consists of review information of fine foods from Amazon. Like Yelp, we process this dataset by extracting the first sentence as the source text and the rest as the target text. The processed Amazon dataset contains 400K, 100K, and 12K pairs for training, validation, and testing, respectively.

OpenSubtitles Dialogue Dataset (Dialogue): This dataset[4] is used for dialogue generation. Following previous work, we treat each turn in the dataset as the target text and the two previous sentences as the source text. We remove the pairs whose response is shorter than 5 words. We randomly sample 1,800K, 500K, and 12K turns for training, validation, and testing, respectively.

Yelp	Token	Dist-1	Dist-2	Dist-3	Dist-S
MLE	151.2K	1.2K	3.9K	6.6K	3.9K
PG-BLEU	131.1K	1.1K	3.3K	5.5K	3.1K
SeqGAN	140.5K	1.1K	3.5K	6.1K	3.6K
DP-GAN(S)	**438.6K**	1.7K	7.5K	15.7K	10.6K
DP-GAN(W)	271.9K	2.8K	14.8K	29.0K	12.6K
DP-GAN(SW)	406.8K	**3.4K**	**22.3K**	**49.6K**	**17.3K**

Amazon	Token	Dist-1	Dist-2	Dist-3	Dist-S
MLE	176.1K	0.6K	2.1K	3.5K	2.6K
PG-BLEU	124.5K	0.6K	1.9K	3.5K	2.3K
SeqGAN	217.3K	0.7K	2.6K	4.6K	3.2K
DP-GAN(S)	**467.6K**	0.8K	3.6K	7.6K	7.0K
DP-GAN(W)	279.4K	1.6K	8.9K	18.4K	9.6K
DP-GAN(SW)	383.6K	**1.9K**	**11.7K**	**26.3K**	**13.6K**

Dialogue	Token	Dist-1	Dist-2	Dist-3	Dist-S
MLE	81.1K	1.4K	4.4K	6.3K	4.1K
PG-BLEU	97.9K	1.2K	3.9K	5.5K	3.3K
SeqGAN	83.4K	1.4K	4.5K	6.5K	4.5K
DP-GAN(S)	**112.2K**	1.5K	5.2K	8.5K	5.6K
DP-GAN(W)	79.4K	1.9K	7.7K	11.4K	6.0K
DP-GAN(SW)	97.3K	**2.1K**	**10.8K**	**19.1K**	**8.0K**

Table 1: Performance of the DP-GAN and three baselines on review generation and dialogue generation tasks. Higher is better. DP-GAN(S), DP-GAN(W), and DP-GAN(SW) represent DP-GAN with only sentence-level reward, only word-level reward, and combined reward, respectively. *Token* represents the number of generated words. Dist-1, Dist-2, Dist-3, and Dist-S are respectively the number of distinct unigrams, bigrams, trigrms, and sentences in the generated text. For example, 1.2K in Dist-1 means 1200 distinct unigrams.

4.2 Baselines

We compare the proposed DP-GAN with the following baseline models:

MLE: The generator is a sequence-to-sequence model. The generator is trained with traditional MLE.

PG-BLEU: The generator is a sequence-to-sequence model. It is trained by policy gradient with the BLEU score of the generated text as the reward (Bahdanau et al., 2017). The advantage is that this model can directly optimize the task-specific score: BLEU.

SeqGAN: Sequence GAN (Yu et al., 2017) uses a binary classifier as the discriminator. Since it is originally for unconditional generation, for a fair comparison, we expand it to the version of conditional generation. We re-implement the generator by replacing a language model with a sequence-to-sequence model.

---

Yelp	Relevance	Diversity	Fluency	All
MLE	1.49	1.73	1.78	1.89
PG-BLEU	1.47	2.59	**1.38**	2.22
SeqGAN	1.48	2.40	1.54	2.12
DP-GAN	**1.32**	**1.23**	1.66	**1.51**
Amazon	Relevance	Diversity	Fluency	All
MLE	1.52	1.81	1.72	1.93
PG-BLEU	1.62	2.48	1.63	2.24
SeqGAN	1.56	2.37	**1.40**	1.97
DP-GAN	**1.31**	**1.25**	1.52	**1.50**
Dialogue	Relevance	Diversity	Fluency	All
MLE	1.19	1.84	1.37	1.87
PG-BLEU	**1.13**	1.85	1.21	1.75
SeqGAN	**1.13**	1.71	**1.20**	1.64
DP-GAN	**1.13**	**1.50**	1.30	**1.55**

Table 2: Results of human evaluation on the three datasets. The score represents the averaged ranking of each model and lower is better. *All* represents the ranking given by annotators based on a comprehensive consideration. It can be seen that DP-GAN results in the largest improvement in terms of diversity and relevance while slightly reducing fluency.

4.3 Training Details

For review generation, we set the number of generated sentences to 6 with the maximum length of 40 words for each generated sentence. Based on the performance on the validation set, we set the hidden size to 256, embedding size to 128, vocabulary size to 50K, and batch size to 64 for the proposed model and the baselines. We use the Adagrad (Duchi et al., 2011) optimizer with the initial learning rate 0.1. In adversarial training, the step for training the generator is 1K, the step for training the discriminator is 5K. Both the generator and the discriminator are pre-trained for 10 epochs before adversarial learning. In particular, for PG-BLEU and SeqGAN, before reinforcement learning or adversarial learning, we pre-train the sequence-to-sequence model for 10 epochs like DP-GAN. For dialogue generation, the settings are the same with review generation, except that we set the number of generated sentences to 1 with the maximum length of 40 words because there is only one sentence in the response.

4.4 Experimental Results

We conduct two kinds of evaluations in this work, automatic evaluation and human evaluation. The details of evaluation results are shown as follows.

4.4.1 Automatic Evaluation

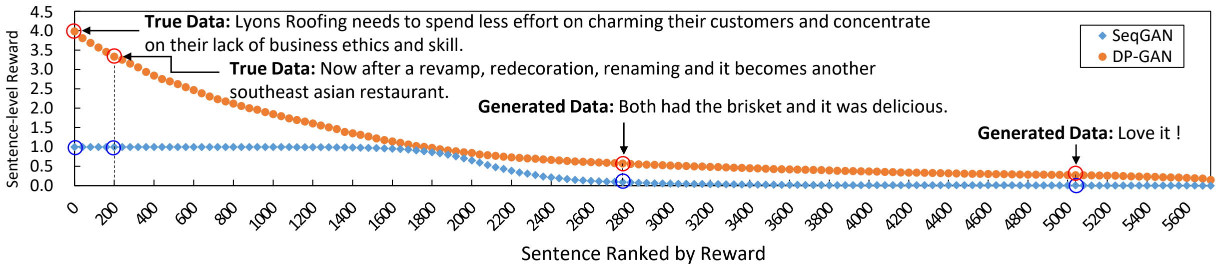
We evaluate the proposed model in terms of several metrics that can reflect the diversity. The results are shown in Table 1. *Token* represents the total number of generated words. Dist-1, Dist-2, Dist-3, and Dist-S are respectively the number of distinct unigrams, bigrams, trigrms, and sentences. DP-GAN(S), DP-GAN(W), and DP-GAN(SW) represent DP-GAN with only sentence-level reward, only word-level reward, and combined reward, respectively. From the results, it is obvious that the proposed model substantially outperforms the existing models. PG-BLEU achieves slightly weaker results compared with MLE. The reason is that PG-BLEU uses BLEU score as the reward for reinforcement learning. However, the BLEU score is low for most of the generated text. The low reward makes it hard to learn from the real data. SeqGAN does not achieve better results, which suggests that the classifier-based discriminator fails to encourage the generator to produce diverse text.

In terms of the total number of generated words, DP-GAN(S) achieves better results than DP-GAN(W). Since the sentence-level reward reflects the novelty of the whole sentence, it gives repeated and short text low reward while novel and longer text high reward. Thus, the generator is encouraged to generate novel text. In terms of the number of distinct n-grams, DP-GAN(W) achieves better results than DP-GAN(S). It is because the word-level reward gives each word more precise score and novel n-grams could be better encouraged. As we can see, DP-GAN(SW), which combines the advantages of sentence-level and word-level rewards, generates not only more diverse n-grams than DP-GAN(S) but also longer text than DP-GAN(W). Since combining the word-level and sentence-level rewards achieves better results than using just one of them, we focus more on the combined reward in the following parts.

In review generation and dialogue generation tasks, it is a widely debated question how well the BLEU score against a single reference can reflect the quality of the generated text (Liu et al., 2016). Thus, although the proposed model achieves better BLEU scores compared with baselines, we omit the detailed comparisons in terms of BLEU for space.

4.4.2 Human Evaluation

We conduct a human evaluation on the test set. For all tasks, we randomly extract 200 samples from the test sets. Each item contains the input text and the text generated by the different systems. The items are distributed to three anno-



True Data: Lyons Roofing needs to spend less effort on charming their customers and concentrate on their lack of business ethics and skill.

True Data: Now after a revamp, redecoration, renaming and it becomes another southeast asian restaurant.

Generated Data: Both had the brisket and it was delicious.

Generated Data: Love it !

Figure 2: Distribution of rewards between SeqGAN and DP-GAN. The upper two sentences are sampled from the real-world data and the lower two sentences are sampled from the generated data. It is important to note that the sentence-level reward of DP-GAN is averaged word-level reward and a long sentence does not indicate a high score. As we can see, the reward distribution of SeqGAN saturates and cannot distinguish the novelty of the text accurately. In contrast, DP-GAN has a strong ability of resisting reward saturation and can give more precise reward for text in terms of novelty.

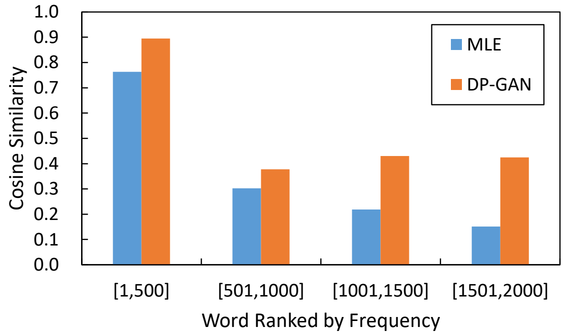


Figure 3: Cosine similarity between the real-world data distribution and the generated data distributions of various models. For example, the first column represents the cosine similarity on top 500 words with the highest frequencies in real-world data. As we can see, the generated data distribution of DP-GAN is closer to the real-world data distribution, especially considering the words of low frequency.

tators who have no knowledge about which system the text is from. Following the work of Li et al. (2017), we require them to rank the generated text considering relevance, diversity, and fluency. It is important to note that all the annotators have linguistic background. Relevance means that how likely the generated text is related to the input text. Diversity means that how much the generated text provides specific information, rather than "dull" and repeated information. Fluency means that how likely the generated text is produced by human. *All* represents the ranking given by annotators based on a comprehensive consideration of all human evaluation metrics. The results of human evaluation are shown in Table 2. It needs to be mentioned that in the special case that several pieces of generated text are exactly the same, they are given the same ranking. The inter-annotator agreement is satisfactory considering the difficulty in the human evaluation. The Pearson's correlation coefficient is 0.76 on diversity, 0.59 on fluency and 0.27 on relevance, with $p < 0.0001$. The p-value is all below 0.001, indicating high correlation and agreement. Table 2 shows that DP-GAN brings the largest improvement in terms of diversity and relevance while scarcely reducing fluency. First, DP-GAN significantly outperforms baselines in term of diversity. Second, DP-GAN achieves the best performance in terms of relevance. Diverse text generated by DP-GAN brings more specific expressions, increasing the performance of relevance. For example, given input sentence*"food is good"*, the relevance of *"love it, beef is the best"* is obviously better than that of *"love it"*. Third, the fluency of DP-GAN is slightly worse than that of baselines. It is mainly due to the fact that the text generated by DP-GAN is much longer. From Table 1, we can see that the number of words generated by DP-GAN is almost three times than that of baselines in the Yelp dataset.

4.4.3 Analysis: Why It Works

In this section, we provide detailed analysis to see why our proposed method works better.

In Figure 2, we demonstrate the reward distributions of our model and SeqGAN. It can be seen that the reward of SeqGAN cannot reflect the novelty of text accurately. First, when the novelty of text is relatively high, the reward given by SeqGAN saturates and cannot tell the difference between high-novelty text. Even with different degrees of novelty, the two high-novelty sentences sampled from the true data in the figure get nearly

Input: *One of my favorite places to eat.*
MLE: *Service is great.*
PG-BLEU: *Service is always good.*
SeqGAN: *Love the chicken and waffles. Service is always great.*
DP-GAN: *Love the fact that they have a large selection of food. Service is always great and the food is always fresh. I've been to this place a few times and have never been disappointed.*

Input: *Excellent service, clean, nice ambience.*
MLE: *Food is very good.*
PG-BLEU: *Food is very good.*
SeqGAN: *Food is very good.*
DP-GAN: *I had the chicken and beef and it was delicious. Food is good and the service is great. I would recommend this place to anyone who wants to eat here.*

Input: *I brought friends – seven of them – who'd never been to a Bar Louie before.*
MLE: *Food was mediocre, but the service was great. I will not be returning.*
PG-BLEU: *Food was terrible. Wouldn't recommend this place to anyone.*
SeqGAN: *Food was just okay. I wouldn't recommend this place.*
DP-GAN: *Ordered a chicken salad with a side of fries, and it was just ok. Food was good, but the service was slow. I had to ask for a refill on my drink, and the bartender was rude. I wouldn't recommend this place to anyone.*

Input: *I don't think it's too spicy, so i add a little hot curry spice to the sauce.*
MLE: *It's great for cooking. I have to say, I'm not sure if it is the same.*
PG-BLEU: *Love it!*
SeqGAN: *Love it! Love this stuff. I have used it for years and it is very good.*
DP-GAN:*I've tried many different brands of hot sauces but this one is the best. I've also used it in soups and stews. I also like that it is organic and has a great flavor.*

Table 3: Examples generated by DP-GAN and the state-of-the-art models on the Yelp dataset. It can be found that the text generated by baselines is more generic and repeated, while our model generates text with more specific details and higher diversity.

the same reward in SeqGAN. Second, most generated text receives reward around zero because of the high accuracy of classifier. It is hard for such reward to distinguish the difference between low-novelty text. For example, as shown in the figure, "*Both had the brisket and it was delicious*" is much more informative than "*Love it!*". The discriminator of SeqGAN gives them practically the same reward, while the proposed discriminator can better distinguish the two sentences in terms of novelty. In fact, the classifier in SeqGAN trained for 10 epochs can reach very high accuracy, that is, 98.35% and 99.63% for Yelp and Amazon, respectively. If the accuracy of classifier is too high, the classifier cannot give reasonable reward to the generator for generating real and diverse text (Arjovsky et al., 2017).

In contrast, the language-model based reward given by DP-GAN better reflect the novelty of the text. The novel text is given high reward that does not saturate. The generated data, which can be less novel, is given relatively low but nonzero reward that can encourage the generator to generate diverse expressions. The refined reward leads to more efficient training, thus resulting in better performance.

We also compare the cosine similarity between the real-world data distribution and the generated data distributions of various models. Figure 3 shows the results. We calculate the cosine distance between two vectors, where each element is the frequency of a word indexed by its rank in real-world data. For example, the first element in the vector means the frequency of the word that ranks first in real-world data. The word frequency vector is divided into 4 vectors to show the similarity of words of different frequencies. The distribution of words are more similar when they occur more frequently in real-world data. As DP-GAN promotes diversity, words of low frequency in real-world data are better learned and the similarity is much better than that of MLE. In all, the generated data distribution of DP-GAN is closer to the real-world data distribution in all intervals, especially considering the words of low frequency.

Table 3 presents the examples generated by different models on the Yelp dataset. It can be found that the text generated by MLE is more generic and repeated, while PG-BLEU and SeqGAN do not perform obviously better than MLE. Moreover, it can be clearly seen that our model generates text with more specific details and higher diversity.

5 Conclusions

In this paper, we propose a new model, called DP-GAN, to promote the diversity of the generated text. DP-GAN assigns low reward for repeated text and high reward for novel and fluent text, encouraging the generator to produce novel and diverse text. We evaluate DP-GAN on two tasks and the findings are concluded as follows: First, the proposed method substantially outperforms the baseline methods in automatic and human evaluations. It shows that DP-GAN is capable of producing more diverse and informative text. Second, the proposed discriminator can better distinguish novel text from repeated text with the saturation problem compared without traditional classifier-based discriminators. Third, with the improvement of diversity, the generated data distribution of DP-GAN is closer to the real-world data distribution compared with that of MLE.

Towards a Better Metric for Evaluating Question Generation Systems

Abstract

There has always been criticism for using n-gram based similarity metrics, such as BLEU, NIST, *etc*, for evaluating the performance of NLG systems. However, these metrics continue to remain popular and are recently being used for evaluating the performance of systems which automatically generate questions from documents, knowledge graphs, images, *etc*. Given the rising interest in such automatic question generation (AQG) systems, it is important to objectively examine whether these metrics are suitable for this task. In particular, it is important to verify whether such metrics used for evaluating AQG systems focus on *answerability* of the generated question by preferring questions which contain all relevant information such as question type (Wh-types), entities, relations, *etc*. In this work, we show that current automatic evaluation metrics based on n-gram similarity do not always correlate well with human judgments about *answerability* of a question. To alleviate this problem and as a first step towards better evaluation metrics for AQG, we introduce a scoring function to capture *answerability* and show that when this scoring function is integrated with existing metrics, they correlate significantly better with human judgments. The scripts and data developed as a part of this work are made publicly available.[1]

1 Introduction

The advent of large scale datasets for document Question Answering (QA) (Rajpurkar et al., 2016; Nguyen et al., 2016; Joshi et al., 2017; Saha et al., 2018a) knowledge base driven QA (Bordes et al., 2015; Saha et al., 2018b) and Visual QA (Antol et al., 2015; Johnson et al., 2017) has enabled the development of end-to-end supervised models for QA. However, as is always the case, data-hungry neural network based solutions could benefit from even more training data, especially in specific domains which existing datasets do not cater to. Creating newer datasets for specific domains or augmenting existing datasets with more data is a tedious, time-consuming and expensive process. To alleviate this problem and create even more training data, there is growing interest in developing techniques that can automatically generate questions from a given source, say a document (Du et al., 2017; Du and Cardie, 2017), knowledge base (Reddy et al., 2017; Serban et al., 2016), or image (Li et al., 2017) . We refer to this task as Automatic Question Generation (AQG). For example, given the document in Table 1, the task is to automatically generate a question whose answer is also contained in the document.

Document: In **1648** before the term “genocide” had been coined , the Peace of Westphalia was established to protect ethnic, racial and in some instances religious groups.
Possible Question: In which year was the Peace of Westphalia established ?

Table 1: A sample question generated by a human.

Given the practical importance of AQG and its potential to influence research in QA, it is not surprising that there has been prolific work in this field in the past one year itself (Jain et al., 2017; Li et al., 2017; Zhang et al., 2017; Du et al., 2017; Duan et al., 2017). Before this field grows further, it is important that the community critically examines the current evaluation metrics being used for this task. In particular, there is a need to closely examine the utility of existing n-gram based similarity metrics such as BLEU (Papineni et al., 2002), METEOR (Lavie and Denkowski,

Brussels, Belgium, October 31 - November 4, 2018.

2009), NIST (Doddington, 2002), *etc.* which have been adopted for this task. This work is a first step in that direction where we propose that apart from n-gram similarity, any metric for AQG should also take into account the *answerability* of the generated questions. With the help of a few examples below, we illustrate that *answerability* depends on the presence of relevant information such as question type (Wh-types), entities, relations, *etc*, and it is possible that a generated question has a high BLEU score but is still unanswerable and hence not useful.

To begin with, consider the task of answering questions from a Knowledge Base. Let us assume that the intended (gold standard) question is "Who was the director of Titanic?" and two different AQG systems generate the following questions "S1: director of Titanic?" and "S2: Who was the director of?". Any n-gram based evaluation metric would obviously assign a higher score to S2 (BLEU3: 81.9) than S1 (BLEU3: 36.8). However, as should be obvious S1 contains all the relevant information, and most humans would be easily able to understand and answer this question. A good evaluation metric should capture this notion of *answerability* and give more importance to relevant words in the question which brings us to the question "Which words are relevant?"

The above example might give the impression that *named entities* are essential but other words are not. However, this is misleading and may not always be the case. For example, consider these questions over an image: "Are the cats drinking milk?" v/s "How many cats are drinking milk?". These two questions have very different meaning indicating that even words like *are* and *how* are also crucial. Similarly, consider the task of answering questions from a passage titled "Matt Damon". In this case, most humans will be able to answer the question "What is the birth date of" even though the named entity is missing given that the passage only talks about "Matt Damon". Thus, in some cases, depending on the source (document, knowledge base, image) different portions of the question may be important.

To concretize the intuitions developed with the help of the above examples, we first collect human judgments. Specifically, we take questions from existing datasets for document QA, knowledge base QA and visual QA and add systematic noise to these questions. We show these questions to humans and ask them to assign scores to these questions based on the *answerability* and hence the usefulness of these questions (*i.e.*, whether the question contains enough information for them to be able to answer it correctly). We also compute various n-gram similarity metrics (BLEU, METEOR, NIST) comparing the noisy questions to the original questions and show that these metrics do not correlate well with human judgments. Similar studies (Callison-Burch et al., 2006; Liu et al., 2016) have already shown that these metrics do not correlate well with *fluency, adequacy, coherence* but in this work, we focus on *answerability*.

Based on the human evaluations, we propose to modify existing metrics to focus on *answerability* in addition to n-gram similarity. The idea is to make these metrics flexible such that, if needed, the weight assigned to *answerability* and n-gram similarity can be adjusted depending on the task (document QA, Knowledge-Base QA, Visual QA). Further, for capturing *answerability* we propose additional weights for different components of the question (question type, content words, function words, and named entities) These weights can be learned from a small amount of human annotated data and may differ from task to task.

2 Related Work

We have organized our literature survey into 2 parts: (i) question generation systems (ii) studies which analyze evaluation metrics used for NLG.

Question Generation: Early work on question generation used rule-based approaches to generate questions from declarative sentences (Heilman and Smith, 2010; Mostow and Chen, 2009; Lindberg et al., 2013; Labutov et al., 2015). More recent works use attention based neural models for question generation (Du and Cardie, 2017; Du et al., 2017). Some models (Yuan et al., 2017) feed the generated questions to a QA system and use the performance of the QA system as an indicator of the quality of the questions. A few models (Wang et al., 2017; Tang et al., 2017) treat question answering (QA) and question generation (QG) as complementary tasks and focus on jointly training for these two tasks. Other models focus only on the performance of the QA task (Yang et al., 2017; Duan et al., 2017) and not explicitly on the quality of the generated questions. Apart from generating questions from text there is also research on generating questions from images (Jain et al., 2017; Li et al., 2017; Zhang et al., 2017) and knowledge base (Serban et al., 2016; Reddy et al., 2017).

Evaluation metrics for NLG: Current popular metrics for NLG such as BLEU (Papineni et al., 2002), METEOR(Lavie and Denkowski, 2009), ROUGE (Lin, 2004) and NIST (Doddington, 2002) essentially compute the n-gram similarity between the reference sentence and the generated sentence. Though these metrics are very popular and are used for a wide range of NLG tasks including AQG, there has always been criticism for using these metrics (for example, see (Callison-Burch et al., 2006; R et al., 2007; Callison-Burch, 2009)). More recently, there has been criticism (Liu et al., 2016) for using such metrics for evaluating dialog systems eventually resulting in a new metric (Lowe et al., 2017). This new metric while very important, came a bit late in the day and much after several dialog systems were proposed, evaluated and compared using the above n-gram based metrics. It is very important to prevent a similar situation in question generation where many systems get proposed without evaluating them using the right metric. Our work is a first step in this direction, and we hope it will lead to more research in designing the right metrics for AQG.

3 Current Evaluation Metrics

We give a quick overview of the metrics which are currently used for evaluating AQG systems.

BLEU: BLEU is a precision-based evaluation metric which considers exact n-gram matches. For a given value of n, the precision is computed as the fraction of n-grams in the generated hypothesis which match some n-gram in the reference hypothesis. The final BLEU score is computed as the geometric mean of the n-gram precisions obtained by varying n from 1 to N where N is typically 3 or 4. It also contains a brevity penalty to penalize hypothesis that are too short.

METEOR: As opposed to BLEU, METEOR uses both precision and recall, *i.e.*, it computes the fraction of the hypothesis which matches the reference (precision) as well as the fraction of the reference which is contained in the hypothesis (recall). Further, unlike BLEU which only considers exact matches, METEOR also considers matches with stemmed words, synonyms, and paraphrases. It also gives different weightage to matches corresponding to function words and matches corresponding to content words. The final score is the harmonic mean of the precision and recall calculated based on these four matches. Additionally, it also includes a fragmentation penalty to account for gaps and differences in word order. In effect, METEOR is a parametric metric where the different parameters, *viz.*, (i) fragmentation penalty, (ii) weights of different matchers (exact, stemmed, synonyms, paraphrases) and (iii) weights of function and content words, are tuned to maximize correlation with human judgments.

NIST: NIST is a variant of the standard BLEU metric that takes into account the relative importance of each n-grams in the sentence. In particular, the metric gives a high weightage to n-grams which have a lower frequency in the corpus and hence are more informative as compared to very frequent n-grams which are less informative. Further, unlike BLEU which takes the geometric mean of n-gram precisions, NIST takes the arithmetic mean of these precisions. Additionally, they make a small change to the brevity penalty to minimize the impact of minor variations in the length of the hypothesis.

ROUGE: ROUGE is a set of evaluation metrics which were proposed in the context of automatic summarization. Typically, most studies use ROUGE-L, which is F-measure based on the Longest Common Subsequence (LCS) between a candidate and target sentence. Given two sequences, a common subsequence is the set of words which appear in both the sequences in the same order but unlike n-grams the common subsequence does not need to be contiguous. LCS is the longest of such common subsequences. For example, given the sentences candidate:"the boy went home" and reference:"the boy will go home", "the boy home" is the longest common subsequence even though it is not contiguous.

4 Human Judgments For Answerability

As mentioned earlier, for AQG, in addition to n-gram similarity, we also need to focus on the *answerability* of the generated questions. As illustrated in Section 1, answerability of a question depends on whether it contains all relevant information, such as question type (Wh-types), named entities and content words (often relations). Further, depending on the task (document QA, knowledge-base QA or visual QA) the importance of these words may vary. We perform human evaluations to ascertain the importance of each of these components across different QA tasks. These evaluations allow us to independently analyze the importance of each of these components for the 3 QA tasks. In the remainder of this section, we describe the (i) process of creating noisy questions (ii) instructions given to the evaluators and the (iii) inferences drawn from human evaluations.

4.1 Creating Noisy Questions

We took 1000 questions each from 3 popular QA datasets, *viz.*, SQuAD, WikiMovies, and VQA. SQuAD (Rajpurkar et al., 2016) is a reading comprehension dataset consisting of around 100K questions based on passages from around 500 Wikipedia articles. The WikiMovies dataset contains around 100K questions which can be answered from a movie knowledge graph containing 43K entities and 9 relations *(director, writer, actor, etc.)*. The VQA dataset is an image QA dataset containing $265,016$ images with around 5.4 questions on average per image.

We then created noisy versions of these questions using one of the following four methods:

Dropping function words: We refer to the list of English function words as defined in NLTK (Loper and Bird, 2002) and drop all such words from the question. Note that a noisy question with all function words dropped will have a very low BLEU score compared to the original question.

Dropping Named Entities: In our setup, identifying named entities in questions was easy because the questions were well formed and all named entities were capitalized. Alternately, we could have used the Stanford NER. However, on manual inspection, we found that marking the capitalized words as named entities were sufficient. We randomly dropped at most three named entities per question. This allows us to study how humans rate the output of an AQG system which does not contain the correct named entities.

Dropping Content Words: Words other than function words and named entities are also crucial for *answerability*. For example, "Who killed Jane?" and "Who married Jane?" lead to totally different answers. The word "killed/married" is very relevant to ascertain the correct answer. These words typically capture the relation between the entities involved (for example, *killed (John, Jane)*). We identify such important (content) words as ones which are neither question types (7-Wh questions) nor named entities nor stop-words. This perturbation allows us to study how humans rate an AQG system which does not produce the correct content (relation) words.

Changing the Question type: Changing the question type can lead to a different answer altogether or can make the question incoherent. For example the answers to "Who killed Jane?" and "What killed Jane?" are completely different. We create a noisy question by randomly changing the type of the question (for example. replace "who" with "what"). These question types are well defined (7-Wh questions including "*how*") and hence it is easy to identify and replace them. This allows us to study the importance of correct question type in the output of an AQG system.

Note that, an alternate way of collecting human judgments would have been to take the output of existing AQG systems and ask humans to assign answerability scores to these questions based on the presence/absence of the above mentioned relevant information. However, when we asked human evaluators to analyze 200 questions generated by an existing AQG system, they reported that the quality was poor. In particular, after having discussions with annotators, we found that using this output, it would be very difficult to conduct such a systematic study to assess the importance of different words in the question. Hence, we chose to use systematically simulated noisy questions.

4.2 Instructions

We asked the annotators to rate the *answerability* of the above noisy questions on a scale of 1-5. The annotators were clearly told whether the questions belonged to documents or knowledge bases or images. In our initial evaluations, we also tried showing the actual source (image or document) to the annotators. However, we realized that this did not allow us to do an unbiased evaluation of the quality of the questions. The annotators inferred missing information from the document or image and marked the question as answerable (even though the relevant entity *cat* is missing in the question). For example, consider the image of a cat drinking milk and the question "What is the drinking ?" If a human is shown the image then she can easily infer that the missing information is "cat" and hence mark the question as answerable. This clearly biases the study, and therefore we did not show the source to the evaluators.

Rating	**Description**	**Examples**
1	All important information is missing and it is impossible to answer the question	“What is against the ~~sign~~ ?”, “Why is using ~~O2~~ instead of ~~CO2~~ less efficient?”
2	Most of the important information is missing and I can’t infer the answer to the question	“Which films did ~~Lee H. Katzin~~ direct ?”, “Low doses of ~~anti-inflammatories~~ are sometimes used with what ~~classes~~ of drugs?”
3	Some important information is missing leading to multiple answers	“What Harvard Alumni ~~was the~~ Palestine Prime Minister?”, “What country ~~is the~~ teaching subject discussing?”
4	Most of the important information is present and I can infer the answer	“How ~~far~~ from the Yard is the Quad located?”,“what ~~films~~ did Melvin Van Peebles star in?”
5	All important information is present and I can answer the question	“What globally popular half marathon began ~~in~~ 1981?”, “What kind ~~of~~ vehicle ~~is~~ parked ~~the~~ sidewalk?”

Table 2: Instructions along with the examples. The striked out words were removed as a part of systematic noise from the original question.

Dataset	κ	Pearson	Spearman
SQuAD	0.63	0.823	0.795
WikiMovies	0.81	0.934	0.927
VQA	0.70	0.842	0.822

Table 3: Inter annotator agreement, Pearson and Spearman coefficients between Human Scores.

A total of 25 in-house annotators participated in our study, and we got each question evaluated by two annotators. The annotators were Computer Science graduates competent in English. We did an initial pilot using the instructions mentioned in Table 2, but due to the subjective nature of the task, it was difficult for the annotators to agree on the notion of *important information*. In particular, we found that the annotators disagreed between *most important information* and *all important information* (*i.e.*, they were confused between rating 1 v/s 2 and 4 v/s 5). We, therefore, did a small pilot with a group of 10 annotators and asked them to evaluate around 30 questions from each dataset and help us refine the guidelines to define the notion of importance clearly. Based on group discussions with the annotators we arrived at additional example based guidelines to help them distinguish between cases where *“all the”*, *“most of the”* and *“some of the”* important information is present. The original instructions and various examples (some of which are shown in Table 2) were then shared and explained to all the annotators, and they used these to provide their judgments.

4.3 Human-Human Correlation

In Table 3, we report the average inter-annotator agreement between the ratings using Cohen’s kappa (κ) score (Cohen, 1968). Based on guidelines in (McHugh, 2012) we note that we have a strong inter-annotator agreement for WikiMovies and moderate agreement for SQuAD and VQA. Figure 1 indicates that there is a linear correlation between the two ratings for each question and hence we measured the correlation using Pearson coefficient. For completeness, we also measure the monotonic correlation using Spearman coefficient. The Spearman coefficient is slightly lower than the Pearson coefficient because the inter-annotator agreement is stronger at the tail of the distribution *i.e.*, when the question is either very bad (Rating: 1) or very good (Rating: 5).

Metric	**SQuAD**		**WikiMovies**		**VQA**	
	Pearson	*Spearman*	*Pearson*	*Spearman*	*Pearson*	*Spearman*
BLEU1	0.167	0.165	0.179	0.144	-0.025*	-0.048*
BLEU2	0.100*	0.103*	0.072*	0.087*	-0.075*	-0.091*
BLEU3	0.080*	0.086*	0.036*	0.001*	-0.126	-0.114
BLEU4	0.065*	0.067*	-0.020*	-0.011*	-0.086*	-0.127
ROUGE-L	0.165	0.158	0.091*	0.043*	-0.009*	-0.053*
METEOR	0.107	0.124	0.198	0.214	-0.035*	0.009*
NIST	0.173	0.158	0.088*	-0.033*	0.158	0.169

Table 4: Correlation between existing metrics and human judgments. Note that the values with $*$ are **not** statistically significant (p-value > 0.01).

4.4 Correlation between human scores and existing evaluation metrics

We first compute BLEU, METEOR, NIST and ROUGE-L score for each noisy question by comparing it to the original question. We then compute the correlation of each of these scores with annotator ratings. Note that to compute correlation, the annotator ratings are combined to obtain a gold score. The ratings are normalized using the normalization method mentioned in (Blatz et al., 2004) and then averaged to obtain the gold score. For SQuAD and VQA, we observe that NIST which gives more weightage to informative n-grams correlates better than other metrics. For WikiMovies, METEOR which even allows non-

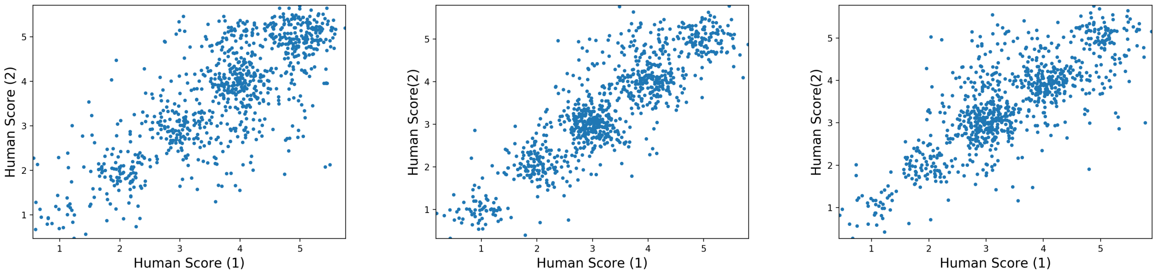

Figure 1: Human-Human Correlation for SQUAD, WikiMovies and VQA respectively.

exact word matches correlates better than other metrics. For SQuAD and WikiMovies, the correlation of human scores with the simple unigram based BLEU1 score is higher than that with other metrics. This is in line with the observation we made earlier that humans can understand and answer questions that are not well-formed, *e.g.*, "What birth-date Damon?".

5 Modifying existing metrics for AQG

The above study suggests that existing metrics do not correlate well with human judgments about *answerability*. We propose modifications to these metrics so that in addition to n-gram similarity they also account for *answerability*. Based on the human evaluations, we found that *answerability* mainly depends on the presence of 4 types of elements, *viz.*, *relevant content words*, *named entities* and *question types* and *function words*. As outlined in Section 4.1 it is easy to identify these elements in the question. Let $c(S_r), c(S_n), c(S_q)$ and $c(S_f)$ be the number of **r**elevant words, **n**amed entities, **q**uestion words and **f**unction words respectively in the noisy question which have corresponding matching words in the gold standard reference question. We can then compute the weighted average of the precision and recall of each of these elements as

$$P_{avg} = \sum_i w_i \frac{c(S_i)}{|l_i|} \qquad R_{avg} = \sum_i w_i \frac{c(S_i)}{|r_i|}$$

where $i \in \{r, n, q, f\}$, $\sum_i w_i = 1$ and $|l_i|$, $|r_i|$ is the number of the words belonging to i^{th} type of element in the noisy question and reference sentences respectively. Just to be clear r, n, q, f stand for *relevant content words*, *named entities* and *question types* and *function words* respectively. Note that w_i's are tunable weights and in Section 5.1, we explain how to tune these weights.

Datasets	w_{ner}	w_{imp}	w_{sw}	w_{qt}	δ

Table 5: Coefficients learnt for Q-BLEU1 from human judgments across different datasets.

$$\text{Answerability} = 2.\frac{P_{avg} R_{avg}}{P_{avg} + R_{avg}}$$

We can combine this *answerability* score with any existing metric (say, BLEU4) to derive a modified metric for AQG as shown below:

$$Q\text{-BLEU4} = \delta \text{Answerability} + (1 - \delta)\text{BLEU4} \tag{1}$$

such that $\delta \in \{0, 1\}$ to make sure that Q-Metric ranges between 0 to 1. Similarly, we can derive Q-NIST, Q-METEOR and so on.

5.1 Tuning the weights w_i's and δ

We tuned the weights (w_i's and δ) using the human annotation data. For each source (document, knowledge-base, and images), annotators evaluated 1000 noisy questions. The annotator scores were first scaled between 0 to 1 using the normalization method in (Blatz et al., 2004), and the normalized scores were averaged to obtain the final gold score. For each source, we used 300 of these annotations and used bagging to find the optimal weights. In particular, we drew 200 samples randomly from the given set of 300 samples and did a grid search to find w_i's and δ such that the Q-METRIC computed using Equation 1 had maximum correlation with human scores. We repeated this process for $k = 20$ times and computed the optimal w_i's and δ each time. We found that for

Q-Metric	SQuAD		WikiMovies		VQA	
	Pearson	*Spearman*	*Pearson*	*Spearman*	*Pearson*	*Spearman*
Q-BLEU1	0.258	0.255	0.828	0.841	0.405	0.384
Q-BLEU2	0.244	0.243	0.825	0.835	0.390	0.360
Q-BLEU3	0.239	0.240	0.824	0.837	0.374	0.331
Q-BLEU4	0.233	0.232	0.826	0.837	0.373	0.311
Q-ROUGE-L	0.253	0.249	0.821	0.841	0.402	0.385
Q-METEOR	0.158	0.157	0.821	0.837	0.402	0.378
Q-NIST	0.246	0.248	0.824	0.845	0.384	0.346

Table 6: Correlation between proposed Q-Metric and human judgments. All the correlations have a p-value < 0.01 and hence statistically significant.

any given weight (w_i) the standard deviation was very low across these k experiments. For each w_i and δ we obtained the final value by taking an average of the values learned in each of the k experiments. We also observed that the weights did not change much even when we used more data for tuning. Also note that we tuned these weights separately for each metric (*i.e.*, Q-BLEU4, Q-NIST, Q-METEOR and so on). For illustration, we report these weights for Q-BLEU1 metric in Table 5. As expected, the weights depend on the source from which the question was generated. Note that for WikiMovies, named entities have the highest weight. For VQA content words are most important, as they provide information about the entity being referred to in the question. Note that for SQuAD and VQA, the original base metric also gets weightage comparable to other components, indicating that a fluent question makes it easier to understand thus making it answerable. The overall trend for the values of w_i's was similar for other Q-METRICs also (*i.e.*, for Q-NIST, Q-METEOR and so on).

5.2 Correlation between Human scores and different Q-METRICs

Once the weights are tuned, we fix these weights and compute the Q-METRIC for the remaining 600-700 examples and report the correlation with human judgments for the same set of examples (see Table 6). For a fair comparison, the correlation scores reported in Table 4 are also on the same 600-700 examples. The correlation scores obtained for different Q-METRICs are indeed encouraging. In particular, we observe that while the correlation of existing metrics with noisy questions generated was very low (Table 4), the correlation of the modified metrics is much higher. This suggests that adding the learnable component for *answerability* and tuning its weights indeed leads to a better-correlated metric. Note that for VQA and SQuAD the correlations are not as high as human-human correlations, but the correlations are still statistically significant. We acknowledge that there is clearly scope for further improvement and the proposed metric is perhaps only a first step towards designing an appropriate metric for AQG. Hopefully, the human evaluation data released as a part of this work will help to design even better metrics for AQG.

5.3 Qualitative Analysis

We have listed some examples in Table 7, which highlight some strengths and weakness of the proposed Q-METRIC. We categorize examples as positive/negative depending on the similarity between human scores for answerability and the Q-BLEU score. For the examples marked as positive, the Q-BLEU score is very close to the *answerability* score given by humans.

6 Extrinsic evaluation

So far we have shown that existing metrics do not always correlate well with human judgments and it is possible to design metrics which correlate better with human judgments by including a learnable component to focus on *answerability*. We would now like to propose an extrinsic way of evaluating the usefulness of the proposed metric. The motivation for this extrinsic evaluation comes from the fact that one of the intended purposes of the modified metrics is to use them for training QA systems. Suppose we use a particular metric for evaluating the quality of an AQG system and suppose this metric suggests that the questions generated by this system are poor. We would obviously

Dataset		Original Question	Modified Question	Human Scores	QBLEU

discard this system and not use the questions generated by it to train a QA system. However, if the metric itself is questionable, then it is possible that the questions were good enough, but the metric was not good to evaluate their quality. To study this effect, we create a noisy version of the training data of SQuAD, WikiMovies, and VQA using the same methods outlined in Section 4.1. We then train a state of the art model for each of these tasks on this noisy data and evaluate the trained model on the original test set of each of these datasets. The models that we considered were (Seo et al., 2016) for SQuAD, (Miller et al., 2016) for WikiMovies and (Ben-younes et al., 2017) for VQA.

The results of our experiments are summarized in Table 8 - 10. The first column for each table shows the manner in which the noisy training data was created. The second column shows the BLEU4 score of the noisy questions when compared to the original reference questions (thus it tells us the perceived quality of these questions under the BLEU4 metric). We consider BLEU4 because of all the current metrics used for AQG it is the most popular. Similarly, the third column tells us the perceived quality of these questions under the Q-BLEU4 metric. Ideally, we would want that the performance of the model should correlate better with the perceived quality of the training questions as identified by a given metric. We observe that the general trend is better *w.r.t.* the Q-BLEU4 metric than the BLEU4 metric (*i.e.*, in general, higher Q-BLEU4 indicates better performance and lower Q-BLEU4 indicates poor performance). In particular, notice that BLEU4 gives much importance to stop words, but these words hardly have any influence on the final performance. We believe that such an extrinsic evaluation should also be used while designing better metrics and it would help us get better insights.

7 Conclusion

The main aim of this work was to objectively examine the utility of existing metrics for AQG. Specifically, we wanted to see if existing metrics account for the *answerability* of the generated questions. To do so, we took noisy generated questions from three different tasks, *viz.*, document QA, knowledge base QA and visual QA, and showed that the *answerability* scores assigned by humans did not correlate well with existing metrics. Based on these studies, we proposed a modification for existing metrics and showed that with the proposed modification these metrics correlate better with human judgments. The proposed modification involves learnable weights which can be tuned (depending on the source) using the human judgments released as a part of this work. Finally, we propose an extrinsic evaluation with the aim of assessing the end utility of these metrics in selecting good AQG systems for creating training data for QA systems. Though the proposed metric correlates better with human judgments, there is still scope for improvement especially for document QA and visual QA. As future work, we would like to design better metrics for answerability and check if a non-linear combination of different elements in the Q-Metric leads to better correlation with human judgments.

Abstract

The ability to write diverse poems in different styles under the same poetic imagery is an important characteristic of human poetry writing. Most previous works on automatic Chinese poetry generation focused on improving the coherency among lines. Some work explored style transfer but suffered from expensive expert labeling of poem styles. In this paper, we target on stylistic poetry generation in a fully unsupervised manner for the first time. We propose a novel model which requires no supervised style labeling by incorporating mutual information, a concept in information theory, into modeling. Experimental results show that our model is able to generate stylistic poems without losing fluency and coherency.

1 Introduction

Classical Chinese poetries are great heritages of the history of Chinese culture. One of the most popular genres of classical Chinese poems, *i.e. quatrains*, contains four lines with five or seven characters each and additional rhythm and tune restrictions. During 1,000 years history of quatrains, various styles, *e.g.* pastoral, descriptive and romantic, have been developed to express different feelings of poets. In human poetry writing, poets are able to write completely different poems in diverse styles even given the same keyword or first sentence. For example, as shown in Fig. 1, when a poet mentioned "月" (the moon), she/he may write about the Great Wall in the battlefield style or the sleepless feeling in the romantic style. Such ability to write stylistic poems under the same poetic imagery is an important characteristic of human poetries.

Automatic poetry generation is one of the first attempts towards computer writing. Chinese quatrain generation has also attracted much attention in recent years. Early works inspired by statistical machine translation explored rule-based and template-based methods (He et al., 2012; Yan et al., 2013), while recent works (Zhang and Lapata, 2014; Wang et al., 2016; Yan, 2016; Zhang et al., 2017; Yang et al., 2017; Yi et al., 2017) employed neural network based sequence-to-sequence approaches which have shown their effectiveness in neural machine translation for poem generation. Most works target on improving the coherency among all lines and the conformity between the theme and subsequent lines by planning (Wang et al., 2016), polishing schema (Yan, 2016), poem block (Yi et al., 2017) and conditional variational autoencoder (Yang et al., 2017). Different from these previous works, we aim to learn the ability of diverse stylistic poetry generation which can generate multiple outputs (poems) in various styles under the same input (keywords or the first sentence). This ability enables a poetry generation system to be closer to a real poet and allows the model to generate more expressive and creative poems.

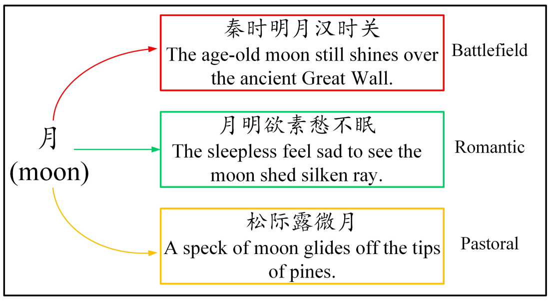

Figure 1: An example of poems in diverse styles under the same keyword.

However, there is no explicit label about what style or category a poem or a sentence is for thousands of poems in the database. Therefore, traditional supervised sequence-to-sequence mod-

els (Zhang et al., 2017) are not capable to generate stylistic poems without expert labeling. To the best of our knowledge, we are the first effort at stylistic poetry generation in a fully unsupervised manner.

In this paper, we propose a novel poetry generation model which can disentangle the poems in different styles and generate style-specific outputs conditioned on the manually selected style input. We employ sequence-to-sequence model with attention mechanism (Bahdanau et al., 2014) as our basis and maximize the mutual information which measures the dependency between two random variables in information theory to strengthen the relationship between manually selected style inputs and generated style-specific outputs. Experimental results show that our model is able to generate poems in various styles without losing fluency and coherency.

To summarize, our effort provides the following three contributions:

- To the best of our knowledge, we are the first effort at stylistic poetry generation which is an important characteristic of human poetries in a fully unsupervised manner.
- We innovatively incorporate mutual information, a measurement in information theory, for unsupervised style disentanglement and style-specific generation.
- Experimental results show that our model is able to generate diverse poems in various styles without losing fluency and coherency.

2 Related Works and Motivations

Poetry generation is a classic task in computer writing (Gervás, 2001; Levy, 2001; Netzer et al., 2009; Oliveira, 2012). Chinese poetry generation has also attracted much attention during the last decade. Early works are mostly rule-based and template-based (Wu et al., 2009). (He et al., 2012) employed statistical machine translation and (Yan et al., 2013) adopted automatic summarization techniques for classical poem generation.

As neural network based approaches have been successfully applied in various applications such as machine translation (Bahdanau et al., 2014), people came up with the idea to apply sequence-to-sequence models for poem generation. (Zhang and Lapata, 2014) employed the Recurrent Neural Network (RNN) as their basis and further considered the global context using Convolutional Neural Network (CNN). They also incorporated other hand-crafted features into the model to improve the coherency. (Yan, 2016) proposed an iterative polishing schema based on two RNNs, which can refine the generated poems for several times. (Wang et al., 2016) generated poetries in a two-stage process: planning the keywords of each line first and then generating each line sequentially. (Yi et al., 2017) proposed poem blocks to learn semantic meaning within a single line and semantic relevance among lines in a poem. (Yang et al., 2017) employed a conditional variational autoencoder with augmented word2vec architecture to enhance the conformity between the theme and generated poems. All previous works above target on improving the coherency and conformity of poetry generation while a recent work (Zhang et al., 2017) was proposed to improve the novelty of generated poems using external memories. Their model can also transfer the style of a poem into three predefined topics. However, they need to manually label many poems in these three predefined topics to learn the patterns.

Formally, a traditional sequence-to-sequence model actually learns a conditional probability distribution $\Pr(s_{output}|s_{input})$ where s_{output} is the generated poems and s_{input} is the input keyword or the first sentence. Different from machine translation tasks where the output sentence s_{output} is rather certain and compact given input sentence s_{input}, the conditional probability distribution $\Pr(s_{output}|s_{input})$ has strong uncertainty in literary creation scenarios such as poem generation. To support this point, we further train a topic model based on LDA (Blei et al., 2003) by treating each poem as a document. We train a 10-topic and a 20-topic LDA model and then reanalyze the largest topic component of each sentence in a poem. Surprisingly, we find that only 20% and 10% consecutive sentences in a poem have the same largest topic components respectively though we assume that each poem is generated by the same topic when training the LDA model. The fact indicates that even given the former sentence, the style of the latter one could still be diverse and flexible. Intuitively, poets will choose a style or topic in their minds and then write the next sentence based on the style they choose in poetry creation. Therefore, we propose to learn a stylistic poetry generation model which can disentangle the poems in different styles and generate style-specific outputs as real human poets could do. Note that no explicit style labels are given to the training data and thus previous supervised algorithms cannot be adapted for the purpose easily.

Recently, a few works have been proposed for disentangled representation learning. InfoGAN (Chen et al., 2016) was proposed for generating continuous image data conditioned on image labels and disentangled text generation (Hu et al., 2017) focused on controllable generation in the semi-supervised setting. Though inspired by them, the motivation and proposed models of our work differ from these methods by a large margin. To the best of our knowledge, we are the first effort at stylistic poetry generation in a fully unsupervised manner.

3 Method

We hope our generation model can generate multiple outputs in various styles. Formally, our model takes two arguments as input: input sentence s_{input} and style id $k \in 1, 2 \ldots K$ where K is the total number of different styles. Then we can enumerate each style id k and generate style-specific output sentence s^k_{output} respectively.

In this section, we will start by introducing the background knowledge about mutual information and sequence-to-sequence model with attention mechanism. Then we propose our framework of decoder model for style disentanglement by taking the mutual information as an additional regularization term. Finally, we will present the details of our implementations of each component in the framework.

3.1 Mutual Information

Inspired by previous works on image generation (Chen et al., 2016) and semi-supervised generation (Hu et al., 2017), we propose to incorporate the concept of mutual information in information theory for style disentanglement. Given two random variables X and Y, the mutual information $I(X, Y)$ measures "the amount of information" obtained about one random variable given another one [1]. Mutual information can also be interpreted as a measurement about how similar the joint probability distribution $p(X, Y)$ is to the product of marginal distributions $p(X)p(Y)$. The definition of mutual information is

$$I(X, Y) = \int_Y \int_X p(X, Y) \log \frac{p(X, Y)}{p(X)p(Y)} dX dY. \quad (1)$$

3.2 Sequence-to-Sequence Model with Attention Mechanism

We employ a widely used Encoder-Decoder framework (Sutskever et al., 2014) which was firstly proposed in machine translation as our basis. Suppose sentence $X = (x_1 x_2 \ldots x_T)$ and $Y = (y_1 y_2 \ldots y_T)$ are the input sentence (source sentence) and output sentence (target sentence) respectively where x_i, y_i for $i = 1, 2 \ldots T$ are characters and T is the total number of characters in the sentence. We denote the character vocabulary as V.

Specifically, we use bidirectional LSTM (biLSTM) (Hochreiter and Schmidhuber, 1997; Schuster and Paliwal, 1997) model as the encoder to project the input sentence X into the vector space. Formally, the hidden state of LSTM are computed by

$$\overrightarrow{h_i} = LSTM_{forward}(\overrightarrow{h_{i-1}}, e(x_i)), \quad (2)$$

$$\overleftarrow{h_i} = LSTM_{backward}(\overleftarrow{h_{i-1}}, e(x_{T-i+1})), \quad (3)$$

for $i = 1, 2 \ldots T$ where $\overrightarrow{h_i}$ and $\overleftarrow{h_i}$ are the i-th hidden state of forward and backward LSTM respectively, $e(x_i) \in \mathcal{R}^d$ is the character embedding of character x_i and d is the dimension of character embeddings. Then we concatenate corresponding hidden states of forward and backward LSTM $h_i = [\overrightarrow{h_i}, \overleftarrow{h_{T-i+1}}]$ as the i-th hidden state of biLSTM. In specific, we use the last hidden state h_T as the embedding vector and feed it to the decoder.

The decoder module contains an LSTM decoder with attention mechanism (Bahdanau et al., 2014) which computes a context vector as a weighted sum of all encoder hidden states to represent the most relevant information at each stage. The character probability distribution when decoding the i-th character can be expressed as

$$p(y_i | y_1 y_2 \ldots y_{i-1}, X) = g(y_i | s_i), \quad (4)$$

where $g(\cdot)$ is a linear projection function with softmax regularization, s_i is the i-th hidden state in the decoder LSTM:

$$s_i = LSTM_{decoder}(s_{i-1}, [e(y_{i-1}), a_i]), \quad (5)$$

for $i = 2, \ldots T$ and $s_1 = h_T$, where $[\,]$ indicates concatenation operation, $e(y_{i-1})$ is character embedding of y_{i-1} and a_i is the context vector

---

[1] `https://en.wikipedia.org/wiki/Mutual_information`

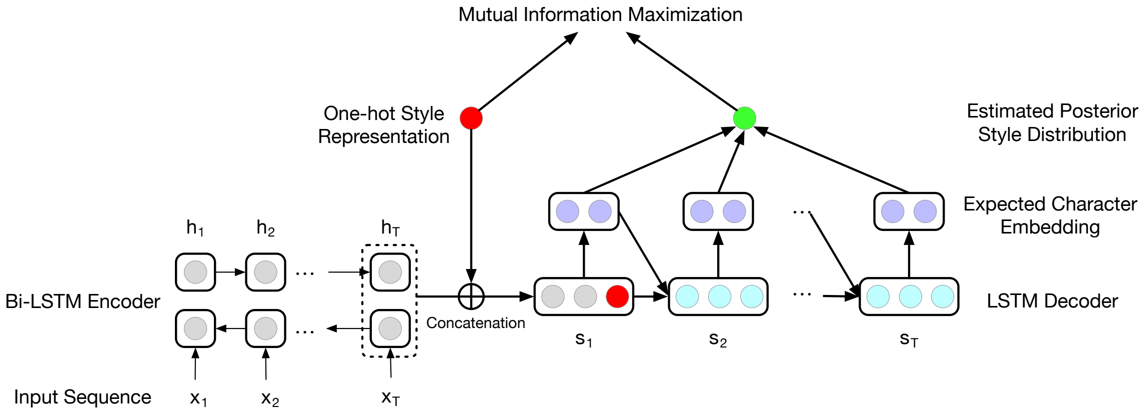

Figure 2: An overview of style disentanglement by mutual information maximization.

learned by attention mechanism (Bahdanau et al., 2014)

$$a_i = attention(s_{i-1}, h_{1:T}). \tag{6}$$

3.3 Decoder Model with Style Disentanglement

To accept two arguments, *i.e.*, input sentence X and style id k, we can directly concatenate the one-hot representation of style id $one\_hot(k)$ and the embedding vector h_T obtained by bi-LSTM encoder and then feed the concatenated vector $[one\_hot(k), h_T]$ instead of h_T into the decoder model without changing anything else.

However, there is no theoretical guarantee that the output sentence generated by the decoder is strongly correlated to the style id input $one\_hot(k)$. In other words, when the input style id is changed, the output sentence would probably be the same because no supervised loss is given to force the output sentences to follow the one-hot style representation. Therefore, we naturally come up with the idea to add a regularization term to force a strong dependency relationship between the input style id and generated sentence.

Without loss of generality, we assume that the input style id is a uniformly distributed random variable Sty and $\Pr(Sty = k) = \frac{1}{K}$ for $k = 1, 2 \ldots K$ where K is the total number of styles. Recall that mutual information quantifies the mutual dependency between two random variables. Hence we propose to maximize the mutual information between the style distribution $\Pr(Sty)$ and the generated sentence distribution $\Pr(Y; X)$ given input sentence X to strengthen the dependency between them as shown in Fig. 2. The mutual information is computed as

$$\begin{aligned}
&I(\Pr(Sty), \Pr(Y;X)) \\
=&\sum_{k=1}^{K}\Pr(Sty=k)\int_{Y|k;X}\log\frac{\Pr(Y,Sty=k;X)}{\Pr(Sty=k)\Pr(Y;X)}dY \\
=&\sum_{k=1}^{K}\Pr(Sty=k)\int_{Y|k;X}\log\frac{\Pr(Y,Sty=k;X)}{\Pr(Y;X)}dY \\
&-\sum_{k=1}^{K}\Pr(Sty=k)\log\Pr(Sty=k) \\
=&\sum_{k=1}^{K}\Pr(Sty=k)\int_{Y|k;X}\log\Pr(Sty=k|Y)dY+\log K \\
=&\int_{Y;X}\sum_{k=1}^{K}\Pr(Sty=k|Y)\log P(Sty=k|Y)dY+\log K.
\end{aligned} \tag{7}$$

Note that the input sequence X and style Sty are both input arguments and thus independent with each other. Therefore, posterior distribution $\Pr(Sty = k|Y; X) = \Pr(Sty = k|Y)$.

But the posterior probability distribution $\Pr(Sty = k|Y)$ is actually unknown, we cannot compute the integration directly. Fortunately, with the help of variational inference maximization (Barber and Agakov, 2003), we can train a parameterized function $Q(Sty = k|Y)$ which estimates the posterior distribution and maximize a lower bound of mutual information in Eq. 7 instead:

$$\begin{aligned}
&I(\Pr(Sty), \Pr(Y;X)) - \log K \\
=&\int_{Y;X}\sum_{k=1}^{K}\Pr(Sty=k|Y)\log\Pr(Sty=k|Y)dY \\
=&\int_{Y;X}\sum_{k=1}^{K}\Pr(Sty=k|Y)\log Q(Sty=k|Y)dY \\
&+\int_{Y;X}\sum_{k=1}^{K}\Pr(Sty=k|Y)\log\frac{\Pr(Sty=k|Y)}{Q(Sty=k|Y)}dY
\end{aligned}$$

$$
\begin{aligned}
&= \int_{Y;X} \sum_{k=1}^{K} \Pr(Sty = k|Y) \log Q(Sty = k|Y) dY \\
&\quad + \int_{Y;X} KL(\Pr(Sty|Y), Q(Sty|Y)) dY \\
&\geq \int_{Y;X} \sum_{k=1}^{K} \Pr(Sty = k|Y) \log Q(Sty = k|Y) dY \\
&= \sum_{k=1}^{K} \Pr(Sty = k) \int_{Y|k;X} \log Q(Sty = k|Y) dY.
\end{aligned} \tag{8}
$$

Here $KL(\Pr(\cdot)||Q(\cdot))$ indicates the KL-divergence distance between probability distribution $\Pr(\cdot)$ and $Q(\cdot)$. The inequality comes from the fact that the KL-divergence is always no less than zero and is tight when $\Pr(\cdot) = Q(\cdot)$.

We use the lower bound parameterized by function Q in Eq. 8 as an additional maximization term. Intuitively, the lower bound is maximized if we can perfectly infer the style id from generated style-specific outputs by inference function Q. It also indicates that generated outputs will heavily depend on the input style id and outputs generated by different styles are distinguishable, which follows our motivation of stylistic poetry generation. Now we will introduce how to design the posterior distribution estimation function Q and compute the integration in the lower bound.

3.4 Posterior Distribution Estimation

Given an output sequence Y, the function Q estimates the probability distribution of the style of sequence Y and therefore disentangles different styles. In this paper, we employ neural network to parametrize the posterior distribution estimation function Q. Specifically, we first compute the average character embeddings of sequence Y and then use a linear projection with softmax normalizer to get the style distribution. Formally, $Q(Sty|Y)$ is computed as

$$
Q(Sty|Y) = \mathit{softmax}(W \cdot \frac{1}{T} \sum_{i=1}^{T} e(y_i)), \tag{9}
$$

where $W \in \mathcal{R}^{K \times d}$ is the linear projection matrix.

Then the last thing to do is to compute the integration over $Y|k;X$. However, the search space of sequence Y is exponential to the size of vocabulary. Hence it's impossible to enumerate all possible sequence Y for computing the integration. Also, it is not differentiable if we sample sequence Y according to generation probability for approximation. Therefore, we propose to use expected character embedding to approximate the integration.

3.5 Expected Character Embedding

Inspired by previous works (Kočiský et al., 2016), we use expected character embedding to approximate the probabilistic space of output sequences: we only generate an expected embedding sequence and suppose $Y|k;X$ has one hundred percent probability generating this one. Formally, Eq. 4 gives a probability distribution of generating the i-th character given previous ones. Then the "expected" generated character embedding is

$$
\mathit{expect}(i;k,X) = \sum_{c \in V} g(c|s_i) e(c), \tag{10}
$$

where $\mathit{expect}(i;k,X) \in \mathcal{R}^d$ represents the expected character embedding at i-th output given style id k and input sequence X and $c \in V$ enumerates all characters in the vocabulary.

Then $\mathit{expect}(i;k,X)$ is fed into the LSTM in decoder to update the hidden state for generating next expected character embedding:

$$
s_{i+1} = LSTM_{decoder}(s_i, [\mathit{expect}(i;k,X), a_{i+1}]). \tag{11}
$$

Finally, we use the expected embeddings $\mathit{expect}(i;k,X)$ for $i = 1, 2 \ldots T$ as an approximation of the whole probability space of $Y|k;X$. The lower bound in Eq. 8 can be rewritten as

$$
\mathcal{L}_{reg} = \frac{1}{K} \sum_{k=1}^{K} \log\{\mathit{softmax}(W \cdot \frac{1}{T} \sum_{i=1}^{T} \mathit{expect}(i;k,X))[k]\}, \tag{12}
$$

where $x[j]$ represents the j-th dimension of vector x.

We add the lower bound $\mathcal{L}_{reg}$ to the overall training objective as a regularization term. The computing process is shown in Fig. 2. Then for each training pair (X,Y), we aim to maximize

$$
\mathit{Train}(X,Y) = \sum_{i=1}^{T} \log p(y_i|y_1 y_2 \ldots y_{i-1}, X) + \lambda \mathcal{L}_{reg}, \tag{13}
$$

where $p(y_i|y_1 y_2 \ldots y_{i-1}, X)$ is style irrelevant generation likelihood and computed by setting one-hot style representation to an all-zero vector, and λ is a harmonic hyperparameter to balance the log-likelihood of generating sequence Y and the lower bound of mutual information. The first term ensures that the decoder can generate fluent and coherent outputs and the second term guarantees the style-specific output has a strong dependency on the one-hot style representation input.

Note that unlike machine translation task where the trained model is desired to generate exactly the same as the target, poetry generation encourages novelty as an important requirement. In Eq. 13, we can also enumerate the style id representation as a one-hot vector instead of an all-zero one. However, this will force the generation of all styles to be close to the training target and discourage the diversity and novelty.

Moreover, our model is not task-specific: the regularization term $\mathcal{L}_{reg}$ can be added to other models conveniently for diverse or stylistic generations. A Chinese quatrain has at most 4*7=28 characters and clear rhyme requirements. As the first attempt on unsupervised style disentanglement, we find Chinese poetry generation is an ideal choice for evaluation because we can better focus on stylistic generation rather than dealing with genre requirements. We will explore the applicability of our model on other languages and tasks for future work.

4 Experiments

Following the experimental settings in previous works (Zhang et al., 2017), we conduct human judgment to evaluate the performance of our model and state-of-the-art baseline methods. We will first introduce the dataset, our model details, baseline methods and evaluation settings. Then we will present the experimental results and give further analysis about the evaluation. Finally, we will present some example generations for case study.

4.1 Dataset and Model Details

We collect 168,000 poems (half *wuyan*: five characters per line, half *qiyan*: seven characters per line) over 1,000 years history of classical Chinese poetries as our corpus. We randomly select 80% of the corpus as training set, 10% as validation set and leave the rest for test. We extract all consecutive sentences in a poem as training pairs (X, Y) and feed them into our model.

For hyperparameter settings of our model, *i.e.* stylistic poetry generation (SPG), we set the dimensions of character embeddings and encoder hidden states as $d = 512$. The total number of styles is set to $K = 10$. Hence the dimension of decoder hidden states is $512 + 512 + 10 = 1034$. We pack the training pairs to mini-batches and the size of mini-batches is set to 50. The harmonic hyperparameter is set to $\lambda = 0$ for the first $50,000$ mini-batches as pretraining and $\lambda = 1.0$ for subsequent batches. We use Adam optimizer (Kingma and Ba, 2014) for stochastic gradient descent. We also employ dropout (Srivastava et al., 2014) strategy with dropout rate 0.2 to avoid overfitting problem. We terminate the training process when the optimization loss on validation set is stable, *i.e.* $300,000$ mini-batches in total.

4.2 Baselines

We consider the following state-of-the-art poetry generation models for comparison:

- **Seq2seq** (Bahdanau et al., 2014) is the sequence-to-sequence model with attention mechanism. Note that seq2seq is the basis of our SPG model. We can better analyze the improvement by style disentanglement from the comparison with seq2seq.
- **Polish** (Yan, 2016) proposed an iterative schema to polish and refine the generated sentences for several times instead of a one-pass generation.
- **Memory** (Zhang et al., 2017) incorporated external memory into poem generation for better novelty. The memory can be seen as a regularization to constrain the behavior of the neural model.

Rule-based and template-based methods are not considered as our baselines as they have been already thoroughly compared in (He et al., 2012; Yan, 2016).

4.3 Evaluation Settings

Following the settings in (Zhang et al., 2017), we employ human judgment for evaluation. To better compare the ability to generate fluent and coherent poems, we fix the first sentence as input and let all models generate three subsequent sentences. The first sentences are randomly chosen from the poems in the test set. Therefore we also consider the original poems written by real poets for comparison.

Note that our SPG model need a manually specified style id as input. For fully automatic poem generation, we use the posterior style estimation function $Q(\cdot)$ to infer the style of the first sentence and then generate next three sentences sequentially using the same style.

As previous works (Manurung, 2004; Yi et al., 2017) did, we design four criteria for human judgment: **Fluency** (are the generated poems fluent and well-formed?), **Coherence** (is the topic of the whole quatrain consistent?), **Meaningfulness**

Group	Methods	Fluency		Coherence		Meaningfulness		Poeticness	
		wuyan	qiyan	wuyan	qiyan	wuyan	qiyan	wuyan	qiyan
Group 1	seq2seq	2.75	2.48	2.60	2.33	2.38	2.15	2.40	2.35
	SPG	**3.43**	**3.23**	**3.13**	**3.05**	**2.83**	**3.10**	**3.10**	**3.10**
Group 2	memory	2.50	2.60	2.30	2.38	2.18	2.25	2.05	2.40
	polish	2.53	2.90	2.28	2.55	2.15	2.55	2.20	2.50
	SPG	**3.38**	**3.53**	**3.38**	**3.30**	**3.13**	**3.25**	**3.20**	**3.20**
	human poet	3.85	3.68	4.05	3.83	4.00	3.83	3.53	3.75

Table 1: Human judgment results. We bold the best performing model in each group.

(does the poem convey some certain messages?) and **Poeticness** (does the poem have some poetic features?). Each criterion needs to be scored on a 5-point scale ranging from 1 to 5.

For each model, we generate 20 *wuyan* and 20 *qiyan* quatrains given the first sentence. We invite 10 experts who major in Chinese literature or are members of a poetry association to evaluate these quatrains. We divide the baseline methods into two groups: In the first group, we compare SPG with seq2seq (Bahdanau et al., 2014) to present the advantages of style disentanglement; In the second group, we compare SPG with state-of-the-art poetry generation methods, memory (Zhang et al., 2017) and polish (Yan, 2016), and the original poems written by poets to demonstrate the effectiveness of our algorithm. Note that the scores of human judgment are relative, not absolute. Thus we compare with seq2seq separately to avoid mutual interference.

4.4 Experimental Results

We report the average scores of expert judgments in Table 1. From the experimental results, we have the following observations:

Firstly, the experimental results in group 1 demonstrate that SPG outperforms seq2seq, the basis of our model, by learning a style-disentangled generation model. The only difference between seq2seq and our model is that we append a one-hot style id to the encoder state and add mutual information regularization in Eq. 12 to the loss function. Note that our model is fully unsupervised: the one-hot style id conveys no meaningful message unless the mutual information regularization is considered. In other words, the one-hot style id and mutual information regularization cannot be torn apart. Therefore, the improvements over seq2seq all come from the part of style disentanglement modeling because seq2seq and our model share all the other components. The comparisons in group 1 of Table 1 are sufficient to show the effectiveness of style modeling.

Secondly, the experimental results in group 2 show that SPG consistently outperforms two state-of-the-art poem generation methods. SPG is able to generate poetries in diverse styles without losing fluency and coherency. Our advantages are two-fold: On one hand, SPG better fits the diversity characteristic of human poetry writing. Intuitively, seq2seq learns a generation model that mixes poems in various styles and is more likely to generate meaningless common sentences. By disentangling poems in different styles, our model can learn a more compact generation model for each style and write more fluent and meaningful poems. On the other hand, by fixing the style when generating three lines in a quatrain, SPG is able to generate more coherent poems.

One can also imagine that the generation probability distribution actually consists of several peaks where each peak identifies a cluster of poems in similar styles. A traditional model mixes all the stuff together and learns a one-peak generation model which is more likely to generate meaningless common sentences. In contrast, our model disentangles different clusters (styles) and learns a more accurate and compact generation model for each cluster (style). Hence our model can generate poems with higher quality and beat the baselines in terms of human evaluation. This observation demonstrates the effectiveness and robustness of our model.

Finally, there is still a large margin between SPG and human poets. In this paper, we focus on poem generation in diverse styles. Other poetry characteristics are also important for the quality of generations. We will consider applying our style-disentangle regularization on other poem models for better performance in the future.

Style id	Keywords
1	loneliness, melancholy
2	the portrait of landscape
3	sorrow during roaming
4	hermit, rural scenes
5	grand scenery, regrets about old events
6	sorrow during drinking
7	emotions towards life experience
8	the portrait of hazy sceneries
9	reminiscence, homesickness
10	sadness about seasons

Table 2: Representative keywords for poems generated by each learned style.

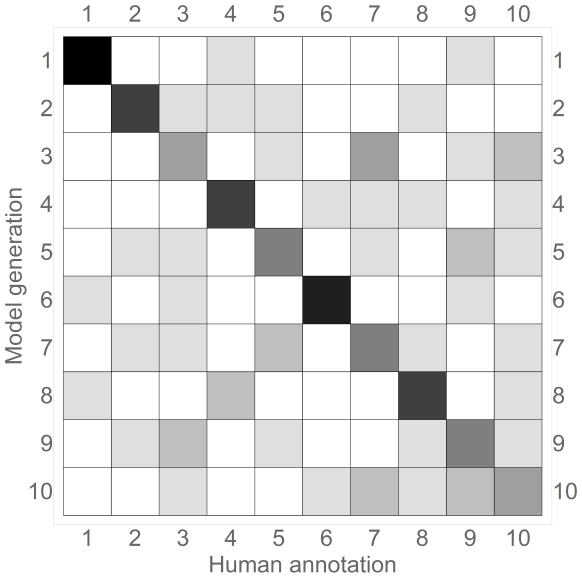

Figure 3: Experimental results on style recognition. Each row represents the human annotation of corresponding style generations. The diagonal blocks are correct classifications. Darker block indicates higher probability.

4.5 Interpretability of Learned Styles

In this subsection, we conduct experiments to understand the semantic meanings of each learned style. To this end, we first generate 50 poems in each style and then manually select two or three keywords to sketch the overall feelings of every style. The keywords of all 10 styles are listed in Table 2. Note that the learned styles may not strictly align the traditional writing styles recognized by human such as romantic or pastoral because our model is fully unsupervised.

Then we generate another 50 poems (5 poems per style) and ask the experts to classify these poems into the 10 styles according to the relationship between generated poems and style keywords in Table 2. The human annotation results are shown in Fig. 3.

We can see that many learned styles can be successfully recognized by human with a higher probability, e.g. the first style can be correctly classified by 80% probability. This observation indicates that the learned styles of SPG are meaningful and recognizable through only two or three keywords. Also, the generated poems are diverse otherwise they cannot be differentiated and correctly classified.

4.6 Case Study

We present three poems generated by SPG with the same first sentence for case study. We only list the results of three most representative styles in Fig. 4 and put other generation examples in supplementary materials (in Chinese). We can see that the poems generated by different style inputs differ a lot from each other and follow the style keywords. To conclude, SPG can generate fluent and coherent poetries in diverse styles.

5 Conclusion

In this paper, we propose a stylistic poetry generation (SPG) model to learn the ability to write poems in different styles under the same poetic imagery. To the best of our knowledge, we are the first effort at stylistic poetry generation in a fully unsupervised manner. Therefore, our model requires no expensive expert style annotation for thousands of poems in the database. We innovatively employ mutual information, a concept in information theory, to develop our model. Experimental results show that SPG is able to generate fluent and coherent poetries in diverse styles without losing fluency and coherency. The learned styles are meaningful and recognizable given only two or three keywords. Our algorithm has been incorporated into Jiuge[2] poetry generation system.

For future works, we will consider adopting the mutual information regularization for other text generation tasks which encourage stylistic generation or diversity to improve their performances. Another intriguing direction is to refine our model for more task-specific scenarios. Besides, our model simplifies the prior of style distribution as a uniform distribution. This assumption could be further improved by an iteratively updating approach.

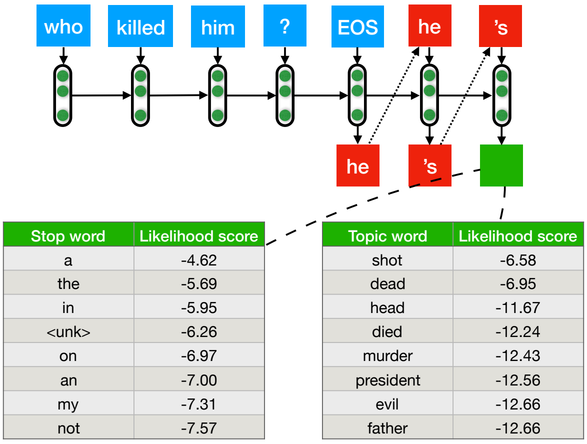
Abstract

Neural conversation models tend to generate safe, generic responses for most inputs. This is due to the limitations of likelihood-based decoding objectives in generation tasks with diverse outputs, such as conversation. To address this challenge, we propose a simple yet effective approach for incorporating side information in the form of distributional constraints over the generated responses. We propose two constraints that help generate more content rich responses that are based on a model of syntax and topics (Griffiths et al., 2005) and semantic similarity (Arora et al., 2016). We evaluate our approach against a variety of competitive baselines, using both automatic metrics and human judgments, showing that our proposed approach generates responses that are much less generic without sacrificing plausibility. A working demo of our code can be found at `https://github.com/abaheti95/DC-NeuralConversation`.

1 Introduction

Recent years have seen growing interest in neural generation methods for data-driven conversation. This approach has the potential to leverage massive conversational datasets on the web to learn *open-domain* dialogue agents, without relying on hand-written rules or manual annotation. Such response generation models could be combined with traditional dialogue systems to enable more natural and adaptive conversation, in addition to new applications such as predictive response suggestion (Kannan et al., 2016), however many challenges remain.

A major drawback of neural conversation generation is that it tends to produce too many "safe" or generic responses, for example: *"I don't know"* or *"What are you talking about ?"*. This is a pervasive problem that has been independently reported by multiple research groups (Li et al., 2016a; Serban et al., 2016; Li et al., 2016c).[1] The effect is due to the use of conditional likelihood as a decoding objective – maximizing conditional likelihood is a suitable choice for text-to-text generation tasks such as machine translation, where the source and target are semantically equivalent, however, in conversation there are many acceptable ways to respond. Simply choosing most predictable reply often leads to very dull conversation.



Stop word	Likelihood score
a	-4.62
the	-5.69
in	-5.95
<unk>	-6.26
on	-6.97
an	-7.00
my	-7.31
not	-7.57

Topic word	Likelihood score
shot	-6.58
dead	-6.95
head	-11.67
died	-12.24
murder	-12.43
president	-12.56
evil	-12.66
father	-12.66

Figure 1: Illustration of the dull response problem in maximum likelihood neural conversation generation using an example from the OpenSubtitles corpus. Function (stop) words tend to receive higher log probabilities than content (topic) words. The highest likelihood stop words and topic words in this context are listed.

Figure 1 illustrates the problem with conditional likelihood using an example. After encoding the source message using a bidirectional LSTM with attention, and fixing the first two words of the response, we show the highest ranked words (according to log-likelihood scores) taken from a list

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3970–3980
Brussels, Belgium, October 31 - November 4, 2018.

of stop words[2] in contrast to those selected from a list of topic words.[3] As illustrated in the figure, response generation that is based on maximum likelihood is biased towards stop-words and therefore results in responses that are *safe* (likely to be plausible in the context of the input), but also *bland* (don't contribute any new information to the conversation). This motivates the need for augmenting the decoding objective to encourage the use of more content words.

To address the *dull-response* problem in neural conversation, in this paper, we propose a new decoding objective that flexibly incorporates side-information in the form of distributional constraints. We explore two constraints, one which encourages the distribution over topics and syntax in the response to match that found in the user's input. To estimate these distributions, we leverage the unsupervised model of topics and syntax proposed by Griffiths and Steyvers (2005). The second constraint encourages generated responses to be semantically similar to the user's input; semantic similarity is measured using fixed-dimensional sentence embeddings (Arora et al., 2016).

After introducing distributional constraints into the decoding objective, we empirically demonstrate, in an evaluation that is based on human judgments, that our approach generates more content-rich responses when compared with two competitive baselines: Maximum Mutual Information (MMI) (Li et al., 2016a), in addition to an approach that conditions on topic models as additional context in neural conversation (Xing et al., 2017). While encouraging the model to generate less bland responses can be risky, we find that our approach achieves comparable plausibility while introducing significantly more content.

2 Neural Conversation Generation

As a starting point for our approach we leverage the Seq2Seq model (Sutskever et al., 2014; Bahdanau et al., 2014) which has been used as a basis for a broad range of recent work on neural conversation (Kannan et al., 2016; Li et al., 2016a; Serban et al., 2016; Shao et al., 2017). This model consists of two parts, an *encoder* and a *decoder* both of which are typically stacked LSTM layers. The encoder reads the input sequence and creates a hidden representation. The decoder conditions on this representation, using attention, and generates the response using a neural network language model (Bengio et al., 2003; Sutskever et al., 2011).

3 Distributional Topic and Semantic Similarity Constraints

Neural generation models select a response, $\hat{Y}$ by maximizing over a decoding objective, typically using greedy beam search from left to right over partially completed responses, which are scored using the decoder RNN language model. A commonly used decoding objective is the conditional likelihood of the target given the source, $P(Y|X)$:

$$\begin{aligned} \hat{Y} &= \arg\max_{Y} \{\log P(Y|X)\} \qquad (1) \\ &= \arg\max_{w_1,\ldots,w_n} \{\sum_{i=1}^{n} \log P(w_i|w_1,\ldots w_{i-1},X)\} \end{aligned}$$

As discussed in Section 1, models trained to maximize conditional likelihood tend to assign low probability to content words as compared to (more frequent) function words, leading to bland, generic responses most of the time. To ameliorate this, we introduce distributional constraints in the form of additional terms in the decoding objective that favor hypotheses containing more content words that are similar to the source in the *Topical* and *Semantic* sense.

For the constraint in the topic domain, we are interested in the topic probability distributions of the source, X, and target Y, $P(T|X)$ and $P(T|Y)$, where T is a random variable defined over k topics. Then we can modify the decoding objective from Eq 1:

$$\begin{aligned} \hat{Y}^T = \arg\max_{Y} \{ &\log P(Y|X) + \qquad (2) \\ &\alpha \times \Delta(P(T|X), P(T|Y))\} \end{aligned}$$

Here, Δ is a similarity function between the two probability distributions and α is a tunable hyper-parameter to adjust impact of this constraint.

Much recent work has investigated how to encode the semantic meaning of a sentence into a fixed high dimensional embedding space (Kiros et al., 2015; Wieting and Gimpel, 2017). Given such an embedding representation of X and Y, one can find the semantic similarity between the two and similar to Eq 2 we can add a semantic similarity constraint to the likelihood objective as

---

[2] `https://www.ranks.nl/stopwords`

[3] The top 10 topic words were taken from each of the 50 topics inferred by an HMM-LDA model (after removing stop words).

follows:

$$\hat{Y}^{Emb} = \arg\max_{Y}\{\log(P(Y|X)) + \beta \times \nabla(Emb(X), Emb(Y))\} \tag{3}$$

where, $Emb()$ is a function that maps an utterance to a semantic vector representation, ∇ is a function that computes similarity of the two embeddings and β is a tunable parameter.

Both of the constraint terms from Eq 2 and Eq 3 are additive in nature and thus can be combined in a straightforward fashion. This formulation allows us to systematically combine information from three different models to produce better responses in terms of topic and semantic relevance. Conceptually, the likelihood term governs the grammatical structure of the response while the topic and semantic constraints drive content selection (Nenkova and Passonneau, 2004; Barzilay and Lapata, 2005).

4 Decoding with Distributional Constraints

In Section 3, we defined two constraints (one topic constraint and one semantic) for use in the decoding objective. Incorporating these constraints during decoding requires that they factorize in a way that is compatible with left-to-right beam search over words in the response. The standard approach to computing posterior distributions in topic models requires a probabilistic inference procedure over the entire source and target. Furthermore, computing semantic representations can involve the use of complex neural architectures. Both of these proceedures are difficult to integrate into decoding, because they are computationally expensive and would need to be called repeatedly within the inner loop of the decoder. Furthermore, when performing left-to-right beam search, as is common practice in neural generation, the complete response is generally not available. To address these challenges, we propose using simple additive variants of these methods that factorize over words and which we found to enable efficient decoding without sacrificing performance.

4.1 Topic Similarity

Estimating the topic distribution of the source, $P(T|X)$, and response, $P(T|Y)$, is a key step in implementing the topic-similarity constraint. HMM-LDA is a generative model that is able to separate topic and syntax words, by inferring topic distributions in a corpus while flexibly modeling function words. We briefly summarize this model before describing our implementation.

4.1.1 Syntax-Topics model

Griffiths et. al. (2005) suggested an unsupervised generative model that simultaneously labels each word in a document with a syntax (c) and topic (z) state. They modify the Latent Dirichlet Allocation model to include a syntactic component akin to a Hidden Markov Model (HMM). In LDA, each topic (z) is associated with a probability distribution over the vocabulary $\phi^{(z)}$. HMM-LDA adds additional distributions over words for each syntactic class (c) as $\phi^{(c)}$. A special class, $c = 0$, is reserved for topics. The transition model between classes c_{i-1} to c_i follows a multinomial distribution distribution $\pi^{(c_{i-1})}$. Each document has an associated distribution over topics $\theta^{(d)}$; each word, w_j, in the document has an associated latent topic variable, z_j, that is drawn from $\theta^{(d)}$ and c_j is drawn from $\pi^{(c_{j-1})}$. If $c_j = 0$, then w_j is drawn from $\phi^{(z_j)}$, otherwise it is drawn from $\phi^{(c_j)}$. Markov Chain Monte Carlo inference (MCMC) is used to infer values for the hidden topic and syntax variables associated with a given document collection. To estimate topic and syntax distributions, we performed collapsed Gibbs sampling over our training corpus of conversations, where each conversation is treated as a document. One sample of the hidden variables was used to estimate model parameters after 2,500 iterations of burn in. Our code for training the HMM-LDA model is available online[4].

4.1.2 Estimating Topic Distributions with HMM-LDA

To compute distributional topic constraints in neural response generation, we first need an efficient method for estimating topic distributions that factorizes over words, given a point estimate of an HMM-LDA model's parameters. We would like to estimate topic distributions based on content words contained in a sentence and ignore function words. HMM-LDA provides us with topic, $\phi^{(z)}$, and syntax, $\phi^{(c)}$, distributions over the vocabulary of words, $w \in V$. Treating a sentence as a bag-of-words we can estimate its distribution over topics as a sum of topic distributions over all words normalized by sentence length. However, we found this approach does not to work well in

---

[4] `https://github.com/abaheti95/HMM-LDA`

practice because it gives equal weight to topic and syntax words. To address this issue, we weighted each word's topic distribution $P(T|w)$ by its probability of being generated by the topic component of the HMM-LDA model (i.e. $P(C = 0|w)$). The topic distribution of a sentence, S, is estimated as:

$$P(T|S) = \frac{1}{Z}\Sigma_{w \in S} P(T|w)P(C = 0|w) \qquad (4)$$

where $Z = \Sigma_{w \in S} P(C = 0|w)$ is a normalizing constant that corresponds to the expected number of content words in the sentence. As mentioned earlier, a more accurate estimate of the topic distribution could be obtained using MCMC inference or by applying the forward-backward algorithm. However, these methods are computationally expensive and not well-suited to the decoding framework used in neural generation.

The method described above allows us to efficiently compute the topic distribution of a sentence for use in the topic constraint in Eq 2. For a similarity function, Δ, we simply use the vector dot product, which is closely related to cosine similarity. This formulation has the advantage that it enables memoization during decoding. Another advantage is that it captures the ratio of topic to syntax words due to the weights $P(C = 0|w)$.[5] Therefore, the overall constraint has the effect of keeping the syntax-topics ratio in generated hypothesis similar to the source.

4.2 Semantic Similarity

To define the semantic similarity constraint we first encode a semantic representation of the source and target into a fixed dimensional embedding space. There are many sentence embedding methods that could be used, however we want this encoding to be relatively efficient as it will be used many times during beam search.

Arora et. al. (2016) recently proposed a simple sentence embedding method, which was shown to have competitive performance across a variety of tasks. Their approach uses a weighted average of word embeddings where each word is weighted by $\frac{a}{a+P(w)}$; here, $P(w)$ is the unigram probability and a is a hyperparameter. Such a weighting scheme reduces the impact of frequent words (typically function words) in the overall sentence embedding. Next the first principal component of all the sentence embeddings in the corpus is removed. (Arora et al., 2016) points that the first principal component has high cosine similarity with common function words. Removing this component gives sentence embeddings that encapsulate the semantic meaning of the sentence. We use this technique in our implementation of $Emb()$ in Eq 3. For the similarity function, Δ, we use the dot product. Analogous to the topic constraint described above, this approach to measuring semantic similarity also decomposes over words and works well in the decoding framework.

Parameter	Value

b2 (7-15 words)	15794	333
b3 (16-25 words)	5167	333
total	31955	1000

Table 2: Test set from Cornell Movie Dialogue Corpus. Column 2 shows the total number of dialogues that we got after all pre-processing and Column 3 shows the number of sampled dialogues in the test set.

5 Datasets

For training purposes we use OpenSubtitles (Tiedemann, 2009), a large corpus of movie subtitles (roughly 60M-70M lines) that is freely available and has been used in a broad range of recent work on data-driven conversation. OpenSubtitles does not contain speaker annotations on the dialogue turns, so as previously noted when used for learning data-driven conversation models the data is somewhat noisy. Nonetheless, it is possible to create a useful corpus of conversations from this data by assuming each line corresponds to a full speaker turn. Although this assumption is often violated, prior work has successfully trained

---

[5] Assuming topic distribution of syntax words to be uniform, a sentence with more syntax words will dampen modes in the distribution. Alternately, with less syntax words the overall distribution will be more peaked.

and evaluated neural conversation models using this corpus. In our experiments we used a preprocessed version of this dataset distributed by Li et. al. (2016a).[6] The dataset contains large number of two turn dialogues out of which we sampled 23M to use as our training set and 10k as a validation set.

Due to the noisy nature of the OpenSubtitles conversations we do not use them for evaluation. Instead, we leverage the Cornell Movie Dialogue Corpus (Danescu-Niculescu-Mizil and Lee, 2011) which is much smaller but contains accurate speaker annotations. We extracted all two turn conversations (source target pair) from this corpus and removed those with less than three and more than 25 words. After this, we divided the remaining conversations into three buckets based on source length. The numbers can be found in Table 2. From each bucket we randomly sampled ≈333 dialogues for a total of 1000 dialogues in our test set. We evaluate all models on this test set. Since automatic metrics do not correlate with human judgment, we manually tuned the hyperparameters (α and β) on a small development set (4 dialogues from each bucket to create a small 12 sentence development set; disjoint from test set). We manually inspected the responses generated by the model on the development set for different values of α and β and choose those that performed best.

6 Experimental Conditions and Baselines

During learning we use the same hyperparameters for all models; these are displayed in Table 1, and are based on those reported by Li et. al. (2016a).[7] We compare our approach with the following baselines:

MMI: We re-implemented the MMI-bidi method proposed by Li et. al. (2016a). MMI is a particularly appropriate baseline for comparison, as it encourages responses that have higher relevance to the input in contrast to conditional likelihood, which tends to favor responses with higher unconditional probability. MMI-bidi generates B candidates using Beam search on a Seq2Seq model trained to maximize conditional likelihood of the target given the source, $P(Y|X)$, then re-ranks them using a separately trained source given target model, $P(X|Y)$. Combining both directions in this way has the effect of maximizing mutual information (Li et al., 2016a).

TA-Seq2Seq: Another relevant baseline is the TA-Seq2Seq model of Xing et. al. (2017) that integrates information from a pre-trained topic model into neural response generation using an attention mechanism to condition on relevant topic words. They evaluate their model on a dataset of Chinese forum posts. Unfortunately we could not use the code provided by the authors due to data-mismatch (their model makes use of user identities which are not available in the OpenSubtitles corpus). We therefore compare with a re-implementation of their approach in which we modify each source sentence to include a list of the 20 most relevant topic words from HMM-LDA and then train using the same Seq2Seq framework with attention. This enables the model to condition on the relevant topic words. In addition to incorporating attention over topics, Xing et. al. also introduced an approach to *biased generation* - to replicate this we add a constant factor to all topic words during the prediction.

7 Results and Analysis

Our proposed decoding objective constraints (topic and semantic) are complementary to the MMI objective, which encourages diversity and relevance to the source input. Therefore, in addition to comparing against the baselines described above, we evaluated three variants of our model: **(1)** maximum conditional likelihood combined with semantic and topic distributional constraints with a beam size of 10 (DC-10) **(2)** The same configuration with MMI-bidi re-ranking using a beam size of 10 DC-MMI10 and **(3)** MMI-bidi reranking with a beam size of 200 (DC-MMI200). We test all configurations on the 1000 conversations test set described in Section 5 and compare them on automatic metrics and also in a crowd-sourced human evaluation. We do not consider TA-200 (TA-Seq2Seq, Beam=200), DC-200 and MMI-10 for human evaluation as they appear to perform worse than other model variants in automatic metrics and also on our set of development sentences. Sample responses for all the remaining models are presented in Table 3.

7.1 Automatic Metrics

Following Li et. al. (2016a), we report distinct-1 and distinct-2, which measure the diversity of re-

Table 3: Sample responses of all the models on the dev set

sponses. These are the ratios of types to tokens for unigrams and bigrams, respectively. We also report BLEU-1 scores following previous work, however it should be noted that BLEU-1 is not generally accepted to correlate with human judgments in conversation generation tasks (Liu et al., 2016) as there are many acceptable ways to reply to an input which may not match a reference response. Lastly, we compare the percentage of stop-words[8] of the responses generated by each model (smaller values, that are closer to the distribution of human conversations are preferred). The automatic evaluation is presented in Table 4.

For brevity we define aliases for each system in the 2^{nd} column of Table 4 which are used in subsequent discussion. The human responses are diverse and also generally longer than automatically generated responses. MMI200 has higher diversity than TA-Seq2Seq in terms of distinct-1 and distinct-2. This illustrates the importance of re-ranking using MMI. Our approach produces almost twice as many distinct unigrams and bigrams. We also observe MMI200 and TA-Seq2Seq achieve higher BLEU scores than our models, however this is not surprising since our models are designed to generate more interesting responses containing rarer content words that are less likely to appear in reference responses.

---

[8] Long Stopword List from `https://www.ranks.nl/stopwords`. We appended punctuations to this list.

Model	Alias	distinct-1	distinct-2	BLEU -1	Avg. length	Stop-word%

DC-MMI200	20.021	26.660	53.319

Table 6: Comparing the model variation by reducing beam size to 10 and also comparing decoder constraints without MMI reranking

As expected we observe that MMI200 and TA-10 have a higher percentage of stop-words than human responses. According to the human evaluation discussed in Section 7.2, these models were also found to have lower content richness.

7.2 Human Evaluation

We conducted a survey on the crowd-sourcing platform, Amazon Mechanical Turk. Every model response is scored on 2 categories: 1) **P**lausibility - *is the response plausible for the given source?* and 2) **C**ontent Richness - *does the response add new information to the conversation?* We asked the evaluators to respond on a 5-point scale to the questions above (Strongly Agree, Agree, Unsure, Disagree, Strongly Disagree). These were later collapsed to 3 categories (Agree, Unsure, Disagree). The results for plausibility and content richness of our model in addition to the MMI and TA-Seq2Seq baselines and human responses are presented in Table 5.

We observe that MMI200 and TA-10 models achieve slightly better plausibility scores since they tend to generate safe, dull responses. However, we find that when using a beam size of 200 and MMI re-ranking, our approach which incorporates distributional constraints, DC-MMI200, achieves competitive plausibility, while achieving significantly higher content richness.

7.2.1 Statistical Significance of Results

To verify the statistical significance of our findings, we conducted a pairwise bootstrap test (Efron and Tibshirani, 1994; Berg-Kirkpatrick et al., 2012) comparing the difference between percentage of *Agree* annotations (Yes column in the Table 5). We computed p-values for each pair of models: MMI200 vs DC-MMI200 and TA vs DC-MMI200. For plausibility, we did not find a significant difference in either comparison (p-value $\approx$ 0.25) while for content richness, both differences were found to be significant (p-value $<10^{-4}$). To summarize: our model significantly beats both baselines in terms of content richness while the difference in plausibility was not found to be statistically significant.

7.2.2 Pairwise Evaluation of Interestingness

To further validate our claims we also did a side by side comparison study between MMI200 and DC-MMI200. For every test case, we showed Mechanical Turk workers the source sentence along with responses generated by both systems and asked them select which is more interesting. We observe that in 56% out of 1000 cases, DC-MMI200 was rated as the more interesting response. The result is statistically significant with p-value $<4 \times 10^{-4}$ (using an exact binomial test).

7.3 Model Variations

To see the effectiveness of our decoding constraints separately, we compare the best performing DC-MMI200 model with DC-10 and DC-MMI10, both of which use a beam size of 10 – DC-10 does not include MMI reranking. The results of Mechanical Turk evaluation, following the approach described in Section 7.2, are presented in Table 6. We observe that with a beam size of 10 our model is able to generate content rich responses, but suffers in terms of plausibility. The values in the table suggests the decoding constraints defined in this work successfully inject content words into candidate hypotheses and that MMI is able to effectively choose plausible candidates. In the case of DC-10 and DC-MMI10, both models generate the same candidates, but MMI is able to re-rank the results and thus improves plausibility.

8 Related Work

Conversational agents primarily fall into two categories: task oriented dialogue systems (Williams et al., 2013; Wen et al., 2015) and chatbots (Weizenbaum, 1966), although there have been some efforts to integrate the two (Dodge et al., 2015; Yu et al., 2017). Some of the earliest work on data-driven chatbots (Ritter et al., 2011) explored the use of phrase-based Statistical Machine Translation (SMT) on large numbers of conversations gathered from Twitter (Ritter et al., 2010). Subsequent progress on the use of neural networks in machine translation inspired the use of Sequence-to-Sequence (Seq2Seq) models for data-driven response generation (Shang et al., 2015; Sordoni et al., 2015; Li et al., 2016a).

Our approach, which incorporates distributional constraints into the decoding objective, is related to prior work on posterior regularization (Mann and McCallum, 2008; Ganchev et al., 2010; Zhu et al., 2014). Posterior regularization introduces similar distributional constraints on expectations computed over unlabeled data using a model's parameters. These are typically added to the learning objective for semi-supervised scenarios where available labeled data is limited. In contrast, our approach introduces distributional constraints into the decoding objective as a way to combine neural conversation models trained on large quantities of conversational data with separately trained models of topics and semantic similarity that can drive content selection.

There are numerous examples of related work on improving neural conversation models. Shao et. al. (2017) introduced a stochastic approach to beam search that does segment-by-segment reranking to promote diversity. Zhang et. al. (2018) develop models which converse while assuming a persona defined by a short description of attributes. Wang et. al. (2017) suggested decoding methods that influence the style and topic of the generated response. Bosselutet al. (2018) develop discourse-aware rewards with reinforcement learning (RL) to generate long and coherent texts. Li et. al. (2016c) applied deep reinforcement learning to dialogue generation to maximize long-term reward of the conversation, as opposed to directly maximizing likelihood of the response. This line of work was further extended with adversarial learning (Li et al., 2017) that rewards generated conversations that are indistinguishable from real conversations in the data. Lewis et. al. (2017) applied reinforcement learning with dialogue rollouts to generate replies that maximize expected reward, while learning to generate responses from a crowdsourced dataset of negotiation dialogues. Choi et. al. (2018) used crowd-workers to gather a corpus of 100K information-seeking QA dialogues that are answerable using text spans from Wikipedia. Niu and Bansal (2018) designed a number of weakly-supervised models that generate polite, neutral or rude responses. Their fusion model combines a language model trained on polite utterances with the decoder. In the second method they prepend the utterance with a politeness label and scale its embedding to vary politeness. The third model is Polite-RL which assigns a reward based on a politeness classifier. Gimpel et. al. (2013) explored methods for increasing the diversity of N-best lists in machine translation by introducing a pairwise dissimilarity function. Similar ideas have been explored in the context of neural generation models. (Vijayakumar et al., 2016; Li and Jurafsky, 2016; Li et al., 2016b)

Following previous work we evaluated our approach using a combination of automatic metrics and human judgments. Some recent work has explored the possibility of adversarial evaluation of neural conversation models (Lowe et al., 2017; Li et al., 2017).

9 Conclusions

We presented an approach to generate more interesting responses in neural conversation models by incorporating side information in the form of distributional constraints. When using maximum likelihood decoding objectives, neural conversation models tend to generate safe responses, such as "I don't know" for most inputs. Our proposed approach provides a flexible method of incorporating a broad range of distributional constraints into the decoding objective. We proposed and empirically evaluated two constraints that factorize over words, and therefore naturally fit into the commonly used left-to-right beam search decoding framework. The first encourages the use of more relevant topic words in the response the second encourages semantic similarity between the source and target. We empirically demonstrated, through human evaluation, that when taken together these constraints lead to responses that contribute significantly more information to the conversation, while maintaining plausibility in the context of the input.

Abstract

We present three enhancements to existing encoder-decoder models for open-domain conversational agents, aimed at effectively modeling coherence and promoting output diversity: (1) We introduce a measure of coherence as the GloVe embedding similarity between the dialogue context and the generated response, (2) we filter our training corpora based on the measure of coherence to obtain topically coherent and lexically diverse context-response pairs, (3) we then train a response generator using a conditional variational autoencoder model that incorporates the measure of coherence as a latent variable and uses a context gate to guarantee topical consistency with the context and promote lexical diversity. Experiments on the OpenSubtitles corpus show a substantial improvement over competitive neural models in terms of BLEU score as well as metrics of coherence and diversity.

1 Introduction

End-to-end neural response generation methods are promising for developing open domain dialogue systems as they allow to learn from very large unlabeled datasets (Shang et al., 2015; Sordoni et al., 2015; Vinyals and Le, 2015). However, these models have also been shown to generate generic, uninformative, and non-coherent replies (e.g., *"I don't know."* in Figure 1), mainly due to the fact that neural systems tend to settle for the most frequent options, thus penalizing length and favoring high-frequency word sequences (Sountsov and Sarawagi, 2016; Wei et al., 2017).

To address these problems, Li et al. (2016a) and Li et al. (2017a) attempt to promote diversity by improving the objective function, but do not model diversity explicitly. Serban et al. (2017) focus on model structure without any upgrades to the objective function. Other works control the style of the output by leveraging external resources (Hu et al. (2017): sentiment classifier, time annotation; Zhao et al. (2017): dialogue acts) or focus on well-structured input such as paragraphs (Li and Jurafsky, 2017).

Conversational history	**Response**
A: You stay out of this. B: So you want water, huh? A: That's right.	B-Coh: Well, I got water. B-Incoh: I don't know.
A: Where do we start? B: Kitchen. A: Definitely the kitchen.	B-Coh: Specifically the stove. B-Incoh: Let's go for a walk.

Figure 1: Examples of conversational history (left) with two alternative responses to follow it (right): (B-Coh) a more coherent, topical utterance, and (B-Incoh) a generic, inconsistent response.

This paper extends previous attempts to model diversity and coherence by enhancing all three aspects of the learning process: the data, the model, and the objective function. While previous research has addressed these aspects individually, this paper is the first to address all three in a unified framework. Instead of using existing linguistic knowledge or labeled datasets, we aim to control for coherence by learning directly from data, using a fully unsupervised approach. This is also the first work encoding and evaluating coherence explicitly in the dialogue generation task, as opposed to using diversity, style, or other properties of responses as a proxy.

In this work, given a dialogue history, we regard as a coherent response an utterance that is thematically correlated and naturally continuing from the previous turns, as well as lexically diverse. For example, in Figure 1 the response *"Specifically the stove."* is a very natural and coherent response, elaborating on the topic of *kitchen* introduced in

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3981–3991
Brussels, Belgium, October 31 - November 4, 2018.

the previous two utterances and containing rich thematic words, whereas the response *"Let's go for a walk."* is unrelated and uninteresting.

In order to obtain coherent responses, we present three generic enhancements to existing encoder-decoder (E-D) models:

1. We define a *measure of coherence* simply as the averaged word embedding similarity between the words of the context and the response computed using GloVe vectors (Pennington et al., 2014).
2. We filter a corpus of conversations based on our measure of coherence, which leaves us with context-response pairs that are both topically coherent and lexically diverse.
3. We train an E-D generator recast as a conditional Variational Autoencoder (cVAE; Zhao et al., 2017) model that incorporates two latent variables, one for encoding the context and another for conditioning on the measure of coherence, trained jointly as in Hu et al. (2017). We then decode using a context gate (Tu et al., 2017) to control the generation of words that directly relate to the most topical words of the context and promote coherence.

Experiments on the OpenSubtitles (Lison and Meena, 2016) corpus demonstrate the effectiveness of the overall approach. Our models achieve a substantial improvement over competitive neural models. We provide an ablation analysis, quantifying the contributions that come from effective modeling of coherence into our models. All our experimental code is freely available on GitHub.[1]

2 Coherence-based Dialogue Generation

Our model aims to generate responses given a dialogue context, incorporating measures of coherence estimated purely from the training data. We propose the following enhancements to the attention-based E-D architecture (Bahdanau et al., 2015; Luong et al., 2015):

- We introduce a stochastic latent variable $\mathbf{z}$ conditioned on previous dialogue context to store the global information about the conversation (Bowman et al., 2016; Chung et al., 2015; Li and Jurafsky, 2017; Hu et al., 2017).
- We force the model to condition on the measure of coherence explicitly by encoding a latent variable (code) c learned from data.
- We incorporate a context gate (Tu et al., 2017) that dynamically controls the ratio at which the generated words in the response derive directly from the coherence-enhanced dialogue context or the previously generated parts of the response.

In the rest of this section, we introduce the measure of coherence (Section 2.1), we present an overview of our model (Section 2.2), and finally describe the model in detail (Sections 2.3–2.4).

2.1 Measure of Dialogue Coherence

Semantic vector space models of language represent each word with a real-valued word embedding vector (Pennington et al., 2014). By simply taking a weighted average of all its word embeddings, a whole sentence can be mapped into the semantic vector space. We define the coherence of a dialogue as the average distance between semantic vectors of preceding dialogue context and its response.

Let $\mathbf{x} = \{x_1, \dots x_j, \dots x_J\}$ represent a dialogue context and $\mathbf{y} = \{y_1, \dots y_i, \dots y_I\}$ a response. J and I are the numbers of words in the dialogue context and its response, respectively. Semantic vector space models map each word x_j into embeddings $\mathbf{x}_j^{emb}$, and y_i into $\mathbf{y}_i^{emb}$. The semantic representation of a dialogue context $\mathbf{x}$ is then $\mathbf{x}^{emb} = \sum_{j=1}^{J} w_j \mathbf{x}_j^{emb}$; for a response $\mathbf{y}$, it is $\mathbf{y}^{emb} = \sum_{i=1}^{I} v_i \mathbf{y}_i^{emb}$. Here, w_j and v_i are importance weights for each word in the sentence.[2] The measure of coherence is then defined as the cosine distance of the two semantic vectors of the dialogue context and its response:

$$C(\mathbf{x}, \mathbf{y}) = \cos\left(\mathbf{x}^{emb}, \mathbf{y}^{emb}\right) \qquad (1)$$

2.2 Model Overview

End-to-end response generation for dialogue can be formalized as follows: Given a dialogue context $\mathbf{x}$, a dialogue generator generates the next utterance $\mathbf{y}$. During the training process, the aim for a dialogue generator is to maximize the probability $p(\mathbf{y}|\mathbf{x})$ over the training dataset. To encode

---

[1] `https://github.com/XinnuoXu/CVAE_Dial`

[2] We set the importance weights to 0 for a list of stop words (high-frequency words such as articles and prepositions, names, punctuation marks), 1 otherwise.

dialogue contexts that adequately incorporate coherence information, we build our generator based on the cVAE model of Hu et al. (2017), which has been used to control text generation with respect to linguistic properties, such as tense or sentiment.

In our model, the response $\mathbf{y}$ is generated conditioned on the previous conversation $\mathbf{x}$, a diversity-promoting latent variable $\mathbf{z}$, and a latent variable c indicating dialogue coherence; $\mathbf{z}$ and c are independent. The generation probability $p\left(\mathbf{y}|\mathbf{x}\right)$ is defined as:

$$\begin{aligned} p\left(\mathbf{y}|\mathbf{x}\right) &= \int_{\mathbf{z},c} p\left(\mathbf{y}|\mathbf{x},\mathbf{z},c\right) p\left(\mathbf{z},c|\mathbf{x}\right) \mathrm{d}\mathbf{z}\,\mathrm{d}c \\ &= \int_{\mathbf{z},c} p\left(\mathbf{y}|\mathbf{x},\mathbf{z},c\right) p\left(\mathbf{z}|\mathbf{x}\right) p\left(c|\mathbf{x}\right) \mathrm{d}\mathbf{z}\,\mathrm{d}c \end{aligned} \tag{2}$$

Unfortunately, optimizing Eq (2) during training is intractable; therefore, we apply variational inference and optimize instead the variational lower bound:

$$\begin{aligned} \log p\left(\mathbf{y}|\mathbf{x}\right) &= \log \int_{\mathbf{z},c} p\left(\mathbf{y}|\mathbf{x},\mathbf{z},c\right) p\left(\mathbf{z},c|\mathbf{x}\right) \mathrm{d}\mathbf{z}\,\mathrm{d}c \\ &\geq \mathbb{E}_{q(\mathbf{z}|\mathbf{x},\mathbf{y})p(c|\mathbf{x},\mathbf{y})}\left[\log p\left(\mathbf{y}|\mathbf{x},\mathbf{z},c\right)\right] \\ &\quad - D_{KL}\left(q\left(\mathbf{z}|\mathbf{x},\mathbf{y}\right) \parallel p\left(\mathbf{z}|\mathbf{x}\right)\right) \end{aligned} \tag{3}$$

where $p\left(\mathbf{y}|\mathbf{x},\mathbf{z},c\right)$ is the probability of generating utterance $\mathbf{y}$ given $\mathbf{x}$, $\mathbf{z}$ and c; $q\left(\mathbf{z}|\mathbf{x},\mathbf{y}\right)$ stands for the approximate posterior distribution of the latent variable $\mathbf{z}$ conditioned on dialogue context $\mathbf{x}$ and the gold response $\mathbf{y}$; $p\left(c|\mathbf{x},\mathbf{y}\right)$ is the measure of coherence between context $\mathbf{x}$ and response $\mathbf{y}$; $p\left(\mathbf{z}|\mathbf{x}\right)$ is the true prior distribution of $\mathbf{z}$ conditioned only on dialogue context $\mathbf{x}$; $D_{KL}\left(\cdot|\cdot\right)$ denotes the KL-divergence. We assume that both $q\left(\mathbf{z}|\mathbf{x},\mathbf{y}\right)$ and $p\left(\mathbf{z}|\mathbf{x}\right)$ are Gaussian with mean vectors μ_{appr}, μ_{true} and covariance matrices Σ_{appr}, Σ_{true}.

2.2.1 Model Details

Optimizing Eq (3) consists of two parts: (1) minimizing the KL-divergence between the approximate posterior distribution and the true prior distribution of $\mathbf{z}$, (2) maximizing the probability of generating the gold response $\mathbf{y}$ conditioned on dialogue context $\mathbf{x}$ and coherence factors $\mathbf{z}$ and c. Figure 2 shows the pipeline of the training procedure.

Encoder: First, we encode a dialogue context $\mathbf{x}$ into a hidden state $\mathbf{h}$ using the *context encoder*, which is based on Recurrent Neural Networks (RNNs). Then the *posterior network* encodes both dialogue context $\mathbf{x}$ and gold response $\mathbf{y}$ into a hidden state $\mathbf{h}_{appr}$ followed by two linear transformations $f_{appr}\left(\cdot\right)$ and $g_{appr}\left(\cdot\right)$ to map $\mathbf{h}_{appr}$ into mean vector μ_{appr} and covariance matrix Σ_{appr}. The latent variable $\mathbf{z}$ can be sampled from the distribution $N\left(\mu_{appr}, \Sigma_{appr}\right)$:

$$\begin{aligned} \mu_{appr} &= f_{appr}\left(\mathbf{h}_{appr}\right) \\ \Sigma_{appr} &= g_{appr}\left(\mathbf{h}_{appr}\right) \\ q\left(\mathbf{z}|\mathbf{x},\mathbf{y}\right) &= N\left(\mu_{appr}, \Sigma_{appr}\right) \end{aligned} \tag{4}$$

The *prior network* in Figure 2 takes a form similar to the posterior network:

$$\begin{aligned} \mu_{true} &= f_{true}\left(\mathbf{h}_{true}\right) \\ \Sigma_{true} &= g_{true}\left(\mathbf{h}_{true}\right) \\ p\left(\mathbf{z}|\mathbf{x}\right) &= N\left(\mu_{true}, \Sigma_{true}\right) \end{aligned} \tag{5}$$

where $\mathbf{h}_{true}$ is the final hidden state of an RNN encoding only the dialogue context $\mathbf{x}$, and $f_{true}\left(\cdot\right)$, $g_{true}\left(\cdot\right)$ are linear transformations. Code c is given by the *coherence measure* from Eq (1).

Decoder: We build an attention-based decoder (Bahdanau et al., 2015; Luong et al., 2015) using RNNs to generate responses conditioned on encoded dialogue context $\mathbf{h}$, diversity signal $\mathbf{z}$, and coherence signal c. We concatenate the latent variables $\mathbf{z}$ and c to the context encoder hidden state $\mathbf{h}$ and feed them into the decoder as the initial hidden state $\mathbf{s}_0$, similar to Hu et al. (2017).

During the decoding process, tokens are generated sequentially under the following probability distribution:

$$\begin{aligned} p\left(\mathbf{y}|\mathbf{x},\mathbf{z},c\right) &= \prod_{i=1}^{I} p\left(y_i|y^{<i},\mathbf{x},\mathbf{z},c\right) \\ &= \prod_{i=1}^{I} g\left(y_{i-1},\mathbf{s}_i,\mathbf{a}_i\right) \end{aligned} \tag{6}$$

where I is the length of the produced response; $g\left(\cdot\right)$ is an RNN; $\mathbf{s}_i$ is the hidden state of the decoder at time step i which is conditioned on the previously generated token y_{i-1}, the previous hidden state $\mathbf{s}_{i-1}$, and the weighted attention vector

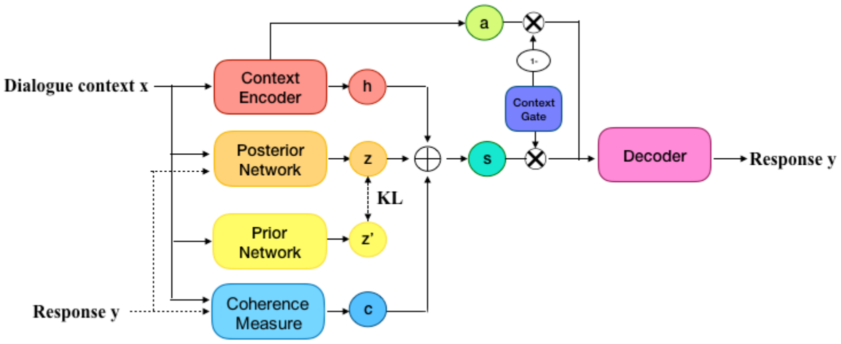

Figure 2: The training process of the generative model. First, the dialogue context is encoded: $\mathbf{h}$ is the final hidden state of the context encoder. Then we derive the diversity-promoting latent variable $\mathbf{z}$. Next, we compute the latent variable c that corresponds to the measure of coherence between the dialogue context x and the generated response y. We concatenate all three vectors into $\mathbf{s}$ to feed the decoder. $\mathbf{a}$ is the attention matrix calculated for every time step of the decoding process.

$\mathbf{a}_i$:

$$\mathbf{s}_i = f\left(y_{i-1}, \mathbf{s}_{i-1}, \mathbf{a}_i\right) \qquad (7)$$

$$\mathbf{a}_i = \sum_{j=1}^{J} \mathbf{w}_{ij}\mathbf{h}_i \qquad (8)$$

where J is the number of tokens of the dialogue context; $\mathbf{h}_i$ is the i^{th} hidden state of the encoder; the attention weight $\mathbf{w}_{ij}$ of each context hidden state $\mathbf{h}_i$ is computed following Luong et al. (2015).

Context Gate: To increase the influence of code c, we introduce the context gate k. Unlike Tu et al. (2017), whose context gate assigns an element-wise weight to the input signal deriving from the encoder RNN, we build the context gate conditioned only on the coherence signal:

$$k_i = \lambda\sigma\left(c - c_i'\right) \qquad (9)$$

where σ is the sigmoid function; λ is a bias term;[3] c is the target value of the measure of coherence, calculated by $C\left(\mathbf{x}, \mathbf{y}\right)$ (see Section 2.1); c_i' is the measure of coherence between the dialogue context and the generated prefix sentence at time step i, calculated by $C\left(\mathbf{x}, \mathbf{y}^{<i}\right)$. Now Eq (7) with the context gate applied to $\mathbf{s}_i$ can be rewritten as:

$$\mathbf{s}_i = f\left(y_{i-1}, (1 - k_i) \circ \mathbf{s}_{i-1}, k_i \circ \mathbf{a}_i\right) \qquad (10)$$

where $\circ$ denotes element-wise multiplication.

The coherence-informed context gate aims to dynamically control the ratio at which preceding dialogue context and previously generated tokens of the current response contribute to the generation of the next token in the response.

2.3 Training

Our generator is trained similarly to Hu et al. (2017). The objective function is a weighted combination of three losses (generation, coherence, and diversity):

$$\mathcal{L} = \mathcal{L}_G + \lambda_c\mathcal{L}_c + \lambda_{\mathbf{z}}\mathcal{L}_{\mathbf{z}} \qquad (11)$$

To teach the generator to produce responses close to the training data, we maximize the generation probability of the training response $\log p\left(\mathbf{y}|\mathbf{x}\right)$ given the dialogue context according to Eq (2). During training, we set $\mathcal{L}_G = -\log p\left(\mathbf{y}|\mathbf{x}\right)$ and minimize the following:

$$\begin{aligned}\mathcal{L}_G =& D_{KL}\left(q\left(\mathbf{z}|\mathbf{x},\mathbf{y}\right) \parallel p\left(\mathbf{z}|\mathbf{x}\right)\right) \\ &- \mathbb{E}_{q(\mathbf{z}|\mathbf{x},\mathbf{y})p(c|\mathbf{x},\mathbf{y})}\left[\log p\left(\mathbf{y}|\mathbf{x},\mathbf{z},c\right)\right]\end{aligned} \qquad (12)$$

Apart from the generation loss, the coherence measure provides an extra learning signal $\mathcal{L}_c$ which pushes the generator to produce responses that match the coherence signal given by the latent variable c.

$$\mathcal{L}_c = -\mathbb{E}_{p(\mathbf{z}|\mathbf{x})p(c)}\left[\log p\left(c|\mathbf{x}, \widetilde{G}\left(\mathbf{x},\mathbf{z},c\right)\right)\right] \qquad (13)$$

In Eq (13), $p\left(c\right) = N\left(0,1\right)$ is the prior distribution of the coherence variable c. To ensure that the loss is differentiable, we cannot sample words from the response vocabulary. Instead we define $\widetilde{G}\left(\mathbf{x},\mathbf{z},c\right) = \mathbf{y}^s = \{\mathbf{y}_1^s, \ldots \mathbf{y}_i^s, \ldots \mathbf{y}_I^s\}$ as the sequence of output word probability distributions. $p\left(c|\mathbf{x}, \widetilde{G}\left(\mathbf{x},\mathbf{z},c\right)\right)$ is predicted by the coherence measure defined in Eq (1) with $\mathbf{y}^{emb}$ set as:

$$\mathbf{y}^{emb} = \sum_{i=1}^{I} \mathbf{y}_j^{s\top} M_{glv} \qquad (14)$$

---

[3] We set λ empirically against the development set.

where M_{glv} is the word embedding matrix trained using GloVe (Section 2.1).

The last component in Eq (11) is the independent constraint $\mathcal{L}_{\mathbf{z}}$ that forces the soft distribution over the generated response $\widetilde{G}$ to be diverse, so that it is able to faithfully reproduce the latent variable $\mathbf{z}$:

$$\mathcal{L}_{\mathbf{z}} = -\mathbb{E}_{p(\mathbf{z}|\mathbf{x})p(c)} \left[\log q \left(\mathbf{z} | \mathbf{x}, \widetilde{G} \left(\mathbf{x}, \mathbf{z}, c \right) \right) \right] \tag{15}$$

where $q \left(\mathbf{z} | \mathbf{x}, \widetilde{G} \left(\mathbf{x}, \mathbf{z}, c \right) \right)$ is predicted by the posterior network with $\mathbf{y}_j^s$ as the soft input to the RNN encoder at each time step j.

2.4 Inference

Figure 3 shows the inference process of the generative model. Given a dialogue context $\mathbf{x}$ and an expected coherence value c, the context encoder first encodes the dialogue context into a hidden state $\mathbf{h}$. The prior network then generates a sample $\mathbf{z}'$ conditioned on the dialogue context. The decoder is initialized with $\mathbf{s}$, i.e., the concatenation of $\mathbf{h}$, $\mathbf{z}$ and c. During decoding, the next word is generated via the context gate modulating between the attention-reweighted context and the previously generated words of the response.

3 Dataset and Filtering

Dataset for Generator

We train and evaluate our models on the OpenSubtitles corpus (Lison and Tiedemann, 2016) with automatic dialogue turn segmentation (Lison and Meena, 2016).[4] A training pair consists of a dialogue context and a corresponding response. We consider three consecutive turns as the dialogue context and the following turn as the response. From a total of 65M instances, we select those that have context and response lengths of less than 120 and 30 words, respectively. We create two datasets:

1. **OST** (plain OpenSubtitles) consists of 2M/4K/4K instances as our training/development/test sets, selected randomly from the whole corpus;
2. **fOST** (filtered OpenSubtitles) contains the same amount of instances, but randomly selected only among those that have a measure of coherence score $C(\mathbf{x}, \mathbf{y}) \geq 0.68$.[5]

Dataset	Coh	D-1%	D-2%	D-Sent%
OST	0.390	14.3	57.9	83.8
fOST	0.801	15.5	62.9	89.3

Table 1: Coherence and diversity metrics[7] for the OST and fOST datasets (see Section 3 for the datasets and Section 4.2 for metrics definition).

Filtering of the OpenSubtitles corpus is motivated by the fact that by removing the video and audio modalities which the subtitles originally accompanied, we are very often left with incomplete and incoherent dialogues. Therefore, by keeping dialogues with high coherence scores, we aim at building a high quality corpus with (1) more semantically coherent and topically related contexts and responses, and (2) fewer general and dull responses. Table 3 shows the coherence and diversity metrics (cf. Section 4.2) between OST and fOST. Unsurprisingly, coherence for fOST is much higher than OST, with a slightly higher diversity. We list dialogue examples for different coherence scores in Supplemental Material B.

Dataset for Coherence Measure

In order to accurately measure coherence on our domain using the semantic distance as defined in Section 2.1, we train GloVe embeddings on the full OpenSubtitles corpus (i.e. 100K movies).

4 Experiments

Our generator model, ablative variants, and baselines are implemented using the publicly available OpenNMT-py framework (Klein et al., 2017) based on Bahdanau et al. (2015) and Luong et al. (2015). We used the publicly available glove-python package[8] to implement our coherence measure.

We experiment on two versions of our model: (1) cVAE with the coherence context gate as described in Section 2.3 (*cVAE-XGate*), (2) cVAE with the original context gate implementation of

---

[4] `http://www.opensubtitles.org`

[5] The coherence score is calculated as shown in Eq (1). We observed that the scores on the training set follow a normal distribution with a slight tail on the negatively correlated side, so we fit a normal distribution to the data with parameters $N(0.25, 0.22)$ and set the cut-off to $+2\sigma$. A histogram of coherence scores is shown in Figure 5 in Supplemental Material A.

[7] Note that Distinct-1 and Distinct-2 are computed on a randomly selected subsets of 4k responses.

[8] `https://github.com/maciejkula/glove-python`

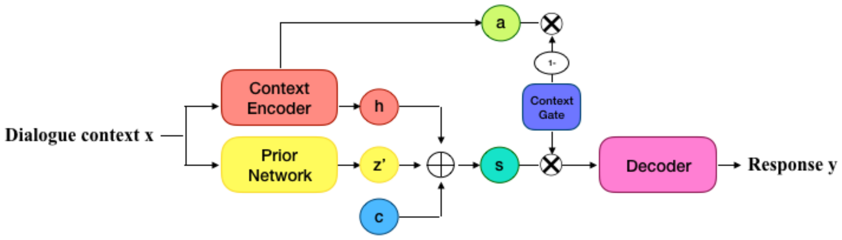

Figure 3: The inference process of the generative model, where the latent variable c is given as an input.

(Tu et al., 2017) (*cVAE-CGate*). For each of these, we consider the main variant where the input coherence measure c is preset to a fixed ideal value as estimated on development data (1.0 for OST and 0.95 for fOST), as well as an oracle variant where we use the true coherence measure between the context and the gold-standard response in the test set (indicated with "(C)" in Tables 2 and 3).

We compare against two baseline models: (1) a vanilla E-D with attention (*Attention*) (Luong et al., 2015); (2) an enhancement where output beams are rescored using the maximum mutual information anti-language model (MMI-antiLM) of Li et al. (2016a) (*MMI*).

4.1 Parameter Settings

We set our model parameters based on preliminary experiments on the development data.

We use 2-layer RNNs with LSTM cells (Hochreiter and Schmidhuber, 1997) with input/hidden dimension of 128 for both the context encoder and the decoder. The dropout rate is set to 0.2 and the Adam optimizer (Kingma and Ba, 2015) is used to update the parameters. A vocabulary of 25,000 words is shared between the encoder and the decoder.

Both the posterior network and prior network for the latent variable learning are built with 2-layer LSTM RNNs with input/hidden dimension of 64. The dimension of the latent variable $\mathbf{z}$ is set to 20. Same as for the encoder and decoder, the dropout rate is 0.2 and the Adam optimizer is used to update the parameters.

The window size for GloVe computation in our coherence measure is set to 10.

4.2 Evaluation metrics

We use a number of metrics to evaluate the outputs of our models:

- **BLEU, B1, B2, B3** – the word-overlap score against gold-standard responses (Papineni et al., 2002) used by the vast majority of recent dialogue generation works (Zhao et al., 2017; Yao et al., 2017; Li et al., 2017a, 2016c; Sordoni et al., 2015; Li et al., 2016a; Ghazvininejad et al., 2017). BLEU in this paper refers to the default BLEU-4, but we also report on lower n-gram scores (B1, B2, B3).[9]
- **Coh** – our novel GloVe-based coherence score calculated using Eq (1) showing the semantic distance of dialogue contexts and generated responses.
- **D-1, D-2, D-Sent** – common metrics used to evaluate the diversity of generated responses (e.g. Li et al., 2016a; Xu et al., 2017; Xing et al., 2017; Dhingra et al., 2017): the proportion of distinct unigrams, bigrams, and sentences in the outputs.

5 Results

All model variants described in Section 4 are trained on both OST and fOST datasets. Tables 2 and 3 present the scores of all models tested on the OST and fOST test sets, respectively. Note that in addition to testing the models on the respective test sections of their training datasets, we also test them on the other dataset (OST-trained models on fOST and vice-versa). This way, we can observe the performance of the fOST-trained models in more noisy contexts and see how good the OST-trained models are when evaluated against coherent responses only.

Given all the evaluated model variants, we can observe the effects and contributions of the individual components of our setup:

- *Data filtering:* The models trained on fOST consistently outperform the same models trained on OST – for all evaluation metrics and on both test sets. This shows that coherence-based training data filtering is generally beneficial.

---

[9] We use the Multi-BLEU script from OpenNMT to measure BLEU scores.

Training data	Model	BLEU%	B1%	B2%	B3%	Coh	D-1%	D-2%	D-Sent%
OST	Attention	1.32	10.92	3.85	2.10	0.293	3.4	14.2	25.6

	cVAE-CGate (0.95)	**4.98**	20.95	**10.93**	**7.02**	**0.814**	12.1	**51.4**	**98.2**
	cVAE-XGate (0.95)	4.47	**20.98**	10.43	6.50	0.797	10.4	42.5	97.6

Table 3: Evaluation results on the fOST test set (see Section 4 and Table 2 for model description; see Section 4.2 for metrics definition). BLEU score reported here is BLEU-4; B1, B2 and B3 denote lower n-gram BLEU scores.

- *cVAE-Context Gate models:* Nearly all cVAE-based models perform markedly better than the baselines w.r.t. BLEU, coherence, and diversity.[10]

  If we look at models trained on OST and tested on fOST (the top half of Table 3), we can see that all cVAE-based models, especially cVAE-XGate, are able to learn to produce coherent and diverse response even when trained on a noisy, incoherent corpus. Examples of responses generated by the baseline MMI model and by cVAE-XGate in Figure 4 show that cVAE-XGate mostly produces more diverse and coherent responses than MMI.

- *Preset c vs. oracle models with gold-standard c:* Table 2 shows that on the noisy OST test set, cVAE-based models using the gold-standard value of c achieve higher BLEU scores than models using preset c. This is expected since many gold-standard responses in the unfiltered set have a low coherence score; – the model can generate a more generic response if the gold-standard c is low. The models with preset c always attempt to generate coherent responses, which is apparent from the other metrics: Coh and D-Sent are consistently higher than for models using gold-standard c.

  On the fOST test set where only high-coherence responses are expected, models using fixed c consistently reach higher scores in all metrics including BLEU (see Table 3). This shows that in general, using a preset constant value of c works well, even better than using the gold-standard c.

In sum, using our coherence measure both for data filtering and inside the models leads to output performance improvements.

---

[10] We performed paired bootstrap re-sampling for the best cVAE model and the best baseline model in each experiments set (Table 2 and Table 3) as is done for MT (Koehn, 2004), which confirmed statistical significance at 99% confidence level for all cases except for models trained on fOST and tested on OST (bottom half of Table 2).

		Dialogue context	Response
1	A:	i have an audition at 4:00.	B-GT: you volunteered.
	B:	apparently now i'm cooking dinner.	B-MMI: i don 't know.
	A:	how did this all happen?	B-XGT: well , i'm going to have a dinner.
2	A:	it's not that easy.	B-GT: the waiting list would take too long.
	B:	we can't contact potential donors.	B-MMI: i don't know.
	A:	if we want to save frank, his brother is his only hope	B-XGT: we can't save him.
3	A:	that fish ate my fish!	B-GT: you'll wait till next year to win one of these.
	B:	you cost me £30,000	B-MMI: i'm sorry.
	A:	sorry, folks.	B-XGT: you owe me a little fish.
4	A:	was it what you wanted?	B-GT: you like model planes?
	B:	no.	B-MMI: i wanted to know.
	A:	i wanted an airplane.	B-XGT: i wanted a helicopter.
5	A:	great.	B-GT: yeah, a vanilla decaf latte.
	B:	thanks so much.	B-MMI: no.
	A:	vanilla decaf latte?	B-XGT: yeah , that 's a good coffee
6	A:	to make everybody happy.	B-GT: and stick it in your mouth.
	B:	which means that sometimes	B-MMI: and you got to take a shower.
	A:	you got to take a pile of poop	B-XGT: and you got to take a walk.
7	A:	now you'll knock again and say you forgot to ask	B-GT: should i knock and make her come here for that?
	B:	if she has a friend for your friend.	B-MMI: you're crazy!
	A:	are you crazy?	B-XGT: i'm crazy, i'm crazy.
8	A:	i knew you would say that.	B-GT: you are all way too pretty to be arguing.
	B:	mr. kerem is a charming and decent guy.	B-MMI: he's a very good man.
	A:	and he's really into you.	B-XGT: i didn't say that.

Figure 4: Generation output examples comparing two models trained on the OST dataset and tested on the fOST test set: the MMI baseline (B-MMI) and our cVAE-XGate (1.0) model (B-XGT). B-GT is the ground-truth response from the test set. The three sequential dialog turns on the left are the preceding dialogue context used to generate the responses. Corresponding topical phrases are underlined. We can see that cVAE-XGate (1.0) mostly produces markedly more coherent and specific outputs than MMI (1-5). In some cases, it is comparable with MMI (6-7) and occasionally, it is less coherent (8).

6 Related Work

Our work fits into the context of the very active area of end-to-end generative conversation models, where neural E-D approaches have been first applied by Vinyals and Le (2015) and extended by many others since.

Many works address the lack of diversity and coherence in E-D outputs (Sountsov and Sarawagi, 2016; Wei et al., 2017) but do not attempt to model coherence directly, unlike our work: Li et al. (2016a) use anti-LM reranking; Li et al. (2016c) modify the beam search decoding algorithm, similar to Shao et al. (2017) in addition to using a self-attention model. Mou et al. (2016) predict keywords for the output in a preprocessing step while Wu et al. (2018) preselect a vocabulary subset to be used for decoding. Li et al. (2016b) focus specifically on personality generation (using personality embeddings) and Wang et al. (2017) promote topic-specific outputs by language-model rescoring and sampling.

A lot of recent works explore the use of additional training signals and VAE setups in dialogue generation. In contrast to this paper, they do not focus explicitly on coherence: Asghar et al. (2017) use reinforcement learning with human-provided feedback, Li et al. (2017a) use a RL scenario with length as reward signal. Li et al. (2017b) add an adversarial discriminator to provide RL rewards (discriminating between human and machine outputs), Xu et al. (2017) use a full adversarial training setup. The most recent works explore the usage of VAEs: Cao and Clark (2017) explore a vanilla VAE setup conditioned on dual encoder (for contexts and responses) during training, the model of Serban et al. (2017) uses a VAE in a hierarchical E-D model. Shen et al. (2017) use a cVAE conditioned on sentiment and response genericity (based on a handwritten list of phrases). Shen et al. (2018) combine a cVAE with a plain VAE in an adversarial fashion.

We also draw on ideas from other areas than dialogue generation to build our models: Tu et al. (2017)'s context gates originate from machine translation and Hu et al. (2017)'s cVAE training stems from free-text generation.

7 Conclusions and Future Work

We showed that explicitly modeling coherence and optimizing towards coherence and diversity leads to better-quality outputs in dialogue response generation. We introduced three extensions to current encoder-decoder response generation models: (1) we defined a measure of coherence based on GloVe embeddings (Pennington et al., 2014), (2) we filtered the OpenSubtitles training corpus (Lison and Meena, 2016) based on this measure to obtain coherent and diverse training instances, (3) we trained a cVAE model based on (Hu et al., 2017) and (Tu et al., 2017) that uses our coherence measure as one of the training signals. Our experimental results showed a considerable improvement in the output quality over competitive models, which demonstrates the effectiveness of our approach.

In future work, we plan to replace the GloVe-based measure of coherence with a trained discriminator that distinguishes between coherent and incoherent responses (Li and Jurafsky, 2017). This will allow us to use extend the notion of coherence to account for phenomena such as topic shifts. We also plan to verify the results with a human evaluation study.

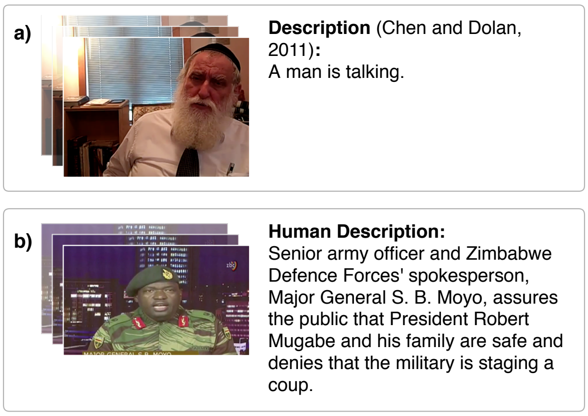
Abstract

Most previous efforts toward video captioning focus on generating generic descriptions, such as, “A man is talking.” We collect a news video dataset to generate enriched descriptions that include important background knowledge, such as named entities and related events, which allows the user to fully understand the video content. We develop an approach that uses video meta-data to retrieve topically related news documents for a video and extracts the events and named entities from these documents. Then, given the video as well as the extracted events and entities, we generate a description using a *Knowledge-aware Video Description* network. The model learns to incorporate entities found in the topically related documents into the description via an *entity pointer network* and the generation procedure is guided by the event and entity types from the topically related documents through a *knowledge gate*, which is a gating mechanism added to the model’s decoder that takes a one-hot vector of these types. We evaluate our approach on the new dataset of news videos we have collected, establishing the first benchmark for this dataset as well as proposing a new metric to evaluate these descriptions.

1 Introduction

Video captioning is a challenging task that seeks to automatically generate a natural language description of the content of a video. Many video captioning efforts focus on learning video representations that model the spatial and temporal dynamics of the videos (Yao et al., 2015; Venugopalan et al., 2016; Yu et al., 2017). Although the language generation component within this task is of great importance, less work has been done to enhance the contextual knowledge conveyed by the descriptions. The descriptions generated by previous methods tend to be “generic”, describing only what is evidently visible and lacking specific knowledge, like named entities and event participants, as shown in Figure 1a. In many situations, however, generic descriptions are uninformative as they do not provide contextual knowledge. For example, in Figure 1b, details such as *who is speaking* or *why they are speaking* are imperative to truly understanding the video, since contextual knowledge gives the surrounding circumstances or cause of the depicted events.



Description (Chen and Dolan, 2011)**:**
A man is talking.

Human Description:
Senior army officer and Zimbabwe Defence Forces' spokesperson, Major General S. B. Moyo, assures the public that President Robert Mugabe and his family are safe and denies that the military is staging a coup.

Figure 1: Comparison of machine (a) and human (b) generated descriptions.[1]

To address this problem, we collect a news video dataset, where each video is accompanied by meta-data (*e.g.*, tags and date) and a natural language description of the content in, and/or context around, the video. We create an approach to this task that is motivated by two observations.

First, the video content alone is insufficient to generate the description. Named entities or specific events are necessary to identify the participants, location, and/or cause of the video content. Although knowledge could potentially be mined from visual evidence (*e.g.*, recognizing the location), training such a system is exceedingly diffi-

cult (Tran et al., 2016). Further, not all the knowledge necessary for the description may appear in the video. In Figure 2a, the video depicts much of the description content, but knowledge of the speaker ("*Carles Puigdemont*") is unavailable if limited to the visual evidence because the speaker never appears in the video, making it intractable to incorporate this knowledge into the description.

Second, one may use a video's meta-data to retrieve topically related news documents that contain the named entities or events that appear in the video's description, but these may not be specific to the video content. For example, in Figure 2b, the video discusses the "*heightened security*" and does not depict the arrest directly. Topically related news documents capture background knowledge about the attack that led to the "*heightened security*" as well as the arrest, but they may not describe the actual video content, which displays some of the increased security measures.

Thus, we propose to retrieve topically related news documents from which we seek to extract named entities (Pan et al., 2017) and events (Li et al., 2013) likely relevant to the video. We then propose to use this knowledge in the generation process through an *entity pointer network*, which learns to dynamically incorporate extracted entities into the description, and through a new *knowledge gate*, which conditions the generator on the extracted event and entity types. We include the video content in the generation by learning video representations using a spatio-temporal hierarchical attention that spatially attends to regions of each frame and temporally attends to different frames. We call the combination of these generation components the *Knowledge-aware Video Description* (KaVD) network. The contributions of this paper are as follows:

- We create a knowledge-rich video captioning dataset, which can serve as a new benchmark for future work.
- We propose a new *Knowledge-aware Video Description* network that can generate descriptions using the video and background knowledge mined from topically related documents.
- We present a knowledge reconstruction based metric, using entity and event F1 scores, to evaluate the correctness of the knowledge conveyed in the generated descriptions.

Figure 2: Examples from the news video dataset (video, meta-data, and description) with some retrieved topically related documents.[2]

2 Approach

Figure 3 shows our overall approach. We first retrieve topically related news documents using tags from the video meta-data. Next, we apply entity discovery and linking as well as event extraction methods to the documents, which yields a set of entities and events relevant to the video. We represent this background knowledge in two ways: 1) we encode the entities through entity embeddings and 2) we encode the event and entity typing information into a *knowledge gate vector*, which is a one-hot vector where each entry represents an entity or event type. Finally, with the video and these representations of the background knowledge, we employ our KaVD network, an encoder-decoder (Cho et al., 2014) style model, to generate the description.

2.1 Document Retrieval and Knowledge Extraction

We gather topically related news documents as a source of background knowledge using the video meta-data. For each video, we use the corresponding tags to perform a keyword search on documents from a number of popular news outlet web-

---

[2] (a) https://goo.gl/3cF1oU, (b) https://goo.gl/NkwHvJ

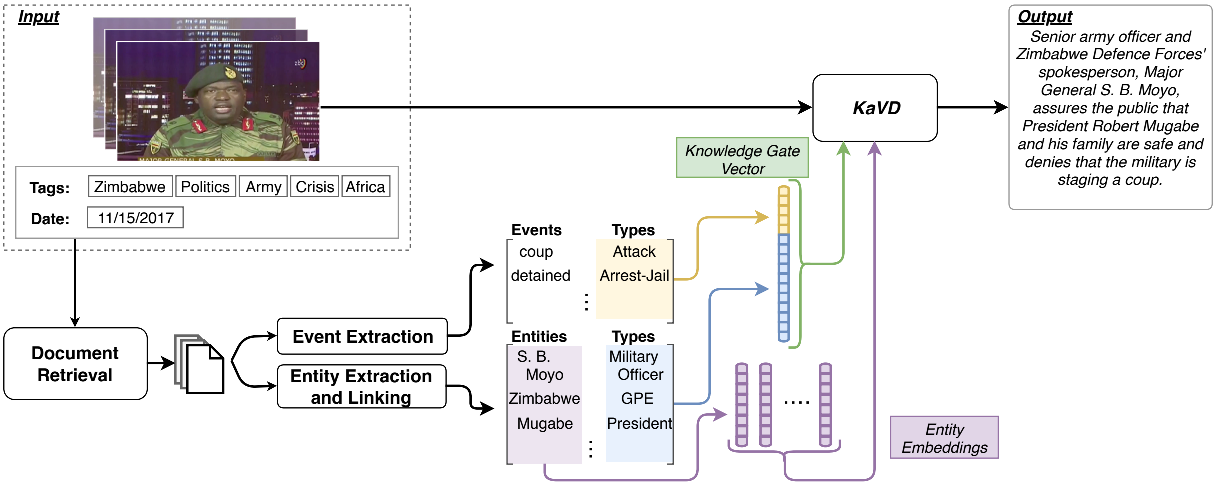

Figure 3: Overall pipeline of our approach.

sites.[3] We filter these documents by the date associated with video, only keeping documents that are written within d days before and after the video upload date.[4] The keyword search gathers documents that are at least somewhat topically relevant and filtering by date increases the likelihood that the documents reference the specific events and entities of the video, since the occurrences of entity and event mentions across news documents tend to be temporally correlated. We retrieve an average of 3.1 articles per video and find that on average 68.8% of the event types and 70.6% of the entities in the ground truth description also appear in corresponding news articles. In Figure 3, the retrieved background documents include the entity "*Mugabe*" and the event "*detained*", which are relevant to the video description.

We apply a high-performing, publicly available entity discovery and linking system (Pan et al., 2017) to extract named entities and their types. This system is able to discover entities and link them to rich knowledge bases that provide fine-grained types that we can exploit to better discern between entities in the news documents (*e.g.*, "`President`" versus "`Military Officer`").[5] Additionally, we use a high-performing event extraction system (Li et al., 2013) to extract events and their arguments. For example, in Figure 3, we get entities "*S. B. Moyo*", "*Zimbabwe*", and "*Mugabe*" with their respective types, "`Military Officer`", "`GPE`", and "`President`". Likewise, we obtain events "*coup*" and "*detained*" with their respective types, "`Attack`" and "`Arrest-Jail`". The entities and events along with their types provide valuable insight into the context of the video and can bias the decoder to generate the correct event mentions and incorporate the proper entities.

We encode the entities and events into representations that can be fed to the model. First, we obtain an entity embedding, $\mathbf{e}_m$, for each entity by averaging the embeddings of the words in the entity mention. Second, we encode the entity and event types into a one-hot knowledge gate vector, $\mathbf{k}_0$. Each element of $\mathbf{k}_0$ corresponds to an event or entity type (*e.g.*, "`Arrest-Jail`" event type or "`President`" entity type), so the j^{th} element, $k^{(j)}$, is 1 if the entity or event type is found in the related documents and 0 otherwise. $\mathbf{k}_0$ serves as the initial knowledge gate vector of the decoder (Section 2.2). The entity embeddings give the model access to semantic representations of the entities, while the knowledge gate vector aids the generation process by providing the model with the event and entity types.

2.2 KaVD Network

Our model learns video representations using hierarchical, or multi-level, attention (Yang et al., 2016; Qin et al., 2017). The encoder is comprised of a spatial attention (Xu et al., 2015) and bidirectional Long Short-Term Memory network (LSTM) (Hochreiter and Schmidhuber, 1997) temporal encoder. The spatial attention allows the model to attend to different locations of each frame (Figure 4), yielding frame representations

[4] $d = 3$ in our experiments.

[5] We only use types that appear in the training data and are within 4 steps from the top of the 7,309 type hierarchy *here*.

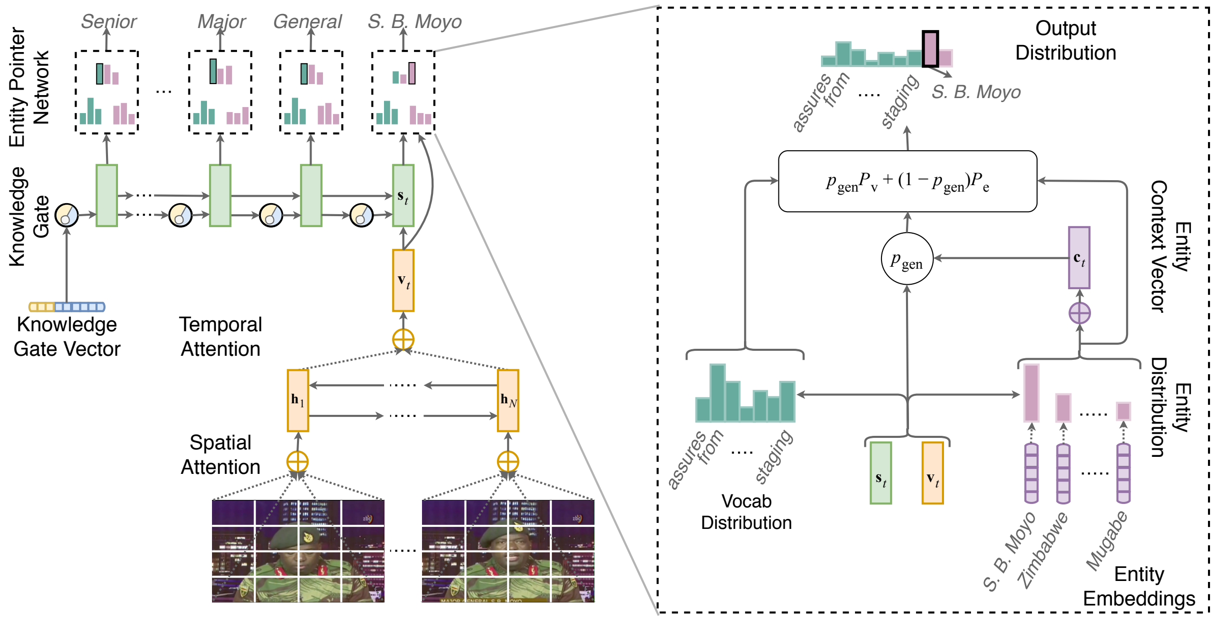

Figure 4: KaVD Network. At each decoder time step, the model computes p_{gen} to determine whether to emit a vocabulary word or a named entity from the topically related documents.

that emphasize the most important regions of each frame. The temporal encoder incorporates motion into the frame representations by encoding information from the preceding and subsequent frames (Yao et al., 2015). We use a LSTM decoder, which applies a temporal attention (Bahdanau et al., 2015) to the frame representations at each step. To generate each word, the decoder computes its hidden state, adjusts this hidden state with the *knowledge gate* output at the current time step, and determines the most probable word by utilizing the *entity pointer network* to decide whether to generate a named entity or vocabulary word. Pointer networks are effective at incorporating out-of-vocabulary (OOV) words in output sequences (Miao and Blunsom, 2016; See et al., 2017). In previous research, OOV words may appear in the input sequence, in which case they are copied into the output. Analogously, in our approach, named entities can be considered as OOV words that are from a separate set instead of the input sequence. In the following equations, where appropriate, we omit bias terms for brevity.

Encoder. The input to the encoder is a sequence of video frames, $\{F_1, ..., F_N\}$. First, we extract frame-level features by applying a Convolutional Neural Network (CNN) (Krizhevsky et al., 2012; Simonyan and Zisserman, 2014; Ioffe and Szegedy, 2015; Szegedy et al., 2015, 2017) to each frame, F_i, and obtaining the response of a convolutional layer, $\{\mathbf{a}_{i,1}, ..., \mathbf{a}_{i,L}\}$, where $\mathbf{a}_{i,l}$ is a D-dimensional representation of the l^{th} location of the i^{th} frame (*e.g.*, the top left box of the first frame in Figure 4). We apply a spatial attention to these location representations, given by

$$\alpha_{i,l} = a_{\text{space}}\left(\mathbf{a}_{i,l}\right) \tag{1}$$

$$\xi_{i,l} = \text{softmax}\left(\alpha_{i,l}\right) \tag{2}$$

$$\mathbf{z}_i = \sum_{l=1}^{L} \xi_{i,l}\mathbf{a}_{i,l} \tag{3}$$

where a_{space} is a scoring function (Bahdanau et al., 2015). Frame representations $\{\mathbf{z}_1, ..., \mathbf{z}_N\}$ are input to a bi-directional LSTM, producing temporally encoded frame representations $\{\mathbf{h}_1, ..., \mathbf{h}_N\}$.

Decoder. The decoder is an attentive LSTM cell with the addition of a *knowledge gate* and *entity pointer network*. At each decoder step t, we apply a temporal attention to the frame representations,

$$\beta_{t,i} = a_{\text{time}}\left(\mathbf{h}_i, \mathbf{s}_{t-1}\right) \tag{4}$$

$$\eta_{t,i} = \text{softmax}\left(\beta_{t,i}\right) \tag{5}$$

$$\mathbf{v}_t = \sum_{i=1}^{N} \eta_{t,i}\mathbf{h}_i \tag{6}$$

where $\mathbf{s}_{t-1}$ is the previous decoder hidden state and a_{time} is another scoring function. This yields a single, spatio-temporally attentive video representation, $\mathbf{v}_t$. We then compute an intermediate hidden state, $\hat{\mathbf{s}}_t$, by applying the decoder LSTM to $\mathbf{s}_{t-1}$, $\mathbf{v}_t$, and previous word embedding, $\mathbf{x}_{t-1}$. The final decoder hidden state is determined after the knowledge gate computation.

The motivation for the knowledge gate is that it biases the model to generate sentences that contain specific knowledge relevant to the video and topically related documents, acting as a kind of coverage mechanism (Tu et al., 2016). For example, given the retrieved event types in Figure 3, the knowledge gate encourages the decoder to generate the event trigger "*coup*" due to the presence of the "`Attack`" event type. Inspired by the gating mechanisms from natural language generation (Wen et al., 2015; Tran and Nguyen, 2017), the knowledge gate, $\mathbf{g}_t$, is given by

$$\mathbf{g}_t = \sigma\left(\mathbf{W}_{g,v}[\mathbf{x}_{t-1}, \mathbf{v}_t] + \mathbf{W}_{g,s}\hat{\mathbf{s}}_t\right) \quad (7)$$

$$\mathbf{k}_t = \mathbf{g}_t \odot \mathbf{k}_{t-1} \quad (8)$$

where all $\mathbf{W}$ are learned parameters and $[\mathbf{x}_{t-1}, \mathbf{v}_t]$ is the concatenation of these two vectors. This gating step determines the amount of the entity and event type features contained in $\mathbf{k}_{t-1}$ to carry to the next step. With the updated $\mathbf{k}_t$, we compute the decoder hidden state, $\mathbf{s}_t$, as

$$\mathbf{s}_t = \hat{\mathbf{s}}_t + (\mathbf{o}_t \odot \tanh\left(\mathbf{W}_{s,k}\mathbf{k}_t\right)) \quad (9)$$

where $\mathbf{o}_t$ is the output gate of the LSTM and $\mathbf{W}_{s,k}$ is a learned parameter.

Our next step is to generate the next word. The model needs to produce named entities (*e.g.*, "*S. B. Moyo*" and "*Robert Mugabe*") throughout the generation process. These named entities tend to occur rarely if at all in many datasets, including ours. We overcome this issue by using the entity embeddings from the topically related documents as potential entities to incorporate in the description. We adopt a soft switch pointer network (See et al., 2017), as our entity pointer network, to perform the selection of generating words or entities.

For our entity pointer network to predict the next word, we first predict a vocabulary distribution, $P_{\text{v}} = \psi\left(\mathbf{s}_t, \mathbf{v}_t\right)$, where $\psi(\cdot)$ is a softmax output layer. $P_{\text{v}}(w)$ is the probability of generating word w from the decoder vocabulary. Next, we compute an entity context vector, $\mathbf{c}_t$, using a soft attention mechanism:

$$\gamma_{t,m} = a_{\text{entity}}\left(\mathbf{e}_m, \mathbf{s}_t, \mathbf{v}_t\right) \quad (10)$$

$$\epsilon_{t,m} = \text{softmax}\left(\gamma_{t,m}\right) \quad (11)$$

$$\mathbf{c}_t = \sum_{m=1}^{M} \epsilon_{t,m}\mathbf{e}_m \quad (12)$$

Here, a_{entity} is yet another scoring function. We use the scalars $\epsilon_{t,m}$ as our entity probability distribution, P_{e}, where $P_{\text{e}}\left(E_m\right) = \epsilon_{t,m}$ is the probability of generating entity mention E_m. We compute the probability of generating a word from the vocabulary, p_{gen}, as

$$p_{\text{gen}} = \sigma(\mathbf{w}_c^\top\mathbf{c}_t + \mathbf{w}_s^\top\mathbf{s}_t + \mathbf{w}_x^\top\mathbf{x}_{t-1} + \mathbf{w}_v^\top\mathbf{v}_t) \quad (13)$$

where all $\mathbf{w}$ are learned parameters. Finally, we predict the probability of word w by

$$P(w) = p_{\text{gen}}P_{\text{v}}(w) + (1 - p_{\text{gen}})P_{\text{e}}(w) \quad (14)$$

and select the word of maximum probability. In Equation 14, $P_{\text{e}}(w)$ is 0 when w is not a named entity. Likewise, P_{v} is 0 when w is an OOV word. For the example in Figure 4, the vocabulary distribution, P_{v}, has the word "*from*" as the most probable word and the entity distribution, P_{e}, has the entity "*S. B. Moyo*" as the most probable entity. However, by combining these two distribution using p_{gen}, the model switches to the entity distribution and correctly generates "*S. B. Moyo*".

3 News Video Dataset

Current datasets for video description generation focus on specific (Rohrbach et al., 2014) and general (Chen and Dolan, 2011; Xu et al., 2016) domains, but do not contain a large proportion of descriptions with specific knowledge like named entities as shown in Table 1. In our news video dataset, the descriptions are replete with important knowledge that is both necessary and challenging to incorporate into the generated descriptions.

Our news video dataset contains AFP international news videos from YouTube.[6] These videos are from October, 2015 to November, 2017 and cover a variety of topics, such as protests, attacks, natural disasters, trials, and political movements. The videos are "on-the-scene" and contain some depiction of the content in the description. For each video, we take the YouTube descriptions given by AFP News as the ground-truth descriptions we wish to generate. We collect the tags and meta-data (*e.g.*, upload date). We filter videos by length, with a cutoff of 2 minutes, and remove videos which are videographics or animations. For preprocessing, we tokenize each sentence, remove punctuation characters other than

4 Experiments

4.1 Model Comparisons

We test our method against the following baselines: **Article-only.** We use the summarization model of See et al. (2017) to generate the description by summarizing the topically related documents. **Video-only (VD).** We train a model that does not receive any background knowledge and generates the description directly from the video. **VD with knowledge gate only (VD+Knowledge Gate), VD with entity pointer network only (VD+Entity Pointer), and no-video (Entity Pointer+Knowledge Gate).** These test the effects of the knowledge gate, entity pointer network, and video encoder in isolation.

Each model uses a cross entropy loss. Video-based models are trained using the Adam optimizer (Kingma and Ba, 2015) with a learning rate of 0.0002 and have a hidden state size of 512 as well as an embedding size of 300. We use Google News pre-trained word embeddings (Mikolov et al., 2013) to initialize our word embeddings and compute entity embeddings. For visual features, we use the Conv3-512 layer response of VGGNet (Simonyan and Zisserman, 2014) pre-trained on ImageNet (Deng et al., 2009).

4.2 Evaluations

METEOR (Denkowski and Lavie, 2014) and ROUGE-L (Lin, 2004) are adopted as metrics for evaluating the generated descriptions. We choose METEOR because we only have one reference description per video and this metric accounts for stemming and synonym matching. We also use ROUGE-L for comparison to summarization work. These capture the coherence and relevance of the generated descriptions to the ground truth.

Generating these descriptions is concerned with not only generating fluent text, but also the amount of knowledge conveyed and the accuracy of the knowledge elements (*e.g.*, named entities or event structures). Previous work in natural language generation and summarization (Nenkova and Passonneau, 2004; Novikova et al., 2017; Wiseman et al., 2017; Pasunuru and Bansal, 2018) scores and/or assigns weights to overlapping text, salient phrases, or information units (*e.g.*, entity relations (Wiseman et al., 2017)). However, knowledge elements cannot be simply represented as a set of isolated information units since they are inherently interconnected through some structure.

Therefore, for this knowledge-centric generation task, we compute F1 scores on event and entity extraction results from the generated descriptions against the extraction results on the ground truth. For entities, we measure the F1 score of the named entities in the generated description compared to the ground truth. For events, given a generated description, w^s, and the ground truth description, w^c, we extract a set of event structures, $\mathcal{Y}^s$ and $\mathcal{Y}^c$, for both descriptions such that $\mathcal{Y} = \{(t_k, r_{k,1}, a_{k,1}, ..., r_{k,m}, a_{k,m})\}_{k=1}^{K}$ where there are K events extracted from the description, t_k is the k^{th} event type, $r_{k,m}$ is the m^{th} argument role of t_k, and $a_{k,m}$ is the m^{th} argument of t_k. For the description in Figure 2a, one may obtain:

$$\mathcal{Y} = \{(\texttt{Demonstrate}, \texttt{Entity}, \text{“\textit{Pro-independence supporters}”}, \texttt{Place}, \text{“\textit{Barcelona}”})\}$$

Next, we form event type, argument role, and argument triples $(t^s_k, r^s_{k,m}, a^s_{k,m})$ and $(t^c_j, r^c_{j,m}, a^c_{j,m})$ for each event structure in $\mathcal{Y}^s$ and $\mathcal{Y}^c$, respectively. We compute the F1 score of the triples, considering a triple correct if and only if it appears in the ground truth triples.[7] This metric enables us to evaluate how well a generated description captures the overall events, while still giving credit to partially correct event structures. We compute these F1 scores on 50 descriptions based on manually annotated event structures. We also perform automatic F1 score evaluation on the entire test set using the entity and event extraction systems of Pan et al. (2017) and Li et al. (2013), respectively. The manual evaluations offer accurate comparisons and control for correctness, while the automated evaluations explore the viability of using automated IE tools to measure performance, which is desirable for scaling to larger datasets for which manual evaluations are too expensive.

5 Results and Analysis

The KaVD network outperforms almost all of the baselines, as shown in Table 2, achieving statistically significant improvements in METEOR and ROUGE-L w.r.t. all other models besides the no-video model ($p < 0.05$).[8] The additions of the entity pointer network and knowledge gate are complementary and greatly improve the entity incorporation performance, increasing the entity F1 scores by at least 6% in both the manual and automatic evaluations. In Figure 5a, the entity pointer network is able to incorporate the entity "*Abdiaziz Abu Musab*", who is a leader of the group responsible for the attack. We find that the entity and event type features from the knowledge gate help generate more precise entities. However, noise in the article retrieval process and entity extraction system limits our entity incorporation capabilities, since on average only 70.6% of the entities in the ground truth description are retrieved from the articles. Lastly, the video encoder helps generate the correct events and offers qualitative benefits, such as allowing the model to generate more concise and diverse descriptions, though it negatively affects the entity incorporation performance.

The video alone is insufficient to generate the correct entities (Table 2). In Figure 5a, the VD baseline generates the correct event, but generates the incorrect location "*Kabul*". We observe that when the visual evidence is ambiguous, this model may fail to generate the correct events and entities. For example, if a video depicts the destruction of buildings after a hurricane, then the VD baseline may mistakenly describe the video as an explosion since the visual evidence is similar.

The article-only baseline tends to mention the correct entities as shown in Figure 5a, where the description is generally on topic but provides some irrelevant information. Indeed, this model can generate descriptions unrelated to the video itself. In Figure 5b, the article-only baseline's description contains some correct entities (*e.g.*, "*Colombia*"), but is not focused on the announcement depicted in the video. As See et al. (2017) discuss, this model can be more extractive than abstractive, copying many sequences from the documents. This can lead to irrelevant descriptions as the articles may not be specific to the video.

Our entity and event F1 score based metrics correlate well with the correctness of the knowledge conveyed in the generated description. The consistency in model rankings between the manual and automatic entity metrics shows the potential of using automated entity extraction approaches to evaluate with this metric. We observe discrepancies between the manual and automatic event metrics, in part, due to errors in the automated extraction and the addition of more test points. For example, in the generated sentence, "*Hundreds of people are to take to the streets of...*", the event extraction system mistakenly assigns a "`Transport`" event type instead of the correct "`Demonstrate`" event type. In contrast, such mistakes do not appear in the manual evaluations.

6 Related Work

Most previous video captioning efforts focus on learning video representations through different encoding techniques (Venugopalan et al., 2015a,b), using spatial or temporal attentions (Yao et al., 2015; Pan et al., 2016; Yu et al., 2016; Zanfir et al., 2016), using 3D CNN features (Tran et al., 2015; Yao et al., 2015; Pan et al., 2016), or easing the learning process via multi-task learning or reinforcement rewards (Pasunuru and Bansal, 2017a,b). Compared to other hierarchical models (Pan et al., 2016; Yu et al., 2016), each level of our hierarchy encodes a different dimension of the video, leveraging global temporal features and local spatial features, which are shown to be effective for different tasks (Ballas et al., 2015; Xu et al., 2015; Yu et al., 2017).

We move towards using datasets with captions that have specific knowledge rather than generic

captions as in previous work (Chen and Dolan, 2011; Rohrbach et al., 2014; Xu et al., 2016). There are efforts in image captioning to personalize captions (Park et al., 2017), incorporate novel objects into captions (Venugopalan et al., 2016), and perform open domain captioning (Tran et al., 2016). To the best of our knowledge, our dataset is the first of its kind and offers challenges in entity and activity recognition as well as the generation low probability words. Datasets with captions rich in knowledge elements, like those in our dataset, take a necessary step towards increasing the utility of video captioning systems.

We employ similar approaches to those in automatic summarization, where pointer networks (Vinyals et al., 2015) and copy mechanisms (Gu et al., 2016) are used (Gulcehre et al., 2016; Nallapati et al., 2016; Miao and Blunsom, 2016; See et al., 2017), and natural language generation for dialogue systems (Wen et al., 2015; Tran and Nguyen, 2017). The KaVD network combines the copying capabilities of pointer networks (See et al., 2017) and semantic control of gating mechanisms (Wen et al., 2015; Tran and Nguyen, 2017) in a complementary fashion to address a new, multi-modal task.

7 Conclusions and Future Work

We collect a news video dataset with knowledge-rich descriptions and present a multi-modal approach to this task that uses a novel Knowledge-aware Video Description network, which can utilize background knowledge mined from topically related documents. We offer a new metric to measure a model's ability to incorporate named entities and specific events into the descriptions. We show the effectiveness of our approach and set a new benchmark for this dataset. In future work, we are increasing the size of dataset and exploring other knowledge-centric metrics for this task.

Abstract

Generating natural questions from an image is a semantic task that requires using visual and language modality to learn multimodal representations. Images can have multiple visual and language contexts that are relevant for generating questions namely places, captions, and tags. In this paper, we propose the use of exemplars for obtaining the relevant context. We obtain this by using a Multimodal Differential Network to produce natural and engaging questions. The generated questions show a remarkable similarity to the natural questions as validated by a human study. Further, we observe that the proposed approach substantially improves over state-of-the-art benchmarks on the quantitative metrics (BLEU, METEOR, ROUGE, and CIDEr).

1 Introduction

To understand the progress towards multimedia vision and language understanding, a visual Turing test was proposed by (Geman et al., 2015) that was aimed at visual question answering (Antol et al., 2015). Visual Dialog (Das et al., 2017) is a natural extension for VQA. Current dialog systems as evaluated in (Chattopadhyay et al., 2017) show that when trained between bots, AI-AI dialog systems show improvement, but that does not translate to actual improvement for Human-AI dialog. We believe that this is because, the questions generated by bots are not natural (human-like) and therefore does not translate to improved human dialog. Therefore an improvement in the quality of questions could enable dialog agents to perform well in human interactions. Further, (Ganju et al., 2017) show that unanswered questions can be used for improving VQA, Image captioning and Object Classification.

An interesting line of work in this respect is the work of (Mostafazadeh et al., 2016). Here the authors have proposed the challenging task of generating *natural* questions for an image. One aspect that is central to a question is the context that is relevant to generate it. However, this context changes for every image. As can be seen in Figure 1, an image with a person on a skateboard would result in questions related to the event. Whereas for a little girl, the questions could be related to age rather than the action. How can one have widely varying context provided for generating questions? To solve this problem, we use the context obtained by considering exemplars, specifically we use the difference between relevant and irrelevant exemplars. We consider different contexts in the form of Location, Caption, and Part of Speech tags.

Figure 1: Can you guess which among the given questions is human annotated and which is machine generated? [0]

Our method implicitly uses a differential context obtained through supporting and contrasting exemplars to obtain a differential embedding. This embedding is used by a question decoder to decode the appropriate question. As discussed further, we observe this implicit differential context to perform better than an explicit keyword

---

[0] The human annotated questions are (b) for the first image and (a) for the second image.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4002–4012
Brussels, Belgium, October 31 - November 4, 2018. ©2018 Association for Computational Linguistics

based context. The difference between the two approaches is illustrated in Figure 2. This also allows for better optimization as we can backpropagate through the whole network. We provide detailed empirical evidence to support our hypothesis. As seen in Figure 1 our method generates natural questions and improves over the state-of-the-art techniques for this problem.

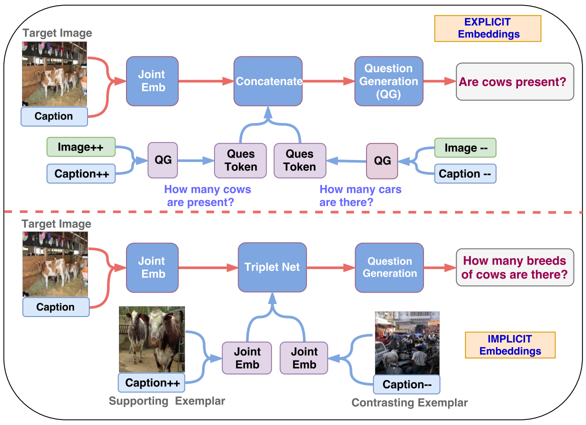

Figure 2: Here we provide intuition for using implicit embeddings instead of explicit ones. As explained in section 1, the question obtained by the implicit embeddings are natural and holistic than the explicit ones.

To summarize, we propose a multimodal differential network to solve the task of visual question generation. Our contributions are: (1) A method to incorporate exemplars to learn differential embeddings that captures the subtle differences between supporting and contrasting examples and aid in generating natural questions. (2) We provide Multimodal differential embeddings, as image or text alone does not capture the whole context and we show that these embeddings outperform the ablations which incorporate cues such as only image, or tags or place information. (3) We provide a thorough comparison of the proposed network against state-of-the-art benchmarks along with a user study and statistical significance test.

2 Related Work

Generating a natural and engaging question is an interesting and challenging task for a smart robot (like chat-bot). It is a step towards having a natural visual dialog instead of the widely prevalent visual question answering bots. Further, having the ability to ask natural questions based on different contexts is also useful for artificial agents that can interact with visually impaired people. While the task of generating question automatically is well studied in NLP community, it has been relatively less studied for image-related natural questions. This is still a difficult task (Mostafazadeh et al., 2016) that has gained recent interest in the community.

Recently there have been many deep learning based approaches as well for solving the text-based question generation task such as (Du et al., 2017). Further, (Serban et al., 2016) have proposed a method to generate a factoid based question based on triplet set {subject, relation and object} to capture the structural representation of text and the corresponding generated question.

These methods, however, were limited to text-based question generation. There has been extensive work done in the Vision and Language domain for solving image captioning, paragraph generation, Visual Question Answering (VQA) and Visual Dialog. (Barnard et al., 2003; Farhadi et al., 2010; Kulkarni et al., 2011) proposed conventional machine learning methods for image description. (Socher et al., 2014; Vinyals et al., 2015; Karpathy and Fei-Fei, 2015; Xu et al., 2015; Fang et al., 2015; Chen and Lawrence Zitnick, 2015; Johnson et al., 2016; Yan et al., 2016) have generated descriptive sentences from images with the help of Deep Networks. There have been many works for solving Visual Dialog (Chappell et al., 2004; Das et al., 2016, 2017; De Vries et al., 2017; Strub et al., 2017). A variety of methods have been proposed by (Malinowski and Fritz, 2014; Lin et al., 2014; Antol et al., 2015; Ren et al., 2015; Ma et al., 2016; Noh et al., 2016) for solving VQA task including attention-based methods (Zhu et al., 2016; Fukui et al., 2016; Gao et al., 2015; Xu and Saenko, 2016; Lu et al., 2016; Shih et al., 2016; Patro and Namboodiri, 2018). However, Visual Question Generation (VQG) is a separate task which is of interest in its own right and has not been so well explored (Mostafazadeh et al., 2016). This is a vision based novel task aimed at generating natural and engaging question for an image. (Yang et al., 2015) proposed a method for continuously generating questions from an image and subsequently answering those questions. The works closely related to ours are that of (Mostafazadeh et al., 2016) and (Jain et al., 2017). In the former work, the authors used an encoder-decoder based framework whereas in the latter work, the authors extend it by using a variational autoencoder based sequential routine to obtain natural questions by performing sampling of the latent variable.

3 Approach

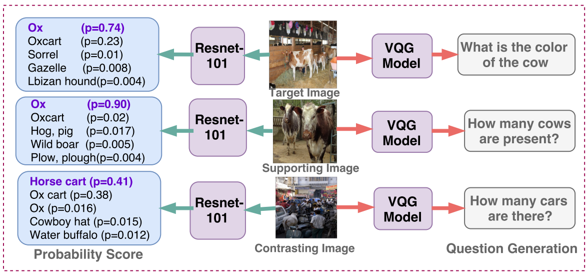

Figure 3: An illustrative example shows the validity of our obtained exemplars with the help of an object classification network, RESNET-101. We see that the probability scores of target and supporting exemplar image are similar. That is not the case with the contrasting exemplar. The corresponding generated questions when considering the individual images are also shown.

In this section, we clarify the basis for our approach of using exemplars for question generation. To use exemplars for our method, we need to ensure that our exemplars can provide context and that our method generates valid exemplars.

We first analyze whether the exemplars are valid or not. We illustrate this in figure 3. We used a pre-trained RESNET-101 (He et al., 2016) object classification network on the target, supporting and contrasting images. We observed that the supporting image and target image have quite similar probability scores. The contrasting exemplar image, on the other hand, has completely different probability scores.

Exemplars aim to provide appropriate context. To better understand the context, we experimented by analysing the questions generated through an exemplar. We observed that indeed a supporting exemplar could identify relevant tags (cows in Figure 3) for generating questions. We improve use of exemplars by using a triplet network. This network ensures that the joint image-caption embedding for the supporting exemplar are closer to that of the target image-caption and vice-versa. We empirically evaluated whether an explicit approach that uses the differential set of tags as a one-hot encoding improves the question generation, or the implicit embedding obtained based on the triplet network. We observed that the implicit multimodal differential network empirically provided better context for generating questions. Our understanding of this phenomenon is that both target and supporting exemplars generate similar questions whereas contrasting exemplars generate very different questions from the target question. The triplet network that enhances the joint embedding thus aids to improve the generation of target question. These are observed to be better than the explicitly obtained context tags as can be seen in Figure 2. We now explain our method in detail.

4 Method

The task in visual question generation (VQG) is to generate a natural language question $\hat{Q}$, for an image I. We consider a set of pre-generated context C from image I. We maximize the conditional probability of generated question given image and context as follows:

$$\hat{\theta} = \arg\max_{\theta} \sum_{(I,C,Q)} \log P(Q|\, I, C, \theta) \qquad (1)$$

where θ is a vector for all possible parameters of our model. Q is the ground truth question. The log probability for the question is calculated by using joint probability over $\{q_0, q_1, ..., q_N\}$ with the help of chain rule. For a particular question, the above term is obtained as:

$$\log P(\hat{Q}|I, C) = \sum_{t=0}^{N} \log P(q_t|I, C, q_0, .., q_{t-1})$$

where N is length of the sequence, and q_t is the t^{th} word of the question. We have removed θ for simplicity.

Our method is based on a sequence to sequence network (Sutskever et al., 2014; Vinyals et al., 2015; Bahdanau et al., 2014). The sequence to sequence network has a text sequence as input and output. In our method, we take an image as input and generate a natural question as output. The architecture for our model is shown in Figure 4. Our model contains three main modules, (a) Representation Module that extracts multimodal features (b) Mixture Module that fuses the multimodal representation and (c) Decoder that generates question using an LSTM-based language model.

During inference, we sample a question word q_i from the softmax distribution and continue sampling until the end token or maximum length for the question is reached. We experimented with both sampling and *argmax* and found out that *argmax* works better. This result is provided in the supplementary material.

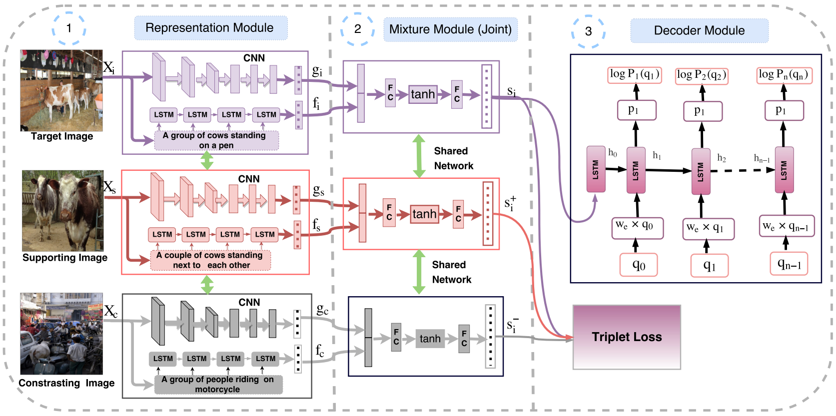

Figure 4: This is an overview of our Multimodal Differential Network for Visual Question Generation. It consists of a Representation Module which extracts multimodal features, a Mixture Module that fuses the multimodal representation and a Decoder that generates question using an LSTM based language model. In this figure, we have shown the Joint Mixture Module. We train our network with a Cross-Entropy and Triplet Loss.

4.1 Multimodal Differential Network

The proposed Multimodal Differential Network (MDN) consists of a representation module and a joint mixture module.

4.1.1 Finding Exemplars

We used an efficient KNN-based approach (k-d tree) with Euclidean metric to obtain the exemplars. This is obtained through a coarse quantization of nearest neighbors of the training examples into 50 clusters, and selecting the nearest as supporting and farthest as the contrasting exemplars. We experimented with ITML based metric learning (Davis et al., 2007) for image features. Surprisingly, the KNN-based approach outperforms the latter one. We also tried random exemplars and different number of exemplars and found that $k = 5$ works best. We provide these results in the supplementary material.

4.1.2 Representation Module

We use a triplet network (Frome et al., 2007; Hoffer and Ailon, 2015) in our representation module. We refereed a similar kind of work done in (Patro and Namboodiri, 2018) for building our triplet network. The triplet network consists of three subparts: target, supporting, and contrasting networks. All three networks share the same parameters. Given an image x_i we obtain an embedding g_i using a CNN parameterized by a function $G(x_i, W_c)$ where W_c are the weights for the CNN. The caption C_i results in a caption embedding f_i through an LSTM parameterized by a function $F(C_i, W_l)$ where W_l are the weights for the LSTM. This is shown in part 1 of Figure 4. Similarly we obtain image embeddings g_s & g_c and caption embeddings f_s & f_c.

$$\begin{aligned} g_i &= G(x_i, W_c) = CNN(x_i) \\ f_i &= F(C_i, W_l) = LSTM(C_i) \end{aligned} \tag{2}$$

4.1.3 Mixture Module

The Mixture module brings the image and caption embeddings to a joint feature embedding space. The input to the module is the embeddings obtained from the representation module. We have evaluated four different approaches for fusion viz., joint, element-wise addition, Hadamard and attention method. Each of these variants receives image features g_i & the caption embedding f_i, and outputs a fixed dimensional feature vector s_i. The Joint method concatenates g_i & f_i and maps them to a fixed length feature vector s_i as follows:

$$s_i = W_j^T * \tanh(W_{ij} g_i \frown (W_{cj} f_i + b_j)) \tag{3}$$

where g_i is the 4096-dimensional convolutional feature from the FC7 layer of pretrained VGG-19 Net (Simonyan and Zisserman, 2014). W_{ij}, W_{cj}, W_j are the weights and b_j is the bias for different layers. $\frown$ is the concatenation operator.

Similarly, we obtain context vectors s_i^+ & s_i^- for the supporting and contrasting exemplars. Details for other fusion methods are present in supplementary.The aim of the triplet network (Schroff et al., 2015) is to obtain context vectors that bring the supporting exemplar embeddings closer to the target embedding and vice-versa. This is obtained as follows:

$$\begin{aligned} &D(t(s_i), t(s_i^+)) + \alpha < D(t(s_i), t(s_i^-)) \\ &\forall (t(s_i), t(s_i^+), t(s_i^-)) \in M, \end{aligned} \tag{4}$$

where $D(t(s_i), t(s_j)) = ||t(s_i) - t(s_j)||_2^2$ is the Euclidean distance between two embeddings $t(s_i)$ and $t(s_j)$. M is the training dataset that contains all set of possible triplets. $T(s_i, s_i^+, s_i^-)$ is the triplet loss function. This is decomposed into two terms, one that brings the supporting sample closer and one that pushes the contrasting sample further. This is given by

$$T(s_i, s_i^+, s_i^-) = \texttt{max}(0, D^+ + \alpha - D^-) \quad (5)$$

Here D^+, D^- represent the Euclidean distance between the target and supporting sample, and target and opposing sample respectively. The parameter $\alpha(= 0.2)$ controls the separation margin between these and is obtained through validation data.

4.2 Decoder: Question Generator

The role of decoder is to predict the probability for a question, given s_i. RNN provides a nice way to perform conditioning on previous state value using a fixed length hidden vector. The conditional probability of a question token at particular time step q_t is modeled using an LSTM as used in machine translation (Sutskever et al., 2014). At time step t, the conditional probability is denoted by $P(q_t|I, C, q_0, ...q_{t-1}) = P(q_t|I, C, h_t)$, where h_t is the hidden state of the LSTM cell at time step t, which is conditioned on all the previously generated words $\{q_0, q_1, ...q_{N-1}\}$. The word with maximum probability in the probability distribution of the LSTM cell at step k is provided as an input to the LSTM cell at step $k+1$ as shown in part 3 of Figure 4. At $t = -1$, we are feeding the output of the mixture module to LSTM. $\hat{Q} = \{\hat{q_0}, \hat{q_1}, ...\hat{q_{N-1}}\}$ are the predicted question tokens for the input image I. Here, we are using $\hat{q_0}$ and $\hat{q_{N-1}}$ as the special token START and STOP respectively. The softmax probability for the predicted question token at different time steps is given by the following equations where LSTM refers to the standard LSTM cell equations:

$$
\begin{aligned}
&x_{-1} = S_i = \text{Mixture Module}(g_i, f_i)\\
&h_0 = \text{LSTM}(x_{-1})\\
&x_t = W_e * q_t, \forall t \in \{0, 1, 2, ...N-1\}\\
&h_{t+1} = \text{LSTM}(x_t, h_t), \forall t \in \{0, 1, 2, ...N-1\}\\
&o_{t+1} = W_o * h_{t+1}\\
&\hat{y}_{t+1} = P(q_{t+1}|I, C, h_t) = \text{Softmax}(o_{t+1})\\
&Loss_{t+1} = loss(\hat{y}_{t+1}, y_{t+1})
\end{aligned}
$$

Where $\hat{y}_{t+1}$ is the probability distribution over all question tokens. $loss$ is cross entropy loss.

4.3 Cost function

Our objective is to minimize the total loss, that is the sum of cross entropy loss and triplet loss over all training examples. The total loss is:

$$L = \frac{1}{M}\sum_{i=1}^{M}(L_{cross} + \gamma L_{triplet}) \quad (6)$$

where M is the total number of samples,γ is a constant, which controls both the loss. $L_{triplet}$ is the triplet loss function 5. L_{cross} is the cross entropy loss between the predicted and ground truth questions and is given by:

$$L_{cross} = \frac{-1}{N}\sum_{t=1}^{N} y_t \texttt{log} P(\hat{q_t}|I_i, C_i, \hat{q_0}, ..\hat{q_{t-1}})$$

where, N is the total number of question tokens, y_t is the ground truth label. The code for MDN-VQG model is provided [1].

4.4 Variations of Proposed Method

While, we advocate the use of multimodal differential network for generating embeddings that can be used by the decoder for generating questions, we also evaluate several variants of this architecture. These are as follows:

Tag Net: In this variant, we consider extracting the part-of-speech (POS) tags for the words present in the caption and obtaining a Tag embedding by considering different methods of combining the one-hot vectors. Further details and experimental results are present in the supplementary. This Tag embedding is then combined with the image embedding and provided to the decoder network.

Place Net: In this variant we explore obtaining embeddings based on the visual scene understanding. This is obtained using a pre-trained PlaceCNN (Zhou et al., 2017) that is trained to classify 365 different types of scene categories. We then combine the activation map for the input image and the VGG-19 based place embedding to obtain the joint embedding used by the decoder.

Differential Image Network: Instead of using multimodal differential network for generating embeddings, we also evaluate differential image network for the same. In this case, the embedding does not include the caption but is based only on

---

[1] The project page for MDN-VQG Model is `https://badripatro.github.io/MDN-VQG/`

Figure 5: These are some examples from the VQG-COCO dataset which provide a comparison between our generated questions and human annotated questions. (a) is the human annotated question for all the images. More qualitative results are present in the supplementary material.

the image feature. We also exeperimented with using multiple exemplars and random exemplars. Further details, pseudocode and results regarding these are present in the supplementary material.

4.5 Dataset

We conduct our experiments on Visual Question Generation (VQG) dataset (Mostafazadeh et al., 2016), which contains human annotated questions based on images of MS-COCO dataset. This dataset was developed for generating natural and engaging questions based on common sense reasoning. We use VQG-COCO dataset for our experiments which contains a total of 2500 training images, 1250 validation images, and 1250 testing images. Each image in the dataset contains five natural questions and five ground truth captions. It is worth noting that the work of (Jain et al., 2017) also used the questions from VQA dataset (Antol et al., 2015) for training purpose, whereas the work by (Mostafazadeh et al., 2016) uses only the VQG-COCO dataset. VQA-1.0 dataset is also built on images from MS-COCO dataset. It contains a total of 82783 images for training, 40504 for validation and 81434 for testing. Each image is associated with 3 questions. We used pretrained caption generation model (Karpathy and Fei-Fei, 2015) to extract captions for VQA dataset as the human annotated captions are not there in the dataset. We also get good results on the VQA dataset (as shown in Table 2) which shows that our method doesn't necessitate the presence of ground truth captions. We train our model separately for VQG-COCO and VQA dataset.

4.6 Inference

We made use of the 1250 validation images to tune the hyperparameters and are providing the results on test set of VQG-COCO dataset. During inference, We use the Representation module to find the embeddings for the image and ground truth caption without using the supporting and contrasting exemplars. The mixture module provides the joint representation of the target image and ground truth caption. Finally, the decoder takes in the joint features and generates the question. We also experimented with the captions generated by an Image-Captioning network (Karpathy and Fei-Fei, 2015) for VQG-COCO dataset and the result for that and training details are present in the supplementary material.

5 Experiments

We evaluate our proposed MDN method in the following ways: First, we evaluate it against other variants described in section 4.4 and 4.1.3. Second, we further compare our network with state-of-the-art methods for VQA 1.0 and VQG-COCO dataset. We perform a user study to gauge human opinion on naturalness of the generated question and analyze the word statistics in Figure 6. This is an important test as humans are the best

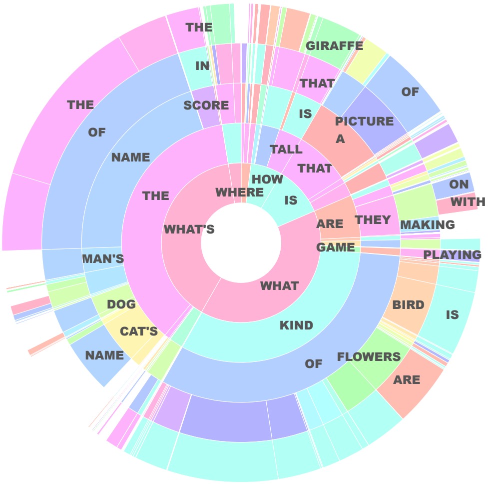

Figure 6: Sunburst plot for VQG-COCO: The i^{th} ring captures the frequency distribution over words for the i^{th} word of the generated question. The angle subtended at the center is proportional to the frequency of the word. While some words have high frequency, the outer rings illustrate a fine blend of words. We have restricted the plot to 5 rings for easy readability. Best viewed in color.

deciders of naturalness. We further consider the statistical significance for the various ablations as well as the state-of-the-art models. The quantitative evaluation is conducted using standard metrics like BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), ROUGE (Lin, 2004), CIDEr (Vedantam et al., 2015). Although these metrics have not been shown to correlate with 'naturalness' of the question these still provide a reasonable quantitative measure for comparison. Here we only provide the BLEU1 scores, but the remaining BLEU-n metric scores are present in the supplementary. We observe that the proposed MDN provides improved embeddings to the decoder. We believe that these embeddings capture instance specific differential information that helps in guiding the question generation. Details regarding the metrics are given in the supplementary material.

5.1 Ablation Analysis

We considered different variations of our method mentioned in section 4.4 and the various ways to obtain the joint multimodal embedding as described in section 4.1.3. The results for the VQG-COCO test set are given in table 1. In this table, every block provides the results for one of the variations of obtaining the embeddings and different ways of combining them. We observe that the Joint Method (JM) of combining the embeddings works the best in all cases except the Tag Embeddings. Among the ablations, the proposed MDN method works way better than the other variants in terms of BLEU, METEOR and ROUGE metrics by achieving an improvement of 6%, 12% and 18% in the scores respectively over the best other variant.

Emb.	**Method**	**B1**	**METEOR**	**ROUGE**	**CIDEr**
Tag	AtM	22.4	8.6	22.5	20.8
Tag	HM	**24.4**	**10.8**	**24.3**	**55.0**
Tag	AM	24.4	10.6	23.9	49.4
Tag	JM	22.2	10.5	22.8	50.1
PlaceCNN	AtM	24.4	10.3	24.0	51.8
PlaceCNN	HM	24.0	10.4	24.3	49.8
PlaceCNN	AM	24.1	10.6	24.3	51.5
PlaceCNN	JM	**25.7**	**10.8**	**24.5**	**56.1**
Diff. Img	AtM	20.5	8.5	**24.4**	19.2
Diff. Img	HM	23.6	8.6	22.3	22.0
Diff. Img	AM	20.6	8.5	24.4	19.2
Diff. Img	JM	**30.4**	**11.7**	22.3	**22.8**
MDN	AtM	22.4	8.8	24.6	22.4
MDN	HM	26.6	12.8	30.1	31.4
MDN	AM	29.6	15.4	32.8	41.6
MDN(**Ours**)	JM	**36.0**	**23.4**	**41.8**	**50.7**

Table 1: Analysis of variants of our proposed method on VQG-COCO Dataset as mentioned in section 4.4 and different ways of getting a joint embedding (Attention (AtM), Hadamard (HM), Addition (AM) and Joint (JM) method as given in section 4.1.3) for each method. Refer section 5.1 for more details. B1 is BLEU1.

5.2 Baseline and State-of-the-Art

The comparison of our method with various baselines and state-of-the-art methods is provided in table 2 for VQA 1.0 and table 3 for VQG-COCO dataset. The comparable baselines for our method are the image based and caption based models in which we use either only the image or the caption embedding and generate the question. In both the tables, the first block consists of the current state-of-the-art methods on that dataset and the second contains the baselines. We observe that for the VQA dataset we achieve an improvement of 8% in BLEU and 7% in METEOR metric scores over the baselines, whereas for VQG-COCO dataset this is 15% for both the metrics. We improve over the previous state-of-the-art (Yang et al., 2015) for VQA dataset by around 6% in BLEU score and 10% in METEOR score. In the VQG-COCO dataset, we improve over (Mostafazadeh et al., 2016) by 3.7% and (Jain et al., 2017) by 3.5% in terms of METEOR scores.

5.3 Statistical Significance Analysis

We have analysed Statistical Significance (Demšar, 2006) of our MDN model for VQG for different variations of the mixture

Methods	BLEU1	METEOR	ROUGE	CIDEr
Sample(Yang,2015)	38.8	12.7	34.2	13.3
Max(Yang,2015)	59.4	17.8	49.3	33.1
Image Only	56.6	15.1	40.0	31.0
Caption Only	57.1	15.5	36.6	30.5
MDN-Attention	60.7	16.7	49.8	33.6
MDN-Hadamard	61.7	16.7	50.1	29.3
MDN-Addition	61.7	18.3	50.4	**42.6**
MDN-Joint (**Ours**)	**65.1**	**22.7**	**52.0**	33.1

Table 2: State-of-the-Art comparison on VQA-1.0 Dataset. The first block consists of the state-of-the-art results, second block refers to the baselines mentioned in section 5.2, third block provides the results for the variants of mixture module present in section 4.1.3.

Context	BLEU1	METEOR	ROUGE	CIDEr
Natural 2016	19.2	19.7	-	-
Creative 2017	35.6	19.9	-	-
Image Only	20.8	8.6	22.6	18.8
Caption Only	21.1	8.5	25.9	22.3
Tag-Hadamard	24.4	10.8	24.3	55.0
Place CNN-Joint	25.7	10.8	24.5	**56.1**
Diff.Image-Joint	30.4	11.7	26.3	38.8
MDN-Joint (**Ours**)	**36.0**	**23.4**	**41.8**	50.7
Humans 2016	**86.0**	**60.8**	**-**	-

Table 3: State-of-the-Art (SOTA) comparison on VQG-COCO Dataset. The first block consists of the SOTA results, second block refers to the baselines mentioned in section 5.2, third block shows the results for the best method for different ablations mentioned in table 1.

module mentioned in section 4.1.3 and also against the state-of-the-art methods. The Critical Difference (CD) for Nemenyi (Fišer et al., 2016) test depends upon the given α (confidence level, which is 0.05 in our case) for average ranks and N (number of tested datasets). If the difference in the rank of the two methods lies within CD, then they are not significantly different and vice-versa. Figure 7 visualizes the post hoc analysis using the CD diagram. From the figure, it is clear that MDN-Joint works best and is statistically significantly different from the state-of-the-art methods.

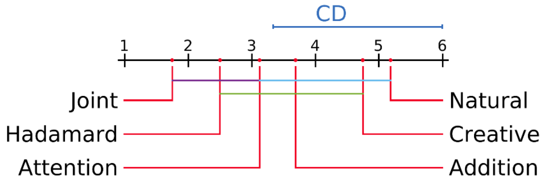

Figure 7: The mean rank of all the models on the basis of METEOR score are plotted on the x-axis. Here Joint refers to our MDN-Joint model and others are the different variations described in section 4.1.3 and Natural (Mostafazadeh et al., 2016), Creative (Jain et al., 2017). The colored lines between the two models represents that these models are not significantly different from each other.

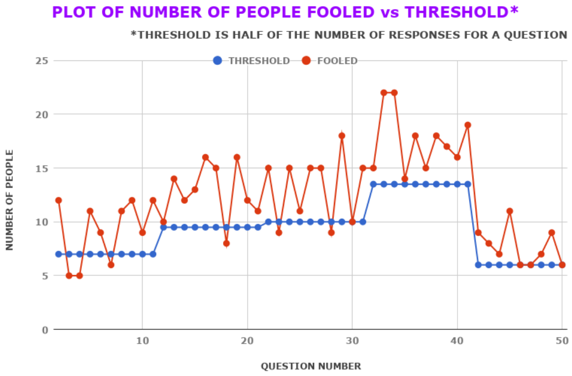

Figure 8: Perceptual Realism Plot for human survey. Here every question has different number of responses and hence the threshold which is the half of total responses for each question is varying. This plot is only for 50 of the 100 questions involved in the survey. See section 5.4 for more details.

5.4 Perceptual Realism

A human is the best judge of naturalness of any question, We evaluated our proposed MDN method using a 'Naturalness' Turing test (Zhang et al., 2016) on 175 people. People were shown an image with 2 questions just as in figure 1 and were asked to rate the naturalness of both the questions on a scale of 1 to 5 where 1 means 'Least Natural' and 5 is the 'Most Natural'. We provided 175 people with 100 such images from the VQG-COCO validation dataset which has 1250 images. Figure 8 indicates the number of people who were fooled (rated the generated question more or equal to the ground truth question). For the 100 images, on an average 59.7% people were fooled in this experiment and this shows that our model is able to generate natural questions.

6 Conclusion

In this paper we have proposed a novel method for generating natural questions for an image. The approach relies on obtaining multimodal differential embeddings from image and its caption. We also provide ablation analysis and a detailed comparison with state-of-the-art methods, perform a user study to evaluate the naturalness of our generated questions and also ensure that the results are statistically significant. In future, we would like to analyse means of obtaining composite embeddings. We also aim to consider the generalisation of this approach to other vision and language tasks.

Abstract

Current image captioning approaches generate descriptions which lack specific information, such as named entities that are involved in the images. In this paper we propose a new task which aims to generate informative image captions, given images and hashtags as input. We propose a simple but effective approach to tackle this problem. We first train a convolutional neural networks - long short term memory networks (CNN-LSTM) model to generate a template caption based on the input image. Then we use a knowledge graph based collective inference algorithm to fill in the template with specific named entities retrieved via the hashtags. Experiments on a new benchmark dataset collected from Flickr show that our model generates news-style image descriptions with much richer information. Our model outperforms unimodal baselines significantly with various evaluation metrics. [1]

1 Introduction

As information regarding emergent situations disseminates through social media, the information is presented in a variety of data modalities (*e.g.* text, images, and videos), with each modality providing a slightly different perspective. Images have the capability to vividly represent events and entities, but without proper contextual information they become less meaningful and lose utility. While images may be accompanied by associated tags or other meta-data, which are inadequate to convey detailed events, many lack the descriptive text to provide such context. For example, there are 17,285 images on Flickr from the Women's March on January 21, 2017,[2] most of which contain only a few tags and lack any detailed text descriptions. The absence of context leaves individuals with no knowledge of details such as the purpose or location of the march.

Image captioning offers a viable method to directly provide images with the necessary contextual information through textual descriptions. Advances in image captioning (Xu et al., 2015; Fang et al., 2015; Karpathy and Fei-Fei, 2015; Vinyals et al., 2015) are effective in generating sentence-level descriptions. However, sentences generated by these approaches are usually generic descriptions of the visual content and ignore background information. Such generic descriptions do not suffice in emergent situations as they, essentially, mirror the information present in the images and do not provide detailed descriptions regarding events and entities present in, or related to, the images, which is imperative to understanding emergent situations. For example, given the image in Figure 1, the state-of-the-art automatically generated caption is '*Several women hold signs in front of a building.*', which is lacking information regarding relevant entities (*e.g.* ' *Junior doctors*', '*Tories*').

In our work, we propose an ambitious task: **entity-aware image caption generation**: automatically generate an image description that incorporates specific information such as named entities, relevant to the image, given limited text information, such as associated tags and meta-data (*e.g.* time of photo and geo-location). Our approach to this task generally follows three steps. First, instead of directly generating a sentence for an image, we generate a ***template*** sentence with fillable slots by training an image captioning architecture on image-caption pairs, where we replace the entities from the captions with slot types indicating the type of entity that should be used

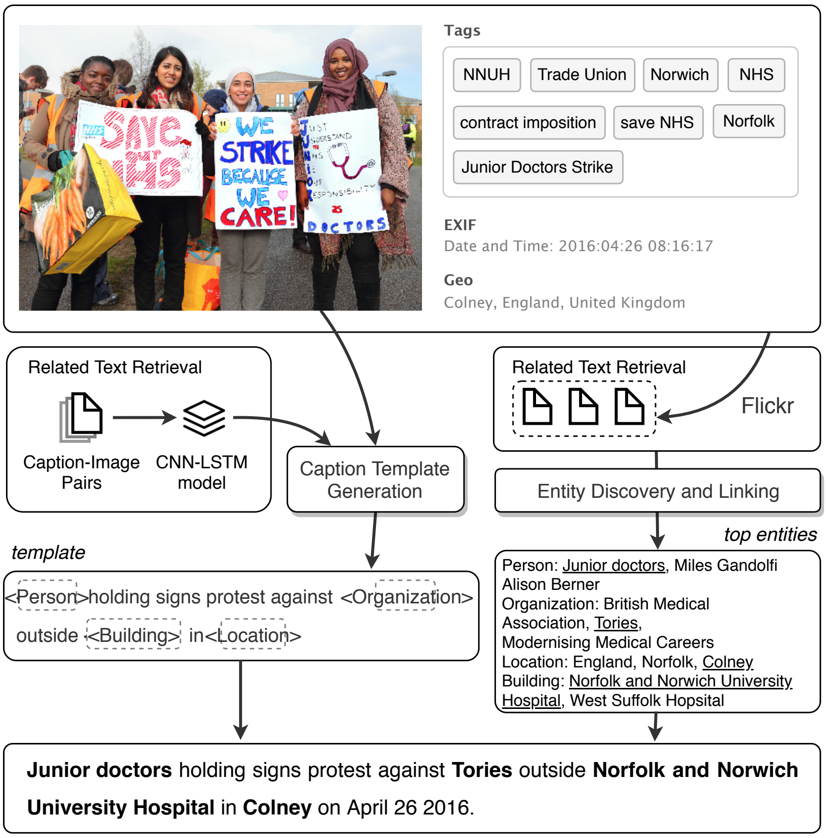

Figure 1: The overall framework.

to fill the slot. A ***template*** for the example in Figure 1 is: `<Person>` holding signs protest against `<Organization>` outside `<Building>` in `<Location>`.

Second, given the associated tags of an image, we apply entity discovery and linking (EDL) methods to extract specific entities from previous posts that embed the same tags. Finally, we select appropriate candidates for each slot based upon the entity type and frequency. For example, we select the person name '*Junior doctors*' to fill in the slot `<Person>` because it co-occurs frequently with other entities such as '*Tories*' in the text related to the tags $\#NHS, \#JuniorDoctorsStrike$. This framework offers a distinct advantage in that it is very flexible, so more advanced captioning or EDL methods as well as other data can be used almost interchangeably within the framework.

To the best of our knowledge, we are the first to incorporate contextual information into image captioning without large-scale training data or topically related news articles and the generated image captions are closer to news captions.

2 Approach Overview

Figure 1 shows the overall framework of our proposed model. Given an image with associated tags and other meta-data, such as geographical tags and EXIF data,[3] we first feed the image into a template caption generator to generate a sentence composed of context words, such as "*stand*", and slots, such as `<person>`, to represent missing specific information like named entities (Section 3). The template caption generator, which follows the encoder-decoder model (Cho et al., 2014) with a CNN encoder and LSTM decoder (Vinyals et al., 2015), is trained using news image-template caption pairs.

We then retrieve topically-related images from the Flickr database, which have the same tags as the input image. Next, we apply EDL algorithms to the image titles to extract entities and link them to external knowledge bases to retrieve their fine-grained entity types. Finally, for each slot generated by the template generator, we choose to fill the slot with the appropriate candidate based on entity type and frequency (Section 4).

---

[3] EXIF data contains meta-data tags of photos such as date, time, and camera settings.

3 Template Caption Generation

Language models (LM) are widely used to generate text (Wen et al., 2015; Tran and Nguyen, 2017) and play a crucial role in most of the existing image captioning approaches (Vinyals et al., 2015; Xu et al., 2015). These models, learned from large-scale corpora, are able to predict a probability distribution over a vocabulary. However, LM struggle to generate specific entities, which occur sparsely, if at all, within training corpora. Moreover, the desired entity-aware captions may contain information not directly present in the image alone. Unless the LM is trained or conditioned on data specific to the emergent situation of interest, the LM alone cannot generate a caption that incorporates the specific background information. We address this issue by only relying on the LM to generate abstract slot tokens and connecting words or phrases, while slot filling is used to incorporate specific information. This approach allows the LM to focus on generating words or phrases with higher probability, since each slot token effectively has a probability equal to the sum of all the specific entities that it represents, thereby circumventing the issue of generating lower probability or out-of-vocabulary (OOV) words.

In this section, we describe a novel method to train a model to automatically generate template captions with slots as '*placeholders*' for specific background information. We first present the schemas which define the slot types (Section 3.1) and the procedure to acquire training data for template generation (Section 3.2). Finally, we introduce the model for template caption generation (Section 3.3).

3.1 Template Caption Definition

Named entities are the most specific information which cannot be easily learned by LM. Thus, in this work, we define slots as placeholders for entities with the same types. We use the fine grained entity types defined in DBpedia [4] (Auer et al., 2007) to name the slots because these types are specific enough to differentiate between a wide range of entities and still general enough so that the slots have higher probabilities in the language model. For example, `Person` is further divided into `Athlete`, `Singer`, `Politician`, and so on. Therefore, a template caption like '`Athlete` celebrates after scoring.' can be generated by the language model through leveraging image features, where the slot `Athlete` means a sports player (e.g., Cristiano Ronaldo, Lionel Messi).

3.2 Acquisition of Image-Template Caption Pairs

High quality training data is crucial to train a template caption generator. However, the image-caption datasets used in previous work, such as Microsoft Common Objects in Context (MS COCO) (Lin et al., 2014) and Flickr30K (Rashtchian et al., 2010), are not suitable for this task because they are designed for non-specific caption generation and do not contain detailed, specific information such as named entities. Further, manual creation of captions is expensive. In this work, we utilize news image-caption pairs, which are well written and can be easily collected. We use the example in Figure 2 to describe our procedure to convert image-caption to image-template caption pairs: **preprocessing**, **compression**, **generalization**.

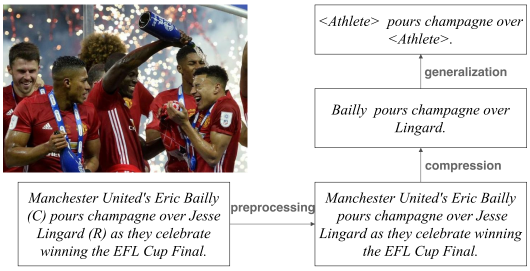

Figure 2: Procedure of Converting News Captions into Templates.

Preprocessing: We first apply the following pre-processing steps: (1) remove words in parentheses, such as *'(C)'* and *'(R)'* in Figure 2, because they usually represent auxiliary information and are not aligned with visual concepts in images; (2) if a caption includes more than one sentence, we choose the longer one. Based on our observation, shorter sentences usually play the role of background introduction, which are not aligned with the key content in images; (3) remove captions with less than 10 tokens because they tend to be not informative enough. The average length of the news image captions is 37 tokens.

Compression: The goal of compression is to make news captions short and aligned with images as much as possible by keeping informa-

---

[4] We use the sixth level entity types in Yago ontology (Wordnet types only).

tion related to objects and concepts in the images, which are usually subjects, verbs and objects in sentences. In this paper, we propose a simple but efficient compression method based on dependency parsing. We do not use other complicated compressions (Kuznetsova et al., 2014) because our simple method achieves comparative results on image caption dataset. We first apply the Stanford dependency parser (De Marneffe and Manning, 2008) on preprocessed captions. Then, we traverse the parse tree from the root (*e.g.'pours'*) via `<governor, grammatical relations, dependent>` triples using breadth-first search. We decide to keep a dependent or not based on its grammatical relation with the governor. Based on our observations, among the 50 grammatical relations in the Stanford dependency parser, we keep the dependents that have the following grammatical relations with their governors: *nsubj, obj, iobj, dobj, acomp, det, neg, nsubjpass, pobj, predet, prep, prt, vmod, nmod, cc*.

Generalization: The last step for preparing training data is to extract entities from captions and replace them with the slot types we defined in Section 3.1. We apply Stanford CoreNLP name tagger (Manning et al., 2014) to the captions to extract entity mentions of the following types: `Person`, `Location`, `Organization`, and `Miscellaneous`. Next, we use an English Entity Linking algorithm (Pan et al., 2015) to link the entity mentions to DBpedia and retrieve their fine-grained types.[5] We choose the higher level type if there are multiple fine-grained types for a name. For example, the entity types of *Manchester United*, *Eric Bailly*, and *Jesse Lingard* are *SoccerTeam*, *Athlete*, and *Athlete*, respectively. For entity mentions that cannot be linked to DBpedia, we use their coarse-grained entity types, which are the outputs of name tagger.

Finally, we replace the entities in the compressed captions with their corresponding slots:

Generalized Template: `<Athlete>` pours champagne over `<Athlete>`.

3.3 Generation Model

Using the template caption and image pairs *(S, I)* as training data, we regard the template caption generation as a regular image captioning task. Thus, we adapt the encoder-decoder architecture which is successful in the image captioning task (Vinyals et al., 2015; Xu et al., 2015). Our model (Figure 3) is most similar to the one proposed in (Vinyals et al., 2015). Note, other captioning methods may easily be used instead.

Encoder: Similar to previous work (Vinyals et al., 2015; Xu et al., 2015; Karpathy and Fei-Fei, 2015; Venugopalan et al., 2017), we encode images into representations using a ResNet (He et al., 2016) model pre-trained on the ImageNet dataset (Deng et al., 2009) and use the outputs before the last fully-connected layer.

Decoder: We employ a Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) based language model to decode image representations into template captions. We provide the LSTM the image representation, I, as the initial hidden state. At the t^{th} step, the model predicts the probabilities of words/slots, y_t, based on the word/slot generated at last time step, y_{t-1}, as well as the hidden state, s_t.

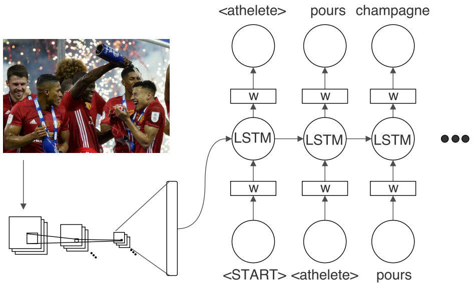

Figure 3: LSTM language generator.

4 Template Caption Entity Population

With the generated template captions, our next step is to fill in the slots with the appropriate specific entities to make the caption complete and entity-aware. In this section, we expand our method to extract candidate entities from contextual information (*i.e.*, images in Flickr with the same tags). Once we extract candidate entities, we apply the Quantified Collective Validation (QCV) algorithm (Wang et al., 2015), which constructs a number of candidate graphs and performs collective validation on those candidate graphs to choose the appropriate entities for the slots in the template caption.

---

[5] This yields a total of 95 types after manually cleaning.

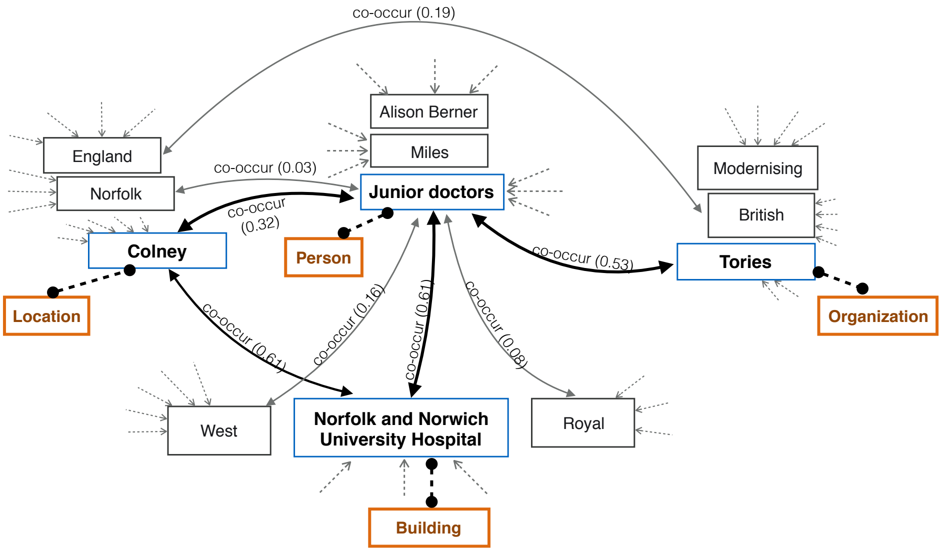

Figure 4: Knowledge graph construction.

4.1 Candidate Entity Retrieval

Users on social media typically post images with tags that are event-related (e.g. #occupywallstreet), entity-related (e.g. #lakers), or topic-related (e.g. #basketball). On our Flickr testing dataset, the average number of tags associated with an image is 11.5 and posts with the same tags likely share common entities. Therefore, given an image and its tags, we retrieve images from Flickr with the same tags by a window size of seven-day based on taken date of the photo, and then utilize the textual information accompanying the retrieved images as context. We filter out the high frequency hashtags($>$ 200 in testing dataset). Because some common tags, such as '#concert', appear in lots of posts related to different concerts.

Given the related text, we apply EDL algorithms (Pan et al., 2015) to extract named entities and link them to DBpedia to obtain their entity types. For each entity type, we rank the candidates based on their frequency in the context and only keep the top 5 candidate entities.

4.2 Quantified Collective Validation

Each slot in the template must be filled with an entity from its corresponding candidate entities. We can regard this step as an entity linking problem, whose goal is to choose an entity from several candidates given an entity mention. We utilize the QCV algorithm to construct a number of candidate graphs for a given set of slots (Wang et al., 2015), where each combination of candidate entities substituted into the slots yields a different graph (Figure 4). For each candidate combination graph, G_c^i, we compute the edge weights between each pair of candidates in the graph as

$$H_r = \frac{f_{c_h c_t}}{max(f_{c_h}, f_{c_t})} \tag{1}$$

where $r \in E(G_c^i)$ is an edge in G_c^i, c_h and c_t are the head candidate and tail candidate of the edge, $f_{c_h c_t}$ is the co-occurrence frequency of the pair of candidates, and f_{c_h} and f_{c_t} are the individual frequencies of head candidate and tail candidate, respectively. For example, in Figure 4, *Colney* (`Location`) and *Junior doctors* (`Person`) co-occur frequently, therefore the edge between them has a larger weight.

We compute the summed edge weight, $\omega(G_c^i)$, for each G_c^i by

$$\omega(G_c^i) = \sum_{r \in E(G_c^i)} H_r \tag{2}$$

and select the combination of candidates with the largest $\omega(G_c^i)$ to fill in the set of slots.

As a result of this process, given the template: '`<Person>` holding signs protest against `<Organization>` outside `<Building>` in `<Location>`.', we obtain an entity-aware caption: '***Junior doctors** holding signs protest against **Tories** outside **Norfolk and Norwich University Hospital** in **Colney***'.

4.3 Post-processing

Some images in Flickr have EXIF data which gives the date that an image is taken. We convert this information into the format such as '***April 26 2016***' and add it to the generated captions as post-processing, by which we obtain the complete caption: '*Junior doctors holding signs protest against Tories outside Norfolk and Norwich University Hospital in Colney on **April 26 2016**.*'. We leave the generated caption without adding date information if it is not available. For those slots that cannot be filled by names, we use general words to replace them, such as using the word *'Athlete'* to replace the slot `Athlete`.

5 Experiments

5.1 Data

We require images with well-aligned, news-style captions for training. However, we want to test our model on real social media data and it is difficult to collect these informative captions for social media data. Therefore, we acquire training data from news outlets and testing data from social media. We select two different topics, social events and sports events, as our case studies.

	Train	Dev	Test
Number of Images	29,390	4,306	3,688
Number of Tokens	1,086,350	161,281	136,784
Social Event	6,998	976	872
Sports Event	22,392	3,330	2,816
Person	32,878	4,539	4,156
Location	42,786	5,657	5,432
Organization	17,290	2,370	2,124
Miscellaneous	8,398	1,103	1,020

Table 1: Statistics of datasets for template generation.

Template Generator Training and Testing. To train the template caption generator, we collect 43,586 image-caption pairs from Reuters[6], using topically-related keywords[7] as queries. We do not use existing image caption datasets, such as MSCOCO (Lin et al., 2014), because they do not contain many named entities. After the compression and generalization procedures (Section 3.2) we keep 37,384 images and split them into train, development, and test sets. Table 1 shows the statistics of the datasets.

Entity-aware Caption Testing. Since news images do not have associated tags, for the purpose of testing our model in a real social media setting, we use images from Flickr for our caption evaluation[8], which is an image-centric, representative social media platform. We use the same keywords as for template generator training to retrieve multi-modal data with Creative Commons license[9], for social and sports events. We choose the images that already have news-style descriptions from users and manually confirm they are well-aligned. In total, we collect 2,594 images for evaluation. For each image, we also obtain the tags (30,148 totally) and meta-data, such as EXIF and geotag data, when they are available.

5.2 Models for Comparison

We compare our entity-aware model with the following baselines:

CNN-RNN-raw. We use the model proposed by Vinyals et al. (2015) to train an image captioning model on the raw news image-caption pairs, and apply to Flickr testing data directly.

CNN-RNN-compressed. We use the model proposed by Vinyals et al. (2015) to train a model on the compressed news image-caption pairs.

Text-summarization. We apply SumBasic summarization algorithms (Vanderwende et al., 2007), that is a summarization for multiple documents based on frequency of word and semantic content units, to text documents retrieved by hashtag.

Entity-aware. We apply trained template generator on Flickr testing data, and then fill in the slots with extracted background information.

5.3 Evaluation Metrics

We use three standard image captioning evaluation metrics, BLEU (Papineni et al., 2002) and METEOR (Denkowski and Lavie, 2014), ROUGE (Lin, 2004) and CIDEr (Vedantam et al., 2015), to evaluate the quality of both the generated templates and generated captions. BLEU is a metric based on correlations at the sentence level. METEOR is a metric with recall weighted higher than precision and it takes into account stemming as well as synonym matching. ROUGE is proposed for evaluation of summarization and relies

[7] Social Events: concert, festival, parade, protest, ceremony; Sports Events: Soccer, Basketball, Soccer, Baseball, Ice Hockey

[8] https://www.flickr.com/

[9] https://creativecommons.org/licenses/

highly on recall. CIDEr metric downweights the n-grams common in all image captions, which are similar to tf-idf. Since the goal of this task is to generate entity-aware descriptions, we also measure the entity F1 scores for the final captions, where we do fuzzy matching to manually count the overlapped entities between the system output and reference captions. Besides, we do human evaluation with a score in range of 0 to 3 using the criteria as follows: Score 0: generated caption is not related to the ground-truth; Score 1: generated caption is topically-related to the ground-truth, but has obvious errors; Score 2: generated caption is topically-related to the ground-truth, and has overlapped named entities; Score 3: generated caption well describes the image.

5.4 Template Evaluation

Raw: new york giants kicker josh brown kicks a field goal during the first quarter against the san francisco 49ers at metlife stadium.

Generated Coarse Template: `<Person>` runs with ball against `<Location>` `<Location>` in the first half of their `<Miscellaneous>` football game in `<Location>`

Generated Fine Template: `<Footballteam>` kicker `<Player>` kicks a field goal out of the game against the `<Footballteam>` at `<Organization>` stadium

Figure 5: Example of generated template.

Table 2 shows the performances of template generator based on coarse-grained and fine-grained type respectively, and Figure 5 shows an example of the template generated. Coarse templates are the ones after we replace names with these coarse-grained types. Entity Linking classifies names into more fine-grained types, so the corresponding templates are fine templates. The generalization method of replacing the named entities with entity types can reduce the vocabulary size significantly, which reduces the impact of sparse named entities in training data. The template generation achieves close performance with state-of-the-art generic image captioning on MSCOCO dataset (Xu et al., 2015). The template generator based on coarse-grained entity type outperforms the one based on fine-grained entity type for two reasons: (1) fine template relies on EDL, and incorrect linkings import noise; (2) named entities usually has multiple types, but we only choose one during generalization. Thus the caption, '*Bob Dylan performs at the Wiltern Theatre in Los Angeles*', is generalized into '`<Writer>` *performs at the* `<Theater>` *in* `<Loaction>`', but the correct type for *Bob Dylan* in this context should be `Artist`.

5.5 Flickr Caption Results

Table 4 shows the comparison between our model and the baselines. The scores are much lower than traditional caption generation tasks such as COCO, because we use the real captions as ground-truth. Our model outperforms all the baselines on all metrics except BLEU-4, where Text-summarization model achieves better score. Generally, the model based on textual features (Text-summarization) has better performance than vision-based models (CNN-RNN-raw and CNN-RNN-compressed). It indicates textual summarization algorithm is more effective when it involves specific knowledge generation. Text-summarization model generates results from documents retrieved by hashtags, so it tends to include some long phrases common in those documents. However the templates generated by our model is based on the language model trained from the news captions, which has different style with Flickr captions. It results in that Text-summarization model achieves better BLEU-4 score. Our model improves CIDEr score more significantly compared with other metrics, because CIDEr downweights the n-grams common in all captions, where more specific information such as named entities contribute more to the scores. The experimental results demonstrate that our model is effective to generate image captions with specific knowledge.

5.6 Analysis

Figure 6 shows some examples of the captions generated by the entity-aware model.

Good Examples: (A) in Figure 6 describes the events in the images well ('*performs*') and include correct, well-placed entities, such as '*Little Dragon*' and '*House of Blues*'.

Approach	Vocabulary	BLEU-1	BLEU-2	BLEU-3	BLEU-4	METEOR	ROUGE	CIDEr
Raw-caption	10,979	15.1	11.7	9.9	8.8	8.8	24.2	34.7
Coarse Template	3,533	**46.7**	**36.1**	**29.8**	**25.7**	**22.4**	**43.5**	161.6
Fine Template	3,642	43.0	33.4	27.8	24.3	20.3	39.8	**165.3**

Table 2: Comparison of Template Generator with coarse/fine-grained entity type. Coarse Template is generalized by coarse-grained entity type (name tagger) and fine template is generalized by fine-grained entity type (EDL).

Table 4: Comparison between our entity-aware model and baseline models on various topics. (* We make human evaluation on 259 images randomly selected.)

Relation Error of Filled Entities: Some of our errors result from ignoring of relations between entities. In Example (B) of Figure 6 our model generate a good template, but connects '*Joe Kelly*', who is actually a pitcher of '*Res Sox*', with '*Baltimore Orioles*' incorrectly. One possible solution is to incorporate relation information when the model fills in the slots with entities.

Template Error: Another category of errors results from wrong templates generated by our model. Examples (C) in Figure 6 is about a film festival, but the model generates a template about protest, which is not related to the image. One potential improvement is to incorporate the information from associated tags, such as the number of tags and the named entity types related to the tags, as features during template caption generation to make generated templates dynamically change according to the context.

6 Related Work

The goal of image captioning is to automatically generate a natural language sentence given an image. (Kulkarni et al., 2013; Yang et al., 2011; Mitchell et al., 2012) perform object recognition in images and fill hand-made templates with the recognized objects. (Kuznetsova et al., 2012, 2014) retrieve similar images, parse associated captions into phrases, and compose them into new sentences. Due to the use of static, handmade templates, these approaches are unable to generate a variety of sentence realizations, which can result in poorly generated sentences and requires one to manually create more templates to extend the generation. Our approach overcomes this by dynamically generating the output.

More recent work utilizes neural networks and applies an encoder-decoder model (Cho et al., 2014). Vinyals et al. (2015) use a CNN to encode images into a fixed size vector representation and a LSTM to decode the image representations into a sentence. Xu et al. (2015) incorporate an attention mechanism (Bahdanau et al., 2015) and attend to the output from a convolutional layer of a CNN to produce the image representations for the decoder. Instead of encoding a whole image as a vector, (Johnson et al., 2016) apply R-CNN object detection (Girshick et al., 2014), match text snippets to the regions of the image detected by the R-CNN, and use a recurrent neural network (RNN) language model, similar to (Vinyals et al., 2015), to generate a description of each region.

The surface realization for state-of-the-art neural approaches is impressive, but, in the context of generating entity-aware captions, these methods fall short as they heavily rely on training data for language modeling. (Tran et al., 2016) leverage face and landmark recognition to generate captions containing named persons, but such large-scale training is difficult. Consequently, OOV words like named entities, which are a quintessential aspect of entity-aware captions because OOV words typically represent entities or events, are difficult to generate due to low training probabilities. Some work has been done to incorporate novel objects into captions (Venugopalan et al., 2017), but this does not address the need to generate entity-aware captions and incorporate contextual information; rather, it gives the ability to generate more fine-grained entities within captions that still lack the necessary context. (Feng and Lapata, 2013) also generates a caption with named entities, but from associated news articles, in which there is much more textual context than our setting. Our approach uses neural networks to generate dynamic templates and then fills in the templates with specific entities. Thus, we are able to combine the sentence variation and surface realization quality of neural language modeling and the capability to incorporate novel words of template-based approaches.

7 Conclusions and Future Work

In this paper we propose a new task which aims to automatically generate entity-aware image descriptions with limited textual information. Experiments on a new benchmark dataset collected from Flickr show that our approach generates more informative captions compared to traditional image captioning methods. Moreover, our two-step approach can easily be applied to other language generation tasks involving specific information.

In the future, we will expand the entity-aware model to incorporate the relations between candidates when the model fills in the slots, which can avoid the cases such as *'Cristiano Ronaldo of Barcelona'*. We will also make further research on context-aware fine-grained entity typing to train a better template generator. Another research direction based on this work is to develop an end-to-end neural architecture to make the model more flexible without generating a template in the middle.

Learning to Describe Differences Between Pairs of Similar Images

Harsh Jhamtani, Taylor Berg-Kirkpatrick

Abstract

In this paper, we introduce the task of automatically generating text to describe the differences between two similar images. We collect a new dataset by crowd-sourcing difference descriptions for pairs of image frames extracted from video-surveillance footage. Annotators were asked to succinctly describe *all* the differences in a short paragraph. As a result, our novel dataset provides an opportunity to explore models that align language and vision, and capture visual salience. The dataset may also be a useful benchmark for coherent multi-sentence generation. We perform a first-pass visual analysis that exposes clusters of differing pixels as a proxy for object-level differences. We propose a model that captures visual salience by using a latent variable to align clusters of differing pixels with output sentences. We find that, for both single-sentence generation and as well as multi-sentence generation, the proposed model outperforms the models that use attention alone.

Man by yellow poles in after pic wasn't there before.
There are two people in middle of court that were not there earlier.
Person crossing crosswalk is no longer there

The blue truck is no longer there.
A car is approaching the parking lot from the right

Figure 1: Examples from Spot-the-diff dataset: We collect text descriptions of all the differences between a pair of images. Note that the annotations in our dataset are exhaustive wrt differences in the two images i.e. annotators were asked to describe all the visible differences. Thus, the annotations contain multi-sentence descriptions.

1 Introduction

The interface between human users and collections of data is an important application area for artificial intelligence (AI) technologies. Can we build systems that effectively interpret data and present their results concisely in natural language? One recent goal in artificial intelligence has been to build models that are able to interpret and describe visual data to assist humans in various tasks. For example, image captioning systems (Vinyals et al., 2015b; Xu et al., 2015; Rennie et al., 2017; Zhang et al., 2017) and visual question answering systems (Antol et al., 2015; Lu et al., 2016; Xu and Saenko, 2016) can help visually impaired people in interacting with the world. Another way in which machines can assist humans is by identifying meaningful patterns in data, selecting and combining salient patterns, and generating concise and fluent 'human-consumable' descriptions. For instance, text summarization (Mani and Maybury, 1999; Gupta and Lehal, 2010; Rush et al., 2015) has been a long standing problem in natural language processing aimed at providing a concise text summary of a collection of documents.

In this paper, we propose a new task and accompanying dataset that combines elements of image captioning and summarization: the goal of 'spot-the-diff' is to generate a succinct text description of *all* the salient differences between a pair of similar images. Apart from being a fun puzzle, solutions to this task may have applications in assisted surveillance, as well as computer assisted tracking of changes in media assets. We collect and release a novel dataset for this task, which will be potentially useful for both natural language and computer vision research communities. We

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4024–4034
Brussels, Belgium, October 31 - November 4, 2018.

used crowd-sourcing to collect text descriptions of differences between pairs of image frames from video-surveillance footage (Oh et al., 2011), asking annotators to succinctly describe *all* salient differences. In total, our datasets consist of descriptions for 13,192 image pairs. Figure 1 shows a sample data point - a pair of images along with a text description of the differences between the two images as per a human annotator.

There are multiple interesting modeling challenges associated with the task of generating natural language summaries of differences between images. First, not all low-level visual differences are sufficiently salient to warrant description. The dataset presents an interesting source of supervision for methods that attempt to learn models of visual salience (we additionally conduct exploratory experiments with a baseline salience model, as described later). Second, humans use different levels of abstraction when describing visual differences. For example, when multiple nearby objects have all moved in coordination between images in a pair, an annotator may refer to the group as a single concept (e.g. 'the row of cars'). Third, given a set of salient differences, planning the order of description and generating a fluent sequence of multiple sentences is itself a challenging problem. Together, these aspects of the proposed task make it a useful benchmark for several directions of research.

Finally, we experiment with neural image captioning based methods. Since salient differences are usually described at an object-level rather than at a pixel-level, we condition these systems on a first-pass visual analysis that exposes clusters of differing pixels as a proxy for object-level differences. We propose a model which uses latent discrete variables in order to directly align difference clusters to output sentences. Additionally we incorporate a learned prior that models the visual salience of these difference clusters. We observe that the proposed model which uses alignment as a discrete latent variable outperforms those that use attention alone.

2 'Spot-the-diff' Task and Dataset

We introduce 'spot-the-diff' dataset consisting of 13,192 image pairs along with corresponding human provided text annotations stating the differences between the two images. Our goal was to create a dataset wherein there are meaningful differences between two similar images. To achieve this, we work with image frames extracted from VIRAT surveillance video dataset (Oh et al., 2011), which consists of 329 videos across 11 frames of reference totalling to about 8.5 hours of videos.

Total number of annotations	$13,192$
Mean (std dev.) number of sentences per annotation	$1.86(1.01)$
Vocabulary size	2404
Frequent word types (>=5 occurrences)	1000
Word tokens that are frequent word types	97%
Mean (std dev.) number of words in sentence:	$10.96(4.97)$
% Long sentences ($>$ 20 words)	5%

Table 1: Summary statistics for spot-the-diff dataset

2.1 Extracting Pairs of Image Frames

To construct our dataset, we first need to identify image pairs such that some objects have changed positions or have entered or left in the second image compared to the first image. To achieve this, we first extract a certain number of randomly selected image frame pairs from a given video. Thereafter, we compute the L_2 distance between the two images in each pair (under RGB representation). Finally, we set a lower and a upper threshold on the L_2 distance values so calculated to filter out the image pairs with potentially too less or too many changes. These thresholds are selected based on manual inspection. The resulting image pairs are used for collecting the difference descriptions.

2.2 Human Annotation

We crowd-sourced natural language differences between images using Amazon Mechanical Turk. We restrict to annotators from primarily Anglophone countries: USA, Australia, United Kingdom, and Canada, as we are working with English language annotations. We limit to those participants which have lifetime HIT $> 80\%$. We award 5 cents per HIT (Human Intelligence Task) to participants. We provide the annotators with an example on how to work on the task. We request the annotators to write complete English sentences, with each sentence on a separate line. We collect a total of 13192 annotations.

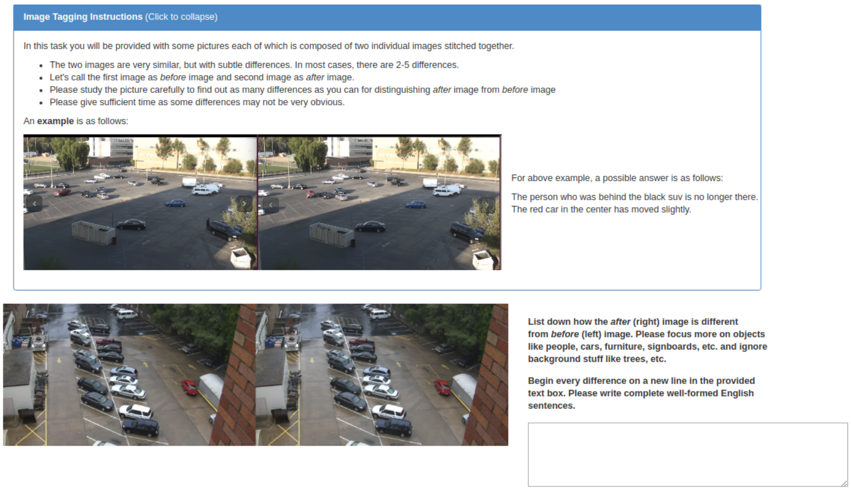

Image Tagging Instructions (Click to collapse)

In this task you will be provided with some pictures each of which is composed of two individual images stitched together.

- The two images are very similar, but with subtle differences. In most cases, there are 2-5 differences.
- Let's call the first image as *before* image and second image as *after* image.
- Please study the picture carefully to find out as many differences as you can for distinguishing *after* image from *before* image
- Please give sufficient time as some differences may not be very obvious.

An **example** is as follows:

For above example, a possible answer is as follows:

The person who was behind the black suv is no longer there.
The red car in the center has moved slightly.

List down how the *after* (right) image is different from *before* (left) image. Please focus more on objects like people, cars, furniture, signboards, etc. and ignore background stuff like trees, etc.

Begin every difference on a new line in the provided text box. Please write complete well-formed English sentences.

Figure 2: AMT (Amazon Mechanical Turk) HIT (Human Intelligence Task) setup for data collection. We provide the annotators with detailed instructions, along with an example showing how to perform the task. We request the annotators to write complete English sentences, with each sentence on a separate line. We collect a total of 13,192 annotations.

Dataset	BLEU-1/2/3/4	ROUGE-L
Spot-the-diff ($A = 3$)	$0.41/0.25/0.15/0.08$	0.31
MS-COCO ($A = 3$)	$0.38/0.22/0.13/0.08$	0.34
MS-COCO ($A = 5$)	$0.66/0.47/0.32/0.22$	0.48

Table 2: Human agreement for our dataset: We report measures such as BLEU and ROUGE when 'evaluating' one set of human generated captions against the remaining sets. $A = k$ represents k captions per data point, out of which 1 is chosen as hypothesis, while remaining $k - 1$ act as references.

2.3 Dataset statistics

Table 1 shows some summary statistics about the collected dataset. Since we deal with a focused domain, we observe a small vocabulary size. On an average there are 1.86 reported differences / sentences per image pair. We also report inter-annotator agreement as measured using text overlap of multiple annotations for the same image pair. We collect three sets of annotations for a small subset of the data (467 data points) for the purpose of reporting inter-annotator agreements. We thereby calculate BLEU and ROUGE-L scores by treating one set of annotations as 'hypothesis' while remaining two sets act as 'references'(Table 2). We repeat the same analysis for MS-COCO dataset and report these measures for reference. The BLEU and METEOR values for our dataset seem reasonable and are comparable to the values observed for MS-COCO dataset.

3 Modeling Difference Description Generation

We propose a neural model for describing visual difference based on the input pair of images that uses latent alignment variable to capture visual salience. Since most descriptions talk about higher-level differences rather than individual pixels, we first perform a visual analysis that precomputes a set of difference clusters in order to approximate object-level differences, as described next. The output of this analysis is treated as input to a neural encoder-decoder text generation model that incorporates a latent alignment variable and is trained on our new dataset.

3.1 Exposing Object-level Differences

We first analyze the input image pair for the pixel-level differences by computing a *pixel-difference mask*, followed by a local spatial analysis which segments the difference mask into clusters that approximate the set of object-level differences. Thereafter, we extract image features using convolutional neural models and use these as input to a neural text generation model, described later.

Pixel-level analysis: The lowest level of visual difference is individual differences between corresponding pixels in the input pair. Instead of requiring our description model to learn to compute pixel-level differences as a first step, we precompute and directly expose these to the model. Let $X = (\boldsymbol{I_1}, \boldsymbol{I_2})$ represent the image pair in a datum. For each such image pair in our dataset, we obtain a corresponding pixel-difference mask $\boldsymbol{M}$. M is a *binary-valued* matrix of the same dimensions (length and width) as each of the images in the corresponding image pair, wherein each element in the matrix is 1 (active) if the corresponding pixel is *different* between the input pair, and

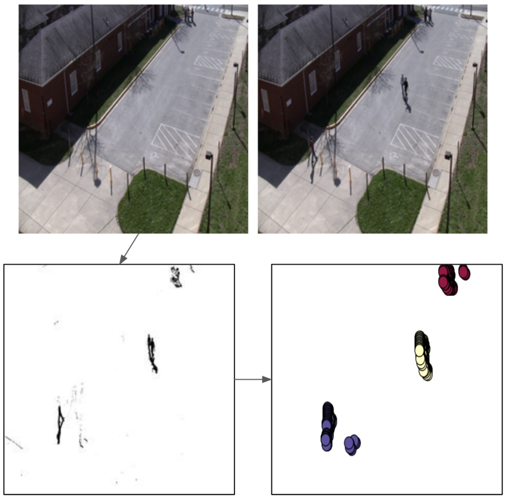

Figure 3: Exposing Object-level Differences: Before training a model to describe visual difference, we first compute pixel-level differences, as well as a segmentation of these differences into clusters, as a proxy for exposing object-level differences. The first row shows the original image pair. Bottom left depicts the pixel-difference mask, which represents extracted pixel-level differences. The segmentation of the pixel-difference mask into clusters is shown in the bottom right.

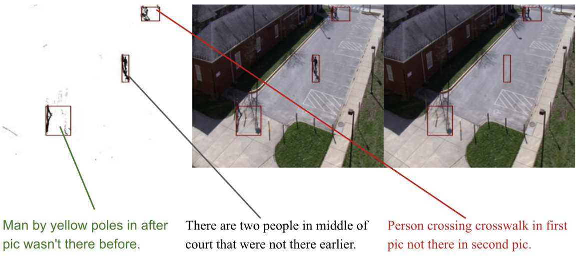

Figure 4: The figure shows the *pixel-difference* mask for the running example, along with the two original images, with bounding boxes around clusters. Typically one or more difference clusters are used to frame one reported difference / sentence, and it is rare for a difference cluster to participate in more than one reported difference.

0 otherwise. To decide whether a pair of corresponding pixels in the input image pair are sufficiently *different*, we calculate the L_2-distance between the vectors corresponding to each pixel's color value (three channels) and check whether this difference is greater than a threshold δ (set based on manual inspections).

While the images are extracted from supposedly still cameras, we do find some minor shifts in the camera alignment, which is probably due to occasional wind but may also be due to manual human interventions. These shifts are rare and small, and we align the images in the pair by iterating over a small range of vertical and horizontal shifts to find the shift with minimum corresponding L_2-distance between the two images.

Object-level analysis: Most visual descriptions refer to object-level differences rather than pixel-level differences. Again, rather than requiring the model to learn to group pixel differences into objects, we attempt to expose this to the model via pre-processing. As a proxy for object-level difference, we segment the pixel-level differences in the pixel-difference mask into clusters, and pass these clusters as additional inputs to the model. Based on manual inspection, we find that with the right clustering technique, this process results in groupings that roughly correspond to objects that have moved, appeared, and disappeared between the input pair. Here, we find that density based clustering algorithms like DBScan (Ester et al., 1996) work well in practice for this purpose. In our scenario, the DBScan algorithm predicts clusters of nearby active pixels, and marks outliers consisting of small groups of isolated active pixels, based on a calculation of local density. This also serves as a method for pruning any noisy pixel differences which may have passed through the pixel-level analysis.

As the output of DBScan, we obtain segmentation of the pixel difference matrix M into *difference clusters*. Let the number of *difference clusters* be represented by K (DBScan is a non-parametric clustering method, and as such the number of clusters K is different for each data point.). Now, let's define $\boldsymbol{C_k}$ as another binary-valued mask matrix such that the elements in matrix corresponding to the k^{th} difference cluster are 1 (active) while rest of the elements are 0.

3.2 Text Generation Model

We observe from annotated data that each individual sentence in a full description typically refers only to visual differences within a single cluster (see Figure 4). Further, on average, there are more clusters than there are sentences. While many uninteresting and *noisy* pixel-level differences get screened out in preprocessing, some uninteresting clusters are still identified. These are unlikely to be described by annotators because, even though they correspond to legitimate visual differences, they are not visually salient. Thus, we can roughly model description generation as a cluster selection process.

In our model, which is depicted in Figure 5, we

X=(I_1,I_2)	:	Image pair in the datum
M	:	Pixel-difference mask is a binary-valued matrix depicting pixel-level changes
F_1, F_2	:	Image feature tensors for I_1 and I_2 respectively
K	:	Number of segments
C_k	:	Cluster mask corresponding to k^{th} difference cluster
T	:	Number of reported differences / sentences
z_i	:	Discrete alignment variable for the i^{th} sentence. $z_i \in \{1, 2, ..., K\}$
$S_1, .., S_T$	:	List of T Sentences

Table 3: Summary of notation used in description of the method.

assume that each output description, which consists of sentences $S_1, \ldots, S_T$, is generated sentence by sentence conditioned on the input image pair $X = (I_1, I_2)$. Further, we let each sentence S_i be associated with a latent alignment variable, $z_i \in \{1, \ldots, K\}$, that chooses a cluster to focus on (Vinyals et al., 2015a). The choice of z_i is itself conditioned on the input image pair, and parameterized in a way that lets the model learn which types of clusters are visually salient and therefore likely to be described as sentences. Together, the probability of a description given an image pair is given by:

$$P(S_1, .., S_T|X) \\ = \sum_{z_1,..,z_T} \prod_{i=1}^{T} \underbrace{P(S_i|z_i, X; \theta))}_{\text{decoder}} \underbrace{P(z_i|X; w)}_{\text{alignment prior}} \quad (1)$$

The various components of this equation are described in detail in the next few sections. Here, we briefly summarize each. The term $P(z_i|X; w)$ represents the prior over the latent variable z_i and is parameterized in a way that lets the model learn which types of clusters are visually salient. The term $P(S_i|z_i, X; \theta)$ represents the likelihood of sentence S_i given the input image pair and alignment z_i. We employ masking and attention mechanisms to encourage this decoder to focus on the cluster chosen by z_i. Each of these components conditions on visual features produced by a pre-trained image encoder.

The alignment variable z_i for each sentence is chosen independently, and thus our model is similar to IBM Model 1 (Brown et al., 1993) in terms of its factorization structure. This will allow tractable learning and inference as described in Section 3.3. We refer to our approach as DDLA (**D**ifference **D**escription with **L**atent **A**lignment).

Alignment prior: We define a learnable prior over alignment variable z_i. In particular, we let the multinomial distribution on z_i be parameterized in a log-linear fashion using feature function $g(z_i)$. Specifically, we consider the following four features: the length, width, and area of the smallest rectangular region enclosing cluster z_i, and the number of active elements in mask C_{z_i}. Specifically, we let $P(z_i|X; w) \propto \exp(w^T g(z_i))$.

Visual encoder: We extract images features using ResNet (He et al., 2016) pre-trained on Imagenet data. Similar to prior work (Xu et al., 2015), we extract features using a lower level convolutional layer instead of fully connected layer. In this way, we obtain image features of dimensionality $14 * 14 * 2096$, where the first two dimensions correspond to a grid of coarse, spatially localized, feature vectors. Let F_1 and F_2 represent the extracted feature tensors for I_1 and I_2 respectively.

Sentence decoder: We use an LSTM decoder (Hochreiter and Schmidhuber, 1997) to generate the sequence of words in each output sentence, conditioned on the image pair and latent alignments. We use a matrix transformation of the extracted image features to initialize the hidden state of the LSTM decoder for each sentence, independent of the setting of z_i. Additionally, we use an attention mechanism over the image features at every decoding step, similar to the previous work (Xu et al., 2015). However, instead of considering attention over the entire image, we restrict attention over image features to the cluster mask determined by the alignment variable, C_{z_i}. Specifically, we project binary mask C_{z_i} from the input image dimensionality (224*224) to the dimensionality of the visual features (14*14). To achieve this, we use pyramid reduce downsampling on a smoothed version of cluster mask C_{z_i}. The resulting projection roughly corresponds to the subset of visual features with the cluster region in their receptive field. This projection is multiplied to attention weights.

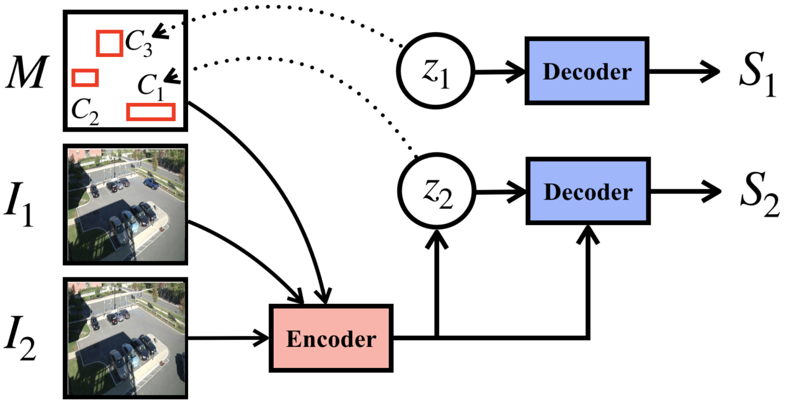

Figure 5: Model architecture for generating difference descriptions. We incorporate a discrete latent variable z which selects one of the clusters as a proxy for object-level focus. Conditioned on the cluster and visual features in the corresponding region, the model generates a sentence using an LSTM decoder. During training, each sentence in the full description receives its own latent alignment variable, z.

3.3 Learning and Decoding

Learning in our model is accomplished by stochastic gradient ascent on the marginal likelihood of each description with alignment variables marginalized out. Since alignment variables are independent of one another, we can marginalize over each z_i separately. This means running back-propagation through the decoder K times for each sentence, where K is the number of clusters. In practice K is relatively small and this direct approach to training is feasible. Following equation 1, we train both the generation and prior in an end-to-end fashion.

For decoding, we consider the following two problem settings. In the first setting, we consider the task of producing a single sentence in isolation. We evaluate in this setting by treating the sentences in the ground truth description as multiple reference captions. This setting is similar to the typical image captioning setting. In the second setting, we consider the full multi-sentence generation task where the system is required to produce a full description consisting of multiple sentences describing all differences in the input. Here, the generated multi-sentence text is directly evaluated against the multi-sentence annotation in the crowd-soured data.

Single-sentence decoding: For single sentence generation, we first select the value of z_i which maximizes the prior $P(z_i|X;w)$. Thereafter, we simply use greedy decoding to generate a sentence conditioned on the chosen z_i and the input image pair.

Multi-sentence decoding: Here, we first select a set of clusters to include in the output description, and then generate a single sentence for each cluster using greedy decoding. Since typically there are more clusters than sentences, we condition on the ground truth number of sentences and choose the corresponding number of clusters. We rank clusters by decreasing likelihood under the alignment prior and then choose the top T.

4 Experiments

We split videos used to create the dataset into train, test, and validation in the ratio 80:10:10. This is done to ensure that all data points using images from the same video are entirely in one split. We report quantitative metrics like CIDEr (Vedantam et al., 2015), BLEU (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2014), and ROUGE-L, as is often reported by works in image captioning. We report these measures for both sentence level setting and multi-sentence generation settings. Thereafter, we also discuss some qualitative examples. We implement our models in PyTorch (Paszke et al., 2017). We use mini-batches of size 8 and use Adam optimizer[1]. We use CIDEr scores on validation set as a criteria for early stopping.

Baseline models: We consider following baseline models: CAPT model considers soft attention over the input pair of images (This atten-

Table 5: **Multi-sentence decoding** We report automatic evaluation scores for various models under multi-sentence generation setting. DDLA model achieves better scores compared to the baseline methods. Note that these scores are not directly comparable with single sentence generation setting. **LenRatio** is the ratio of the average number of tokens in the prediction to the average number of tokens in the ground truth for the test set.

tion mechanism is similar to that used in prior image captioning works (Xu et al., 2015), except that we have two images instead of a single image input). We do not perform any masking in case of CAPT model, and simply ignore the cluster information. The model is trained to generate a single sentence. Thus, this model is similar to a typical captioning model but with soft attention over two images. CAPT-MASK model is similar to CAPT model except that it incorporates the masking mechanism defined earlier using the union of all the cluster masks in the corresponding image. We also consider a version of the CAPT model wherein the target prediction is the whole multi-sentence description – CAPT-MULTI – for this setting, we simply concatenate the sentences in any arbitrary order [2]. Additionally, we consider a nearest neighbor baseline (NN-MULTI), wherein we simply use the annotation of the closest matching training data point. We compute the closeness based on the extracted features of the image pair, and leverage sklearns (Pedregosa et al., 2011) Nearest-Neighbor module. For single sentence setting (NN), we randomly pick one of the sentences in the annotation.

We also consider a version of DDLA model with fixed uniform prior, and refer to this model as DDLA-UNIFORM . For single sentence generation, we sample z_j randomly from the uniform distribution and then perform decoding. For the multi-sentence generation setting, we employ simple heuristics to order the clusters at test time. One such heuristic we consider is to order the clusters as per the decreasing area of the bounding box (smallest rectangular area enclosing the cluster).

Results: We report various automated metrics for the different methods under single sentence generation and multi-sentence generation in Tables 4 and 5 respectively. For the single sentence generation setting, we observe that the DDLA model outperforms various baselines as per most of the scores on the test data split. DDLA-UNIFORM method performs similar to the CAPT baseline methods. For the multi-sentence generation, the DDLA model again outperforms other methods. This means that having a learned prior is useful in our proposed method. Figure 6 shows an example data point with predicted outputs by different methods.

5 Discussion and Analysis

Qualitative Analysis of Outputs We perform a qualitative analysis on the outputs to understand the drawbacks in the current methods. One apparent limitation of the current methods is the failure to explicitly model the movement of same object in the two images (Figure 7) – prior works on object tracking can be useful here. Sometimes the models get certain attributes of the objects wrong. e.g. 'blue car' instead of 'red car'. Some output predictions state an object to have 'appeared' instead of 'disappeared' and vice

---

[2] Note that we do not provide CAPT-MULTI with ground truth number of sentences

HUMAN: A white truck has appeared in the after image. A person is now walking on the footpath.
DDLA (multi-sentence): A white truck appeared on the road. There is a person walking in the after image
CAPT-multi (multi-sentence): There is a car. There is a person walking in the parking lot.

HUMAN: There are more people in the group.
DDLA (multi-sentence): There are more people in the after image
CAPT-multi (multi-sentence): The people in the right image.

Figure 6: Predictions from various methods for two input image pairs.

DDLA: The blue truck is gone.

Figure 7: Some drawbacks with the current models: One apparent drawback with the single cluster selection is that it misses opportunity to identify an object which has moved significantly- considering it as appeared or disappeared as the case may be. In this example, the blue truck moved, but the DDLA model predicts that the truck is no longer there.

versa.

Do models learn alignment between sentence and difference clusters? We performed a study on 50 image pairs by having two humans manually annotate gold alignments between sentences and difference clusters. We then computed alignment precision for the model's predicted alignments. To obtain model's predicted alignment for a given sentence S_i, we compute $argmax_k P(z_i = k|X)P(S_i|z_i = k, X)$. Our proposed model achieved a precision of 54.6%, an improvement over random chance at 27.4%.

Clustering for pre-processing Our generation algorithm assumed one sentence uses only one cluster and as such we tune the hyper-parameters of clustering method to get large clusters so that typically a cluster will entirely contain a reported difference. On inspecting randomly selected data points, we observe that in some cases too large clusters are marked by the clustering procedure. One way to mitigate this is to tune clustering parameters to get smaller clusters and update the generation part to use a subset of clusters. As mentioned earlier, we consider clustering as a means to achieve object level pre-processing. One possible future direction is to leverage pre-trained object detection models to detect cars, trucks, people, etc. and make these predictions readily available to the generation model.

Multi-sentence Training and Decoding As mentioned previously, we query the models for a desired number of 'sentences'. In future works we would like to relax this assumption and design models which can predict the number of sentences as well. Additionally, our proposed model doesn't not explicitly ensure consistency in the latent variables for different sentences of a given data point i.e the model does not make explicit use of the fact that sentences report non-overlapping visual differences. Enforcing this knowledge while retaining the feasibility of training is a potential future direction of work.

6 Related Work

Modeling pragmatics: The dataset presents an opportunity to test methods which can model pragmatics and reason about semantic, spatial and visual similarity to generate a textual description of what has changed from one image to another. Some prior work in this direction (Andreas and Klein, 2016; Vedantam et al., 2017) contrastively describe a target scene in presence of a distractor. In another related task – referring expression comprehension (Kazemzadeh et al., 2014; Mao et al., 2016; Hu et al., 2017) – the model has to identify which object in the image is being referred to by the given sentence. However, our proposed task comes with a pragmatic goal related to summarization: the goal is to identify and describe *all* the differences. Since the goal is well defined, it may be used to constrain models that attempt to learn how humans describe visual difference.

Natural language generation: Natural language generation (NLG) has a rich history of previous work, including, for example, recent works on biography generation (Lebret et al., 2016), weather report generation (Mei et al., 2016), and recipe generation (Kiddon et al., 2016). Our task can viewed as a potential benchmark for coherent multi-sentence text generation since it involves assembling multiple sentences to succinctly cover a set of differences.

Visual grounding: Our dataset may also provide a useful benchmark for training unsupervised and semi-supervised models that learn to align vision and language. Plummer et al. (2015) collected annotation for phrase-region alignment in an image captioning dataset, and follow up work has attempted to predict these alignments (Wang et al., 2016; Plummer et al., 2017; Rohrbach et al., 2016). Our proposed dataset poses a related alignment problem: attempting to align sentences or phrases to visual differences. However, since differences are contextual and depend on visual comparison, our new task may represent a more challenging scenario as modeling techniques advance.

Image change detection: There are some works on land use pattern change detection ((Radke et al., 2005)). These works are related since they try to screen out noise and mark the regions of change between two images of same area at different time stamps. Bruzzone and Prieto (2000) propose an unsupervised change detection algorithms aim to discriminate between changed and unchanged pixels for multi-temporal remote sensing images. Zanetti and Bruzzone (2016) propose a method that allows unchanged class to be more complex rather than having a single unchanged class. Though image diff detection is part of our pipeline, our end task is to generate natural language descriptors. Moreover, we observe that simple clustering seems to work well for our dataset.

Other relevant works: Maji (2012) aim to construct a lexicon of parts and attributes by formulating an annotation task where annotators are asked to describe differences between two images. Some other related works model phrases describing change in color (Winn and Muresan, 2018), move-by-move game commentary for describing change in game state (Jhamtani et al., 2018), and code commit message summarizing changes in code-base from one commit to another (Jiang et al., 2017). There exist some prior works on fine grained image classification and captioning (Wah et al., 2014; Nilsback and Zisserman, 2006; Khosla et al., 2011). The premise of such works is that it is difficult for machine to find discriminative features between similar objects e.g. birds of different species. Such works are relevant for us as the type of data we deal with are usually of same object or scene taken at a different time or conditions.

7 Conclusion

In this paper, we proposed the new task of describing differences between pairs of similar images and introduced a corresponding dataset. Compared to many prior image captioning datasets, text descriptions in the ‘Spot-the-diff’ dataset are often multi-sentence, consisting of all the differences in two similar images in most of the cases. We performed exploratory analysis of the dataset and highlighted potential research challenges. We discuss how our ’Spot-the-diff’ dataset is useful for tasks such as language vision alignment, referring expression comprehension, and multi-sentence generation. We performed pixel and object level preprocessing on the images to identify clusters of differing pixels. We observe that the proposed model which aligns clusters of differing pixels to output sentences performs better than the models which use attention alone. We also discuss some limitations of current methods and scope for future directions.

Object Hallucination in Image Captioning

^{1} UC Berkeley, ^{2} Boston University

Abstract

Despite continuously improving performance, contemporary image captioning models are prone to "hallucinating" objects that are not actually in a scene. One problem is that standard metrics only measure similarity to ground truth captions and may not fully capture image relevance. In this work, we propose a new image relevance metric to evaluate current models with veridical visual labels and assess their rate of object hallucination. We analyze how captioning model architectures and learning objectives contribute to object hallucination, explore when hallucination is likely due to image misclassification or language priors, and assess how well current sentence metrics capture object hallucination. We investigate these questions on the standard image captioning benchmark, MSCOCO, using a diverse set of models. Our analysis yields several interesting findings, including that models which score best on standard sentence metrics do not always have lower hallucination and that models which hallucinate more tend to make errors driven by language priors.

1 Introduction

Image captioning performance has dramatically improved over the past decade. Despite such impressive results, it is unclear to what extent captioning models actually rely on image content: as we show, existing metrics fall short of fully capturing the captions' relevance to the image. In Figure 1 we show an example where a competitive captioning model, Neural Baby Talk (NBT) (Lu et al., 2018), incorrectly generates the object "bench." We refer to this issue as object *hallucination*.

While missing salient objects is also a failure mode, captions are summaries and thus generally not expected to describe all objects in the scene. On the other hand, describing objects that are *not present* in the image has been shown to be less preferable to humans. For example, the LSMDC challenge (Rohrbach et al., 2017a) documents that correctness is more important to human judges than specificity. In another study, (MacLeod et al., 2017) analyzed how visually impaired people react to automatic image captions. They found that people vary in their preference of either coverage or correctness. For many visually impaired who value correctness over coverage, hallucination is an obvious concern.

NBT: A woman talking on a cell phone while sitting on a ***bench***.
CIDEr: **0.87**, METEOR: 0.23, SPICE: **0.22,** CHs: **1.00**, CHi: **0.33**

TopDown: A woman is talking on a cell phone.
CIDEr: 0.54, METEOR: **0.26**, SPICE: 0.13, CHs: **0.00**, CHi: **0.00**

Figure 1: Image captioning models often "hallucinate" objects that may appear in a given context, like e.g. a *bench* here. Moreover, the sentence metrics do not always appropriately penalize such hallucination. Our proposed metrics (CHAIRs and CHAIRi) reflect hallucination. For CHAIR *lower is better*.

Besides being poorly received by humans, object hallucination reveals an internal issue of a captioning model, such as not learning a very good representation of the visual scene or overfitting to its loss function.

In this paper we assess the phenomenon of object hallucination in contemporary captioning models, and consider several key questions. The

Brussels, Belgium, October 31 - November 4, 2018.

first question we aim to answer is: *Which models are more prone to hallucination?* We analyze this question on a diverse set of captioning models, spanning different architectures and learning objectives. To measure object hallucination, we propose a new metric, *CHAIR (Caption Hallucination Assessment with Image Relevance)*, which captures image relevance of the generated captions. Specifically, we consider both ground truth object annotations (MSCOCO Object segmentation (Lin et al., 2014)) and ground truth sentence annotations (MSCOCO Captions (Chen et al., 2015)). Interestingly, we find that models which score best on standard sentence metrics do not always hallucinate less.

The second question we raise is: *What are the likely causes of hallucination?* While hallucination may occur due to a number of reasons, we believe the top factors include visual misclassification and over-reliance on language priors. The latter may result in memorizing which words "go together" regardless of image content, which may lead to poor generalization, once the test distribution is changed. We propose *image and language model consistency* scores to investigate this issue, and find that models which hallucinate more tend to make mistakes consistent with a language model.

Finally, we ask: *How well do the standard metrics capture hallucination?* It is a common practice to rely on automatic sentence metrics, e.g. CIDEr (Vedantam et al., 2015), to evaluate captioning performance during development, and few employ human evaluation to measure the final performance of their models. As we largely rely on these metrics, it is important to understand how well they capture the hallucination phenomenon. In Figure 1 we show how two sentences, from NBT with hallucination and from TopDown model (Anderson et al., 2018) – without, are scored by the standard metrics. As we see, hallucination is not always appropriately penalized. We find that by using additional ground truth data about the image in the form of object labels, our metric CHAIR allows us to catch discrepancies that the standard captioning metrics cannot fully capture. We then investigate ways to assess object hallucination risk with the standard metrics. Finally, we show that CHAIR is complementary to the standard metrics in terms of capturing human preference.

2 Caption Hallucination Assessment

We first introduce our image relevance metric, *CHAIR*, which assesses captions w.r.t. objects that are actually in an image. It is used as a main tool in our evaluation. Next we discuss the notions of *image and language model consistency*, which we use to reason about the causes of hallucination.

2.1 The CHAIR Metric

To measure object hallucination, we propose the *CHAIR (Caption Hallucination Assessment with Image Relevance)* metric, which calculates what proportion of words generated are actually in the image according to the ground truth sentences and object segmentations. This metric has two variants: per-instance, or what fraction of object instances are hallucinated (denoted as CHAIRi), and per-sentence, or what fraction of sentences include a hallucinated object (denoted as CHAIRs):

$$\text{CHAIR}_i = \frac{|\{\text{hallucinated objects}\}|}{|\{\text{all objects mentioned}\}|}$$

$$\text{CHAIR}_s = \frac{|\{\text{sentences with hallucinated object}\}|}{|\{\text{ all sentences}\}|}$$

For easier analysis, we restrict our study to the 80 MSCOCO objects which appear in the MSCOCO segmentation challenge. To determine whether a generated sentence contains hallucinated objects, we first tokenize each sentence and then singularize each word. We then use a list of synonyms for MSCOCO objects (based on the list from Lu et al. (2018)) to map words (e.g., "player") to MSCOCO objects (e.g., "person"). Additionally, for sentences which include two word compounds (e.g., "hot dog") we take care that other MSCOCO objects (in this case "dog") are not incorrectly assigned to the list of MSCOCO objects in the sentence. For each ground truth sentence, we determine a list of MSCOCO objects in the same way. The MSCOCO segmentation annotations are used by simply relying on the provided object labels.

We find that considering both sources of annotation is important. For example, MSCOCO contains an object "dining table" annotated with segmentation maps. However, humans refer to many different kinds of objects as "table" (e.g., "coffee table" or "side table"), though these objects are not annotated as they are not specifically "dining table". By using sentence annotations to scrape ground truth objects, we account for variation in how human annotators refer to different objects. Inversely, we find that frequently humans will not mention all objects in a scene. Qualitatively, we observe that both annotations are important to capture hallucination. Empirically, we verify that using only segmentation labels or only reference captions leads to higher hallucination (and practically incorrect) rates.

2.2 Image Consistency

We define a notion of *image consistency*, or how consistent errors from the captioning model are with a model which predicts objects based on an image alone. To measure image consistency for a particular generated word, we train an image model and record $P(w|I)$ or the probability of predicting the word given only the image. To score the image consistency of a caption we use the average of $P(w|I)$ for all MSCOCO objects, where higher values mean that errors are *more* consistent with the image model. Our image model is a multi-label classification model with labels corresponding to MSCOCO objects (labels determined the same way as is done for CHAIR) which shares the visual features with the caption models.

2.3 Language Consistency

We also introduce a notion of *language consistency*, i.e. how consistent errors from the captioning model are with a model which predicts words based only on previously generated words. We train an LSTM (Hochreiter and Schmidhuber, 1997) based language model which predicts a word w_t given previous words $w_{0:t-1}$ on MSCOCO data. We report language consistency as $1/R(w_t)$ where $R(w_t)$ is the rank of the predicted word in the language model. Again, for a caption we report average rank across all MSCOCO objects in the sentence and higher language consistency implies that errors are *more* consistent with the language model.

We illustrate image and language consistency in Figure 2, i.e. the hallucination error ("fork") is more consistent with the Language Model predictions than with the Image Model predictions. We use these consistency measures in Section 3.3 to help us investigate the causes of hallucination.

Image Model predictions:
bowl, broccoli, carrot, dining table

Language Model predictions for the last word:
fork, spoon, bowl

Generated caption: A plate of food with broccoli and a ***fork***.

Figure 2: Example of image and language consistency. The hallucination error ("fork") is more consistent with the Language Model.

3 Evaluation

In this section we present the findings of our study, where we aim to answer the questions posed in Section 1: *Which models are more prone to hallucination? What are the likely causes of hallucination? How well do the standard metrics capture hallucination?*

3.1 Baseline Captioning Models

We compare object hallucination across a wide range of models. We define two axes for comparison: model architecture and learning objective.

Model architecture. Regarding model architecture, we consider models both with and without attention mechanisms. In this work, we use "attention" to refer to any mechanism which learns to focus on different image regions, whether image regions be determined by a high level feature map, or by object proposals from a trained detector. All models are end-to-end trainable and use a recurrent neural network (LSTM (Hochreiter and Schmidhuber, 1997) in our case) to output text. For non-attention based methods we consider the **FC model** from Rennie et al. (2017) which incorporates visual information by initializing the LSTM hidden state with high level image features. We also consider **LRCN** (Donahue et al., 2015) which considers visual information at each time step, as opposed to just initializing the LSTM hidden state with extracted features.

For attention based models, we consider **Att2In** (Rennie et al., 2017), which is similar to the original attention based model proposed by (Xu et al., 2015), except the image feature is only input into the cell gate as this was shown to lead to better performance. We then consider the attention model proposed by (Anderson et al., 2018) which proposes a specific "top-down attention" LSTM as well as a "language" LSTM.

Generally attention mechanisms operate over high level convolutional layers. The attention mechanism from (Anderson et al., 2018) can be used on such feature maps, but Anderson et al. also consider feature maps corresponding to object proposals from a detection model. We consider both models, denoted as **TopDown** (feature map extracted from high level convolutional layer) and **TopDown-BB** (feature map extracted from object proposals from a detection model). Finally, we consider the recently proposed **Neural Baby Talk (NBT)** model (Lu et al., 2018) which explicitly uses object detections (as opposed to just bounding boxes) for sentence generation.

Learning objective. All of the above models are trained with the standard *cross entropy* (CE) loss as well as the *self-critical* (SC) loss proposed by Rennie et al. (2017) (with an exception of NBT, where only the CE version is included). The SC loss directly optimizes the CIDEr metric with a reinforcement learning technique. We additionally consider a model trained with a *GAN* loss (Shetty et al., 2017) (denoted **GAN**), which applies adversarial training to obtain more diverse and "human-like" captions, and their respective non-GAN baseline with the CE loss.

TopDown deconstruction. To better evaluate how each component of a model might influence hallucination, we "deconstruct" the TopDown model by gradually removing components until it is equivalent to the FC model. The intermediate networks are *NoAttention*, in which the attention mechanism is replaced by mean pooling, *NoConv* in which spatial feature maps are not input into the network (the model is provided with fully connected feature maps), *SingleLayer* in which only one LSTM is included in the model, and finally, instead of inputting visual features at each time step, visual features are used to initialize the LSTM embedding as is done in the FC model. By deconstructing the TopDown model in this way, we ensure that model design choices and hyperparameters do not confound results.

Implementation details. All the baseline models employ features extracted from the fourth layer of ResNet-101 (He et al., 2016), except for the GAN model which employs ResNet-152. Models without attention traditionally use fully connected layers as opposed to convolutional layers. However, as ResNet-101 does not have intermediate fully connected layers, it is standard to average pool convolutional activations and input these features into non-attention based description models. Note that this means the difference between the *NoAttention* and *NoConv* model is that the *NoAttention* model learns a visual embedding of spatial feature maps as opposed to relying on pre-pooled feature maps. All models except for TopDown-BB, NBT, and GAN are implemented in the same open source framework from Luo et al. (2018).[1]

Training/Test splits. We evaluate the captioning models on two MSCOCO splits. First, we consider the split from Karpathy et al. (Karpathy and Fei-Fei, 2015), specifically in that case the models are trained on the respective Karpathy Training set, tuned on Karpathy Validation set and the reported numbers are on the Karpathy Test set. We also consider the *Robust* split, introduced in (Lu et al., 2018), which provides a compositional split for MSCOCO. Specifically, it is ensured that the object pairs present in the training, validation and test captions do not overlap. In this case the captioning models are trained on the Robust Training set, tuned on the Robust Validation set and the reported numbers are on the Robust Test set.

3.2 Which Models Are More Prone To Hallucination?

We first present how well competitive models perform on our proposed CHAIR metric (Table 1). We report CHAIR at sentence-level and at instance-level (CHs and CHi in the table). In general, we see that models which perform better on standard evaluation metrics, perform better on CHAIR, though this is not always true. In particular, models which optimize for CIDEr frequently hallucinate more. Out of all generated captions on the Karpathy Test set, anywhere between 7.4% and 17.7% include a hallucinated object. When shifting to more difficult training scenarios in which new combinations of objects are seen at test time, hallucination consistently increases (Table 2).

Karpathy Test set. Table 1 presents object hallucination on the Karpathy Test set. All sentences are generated using beam search and a beam size of 5. We note a few important trends. First, models with attention tend to perform better on the CHAIR metric than models without attention. As we explore later, this is likely because they have

For discussion see Section 3.2.

a better understanding of the image. In particular, methods that incorporate bounding box attention (as opposed to relying on coarse feature maps), consistently have lower hallucination as measured by our CHAIR metric. Note that the NBT model does not perform as well on standard captioning metrics as the TopDown-BB model but has lower hallucination. This is perhaps because bounding box proposals come from the MSCOCO detection task and are thus "in-domain" as opposed to the TopDown-BB model which relies on proposals learned from the Visual Genome (Krishna et al., 2017) dataset. Second, frequently training models with the self-critical loss actually increases the amount of hallucination. One hypothesis is that CIDEr does not penalize object hallucination sufficiently, leading to both increased CIDEr and increased hallucination. Finally, the LRCN model has a higher hallucination rate than the FC model, indicating that inputting the visual features only at the first step, instead of at every step, leads to more image relevant captions.

We also consider a GAN based model (Shetty et al., 2017) in our analysis. We include a baseline model (trained with CE) as well as a model trained with the GAN loss.[2] Unlike other models, the GAN model uses a stronger visual network (ResNet-152) which could explain the lower hallucination rate for both the baseline and the GAN model. Interestingly, when comparing the baseline and the GAN model (both trained with ResNet-152), standard metrics decrease substantially, even though human evaluations from (Shetty et al., 2017) demonstrate that sentences are of comparable quality. On the other hand, hallucination decreases, implying that the GAN loss actually helps decrease hallucination. Unlike the self critical loss, the GAN loss encourages sentences to be human-like as opposed to optimizing a metric. Human-like sentences are not likely to hallucinate objects, and a hallucinated object is likely a strong signal to the discriminator that a sentence is generated, and is not from a human.

Table 2: Hallucination Analysis on the Robust Test set: Spice (S), CIDEr (C) and METEOR (M) scores across different image captioning models as well as CHAIRs (sentence level, CHs) and CHAIRi (instance level, CHi). * are trained/evaluated within the same implementation (Luo et al., 2018), † are trained/evaluated with implementation publicly released with corresponding papers. All models trained with cross-entropy loss. See Section 3.2.

We also assess the effect of beam size on CHAIR. We find that generally beam search decreases hallucination. We use beam size of 5, and for all models trained with cross entropy, it outperforms lower beam sizes on CHAIR. However, when training models with the self-critical loss, beam size sometimes leads to worse performance on CHAIR. For example, on the Att2In model trained with SC loss, a beam size of 5 leads to 12.8 on CHAIRs and 8.7 on CHAIRi, while a beam size of 1 leads to 10.8 on CHAIRs and 8.1 on CHAIRi.

Robust Test set. Next we review the hallucination behavior on the Robust Test set (Table 2). For almost all models the hallucination increases on the Robust split (e.g. for TopDown from 8.4% to 11.4% of sentences), indicating that the issue of

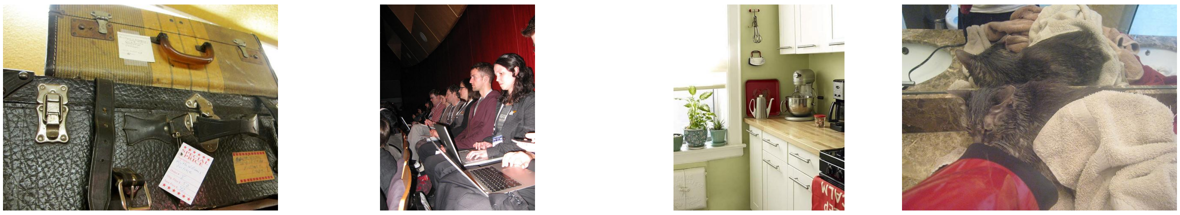
[2] Sentences were procured directly from the authors.



TopDown: A pile of luggage sitting on top of a ***table***.
NBT: Several pieces of luggage sitting on a ***table***.

TopDown: A group of people sitting around a ***table*** with laptops.
NBT: A group of people sitting around a ***table*** with laptop.

TopDown: A kitchen with a stove and a ***sink***.
NBT: A kitchen with a stove and a ***sink***.

TopDown: A couple of cats laying on top of a ***bed***.
NBT: A couple of cats laying on top of a ***bed***.

TopDown: A cat sitting on top of a ***laptop computer***.
NBT: A cat sitting on a table next to a ***computer***.

TopDown: A brown dog sitting on top of a ***chair***.
NBT: A brown and white dog sitting under an ***umbrella***.

TopDown: Aa man and a woman are playing with a ***frisbee***.
NBT: A man riding a skateboard down a street.

TopDown: A man standing on a beach holding a ***surfboard***.
NBT: A man standing on top of a sandy beach.

Figure 3: Examples of object hallucination from two state-of-the-art captioning models, TopDown and NBT, see Section 3.2.

hallucination is more critical in scenarios where test examples can not be assumed to have the same distribution as train examples. We again note that attention is helpful for decreasing hallucination. We note that the NBT model actually has lower hallucination scores on the robust split. This is in part because when generating sentences we use the detector outputs provided by Lu et al. (2018). Separate detectors on the Karpathy test and robust split are not available and the detector has access to images in the robust split during training. Consequently, the comparison between NBT and other models is not completely fair, but we include the number for completeness.

In addition to the Robust Test set, we also consider a set of MSCOCO in which certain objects are held out, which we call the *Novel Object split* (Hendricks et al., 2016). We train on the training set outlined in (Hendricks et al., 2016) and test on the Karpathy test split, which includes objects unseen during training. Similarly to the Robust Test set, we see hallucination increase substantially on this split. For example, for the TopDown model hallucination increases from 8.4% to 12.1% for CHAIRs and 6.0% to 9.1% for CHAIRi.

We find no obvious correlation between the average length of the generated captions and the hallucination rate. Moreover, vocabulary size does not correlate with hallucination either, i.e. models with *more diverse* descriptions may actually *hallucinate less*. We notice that hallucinated objects tend to be mentioned towards *the end of the sentence* (on average at position 6, with average sentence length 9), suggesting that some of the preceding words may have triggered hallucination. We investigate this below.

Which objects are hallucinated and in what context? Here we analyze which MSCOCO objects tend to be hallucinated more often and what are the common preceding words and image context. Across all models the super-category *Furniture* is hallucinated most often, accounting for $20-50\%$ of all hallucinated objects. Other common super-categories are *Outdoor objects*, *Sports* and *Kitchenware*. On the Robust Test set, *Animals* are often hallucinated. The *dining table* is the most frequently hallucinated object across all models (with an exception of GAN, where *person* is the most hallucinated object). We find that often words like “sitting” and “top” precede the “dining table” hallucination, implying the two common scenarios: a person “sitting at the table” and an object “sitting on top of the table” (Figure 3, row 1, examples 1, 2). Similar observations can be made for other objects, e.g. word “kitchen” often precedes “sink” hallucination (Figure 3, row 1, example 3) and “laying” precedes “bed” (Figure 3, row 1, example 4). At the same time, if we look at which objects are actually present in the image (based on MSCOCO object annotations), we can similarly identify that presence of a “cat” co-occurs with hallucinating a “laptop” (Figure 3, row 2, example 1), a “dog” – with a “chair” (Figure 3, row 2, example 2) etc. In most cases we observe that the hallucinated objects appear in the relevant scenes (e.g. “surfboard” on a beach), but

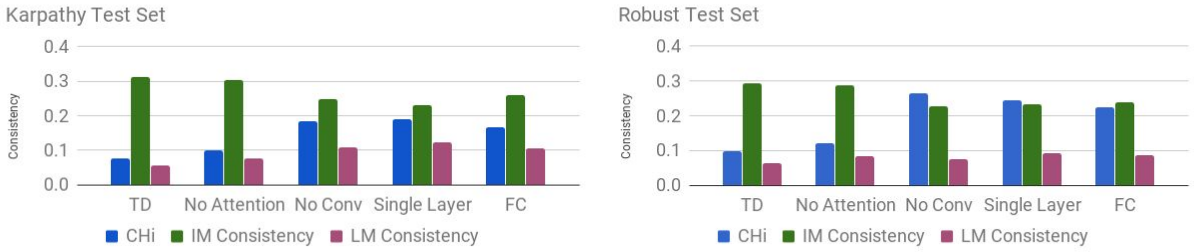


Figure 4: Image and Language model consistency (IM, LM) and CHAIRi (instance-level, CHi) on deconstructed TopDown models. Images with less hallucination tend to make errors consistent with the image model, whereas models with more hallucination tend to make errors consistent with the language model, see Section 3.3.

there are cases where objects are hallucinated out of context (e.g. "bed" in the bathroom, Figure 3, row 1, example 4).

3.3 What Are The Likely Causes Of Hallucination?

In this section we investigate the likely causes of object hallucination. We have earlier described how we deconstruct the TopDown model to enable a controlled experimental setup. We rely on the deconstructed TopDown models to analyze the impact of model components on hallucination.

First, we summarize the hallucination analysis on the deconstructed TopDown models (Table 3). Interestingly, the *NoAttention* model does not do substantially worse than the full model (w.r.t. sentence metrics and CHAIR). However, removing Conv input (*NoConv* model) and relying only on FC features, decreases the performance dramatically. This suggests that much of the gain in attention based models is primarily due to *access to feature maps with spatial locality*, not the actual attention mechanism. Also, similar to LRCN vs. FC in Table 1, initializing the LSTM hidden state with image features, as opposed to inputting image features at each time step, leads to lower hallucination (*Single Layer* vs. *FC*). This is somewhat surprising, as a model which has access to image information at each time step should be less likely to "forget" image content and hallucinate objects. However, it is possible that models which include image inputs at each time step with no access to spatial features overfit to the visual features.

Now we investigate what causes hallucination using the deconstructed TopDown models and the *image consistency* and *language consistency* scores, introduced in Sections 2.2 and 2.3 which capture how consistent the hallucinations errors are with image- / language-only models.

Karpathy Split	METEOR	CIDEr	SPICE	CHs	CHi
TD	26.10	103.40	19.50	10.80	7.40
No Attention	25.60	99.70	18.80	14.20	9.40
No Conv	22.90	81.30	15.70	25.70	17.70
Single Layer	22.70	80.20	15.50	25.60	18.00
FC	23.30	85.10	16.40	23.60	15.70

Table 3: Hallucination analysis on deconstructed TopDown models with sentence metrics, CHAIRs (sentence level, CHs) and CHAIRi (instance level, CHi). See Section 3.3.

Figure 4 shows the CHAIR metric, image consistency and language consistency for the deconstructed TopDown models on the Karpathy Test set (left) and the Robust Test set (right). We note that models with *less* hallucination tend to make errors consistent with the image model, whereas models with *more* hallucination tend to make errors consistent with the language model. This implies that models with less hallucination are better at integrating knowledge from an image into the sentence generation process. When looking at the Robust Test set, Figure 4 (right), which is more challenging, as we have shown earlier, we see that image consistency *decreases* when comparing to the same models on the Karpathy split, whereas language consistency is similar across all models trained on the Robust split. This is perhaps because the Robust split contains novel compositions of objects at test time, and all of the models are heavily biased by language.

Finally, we measure image and language consistency during training for the FC model and note that at the beginning of training errors are more consistent with the language model, whereas towards the end of training, errors are more consistent with the image model. This suggests that models first learn to produce fluent language before learning to incorporate visual information.

TD: A cat is sitting on a bed in a room.
S: 12.1 M: 23.8 C: 69.7
TD Restrict: A bed with a blanket and a pillow on it.
S: 23.5 M: 25.4 C: 52.5

TD: A cat laying on the ground with a frisbee.
S: 8.0 M: 13.1 C: 37.0
TD Restrict: A black and white animal laying on the ground.
S: 7.7 M: 15.9 C: 17.4

Figure 5: Examples of how TopDown (TD) sentences change when we enforce that objects cannot be hallucinated: SPICE (S), Meteor (M), CIDEr (C), see Section 3.4.

3.4 How Well Do The Standard Metrics Capture Hallucination?

In this section we analyze how well SPICE (Anderson et al., 2016), METEOR (Banerjee and Lavie, 2005), and CIDEr (Vedantam et al., 2015) capture hallucination. All three metrics do penalize sentences for mentioning incorrect words, either via an F score (METEOR and SPICE) or cosine distance (CIDEr). However, if a caption mentions enough words correctly, it can have a high METEOR, SPICE, or CIDEr score while still hallucinating specific objects.

Our first analysis tool is the TD-Restrict model. This is a modification of the TopDown model, where we enforce that MSCOCO objects which are not present in an image are *not generated* in the caption. We determine which words refer to objects absent in an image following our approach in Section 2.1. We then set the log probability for such words to a very low value. We generate sentences with the TopDown and TD-Restrict model with beam search of size 1, meaning all words produced by both models are the same, until the TopDown model produces a hallucinated word.

We compare which scores are assigned to such captions in Figure 5. TD-Restrict generates captions that do not contain hallucinated objects, while TD hallucinates a “cat” in both cases. In Figure 5 (left) we see that CIDEr scores the more correct caption much lower. In Figure 5 (right), the TopDown model incorrectly calls the animal a “cat.” Interestingly, it then correctly identifies the “frisbee,” which the TD-Restrict model fails to mention, leading to lower SPICE and CIDEr.

	CIDEr	METEOR	SPICE
FC	0.197	0.198	0.266
Att2In	0.177	0.178	0.246
TopDown	0.135	0.140	0.172

Table 4: Pearson correlation coefficients between 1-CHs and CIDEr, METEOR, and SPICE scores, see Section 3.4.

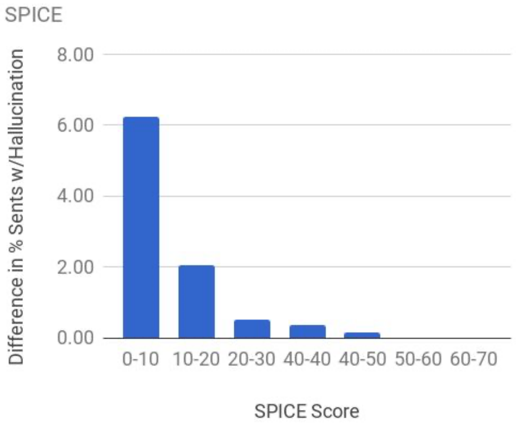

Figure 6: Difference in percentage of sentences with *no* hallucination for TopDown and FC models when SPICE scores fall into specific ranges. For sentences with low SPICE scores, the hallucination is generally larger for the FC model, even though the SPICE scores are similar, see Section 3.4.

In Table 4 we compute Pearson correlation coefficient between individual sentence scores and the *absence* of hallucination, i.e. $1-$CHAIRs; we find that SPICE consistently correlates higher with $1-$CHAIRs. E.g., for the FC model the correlation for SPICE is 0.27, while for METEOR and CIDEr – around 0.2.

We further analyze the metrics in terms of their predictiveness of hallucination risk. Predictiveness means that a certain score should imply a certain percentage of hallucination. Here we show the results for SPICE and the captioning models FC and TopDown. For each model and a score interval (e.g. $10-20$) we compute the percentage of captions *without* hallucination ($1-$CHAIRs). We plot the difference between the percentages from both models (TopDown - FC) in Figure 6. Comparing the models, we note that even when scores are similar (e.g., all sentences with SPICE score in the range of $10-20$), the TopDown model has fewer sentences with hallucinated objects. We see similar trends across other metrics. Consequently, object hallucination can *not* be always predicted based on the traditional sentence metrics.

Is CHAIR complementary to standard metrics? In order to measure usefulness of our proposed metrics, we have conducted the following

	Metric	Metric +(1-CHs)	Metric +(1-CHi)
METEOR	0.269	0.299	0.304
CIDEr	0.282	0.321	0.322
SPICE	0.248	0.277	0.281

Table 5: Pearson correlation coefficients between individual/combined metrics and human scores. See Section 3.4.

human evaluation (via the Amazon Mechanical Turk). We have randomly selected 500 test images and respective captions from 5 models: non-GAN baseline, GAN, NBT, TopDown and TopDown - Self Critical. The AMT workers were asked to score the presented captions w.r.t. the given image based on their preference. They could score each caption from 5 (very good) to 1 (very bad). We did not use ranking, i.e. different captions could get the same score; each image was scored by three annotators, and the average score is used as the final human score. For each image we consider the 5 captions from all models and their corresponding sentence scores (METEOR, CIDEr, SPICE). We then compute Pearson correlation between the human scores and sentence scores; we also consider a simple combination of sentence metrics and 1-CHAIRs or 1-CHAIRi by summation. The final correlation is computed by averaging across all 500 images. The results are presented in Table 5. Our findings indicate that a simple combination of CHAIRs or CHAIRi with the sentence metrics leads to an increased correlation with the human scores, showing the usefulness and complementarity of our proposed metrics.

Does hallucination impact generation of other words? Hallucinating objects impacts sentence quality not only because an object is predicted incorrectly, but also because the hallucinated word impacts generation of other words in the sentence. Comparing the sentences generated by TopDown and TD-Restrict allows us to analyze this phenomenon. We find that after the hallucinated word is generated, the following words in the sentence are different 47.3% of the time. This implies that hallucination impacts sentence quality beyond simply naming an incorrect object. We observe that one hallucination may lead to another, e.g. hallucinating a “cat” leading to hallucinating a “chair”, hallucinating a “dog” – to a “frisbee”.

4 Discussion

In this work we closely analyze hallucination in object captioning models. Our work is similar to other works which attempt to characterize flaws of different evaluation metrics (Kilickaya et al., 2016), though we focus specifically on hallucination. Likewise, our work is related to other work which aims to build better evaluation tools ((Vedantam et al., 2015), (Anderson et al., 2016), (Cui et al., 2018)). However, we focus on carefully quantifying and characterizing one important type of error: object hallucination.

A significant number of objects are hallucinated in current captioning models (between 5.5% and 13.1% of MSCOCO objects). Furthermore, hallucination does not always agree with the output of standard captioning metrics. For instance, the popular self critical loss increases CIDEr score, but also the amount of hallucination. Additionally, we find that given two sentences with similar CIDEr, SPICE, or METEOR scores from two different models, the number of hallucinated objects might be quite different. This is especially apparent when standard metrics assign a low score to a generated sentence. Thus, for challenging caption tasks on which standard metrics are currently poor (e.g., the LSMDC dataset (Rohrbach et al., 2017b)), the CHAIR metric might be helpful to tease apart the most favorable model. Our results indicate that CHAIR complements the standard sentence metrics in capturing human preference.

Additionally, attention lowers hallucination, but it appears that much of the gain from attention models is due to access to the underlying convolutional features as opposed the attention mechanism itself. Furthermore, we see that models with stronger *image consistency* frequently hallucinate fewer objects, suggesting that strong visual processing is important for avoiding hallucination.

Based on our results, we argue that the design and training of captioning models should be guided not only by cross-entropy loss or standard sentence metrics, but also by image relevance. Our CHAIR metric gives a way to evaluate the phenomenon of hallucination, but other image relevance metrics e.g. those that incorporate missed salient objects, should also be investigated. We believe that incorporating visual information in the form of ground truth objects in a scene (as opposed to only reference captions) helps us better understand the performance of captioning models.

Abstract

Rapid growth of multi-modal documents on the Internet makes multi-modal summarization research necessary. Most previous research summarizes texts or images separately. Recent neural summarization research shows the strength of the Encoder-Decoder model in text summarization. This paper proposes an abstractive text-image summarization model using the attentional hierarchical Encoder-Decoder model to summarize a text document and its accompanying images simultaneously, and then to align the sentences and images in summaries. A multi-modal attentional mechanism is proposed to attend original sentences, images, and captions when decoding. The DailyMail dataset is extended by collecting images and captions from the Web. Experiments show our model outperforms the neural abstractive and extractive text summarization methods that do not consider images. In addition, our model can generate informative summaries of images.

1 Introduction

Summarizing multi-modal documents to get multi-modal summaries is becoming an urgent need with rapid growth of multi-modal documents on the Internet. Text-Image summarization is to summarize a document with text and images to generate a summary with text and images. The summarization approach is different from pure text summarization. It is also different from image summarization which summarizes an image set to get a subset of images.

An image worths thousands of words (Rossiter, et al., 2012). Image plays an important role in information transmission. Incorporating images into text to generate text-image

Former Manchester United striker Alan Smith denies Liverpool fans attacked his ambulance after Anfield horror injury

Alan Smith has rubbished claims that Liverpool fans attacked the ambulance he was travelling to hospital in following the aftermath of his horror injury during Manchester United's FA Cup 1-0 defeat to their fierce rivals nine years ago.
Smith suffered a broken leg and a dislocated ankle while attempting to block a John Arne Riise free-kick during the fifth round clash at Anfield in February 2006.
At the time of the incident, reports circulated that Liverpool fans tried to disrupt Smith's journey to hospital by throwing bottles, beer glasses and stones at the ambulance as well as rocking the vehicle.

Alan Smith has denied claims that Liverpool fans attacked the ambulance he was travelling to hospital in during Manchester United's FA Cup fifth round exit nine years ago

The horror incident occurred after Smith (second right) blocked John Arne Riise's free-kick

But Smith, who made his comeback for United seven months later, insists that was not the case.
'It didn't happen – fans were still in the ground,' he told FourFourTwo exclusively in the May edition of their magazine.
'I went back to Liverpool a few years later with Newcastle and had a great reception.
'I had loads of mail from fans after the injury, including a lot from Liverpool. And Liverpool's medical staff were great. They were worried that because there was no blood flowing that I could have had a club foot.
'It wasn't Riise's fault and he came to see me. The dislocated ankle was worse than the leg break because I snapped ligaments and there were complications.
'I knew I was never going to be the same player. I've appreciated every game I've played since that injury, I know how close I was to being finished.'

Smith suffered a broken leg and a dislocated ankle as a result of the incident at Anfield

Smith was carried off on a stretcher before he was taken to hospital via an ambulance

Figure 1: An example of multi-modal news taken from the DailyMail corpora.

Liverpool beat Manchester United 1-0 in the FA Cup fifth round in 2006.
Alan Smith suffered a broken leg and a dislocated ankle during the game.

Reports claimed Liverpool fans attacked the ambulance with Smith in.

Figure 2: The manually generated text-image summary.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4046–4056
Brussels, Belgium, October 31 - November 4, 2018.

summaries can help people better understand, memorize, and express information. Most of recent research focuses on pure text summarization, or image summarization. Little has been done on text-image summarization.

Figure 1 and Figure 2 show an example of text-image summarization. Figure 1 is the original multi-modal news with text and images. The news has 17 sentences (with 322 words) and 4 images each of which has a caption. Figure 2 is the manually generated multi-modal summary. In the summary, the news is distilled to 3 sentences (with 36 words) and 2 images, and each summary sentence is aligned with an image.

To generate such a text-image summary, the following problems should be considered: How to generate the text part? How to measure the importance of images, and extract important images to form the image summary? How to align sentences with images?

In this paper, we propose a neural text-image summarization model based on the attentional hierarchical Encoder-Decoder model to solve the above problems. The attentional Encoder-Decoder model has been successfully used in sequence-to-sequence applications such as machine translation (Luong et al., 2015), text summarization (Cheng and Lapata, 2016; Tan et al., 2017), image captioning (Liu et al., 2017a), and machine reading comprehension (Cui et al., 2016).

At the encoding stage, we use the hierarchical bi-directional RNN to encode the sentences and the text document, use the RNN and the CNN to encode the image set. In the decoding stage, we combine text encoding and image encoding as the initial state, and use the attentional hierarchical decoder which attends original sentences, images and captions to generate the text summary. Each generated sentence is aligned with a sentence, an image, or a caption in the original document. Based on the alignment scores, images are selected and aligned with the generated sentences. In the inference stage, we adopt the multi-modal beam search algorithm which scores beams based on bigram overlaps of the generated sentences and the attended captions.

The main contributions are as follows:

1) We propose the text-image summarization task, and extend the standard DailyMail corpora by collecting images and captions of each news from the Web for the task.
2) We propose an RNN model to encode the ordered image set of the multi-model document as one of the initial states (the other is the text encoding) of the decoder.
3) We propose three multi-modal attentional mechanisms which attend the text and the images simultaneously when decoding.
4) Experiments show that attending images when decoding can improve text summarization, and that our model can generate informative image summaries.

2 Related Work

Recent research on text summarization focuses on neural methods. Attentional Encoder-Decoder model is first proposed in (Bahdanau et al., 2014) and (Luond et al., 2015) to align the original text and the translated text in machine translation. The attention model is applied to sentence summarization by considering the neural language model and the attention model when generating next words (Rush et al., 2015). A selective Encoder-Decoder model that uses a selective gate network to control information from the encoder to the decoder for sentence summarization is proposed (Zhou et al., 2017).

A neural document summarization model by extracting sentences and words is proposed (Cheng and Lapata, 2016). They use a CNN model to encode sentences, and then use a RNN model to encode documents. The model extracts sentences by computing the probability of sentences belonging to the summary based on an RNN model. The model extracts words from the original document based on an attentional decoder. An RNN-based extractive summarization named SummaRuNNer, treating summarization as a sentence classification problem is proposed (Nallapati et al., 2016). A logistic classifier is then applied using features computed based on the RNN model. A hierarchical Encoder-Decoder model, conserving the hierarchical structure of documents is proposed (Li et al., 2015). A graph-based attentional Encoder-Decoder model using a PageRank algorithm to compute the attention is proposed (Tan et al., 2017).

Image captioning generates a caption for an image. Text-image summarization is similar to image captioning in that both utilize image information to generate text. Images are encoded with CNN models such as VGGNet (Simonyan and Zisserman, 2014), AlexNet (Krizhevsky et al., 2012) and GoogleNet (Szegedy et al., 2014) by extracting the last full-connected layers. An attentional model is used in image captioning by splitting an image into multiple parts which is attended in the decoding process (Xu et al., 2015). Image tags was used as additional information, and semantic attention model which attends image tags when decoding was proposed（You et al., 2016). The attention-based alignment of image parts and text is studied（Liu et al., 2017a), and the results show that the alignments is in high accordance with manual alignments. An image to an ordered recognized object set is encoded, and the attentional decoder is applied to generate captions（Liu et al., 2017b).

Multi-modal summarization summarizes text, images, videos, and etc. It is an important branch of automatic summarization. Traditional multi-modal summarization inputs multi-modal documents or pure text documents, and outputs multi-modal documents (Wu, 2011; Greenbacker, 2011; Yan, 2012; Agrawal, 2011; Zhu, 2007; UzZaman, 2011). For example, Yan et al., (2012) generate multi-modal timeline summaries for news sets by constructing a bi-graph between text and images, and apply a heterogeneous reinforcement ranking algorithm. Strategies to summarizing texts with images and the notion of summarization of things are proposed in (Zhuge, 2016). The deep learning related work (Wang et al. 2016) treats text summarization as a sentence recommendation task and applies matrix factorization algorithm. They first retrieve images from Yahoo!, use the CNN to extract image features as the additional information of sentences, use Rouge maximization as the training object function which are trained with SGD. In test time, sentences are extracted based on the model and images are retrieved from the Search Engine.

3 Method

Figure 3 shows the framework, a multi-modal attentional hierarchical encoder-decoder model. The hierarchical encoder-decoder is proposed in (Li et al., 2015) and extended by (Tan et al. , 2017) for document summarization through bringing in the graph-based attentional model.

Our model consists of three parts: a hierarchical RNN to encode the original sentences and the captions, a CNN+RNN encoder to encode the image set, and a multi-modal attentional hierarchical RNN decoder.

The input of our model is a multi-modal document *MD* = {*D*, *PicSet*}, where *D* is the main text of the multi-modal document and *PicSet* is the image-caption set ordered by the occurring order of images in the document.

3.1 Main Text Encoder

The main text *D* consists of sentences, each of which consists of words. Let $D=[s_1, s_2, \ldots, s_{|d|}]$, and $s_i = [x_{i,1}, x_{i,2}, \ldots, x_{i,|s_i|}]$ where $x_{i,j}$ is the word embedding of the j^{th} word in the s_i. We use word2vec (Mikolov et al., 2013) to create word embeddings. GRU is used as the RNN cell (Cho et al., 2014).

We use a hierarchical RNN encoder to encode the main text *D* to vector representation. The sentence encoder is adopted to encode sentences to vector representations. An <eos> token is appended to the end of each sentence. A bi-directional RNN is used as the sentence encoder:

$$\vec{h}_{i,j} = \overrightarrow{GRU}^{s}(\vec{h}_{i,j-1}, x_{i,j}) \quad (1)$$

$$\overleftarrow{h}_{i,j} = \overleftarrow{GRU}^{s}(\overleftarrow{h}_{i,j}, x_{i,j+1}) \quad (2)$$

$$enc^{sent}_{i} = [\vec{h}_{i,1}, \overleftarrow{h}_{i,-1}] \quad (3)$$

where enc^{sent}_{i} denotes the vector representation of s_i. It is the concatenation of $\vec{h}_{i,1}$ and $\overleftarrow{h}_{i,-1}$.

We use enc^{sent}_{i} as inputs to the document encoder to encode the main text to vector representations. A bi-directional RNN is adopted as the document encoder:

$$\vec{h}_{i} = \overrightarrow{GRU}^{d}(\vec{h}_{i-1}, enc^{sent}_{i}) \quad (4)$$

$$\overleftarrow{h}_{i} = \overleftarrow{GRU}^{d}(\overleftarrow{h}_{i+1}, enc^{sent}_{i}) \quad (5)$$

$$h_i = [\vec{h}_i, \overleftarrow{h}_i] \quad (6)$$

$$enc^{doc}_{d} = [\vec{h}_1, \overleftarrow{h}_{-1}] \quad (7)$$

where enc^{doc} denotes the vector representation of the *D*, and h_i is the concatenated hidden state of s_i.

3.2 CaptionSet and ImageSet Encoder

The ordered image-caption set *PicSet* consists of an ordered image set and an ordered caption set

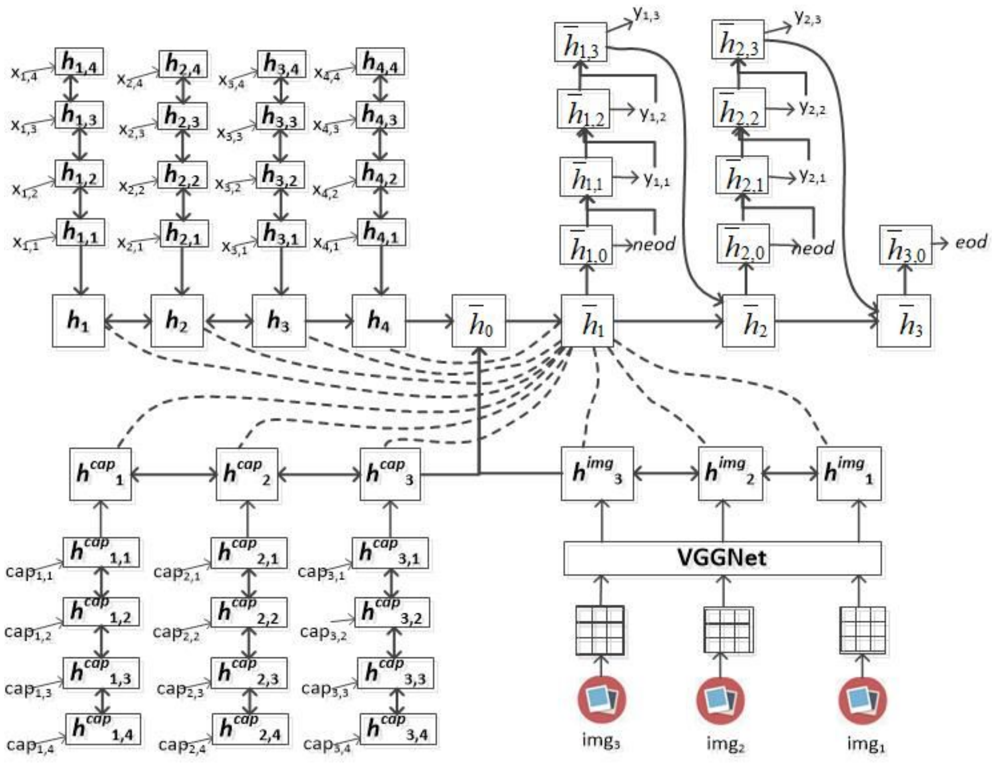

Figure 3: The framework of our neural text-image summarization model.

which are ordered by the occurring order in the multi-modal document. The image occurring order makes sense because images are often put near the most related sentences, and the sentences have strict order in the document.

We treat the ordered caption set as a document, and apply the sentence encoder and the document encoder to the caption document. Then, we get the hidden state h^{cap}_i and the vector representation enc^{cap} of the caption document.

We use the CNN model to extract the vector representation of each image, and then use the RNN model to encode the ordered image set to vector representation. The CNN model we adopted is 19-layer VGGNet (Simonyan and Zisserman, 2014). We drop the last dropout layer and keep the last full-connected layer as the image's vector representation, the dimension of which is 4096.

We then use a bi-directional RNN model to encode the ordered image set and the image features are used as inputs of the RNN model.

$$\overrightarrow{h}^{img}_i = \overrightarrow{GRU}^{img}(\overrightarrow{h}^{img}_{i-1}, img^{fea}_i) \quad (8)$$

$$\overleftarrow{h}^{img}_i = \overleftarrow{GRU}^{img}(\overleftarrow{h}^{img}_{i+1}, img^{fea}_i) \quad (9)$$

$$h^{img}_i = [\overrightarrow{h}^{img}_i, \overleftarrow{h}^{img}_i] \quad (10)$$

$$enc^{img} = [\overrightarrow{h}^{img}_1, \overleftarrow{h}^{img}_{-1}] \quad (11)$$

where img^{fea}_i is the vector representation of img_i, enc^{img} is the vector representation of the image set, and h^{img}_i is the hidden state of img_i when encoding the image set.

To our best knowledge, we are the first to adopt the RNN model to encode the image set.

3.3 Decoder

In the decoding state, we adopt the hierarchical RNN decoder to generate text summaries.

$$\begin{aligned}\bar{h}_0 = \tanh(&W^{dec\_doc} \times enc^{doc} \\ &+V^{dec\_img} \times enc^{img} \\ &+V^{dec\_cap} \times enc^{cap})\end{aligned} \quad (12)$$

$$\tilde{h}_i = GRU^{dec\_sent1}(\bar{h}_{i-1}, \bar{h}_{i-1,-1}) \quad (13)$$

$$\bar{h}_i = GRU^{dec\_sent2}(\tilde{h}_i, c_i) \quad (14)$$

$$\bar{h}_{i,j} = GRU^{dec\_word}(\bar{h}_{i,j-1}, y_{i,j-1}) \quad (15)$$

$$y_{i,j} \sim soft\max(W^{soft\max}\bar{h}_{i,j} + b) \quad (16)$$

Equation (12) to (16) are the equations of the hierarchical decoder which consists of a sentence decoder and a word decoder.

Equation (12) computes the initial state $\bar{h}_0$ for the sentence decoder by combining the decoding of the main text information and the decoding of the image information of the multi-modal document. To represent image information, we can use both of the image set decoding and the caption set decoding, or only use one of them, depending on the multi-modal attention mechanism introduced in the next subsection.

The sentence decoder uses a two-level hidden output model (Luong et al., 2015) to generate the representation of the next sentence through equation (13) and equation (14). The two-level hidden output model consistently improves the summarization performance on different datasets (Chen et al., 2016). In equation (14), the two-level model computes $\bar{h}_i$ by capturing a direct interaction between $\tilde{h}_i$ and c_i. $\tilde{h}_i$ is computed by equation (13) using the preceding sentence decoder hidden state $\bar{h}_{i-1}$ and the word decoder hidden state $\bar{h}_{i-1,-1}$ which is the last hidden state of the preceding word decoder. And c_i is the context of the sentence decoder computed based on the multi-modal attention model.

The word decoder uses the sentence representation generated by the sentence decoder as the initial state, and use the <sos> (start of sentence) token as the initial input. Equation (15) and equation (16) generate the next hidden state and the next word. The output of the word decoder in the first step is a switch sign which is either <neod> token or <eod> token. The token <neod> means “not end of document”, and the token <eod> means “end of document”. If the first output is <eod>, the whole decoding process is finished. If the first output is <neod>, the token is used as the next input of the word decoder. The word decoding process is finished when it generates the <eos> token. The last hidden state of the word decoder is treated as the vector representation of the generated sentence and is used as next input of the sentence decoder.

3.4 Multi-Modal Attention

We propose three multi-modal attention mechanisms to compute the sentence decoding context c_i.

Traditional attention mechanisms for text summarization computes the importance score of the sentence s_j in the original document based on the relationship between the decoding hidden state $\tilde{h}_i$ and the original sentence encoding hidden state h_j. We call the traditional attention model as **Text Attention (*attT* for short)**, which is computed by equation (17), (18) and (19):

$$att^T(\tilde{h}_i, h_j) = v^T \tanh(W^T \tilde{h}_i + U^T h_j) \quad (17)$$

$$\alpha^T(\tilde{h}_i, h_j) = \frac{\exp(att^T(\tilde{h}_i, h_j))}{\sum_{j=1}^{|D|} \exp(att^T(\tilde{h}_i, h_j))} \quad (18)$$

$$c^T(\tilde{h}_i) = \sum_{j=1}^{|D|} \alpha^T(\tilde{h}_i, h_j) h_j \quad (19)$$

where $att^T(\tilde{h}_i, h_j)$ is the attention (Banahama et al., 2014), $\alpha^T(\tilde{h}_i, h_j)$ is the normalized attention, and $c^T(\tilde{h}_i)$ is the context.

The problem is that the multi-modal document has images and captions besides the main text. Therefore, we propose three multi-modal attention mechanisms which take images and captions into consideration.

Text-Caption Attention (*attTC* for short). This attention model uses captions to represent the image information. *attTC* computes the attention score of the caption cap_j based on the relationship between the caption encoding hidden state $h^{cap}{}_i$ and the decoding hidden state $\tilde{h}_j$.

$$\alpha^{TC}(\tilde{h}_i, h_j) = \frac{\exp(att^{TC}(\tilde{h}_i, h_j))}{\sum_{j=1}^{|D|} \exp(att^{TC}(\tilde{h}_i, h_j)) + \sum_{j=1}^{|PicSet|} \exp(att^{TC}(\tilde{h}_i, h^{cap}{}_j))} \quad (20)$$

$$\alpha^{TC}(\tilde{h}_i, h^{cap}{}_j) = \frac{\exp(att^{TC}(\tilde{h}_i, h^{cap}{}_j))}{\sum_{j=1}^{|D|} \exp(att^{TC}(\tilde{h}_i, h_j)) + \sum_{j=1}^{|PicSet|} \exp(att^{TC}(\tilde{h}_i, h^{cap}{}_j))} \quad (21)$$

$$c^{TC}(\tilde{h}_i) = \sum_{j=1}^{|D|} \alpha^{TC}(\tilde{h}_i, h_j) h_j + \sum_{j=1}^{|PicSet|} \alpha^{TC}(\tilde{h}_i, h^{cap}{}_j) h^{cap}{}_j \quad (22)$$

Text-Image Attention (*attTI* for short). This attention model only uses images to represent the image information neglecting the captions. *attTI* computes the importance score of the image img_j based on the relationship between the image encoding hidden state $h^{img}{}_i$ and the decoding hidden state $\tilde{h}_j$.

$$\alpha^{TI}(\tilde{h}_i, h^{img}{}_j) = \frac{\exp(att^{TI}(\tilde{h}_i, h^{img}{}_j))}{\sum_{j=1}^{|D|}\exp(att^{TI}(\tilde{h}_i, h_j)) + \sum_{j=1}^{|PicSet|}\exp(att^{TI}(\tilde{h}_i, h^{img}{}_j))} \quad (23)$$

$$c^{TI}(\tilde{h}_i) = \sum_{j=1}^{|D|}\alpha^{TI}(\tilde{h}_i, h_j)h_j + \sum_{j=1}^{|PicSet|}\alpha^{TI}(\tilde{h}_i, h^{img}{}_j)h^{img}{}_j \quad (24)$$

Text-Image-Caption Attention (*attTIC* for short). This attention model uses both captions and images to represent the image information. *attTIC* computes the importance score of the caption cap_j and the importance score of the image img_j simultaneously, and then compute the context of the decoding hidden state $\tilde{h}_i$ using equation (25).

$$\begin{aligned} c^{TIC}(\tilde{h}_i) &= \sum_{j=1}^{|D|}\alpha^{TIC}(\tilde{h}_i, h_j)h_j \\ &+ \sum_{j=1}^{|PicSet|}\alpha^{TIC}(\tilde{h}_i, h^{cap}{}_j)h^{cap}{}_j + \alpha^{TIC}(\tilde{h}_i, h^{img}{}_j)h^{img}{}_j \end{aligned} \quad (25)$$

In the attention mechanisms, $\alpha(\tilde{h}_i, h_j)$ is the normalized attention score of h_j, $\alpha(\tilde{h}_i, h^{cap}{}_j)$ is the normalized attention score of $h^{cap}{}_j$, $\alpha(\tilde{h}_i, h^{img}{}_j)$ is the normalized attention score of $h^{img}{}_j$, and $c(\tilde{h}_i)$ is the context.

The initial state of the decoder is computed by Equation (12) which can be adjusted according to different attention models.

3.5 Model Training

Since there are no existing manual text-image summaries, and most of the existing training and testing data have pure text summaries, we decide to use pure text summaries as training data to train our models. **The sentence-image alignment relationships can be discovered through training the multi-modal attention models.**

The loss function L of our summarization model is the negative log likelihood of generating text summaries over the training multi-modal document set *MDS*.

$$L = \sum_{(D,PicSet,Y)\in MDS} -\log P(Y \mid D, PicSet) \quad (26)$$

where $Y=[y_1, y_2, \ldots, y_{|Y|}]$ is the word sequences of the summary corresponding to the main text D and the ordered image set *PicSet*, including the tokens <eos>, <neod> and <eod>.

$$\log P(Y \mid D, PicSet) = \sum_{t=1}^{|Y|}\log P(y_t \mid \{y_1, \ldots, y_{t-1}\}, c; \theta) \quad (27)$$

where $\log P(y_t \mid \{y_1, \ldots, y_{t-1}\}, c; \theta)$ is modeled by the multi-modal encoder-decoder model.

We use the Adam (Kingma and Ba, 2014) gradient-based optimization method to optimize the model parameters.

3.6 Multi-Modal Beam Search Algorithm

There are two major problems of the generation of summaries: one is the out-of-vocabulary problem, and the other is the low quality of the generated texts including information incorrectness and repetitions.

For the OOV problem, we use the words in the attended sentences or captions in the original document to replace OOV tokens in the generated summary. Previous research uses the attended words to replace OOV tokens in the flatten encoder-decoder model which attends the words of the original word sequence (Jean, et al., 2015). Our model is hierarchical and multi-modal, and attends sentences, images, and captions when decoding. We use the following algorithm to find the replacement for the j^{th} OOV in a generated sentence:

Step 1: Order the original sentences and captions by the attending scores in descending order.

Step 2: Return the j^{th} OOV word in the ordered sentences and captions as the replacement.

For the *attTI* mechanism that attends images neglecting captions, we use captions instead of the attended images in the algorithm.

For the low-quality generated text problem, we adopt the hierarchical beam search algorithm (Tan el al., 2017). We extend the algorithm by adding caption-level and image-level beam search. The multi-modal hierarchical beam search algorithm comprises *K*-best word-level beam search and *N*-best sentence-caption-level beam search. In particular, we use the corresponding captions instead of images in beam search algorithm for the *attTI* mechanism which attends images.

$$score(y_t) = p(y_t) + \gamma(ref(Y_{t-1} + y_t, s_*) - ref(Y_{t-1}, s_*)) \quad (28)$$

At the word-level search algorithm, we compute the score of generating word y_t using equation (28) where *ref* is a function calculating the ratio of bigram overlap between two texts, s_* is the attended sentence or caption, and γ is the weighting factor. The added term aims to increase the overlap of the generated summary and the original text.

At the sentence level and the caption level, we set the sentence beam width as *N*, and keep *N*-best previously un-referred sentences or captions which have highest attending scores. For each sentence beam, we try *M* sentences or captions and keep the one achieving best word-level scores.

3.7 Image Selection and Alignment

We rank the images, select several most important images as the image summary, and align each sentence with an image in the image summary. The score of images is computed by equation (29).

$$score(img_j) = \sum_{i=1}^{|TextSum|} \alpha_{i,j} \quad (29)$$

where $\alpha_{i,j}$ is the attention score of the j^{th} image when generating the i^{th} sentence of the text summary, and $|TextSum|$ is the number of summary sentences.

The images are ranked by the scores in descending order, and the top K images are selected to form the image summary *ImgSum*. We align each sentence i in *TextSum* to the image j in *ImgSum* such that $\alpha_{i,j}$ is the biggest.

4 Experiments

4.1 Data preparation

We extend the standard DailyMail corpora through extracting the images and the captions from the html-formatted documents. We call the corpora as E-DailyMail. The standard DailyMail and CNN datasets are two widely used datasets for neural document summarization, which are originally built in (Hermann et al., 2015) by collecting human generated highlights and news stories from the news websites. We only extend the DailyMail dataset because it has more images and is easier to collect than the CNN dataset does. We find that the text documents provided by the original DailyMail corpora contain captions. This is due to that all related texts are extracted from the html-formatted news when the corpora are created. We keep the original text documents unchanged in E-DailyMail. The split and statistics of E-DailyMail are shown in Table 1.

4.2 Implementation

We preprocess the text of the E-DailyMail corpora by tokenizing the text and replacing the digits with the <NUM> token. The 40k most frequent words in the corpora are kept and other words are replaced with OOV.

Our model is implemented by using Google's open-source seq2seq-master project written with Tensorflow. We use one layer of the GRU cell. The dimension of the hidden state of the RNN decoder is 512. The dimension of the word embedding vector is 128. The dimension of the hidden state of the bi-directional RNN encoder is 256. We initialize the word embeddings with Google's word2vec tools (Mikolov et al., 2013) trained in the whole text of DailyMail/CNN corpora. We extract the 4096-dimension full-connected layer of 19-layer VGGNet (Simonyan and Zisserman, 2014) as the vector representation of images. We set the parameters of Adam to those provided in (Kingma and Ba, 2014). The batch size is set to 5. Convergence is reached within 800k training steps. It takes about one day for training 40k ~ 50k steps depending on the models on a GTX-1080 TI GPU card. The sentence beam width and the word beam width are set as 2 and 5 respectively. M is set as 3. The parameter γ is set as 3 or 300 tuned on the validation set.

26.0	**3.84**	**5.42**	**26.86**	**24.75**

Table 1: The split and statistics of the E-DailyMail corpora. D.L and S.L indicate the average number of sentences in the document and summary. I.N indicates the average number of images in the story. Sent.L and Cap.L indicates the average number of word in the sentence and the caption respectively.

To train the multi-modal attention mechanism such as *attTIC*, we concatenate the matrix of text representations, image representations, and caption representations to one matrix $M = [h_1, h_2, \ldots h_{|D|}, h^{cap}_1, h^{cap}_2, \ldots, h^{cap}_{|PicSet|}, h^{img}_1, h^{img}_2, \ldots, h^{img}_{|PicSet|}]$. The parameters of the attention mechanisms are trained simultaneously. This way the model training can converge faster.

4.3 Evaluation of Text Summarization

The widely used ROUGE (Lin, 2004) is adopted to evaluate text summaries.

We compare four attention models. *HNNattTC*-3, *HNNattTIC*-3, *HNNattTI*-3, and *HNNattT*-3 are our hierarchical RNN summarization models with the *attTC*, *attIC*, *attTI*, and *attT* attention mechanisms respectively, and 3 is the γ value. *HNNattT* is similar to the model introduced in (Tan et al., 2017) without the graph-based attention. We compare our models with *HNNattT* to show the influence of multi-modal attentions. The first 4 lines in Table 2 are the results with summary length of 75 bytes. The results show that *HNNattTI* has considerable improvement over *HNNattT*. An interesting observation is that *HNNattTC* and *HNNattTIC* are not better than *HNNattT*. One of the

Method	Rouge-1	Rouge-2	Rouge-L
***HNNattTI*-300**	**32.64**	**12.02**	**23.88**
HNNattTC-300	26.75	10.12	19.42
HNNattTIC-300	30.52	11.04	21.81
HNNattT-300	31.34	11.81	22.93

Table 3: Comparison results on the DailyMail test set using full-length F1metric.

reasons is that the text documents provided by the DailyMail corpora contain captions. Captions are already parts of the text documents. The other reason is that captions distract attentions and cannot attract sufficient attentions from the original sentences, which will be discussed in the next subsection.

We compare our methods with state-of-the-art neural summarization methods reported in recent papers on the DailyMail corpora. Extractive models include Lead which is a strong baseline using the leading 3 sentences as the summary, NN-SE (Cheng and Lapata, 2016), and *SummaRuNNer-abs* (Nallapati et al., 2017) which is trained on the abstractive summaries. Abstractive models include *NN-ABS*, *NN-WE*, *LREG*, though they are tested on 500 samples of the test set. *LREG* is a feature-based method using linear regression. *NN-ABS* is a simple hierarchical extension of (Rush et al., 2015). *NN-WE* is the abstractive model restricting the generation of words from the original document. The results are shown in the last 6 rows in Table 2. Our method *HNNattTI* outperforms the three extractive models and the three abstractive models.

We compare our models under the full-length F1 metric by setting the γ value as 300. According to (Tan et al., 2017), a large γ makes the generated summary has more overlaps with the attended texts, and thus partly overcome the repeated sentences problem in the generated summary. We do not incorporate the attention distraction mechanism (Chen et al., 2016) into our model, because we want to focus on our own model to see whether considering images improves text summarization. Results in Table 3 also show that *HNNattTI* performs better than *HNNattT*, *HNNattTC*, and *HNNattTIC*.

Method	Rouge-1	Rouge-2	Rouge-L
***HNNattTI*-3-OOV**	24.03	8.2	16.52
HNNattTC-3-OOV	18.18	6.53	12.87
HNNTattTIC-3-OOV	20.50	7.67	14.36
HNNattT-3-OOV	21.60	7.82	15.05

Table 4: Comparison results using Rouge recall at 75 bytes without OOV replacement. *HNNattTI*-3-OOV is the version of *HNNattTI*-3 without the OOV replacement mechanism.

Method	Rouge-1	Rouge-2	Rouge-L
***HNNattTI*-300-OOV**	32.03	11.52	22.67
HNNattTC-300-OOV	26.13	9.87	19.03
HNNattTIC-300-OOV	30.11	10.87	21.12
HNNattT-300-OOV	30.74	11.21	22.28

Table 5: Comparison results using full-length F1 metric without OOV replacement. *HNNattTI*-300-OOV is the version of *HNNattTI*-300 without the OOV replacement mechanism.

To show the influence of our OOV replacement mechanism, we eliminate the mechanism from our models, and show the evaluation results in Table 4 and Table 5. We can see from the two tables that the scores are lower than the corresponding scores in Table 2 and Table 3. Our OOV replacement mechanism improves the summarization models, though the mechanism is relatively simple.

In short, combining and attending images in the neural summarization model improves document summarization.

4.4 Evaluation of Image Summarization

To evaluation the image summarization, the gold standard image summary is generated based on a greedy algorithm on the captions as follows: at each time i, choose img_k to maximize $Rouge(\{cap_1,\ldots cap_{i-1},cap_k\},\ Abs\_Sum)$ - $Rouge(\{cap_1,\ldots cap_{i-1}\},\ Abs\_Sum))$ where Abs_Sum is the ground truth text summary and

num	*HNNattTI*	*HNNattTC*	*HNNattTIC*	*Random*
1	**0.4978**	0. 4137	0. 4362	0. 4721
2	**0.4783**	0. 3998	0. 4230	0. 4517

Table 6: Image summarization using the recall metric for the 1-image or 2-images summary. γ is set as 300.

cap$_k$ is the caption of *img*$_k$. The average number of images in summaries is 2.15. The average Rouge-1, Rouge-2, and Rouge-L scores of the caption summaries with respect to the ground truth summaries are 43.85, 19.70, and 36.30 respectively.

We use the 1-image and 2-image random selected image summaries as the baselines which we compare our models with. The top 1 or 2 images ranked by our model are selected out to form the summaries. Results in Table 4 show that *HNNattTI* outperforms the random baseline, while *HNNattTC* and *HNNattTIC* perform worse. This implies that attending images can generate better sentence-image alignment in the multi-modal summaries than the model attending captions does. And this can also partly explain why our summarization model attending images when decoding can generate better text summaries than the one attending captions does.

4.5 Instance

Figure 4 shows the text-image summary of the example demonstrated in Figure 1 generated by the *HNNattTI* model. In the summary, there are 2 images and 3 generated sentences, and each sentence is aligned with an image. The image summary has one common image with Figure 2.

S2: smith suffered a broken leg and a dislocated ankle as a result of a broken leg as a result of the incident at anfield.

S1: smith was carried off on a stretcher before he was carried off on a stretcher in a stretcher.

S3: he was travelling to hospital during manchester united's fa cup fifth round exit nine years ago when he was travelling to the ambulance.

Figure 4: The generated text-image summary of the example in Figure 1.

	IMG1	IMG2	IMG3	IMG4
S1	0.0947	0.1089	0.1157	0.1194
S2	0.0893	0.1020	0.1070	0.1052
S3	0.0853	0.0769	0.0946	0.0969

Table 7: The sentence-image alignment scores of the generated summary for the news in Figure 1.

The sentences are named by S1, S2, and S3 respectively.

Table 7 shows the sentence-image alignment scores. The four images in the original document are numbered from top to bottom and left to right by IMG1, IMG2, IMG3, and IMG4. The summation of alignment scores for a summary sentence is less than 1, because the sentence is also aligned with the sentences in the original document.

5 Conclusions

This paper proposes the text-image summarization task to summarize and align texts and images simultaneously. Most previous research summarizes texts and images separately, and few has been done on text-image summarization. We propose the multi-modal attentional mechanism which attends original sentences, images, captions simultaneously in the hierarchical encoder-decoder model, use the RNN model to encode the ordered image set as the initial state of the decoder, and propose the multi-modal beam search algorithm which scores beams using the bigram overlaps of the generated sentences and the captions. The model is trained by using abstractive text summaries as the targets, and the attention scores of images are used to score images. The original DailyMail dataset is extended by collecting images and captions from the Web. Experiments show that our model attending images outperforms the models not attending images, three existing neural abstractive models and three existing extractive models. Experiments also show our model can generate informative summaries of images.

Abstract

In this paper, we study automatic keyphrase generation. Although conventional approaches to this task show promising results, they neglect correlation among keyphrases, resulting in duplication and coverage issues. To solve these problems, we propose a new sequence-to-sequence architecture for keyphrase generation named CorrRNN, which captures correlation among multiple keyphrases in two ways. First, we employ a coverage vector to indicate whether the word in the source document has been summarized by previous phrases to improve the coverage for keyphrases. Second, preceding phrases are taken into account to eliminate duplicate phrases and improve result coherence. Experiment results show that our model significantly outperforms the state-of-the-art method on benchmark datasets in terms of both accuracy and diversity.

1 Introduction

A keyphrase is a piece of text that is able to summarize a long document, organize contents and highlight important concepts, like "virtual organizations" in Table 1. It provides readers with a rough understanding of a document without going through its content, and has many potential applications, such as information retrieval, text summarization and document classification.

Keyphrase can be categorized into present keyphrase which appears in a source document, and absent keyphrase that does not appear in the document. Conventional approaches extract important text spans as candidate phrases and rank them as keyphrases (Hulth, 2003; Medelyan et al., 2008; Liu et al., 2011; Wu et al., 2015; Wang et al., 2016), that show promising results on the present keyphrases but cannot handle absent keyphrases.

Title: Resolving conflict and inconsistency in norm regulated virtual organizations.
Abstract: Norm governed virtual organizations define, govern and facilitate coordinated resource sharing and problem solving in societies of agents. With an explicit account of norms, openness in virtual organizations can be achieved new components, designed by various parties, can be seamlessly accommodated. We focus on virtual organizations realised as multi agent systems ...

Ground truth: virtual organizations; multi agent systems; agent; norm conflict; conflict prohibition; norm inconsistency; ...
Predicted keyphrases: virtual organizations; multi agent systems; artificial intelligence; inter agent; multi agent; action delegation; software agents; resource sharing; grid services; agent systems;

Table 1: The example shows the duplication and coverage issues of state-of-the-art model. The phrases in red are duplicate, and the underlined parts in the source document are not covered by the predicted results, while they are summarized by "norm conflict" and "norm inconsistency" in the golden list.

To predict absent keyphrases, generative methods have been proposed by Meng et al. (2017). The approach employs a sequence-to-sequence (Seq2Seq) framework (Sutskever et al., 2014) with a copy mechanism (Gu et al., 2016) to encourage rare word generation, in which the encoder compresses the text into a dense vector and the decoder generates a phrase with a Recurrent Neural Network (RNN) language model, achieving state-of-the-art performance. Since a document corresponds to multiple keyphrases, the approach divides it into multiple document-keyphrase pairs as training instances. This approach, however, neglects the correlation among target keyphrases since it does not model the one-to-many relationship between the document and keyphrases. Therefore, keyphrase prediction only depends on the source document, and ignores the keyphrases which have been generated. As a consequence, the generated keyphrases suffer from **duplication issue** and **coverage issue**. A duplication issue is defined as at least two phrases expressing the same meaning, hindering readers from obtaining more information from keyphrases. For example, three keyphrases have an identical meaning in Table 1,

including ”multi agent systems”, ”multi agent” and ”agent systems”. A coverage issue means some key points in the document are not covered by the keyphrases, such as ”norm conflict” and ”norm inconsistency” in Table 1.

To mitigate such issues, we mimic human behavior in terms of how to assign keyphrases for an arbitrary document. Given a document in Table 1, an annotator will read it and generate keyphrases according to his understanding of the content, like ”virtual organizations”, ”multi agent systems”. After that, instead of generating duplicate phrases like ”agent systems” and ”multi agent”, the annotator will review the document and preceding keyphrases, then generate a phrase like ”norm conflict” to cover topics that have not been summarized by previous phrases. The iteration does not stop until all of a document’s topics are covered by keyphrases.

We propose a new sequence-to-sequence architecture CorrRNN, capable of capturing correlation among keyphrases. Notably, correlation constraints in this paper are defined as keyphrases that should cover all topics in the source document and differ from each other. Specifically, we employ a coverage mechanism (Tu et al., 2016) to memorize which parts in the source document have been covered by previous phrases. In this way, the document coverage is modeled explicitly, enabling the generated keyphrases to cover more topics. Furthermore, we propose a review mechanism that considers the previous keyphrases in the generation process, in order to avoid the repetition in the final results. Concretely, the review mechanism explicitly models the correlation between the keyphrases that have been generated and the keyphrase that is going to be generated with a novel architecture. It extends the existing Seq2Seq model and captures the one-to-many relationship in keyphrase generation. Augmented with the coverage mechanism and the review mechanism, CorrRNN does not only inherit the advantages of the Seq2Seq model, but also improves the coverage and diversity in the generation process.

We test our model on three benchmark datasets. The results show that our model outperforms state-of-the art methods by a large margin, demonstrating the effectiveness of the correlation constraints. In addition, our model is better than heuristic rules on improving diversity, since it instills the correlation knowledge to the model in an end-to-end fashion.

Our contributions in this paper are three-fold: (1) the proposal of modeling the one-to-many correlation for keyphrase generation, (2) the proposal of a new architecture CorrRNN for keyphrase generation, and (3) empirical verification of the effectiveness of CorrRNN on public datasets.

In the remainder of this paper, we will first review the related work in Section 2, then we elaborate on the proposed model in Section 3. After that, we list the experiment settings in Section 4, results and discussion follow in Section 5. Finally, the conclusion and future work in Section 6.

2 Related Work

How to assign keyphrases to a long document is a fundamental task, that has been studied intensively in previous works. Existing methods can be categorized into two groups: extraction based and generation based methods.

The former group extracts important keyphrases in a document which consists of two phases. The first phase is to construct a set of phrase candidates with heuristic methods, such as extracting important n-grams (Hulth, 2003; Medelyan et al., 2008; Hulth, 2003; Shang et al., 2017) and selecting text chunks with certain postags (Liu et al., 2011; Wang et al., 2016; Le et al., 2016; Liu et al., 2015). The second phase is to rank the candidates with machine learning methods. Specifically, some researchers (Frank et al., 1999; Witten et al., 1999; Hulth, 2003; Medelyan et al., 2009; Gollapalli and Caragea, 2014) formulate the keyphrase extraction as a supervised classification problem, while others apply unsupervised approaches (Mihalcea and Tarau, 2004; Grineva et al., 2009; Liu et al., 2009, 2010; Zhang et al., 2013; Bougouin et al., 2013, 2016) on this task. Besides, Tomokiyo and Hurst (2003) employ two statistical language models to measure the informativeness for phrases. Liu et al. (2011) use a word alignment model to learn translation probabilities between the words in documents and the words in keyphrases, which alleviates the problem of vocabulary gaps.

The latter group, generative methods, assigns keyphrases to a document with natural language generation techniques, and is capable of generating absent keyphrases. Owing to the development of neural networks (Bahdanau et al., 2014), Meng et al. (2017) apply an encoder-decoder framework (Sutskever et al., 2014) with a copy mechanism

(Gu et al., 2016) to this task, achieving state-of-the-art performance.

Our work is a generation based approach. The main difference of our model is that we consider the correlation among keyphrases. Our model proposes a new review mechanism to enhance keyphrase diversity, while employs a coverage mechanism that has proven effective for summarization (See et al., 2017) and machine translation (Tu et al., 2016) to guarantee keyphrase coverage. Some previous works on keyword extraction have already exploited the correlation problem with a re-rank strategy (Habibi and Popescu-Belis, 2013; Ni et al., 2012). In contrast, we model the correlation in an end-to-end fashion.

3 Keyphrase Generation with Correlation

3.1 Problem Formalization

Suppose that we have a data set $\mathcal{D} = \{\mathbf{x}_i, \mathbf{p}_i\}_{i=1}^{N}$, where $\mathbf{x_i}$ is a source text, $\mathbf{p}_i = \{p_{i,j}\}_{j=1}^{M_i}$ is the keyphrase set of $\mathbf{x_i}$, and N is the number of documents. Both the source text and target keyphrase are word sequences, donated as $\mathbf{x}_i = (x_1^i, x_2^i, ..., x_T^i)$ and $p_{i,j} = (y_1^{i,j}, y_2^{i,j}, ..., y_{L^i}^{i,j})$ respectively. T and L^i are the length of word sequences of $\mathbf{x_i}$ and $p_{i,j}$. Prior work aims to maximize the probability of $\prod_{i=1}^{N}\prod_{j=1}^{M_i} P(p_{i,j}|\mathbf{x}_i)$, while our model considers keyphrase correlation to address coverage and duplication issues by maximizing the probability of $\prod_{i=1}^{N}\prod_{j=1}^{M_i} P(p_{i,j}|\mathbf{x}_i, p_{i,l<j})$.

3.2 Seq2Seq Model with Copy Mechanism

A Seq2Seq model (Sutskever et al., 2014) is employed as backbone in this paper. The encoder converts the variable-length input sequence $x = (x_1, x_2, ..., x_T)$ into a set of hidden representation $h = (h_1, h_2, ..., h_T)$ by iterating along time t with the following equation:

$$h_t = f(x_t, h_{t-1}) \tag{1}$$

where f is a non-linear function.

Then the context vector c is computed as a weighted sum of hidden representation set h through an attention mechanism (Bahdanau et al., 2014), which next acts as the representation of the whole input x at time step t.

$$c_t = \sum_{j=1}^{T} \alpha_{tj} h_j \tag{2}$$

where α_{tj} is a coefficient which measures the match degree between the inputs around position j and the output at position t.

With the context vector c_t, decoder generates variable-length word sequence step by step, the generative process which is known as a language model:

$$s_t = f(y_{t-1}, s_{t-1}, c_t) \tag{3}$$

$$p_g(y_t|y_{<t}, x) = g(y_{t-1}, s_t, c_t) \tag{4}$$

where s_t denotes the hidden state of the decoder at time t. y_t is the predicted word from vocabulary based on the largest probability after $g(.)$.

Unfortunately, pure generative mode cannot generate any keyphrase (e.g. noun, entity) which contains out-of-vocabulary words. Thus we incorporate a copy mechanism (Gu et al., 2016) into the encoder-decoder model to predict out-of-vocabulary words by selecting appropriate words from source text. After incorporation, the probability of predicting a new word consists of two parts:

$$p(y_t|y_{<t}, x) = p_g(y_t|y_{<t}, x) + p_c(y_t|y_{<t}, x) \tag{5}$$

$$p_c(y_t|y_{<t}, x) = \frac{1}{Z} \sum_{j:x_j=y_t} e^{\sigma(h_j^T W_c)[y_{t-1}; s_t; c_t]}, y_t \in \mathcal{X} \tag{6}$$

where p_g and p_c denote the probability of generating and coping. $\mathcal{X}$ is the set of unique words in source sequence x, σ is a non-linear function. $W_c \in \mathbb{R}$ is a learned parameter matrix. Z is the sum for normalization. For more details, please see (Gu et al., 2016).

3.3 Model Correlation

Keyphrases should cover more topics and differ from each other, while previous work (Meng et al., 2017) ignored this correlation among multiple keyphrases, resulting in duplication and coverage issues. In this part, we focus on capturing the one-to-many correlation to alleviate above issues. On the one hand, we employ a coverage mechanism (Tu et al., 2016) that diversifies attention distributions to improve the topic coverage of keyphrases. On the other hand, we propose a review mechanism which makes use of contextual information of previous phrases (already generated) to avoid duplicate generation. For better display of the proposed model, the overall framework is illustrated in Figure 1 and the detailed process is described in Algorithm 1.

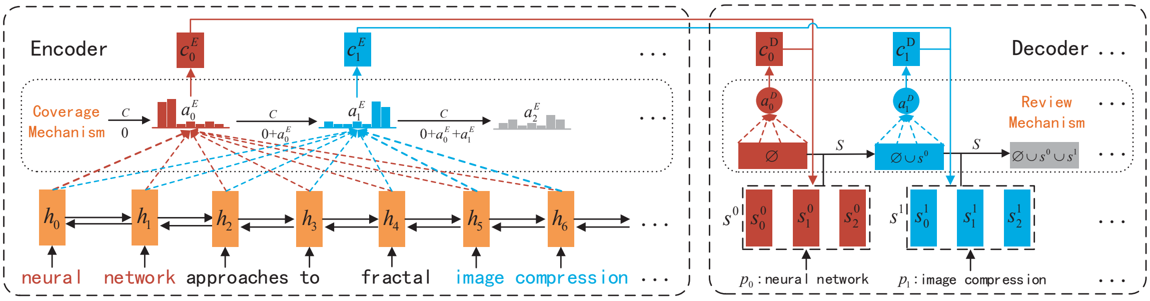

Figure 1: The overall framework structure. Note that p_i indicates a keyphrase (e.g. p_0 ="neural network"), s^i indicates the hidden state set of phrase p_i, coverage vector C and target-side review context S update and transmit along the process of decoding multiple keyphrases.

3.3.1 Coverage Mechanism

As is well known, multiple keyphrases usually correspond to multiple different positions of the source text (see Figure 1), the positions of words that have already been summarized should not be focused again since the attention mechanism automatically focuses on important areas of source text. To overcome the coverage issue, we incorporate a coverage mechanism (Tu et al., 2016) into our model, which diversifies the attention distributions of multiple keyphrases to make sure more important areas in the source document are attended and summarized into keyphrases.

Concretely, we maintain a coverage vector c^t which is the sum of attention distributions over all previous decoder time steps. Intuitively, c^t represents the degree of coverage that those words in the source text have received from the attention mechanism so far.

$$c^t = \sum_{i=0}^{t-1} a^i \tag{7}$$

Note that c^0 is a zero vector since no word in source text has be covered.

Later, the coverage vector c^t is an extra input for the attention mechanism, then the source context set h is read and weight averaged into a contextual representation c_t^E by the attention mechanism with a coverage vector, with Eqn.(2) transforming into Eqn.(8) as follows:

$$c_t^E = \sum_{j=1}^{T} \alpha_{tj} h_j; \quad \alpha_{tj} = \frac{exp(e_{tj}^E)}{\sum_{k=1}^{T} exp(e_{tk}^E)};$$
$$e_{tj}^E = v^T tanh(W_h h_j + W_s s_{t-1} + \mathbf{w_c} \mathbf{c_j^t} + b_{attn}) \tag{8}$$

where E is the encoder and $\mathbf{w_c}$ is a learned parameter with the same length as v.

With the coverage vector, the attention mechanism's decision for choosing where in source text to focus next is informed by a reminder of its previous decisions, which ensures that the attention mechanism avoids repeatedly attending to the same locations in the source text more easily, thus generated phrases cover more topics in the source document.

Algorithm 1 Training procedure of the proposed model.

3.3.2 Review Mechanism

Considering human behavior on assigning keyphrases that review previous phrases to avoid duplicate assignment, we construct a target side review context set which contains contextual information of generated phases. The target context with an attention mechanism can make use of contextual information of generated phrases to help predict the next phrase, which we call the review mechanism.

Like source context c_t^E described above, on the target side, the target context is defined as $s^t = \{s_1, s_2, ..., s_{t-1}\}$, which is the collection of hidden states before time step t. When decoding the word at t-th step, s^t is used to inform an extra contextual representation, thus target side attentive contexts are integrated into c_t^D:

$$c_t^D = \sum_{j=1}^{t-1} \beta_{tj} s_j; \quad \beta_{tj} = \frac{exp(e_{tj}^D)}{\sum_{k=1}^{t-1} exp(e_{tk}^D)};$$

$$e_{tj}^D = v^T tanh(W_h s_j + W_s s_{t-1}) \tag{9}$$

Afterwards, c_t^D is provided as an extra input to derive the hidden state s_t and later the probability distribution for choosing t-th word . The target context gets updated consequently as $s^{t+1} = s^t \cup \{s_t\}$ in the decoding progress.

$$s_t = f(y_{t-1}, s_{t-1}, c_t^E, \mathbf{c_t^D}) \tag{10}$$

$$p_g(y_t|y_{<t}, x) = g(y_{t-1}, s_t, c_t^E, \mathbf{c_t^D}) \tag{11}$$

$$p_c(y_t|y_{<t}, x) = \frac{1}{Z} \sum_{j:x_j=y_t} e^{\sigma(h_j^T W_c)[y_{t-1}; s_t; c_t^E; \mathbf{c_t^D}]}, y_t \in \mathcal{X} \tag{12}$$

Eqn.(10), Eqn.(11) and Eqn.(12) are transformed from Eqn.(3), Eqn.(4) and Eqn.(6) respectively. More mathematical details are displayed below to make Eqn.(10) more clear:

$$\begin{aligned}
r_t &= \sigma(W_r y_{t-1} + U_r s_{t-1} + C_r^E c_t^E + \mathbf{C_r^D c_t^D});\\
z_t &= \sigma(W_z y_{t-1} + U_z s_{t-1} + C_z^E c_t^E + \mathbf{C_z^D c_t^D});\\
\widetilde{s_t} &= tanh(W y_{t-1} + U[r_t \circ s_{t-1}] + C^E c_t^E + \mathbf{C^D c_t^D});\\
s_t &= (1 - z_t) \circ s_{t-1} + z_t \circ \widetilde{s_t}
\end{aligned} \tag{13}$$

where E, D indicate the encoder and decoder, W, U, C are learned parameters of the model, σ is a $sigmoid$ function, $\circ$ indicates an element-wise product.

With the contextual information of previous phrases, review mechanism ensures next predicted phrase less duplication and topic coherence. So far, we transmit and update the coverage vector and review context along the multi-target phrase decoding process to improve the coverage and diversity of keyphrases. We denote our model with coverage only and review only as CorrRNN$_C$ and CorrRNN$_R$, and empirically compare them in experiments. The objectives are to minimize the negative log-likelihood of the target words, given a data sample with source text x and corresponding phrases set $p = \{p_i\}_{i=0}^M$, loss is calculated as follows:

$$loss = -\frac{1}{M} \sum_{i=0}^{M} \sum_{t=0}^{T_i} log(p(y_t^i | y_{<t}^i, x, p_{j,j<i})) \tag{14}$$

4 Experiment Settings

4.1 Implementation Details

In the preprocessing phase, we follow (Meng et al., 2017) to preprocess the text with tokenization, lowercasing, and digit replacement to ensure fairness. Each article consists of one source text and corresponding multiple keyphrases, and the source text is the concatenation of its title and abstract. We set the max number of target phrases to 10 for an article in consideration of the device memory, thus those with more than 10 target phrases are cut into multiple articles. Finally, we have 558830 articles (text-keyphrases pair) for training.

In the training phase, we choose a bidirectional GRU for the encoder and another forward GRU for the decoder. The top 50000 frequent words are chosen as the vocabulary, the dimension of word embeddings is set to 150, the value of embedding is randomly initialized with uniform distribution in [-0.1, 0.1], and the dimension of the hidden layers is set to 300. Adam is adopted to optimize the model with initial learning rate=10^{-4}, gradient clipping=0.1 and dropout rate=0.5. The training is stopped once the loss on the validation set stops dropping for several iterations.

In the generation phase, we use beam search to generate multiple phrases. The beam depth is set to 6 and the beam size is set to 200. Source code will be released at `https://github.com/nanfeng1101/s2s-kg`.

4.2 Datasets

Following Meng et al. (2017), we train our model on the **KP20k** dataset (Meng et al., 2017), which contains articles collected from various online digital libraries. The dataset has 527,830 articles for training and 20000 articles for validation.

We evaluate our model on three benchmark datasets which are widely adopted in previous works, with the details described below:

- **NUS** (Vijayakumar et al., 2016): It contains 211 papers with author-assigned keyphrases, all of which we use as test data.

- **Semeval-2010** (Kim et al., 2010): 288 articles are collected from the ACM Digital Library. 100 of them are used for test data and the rest are added to the training set.
- **Krapivin** (Krapivin et al., 2008): This dataset contains 2304 papers. The first 400 papers in alphabetical order are used for evaluation and the rest are added to the training set.

4.3 Baseline Models

We compare our model with extractive and generative approaches. The extractive baselines include Tf-idf, TextRank (Mihalcea and Tarau, 2004), SingleRank (Wan and Xiao, 2008), ExpandRank (Wan and Xiao, 2008), TopicRank[1] (Bougouin et al., 2013), KEA (Witten et al., 1999) and Maui (Medelyan et al., 2009). The generative baselines include RNN and CopyRNN (Meng et al., 2017). In these baselines, the first five are unsupervised and the later four are supervised. We set up all the baselines following optimal settings in (Hasan and Ng, 2010), (Bougouin et al., 2013) and (Meng et al., 2017).

To demonstrate the effectiveness of end-to-end learning, we compare CorrRNN to CopyRNN with post-processing. In post-precessing, we only keep the first appearence of keyphrase in duplicate predictions, duplication means that a phrase is a substring of another. The baseline can be seen as heuristic rules for improving the diversity, denoted as CopyRNN$_F$.

4.4 Evaluation Metrics

For a fair comparison, we evaluate the experiment results on present keyphrases and absent keyphrases separately, because extractive methods cannot generate absent keyphrases. Following Meng et al. (2017), we employ F1-measure for present keyphrases and recall for absent keyphrases. Here, we use **F1@K** and **R@K** to denote the F1 and recall score in the top K keyphrases. Note that we use Porter Stemmer for preprocessing to determine whether the two keyphrases are identical.

Furthermore, α-NDCG, which is widely used to measure the diversity of keyphrase generation (Habibi and Popescu-Belis, 2013) and information retrieval (Clarke et al., 2008), is adopted to evaluate the diversity of the generative methods, denoted as **N@K**. α is a trade-off between relevance and diversity in α-NDCG, which is set to equal weights of 0.5 according to Habibi and Popescu-Belis (2013). The higher α-NDCG is, the more diverse the results are. We re-implement CopyRNN with the source code[2] provided by the authors in order to evaluate it on the α-NDCG metric.

$$\alpha\text{-}NDCG[k] = \frac{DCG[k]}{DCG'[k]};$$
$$DCG[k] = \sum_{j=1}^{k} G[j]/log_2(j+1);$$
$$G[k] = \sum_{i=1}^{m} J(d_k, i)(1-\alpha)^{r_{i,k-1}}$$

where α is a parameter, m denotes the number of target phrases, k denotes the number of predicted phrases. $J(d_k, i) = 0$ or 1, which indicates whether the k-th predicted phrase is relevant to the i-th target phrase, and $r_{i,k-1}$ indicates how many predicted phrases are relevant to the i-th target phrase before the k-th predicted phrase. Note that relevance here is defined as whether the word set of a keyphrase is a subset of another keyphrase (e.g. ”multi agent” vs ”multi agent system”).

5 Results and Analysis

5.1 Present Phrase Prediction

Present phrase prediction is also known as keyphrase extraction in prior studies. We evaluate how well our model performs on this common task. The results are shown in Tables 2 and 3, which list the performance of the top 5 and top 10 results.

In terms of F1-measure, CorrRNN and CopyRNN outperform other baselines by a large margin, indicating the effectiveness of RNN with a copy mechanism. As we consider the correlation among multiple phrases, the overall results of CorrRNN are better than CopyRNN significantly ($t-$test with $p < 0.01$). This is mainly because CorrRNN alleviates the duplication and coverage issues in existing methods, with more correct phrases boosted in the top 10 results. Heuritic baseline CopyRNN$_F$ is even worse than CopyRNN, indicating that the heuristic rules may hurt the performance of generative approaches. It also proven that it is a better way to model the correlation among keyphrases in an end-to-end fashion.

Regarding α-NDCG, CorrRNN and its variants surpass other methods, demonstrating that incorporating correlation constraints can improve both

---

[2] https://github.com/memray/seq2seq-keyphrase

relevance and diversity. As the heuristic rules influence the relevance of CopyRNN, CopyRNN$_F$ performs a little better than CopyRNN on the α-NDCG.

Table 3: The α-NDCG performance on present phrase prediction.

5.2 Absent Phrase Prediction

We evaluate the performance of generative methods within the recall of the top 10 results, which is shown in Table 4. We can see that both CopyRNN and CorrRNN outperform RNN although the improvement is not as much as in present phrase prediction. It indicates that the copy mechanism is very helpful for predicting absent phrases. We can also see that CopyRNN and CorrRNN are comparable in terms of recall, but CorrRNN is better on diversity, proving that our model can address the duplicate issue in keyphrase generation.

Model	**NUS**		**SemEval**		**Krapivin**

Table 4: The recall and α-NDCG performance on absent phrase prediction.

5.3 Generalization Ability

As described above, CorrRNN performed well on scientific publications. In this part, we construct our experiments on news domain to see if the proposed model works when transferring to a different domain with unfamiliar texts. We adopted the popular news article dataset: DUC-2001 (Wan and Xiao, 2008) for our experiments. The dataset contains 308 news articles with 2488 manually assigned keyphrases, and each article consists of 740 words on average, which is completely different from the datasets we used above (see Table 5).

Dataset	**Length**	**Dataset**	**Length**
NUS	219	SemEval	235
Krapivin	184	DUC-2001	740

Table 5: The average text length of test datasets.

We directly applied CorrRNN, which is trained on scientific publications, on predicting phrases for news articles without any adaptive adjustment. Experiment results from (Hasan and Ng, 2010), (Meng et al., 2017) and our experiments are shown in Table 6, from which we can see that the proposed model CorrRNN can extract a considerable portion of keyphrases correctly from unfamiliar texts. It outperforms TextRank (Mihalcea and Tarau, 2004), KeyCluster (Liu et al., 2009), TopicRank (Bougouin et al., 2013) and CopyRNN (Meng et al., 2017), but it falls behind the other three baselines because the test domain changes. The model should perform better if it is trained on news dataset.

When transferring to news domain, the vocabulary changes a lot, more unknown words occur, and the correlation also may not applicable, the model can still capture positional and syntactic features within the text to predict phrases despite the different text type and length. The experiment verifies the generalization ability of our model, thus we have good reasons to believe that our model has a great potential to be generalized to more domains after sufficient training.

Model	**F1@10**	**Model**	**F1@10**
Tf-idf	0.270	TopicRank	0.154
TextRank	0.097	KeyCluster	0.140
SingleRank	0.256	CopyRNN	0.164
ExpandRank	0.269	CorrRNN	0.173

Table 6: Performance on DUC-2001. CopyRNN and CorrRNN are supervised, and they are trained on scientific publications but evaluated on news.

5.4 Discussion

5.4.1 Model Ablation

We investigate the effect of coverage mechanism and review mechanism in our model with CorrRNN$_C$ and CorrRNN$_R$ respectively, shown in Tables 2, 3 and 4. It is clear that both the coverage mechanism and review mechanism are helpful for improving the coverage and diversity of predicted phrases. We note the inconsistency of ablate models in our experiments. First, no ablate model achieves the best performance on all of the test datasets, the full model CorrRNN gets better perfermance on present phrase prediction, while CorrRNN$_C$ seems better than the others in absent phrase prediction. As the present phrases are the majority, the full model CorrRNN can achieve best overall performance in actual use. Second, proposed models perform better on dataset NUS and SemEval than Kravipin. This may be due to the difference of assignment quality among test datasets, keyphrase assignments with higher coverage and higher diversity benefiting more from our models.

5.4.2 Visualization

In Figure 2, we visualize the coverage vector and review attention with an example to further clarify how our model works. Due to space limitation, we only visualize top5 phrases in the example, they are already enough to support our analysis. For coverage vector, we can see that source attention transfers along the changes of coverage vector. At the first, only relevant words of ”machine learning” are attended. After that, the coverage vector informs attention mechanism to attend other positions instead of repetitive attention, that promotes the generation of later phrases like ”average precision”. After the last one being generated, it is clear that coverage vector basically covers all topics of the source document, including ”machine learning”, ”mean average precision”, ”svm” and ”ranked retrieval systems”. As for the review attention, it’s clear that contextual information of all previous phrases are attended for generating the last phrase ”ranked retrieval systems”, which verifies that the review mechanism helps to alleviate duplication and ensure coherence of results.

5.4.3 Comparison with Heuristic Rules

We design the baseline CopyRNN$_F$ with post-processing to explore whether heuristic rules can alleviate duplication and coverage issues. It is clear from Tables 2, 3 and 4 that the experiment results are negative. Compared to our model CorrRNN, heuristic rules can’t address duplication and coverage issues fundamentally. We offer two explanations for these observations. Firstly, heuristic rules can only handle those phrases which have already been generated in results, that shows no help for enabling phrases to cover more topics in source text. Secondly, although duplication can be reduced by heuristic rules forcibly, the remaining phrases are not guaranteed to be correct, thus it hurts the accuracy badly.

5.4.4 Complexity Analysis

According to our observations during experiment phase, the CopyRNN (Meng et al., 2017) model has 78835750 network parameters, while CorrRNN owns 94886750 parameters because of the incorporation of coverage mechanism (few) and review mechanism (most). However, benefiting from the consideration of one-to-many relationship, and correlation constraints among keyphrases, our model CorrRNN not only achieves better performance but also converges faster than CopyRNN.

5.4.5 Case Study

As shown in Table 7, we compare the phrases generated by CorrRNN and CopyRNN on an example article. Compared to CopyRNN, CorrRNN generates one more correct present phrase ”voip”

Title: Deployment issues of a voip conferencing system in a virtual conferencing environment. **Abstract**: Real time services have been supported by and large on circuitswitched networks. Recent trends favour services ported on packet switched networks. For audio conferencing, we need to consider many issues scalability, quality of the conference application, floor control and load on the clients servers to name a few. In this paper, we describe an audio service framework designed to provide a virtual conferencing environment (vce). The system is designed to accommodate a large number of end users speaking at the same time and spread across the internet. The framework is based on conference servers $\langle DIGIT \rangle$, which facilitate the audio handling, while we exploit the sip capabilities for signaling purposes. Client selection is based on a recent quantifier called loudness number that helps mimic a physical face to face conference. We deal with deployment issues of the proposed solution both in terms of scalability and interactivity, while explaining the techniques we use to reduce the traffic. We have implemented a conference server (cs) application on a campus wide network at our institute.
Present Phrase: **CopyRNN:** deployment; virtual conferencing; real time; distributed systems; **virtual conferencing environment**; client server; **conference server**; distributed applications; audio conferencing; floor control; **CorrRNN:** **voip**; virtual conferencing; voip conferencing; audio conferencing; audio service; real time services; real time; distributed systems; **conference server**; **virtual conferencing environment**;
Absent Phrase: **CopyRNN:** quality of service; distributed conferencing; virtual environments; internet conferencing; conference conferencing; load balancing; packet conferencing; real time systems; distributed computing; virtual server; **CorrRNN:** real time systems; real time voip; voip service; **real time audio**; wireless networks; conference conferencing; real time communications; packet conferencing; audio communication; quality of service;

Table 7: Top10 phrases generated by CopyRNN and CorrRNN. Phrases in bold are correct, and phrases underlined are duplicate.

and one more correct absent phrase ”real time audio” respectively, which covers two important topics, while CopyRNN loses these key points. Moreover, four ”conferencing (noun)” phrases are generated by CopyRNN, including ”distributed conferencing”, ”internet conferencing”, ”conference conferencing” and ”packet conferencing”, which hinders readers from obtaining more information, while CorrRNN only has two.

6 Conclusion and Future Work

In this paper, we propose a new Seq2Seq architecture that models correlation among multiple keyphrases in an end-to-end fashion by incorporating a coverage mechanism and a review mechanism. Comprehensive empirical studies demonstrate that our model can alleviate duplication and coverage issues effectively and improve diversity and coverage for keyphrase generation. To the best of our knowledge, this is the first use of encoder-decoder model for keyphrase generation in an one-to-many way. Our future work will focus on two areas: investigation on multi-document keyphrase generation, and incorporation of structure or syntax information in keyphrase generation.

Closed-Book Training to Improve Summarization Encoder Memory

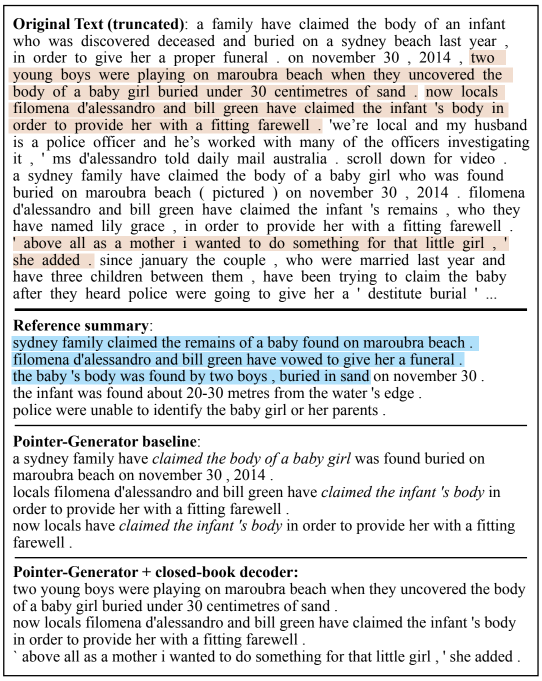
Yichen Jiang and **Mohit Bansal**
UNC Chapel Hill
{yichenj, mbansal}@cs.unc.edu

Abstract

A good neural sequence-to-sequence summarization model should have a strong encoder that can distill and memorize the important information from long input texts so that the decoder can generate salient summaries based on the encoder's memory. In this paper, we aim to improve the memorization capabilities of the encoder of a pointer-generator model by adding an additional 'closed-book' decoder without attention and pointer mechanisms. Such a decoder forces the encoder to be more selective in the information encoded in its memory state because the decoder can't rely on the extra information provided by the attention and possibly copy modules, and hence improves the entire model. On the *CNN/Daily Mail* dataset, our 2-decoder model outperforms the baseline significantly in terms of ROUGE and METEOR metrics, for both cross-entropy and reinforced setups (and on human evaluation). Moreover, our model also achieves higher scores in a test-only DUC-2002 generalizability setup. We further present a memory ability test, two saliency metrics, as well as several sanity-check ablations (based on fixed-encoder, gradient-flow cut, and model capacity) to prove that the encoder of our 2-decoder model does in fact learn stronger memory representations than the baseline encoder.

1 Introduction

Text summarization is the task of condensing a long passage to a shorter version that only covers the most salient information from the original text. Extractive summarization models (Jing and McKeown, 2000; Knight and Marcu, 2002; Clarke and Lapata, 2008; Filippova et al., 2015) directly pick words, phrases, and sentences from the source text to form a summary, while an abstractive model generates (samples) words from a fixed-size vocabulary instead of copying from text directly.



Original Text (truncated): a family have claimed the body of an infant who was discovered deceased and buried on a sydney beach last year , in order to give her a proper funeral . on november 30 , 2014 , two young boys were playing on maroubra beach when they uncovered the body of a baby girl buried under 30 centimetres of sand . now locals filomena d'alessandro and bill green have claimed the infant 's body in order to provide her with a fitting farewell . 'we're local and my husband is a police officer and he's worked with many of the officers investigating it , ' ms d'alessandro told daily mail australia . scroll down for video . a sydney family have claimed the body of a baby girl who was found buried on maroubra beach (pictured) on november 30 , 2014 . filomena d'alessandro and bill green have claimed the infant 's remains , who they have named lily grace , in order to provide her with a fitting farewell . ' above all as a mother i wanted to do something for that little girl , ' she added . since january the couple , who were married last year and have three children between them , have been trying to claim the baby after they heard police were going to give her a ' destitute burial ' ...

Reference summary:
sydney family claimed the remains of a baby found on maroubra beach .
filomena d'alessandro and bill green have vowed to give her a funeral .
the baby 's body was found by two boys , buried in sand on november 30 .
the infant was found about 20-30 metres from the water 's edge .
police were unable to identify the baby girl or her parents .

Pointer-Generator baseline:
a sydney family have *claimed the body of a baby girl* was found buried on maroubra beach on november 30 , 2014 .
locals filomena d'alessandro and bill green have *claimed the infant 's body* in order to provide her with a fitting farewell .
now locals have *claimed the infant 's body* in order to provide her with a fitting farewell .

Pointer-Generator + closed-book decoder:
two young boys were playing on maroubra beach when they uncovered the body of a baby girl buried under 30 centimetres of sand .
now locals filomena d'alessandro and bill green have claimed the infant 's body in order to provide her with a fitting farewell .
` above all as a mother i wanted to do something for that little girl , ' she added .

Figure 1: Baseline model repeats itself twice (italic), and fails to find all salient information (highlighted in red in the original text) from the source text that is covered by our 2-decoder model. The summary generated by our 2-decoder model also recovers most of the information mentioned in the reference summary (highlighted in blue in the reference summary).

The last few years have seen significant progress on both extractive and abstractive approaches, of which a large number of studies are fueled by neural sequence-to-sequence models (Sutskever et al., 2014). One popular formulation of such models is an RNN/LSTM encoder that encodes the source passage to a fixed-size memory-state vector, and another RNN/LSTM decoder that generates the summary from this memory state. This paradigm is enhanced by attention mechanism (Bahdanau et al., 2015) and pointer network (Vinyals et al., 2015), such that the decoder can refer to (and weigh) all the encod-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4067–4077
Brussels, Belgium, October 31 - November 4, 2018.

ing steps' hidden states or directly copy words from the source text, instead of relying solely on encoder's final memory state for all information about the source passage. Recent studies (Rush et al., 2015; Nallapati et al., 2016; Chopra et al., 2016; Zeng et al., 2016; Gu et al., 2016b; Gulcehre et al., 2016; See et al., 2017) have demonstrated success with such seq-attention-seq and pointer models in summarization tasks.

While the advantage of attention and pointer models compared to vanilla sequence-to-sequence models in summarization is well supported by previous studies, these models still struggle to find the most salient information in the source text when generating summaries. This is because summarization, being different from other text-to-text generation tasks (where there is an almost one-to-one correspondence between input and output words, e.g., machine translation), requires the sequence-attention-sequence model to additionally decide where to attend and where to ignore, thus demanding a strong encoder that can determine the importance of different words, phrases, and sentences and flexibly encode salient information in its memory state. To this end, we propose a novel 2-decoder architecture by adding another 'closed book' decoder without attention layer to a popular pointer-generator baseline, such that the 'closed book' decoder and pointer decoder share an encoder. We argue that this additional 'closed book' decoder encourages the encoder to be better at memorizing salient information from the source passage, and hence strengthen the entire model. We provide both intuition and evidence for this argument in the following paragraphs.

Consider the following case. Two students are learning to do summarization from scratch. During training, both students can first scan through the passage once (encoder's pass). Then student A is allowed to constantly look back (attention) at the passage when writing the summary (similar to a pointer-generator model), while student B has to occasionally write the summary without looking back (similar to our 2-decoder model with a non-attention/copy decoder). During the final test, both students can look at the passage while writing summaries. We argue that student B will write more salient summaries in the test because s/he learns to better distill and memorize important information in the first scan/pass by not looking back at the passage in training.

In terms of back-propagation intuition, during the training of a seq-attention-seq model (e.g., See et al. (2017)), most gradients are back-propagated from the decoder to the encoder's hidden states through the attention layer. This encourages the encoder to correctly encode salient words at the corresponding encoding steps, but does make sure that this information is not forgotten (overwritten in the memory state) by the encoder afterward. However, for a plain LSTM (closed-book) decoder without attention, its generated gradient flow is back-propagated to the encoder through the memory state, which is the only connection between itself and the encoder, and this, therefore, encourages the encoder to encode only the salient, important information in its memory state. Hence, to achieve this desired effect, we jointly train the two decoders, which share one encoder, by optimizing the weighted sum of their losses. This approximates the training routine of student B because *the sole encoder has to perform well for both decoders*. During inference, we only employ the pointer decoder due to its copying advantage over the closed-book decoder, similar to the situation of student B being able to refer back to the passage during the test for best performance (but is still trained hard to do well in both situations). Fig. 1 shows an example of our 2-decoder summarizer generating a summary that covers the original passage with more saliency than the baseline model.

Empirically, we test our 2-decoder architecture on the *CNN/Daily Mail* dataset (Hermann et al., 2015; Nallapati et al., 2016), and our model surpasses the strong pointer-generator baseline significantly on both ROUGE (Lin, 2004) and METEOR (Denkowski and Lavie, 2014) metrics, as well as based on human evaluation. This holds true both for a cross-entropy baseline as well as a stronger, policy-gradient based reinforcement learning setup (Williams, 1992). Moreover, our 2-decoder models (both cross-entropy and reinforced) also achieve reasonable improvements on a test-only generalizability/transfer setup on the DUC-2002 dataset.

We further present a series of numeric and qualitative analysis to understand whether the improvements in these automatic metric scores are in fact due to the enhanced memory and saliency strengths of our encoder. First, by evaluating the representation power of the encoder's final memory state after reading long passages (w.r.t.

the memory state after reading ground-truth summaries) via a cosine-similarity test, we prove that our 2-decoder model indeed has a stronger encoder with better memory ability. Next, we conduct three sets of ablation studies based on fixed-encoder, gradient-flow cut, and model capacity to show that the stronger encoder is the reason behind the significant improvements in ROUGE and METEOR scores. Finally, we show that summaries generated by our 2-decoder model are qualitatively better than baseline summaries as the former achieved higher scores on two saliency metrics (based on cloze-Q&A blanks and a keyword classifier) than the baseline summaries, while maintaining similar length and better avoiding repetitions. This directly demonstrates our 2-decoder model's enhanced ability to memorize and recover important information from the input document, which is our main contribution in this paper.

2 Related Work

Extractive and Abstractive Summarization: Early models for automatic text summarization were usually extractive (Jing and McKeown, 2000; Knight and Marcu, 2002; Clarke and Lapata, 2008; Filippova et al., 2015). For abstractive summarization, different early non-neural approaches were applied, based on graphs (Giannakopoulos, 2009; Ganesan et al., 2010), discourse trees (Gerani et al., 2014), syntactic parse trees (Cheung and Penn, 2014; Wang et al., 2013), and a combination of linguistic compression and topic detection (Zajic et al., 2004). Recent neural-network models have tackled abstractive summarization using methods such as hierarchical encoders and attention, coverage, and distraction (Rush et al., 2015; Chopra et al., 2016; Nallapati et al., 2016; Chen et al., 2016; Takase et al., 2016) as well as various initial large-scale, short-length summarization datasets like DUC-2004 and Gigaword. Nallapati et al. (2016) adapted the *CNN/Daily Mail* (Hermann et al., 2015) dataset for long-text summarization, and provided an abstractive baseline using attentional sequence-to-sequence model.

Pointer Network for Summarization: Pointer networks (Vinyals et al., 2015) are useful for summarization models because summaries often need to copy/contain a large number of words that have appeared in the source text. This provides the advantages of both *extractive* and *abstractive* approaches, and usually includes a gating function to model the distribution for the extended vocabulary including the pre-set vocabulary and words from the source text (Zeng et al., 2016; Nallapati et al., 2016; Gu et al., 2016b; Gulcehre et al., 2016; Miao and Blunsom, 2016). See et al. (2017) used a soft gate to control model's behavior of copying versus generating. They further applied coverage mechanism and achieved the state-of-the-art results on *CNN/Daily Mail* dataset.

Memory Enhancement: Some recent works (Wang et al., 2016; Xiong et al., 2018; Gu et al., 2016a) have studied enhancing the memory capacity of sequence-to-sequence models. They studied this problem in Neural Machine Translation by keeping an external memory state analogous to data in the Von Neumann architecture, while the instructions are represented by the sequence-to-sequence model. Our work is novel in that we aim to improve the internal long-term memory of the encoder LSTM by adding a closed-book decoder that has no attention layer, yielding a more efficient internal memory that encodes only important information from the source text, which is crucial for the task of long-document summarization.

Reinforcement Learning: Teacher forcing style maximum likelihood training suffers from exposure bias (Bengio et al., 2015), so recent works instead apply reinforcement learning style policy gradient algorithms (REINFORCE (Williams, 1992)) to directly optimize on metric scores (Henß et al., 2015; Paulus et al., 2018). Reinforced models that employ this method have achieved good results in a number of tasks including image captioning (Liu et al., 2017; Ranzato et al., 2016), machine translation (Bahdanau et al., 2016; Norouzi et al., 2016), and text summarization (Ranzato et al., 2016; Paulus et al., 2018).

3 Models

3.1 Pointer-Generator Baseline

The pointer-generator network proposed in See et al. (2017) can be seen as a hybrid of *extractive* and *abstractive* summarization models. At each decoding step, the model can either sample a word from its vocabulary, or copy a word directly from the source passage. This is enabled by the attention mechanism (Bahdanau et al., 2015), which includes a distribution a_i over all encoding steps, and a context vector c_t that is the weighted sum of encoder's hidden states. The attention mechanism

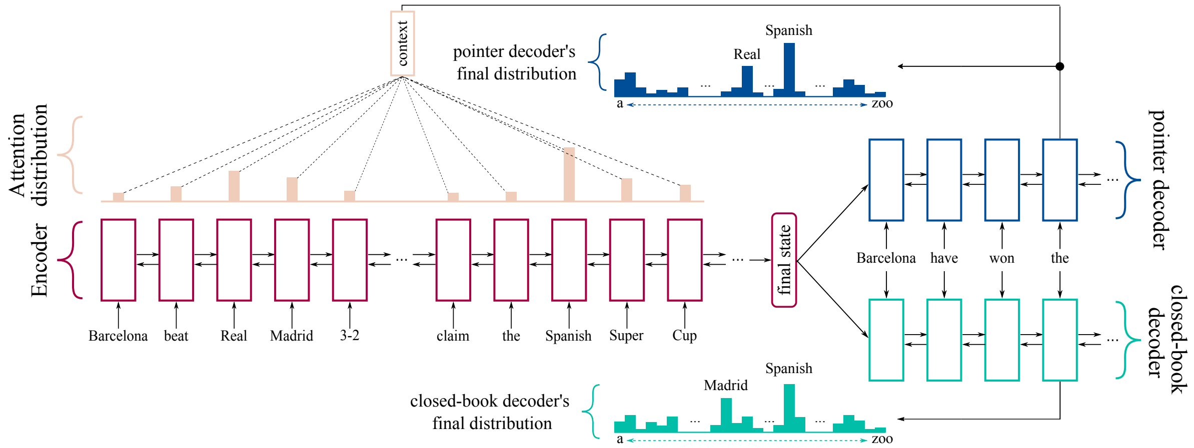


Figure 2: Our 2-decoder summarization model with a pointer decoder and a closed-book decoder, both sharing a single encoder (this is during training; next, at inference time, we only employ the memory-enhanced encoder and the pointer decoder).

is modeled as:

$$e_i^t = v^T \tanh(W_h h_i + W_s s_t + b_{attn})$$
$$a_i^t = \mathrm{softmax}(e_i^t); \quad c_t = \sum_i a_i^t h_i \tag{1}$$

where v, W_h, W_s, and b_{attn} are learnable parameters. h_i is encoder's hidden state at i^{th} encoding step, and s_t is decoder's hidden state at t^{th} decoding step. The distribution a_i^t can be seen as the amount of attention at decode step t towards the i^{th} encoder state. Therefore, the context vector c_t is the sum of the encoder's hidden states weighted by attention distribution a^t.

At each decoding step, the previous context vector c_{t-1} is concatenated with current input x_t, and fed through a non-linear recurrent function along with the previous hidden state s_{t-1} to produce the new hidden state s_t. The context vector c_t is then calculated according to Eqn. 1 and concatenated with the decoder state s_t to produce the logits for the vocabulary distribution P_{vocab} at decode step t: $P_{vocab}^t = \mathrm{softmax}(V_2(V_1[s_t, c_t]+b_1)+b_2)$, where V_1, V_2, b_1, b_2 are learnable parameters. To enable copying out-of-vocabulary words from source text, a pointer similar to Vinyals et al. (2015) is built upon the attention distribution and controlled by the generation probability p_{gen}:

$$p_{gen}^t = \sigma(U_c c_t + U_s s_t + U_x x_t + b_{ptr})$$
$$P_{attn}^t(w) = p_{gen}^t P_{vocab}^t(w) + (1 - p_{gen}^t) \sum_{i:w_i=w} a_i^t$$

where U_c, U_s, U_x, and b_{ptr} are learnable parameters. x_t and s_t are the input token and decoder's state at t^{th} decoding step. σ is the sigmoid function. We can see p_{gen} as a soft gate that controls the model's behavior of copying from text with attention distribution a_i^t versus sampling from vocabulary with generation distribution P_{vocab}^t.

3.2 Closed-Book Decoder

As shown in Eqn. 1, the attention distribution a_i depends on decoder's hidden state s_t, which is derived from decoder's memory state c_t. If c_t does not encode salient information from the source text or encodes too much unimportant information, the decoder will have a hard time to locate relevant encoder states with attention. However, as explained in the introduction, most gradients are back-propagated through attention layer to the encoder's hidden state h_t, not directly to the final memory state, and thus provide little incentive for the encoder to memorize salient information in c_t.

Therefore, to enhance encoder's memory, we add a closed-book decoder, which is a unidirectional LSTM decoder without attention/pointer layer. The two decoders share a single encoder and word-embedding matrix, while out-of-vocabulary (OOV) words are simply represented as [UNK] for the closed-book decoder. The entire 2-decoder model is represented in Fig. 2. During training, we optimize the weighted sum of negative log likelihoods from the two decoders:

$$\mathcal{L}_{XE} = \frac{1}{T} \sum_{t=1}^{T} -\left((1-\gamma) \log P_{attn}^t(w|x_{1:t}) + \gamma \log P_{cbdec}^t(w|x_{1:t})\right) \tag{2}$$

where P_{cbdec} is the generation probability from the closed-book decoder. The mix ratio γ is tuned on the validation set.

3.3 Reinforcement Learning

In the reinforcement learning setting, our summarization model is the policy network that generates words to form a summary. Following Paulus et al. (2018), we use a self-critical policy gradient training algorithm (Rennie et al., 2016; Williams, 1992) for both our baseline and 2-decoder model. For each passage, we sample a summary $y^s = w^s_{1:T+1}$, and greedily generate a summary $\hat{y} = \hat{w}_{1:T+1}$ by selecting the word with the highest probability at each step. Then these two summaries are fed to a reward function r, which is the ROUGE-L scores in our case. The RL loss function is:

$$\mathcal{L}_{RL} = \frac{1}{T}\sum_{t=1}^{T}(r(\hat{y}) - r(y^s)) \log P^t_{attn}(w^s_{t+1}|w^s_{1:t}) \tag{3}$$

where the reward for the greedily-generated summary ($r(\hat{y})$) acts as a baseline to reduce variance. We train our reinforced model using the mixture of Eqn. 3 and Eqn. 2, since Paulus et al. (2018) showed that a pure RL objective would lead to summaries that receive high rewards but are not fluent. The final mixed loss function for RL is: $\mathcal{L}_{XE+RL} = \lambda\mathcal{L}_{RL} + (1-\lambda)\mathcal{L}_{XE}$, where the value of λ is tuned on the validation set.

4 Experimental Setup

We evaluate our models mainly on *CNN/Daily Mail* dataset (Hermann et al., 2015; Nallapati et al., 2016), which is a large-scale, long-paragraph summarization dataset. It has online news articles (781 tokens or ~40 sentences on average) with paired human-generated summaries (56 tokens or 3.75 sentences on average). The entire dataset has 287,226 training pairs, 13,368 validation pairs and 11,490 test pairs. We use the same version of data as See et al. (2017), which is the original text with no preprocessing to replace named entities. We also use DUC-2002, which is also a long-paragraph summarization dataset of news articles. This dataset has 567 articles and 1~2 summaries per article.

All the training details (e.g., vocabulary size, RNN dimension, optimizer, batch size, learning rate, etc.) are provided in the supplementary materials.

5 Results

We first report our evaluation results on *CNN/Daily Mail* dataset. As shown in Table 1, our 2-decoder model achieves statistically significant improvements[1] upon the pointer-generator baseline (pg), with +1.51, +0.74, and +0.96 points advantage in ROUGE-1, ROUGE-2 and ROUGE-L (Lin, 2004), and +1.43 points advantage in METEOR (Denkowski and Lavie, 2014). In the reinforced setting, our 2-decoder model still maintains significant ($p < 0.001$)

---

[1] Our improvements in Table 1 are statistically significant with $p < 0.001$ (using bootstrapped randomization test with 100k samples (Efron and Tibshirani, 1994)) and have a 95% ROUGE-significance interval of at most ±0.25.

Pointer-Gen + closed-book decoder:
the kardashians are a strong example of a large celebrity family where the siblings share very different personality traits.
on asapscience on youtube , the pair discuss how being the first, middle, youngest, or an only child affects us.
the personality traits are also supposedly affected by whether parents have high expectations and how strict they were.

Figure 3: The summary generated by our 2-decoder model covers salient information (highlighted in red) mentioned in the reference summary, which is not presented in the baseline summary.

Model	Score
2-Decoder Wins	49
Pointer-Generator Wins	31
Non-distinguishable	20

Table 4: Human evaluation for our 2-decoder model versus the pointer-generator baseline.

advantage in all metrics over the pointer-generator baseline.

We further add the coverage mechanism as in See et al. (2017) to both baseline and 2-decoder model, and our 2-decoder model (pg + cbdec) again receives significantly higher[2] scores than the original pointer-generator (pg) from See et al. (2017) and our own pg baseline, in all ROUGE and METEOR metrics (see Table 2). In the reinforced setting, our 2-decoder model (RL + pg + cbdec) outperforms our strong RL baseline (RL + pg) by a considerable margin (stat. significance of $p < 0.001$). Fig. 1 and Fig. 3 show two examples of our 2-decoder model generating summaries that cover more salient information than those generated by the pointer-generator baseline (see supplementary materials for more example summaries).

We also evaluate our 2-decoder model with coverage on the DUC-2002 test-only generalizability/transfer setup by decoding the entire dataset with our models pre-trained on *CNN/Daily Mail*, again achieving decent improvements (shown in Table 3) over the single-decoder baseline as well as See et al. (2017), in both a cross-entropy and a reinforcement learning setup.

5.1 Human Evaluation

We also conducted a small-scale human evaluation study by randomly selecting 100 samples from the *CNN/DM* test set and then asking human annotators to rank the baseline summaries versus the 2-decoder's summaries (randomly shuffled to anonymize model identity) according to an overall score based on readability (grammar, fluency, coherence) and relevance (saliency, redundancy, correctness). As shown in Table 4, our 2-decoder model outperforms the pointer-generator baseline (stat. significance of $p < 0.03$).

6 Analysis

In this section, we present a series of analysis and tests in order to understand the improvements of the 2-decoder models reported in the previous section, and to prove that it fulfills our intuition that the closed-book decoder improves the encoder's ability to encode salient information in the memory state.

6.1 Memory Similarity Test

To verify our argument that the closed-book decoder improves the encoder's memory ability, we design a test to numerically evaluate the representation power of encoder's final memory state. We perform two forward passes for each encoder (2-decoder versus pointer-generator baseline). For the first pass, we feed the entire article to the encoder and collect the final memory state; for the second pass we feed the ground-truth summary to the encoder and collect the final memory state. Then we calculate the cosine similarity between these two memory-state vectors. For an optimal summarization model, its encoder's memory state after reading the entire article should be highly similar to its memory state after reading the ground truth summary (which contains all the important information), because this shows that when reading a long passage, the model is only encoding important information in its memory and

---

[2] All our improvements in Table 2 are statistically significant with $p < 0.001$, and have a 95% ROUGE-significance interval of at most ±0.25.

forgets the unimportant information. The results in Table 5 show that the encoder of our 2-decoder model achieves significantly ($p < 0.001$) higher article-summary similarity score than the encoder of a pointer-generator baseline. This observation verifies our hypothesis that the closed-book decoder can improve the memory ability of the encoder.

6.2 Ablation Studies and Sanity Check

Fixed-Encoder Ablation: Next, we conduct an ablation study in order to prove the qualitative superiority of our 2-decoder model's encoder to the baseline encoder. To do this, we train two pointer-generators with randomly initialized decoders and word embeddings. For the first model, we restore the pre-trained encoder from our pointer-generator baseline; for the second model, we restore the pre-trained encoder from our 2-decoder model. We then fix the encoder's parameters for both models during the training, only updating the embeddings and decoders with gradient descent. As shown in the upper half of Table 6, the pointer-generator with our 2-decoder model's encoder receives significantly higher ($p < 0.001$) scores in ROUGE than the pointer-generator with baseline's encoder. Since these two models have the exact same structure with only the encoders initialized according to different pre-trained models, the significant improvements in metric scores suggest that our 2-decoder model does have a stronger encoder than the pointer-generator baseline.

Gradient-Flow-Cut Ablation: We further design another ablation test to identify how the gradients from the closed-book decoder influence the entire model during training. Fig. 4 demonstrates the forward pass (solid line) and gradient flow (dashed line) between encoder, decoders, and embeddings in our 2-decoder model. As we can see, the closed-book decoder only depends on the word embeddings and encoder. Therefore it can affect the entire model during training by influencing either the encoder or the word-embedding matrix. When we stop the gradient flow between the encoder and closed-book decoder (① in Fig. 4), and keep the flow between closed-book decoder and embedding matrix (② in Fig. 4), we observe non-significant improvements in ROUGE compared to the baseline. On the other hand, when we stop the gradient flow at ② and keep ①, the improvements are statistically significant ($p < 0.01$) (see the lower half of Table 6). This proves that the gradients back-propagated from closed-book decoder to the encoder can strengthen the entire model, and hence verifies the gradient-flow intuition discussed in introduction (Sec. 1).

	ROUGE		
	1	2	L
FIXED-ENCODER ABLATION			
pg baseline's encoder	37.59	16.27	34.33
2-decoder's encoder	**38.44**	**16.85**	**35.17**
GRADIENT-FLOW-CUT ABLATION			
pg baseline	37.73	16.52	34.49
stop ①	37.72	16.58	34.54
stop ②	**38.35**	**16.79**	**35.13**

Table 6: ROUGE F1 scores of ablation studies, evaluated on *CNN/Daily Mail* validation set.

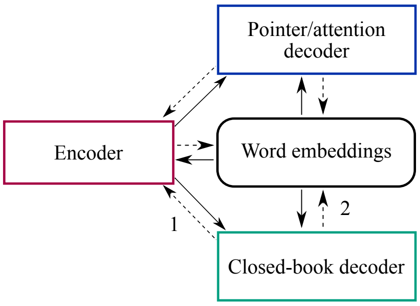

Figure 4: Solid lines represent the forward pass, and dashed lines represent the gradient flow in back-propagation. For the two ablation tests, we stop the gradient at ① and ② respectively.

Model Capacity: To validate and sanity-check that the improvements are the result of the inclusion of our closed-book decoder and not due to some trivial effects of having two decoders or larger model capacity (more parameters), we train a variant of our model with two duplicated (initialized to be different) attention-pointer decoders. We also evaluate a pointer-generator baseline with 2-layer encoder and decoder (pg-2layer) and increase the LSTM hidden dimension and word embedding dimension of the pointer-generator baseline (pg-big) to exceed the total number of parameters of our 2-decoder model (34.5M versus 34.4M parameters). Table 7 shows that neither of these variants can match our 2-decoder model in terms of ROUGE and METEOR scores, and hence proves that the improvements of our model are indeed because of the closed-book decoder rather than due to simply having more parameters.[3]

Mixed-loss Ratio Ablation: We also present eval-

---

[3] It is also important to point out that our model is not a 2-decoder ensemble, because we use only the pointer decoder during inference. Therefore, the number of parameters used for inference is the same as the pointer-generator baseline.

	ROUGE		
	1	2	L
pg baseline	37.73	16.52	34.49
pg + ptrdec	37.66	16.50	34.47
pg-2layer	37.92	16.48	34.62
pg-big	38.03	16.71	34.84
pg + cbdec	**38.87**	**16.93**	**35.38**

Table 7: ROUGE F1 and METEOR scores of sanity check ablations, evaluated on *CNN/DM* validation set.

	ROUGE		
	1	2	L
$\gamma = 0$	37.73	16.52	34.49
$\gamma = 1/2$	38.09	16.71	34.89
$\gamma = 2/3$	**38.87**	**16.93**	**35.38**
$\gamma = 5/6$	38.21	16.69	34.81
$\gamma = 10/11$	37.99	16.39	34.7

Table 8: ROUGE F1 scores on *CNN/DM* validation set, of 2-decoder models with different values of the closed-book-decoder:pointer-decoder mixed loss ratio.

uation results (on the *CNN/Daily Mail* validation set) of our 2-decoder models with different closed-book-decoder:pointer-decoder mixed-loss ratio (γ in Eqn. 2) in Table 8. The model achieves the best ROUGE and METEOR scores at $\gamma = \frac{2}{3}$. Comparing Table 8 with Table 5, we observe a similar trend between the increasing ROUGE/METEOR scores and increasing memory cosine-similarities, which suggests that the performance of a pointer-generator is strongly correlated with the representation power of the encoder's final memory state.

6.3 Saliency and Repetition

Finally, we show that our 2-decoder model can make use of this better encoder memory state to summarize more salient information from the source text, as well as to avoid generating unnecessarily lengthy and repeated sentences besides achieving significant improvements on ROUGE and METEOR metrics.

	saliency 1	saliency 2
pg (See17)	60.4%	27.95%
our pg baseline	59.6%	28.95%
pg + cbdec	62.1%	29.97%
RL + pg	62.5%	30.17%
RL + pg + cbdec	**66.2%**	**31.40%**

Table 9: Saliency scores based on *CNN/Daily Mail* cloze blank-filling task and a keyword-detection approach (Pasunuru and Bansal, 2018). All models in this table are trained with coverage loss.

	3-gram	4-gram	5-gram	sent
pg (baseline)	13.20%	12.32%	11.60%	8.39%
pg + cbdec	**9.66%**	**9.02%**	**8.55%**	**6.72%**

Table 10: Percentage of repeated 3, 4, 5-grams and sentences in generated summaries.

Saliency: To evaluate saliency, we design a keyword-matching test based on the original *CNN/Daily Mail* cloze blank-filling task (Hermann et al., 2015). Each news article in the dataset is marked with a few cloze-blank keywords that represent salient entities, including names, locations, etc. We count the number of keywords that appear in our generated summaries, and found that the output of our best teacher-forcing model (pg+cbdec with coverage) contains 62.1% of those keywords, while the output provided by See et al. (2017) has only 60.4% covered. Our reinforced 2-decoder model (RL + pg + cbdec) further increases this percentage to 66.2%. The full comparison is shown in the first column of Table 9. We also use the saliency metric in Pasunuru and Bansal (2018), which finds important words detected via a keyword classifier (trained on the SQuAD dataset (Rajpurkar et al., 2016)). The results are shown in the second column of Table 9. Both saliency tests again demonstrate our 2-decoder model's ability to memorize important information and address them properly in the generated summary. Fig. 1 and Fig. 3 show two examples of summaries generated by our 2-decoder model compared to baseline summaries.

Summary Length: On average, summaries generated by our 2-decoder model have 66.42 words per summary, while the pointer-generator-baseline summaries have 65.88 words per summary (and the same effect holds true for RL models, where there is less than 1-word difference in average length). This shows that our 2-decoder model is able to achieve higher saliency with similar-length summaries (i.e., it is not capturing more salient content simply by generating longer summaries).

Repetition: We observe that out 2-decoder model can generate summaries that are less redundant compared to the baseline, when both models are not trained with coverage mechanism. Table 10 shows the percentage of repeated n-grams/sentences in summaries generated by the pointer-generator baseline and our 2-decoder model.

Abstractiveness: Abstractiveness is another major challenge for current abstractive summarization models other than saliency. Since our baseline is an abstractive model, we measure the percentage of novel n-grams (n=2, 3, 4) in our generated summaries, and find that our 2-decoder model generates 1.8%, 4.8%, 7.6% novel n-grams while our baseline summaries have 1.6%, 4.4%, 7.1% on the same test set. Even though generating more abstractive summaries is not our focus in this paper, we still show that our improvements in metric and saliency scores are not obtained at the cost of making the model more extractive.

6.4 Discussion: Connection to Multi-Task Learning

Our 2-decoder model somewhat resembles a Multi-Task Learning (MTL) model, in that both try to improve the model with extra knowledge that is not available to the original single-task baseline. While our model uses MTL-style parameter sharing to introduce extra knowledge from the same dataset, traditional Multi-Task Learning usually employs additional/out-of-domain auxiliary tasks/datasets as related knowledge (e.g., translation with 2 language-pairs). Our 2-decoder model is more about how to learn to do a single task from two different points of view, as the pointer decoder is a hybrid of extractive and abstractive summarization models (primary view), and the closed-book decoder is trained for abstractive summarization only (auxiliary view). The two decoders share their encoder and embeddings, which helps enrich the encoder's final memory state representation.

Moreover, as shown in Sec. 6.2, our 2-decoder model (pg + cbdec) significantly outperforms the 2-duplicate-decoder model (pg + ptrdec) as well as single-decoder models with more layers/parameters, hence proving that our design of the auxiliary view (closed-book decoder doing abstractive summarization) is the reason behind the improved performance, rather than some simplistic effects of having a 2-decoder ensemble or higher #parameters.

7 Conclusion

We presented a 2-decoder sequence-to-sequence architecture for summarization with a closed-book decoder that helps the encoder to better memorize salient information from the source text. On *CNN/Daily Mail* dataset, our proposed model significantly outperforms the pointer-generator baselines in terms of ROUGE and METEOR scores (in both a cross-entropy (XE) setup and a reinforcement learning (RL) setup). It also achieves improvements in a test-only transfer setup on the DUC-2002 dataset in both XE and RL cases. We further showed that our 2-decoder model indeed has a stronger encoder with better memory capabilities, and can generate summaries with more salient information from the source text. To the best of our knowledge, this is the first work that studies the "representation power" of the encoders final state in an encoder-decoder model. Furthermore, our simple, insightful 2-decoder architecture can also be useful for other tasks that require long-term memory from the encoder, e.g., long-context QA/dialogue and captioning for long videos.

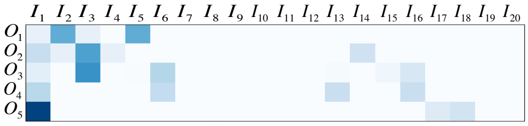
Abstract

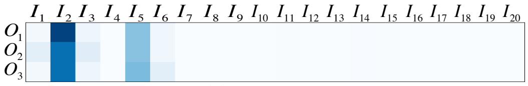
Recent neural sequence-to-sequence models have shown significant progress on short text summarization. However, for document summarization, they fail to capture the long-term structure of both documents and multi-sentence summaries, resulting in information loss and repetitions. In this paper, we propose to leverage the structural information of both documents and multi-sentence summaries to improve the document summarization performance. Specifically, we import both *structural-compression* and *structural-coverage* regularization into the summarization process in order to capture the information compression and information coverage properties, which are the two most important structural properties of document summarization. Experimental results demonstrate that the structural regularization improves the document summarization performance significantly, which enables our model to generate more informative and concise summaries, and thus significantly outperforms state-of-the-art neural abstractive methods.

1 Introduction

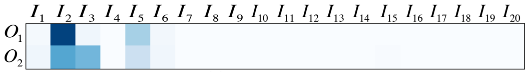
Document summarization is the task of generating a fluent and condensed summary for a document while retaining the gist information. Recent success of neural sequence-to-sequence (seq2seq) architecture on text generation tasks like machine translation (Bahdanau et al., 2014) and image caption (Vinyals et al., 2015), has attracted growing attention to abstractive summarization research. Huge success has been witnessed in abstractive sentence summarization (Rush et al., 2015; Takase et al., 2016; Chopra et al., 2016; Cao et al., 2017; Zhou et al., 2017), which builds one-sentence summaries from one or two-sentence input. However, the extension of sentence abstractive methods to document summarization task is not straightforward.



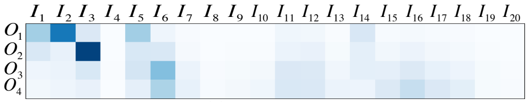
(a) Gold Reference



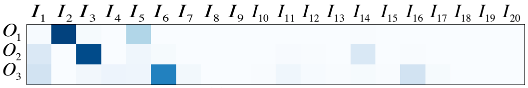
(b) Seq2Seq-baseline



(c) Point-gen-cov



(d) Hierarchical-baseline



(e) Our Method

Figure 1: Comparison of sentence-level attention distributions for the summaries in Table 1 on a news article. (a) is the heatmap for the gold reference summary, (b) is for the *Seq2seq-baseline* system, (c) is for the *Point-gen-cov* (See et al., 2017) system, (d) is for the *Hierarchical-baseline* system and (e) is for our system. I_i and O_i indicate the i-th sentence of the input and output, respectively. Obviously, the seq2seq models, including the *Seq2seq-baseline* model and the *Point-gen-cov* model, lose much salient information of the input document and focus on the same set of sentences repeatedly. The *Hierarchical-baseline* model fails to detect several specific sentences that are salient and relevant for each summary sentence and focuses on the same set of sentences repeatedly. On the contrary, our method with structural regularizations focuses on different sets of source sentences when generating different summary sentences and discovers more salient information from the document.

As long-distance dependencies are difficult to be captured in the recurrent framework (Bengio et al., 1994), the seq2seq models are not yet able to achieve convincing performance in encoding and decoding for a long sequence of multiple sentences (Chen et al., 2017; Koehn and Knowles,

Table 1: Comparison of the generated summaries of four abstractive summarization models and the gold reference summary on a news article. The summaries generated by the seq2seq models, both the Seq2seq-baseline model and the Point-cov model, lose some salient information. The Seq2seq-baseline model even contains serious information repetitions. The Hierarchical-baseline model not only contains serious repetitions, but also makes non-grammatical or non-coherent sentences. On the contrary, the summary generated by our model contains more salient information and is more concise. Our model also shows the ability to generate a summary sentence by compressing several source sentences, such as ~~shortening a long sentence~~.

2017). In document summarization, it is also difficult for the seq2seq models to discover important information from too much input content of a document (Tan et al., 2017a,b). The summary generated by the seq2seq models usually loses salient information of the original document or even contains repetitions (see Table 1).

In fact, both document and summary naturally have document-sentence hierarchical structure, instead of being a flat sequence of words. It is widely aware that the hierarchical structure is necessary and useful for neural document modeling. Hierarchical neural models have already been successfully used in document-level language modeling (Lin et al., 2015) and document classification (Yang et al., 2016). However, few work makes use of the hierarchical structure of document and multi-sentence summary in document summarization. The basic hierarchical encoder-decoder model (Li et al., 2015) is also not yet able to capture the structural properties of both document and summary (see Figure 1[1]), resulting in more serious repetitions and even nonsensical sentences (see Table 1).

In document summarization, information compression and information coverage are the two most important structural properties. Based on the hierarchical structure of document and summary, they can be realized at the sentence-level as: (1) *Structural-compression*: each summary sentence is generated by compressing several specific source sentences; (2) *Structural-coverage*: different summary sentences usually focus on different sets of source sentences to cover more salient information of the original document. Figure 1(a) intuitively shows the two properties in human-written gold reference summaries. We import both structural-compression and structural-coverage regularizations into the document summarization process based on a hierarchical encoder-decoder with hybrid sentence-word attention model. Typically, we design an effective learning and inference algorithm to explicitly model the structural-compression and structural-coverage properties of document summarization process, so as to generate more informative and concise summaries (see Table 1).

We conduct our experiments on benchmark datasets and the results demonstrate that properly modeling the *structural-compression* and *structural-coverage* properties based on the hier-

---

[1] To simulate the sentence-level attention mechanism on the gold reference summary, we compute the words-matching similarities (based on TF-IDF cosine similarity) between a reference-summary sentence and the corresponding source document sentences and normalize them into attention distributions. The sentence-level attention distributions of the Seq2seq-baseline model and the Point-gen-cov model are computed by summing the attention weights of all words in each sentence and then normalized across sentences.

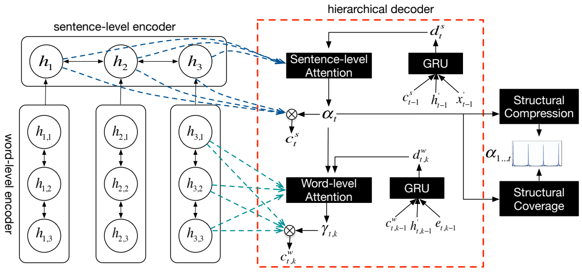

Figure 2: Our hierarchical encoder-decoder model with structural regularization for abstractive document summarization.

archical structure of document and summary, improves document summarization performance significantly. Our model is able to generate more informative and concise summaries by enhancing sentences compression and coverage, and significantly outperforms state-of-the-art seq2seq-based abstractive methods, especially on summarizing long documents with long summaries.

2 Hierarchical Encoder-Decoder Model

In this section, we introduce our baseline hierarchical encoder-decoder model which consists of two parts: a hierarchical encoder and a hierarchical decoder, as shown in Figure 2. Similar to (Li et al., 2015), both the encoder and decoder consists of two levels: a sentence level and a word level. The main distinction is that we design a hybrid sentence-word attention mechanism on the hierarchical decoder to help organize summary content and realize summary sentences.

2.1 Hierarchical Encoder

The goal of the encoder is to map the input document to a hidden vector representation. We consider a source document X as a sequence of sentences: $X = \{s_i\}$, and each sentence s_i as a sequence of words: $s_i = \{w_{ij}\}$. The word-level encoder encodes the words of a sentence into a sentence representation, and the sentence-level encoder encodes the sentences of a document into the document representation. In this work, both the word-level encoder and sentence-level encoder use the bidirectional Gated Recurrent Unit (BiGRU) (Chung et al., 2014). The word-level encoder sequentially updates its hidden state upon each received word, as $h_{i,j} = BiGRU(h_{i,j-1}, e_{i,j})$ where $h_{i,j}$ and $e_{i,j}$ denote the hidden state and the embedding of word $w_{i,j}$, respectively. The concatenation of the forward and backward final hidden states in the word-level encoder is indicated as the vector representation r_i of sentence s_i, which is used as input to the sentence-level encoder. The sentence-level encoder updates its hidden state after receiving each sentence representation, as $h_i = BiGRU(h_{i-1}, r_i)$ where h_i denotes the hidden state of sentence s_i. The concatenation of the forward and backward final states in the sentence-level encoder is used as the vector representation of document $\mathbf{d}$.

In the hierarchical encoder architecture, long dependency problem will be largely reduced at both the sentence level and the word level, so it can better capture the structural information of the input document.

2.2 Hierarchical Decoder with Hybrid Sentence-Word Attention

The goal of the decoder is to generate output summary according to the representation of the input document. Let $Y = \{s'_i\}$ indicates a candidate summary of document X, and each sentence s'_i consists of a sequence of words $s'_i = \{w'_{ij}\}$. The hierarchical decoder organizes summary Y sentence by sentence, and realizes each sentence word by word. In this work, both the sentence-level decoder and word-level decoder use a single layer of unidirectional GRU. The sentence-level decoder receives the document representation $\mathbf{d}$ as initial state h'_0 and predicts sentence representations sequentially by $h'_t = GRU(h'_{t-1}, r'_{t-1})$, where h'_t denotes the hidden state of the tth summary sentence s'_t and r'_{t-1} denotes the encoded representation of the previously generated sentence s'_{t-1}. The word-level decoder receives a sentence representation h'_t as initial state $h'_{t,0}$ and predicts word representations sequentially by $h'_{t,k} = GRU(h'_{t,k-1}, e_{t,k-1})$ where $h'_{t,k}$ denotes the hidden state of word $w'_{t,k}$ in sentence s'_t and $e_{t,k-1}$ denotes the embedding of previously generated word $w'_{t,k-1}$ in sentence s'_t.

In this work, we design a hybrid sentence-word attention mechanism based on the hierarchical encoder-decoder architecture, which contains both **sentence-level attention** and **word-level attention**, to better exploit both the sentence-level information and word-level information from the input document and the output summary.

2.2.1 Sentence-level Attention

The sentence-level attention mechanism is designed on the sentence-level encoder and decoder, which is used to help our model to detect important and relevant source sentences in each sentence generation step. α_t^i indicates how much the t-th summary sentence attends to the i-th source sentence, which is computed by $\alpha_t^i = e^{f(h_i,h'_t)}/\sum_l e^{f(h_l,h'_t)}$ where f is the function modeling the relation between h_i and h'_t. We use the function $f(\mathbf{a},\mathbf{b}) = v^T tanh(W_a\mathbf{a} + W_b\mathbf{b})$, where v, W_a, W_b are all learnable parameters. Then the sentence level context vector c_t^s when generating the tth sentence s'_t can be computed as: $c_t^s = \sum_i \alpha_t^i h_i$, which is incorporated into the sentence-level decoding process.

2.2.2 Word-level Attention with Sentence-level Normalization

The word-level attention is designed on the word-level encoder and decoder, which is used to help our model to realize the summary sentence by locating relevant words in the selected source sentences in each word generation step. Let $\beta_{t,k}^{i,j}$ denotes how much the j-th word in source sentence s_i contributes to generating the k-th word in summary sentence s'_t, which is computed by $\beta_{t,k}^{i,j} = e^{f(h_{i,j},h'_{t,k})}/\sum_l e^{f(h_{i,l},h'_{t,k})}$.

Since the word-level attention above is within each source sentence, we normalize it by sentence-level attentions to get word attention over all source words, as $\gamma_{t,k}^i = \beta_{t,k}^i \alpha_t^i$. Then the word-level context vector when generating word $w'_{t,k}$ can be computed as: $\mathbf{c}_{t,k}^w = \sum_i \sum_j \gamma_{t,k}^{i,j} h_{i,j}$, which is also incorporated into the word-level decoding process.

At each word generation step, the vocabulary distribution is calculated from the context vector $\mathbf{c}_{t,k}^w$ and the decoder state $h_{t,k}^{'}$ by:

$$P_{vocab}(w'_{t,k}) = softmax(W_v(W_c[h_{t,k}^{'}, c_{t,k}^w] + b_c) + b_v) \qquad (1)$$

where W_v, W_c, b_c and b_v are learned parameters. We also incorporate the copy mechanism (See et al., 2017) based on the normalized word-level attention to help generate out-of-vocabulary (OOV) words during the sentence realization process.

3 Structural Regularization

Although the above hierarchical encoder-decoder model is designed based on the document-sentence hierarchical structure, it can't capture the basic structural properties of document summarization (see Figure 1(d) and Table 1). However, the hierarchical architecture makes it possible for importing structural regularization to capture the sentence-level characteristics of document summarization process. In this work, we propose to model the *structural-compression* and *structural-coverage* properties based on the hierarchical encoder-decoder model by adding structural regularization during both the model learning phase and inference phase.

3.1 Structural Compression

Compression is a basic property of document summarization, which has been widely explored in traditional document summarization research, such as sentence compression-based methods which shorten sentences by removing non-salient parts (Li et al., 2013; Durrett et al., 2016) and sentence fusion-based methods which merge information from several different source sentences (Barzilay and McKeown, 2005; Cheung and Penn, 2014). As shown in Figure 1, each summary sentence in the human-written reference summary is also created by compressing several specific source sentences.

In this paper, we propose to model the *structural-compression* property of document summarization based on sentence-level attention distributions by:

$$strCom(\alpha_t) = 1 - \frac{1}{logN}\sum_{i=1}^{N} \alpha_t^i log\alpha_t^i \qquad (2)$$

where α_t denotes the sentence-level attention distribution when generating the tth summary sentence and N denotes the length of distribution α_t. The right part in the above formula is actually the entropy of the distribution α_t. As the attention distribution becomes sparser, the entropy of the distribution becomes lower, so the value of $strCom(\alpha_t)$ defined above will become larger. Sparse sentence-level attentions help the model compress and generalize several specific source sentences which are salient and relevant in the sentence generation process. Note that, $0 \leq strCom(\alpha_t) \leq 1$.

3.2 Structural Coverage

A good summary should have the ability to cover most of the important information of an input document. As shown in Figure 1, the human-written reference summary covers the information of many source sentences. Coverage has been used as a measure in many traditional document summarization research, such as the submodular-based methods which optimize the information coverage of the summary with similarity-based coverage metrics (Lin and Bilmes, 2011; Chali et al., 2017).

In this work, we simply model the *structural-coverage* property of summary based on the hierarchical architecture by encouraging different summary sentences to focus on different sets of source sentences so that the summary can cover more salient sentences of the input document. We measure the *structural-coverage* of summary based on the sentence-level attention distributions:

$$strCov(\alpha_t) = 1 - \sum_i \min(\alpha_t^i, \sum_{t'=0}^{t-1} \alpha_{t'}^i) \quad (3)$$

which is used to encourage different summary sentences to focus on different sets of source sentences during the summary generation process. As the sentence-level attention distributions of different summary sentences become more diversified, the summary will cover more source sentences, which is effective to improve the informativeness and conciseness of summaries. Note that, $0 \leq strCov(\alpha_t) \leq 1$.

3.3 Model Learning

Experimental results reveal that the properties of *structural-compression* and *structural-coverage* are hard to be captured by both the seq2seq models and the hierarchical encoder-decoder baseline model, which largely restricts their performance (Section 4). In this work, we model them explicitly by regulating the sentence-level attention distributions based on the hierarchical encoder-decoder framework. The loss function $\mathcal{L}$ of the model is the mix of negative log-likelihood of generating summaries over training set $\mathcal{T}$, the structural-compression loss and the structural-coverage loss:

$$\mathcal{L} = \sum_{(X,Y)\in\mathcal{T}} \{-logP(Y|X;\theta) + \underbrace{\lambda_1 \sum_t strCom(\alpha_t)}_{structural-compression\ loss} + \underbrace{\lambda_2 \sum_t strCov(\alpha_t)}_{structural-coverage\ loss} \} \quad (4)$$

where λ_1 and λ_2 are hyper-parameters tuned on the validation set. We use Adagrad (Duchi et al., 2011) with learning rate 0.1 and an initial accumulator value 0.1 to optimize the model parameters θ.

3.4 Hierarchical Decoding Algorithm

The traditional beam search algorithm that widely used for text generation can only help generate fluent sentence, and is not easy to extend to the sentence level. The reason is that the K-best sentences generated by a word decoder will mostly be similar to each other (Li et al., 2016; Tan et al., 2017a). We propose a hierarchical beam search algorithm with *structural-compression* and *structural-coverage* regularization.

The hierarchical decoding algorithm has two levels: K-best word-level beam search and N-best sentence-level beam search. At the word-level, the vanilla beam search algorithm is used to maximize the accumulated score $\hat{P}(s'_t)$ of generating current summary sentence s'_t. At the sentence-level, N-best beam search is realized by maximizing the accumulated score $score_t$ of all the sentences generated, including the sentences generation score, structural-compression score and structural-coverage score, which are defined as:

$$score_t = \sum_{t'=0}^{t} \{\hat{P}(s'_{t'}) + \zeta_1 strCom(\alpha_{t'}) + \zeta_2 strCov(\alpha_{t'})\} \quad (5)$$

where ζ_1 and ζ_2 are factors introduced to control the influence of structural regularization during the decoding process.

4 Experiments

4.1 Experimental Settings

We conduct our experiments on the *CNN/Daily Mail* dataset (Hermann et al., 2015), which has been widely used for exploration on summarizing documents with multi-sentence summaries (Nallapati et al., 2016; See et al., 2017; Tan et al., 2017a; Paulus et al., 2017). The CNN/DailyMail dataset contains input sequences of about 800 tokens in average and multi-sentence summaries of up to 200 tokens. The average number of sentences in documents and summaries are 42.1 and 3.8, respectively. We use the same version of non-anonymized data (the original text without pre-processing) as See et al. (2017), which has 287,226 training pairs, 13,368 validation pairs and 11,490 test pairs.

For all experiments, the word-level encoder and decoder both use 256-dimensional hidden states, and the sentence-level encoder and decoder both

use 512-dimensional hidden states. The dimension of word embeddings is 128, which is learned from scratch during training. We use a vocabulary of 50k words for both the encoder and decoder.

We trained our model on a single Tesla K40m GPU with a batch size of 16 and an epoch is set containing 10,000 randomly sampled documents. Convergence is reached within 300 epochs. After tuning on the validation set, parameters λ_1, λ_2, ζ_1 and ζ_2, are set as -0.5, -1.0, 1.2 and 1.4, respectively. At the test time, we use the hierarchical decoding algorithm with sentence-level beam size 4 and word-level beam size 8.

4.2 Evaluation

ROUGE Evaluation. We evaluate our models with the widely used ROUGE (Lin, 2004) toolkit. We compare our system's results with the results of state-of-the-art neural summarization approaches reported in recent papers, including both abstractive models and extractive models. The extractive models include **SummaRuNNer** (Nallapati et al., 2017) and **SummaRuNNer-abs** which is similar to SummaRuNNer but is trained directly on the abstractive summaries. The abstractive models include:

1) **Seq2seq-baseline**, which uses the basic seq2seq encoder-decoder architecture with attention mechanism, and incorporates with copy mechanism (See et al., 2017) to alleviate the OOV problem.
2) **ABS-temp-attn** (Nallapati et al., 2016), which uses *Temporal Attention* on the seq2seq architecture to overcome the repetition problem.
3) **Point-cov** (See et al., 2017), which is an extension of the Seq2seq-baseline model by importing word-coverage mechanism to reduce repetitions in summary.
4) **Graph-attention** (Tan et al., 2017a), which uses a graph-ranking based attention mechanism based on a hierarchical architecture to identify important sentences.
5) **Hierachical-baseline**, which just uses the basic hierarchical encoder-decoder with hybrid attention model proposed in this paper.

Results in Table 2 show that our model significantly outperforms all the neural abstractive baselines and extractive baselines. An interesting observation is that the performance of the **Hierarchical-baseline** model are lower than the **Seq2seq-baseline** model, which demonstrates the difficulty for a traditional model to identify the structural properties of document summarization process. Our model outperforms the **Hierarchical-baseline** model by more than 4 ROUGE points, which demonstrates that the structural regularization improves the document summarization performance significantly.

To verify the superiority of our model on generating long summaries, we also compare our method with the best seq2seq model **Point-cov** (See et al., 2017) by evaluating them on a test set w.r.t. different length of reference summaries. The results are shown in Table 3, which demonstrate that our model is better at generating long summary than the seq2seq model. As the summary becomes longer, our system will obtain larger advantages over the baseline (from +0.22 Rouge-1, +0.08 Rouge-2 and +0.39 Rouge-L for summary less than 100 words, rising to +5.00 Rouge-1, +0.54 Rouge-2 and +4.88 Rouge-L for summaries more than 150 words).

Human Evaluation. In addition to the ROUGE evaluation, we also conducted human evaluation on 50 random samples from CNN/DailyMail test set and compared the summaries generated by our method with the outputs of **Seq2seq-baseline** and **Point-cov** (See et al., 2017). Three data annotators were asked to compare the generated summaries

Method	Informat.	Concise	Coherent	Fluent
Seq2seq-b.	2.79*	2.52*	2.68*	3.57
Point-cov	3.17*	2.92*	3.00*	3.54
Our Model	3.67	3.39	3.51	3.70

Table 4: Human evaluation results. * indicates the difference between **Our Model** and other models are statistic significant ($p < 0.05$) by two-tailed t-test.

Method	R-1	R-2	R-L	strCom	strCov
Hierarchical-b.	34.95	14.79	32.68	0.22	0.31
+*strCom*	37.03	16.21	34.44	0.64	0.71
+*strCov*	39.52	17.12	36.44	0.65	0.87
+hierD	**40.30**	**18.02**	**37.36**	**0.68**	**0.93**

Table 5: Results of adding different components of our method in terms of ROUGE-1, ROUGE-2, ROUGE-L, strCom (Equation 1) and strCov (Equation 2) scores.

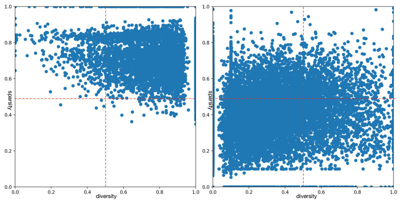
with the human summaries, and assess each summary from four independent perspectives: (1) **Informative**: How informative the summary is? (2) **Concise**: How concise the summary is? (3) **Coherent**: How coherent (between sentences) the summary is? (4) **Fluent**: How fluent, grammatical the sentences of a summary are? Each property is assessed with a score from 1(worst) to 5(best). The average results are presented in Table 4.

The results show that our model consistently outperforms the **Seq2seq-baseline** model and the previous state-of-the-art method **Point-cov**. As shown in Table 1, the summary generated by **Seq2Seq-Baseline** usually contains repetition of sentences or phrases, which seriously affects its informativeness, conciseness as well as coherence. The **Point-cov** model effectively alleviates the information repetition problem, however, it usually loses some salient information and mainly copies original sentences directly from the input document. The summaries generated by our method obviously contains more salient information and are more concise through sentences compression, which shows the effectiveness of the structural regularization in our model. The results also show that the sentence-level modeling of document and summary in our model makes the generated summaries achieve better inter-sentence coherence.

5 Discussion

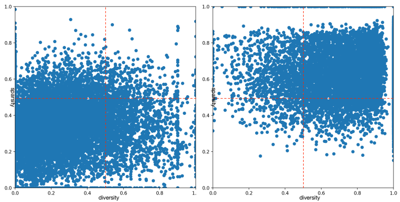
5.1 Model Validation

To verify the effectiveness of each component in our model, we conduct several ablation experiments. Based on the *Hierarchical-baseline* model, several different structural regularizations are added one by one: +*strCom* indicates adding structural-compression regularization during model learning, +*strCov* indicates adding structural-coverage regularization during model learning, +*hierD* indicates using the hierarchical decoding algorithm with both structural-compression and structural-coverage regularizations during inference.



(a) gold reference summary

(b) Seq2seq-baseline



(c) Hierarchical-baseline

(d) Our model with structural regularizations

Figure 3: Comparisons of structural-compression and structural-coverage analysis results on random samples from CNN/Daily Mail datasets, which demonstrate that both the Seq2seq-baseline model and the Hierarchical-baseline model are not yet able to capture them properly, but our model with structural regularizations achieves similar behavior with the gold reference summary.

Results on the test set are shown in Table 5. Our method much outperforms all the compared systems, which verifies the effectiveness of each component of our model. Note that, both the structural-compression and structural-coverage regularization significantly affect the summarization performance. The higher structural-compression and structural-coverage scores will lead to higher ROUGE scores. Therefore, we can conclude that the structural-compression and structural-coverage regularization based on our hierarchical model have significant contributions to the increase of ROUGE scores.

5.2 Structural Properties Analysis

We further compare the ability of different models in capturing the structural-compression and structural-coverage properties of document summarization. Figure 3 shows the comparison results of 4000 document-summary pairs with 14771 reference-summary sentences sampled from CNN/Daily Mail dataset. Figure 3(a) shows that most samples (over 95%) fall into the right-top area in human-made summaries, which indicates high structural-compression and structural-

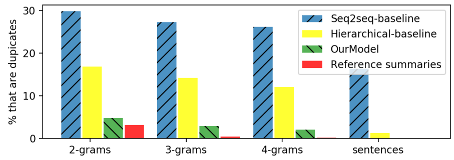


Figure 4: The structural regularization reduces undesirable repetitions while summaries from the Seq2seq-baseline and the Hierarchical-baseline contains many n-gram repetitions.

coverage scores. However, Figure 3 (b) and (c) show that in both the Seq2seq-baseline model and the Hierarchical-baseline model, most samples fall into the left-bottom area (low structural-compression and structural-coverage), and only about 13% and 7% samples fall into the right-top area, respectively. Figure 3 (d) shows that our system with structural regularization achieves similar behaviors to human-made summaries (over 80% samples fall into the right-top area). The results demonstrate that the structural-compression and structural-coverage properties are common in document summarization, but both the seq2seq models and the basic hierarchical encoder-decoder models are not yet able to capture them properly.

5.3 Effects of Structural Regularization

The structural regularization based on our hierarchical encoder-decoder with hybrid attention model improves the quality of summaries from two aspects: (1) The summary covers more salient information and contains very few repetitions, which can be seen both qualitatively (Table 1 and Figure 1) and quantitatively (Table 5 and Figure 4). (2) The model has the ability to shorten a long sentence to generate a more concise one or compress several different sentences to generate a more informative one by merging the information from them. Table 6 shows several examples of abstractive summaries produced by sentence compression in our model.

6 Related Work

Recently some work explored the seq2seq models on document summarization, which exhibit some undesirable behaviors, such as inaccurately reproducing factual details, OOVs and repetitions. To alleviate these issues, copying mechanism (Gu et al., 2016; Gulcehre et al., 2016; Nallapati et al., 2016) has been incorporated into the encoder-decoder architecture to help generate information correctly. Distraction-based attention model (Chen et al., 2016) and word-level coverage mechanism (See et al., 2017) have also been investigated to alleviate the repetition problem. Reinforcement learning has also been studied to improve the document summarization performance from global sequence level (Paulus et al., 2017).

Hierarchical Encoder-Decoder architecture is first proposed by Li et al. (2015) to train an auto-encoder to reconstruct multi-sentence paragraphs. In summarization field, hierarchical encoder has first been used to alleviate the long dependency problem for long inputs (Cheng and Lapata, 2016; Nallapati et al., 2016). Tan et al. (2017b) also propose to use a hierarchical encoder to encode multiple summaries produced by several extractive summarization methods, and then decode them into a headline. However, these models don't model the decoding process hierarchically.

Tan et al. (2017a) first use the hierarchical encoder-decoder architecture on generating multi-sentences summaries. They mainly focus on incorporating sentence ranking into abstractive document summarization to help detect important sentences. Different from that, our work mainly tends to verify the necessity of leveraging document structure in document summarization and studies how to properly capture the structural properties of document summarization based on the hierarchical architecture to improve the performance of document summarization.

7 Conclusions

In this paper we analyze and verify the necessity of leveraging document structure in document summarization, and explore the effectiveness of capturing structural properties of document summarization by importing both *structural-compression* and *structural-coverage* regularization based on the proposed hierarchical encoder-decoder with hybrid attention model. Experimental results demonstrate that the structural regularization enables our model to generate more informative and concise summaries by enhancing sentences compression and coverage. Our model achieves considerable improvement over state-of-the-art seq2seq-based abstractive methods, especially on long document with long summary.

Abstract

In this paper, we introduce Iterative Text Summarization (ITS), an iteration-based model for supervised extractive text summarization, inspired by the observation that it is often necessary for a human to read an article multiple times in order to fully understand and summarize its contents. Current summarization approaches read through a document only once to generate a document representation, resulting in a sub-optimal representation. To address this issue we introduce a model which iteratively polishes the document representation on many passes through the document. As part of our model, we also introduce a selective reading mechanism that decides more accurately the extent to which each sentence in the model should be updated. Experimental results on the CNN/DailyMail and DUC2002 datasets demonstrate that our model significantly outperforms state-of-the-art extractive systems when evaluated by machines and by humans.

1 Introduction

A summary is a shortened version of a text document which maintains the most important ideas from the original article. Automatic text summarization is a process by which a machine gleans the most important concepts from an article, removing secondary or redundant concepts. Nowadays as there is a growing need for storing and digesting large amounts of textual data, automatic summarization systems have significant usage potential in society.

Extractive summarization is a technique for generating summaries by directly choosing a subset of salient sentences from the original document to constitute the summary. Most efforts made towards extractive summarization either rely on human-engineered features such as sentence length, word position, and frequency (Cohen, 2002; Radev et al., 2004; Woodsend and Lapata, 2010; Yan et al., 2011a,b, 2012) or use neural networks to automatically learn features for sentence selection (Cheng and Lapata, 2016; Nallapati et al., 2016a).

Although existing extractive summarization methods have achieved great success, one limitation they share is that they generate the summary after only one pass through the document. However, in real-world human cognitive processes, people read a document multiple times in order to capture the main ideas. Browsing through the document only once often means the model cannot fully get at the document's main ideas, leading to a subpar summarization. We share two examples of this. (1) Consider the situation where we almost finish reading a long article and forget some main points in the beginning. We are likely to go back and review the part that we forget. (2) To write a good summary, we usually first browse through the document to obtain a general understanding of the article, then perform a more intensive reading to select salient points to include in the summary. In terms of model design, we believe that letting a model read through a document multiple times, polishing and updating its internal representation of the document can lead to better understanding and better summarization.

To achieve this, we design a model that we call Iterative Text Summarization (ITS) consisting of a novel "iteration mechanism" and "selective reading module". ITS is an iterative process, reading through the document many times. There is one encoder, one decoder, and one iterative unit in each iteration. They work together to polish document representation. The final labeling part uses outputs from all iterations to generate summaries. The selective reading module we design is a modi-

fied version of a Gated Recurrent Unit (GRU) network, which can decide how much of the hidden state of each sentence should be retained or updated based on its relationship with the document.

Overall, our contribution includes:

1. We propose Iterative Text Summarization (ITS), an iteration based summary generator which uses a sequence classifier to extract salient sentences from documents.
2. We introduce a novel iterative neural network model which repeatedly polishes the distributed representation of document instead of generating that once for all. Besides, we propose a selective reading mechanism, which decides how much information should be updated of each sentence based on its relationship with the polished document representation. Our entire architecture can be trained in an end-to-end fashion.
3. We evaluate our summarization model on representative CNN/DailyMail corpora and benchmark DUC2002 dataset. Experimental results demonstrate that our model outperforms state-of-the-art extractive systems when evaluated automatically and by human.

2 Related Work

Our research builds on previous works in two fields: summarization and iterative modeling.

Text summarization can be classified into extractive summarization and abstractive summarization. Extractive summarization aims to generate a summary by integrating the most salient sentences in the document. Abstractive summarization aims to generate new content that concisely paraphrases the document from scratch.

With the emergence of powerful neural network models for text processing, a vast majority of the literature on document summarization is dedicated to abstractive summarization. These models typically take the form of convolutional neural networks (CNN) or recurrent neural networks (RNN). For example, Rush et al. (2015) propose an encoder-decoder model which uses a local attention mechanism to generate summaries. Nallapati et al. (2016b) further develop this work by addressing problems that had not been adequately solved by the basic architecture, such as keyword modeling and capturing the hierarchy of sentence-to-word structures. In a follow-up work, Nallapati et al. (2017) propose a new summarization model which generates summaries by sampling a topic one sentence at a time, then producing words using an RNN decoder conditioned on the sentence topic. Another related work is by See et al. (2017), where the authors use “pointing” and “coverage” techniques to generate more accurate summaries.

Despite the focus on abstractive summarization, extractive summarization remains an attractive method as it is capable of generating more grammatically and semantically correct summaries. This is the method we follow in this work. In extractive summarization, Cheng and Lapata (2016) propose a general framework for single-document text summarization using a hierarchical article encoder composed with an attention-based extractor. Following this, Nallapati et al. (2016a) propose a simple RNN-based sequence classifier which outperforms or matches the state-of-art models at the time. In another approach, Narayan et al. (2018) use a reinforcement learning method to optimize the Rouge evaluation metric for text summarization. The most recent work on this topic is (Wu and Hu, 2018), where the authors train a reinforced neural extractive summarization model called RNES that captures cross-sentence coherence patterns. Due to the fact that they use a different dataset and have not released their code, we are unable to compare our models with theirs.

The idea of iteration has not been well explored for summarization. One related study is Xiong et al. (2016)’s work on dynamic memory networks, which designs neural networks with memory and attention mechanisms that exhibit certain reasoning capabilities required for question answering. Another related work is (Yan, 2016), where they generate poetry with iterative polishing sn chema. Similiar method can also be applied on couplet generation as in (Yan et al., 2016). We take some inspiration from their work but focus on document summarization. Another related work is (Singh et al., 2017), where the authors present a deep network called Hybrid MemNet for the single document summarization task, using a memory network as the document encoder. Compared to them, we do not borrow the memory network structure but propose a new iterative architecture.

3 Methodology

3.1 Problem Formulation

In this work, we propose Iterative Text Summarization (ITS), an iteration-based supervised model for extractive text summarization. We treat the extractive summarization task as a sequence labeling problem, in which each sentence is visited sequentially and a binary label that determines whether or not it will be included in the final summary is generated.

ITS takes as input a list of sentences $s = \{s_1, \ldots, s_{n_s}\}$, where n_s is the number of sentences in the document. Each sentence s_i is a list of words: $s_i = \{w_1^i, \ldots, w_{n_w}^i\}$, where n_w is the word length of the sentence. The goal of ITS is to generate a score vector $\boldsymbol{y} = \{y_1, \ldots, y_{n_s}\}$ for each sentence, where each score $y_i \in [0, 1]$ denotes the sentence's *extracting probability*, that is, the probability that the corresponding sentence s_i will be extracted to be included in the summary. We train our model in a supervised manner, using a corresponding gold summary written by human experts for each document in training set. We use an unsupervised method to convert the human-written summaries to gold label vector $\boldsymbol{y'} = \{y'_1, ..., y'_{n_s}\}$, where $y'_i \in \{0, 1\}$ denotes whether the i-th sentence is selected (1) or not (0). Next, during training process, the cross entropy loss is calculated between $\boldsymbol{y}$ and $\boldsymbol{y'}$, which is minimized to optimize $\boldsymbol{y}$. Finally, we select three sentences with the highest score according to $\boldsymbol{y}$ to be the extracted summary. We detail our model below.

3.2 Model Architecture

ITS is depicted in Fig.1. It consists of multiple iterations with one encoder, one decoder, and one iteration unit in each iteration. We combine the outputs of decoders in all iterations to generate the extracting probabilities in the final labeling module.

Our encoder is illustrated in the shaded region in the left half of Fig.1. It takes as input all sentences as well as the document representation from the previous unit $\boldsymbol{D_{k-1}}$, processes them through several neural networks, and outputs the final state to the iterative unit module which updates the document representation.

Our decoder takes the form of a bidirectional RNN. It takes the representation of sentence generated by the encoder as input, and its initial state is the polished document representation $\boldsymbol{D_k}$. Our last module, the sentence labeling module, concatenates the hidden states of all decoders together to generate an integrated score for each sentence.

As we apply supervised training, the objective is to maximize the likelihood of all sentence labels $y' = \{y'_1, ..., y'_{n_s}\}$ given the input document s and model parameters θ:

$$\log p(y'|s;\theta) = \sum_{i=1}^{n_s} \log p(y'_i|s;\theta) \qquad (1)$$

4 Our Model

4.1 Encoder

In this subsection, we describe the encoding process of our model. For brevity, we drop the superscript k when focusing on a particular layer. All the $\boldsymbol{W}$'s and $\boldsymbol{b}$'s in this section with different superscripts or subscripts are the parameters to be learned.

Sentence Encoder: Given a discrete set of sentences $s = \{s_1, \ldots, s_{n_s}\}$, we use a word embedding matrix $\boldsymbol{M} \in \mathbb{R}^{V \times D}$ to embed each word w^i in sentence s_i into continuous space $\boldsymbol{\hat{w}^i}$, where V is the vocabulary size, D is the dimension of word embedding.

The sentence encoder can be based on a variety of encoding schemes. Simply taking the average of embeddings of words in a sentence will cause too much information loss, while using GRUs or Long Short-Term Memory (LSTM) requires more computational resources and is prone to overfitting. Considering above, we select *positional encoding* described in (Sukhbaatar et al., 2015) as our sentence encoding method. Each sentence representation $\boldsymbol{\hat{s}_i}$ is calculated by $\boldsymbol{\hat{s}_i} = \sum_{j=1}^{n_w} \boldsymbol{l_j} \circ \boldsymbol{\hat{w}_j^i}$, where $\circ$ is element-wise multiplication, $\boldsymbol{l_j}$ is a column vector computed as $l_{j,d} = (1 - \frac{j}{n_w}) - (\frac{d}{D})(1 - \frac{2j}{n_w})$, $l_{j,d}$ denotes the d-th dimension of $\boldsymbol{l_j}$.

Note that throughout this study, we use GRUs as our RNN cells since they can alleviate the overfitting problem as confirmed by our experiments. As our selective reading mechanism (which will be explained later) is a modified version of original GRU cell, we give the details of the GRU here. GRU is a gating mechanism in recurrent neural networks, introduced in (Cho et al., 2014). Their performance was found to be similar to that of LSTM cell but using fewer parameters as described in (Hochreiter and Schmidhuber, 1997). The GRU cell consists of an update gate vector

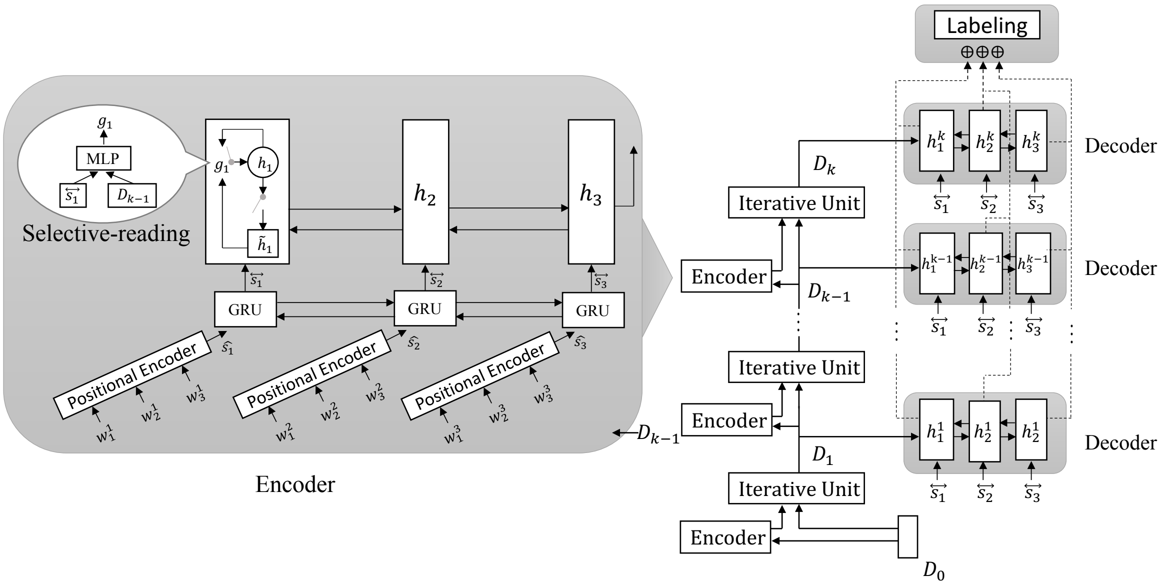

Figure 1: Model Structure: There is one encoder, one decoder and one iterative unit (which is used to polish document representation) in each iteration. The final labeling part is used to generating the extracting probabilities for all sentences combining hidden states of decoders in all iterations. We take a document consists of three sentences for example here.

$\boldsymbol{u_i}$, a reset gate vector $\boldsymbol{r_i}$, and an output vector $\boldsymbol{h_i}$. For each time step i with input $\boldsymbol{x_i}$ and previous hidden state $\boldsymbol{h_{i-1}}$, the updated hidden state $\boldsymbol{h_i} = \mathrm{GRU}(\boldsymbol{x_i}, \boldsymbol{h_{i-1}})$ is computed by:

$$\boldsymbol{u_i} = \sigma(\boldsymbol{W^{(u)}}\boldsymbol{x_i} + \boldsymbol{U^{(u)}}\boldsymbol{h_{i-1}} + \boldsymbol{b^{(u)}}) \quad (2)$$

$$\boldsymbol{r_i} = \sigma(\boldsymbol{W^{(r)}}\boldsymbol{x_i} + \boldsymbol{U^{(r)}}\boldsymbol{h_{i-1}} + \boldsymbol{b^{(r)}}) \quad (3)$$

$$\tilde{\boldsymbol{h_i}} = \tanh(\boldsymbol{W^{(h)}}\boldsymbol{x_i} + \boldsymbol{r_i} \circ \boldsymbol{U}\boldsymbol{h_{i-1}} + \boldsymbol{b^{(h)}}) \quad (4)$$

$$\boldsymbol{h_i} = \boldsymbol{u_i} \circ \tilde{\boldsymbol{h_i}} + (1 - \boldsymbol{u_i}) \circ \boldsymbol{h_{i-1}} \quad (5)$$

where σ is the sigmoid activation function, $\boldsymbol{W^{(u)}}, \boldsymbol{W^{(r)}}, \boldsymbol{W^{(h)}} \in \mathbb{R}^{n_H \times n_I}, \boldsymbol{U^{(u)}}, \boldsymbol{U^{(r)}}, \boldsymbol{U} \in \mathbb{R}^{n_H \times n_H}, n_H$ is the hidden size, n_I is the size of input $\boldsymbol{x_i}$.

To further study the interactions and information exchanges between sentences, we establish a Bi-directional GRU (Bi-GRU) network taking the sentence representation as input:

$$\overrightarrow{\boldsymbol{s_i}} = \mathrm{GRU}_{\mathrm{fwd}}(\hat{\boldsymbol{s}}_{\boldsymbol{i}}, \overrightarrow{\boldsymbol{s_{i-1}}}) \quad (6)$$

$$\overleftarrow{\boldsymbol{s_i}} = \mathrm{GRU}_{\mathrm{bwd}}(\hat{\boldsymbol{s}}_{\boldsymbol{i}}, \overleftarrow{\boldsymbol{s_{i-1}}}) \quad (7)$$

$$\overleftrightarrow{\boldsymbol{s_i}} = \overrightarrow{\boldsymbol{s_i}} + \overleftarrow{\boldsymbol{s_i}} \quad (8)$$

where $\hat{\boldsymbol{s}}_{\boldsymbol{i}}$ is the sentence representation input at time step i, $\overrightarrow{\boldsymbol{s_i}}$ is the hidden state of the forward GRU at time step i, and $\overleftarrow{\boldsymbol{s_i}}$ is the hidden state of the backward GRU. This architecture allows information to flow back and forth to generate new sentence representation $\overleftrightarrow{\boldsymbol{s_i}}$.

Document Encoder: We must initialize a document representation before polishing it. Generating the document representation from sentence representations is a process similar to generating the sentence representation from word embeddings. This time we need to compress the whole document, not just a sentence, into a vector. Because the information a vector can contain is limited, rather than to use another neural network, we simply use a non-linear transformation of the average pooling of the concatenated hidden states of the above Bi-GRU to generate the document representation, as written below:

$$\boldsymbol{D_0} = \tanh(\boldsymbol{W}\frac{1}{n_s}\sum_{i=1}^{n_s}[\overrightarrow{\boldsymbol{s_i}}; \overleftarrow{\boldsymbol{s_i}}] + \boldsymbol{b}) \quad (9)$$

where '[·;·]' is the concatenation operation.

Selective Reading module: Now we can formally introduce the selective reading module in Fig.1. This module is a bidirectional RNN consisting of modified GRU cells whose input is the sentence representation $\overleftrightarrow{\boldsymbol{s}} = \{\overleftrightarrow{\boldsymbol{s_1}}, ..., \overleftrightarrow{\boldsymbol{s_{n_s}}}\}$. In the original version of GRU, the update gate $\boldsymbol{u_i}$ in Equation 2 is used to decide how much of hidden state should be retained and how much should be updated. However, due to the way $\boldsymbol{u_i}$ is calculated, it is sensitive to the position and ordering of sentences, but loses information captured by the polished document representation.

Herein, we propose a modified GRU cell that replace the $\boldsymbol{u_i}$ with the newly computed update gate $\boldsymbol{g_i}$. The new cell takes in two inputs, the sentence representation and the document representation from the last iteration, rather than merely the sentence representation. For each sentence, the selective network generates an update gate vector $\boldsymbol{g_i}$ in the following way:

$$\boldsymbol{f_i} = [\overleftrightarrow{\boldsymbol{s_i}} \circ \boldsymbol{D_{k-1}}; \overleftrightarrow{\boldsymbol{s_i}}; \boldsymbol{D_{k-1}}] \tag{10}$$

$$\boldsymbol{F_i} = \boldsymbol{W^{(2)}}\text{tanh}(\boldsymbol{W^{(1)}}\boldsymbol{f_i} + \boldsymbol{b^{(1)}}) + \boldsymbol{b^{(2)}} \tag{11}$$

$$\boldsymbol{g_i} = \frac{\exp(\boldsymbol{F_i})}{\sum_{j=1}^{n_s}\exp(\boldsymbol{F_j})} \tag{12}$$

where $\overleftrightarrow{\boldsymbol{s_i}}$ is the i-th sentence representation, $\boldsymbol{D_{k-1}}$ is the document representation from last iteration. Equation 5 now becomes:

$$\boldsymbol{h_i} = \boldsymbol{g_i} \circ \tilde{\boldsymbol{h_i}} + (1 - \boldsymbol{g_i}) \circ \boldsymbol{h_{i-1}} \tag{13}$$

We use this “selective reading module” to automatically decide to which extent the information of each sentence should be updated based on its relationship with the polished document. In this way, the modified GRU network can grasp more accurate information from the document.

4.2 Iterative Unit

After each sentence passes through the selective reading module, we wish to update the document representation $\boldsymbol{D_{k-1}}$ with the newly constructed sentence representations. The iterative unit (also depicted above in Fig.1) is designed for this purpose. We use a GRU$_{\text{iter}}$ cell to generate the polished document representation, whose input is the final state of the selective reading network from the previous iteration, $\boldsymbol{h_{n_s}}$ and whose initial state is set to the document representation of the previous iteration, $\boldsymbol{D_{k-1}}$. The updated document representation is computed by:

$$\boldsymbol{D_k} = \text{GRU}_{\text{iter}}(\boldsymbol{h_{n_s}}, \boldsymbol{D_{k-1}}) \tag{14}$$

4.3 Decoder

Next, we describe our decoders, which are depicted shaded in the right part of Fig.1. Following most sequence labeling task (Xue and Palmer, 2004; Carreras and Màrquez, 2005) where they learn a feature vector for each sentence, we use a bidirectional GRU$_{\text{dec}}$ network in each iteration to output features so as to calculate extracting probabilities. For k-th iteration, given the sentence representation $\overleftrightarrow{\boldsymbol{s}}$ as input and the document representation $\boldsymbol{D_k}$ as the initial state, our decoder encodes the features of all sentences in the hidden state $\boldsymbol{h^k} = \{\boldsymbol{h_0^k}, ..., \boldsymbol{h_{n_s}^k}\}$:

$$\boldsymbol{h_i^k} = \text{GRU}_{\text{dec}}(\overleftrightarrow{\boldsymbol{s}}, \boldsymbol{h_{i-1}^k}) \tag{15}$$

$$\boldsymbol{h_0^k} = \boldsymbol{D_k} \tag{16}$$

4.4 Sentence Labeling Module

Next, we use the feature of each sentence to generate corresponding extracting probability. Since we have one decoder in each iteration, if we directly transform the hidden states in each iteration to extracting probabilities, we will end up with several scores for each sentence. Either taking the average or summing them together by specific weights is inappropriate and inelegant. Hence, we concatenate hidden states of all decoders together and apply a multi-layer perceptron to them to generate the extracting probabilities:

$$\boldsymbol{y} = \boldsymbol{W^{(4)}}\text{tanh}(\boldsymbol{W^{(3)}}[\boldsymbol{h^1}; ...; \boldsymbol{h^k}] + \boldsymbol{b^{(3)}}) + \boldsymbol{b^{(4)}} \tag{17}$$

where $\boldsymbol{y} = \{y_1, ..., y_{n_s}\}$, y_i is the extracting probability for each setence. In this way, we let the model learn by itself how to utilize the outputs of all iterations and assign to each hidden state a reliable weight. In section 6, we will show that this labeling method outperforms other methods.

5 Experiment Setup

In this section, we present our experimental setup for training and estimating our summarization model. We first introduce the datasets used for training and evaluation, and then introduce our experimental details and evaluation protocol.

5.1 Datasets

In order to make a fair comparison with our baselines, we used the CNN/Dailymail corpus which was constructed by Hermann et al. (2015). We used the standard splits for training, validation and testing in each corpus (90,266/1,220/1,093 documents for CNN and 196,557/12,147/10,396 for DailyMail). We followed previous studies in using the human-written story highlight in each article as a gold-standard abstractive summary. These highlights were used to generate gold labels when training and testing our model using the greedy search method similar to (Nallapati et al., 2016a).

We also tested ITS on an out-of-domain corpus, DUC2002, which consists of 567 documents. Documents in this corpus belong to 59 various clusters and each cluster has a unique topic. Each document has two gold summaries written by human experts of length around 100 words.

5.2 Implementation Details

We implemented our model in Tensorflow (Abadi et al., 2016). The code for our models is available online[1]. We mostly followed the settings in (Nallapati et al., 2016a) and trained the model using the Adam optimizer (Kingma and Ba, 2014) with initial learning rate 0.001 and anneals of 0.5 every 6 epochs until reaching 30 epochs. We selected three sentences with highest scores as summary. After preliminary exploration, we found that arranging them according to their scores consistently achieved the best performance. Experiments were performed with a batch size of 64 documents. We used 100-dimension GloVe (Pennington et al., 2014) embeddings trained on Wikipedia 2014 as our embedding initialization with a vocabulary size limited to 100k for speed purposes. We initialized out-of-vocabulary word embeddings over a uniform distribution within [-0.2,0,2]. We also padded or cut sentences to contain exactly 70 words. Each GRU module had 1 layer with 200-dimensional hidden states and with either an initial state set up as described above or a random initial state. To prevent overfitting, we used dropout after each GRU network and embedding layer, and also applied L2 loss to all unbiased variables. The iteration number was set to 5 if not specified. A detailed discussion about iteration number can be found in section 7.

5.3 Baselines

On all datasets we used the Lead-3 method as a baseline, which simply chooses the first three sentences in a document as the gold summary. On DailyMail datasets, we report the performance of SummaRuNNer in (Nallapati et al., 2016a) and the model in (Cheng and Lapata, 2016), as well as a logistic regression classifier (LReg) that they used as a baseline. We reimplemented the Hybrid MemNet model in (Singh et al., 2017) as one of our baselines since they only reported the performance of 500 samples in their paper. Also, Narayan et al. (2018) released their code[2] for the REFRESH model, we used their code to produce Rouge recall scores on the DailyMail dataset as they only reported results on CNN/DailyMail joint dataset. Baselines on CNN dataset are similar. On DUC2002 corpus, we compare our model with several baselines such as Integer Linear Programming (ILR) and LReg. We also report the performance of the newest neural networks model including (Nallapati et al., 2016a; Cheng and Lapata, 2016; Singh et al., 2017).

5.4 Evaluation

In the evaluation procedure, we used the Rouge scores, i.e. Rouge-1, Rouge-2, and Rouge-L, corresponding to the matches of unigram, bigrams, and Longest Common Subsequence (LCS) respectively, to estimate our model. We obtained our Rouge scores using the standard pyrouge package[3]. To compare with other related works, we used full-length F1 score on the CNN corpus, limited length of 75 bytes and 275 bytes recall score on DailyMail corpus. As for the DUC2002 corpus, following the official guidelines, we examined the Rouge recall score at the length of 75 words. All results in our experiment are statistically significant using 95% confidence interval as estimated by Rouge script.

Schluter (2017) noted that only using the Rouge metric to evaluate summarization quality can be misleading. Therefore, we also evaluated our model using human evaluation. Five highly educated participants were asked to rank 40 summaries produced by four models: the Lead-3 baseline, Hybrid MemNet, ITS, and human-authored highlights. We chose Hybrid MemNet as one of the human evaluation baselines since its performance is relatively high compared to other baselines. Judging criteria included informativeness and coherence. Test cases were randomly sampled from DailyMail test set.

6 Experiment analysis

Table 1 shows the performance comparison of our model with other baselines on the DailyMail dataset with respect to Rouge score at 75 bytes and 275 bytes of summary length. Our model performs consistently and significantly better than other models on 75 bytes, while on 275 bytes, the improvement margin is smaller. One possible interpretation is that our model has high precision on top rank outputs, but the accuracy is lower for lower rank sentences. In addition, (Cheng and Lapata, 2016) used additional supervised training

to create sentence-level extractive labels to train their model, while our model uses an unsupervised greedy approximation instead.

We also examined the performance of our model on CNN dataset as listed in Table 2. To compare with other models, we used full-length Rouge F1 metric as reported by Narayan et al. (2018). Results demonstrate that our model has a consistently best performance on different datasets.

In Table 3, we present the performance of ITS on the out of domain DUC dataset. Our model outperforms or matches other basic models including LReg and ILR as well as neural network baselines such as SummaRuNNer with respect to the ground truth at 75 bytes, which shows that our model can be adapted to different copora maintaining high accuracy.

In order to explore the impact of internal structure of ITS, we also conducted an ablation study in Table 4. The first variation is the same model without the selective reading module. The second one sets the iteration number to one, that is, a model without iteration process. The last variation is to apply MLP on the output from the last iteration instead of concatenating the hidden states of all decoders. All other settings and parameters are the same. Performances of these models are worse than that of ITS in all metrics, which demonstrates the preeminence of ITS. More importantly, by this controlled experiment, we can verify the contribution of different module in ITS.

7 Further discussion

Analysis of iteration number: We did a broad sweep of experiments to further investigate the influence of iteration process on the generated summary quality. First, we studied the influence of iteration number. In order to make a fair comparison between models with different iteration number, we trained all models for same epochs without tuning. Fig.2 illustrates the relationship between iteration number and the Rouge score at 75 bytes of summary length on DailyMail test dataset. The result shows that the Rouge score increases with the number of iteration to begin with. After reaching the upper limit it begins to drop. Note that

Models	1st	2nd	3rd	4th
Lead-3	0.12	0.11	0.25	**0.52**
Hybrid MemNet	0.24	0.25	**0.28**	0.23
ITS	0.31	**0.34**	0.23	0.12
Gold	**0.33**	0.30	0.24	0.13

Table 5: System ranking comparison with other baselines on DailyMail corpus. Rank 1 is the best and Rank 4 is the worst. Each score represents the percentage of the summary under this rank.

the result of training the model for only one epoch outperforms the state-of-the-art in (Singh et al., 2017), which demonstrates that our selective reading module is effective. The fact that continuing this process increase the performance confirms that the iteration idea behind our model is useful in practice. Based on above observation, we set the default iteration number to be 5.

Analysis of polishing process: Next, to fully investigate how the iterative process influences the extracting results, we draw heatmaps of the extracting probabilities for each decoder at each iteration. We pick two representative cases in Fig.3, where the x-axis represents the sentence index and y-axis is the iteration number, x-axis labels are omitted. The darker the color is, the higher the extracting probability is. In Fig.3(a), it can be seen that when the iteration begins, most sentences have similar probabilities. As we increase the number of iteration, some probabilities begin to fall and others saturate. This means that the model already has preferred sentences to select. Another interesting feature we found is that there is a transitivity between iterations as shown in Fig.3(b). To be specific, the sentences which are not preferred by iteration 3 remain low probabilities in the next two iterations, while sentences with relatively high scores are still preferred by iteration 4 and 5.

Human Evaluation: We gave human evaluators three system-generated summaries, generated by Lead-3, Hybrid MemNet, ITS, as well as the human-written gold standard summary, and asked them to rank these summaries based on summary informativeness and coherence. Table 5 shows the percentages of summaries of different models under each rank scored by human experts. It is not surprising that gold standard has the most summaries of the highest quality. Our model has the most summaries under 2nd rank, thus can be considered 2nd best, following are Hybrid MemNet and Lead-3, as they are ranked mostly 3rd and 4th. By case study, we found that a number of summaries generated by Hybrid MemNet have two sentences the same as ITS out of three, however, the third distinct sentence from our model always leads to a better evaluation result considering overall informativeness and coherence. Readers can refer to the appendix to see our case study.

8 Conclusion

In this work, we introduce ITS, an iteration based extractive summarization model, inspired by the observation that it is often necessary for a human to read the article multiple times to fully understand and summarize it. Experimental results on CNN/DailyMail and DUC corpora demonstrate the effectiveness of our model.

Bottom-Up Abstractive Summarization

Abstract

Neural network-based methods for abstractive summarization produce outputs that are more fluent than other techniques, but which can be poor at content selection. This work proposes a simple technique for addressing this issue: use a data-efficient content selector to over-determine phrases in a source document that should be part of the summary. We use this selector as a *bottom-up* attention step to constrain the model to likely phrases. We show that this approach improves the ability to compress text, while still generating fluent summaries. This two-step process is both simpler and higher performing than other end-to-end content selection models, leading to significant improvements on ROUGE for both the CNN-DM and NYT corpus. Furthermore, the content selector can be trained with as little as 1,000 sentences, making it easy to transfer a trained summarizer to a new domain.

1 Introduction

Text summarization systems aim to generate natural language summaries that compress the information in a longer text. Approaches using neural networks have shown promising results on this task with end-to-end models that encode a source document and then decode it into an abstractive summary. Current state-of-the-art neural abstractive summarization models combine extractive and abstractive techniques by using pointer-generator style models which can copy words from the source document (Gu et al., 2016; See et al., 2017). These end-to-end models produce fluent abstractive summaries but have had mixed success in content selection, i.e. deciding what to summarize, compared to fully extractive models.

There is an appeal to end-to-end models from a modeling perspective; however, there is evidence that when summarizing people follow a two-step approach of first selecting important phrases and then paraphrasing them (Anderson and Hidi, 1988; Jing and McKeown, 1999). A similar argument has been made for image captioning. Anderson et al. (2017) develop a state-of-the-art model with a two-step approach that first pre-computes bounding boxes of segmented objects and then applies attention to these regions. This so-called *bottom-up* attention is inspired by neuroscience research describing attention based on properties in-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4098–4109
Brussels, Belgium, October 31 - November 4, 2018.

herent to a stimulus (Buschman and Miller, 2007).

Motivated by this approach, we consider *bottom-up* attention for neural abstractive summarization. Our approach first selects a selection mask for the source document and then constrains a standard neural model by this mask. This approach can better decide which phrases a model should include in a summary, without sacrificing the fluency advantages of neural abstractive summarizers. Furthermore, it requires much fewer data to train, which makes it more adaptable to new domains.

Our full model incorporates a separate content selection system to decide on relevant aspects of the source document. We frame this selection task as a sequence-tagging problem, with the objective of identifying tokens from a document that are part of its summary. We show that a content selection model that builds on contextual word embeddings (Peters et al., 2018) can identify correct tokens with a recall of over 60%, and a precision of over 50%. To incorporate bottom-up attention into abstractive summarization models, we employ masking to constrain copying words to the selected parts of the text, which produces grammatical outputs. We additionally experiment with multiple methods to incorporate similar constraints into the training process of more complex end-to-end abstractive summarization models, either through multi-task learning or through directly incorporating a fully differentiable mask.

Our experiments compare bottom-up attention with several other state-of-the-art abstractive systems. Compared to our baseline models of See et al. (2017) bottom-up attention leads to an improvement in ROUGE-L score on the CNN-Daily Mail (CNN-DM) corpus from 36.4 to 38.3 while being simpler to train. We also see comparable or better results than recent reinforcement-learning based methods with our MLE trained system. Furthermore, we find that the content selection model is very data-efficient and can be trained with less than 1% of the original training data. This provides opportunities for domain-transfer and low-resource summarization. We show that a summarization model trained on CNN-DM and evaluated on the NYT corpus can be improved by over 5 points in ROUGE-L with a content selector trained on only 1,000 in-domain sentences.

2 Related Work

There is a tension in document summarization between staying close to the source document and allowing compressive or abstractive modification. Many non-neural systems take a select and compress approach. For example, Dorr et al. (2003) introduced a system that first extracts noun and verb phrases from the first sentence of a news article and uses an iterative shortening algorithm to compress it. Recent systems such as Durrett et al. (2016) also learn a model to select sentences and then compress them.

In contrast, recent work in neural network based data-driven extractive summarization has focused on extracting and ordering full sentences (Cheng and Lapata, 2016; Dlikman and Last, 2016). Nallapati et al. (2016b) use a classifier to determine whether to include a sentence and a selector that ranks the positively classified ones. These methods often over-extract, but extraction at a word level requires maintaining grammatically correct output (Cheng and Lapata, 2016), which is difficult. Interestingly, key phrase extraction while ungrammatical often matches closely in content with human-generated summaries (Bui et al., 2016).

A third approach is neural abstractive summarization with sequence-to-sequence models (Sutskever et al., 2014; Bahdanau et al., 2014). These methods have been applied to tasks such as headline generation (Rush et al., 2015) and article summarization (Nallapati et al., 2016a). Chopra et al. (2016) show that attention approaches that are more specific to summarization can further improve the performance of models. Gu et al. (2016) were the first to show that a copy mechanism, introduced by Vinyals et al. (2015), can combine the advantages of both extractive and abstractive summarization by copying words from the source. See et al. (2017) refine this pointer-generator approach and use an additional coverage mechanism (Tu et al., 2016) that makes a model aware of its attention history to prevent repeated attention.

Most recently, reinforcement learning (RL) approaches that optimize objectives for summarization other than maximum likelihood have been shown to further improve performance on these tasks (Paulus et al., 2017; Li et al., 2018b; Celikyilmaz et al., 2018). Paulus et al. (2017) approach the coverage problem with an intra-attention in which a decoder has an attention over previously generated words. However RL-based training can be difficult to tune and slow to train. Our method does not utilize RL training, although in theory this approach can be adapted to RL methods.

Several papers also explore multi-pass extractive-abstractive summarization. Nallapati et al. (2017) create a new source document comprised of the important sentences from the source and then train an abstractive system. Liu et al. (2018) describe an extractive phase that extracts full paragraphs and an abstractive one that determines their order. Finally Zeng et al. (2016) introduce a mechanism that reads a source document in two passes and uses the information from the first pass to bias the second. Our method differs in that we utilize a completely abstractive model, biased with a powerful content selector.

Other recent work explores alternative approaches to content selection. For example, Cohan et al. (2018) use a hierarchical attention to detect relevant sections in a document, Li et al. (2018a) generate a set of keywords that is used to guide the summarization process, and Pasunuru and Bansal (2018) develop a loss-function based on whether salient keywords are included in a summary. Other approaches investigate the content-selection at the sentence-level. Tan et al. (2017) describe a graph-based attention to attend to one sentence at a time, Chen and Bansal (2018) first extract full sentences from a document and then compress them, and Hsu et al. (2018) modulate the attention based on how likely a sentence is included in a summary.

3 Background: Neural Summarization

Throughout this paper, we consider a set of pairs of texts $(\mathcal{X}, \mathcal{Y})$ where $x \in \mathcal{X}$ corresponds to source tokens $x_1, \ldots, x_n$ and $y \in \mathcal{Y}$ to a summary $y_1, \ldots, y_m$ with $m \ll n$.

Abstractive summaries are generated one word at a time. At every time-step, a model is aware of the previously generated words. The problem is to learn a function $f(x)$ parametrized by θ that maximizes the probability of generating the correct sequences. Following previous work, we model the abstractive summarization with an attentional sequence-to-sequence model. The attention distribution $p(a_j|x, y_{1:j-1})$ for a decoding step j, calculated within the neural network, represents an embedded soft distribution over all of the source tokens and can be interpreted as the current focus of the model.

The model additionally has a copy mechanism (Vinyals et al., 2015) to copy words from the source. Copy models extend the decoder by predicting a binary soft switch z_j that determines whether the model copies or generates. The copy distribution is a probability distribution over the source text, and the joint distribution is computed as a convex combination of the two parts of the model,

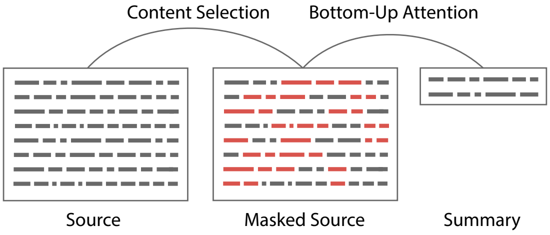

Figure 2: Overview of the selection and generation processes described throughout Section 4.

$$\begin{aligned} &p(y_j \mid y_{1:j\text{-}1}, x) = \\ &p(z_j = 1 \mid y_{1:j\text{-}1}, x) \times p(y_j \mid z_j = 1, y_{1:j\text{-}1}, x) + \\ &p(z_j = 0 \mid y_{1:j\text{-}1}, x) \times p(y_j \mid z_j = 0, y_{1:j\text{-}1}, x) \end{aligned} \tag{1}$$

where the two parts represent copy and generation distribution respectively. Following the *pointer-generator* model of See et al. (2017), we reuse the attention $p(a_j|x, y_{1:j-1})$ distribution as copy distribution, i.e. the copy probability of a token in the source w through the copy attention is computed as the sum of attention towards all occurrences of w. During training, we maximize marginal likelihood with the latent switch variable.

4 Bottom-Up Attention

We next consider techniques for incorporating a content selection into abstractive summarization, illustrated in Figure 2.

4.1 Content Selection

We define the content selection problem as a word-level extractive summarization task. While there has been significant work on custom extractive summarization (see related work), we make a simplifying assumption and treat it as a sequence tagging problem. Let $t_1, \ldots, t_n$ denote binary tags for each of the source tokens, i.e. 1 if a word is copied in the target sequence and 0 otherwise.

While there is no supervised data for this task, we can generate training data by aligning the summaries to the document. We define a word x_i as copied if (1) it is part of the longest possible subsequence of tokens $s = x_{i-j:i:i+k}$, for integers $j \leq i; k \leq (n-i)$, if $s \in x$ and $s \in y$, and (2) there exists no earlier sequence u with $s = u$.

We use a standard bidirectional LSTM model trained with maximum likelihood for the sequence labeling problem. Recent results have shown that better word representations can lead to significantly improved performance in sequence tagging tasks (Peters et al., 2017). Therefore, we first map each token w_i into two embedding channels $e_i^{(\mathrm{w})}$ and $e_i^{(\mathrm{c})}$. The $e^{(\mathrm{w})}$ embedding represents a static channel of pre-trained word embeddings, e.g. GLoVE (Pennington et al., 2014). The $e^{(\mathrm{c})}$ are contextual embeddings from a pretrained language model, e.g. ELMo (Peters et al., 2018) which uses a character-aware token embedding (Kim et al., 2016) followed by two bidirectional LSTM layers $h_i^{(1)}$ and $h_i^{(2)}$. The contextual embeddings are fine-tuned to learn a task-specific embedding $e_i^{(\mathrm{c})}$ as a linear combination of the states of each LSTM layer and the token embedding,

$$e_i^{(\mathrm{c})} = \gamma \times \sum_{\ell=0}^{2} s_j \times h_i^{(\ell)},$$

with γ and $s_{0,1,2}$ as trainable parameters. Since these embeddings only add four additional parameters to the tagger, it remains very data-efficient despite the high-dimensional embedding space.

Both embeddings are concatenated into a single vector that is used as input to a bidirectional LSTM, which computes a representation h_i for a word w_i. We can then calculate the probability q_i that the word is selected as $\sigma(W_s h_i + b_s)$ with trainable parameters W_s and b_s.

4.2 Bottom-Up Copy Attention

Inspired by work in bottom-up attention for images (Anderson et al., 2017) which restricts attention to predetermined bounding boxes within an image, we use these attention masks to limit the available selection of the pointer-generator model.

As shown in Figure 1, a common mistake made by neural copy models is copying very long sequences or even whole sentences. In the baseline model, over 50% of copied tokens are part of copy sequences that are longer than 10 tokens, whereas this number is only 10% for reference summaries. While bottom-up attention could also be used to modify the source encoder representations, we found that a standard encoder over the full text was effective at aggregation and therefore limit the bottom-up step to attention masking.

Concretely, we first train a pointer-generator model on the full dataset as well as the content selector defined above. At inference time, to generate the mask, the content selector computes selection probabilities $q_{1:n}$ for each token in a source document. The selection probabilities are used to modify the copy attention distribution to only include tokens identified by the selector. Let a_j^i denote the attention at decoding step j to encoder word i. Given a threshold ϵ, the selection is applied as a hard mask, such that

$$p(\tilde{a}_j^i | x, y_{1:j-1}) = \begin{cases} p(a_j^i | x, y_{1:j-1}) & q_i > \epsilon \\ 0 & \text{ow.} \end{cases}$$

To ensure that Eq. 1 still yields a correct probability distribution, we first multiply $p(\tilde{a}_j | x, y_{1:j-1})$ by a normalization parameter λ and then renormalize the distribution. The resulting normalized distribution can be used to directly replace a as the new copy probabilities.

4.3 End-to-End Alternatives

Two-step BOTTOM-UP attention has the advantage of training simplicity. In theory, though, standard copy attention should be able to learn how to perform content selection as part of the end-to-end training. We consider several other end-to-end approaches for incorporating content selection into neural training.

Method 1: (MASK ONLY): We first consider whether the alignment used in the bottom-up approach could help a standard summarization system. Inspired by Nallapati et al. (2017), we investigate whether aligning the summary and the source during training and fixing the gold copy attention to pick the "correct" source word is beneficial. We can think of this approach as limiting the set of possible copies to a fixed source word. Here the training is changed, but no mask is used at test time.

Method 2 (MULTI-TASK): Next, we investigate whether the content selector can be trained alongside the abstractive system. We first test this hypothesis by posing summarization as a multi-task problem and training the tagger and summarization model with the same features. For this setup, we use a shared encoder for both abstractive summarization and content selection. At test time, we apply the same masking method as bottom-up attention.

Method 3 (DIFFMASK): Finally we consider training the full system end-to-end with the mask during training. Here we jointly optimize both objectives, but use predicted selection probabilities to softly mask the copy attention $p(\tilde{a}_j^i|x, y_{1:j-1}) = p(a_j^i|x, y_{1:j-1}) \times q_i$, which leads to a fully differentiable model. This model is used with the same soft mask at test time.

5 Inference

Several authors have noted that longer-form neural generation still has significant issues with incorrect length and repeated words than in short-form problems like translation. Proposed solutions include modifying models with extensions such as a coverage mechanism (Tu et al., 2016; See et al., 2017) or intra-sentence attention (Cheng et al., 2016; Paulus et al., 2017). We instead stick to the theme of modifying inference, and modify the scoring function to include a length penalty lp and a coverage penalty cp, and is defined as $s(x, y) = \log p(y|x)/lp(x) + cp(x; y)$.

Length: To encourage the generation of longer sequences, we apply length normalizations during beam search. We use the length penalty by Wu et al. (2016), which is formulated as

$$lp(y) = \frac{(5 + |y|)^\alpha}{(5 + 1)^\alpha},$$

with a tunable parameter α, where increasing α leads to longer summaries. We additionally set a minimum length based on the training data.

Repeats: Copy models often repeatedly attend to the same source tokens, generating the same phrase multiple times. We introduce a new summary specific coverage penalty,

$$cp(x; y) = \beta \left(-n + \sum_{i=1}^{n} \max\left(1.0, \sum_{j=1}^{m} a_i^j\right)\right).$$

Intuitively, this penalty increases whenever the decoder directs more than 1.0 of total attention within a sequence towards a single encoded token. By selecting a sufficiently high β, this penalty blocks summaries whenever they would lead to repetitions. Additionally, we follow (Paulus et al., 2017) and restrict the beam search to never repeat trigrams.

6 Data and Experiments

We evaluate our approach on the CNN-DM corpus (Hermann et al., 2015; Nallapati et al., 2016a), and the NYT corpus (Sandhaus, 2008), which are both standard corpora for news summarization. The summaries for the CNN-DM corpus are bullet points for the articles shown on their respective websites, whereas the NYT corpus contains summaries written by library scientists. CNN-DM summaries are full sentences, with on average 66 tokens ($\sigma = 26$) and 4.9 bullet points. NYT summaries are not always complete sentences and are shorter, with on average 40 tokens ($\sigma = 27$) and 1.9 bullet points. Recent work has used both the anonymized and the non-anonymized versions of on CNN-DM, so direct comparison can be difficult. Following See et al. (2017), we use the non-anonymized version of this corpus and truncate source documents to 400 tokens and the target summaries to 100 tokens in training and validation sets. For experiments with the NYT corpus, we use the preprocessing described by Paulus et al. (2017), and additionally remove author information and truncate source documents to 400 tokens instead of 800. These changes lead to an average of 326 tokens per article, a decrease from the 549 tokens with 800 token truncated articles. The target (non-copy) vocabulary is limited to 50,000 tokens for all models.

The content selection model uses pre-trained GloVe embeddings of size 100, and ELMo with size 1024. The bi-LSTM has two layers and a hidden size of 256. Dropout is set to 0.5, and the model is trained with Adagrad, an initial learning rate of 0.15, and an initial accumulator value of 0.1. We limit the number of training examples to 100,000 on either corpus, which only has a small impact on performance. For the jointly trained content selection models, we use the same configuration as the abstractive model.

For the base model, we re-implemented the Pointer-Generator model as described by See et al. (2017). To have a comparable number of parameters to previous work, we use an encoder with 256 hidden states for both directions in the one-layer LSTM, and 512 for the one-layer decoder. The embedding size is set to 128. We found that increasing model size or changing the model to the Transformer (Vaswani et al., 2017) can lead to slightly improved performance, but at the cost of increased training time and parameters. The

Method	R-1	R-2	R-L
Pointer-Generator (See et al., 2017)	36.44	15.66	33.42
Pointer-Generator + Coverage (See et al., 2017)	39.53	17.28	36.38
ML + Intra-Attention (Paulus et al., 2017)	38.30	14.81	35.49
ML + RL (Paulus et al., 2017)	39.87	15.82	36.90
Saliency + Entailment reward (Pasunuru and Bansal, 2018)	40.43	18.00	37.10
Key information guide network (Li et al., 2018a)	38.95	17.12	35.68
Inconsistency loss (Hsu et al., 2018)	40.68	17.97	37.13
Sentence Rewriting (Chen and Bansal, 2018)	40.88	17.80	**38.54**
Pointer-Generator (our implementation)	36.25	16.17	33.41
Pointer-Generator + Coverage Penalty	39.12	17.35	36.12
Pointer-Generator + Mask Only	37.70	15.63	35.49
Pointer-Generator + Multi-Task	37.67	15.59	35.47
Pointer-Generator + DiffMask	38.45	16.88	35.81
Bottom-Up Summarization	**41.22**	**18.68**	38.34

Table 1: Results of abstractive summarizers on the CNN-DM dataset.[2] The first section shows encoder-decoder abstractive baselines trained with cross-entropy. The second section describes reinforcement-learning based approaches. The third section presents our baselines and the attention masking methods described in this work.

model is trained with the same Adagrad configuration as the content selector. Additionally, the learning rate halves after each epoch once the validation perplexity does not decrease after an epoch. We do not use dropout and use gradient-clipping with a maximum norm of 2.

All inference parameters are tuned on a 200 sentence subset of the validation set. Length penalty parameter α and copy mask ϵ differ across models and baselines, with α ranging from 0.6 to 1.4, and ϵ ranging from 0.1 to 0.2. The minimum length of the generated summary is set to 35 for CNN-DM and 6 for NYT. While the Pointer-Generator uses a beam size of 5 and does not improve with a larger beam, we found that bottom-up attention requires a larger beam size and set it to 10. The coverage penalty parameter β is set to 10, and the copy attention normalization parameter λ to 2 for both approaches.

We use AllenNLP (Gardner et al., 2018) for the content selector, and the abstractive models are implemented in OpenNMT-py (Klein et al., 2017).[3].

7 Results

Table 1 shows our main results on the CNN-DM corpus, with abstractive models shown in the top, and bottom-up attention methods at the bottom. We first observe that using a coverage inference penalty scores the same as a full coverage mechanism, without requiring any additional model parameters. We found that none of our end-to-end models lead to improvements, indicating that it is difficult to apply the masking during training without hurting the training process. The *Mask Only* model with increased supervision on the copy mechanism performs very similar to the *Multi-Task* model. On the other hand, bottom-up attention leads to a major improvement across all three scores. While we would expect better content selection to primarily improve ROUGE-1, the fact all three increase hints that the fluency is not being hurt specifically. Our cross-entropy trained approach even outperforms all of the reinforcement-learning based approaches in ROUGE-1 and 2, while the highest reported ROUGE-L score by Chen and Bansal (2018) falls within the 95% confidence interval of our results.

Table 2 shows experiments with the same systems on the NYT corpus. We see that the 2 point improvement compared to the baseline Pointer-Generator maximum-likelihood approach carries over to this dataset. Here, the model outperforms

[3] These results compare on the non-anonymized version of this corpus used by (See et al., 2017). The best results on the anonymized version are R1:41.69 R2:19.47 RL:37.92 from (Celikyilmaz et al., 2018). We compare to their DCA model on the NYT corpus.

Method	R-1	R-2	R-L
ML*	44.26	27.43	40.41
ML+RL*	47.03	30.72	**43.10**
DCA[†]	**48.08**	31.19	42.33
Point.Gen. + Coverage Pen.	45.13	30.13	39.67
Bottom-Up Summarization	47.38	**31.23**	41.81

Table 2: Results on the NYT corpus, where we compare to RL trained models. * marks models and results by Paulus et al. (2017), and † results by Celikyilmaz et al. (2018).

the RL based model by Paulus et al. (2017) in ROUGE-1 and 2, but not L, and is comparable to the results of (Celikyilmaz et al., 2018) except for ROUGE-L. The same can be observed when comparing ML and our Pointer-Generator. We suspect that a difference in summary lengths due to our inference parameter choices leads to this difference, but did not have access to their models or summaries to investigate this claim. This shows that a bottom-up approach achieves competitive results even to models that are trained on summary-specific objectives.

The main benefit of bottom-up summarization seems to be from the reduction of mistakenly copied words. With the best Pointer-Generator models, the precision of copied words is 50.0% compared to the reference. This precision increases to 52.8%, which mostly drives the increase in R1. An independent-samples t-test shows that this improvement is statistically significant with t=14.7 ($p < 10^{-5}$). We also observe a decrease in average sentence length of summaries from 13 to 12 words when adding content selection compared to the Pointer-Generator while holding all other inference parameters constant.

Domain Transfer While end-to-end training has become common, there are benefits to a two-step method. Since the content selector only needs to solve a binary tagging problem with pretrained vectors, it performs well even with very limited training data. As shown in Figure 3, with only 1,000 sentences, the model achieves an AUC of over 74. Beyond that size, the AUC of the model increases only slightly with increasing training data.

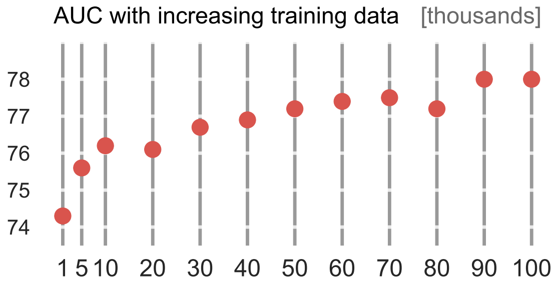

Figure 3: The AUC of the content selector trained on CNN-DM with different training set sizes ranging from 1,000 to 100,000 data points.

	AUC	R-1	R-2	R-L
CNNDM		25.63	11.40	20.55
+1k	80.7	30.62	16.10	25.32
+10k	83.6	32.07	17.60	26.75
+100k	86.6	33.11	18.57	27.69

Table 3: Results of the domain transfer experiment. AUC numbers are shown for content selectors. ROUGE scores represent an abstractive model trained on CNN-DM and evaluated on NYT, with additional copy constraints trained on 1/10/100k training examples of the NYT corpus.

To further evaluate the content selection, we consider an application to domain transfer. In this experiment, we apply the Pointer-Generator trained on CNN-DM to the NYT corpus. In addition, we train three content selectors on 1, 10, and 100 thousand sentences of the NYT set, and use these in the bottom-up summarization. The results, shown in Table 3, demonstrates that even a model trained on the smallest subset leads to an improvement of almost 5 points over the model without bottom-up attention. This improvement increases with the larger subsets to up to 7 points. While this approach does not reach a comparable performance to models trained directly on the NYT dataset, it still represents a significant increase over the not-augmented CNN-DM model and produces summaries that are quite readable. We show two example summaries in Appendix A. This technique could be used for low-resource domains and for problems with limited data availability.

8 Analysis and Discussion

Extractive Summary by Content Selection? Given that the content selector is effective in conjunction with the abstractive model, it is interesting to know whether it has learned an effective extractive summarization system on its own. Table 4 shows experiments comparing content selec-

Method	R-1	R-2	R-L
LEAD-3	40.1	17.5	36.3
NEUSUM (Zhou et al., 2018)	41.6	19.0	38.0
Top-3 sents (Cont. Select.)	40.7	**18.0**	37.0
Oracle Phrase-Selector	67.2	37.8	58.2
Content Selector	**42.0**	15.9	**37.3**

Table 4: Results of extractive approaches on the CNN-DM dataset. The first section shows sentence-extractive scores. The second section first shows an oracle score if the content selector selected all the correct words according to our matching heuristic. Finally, we show results when the Content Selector extracts all phrases above a selection probability threshold.

tion to extractive baselines. The LEAD-3 baseline is a commonly used baseline in news summarization that extracts the first three sentences from an article. Top-3 shows the performance when we extract the top three sentences by average copy probability from the selector. Interestingly, with this method, only 7.1% of the top three sentences are not within the first three, further reinforcing the strength of the LEAD-3 baseline. Our naive sentence-extractor performs slightly worse than the highest reported extractive score by Zhou et al. (2018) that is specifically trained to score combinations of sentences. The final entry shows the performance when all the words above a threshold are extracted such that the resulting summaries are approximately the length of reference summaries. The oracle score represents the results if our model had a perfect accuracy, and shows that the content selector, while yielding competitive results, has room for further improvements in future work.

This result shows that the model is quite effective at finding important words (ROUGE-1) but less effective at chaining them together (ROUGE-2). Similar to Paulus et al. (2017), we find that the decrease in ROUGE-2 indicates a lack of fluency and grammaticality of the generated summaries. A typical example looks like this:

> a man food his first hamburger wrongfully for 36 years. michael hanline, 69, was convicted of murder for the shooting of truck driver jt mcgarry in 1980 on judge charges.

This particular ungrammatical example has a ROUGE-1 of 29.3. This further highlights the benefit of the combined approach where bottom-up predictions are chained together fluently by the abstractive system. However, we also note that the abstractive system requires access to the full source document. Distillation experiments in which we tried to use the output of the content-selection as training-input to abstractive models showed a drastic decrease in model performance.

Data	%Novel	Verb	Noun	Adj
Reference	14.8	30.9	35.5	12.3
Vanilla S2S	6.6	14.5	19.7	5.1
Pointer-Generator	2.2	25.7	39.3	13.9
Bottom-Up Attention	0.5	53.3	24.8	6.5

Table 5: %Novel shows the percentage of words in a summary that are not in the source document. The last three columns show the part-of-speech tag distribution of the novel words in generated summaries.

Analysis of Copying While Pointer-Generator models have the ability to abstract in summary, the use of a copy mechanism causes the summaries to be mostly extractive. Table 5 shows that with copying the percentage of generated words that are not in the source document decreases from 6.6% to 2.2%, while reference summaries are much more abstractive with 14.8% novel words. Bottom-up attention leads to a further reduction to only a half percent. However, since generated summaries are typically not longer than 40-50 words, the difference between an abstractive system with and without bottom-up attention is less than one novel word per summary. This shows that the benefit of abstractive models has been less in their ability to produce better paraphrasing but more in the ability to create fluent summaries from a mostly extractive process.

Table 5 also shows the part-of-speech-tags of the novel generated words, and we can observe an interesting effect. Application of bottom-up attention leads to a sharp decrease in novel adjectives and nouns, whereas the fraction of novel words that are verbs sharply increases. When looking at the novel verbs that are being generated, we notice a very high percentage of tense or number changes, indicated by variation of the word "say", for example "said" or "says", while novel nouns are mostly morphological variants of words in the source.

Figure 4 shows the length of the phrases that are being copied. While most copied phrases in the

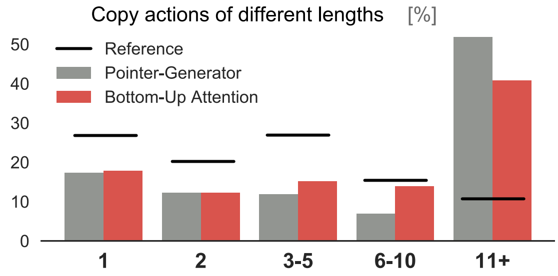

Figure 4: For all copied words, we show the distribution over the length of copied phrases they are part of. The black lines indicate the reference summaries, and the bars the summaries with and without bottom-up attention.

reference summaries are in groups of 1 to 5 words, the Pointer-Generator copies many very long sequences and full sentences of over 11 words. Since the content selection mask interrupts most long copy sequences, the model has to either generate the unselected words using only the generation probability or use a different word instead. While we observed both cases quite frequently in generated summaries, the fraction of very long copied phrases decreases. However, either with or without bottom-up attention, the distribution of the length of copied phrases is still quite different from the reference.

Inference Penalty Analysis We next analyze the effect of the inference-time loss functions. Table 6 presents the marginal improvements over the simple Pointer-Generator when adding one penalty at a time. We observe that all three penalties improve all three scores, even when added on top of the other two. This further indicates that the unmodified Pointer-Generator model has already learned an appropriate representation of the abstractive summarization problem, but is limited by ineffective content selection and inference methods.

9 Conclusion

This work presents a simple but accurate content selection model for summarization that identifies phrases within a document that are likely included in its summary. We showed that this content selector can be used for a bottom-up attention that restricts the ability of abstractive summarizers to copy words from the source. The combined bottom-up summarization system leads to improvements in ROUGE scores of over two points on both the CNN-DM and NYT corpora. A comparison to end-to-end trained methods showed that this particular problem cannot be easily solved with a single model, but instead requires fine-tuned inference restrictions. Finally, we showed that this technique, due to its data-efficiency, can be used to adjust a trained model with few data points, making it easy to transfer to a new domain. Preliminary work that investigates similar bottom-up approaches in other domains that require a content selection, such as grammar correction, or data-to-text generation, have shown some promise and will be investigated in future work.

Data	R-1	R-2	R-L
Pointer Generator	36.3	16.2	33.4
+ Length Penalty	38.0	16.8	35.0
+ Coverage Penalty	38.9	17.2	35.9
+ Trigram Repeat	39.1	17.4	36.1

A Domain Transfer Examples

We present two generated summaries for the CNN-DM to NYT domain transfer experiment in Table 7. S2S refers to a Pointer-Generator with Coverage Penalty trained on CNN-DM that scores 20.6 ROUGE-L on the NYT dataset. The content-selection improves this to 27.7 ROUGE-L without any fine-tuning of the S2S model.

Controlling Length in Abstractive Summarization Using a Convolutional Neural Network

Abstract

Convolutional neural networks (CNNs) have met great success in abstractive summarization, but they cannot effectively generate summaries of desired lengths. Because generated summaries are used in difference scenarios which may have space or length constraints, the ability to control the summary length in abstractive summarization is an important problem. In this paper, we propose an approach to constrain the summary length by extending a convolutional sequence to sequence model. The results show that this approach generates high-quality summaries with user defined length, and outperforms the baselines consistently in terms of ROUGE score, length variations and semantic similarity.

1 Introduction

Great progress (Rush et al., 2015; Chopra et al., 2016; Nallapati et al., 2016; See et al., 2017; Paulus et al., 2017) has been made recently on abstractive summarization. Many use sequence-to-sequence model based on RNN and attention mechanism (Rush et al., 2015), which was originally used for machine translation (Sutskever et al., 2014; Bahdanau et al., 2014). Recently, Gehring et al. (2017) proposed a convolutional sequence to sequence model equipped with Gated Linear Units (Dauphin et al., 2017), residual connections (He et al., 2016) and attention mechanism. Such a convolutional model achieves state-of-the-art accuracies in abstractive summarization on single sentence summarization, and it is much faster than the previous recurrent models as it can be easily parallelized. Furthermore, unlike recurrent models, the convoluational model has more stable gradients because of its backpropagation path.

Constraining summary length, while largely neglected in the past, is actually an important aspect of abstractive summarization. For example, given the same input document, if the summary is to be displayed on mobile devices, or within a fixed area of advertisement slot on a website, we may want to produce a much shorter summary. Unfortunately, most existing abstractive summarization models are not trained to react to summary length constraints. When the constraint is given at test time, the current practice is **i)** to truncate the generated summary after N tokens are generated when you want the summaries of length no more than N, and **ii)** ignore EOS (end of summary) token until the first M tokens are generated when you want the summaries of length at least M. Such a crude way of controlling summary length makes the output summary incomplete or incoherent.

Previous research on controlling length of abstractive summary has been scarce. Fan et al. (2017), who applies convolutional sequence to sequence model on multi-sentence summarization, converts length range as some special markers which are predefined and fixed. These markers are included in the training vocabulary. At training time, the model prepends the input of the summarizer with marker indicating the length of input sequence. At test time, it controls the length of the generated summary also by prepending length marker indicating the desired length. Unfortunately, this approach can not generate summaries of arbitrary lengths. It only generates summaries in predefined ranges of length, thus only meets the length constraints approximately. This is shown in Table 1. The above truncation practice can be used in conjunction with any of the length control methods but the excessive parts (red) will be truncated leaving incomplete sentences.

In our work, we extend the convolutional sequence to sequence model (Gehring et al., 2017) by controlling the length of summarization. Our approach seeks to generate summaries of any de-

sired number of tokens (also shown in Table 1). To do this, a length constraint is added to each convolutional block of the initial layer of the model. This information is propagated layer by layer during training. Our contributions are as follows:

1. We propose a simple but effective method to generate summaries with arbitrary desired length (Section 2.2).
2. Our approach outperforms the state-of-art baseline methods substantially by all evaluation metrics, i.e., ROUGE scores, length variation and semantic similarity (Section 3).
3. The generated summaries from our model are natural and complete, especially when the desired length is short (Section 3).

Next, we present the basic convolutional sequence to sequence model and our extension, followed by the evaluation of our approach and a discussion of related work.

2 Methodology

In this section, we will describe the model architecture used for our experiments and propose our length control method which is implemented by extending the basic model.

For summarization problems based on seq2seq model, given a sequence of tokens $\mathbf{x} = (x_1, x_2, ..., x_m)$ in the source document and a sequence of tokens $\mathbf{y} = (y_1, y_2, ..., y_n)$ in the target summary (i.e. $m > n$), the goal is to estimate the conditional probability $p(\mathbf{y}|\mathbf{x})$:

$$p(\mathbf{y}|\mathbf{x}) = \prod_{t}^{T} p(y_t|y_1, y_2, ..., y_{t-1}, \mathbf{x}) \quad (1)$$

We aim at getting the above conditional probabaility which can generate summaries with arbitrary desired length.

2.1 Basic CNN seq2seq Model

Our basic model consists of a multi-layer convolutional sequence to sequence model (CNN seq2seq)[1] (Gehring et al., 2017; LeCun et al., 1989) and an attention mechanism. Figure 1 illustrates the model.

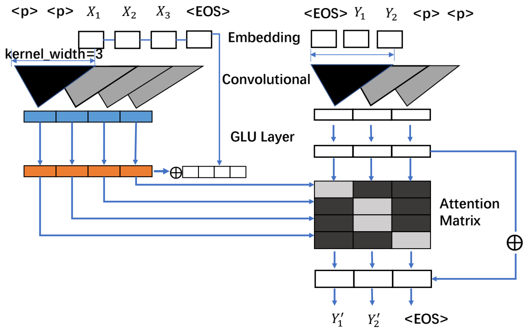

Figure 1: CNN seq2seq model

In the CNN seq2seq model, we obtain the input sequence $\mathbf{X} = (X_1, ..., X_m)$ and output sequence $\mathbf{Y} = (Y_1, ..., Y_n)$ after combining word vectors with their absolute positions in the document. We use $\mathbf{z} = (z_1^l, z_2^l, ..., z_m^l)$ and $\mathbf{h} = (h_1^l, h_2^l, ..., h_n^l)$ to denote the convolutional output of the encoder and decoder in l-th layer. Each element of the output sequence generated by the decoder network is fed back into the next layer of decoder network. Next, we add GLU (Dauphin et al., 2017) and residual connections (He et al., 2016) in each layer:

$$h_i^l = GLU(W^l[h_s^{l-1}, ..., h_t^{l-1}] + b^l) + h_i^{l-1} \quad (2)$$

where $[h_s^{l-1}, ..., h_t^{l-1}]$ corresponds to the h_i^l in the convolutional layers. The choice of s and t is based on kernel width and the padding method used to match the output of convolutional layers to the input length. We compute the probability distribution of generating the next elements y_{i+1} based on the current state and transform the top decoder output h_i^L via softmax:

$$p(y_{i+1}|y_1, ..., y_i, \mathbf{x}) = softmax(W_o h_i^L + b_o) \quad (3)$$

---

[1] `https://github.com/facebookresearch/fairseq-py`.

In addition, a multi-step attention mechanism that connects the encoder and decoder is used in each decoder layer. We define the decoder state d_i^l for attention as following:

$$d_i^l = W_d^l h_i^l + b_d^l + Y_i \tag{4}$$

The attention c_i^l is a weighted sum of the encoder outputs. The weights a_{ij}^l are based on the decoder states.

$$a_{ij}^l = \frac{\exp(d_i^l \cdot z_j^u)}{\sum_{t=1}^{m} \exp(d_i^l \cdot z_t^u)} \tag{5}$$

$$c_i^l = \sum_{j=1}^{m} a_{ij}^l (z_j^u + X_j) \tag{6}$$

At last, we add c_i^l to the current decoder elements h_i^l, which forms the final output or the input of the next layer in the decoder.

2.2 Modified Model with Length Control (LC)

We propose an approach which can control the summary length in CNN seq2seq model. The model can generate different summaries by setting desired length. It has the ability to generate the EOS tag at the appropriate time point in a natural manner.

To produce a summary of a given desired length, we modify the basic model by feeding the desired length as a parameter into the decoder of the CNN seq2seq model. At training time, we use the true length of the gold summary as the desired length. At test time, we can give any desired length len to the model and obtain a summary with length approximate to len. The modified decoder is shown in Figure 2.

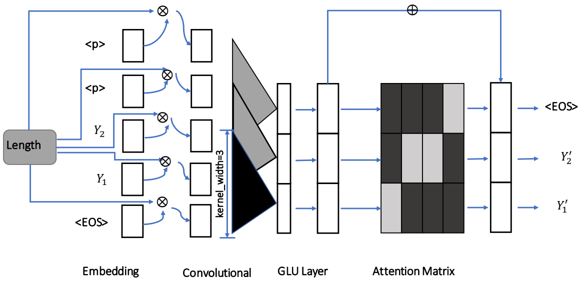

Figure 2: Modified Decoder

The CNN seq2seq model creates hierarchical structure over the input sequence. It is capable of capturing the correlation between elements over short distances at lower layers and between elements over long distances at higher layers. The useful information among the elements is aggregated after GLU. Therefore, we set the desired length as an input to the initial state of the decoder:

$$h_i^1 = v(W^1[h_s^0, ..., h_t^0] + b^1) + h_i^0 * len \tag{7}$$

where W is a trainable parameter, len is the desired length, v is GLU funciton and h_i^0 is the i-th element in the initial layer.

In the above function, we add length information at first layer in CNN model. GLU is like a gate. It can filter some information from a particular unit in each layer. The information attenuation occurs in GLU layer by layer. Different desired lengths have different degrees of information attenuation. Therefore the model is able to learn the probability of generating EOS with its own length information attenuation. This operation enables the model to produce a natural and complete summary for a given length constraint naturally.

3 Evaluation

In this section, our benchmark is the CNN/Daily Mail DMQA dataset (Hermann et al., 2015; Nallapati et al., 2016; See et al., 2017) [2], consisting of pairs of a single source document and a multi-sentence summary. The dataset includes 286,817 training pairs, 13,368 validation pairs and 11,487 test pairs. We follow the same pre-processing step used by See et al. (2017), and fill in the blanks with answer named entities. We show an example of such pairs in Table 4(a).

We compare our length constrained summarization model with the basic CNN seq2seq model and the state-of-the-art length controllable summarization model (Fan et al., 2017) [3]. Following Fan et al., we distribute the dataset into a set of disjoint buckets that correspond to summaries of different lengths. Each bucket contains roughly equal number of documents. The distribution is shown in Figure 3.

All competing methods have three flavors: *free*, *truncated* and *exact*. In the free version(Free), given the desired length N, each method generates summaries naturally until an EOS is generated. In the truncated version(Trunc), each method

---

[3] All datasets, source code and generated summaries can be downloaded from `http://202.120.38.146/sumlen`.

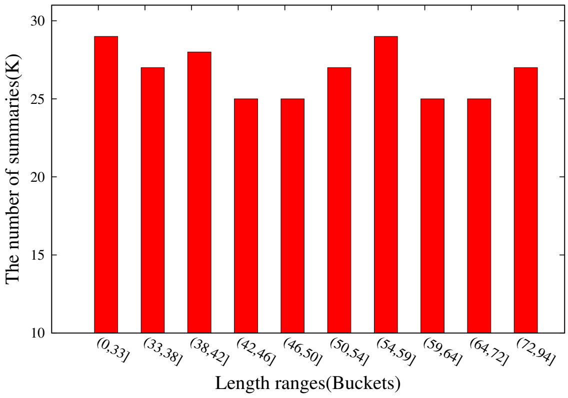

Figure 3: The buckets distribution of the dataset

artificially inserts an EOS if EOS has not been generated in the first N tokens. In the exact version(Exact), each method generates N non-EOS tokens by assigning a score of -∞ to the EOS and inserts an EOS after the N-th token. The purpose of Free version is to evaluate the method's ability to generate summaries with desired length; the purpose of the other two versions is to enable fair comparison of the summaries in terms of their content given that the summaries are of equal length.

3.1 Experimental Setup

In the following experiments, all the competing models have 8 convolutional layers in both encoder and decoder parts with kernel width as 3. For each convolutional layer, we set the hidden vector size as 512 and the embedding size as 256. To alleviate the overfitting problem, we add the dropout ($p = 0.2$) layer for all convolutional layers and fully connected layers.

To optimize the proposed model, we use Nesterov's accelerated gradient method (Sutskever et al., 2013) with gradient clipping 0.1 (Pascanu et al., 2013), momentum 0.99, and learning rate 0.2. We terminate the training process when the learning rate drops below $10e$-5. We set beam size as 5 for the beam search algorithm in the testing step. Next, we introduce the evaluation metrics in the following experiments:

1. *ROUGE* scores (F1 score) of the produced summaries, including ROUGE-1(R-1), ROUGE-2(R-2) and ROUGE-L(R-L) (Lin, 2004). ROUGE-2 is the most popular metric for summarization.

2. *Variance*(Var) of the summary lengths against the desired length len:

$$var = 0.001 * \frac{1}{n}\sum_{i=0}^{n}|l_i - len|^2, \quad (8)$$

where n is the number of pairs in the dataset, and l_i is the length of the generated summary i. We introduce the variance to evaluate the ability of exact control of the output length.

3. *Similarity*(Sim) between generated summaries and their corresponding reference summaries:

$$sim = \frac{1}{n}\sum_{i=0}^{n}\frac{y_i \cdot y_i'}{||y_i||||y_i'||} \quad (9)$$

where n is the number of pairs. y_i is the vector representation of the reference summary i and y_i' is vector of the corresponding generated summary i. Both y_i and y_i' are the sum of GloVe [4] word vectors of the words in these summaries.

We introduce the similarity metric here to complement the ROUGE scores because Yao et al. (2017a) showed that the standard ROUGE scores cannot capture semantic similarity beyond n-grams. Given the same source document, abstractive summarization may create summaries that don't share many words but mean the same. To show the effectiveness of this Sim metric, we design a dataset from the summarization tasks of TAC 2010∼2011[5]. The TAC dataset consists of 90 topics in total, each with 2 subset. Each subset has 4 reference summaries by different humans. We assume reference summaries about the same topic to be semantically similar to each other, while summaries across topics are unrelated. Thus we created 2,160 pairs of similar summaries as postive data and 2,160 pairs of unrelated summaries as negative data. We then compute the Pearson correlation between the ROUGE score and the ground truth as well as between Sim and the ground truth and show the results in Table 2. Sim metric certainly resembles semantic similarity better than ROUGE by this experiment.

In this paper, we don't use manual evaluation as the major metric. The reason is that Lin (2004) showed that the manual evaluation is unstable and

---

[5] https://tac.nist.gov/

Table 2: Pearson correlation with the true semantic relatedness

	TAC 2010	TAC 2011
R-2	0.6107	0.6034
Sim	**0.6653**	**0.7165**

the inter-human agreement is low due to the variety in abstractive summaries. The ROUGE scores and Similarity scores can respectively measure the syntactic similarity and semantic similarity. They are complementary to each other and give better quantitative assessment of the summarization quality.

3.2 Experiment 1: Gold Summary Lengths

In the first experiment, for each test document-summary pair, we set the desired length as the length of the gold summary and ask the competing methods to generate a summary with the desired length. As shown in Table 3, the proposed model (LC) outperforms the other models on all of the evaluation metrics. The ROUGE score shows the accuracy of these models. Lower variance reflects better length control of the model. Higher similarity reflects better quality of generated summaries from the semantic point of view.

Table 3: Desired Length: Gold Summary Lengths

		R-1	R-2	R-L	Var	Sim
Free	CNN	34.49	14.38	25.78	0.3465	0.9220
	Fan	34.53	14.40	25.78	0.3446	0.9216
	LC	**35.45**	**14.50**	**26.02**	**0.0005**	**0.9272**
Trunc	CNN	34.76	**14.53**	26.00	0.3045	0.9201
	Fan	34.74	14.52	25.97	0.3031	0.9197
	LC	**35.44**	14.48	**26.02**	**0.0002**	**0.9268**
Exact	CNN	35.39	14.43	**26.07**	0.0	0.9249
	Fan	35.37	14.42	26.03	0.0	0.9246
	LC	**35.44**	**14.50**	26.02	0.0	**0.9268**

The LC model achieves the highest ROUGE and similarity scores as well as the lowest variance in both Free and Exact version, which shows the effectiveness of LC for generating high quality summaries under length constraint. In the Trunc version, the LC model outperforms the other comparable models on all evaluation metrics except for the ROUGE score. Note that, the ROUGE scores of LC model are very stable, indicating its effective length control. As for the other two models, they have better ROUGE score on Trunc version. However, as the example shown in Table 4[6], higher ROUGE scores do not necessarily mean high quality abstractive summaries.

The ROUGE score consists of Recall(R), Precision(P) and F1-measure(F). The summary tends to achieve a better ROUGE score when the length of generated summary is slightly shorter than the desired length. In Table 4(b), the CNN model has the same R score as LC model and a higher P score than LC model because of its slightly shorter length. We can see that the CNN model achieve a higher F score even its generated summary is not good. Moreover, for the basic model, the generated summary always repeats the sentences when the length of generated summary is longer than the desired length. In Table 4(c), the P score of its Trunc version would be improved by a large margin. Thus, the ROUGE score for the Trunc version biases toward the models with weak length control. The generated summaries of the LC model in Table 4(d), which capture the semantic of the reference summary and satisfy the constraint length very well, are better than the other two models even with a slightly lower ROUGE score. The topic of this example is that Louis Jordan, who is the son of Frank Jordan, got lost during sailing and was finally rescued from his boat. Our model generates the summary with correct information, but other two models get the Louis Jordan and Frank Jordan mixed up. This is correctly measured by the similarity scores.

3.3 Experiment 2: Arbitrary Lengths

In the second experiment, we ask the methods to generate summaries with arbitrary lengths. We report the results of all three methods with five arbitrary lengths: 10, 30, 50, 70 and 90. We show the performance of each model with different length constraints in Table 5, Table 6, Figure 4 and Figure 5. The basic CNN model has the same ROUGE scores in the Free version since it cannot control the length of generated summaries on its own. For Fan et al. (2017), the desired length is mapped to the model's predefined fixed length range(s) that *contains* the desired length before it produces its summaries. For example, the desired length 10 is mapped to the first bucket $(0, 33]$.

To demonstrate the effectiveness of LC model and further illustrate the results, we show an example of generated summaries by LC(Free) model with different lengths. As shown in Table 7, when the desired length (e.g., 10) is very different from the length of the reference summary, the ROUGE

---

score may not be good even though the generated summary matches the reference quite well semantically. The generated summaries from LC model are *natural* and *complete*. The summaries with short desired length on Trunc and Exact version would be more vulnerable to the incomplete problem. We randomly sample 100 summaries generated by each model under Trunc and Exact with desired length of 10 and 30, and manually inspect their readibility. This is a simplified human-evaluation of summarization, which just determines whether the sentences in summaries under length control are complete or not. If complete, the score is 1; if not, it is 0. It is easier to accomplish and more reliable than other sophisticated human-evaluation. Table 8 shows that the LC model has a clear advantage over the other two models in terms of summary fluency.

In this experiment, the desired length is fixed for all the documents which is independent from the corresponding lengths of reference summaries such that the generated summaries may include more versatile words and phrases different from the reference summaries. Thus, the similar-

ity score is more reasonable for evaluation than ROUGE score. As shown in Table 6 and Figure 4, the LC model achieves the highest similarity score except for the length of 10 and 30 in the Free version. The reason is that there is only 5% of testing data with the length of reference summary shorter than 30. Due to the effective length control of LC model, the lengths of generated summaries from LC model are usually much shorter than those from the other models and the length of corresponding reference summaries when we set the desired length as 10 or 30. This leads to a relative lower similarity score shown in Figure 4(b) and Figure 4(c). As shown in Figure 5, the LC model achieves the lowest variance. In Figure 5(a), as the length of most summaries is around 50 and the number of summaries with a length of 10 or 90 is small, the CNN model and Fan model has lowest variance at 50 and highest variance at 90. In Figure 5(b), the length of generated summaries in Trunc version is no more than desired length. So the variances of CNN model and Fan model are incremental. Besides, we can find that the LC model is stable under all conditions because of its effective length control model.

3.4 Significance Test on Similarity Result

We use significance test to prove that similarity metric is reliable even though the numerical difference of similarity scores in experiment is little. Because the similarity scores of generated summaries do not follow normal distribution, we take Kruskal-Wallis test (Loukina et al., 2014; Albert, 2017) as our significance test to measure that the difference of similarity results of three methods is significant or not. As shown in Table 9, all p-values are less than 0.05. The smaller p-value, the higher significant. Thus, the difference of the similarity results is significant.

Table 9: p-value of significance test

Exp.2	0.0	4.6e-39	1.0e-4

4 Related Work

In this section, we discuss some previous work on length control in abstractive summarization and explain why we choose CNN as our basic summarization model.

4.1 Length Control for Abstractive Summarization

When summarizing a document, it is desirable to be able to control the length of summary so as to cater to different users and scenarios. Most abstractive summarization systems are based on encoder-decoder models and generate summaries whose length depends on the training summaries. Due to the variability of the sequence generation models, such as the different structures and functions, it is hard to design a length constraint method on all summarization models.

Previous methods control summary length by generating EOS token at a particular time. Rush et al. (2015) used an ad-hoc method, in which the system is inhibited from generating the EOS tag by assigning a score of $-\infty$ to the tag and generats a fixed number of words. Kikuchi et al. (2016) proposed two different methods for RNN seq2seq model which can control the summary length by taking length embedding as an additional input for the LSTM and adding desired length into initial memory cell for the LSTM. In this model, they use the Gigawords as dataset and focus on the abstractive summarization in sentence level which generates one sentence as the summary. For CNN seq2seq model, Fan et al. (2017) put some special markers into the vocabulary which denote different length ranges. It prepends the input of the summarizer with the marker during training and testing. These special markers are predefined and fixed. In this paper, we aim at generating complete summaries with arbitrary desired length naturally for CNN seq2seq model. We use multi-layers CNN seq2seq model on both encoder and decoder. We set the length constraint at the first layer of decoder to implement the length control of the summarization. Compared with other methods, our approach can effectively control the length of generated summary in a natural manner. Meanwhile, it can generate summaries with length approximate to the desired length without semantic losing in less time.

4.2 Encoder-Decoder for Abstractive Summarization

Automatic document summarization generates short summaries for original documents. A summary should cover the key topics of the original document(s). A good summary should be coherent, non-redundant and readable(Yao et al., 2017b). The research in abstractive summarization with encoder-decoder model (Sutskever et al., 2014; Rush et al., 2015; Chopra et al., 2016; Nallapati et al., 2016; See et al., 2017; Paulus et al., 2017; Fan et al., 2017) has made some progress.

Most of them use RNN with different attention mechanisms (Nallapati et al., 2016; See et al., 2017; Paulus et al., 2017). Rush et al. (2015) used RNN with soft-attention, while Paulus et al. (2017) used the RNN with intra-attention. Recently, research on CNN based summarization has gained momentum. Gehring et al. (2017) proposed the CNN seq2seq model with multi-step attention, which was extended in (Fan et al., 2017). Bai et al. (2018) showed that CNN is more powerful than RNN for sequence modeling. What's more, CNN enables much faster training and more stable gradients than RNN. Therefore we select CNN seq2seq model as our basic model and do not compare our model with RNN seq2seq model.

5 Conclusion

We presented a simple approach to modify existing CNN seq2seq model with a summary length input and were able to train a model that produces summaries of desired length that are fluent and coherent. This is a better solution than the current practice of summary truncation. Compared with the existing summarization methods, we show that our model has the ability to control the output length on its own using its internal state without losing semantic information or sacrificing the ROUGE score.

APRIL: Interactively Learning to Summarise by Combining Active Preference Learning and Reinforcement Learning

Yang Gao, Christian M. Meyer, Iryna Gurevych
Ubiquitous Knowledge Processing Lab (UKP-TUDA)
Department of Computer Science, Technische Universität Darmstadt
`https://www.ukp.tu-darmstadt.de/`

Abstract

We propose a method to perform automatic document summarisation without using reference summaries. Instead, our method interactively learns from users' *preferences*. The merit of preference-based interactive summarisation is that preferences are easier for users to provide than reference summaries. Existing preference-based interactive learning methods suffer from high sample complexity, i.e. they need to interact with the oracle for many rounds in order to converge. In this work, we propose a new objective function, which enables us to leverage active learning, preference learning and reinforcement learning techniques in order to reduce the sample complexity. Both simulation and real-user experiments suggest that our method significantly advances the state of the art. Our source code is freely available at `https://github.com/UKPLab/emnlp2018-april`.

1 Introduction

With the rapid growth of text-based information on the Internet, *automatic document summarisation* attracts increasing research attention from the Natural Language Processing (NLP) community (Nenkova and McKeown, 2012). Most existing document summarisation techniques require access to reference summaries to train their systems. However, obtaining reference summaries is very expensive: Lin (2004) reported that 3,000 hours of human effort were required for a simple evaluation of the summaries for the Document Understanding Conferences (DUC). Although previous work has proposed heuristics-based methods to summarise without reference summaries (Ryang and Abekawa, 2012; Rioux et al., 2014), the gap between their performance and the upper bound is still large: the ROUGE-2 upper bound of .212 on DUC'04 (P.V.S. and Meyer, 2017) is, for example, twice as high as Rioux et al.'s (2014) .114.

The *Structured Prediction from Partial Information* (SPPI) framework has been proposed to learn to make structured predictions without access to gold standard data (Sokolov et al., 2016b). SPPI is an interactive NLP paradigm: It interacts with a user for multiple rounds and learns from the user's feedback. SPPI can learn from two forms of feedback: *point-based* feedback, i.e. a numeric score for the presented prediction, or *preference-based* feedback, i.e. a preference over a pair of predictions. Providing preference-based feedback yields a lower cognitive burden for humans than providing ratings or categorical labels (Thurstone, 1927; Kendall, 1948; Kingsley and Brown, 2010; Zopf, 2018). Preference-based SPPI has been applied to multiple NLP applications, including text classification, chunking and machine translation (Sokolov et al., 2016a; Kreutzer et al., 2017). However, SPPI has prohibitively high sample complexities in the aforementioned NLP tasks, as it needs at least hundreds of thousands rounds of interaction to make near-optimal predictions, even with simulated "perfect" users. Figure 1a illustrates the workflow of the preference-based SPPI.

To reduce the sample complexity, in this work, we propose a novel preference-based interactive learning framework, called *APRIL* (Active Preference ReInforcement Learning). APRIL goes beyond SPPI by proposing a new objective function, which divides the preference-based interactive learning problem into two phases (illustrated in Figure 1b): an *Active Preference Learning* (APL) phase (the right cycle in Figure 1b), and a *Reinforcement Learning* (RL) phase (the left cycle). We show that this separation enables us to query preferences more effectively and to use the collected preferences more efficiently, so as to reduce the sample complexity.

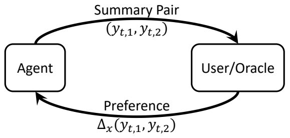
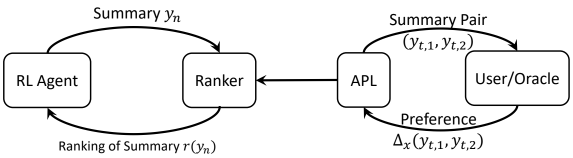
Brussels, Belgium, October 31 - November 4, 2018.



(a) Workflow of preference-based SPPI



(b) Workflow of APRIL

Figure 1: A comparison of workflows of SPPI (a) and APRIL (b) in the EMDS use case. Notation details, e.g., Δ_x and $r(y_n)$, are discussed in §3.

We apply APRIL to *Extractive Multi-Document Summarisation* (EMDS). The task of EMDS is to extract sentences from the original documents to build a summary under a length constraint. We accommodate multiple APL and RL techniques in APRIL and compare their performance under different simulation settings. We also compare APRIL to a state-of-the-art SPPI implementation using both automatic metrics and human evaluation. Our results suggest that APRIL significantly outperforms SPPI.

2 Related Work

RL has been previously used to perform EMDS without using reference summaries. Ryang and Abekawa (2012) formulated EMDS as a *Markov Decision Process* (MDP), designed a heuristics-based reward function considering both information coverage rate and redundancy level, and used the *Temporal Difference* (TD) algorithm (Sutton, 1984) to solve the MDP. In a follow-up work, Rioux et al. (2014) proposed a different reward function, which also did not require reference summaries; their experiments suggested that using their new reward function improved the summary quality. Henß et al. (2015) proposed a different RL formulation of EMDS and jointly used supervised learning and RL to perform the task. However, their method requires the access to reference summaries. More recent works applied encoder-decoder-based RL to document summarisation (Ranzato et al., 2015; Narayan et al., 2018; Paulus et al., 2017; Pasunuru and Bansal, 2018). These works outperformed standard encoder-decoder as RL can directly optimise the ROUGE scores and can tackle the *exposure bias* problems. However, these neural RL methods all used ROUGE scores as their rewards, which in turn relied on reference summaries. APRIL can accommodate these neural RL techniques in its RL phase by using a ranking of summaries instead of the ROUGE scores as rewards. We leave neural APRIL for future study.

P.V.S. and Meyer (2017) proposed a bigram-based interactive EMDS framework. They asked users to label important bigrams in candidate summaries and used *integer linear programming* (ILP) to extract sentences covering as many important bigrams as possible. Their method requires no access to reference summaries, but it requires considerable human effort during the interaction: in simulation experiments, their system needed to collect up to 350 bigram annotations from a (simulated) user. In addition, they did not consider noise in users' annotations but simulated perfect oracles.

Preference learning aims at obtaining the ranking (i.e. total ordering) of objects from pairwise preferences (Fürnkranz and Hüllermeier, 2010). Simpson and Gurevych (2018) proposed to use an improved *Gaussian process preference learning* (Chu and Ghahramani, 2005) for learning to rank arguments in terms of convincingness from crowd-sourced annotations. However, such Bayesian methods can hardly scale and suffer from high computation time. Zopf (2018) recently proposed to learn a sentence ranker from preferences. The resulting ranker can be used to identify the important sentences and thus to evaluate the quality of the summaries. His study also suggests that providing sentence preferences takes less time than writing reference summaries. APRIL not only learns a ranking over summaries from pairwise preferences, but also uses the ranking to "guide" our RL agent to generate good summaries.

There is a recent trend in machine learning to combine active learning, preference learning and RL, for learning to perform complex tasks from preferences (Wirth et al., 2017). The resulting algorithm is termed *Preference-based RL* (PbRL), and has been used in multiple applications, including training robots (Wirth et al., 2016) and Atari-playing agents (Christiano et al., 2017). SPPI and APRIL can both be viewed as PbRL algorithms. But unlike most PbRL methods that learn a utility function of the predictions (in EMDS, predictions are summaries) to guide the RL agent, APRIL is able to directly use a ranking of predictions to guide the RL agent without making assumptions about the underlying structure of the utility functions. This also enables APRIL to use non-utility-based preference learning techniques (e.g., Maystre and Grossglauser, 2017).

3 Background

In this section, we recap necessary details of SPPI, RL and preference learning, and adapt them to the EMDS use case, laying the foundation for APRIL.

3.1 The SPPI Framework

Let $\mathcal{X}$ be the input space and let $\mathcal{Y}(x)$ be the set of possible outputs for input $x \in \mathcal{X}$. In EMDS, $x \in \mathcal{X}$ is a cluster of documents and $\mathcal{Y}(x)$ is the set of all possible summaries for cluster x. The function $\Delta_x\colon \mathcal{Y}(x) \times \mathcal{Y}(x) \to \{0, 1\}$ is the *preference function* such that $\Delta_x(y_i, y_j) = 1$ if the user believes y_j is better than y_i (denoted by $y_j \succ y_i$ or equivalently $y_i \prec y_j$), and 0 otherwise. Throughout this paper we assume that users do not equally prefer two different items. For a given x, the expected loss is:

$$\mathcal{L}^{\text{SPPI}}(w|x) = \mathbb{E}_{p_w(y_i,y_j|x)}[\Delta_x(y_i, y_j)] \\ = \sum_{y_i,y_j \in \mathcal{Y}(x)} \Delta_x(y_i, y_j)\, p_w(y_i, y_j|x), \qquad (1)$$

where $p_w(y_i, y_j|x)$ is the probability of querying the pair (y_i, y_j). Formally,

$$p_w(y_i, y_j|x) \\ = \frac{\exp[w^\intercal(\phi(y_i|x) - \phi(y_j|x))]}{\sum\limits_{y_p,y_q \in \mathcal{Y}(x)} \exp[w^\intercal(\phi(y_p|x) - \phi(y_q|x))]}, \qquad (2)$$

where $\phi(y|x)$ is the vector representation of y given x, and w is the weight vector to be learnt. Eq. (2) is a Gibbs sampling strategy: $w^\intercal(\phi(y_i|x) - \phi(y_j|x))$ can be viewed as the "utility gap" between y_i and y_j. The sampling strategy p_w encourages querying pairs with large utility gaps.

To minimise $\mathcal{L}^{\text{SPPI}}$, SPPI uses gradient descent to update w incrementally. Alg. 1 presents the pseudo code of our adaptation of SPPI to EMDS. In the supplementary material, we provide a detailed derivation of $\nabla_w \mathcal{L}^{\text{SPPI}}(w|x)$.

3.2 Reinforcement Learning

RL amounts to efficient algorithms for searching optimal solutions in MDPs. MDPs are widely used to formulate *sequential decision making* problems, which EMDS falls into: in EMDS, the summariser has to sequentially select sentences from the original documents and add them to the draft summary. An (episodic) MDP is a tuple (S, A, P, R, T). S is the set of *states*, A is the set of *actions*, $P\colon S \times A \times S \to \mathbb{R}$ is the *transition function* with $P(s'|s, a)$ yielding the probability of performing action a in state s and being transited to a new state s'. $R\colon S \times A \to \mathbb{R}$ is the *reward function* with $R(s, a)$ giving the immediate reward for performing action a in state s. $T \subseteq S$ is the set of *terminal states*; visiting a terminal state terminates the current episode.

```
Input  : sequence of learning rates $\gamma_t$; query
         budget $T$; document cluster $x$
initialise $w_0$;
while $t = 0 \ldots T$ do
    sample $(y_i, y_j)$ according to Eq. (2);
    obtain feedback $\Delta_x(y_i, y_j)$;
    $w_{t+1} := w_t - \gamma_t \nabla_w \mathcal{L}^{\text{SPPI}}(w|x)$
end
Output: $y^* = \arg\max_{y \in Y(x)} w_{T+1}^\intercal \phi(y, x)$
```

Algorithm 1: SPPI for preference-based interactive document summarisation (adjusted from Alg. 2 in (Sokolov et al., 2016a)).

In EMDS, we follow the same MDP formulation as Ryang and Abekawa (2012) and Rioux et al. (2014). Given a document cluster, a state s is a draft summary, A includes two types of actions, *concatenate* a new sentence to the current draft summary, or *terminate* the draft summary construction. The transition function P in EMDS is trivial because given the current draft summary and an action, the next state can be easily inferred. The reward function R returns an evaluation score of the summary once the action *terminate* is performed; otherwise it returns 0 because the summary is still under construction and thus not ready to be evaluated. Providing non-zero rewards before the action *terminate* can lead to even worse result, as reported by Rioux et al. (2014).

A *policy* $\pi\colon S \times A \to \mathbb{R}$ in an MDP defines how actions are selected: $\pi(s, a)$ is the probability of selecting action a in state s. In EMDS, a policy corresponds to a strategy to build summaries for a given document cluster. We let $\mathcal{Y}_\pi(x)$ be the set of all possible summaries the policy π can construct in the document cluster x, and we slightly abuse the notation by letting $\pi(y|x)$ denote the probability of policy π generating a summary y in cluster x. Then the expected reward of a policy is:

$$\begin{aligned}\mathcal{R}^{\mathrm{RL}}(\pi|x) &= \mathbb{E}_{y\in\mathcal{Y}_\pi(x)} R(y|x)\\ &= \sum_{y\in\mathcal{Y}_\pi(x)} \pi(y|x)R(y|x), \qquad (3)\end{aligned}$$

where $R(y|x)$ is the reward for summary y in document cluster x. The goal of an MDP is to find the optimal policy π^* that has the highest expected reward: $\pi^* = \arg\max_\pi \mathcal{R}^{\mathrm{RL}}(\pi)$.

Note that the loss function in SPPI (Eq. (1)) and the expected reward function in RL (Eq. (3)) are in similar forms: if we view the pair selection probability p_w in Eq. (2) as a policy, and view the preference function Δ_x in Eq. (1) as a negative reward function, we can view SPPI as an RL problem. The major difference between SPPI and RL is that SPPI selects and evaluates pairs of outputs, while RL selects and evaluates single outputs. We will exploit their connection to propose our new objective function and the APRIL framework.

3.3 Preference Learning

The linear Bradley-Terry (BT) model (Bradley and Terry, 1952) is one of the most widely used methods in preference learning. Given a set of items $\mathcal{Y}$, suppose we have observed T preferences: $Q = \{q_1(y_{1,1}, y_{1,2}), \cdots, q_T(y_{T,1}, y_{T,2})\}$, where $y_{i,1}, y_{i,2} \in \mathcal{Y}$, and $q_i \in \{\prec, \succ\}$ is the oracle's preference in the i^{th} round. The BT model minimises the following cross-entropy loss:

$$\begin{aligned}\mathcal{L}^{\mathrm{BT}}(w) = -\sum_{q_i(y_{i,1},y_{i,2})\in Q} [\,&\mu_{i,1}\log\mathcal{P}_w(y_{i,1}\succ y_{i,2})\\ &+ \mu_{i,2}\log\mathcal{P}_w(y_{i,2}\succ y_{i,1})\,], \qquad (4)\end{aligned}$$

where $\mathcal{P}_w(y_i \succ y_j) = (1 + \exp[w^\intercal(\phi(y_j) - \phi(y_i))])^{-1}$, and $\mu_{i,1}$ and $\mu_{i,2}$ indicate the direction of preferences: if $y_{i,1} \succ y_{i,2}$ then $\mu_{i,1} = 1$ and $\mu_{i,2} = 0$. Let $w^* = \arg\min_w \mathcal{L}^{\mathrm{BT}}(w)$, then w^* can be used to rank all items in $\mathcal{Y}$: for any $y_i, y_j \in \mathcal{Y}$, the ranker prefers y_i over y_j if $w^{*\intercal}\phi(y_i) > w^{*\intercal}\phi(y_j)$.

4 APRIL: Decomposing SPPI into Active Preference Learning and RL

A major problem of SPPI is its high sample complexity. We believe this is due to two reasons. First, SPPI's sampling strategy is inefficient: From Eq. (2) we can see that SPPI tends to select pairs with large quality gaps for querying the user. This strategy can quickly identify the relatively good and relatively bad summaries, but needs many rounds of interaction to find the top summaries. Second, SPPI uses the collected preferences ineffectively: In Alg. 1, each preference is used only once for performing the gradient descent update and is forgotten afterwards. SPPI does not generalise or re-use collected preferences, wasting the useful and expensive information.

These two weaknesses of SPPI motivate us to propose a new learning paradigm that can query and generalise preferences more efficiently. Recall that in EMDS, the goal is to find the optimal summary for a given document cluster x, namely the summary that is preferred over all other possible summaries in $\mathcal{Y}(x)$. Based on this understanding, we define a new expected reward function $\mathcal{R}^{\mathrm{APRIL}}$ for policy π as follows:

$$\begin{aligned}&\mathcal{R}^{\mathrm{APRIL}}(\pi|x) = \mathbb{E}_{y_j\sim\pi}[\frac{1}{|\mathcal{Y}(x)|}\sum_{y_i\in\mathcal{Y}(x)}\Delta_x(y_i, y_j)]\\ &= \frac{1}{|\mathcal{Y}(x)|}\sum_{y_j\in\mathcal{Y}_\pi(x)}\pi(y_j|x)\sum_{y_i\in\mathcal{Y}(x)}\Delta_x(y_i, y_j)\\ &= \sum_{y\in\mathcal{Y}_\pi(x)}\pi(y|x)\, r(y|x), \qquad (5)\end{aligned}$$

where $r(y|x) = \sum_{y_i\in\mathcal{Y}(x)}\Delta_x(y_i, y_j)/|\mathcal{Y}(x)|$. Note that $\Delta_x(y_i, y_j)$ equals 1 if y_j is preferred over y_i and equals 0 otherwise (see §3.1). Thus, $r(y|x)$ is the relative position of y in the (ascending) sorted $\mathcal{Y}(x)$, and it can be approximated by preference learning. The use of preference learning enables us to generalise the observed preferences to a ranker (see §3.3), allowing more effective use of the collected preferences. Also, we can use active learning to select summary pairs for querying more effectively. In addition, the resemblance of $\mathcal{R}^{\mathrm{APRIL}}$ and RL's reward function $\mathcal{R}^{\mathrm{RL}}$ (in Eq. (3)) enables us to use a wide range of RL algorithms to maximise $\mathcal{R}^{\mathrm{APRIL}}$ (see §2).

Based on the new objective function, we split the preference-based interactive learning into two phases: an *Active Preference Learning* (APL) phase (the right cycle in Fig. 1b), responsible for querying preferences from the oracle and approximating the ranking of summaries, and an *RL* phase (the left cycle in Fig. 1b), responsible for learning to summarise based on the learned ranking. The resulting framework APRIL allows for integrating any active preference learning and RL techniques. Note that only the APL phase is online (i.e. in-

```

Table 1: Statistics of the datasets. The target summary length is 100 tokens in all three datasets.

volving humans in the loop) while the RL phase can be performed offline, helping to improve the real-time responsiveness. Also, the learned ranker can provide an unlimited number of rewards (i.e. $r(y|x)$ in Eq. (5)) to the RL agent, enabling us to perform many episodes of RL training with a small number of collected preferences – unlike in SPPI where each collected preference is used to train the system for one round and is forgotten afterwards. Alg. 2 shows APRIL in pseudo code.

5 Experimental Setup

Datasets. We perform experiments on DUC '04 to find the best performing APL and RL techniques. Then we combine the best-performing APL and RL to complete APRIL and compare it against SPPI on the DUC '01, DUC '02 and DUC '04 datasets.[1] Some statistics of these datasets are summarised in Table 1.

Simulated Users. Existing preference-based interactive learning techniques assume that the oracle has an *intrinsic evaluation function* U^* and provides preferences consistent with U^* by preferring higher valued candidates. We term this a *Perfect Oracle* (PO). We believe that assuming a PO is unrealistic for real-world applications, because sometimes real users tend to misjudge the preference direction, especially when the presented candidates have similar quality. In this work, besides PO, we additionally consider two types of noisy oracles based on the user-response models proposed by Viappiani and Boutilier (2010):

- **Constant noisy oracle (CNO)**: with probability $c \in [0, 1]$, this oracle randomly selects which summary is preferred; otherwise it provides preferences consistent with U^*. We consider CNOs with $c = 0.1$ and $c = 0.3$.
- **Logistic noisy oracle (LNO)**: for two summaries y_i and y_j in cluster x, the oracle prefers y_i over y_j with probability $p_{U^*}(y_i \succ y_j|x; m) = (1 + \exp[(U^*(y_j|x) - U^*(y_i|x))/m])^{-1}$. This oracle reflects the intuition that users are more likely to misjudge the preference direction when two summaries have similar quality. Note that the parameter $m \in \mathbb{R}^+$ controls the "noisiness" of the user's responses: higher values of m result in a less steep sigmoid curve, and the resulting oracle is more likely to misjudge. We use LNOs with $m = 0.3$ and $m = 1$.

As for the intrinsic evaluation function U^*, recent work has suggested that human preferences over summaries have high correlations to ROUGE scores (Zopf, 2018). Therefore, we define:

$$U^*(y|x) = \frac{R_1(y|x)}{0.47} + \frac{R_2(y|x)}{0.22} + \frac{R_S(y|x)}{0.18} \quad (6)$$

where R_1, R_2 and R_S stand for ROUGE-1, ROUGE-2 and ROUGE-SU4, respectively. The real values (0.47, 0.22 and 0.18) are used to balance the weights of the three ROUGE scores. We choose them to be around the EMDS upper-bound ROUGE scores reported by P.V.S. and Meyer (2017). As such, an optimal summary's U^* value should be around 3.

Implementation. All code is written in Python and runs on a desktop PC with 8 GB RAM and an i7-2600 CPU. We use NLTK (Bird et al., 2009) to perform sentence tokenisation. Our source code is freely available at `https://github.com/UKPLab/emnlp2018-april`.

6 Simulation Results

We first study the APL phase (§6.1) and the RL phase (§6.2)) separately by comparing the perfor-

---

[1] `http://duc.nist.gov/`

mance of multiple APL and RL algorithms in each phase. Then, in §6.3, we combine the best performing APL and RL algorithm to complete Alg. 2 and compare APRIL against SPPI.

6.1 APL Phase Performance

Recall that the task of APL is to output a ranking of all summaries in a cluster. In this subsection, we test multiple APL techniques and compare the quality of their resulting rankings. Two metrics are used: Kendall's τ (Kendall, 1948) and Spearman's ρ (Spearman, 1904). Both metrics are valued between -1 and 1, with higher values suggesting higher rank correlation. Because the number of possible summaries in a cluster is huge, instead of evaluating the ranking quality on all possible summaries, we evaluate rankings on 10,000 randomly sampled summaries, denoted $\hat{\mathcal{Y}}(x)$. During querying, all candidate summaries presented to the oracle are also selected from $\hat{\mathcal{Y}}(x)$. Sampling $\hat{\mathcal{Y}}(x)$ a priori helps us to reduce the response time to under 500 ms for all APL techniques we test. We compare four active learning strategies under two query budgets, $T = 10$ and $T = 100$:

- **Random Sampling (RND)**: Randomly select two summaries from $\hat{\mathcal{Y}}(x)$ to query.
- **SPPI Sampling (SBT)**: Select summary pairs from $\hat{\mathcal{Y}}(x)$ according to the SPPI strategy in Eq. (2). After each round, the weight vector w is updated according to Eq. (4).
- **Uncertainty Sampling (Unc)**: Query the most *uncertain* summary pairs. In line with P.V.S. and Meyer (2017), the uncertainty of a summary is evaluated as follows: first, we estimate the probability of a summary y being the optimal summary in cluster x as $p_{\text{opt}}(y|x) = (1 + \exp(-w_t^{*\intercal}\phi(x, y)))^{-1}$, where w_t^* is the weights learned by the BT model (see §3.3) in round t. Given $p_{\text{opt}}(y|x)$, we let the uncertainty score $unc(y|x) = 1 - p_{\text{opt}}(y|x)$ if $p_{\text{opt}}(y|x) \geq 0.5$ and $unc(y|x) = p_{\text{opt}}(y|x)$ otherwise.
- **J&N** is the *robust query selection algorithm* proposed by Jamieson and Nowak (2011). It assumes that the items' preferences are dependent on their distances to an unknown reference point in the embedding space: the farther an item to the reference point, the more preferred the item is. After each round of interaction, the algorithm uses all collected preferences to locate the area where the reference point may fall into, and identify the query pairs which can reduce the size of this area, termed *ambiguous query pairs*. To combat noise in preferences, the algorithm selects the most-likely-correct ambiguous pair to query the oracle in each round.

After all preferences are collected, we obtain the ranker as follows: for any $y_i, y_j \in \mathcal{Y}(x)$, the ranker prefers y_i over y_j if

$$\begin{aligned}&\alpha w^{*\intercal}\phi(y_i|x) + (1-\alpha)HU(y_i|x) > \\ &\alpha w^{*\intercal}\phi(y_j|x) + (1-\alpha)HU(y_j|x), \qquad (7)\end{aligned}$$

where w^* is the weights vector learned by the BT model (see Eq. (4)), HU is the heuristics-based summary evaluation function proposed by Ryang and Abekawa (2012), and $\alpha \in [0, 1]$ is a parameter. The aim of using HU and α is to trade off between the *prior knowledge* (i.e. heuristics-based HU) and the *posterior observation* (i.e. the BT-learnt w^*), so as to combat the *cold-start* problem. Based on some preliminary experiments, we set $\alpha = 0.3$ when the query budget is 10, and $\alpha = 0.7$ when the query budget is 100. The intuition is to put more weight to the posterior with increasing rounds of interaction. More systematic research of α can yield better results; we leave it for future work. For the vector $\phi(y|x)$, we use the same bag-of-bigram embeddings as Rioux et al. (2014), and we let its length be 200.

In Table 2, we compare the performance of the four APL methods on the DUC'04 dataset. The baseline we compared against is the prior ranking. We find that Unc significantly[2] outperforms all other APL methods, except when the oracle is LNO-1, where the advantage of Unc to SBT is not significant. Also, both Unc and SBT are able to significantly outperform the baseline under all settings. The competitive performance of SBT, especially with LNO-1, is due to its unique sampling strategy: LNO-1 is more likely to misjudge the preference direction when the presented summaries have similar quality, but SBT has high probability to present summaries with large quality gaps (see Eq. (2)), effectively reducing the chance that LNOs misjudge preference directions. However, SBT is more "conservative" compared to Unc because it tends to exploit the existing

Table 2: Performance of multiple APL algorithms (columns) using different oracles and query budgets (rows). The baseline is the purely prior ranking. All results except the baseline are averaged over 50 document clusters in DUC'04. Asterisk: significant advantage over other active learning strategies given the same oracle and budget T.

ranking to select one good and one bad summary to query, while Unc performs more exploration by querying the summaries that are least confident according to the current ranking. We believe this explains the strong overall performance of Unc.

Additional experiments suggest that when we only use the posterior ranking (i.e. letting $\alpha = 1$), no APL we test can surpass the baseline when $T = 10$. Detailed results are presented in the supplementary material. This observation reflects the severity of the cold-start problem, confirms the effectiveness of our prior-posterior trade-off mechanism in combating cold-start, and indicates the importance of tuning the α value (see Eq. (7)). This opens up exciting avenues for future work.

6.2 RL Phase Performance

We compare two RL algorithms: TD(λ) (Sutton, 1984) and LSTD(λ) (Boyan, 1999). TD(λ) has been used in previous RL-based EMDS work (Ryang and Abekawa, 2012; Rioux et al., 2014). LSTD(λ) is chosen, because it is an improved TD algorithm and has been used in the state-of-the-art PbRL algorithm by Wirth et al. (2016). We let the learning round (see Alg. 2) $N = 5,000$, which we found to yield good results in reasonable time (less than 1 minute to generate a summary for one document cluster). Letting $N = 3,000$ will result in a significant performance drop, while increasing N to 10,000 will only bring marginal improvement at the cost of doubling the runtime. The learning parameters we use for TD(λ) are the same as those by Rioux et al. (2014). For LSTD(λ), we let $\lambda = 1$ and initialise its square matrix as a diagonal matrix with random numbers between 0 and 1, as suggested by Lagoudakis and Parr (2003). The rewards we use are the U^* function introduced in §5. Note that this serves as the upper-bound performance, because U^* relies on the reference summaries (see Eq. (6)), which are not available in the interactive setting. As a baseline, we also present the upper-bound performance of integer linear programming (ILP) reported by P.V.S. and Meyer (2017), optimised for bigram coverage.

Method	R_1	R_2	R_L	R_{SU4}
TD(λ)	**.484**	.184	**.388**	**.199**
LSTD(λ)	.458	.159	.366	.185
ILP	.470	**.212**	N/A	.185

Table 3: Upper-bound performance comparison. Results are averaged over all clusters in DUC'04.

Table 3 shows the performance of RL and ILP on the DUC'04 dataset. TD(λ) significantly outperforms LSTD(λ) in terms of all ROUGE scores we consider. Although the least-square RL algorithms (which LSTD belongs to) have been proved to achieve better performance than standard TD methods in large-scale problems (see Lagoudakis and Parr, 2003), their performance is sensitive to many factors, e.g., initialisation values in the diagonal matrix, regularisation parameters, etc. We note that a similar observation about the inferior performance of least-square RL in EMDS is reported by Rioux et al. (2014).

TD(λ) also significantly outperforms ILP in terms of all metrics except ROUGE-2. This is not surprising, because the bigram-based ILP is optimised for ROUGE-2, whereas our reward function U^* considers other metrics as well (see Eq. (6)). Since ILP is widely used as a strong baseline for EMDS, these results confirm the advantage of using RL for EMDS problems.

6.3 Complete Pipeline Performance

Finally, we combine the best techniques of the APL and RL phase (namely Unc and TD(λ), respectively) to complete APRIL, and compare it against SPPI. As a baseline, we use the heuristic-based rewards HU to train both TD(λ) (ranking-based training, i.e. using HU to produce $r(y|x)$ in Eq. (5) to train) and SPPI (preference-based training, i.e. using HU for generating pairs to train

Table 5: Human ratings for the summaries generated by APRIL and SPPI (mean±standard error).

SPPI) for up to 5,000 episodes. The baseline results are presented in the bottom rows of Table 4.

We make the following observations from Table 4. **(i)** Given the same oracle, the performance of APRIL with 10 rounds of interaction is comparable or even superior than that of SPPI after 100 rounds of interaction (see boldface in Table 4), suggesting the strong advantage of APRIL to reduce sample complexity. **(ii)** APRIL can significantly improve the baseline with either 10 or 100 rounds of interaction, but SPPI's performance can be even worse than the baseline (marked by † in Table 4), especially under the high-noise low-budget settings (i.e., CNO-0.3, LNO-0.3, and LNO-1 with $T = 10$). This is because SPPI lacks a mechanism to balance between prior and posterior ranking, while APRIL can adjust this trade-off by tuning α (Eq. (7)). This endows APRIL with better noise robustness and lower sample complexity in high-noise low-budget settings. Note that the above observations also hold for the other two datasets, indicating the consistently strong performance of APRIL across different datasets.

As for the overall runtime, when budget $T = 100$, APRIL on average takes 2 minutes to interact with an oracle and output a summary, while SPPI takes around 15 minutes due to its expensive gradient descent computation (see §3.1).

7 Human Evaluation

Finally, we invited real users to compare and evaluate the quality of the summaries generated by SPPI and APRIL. We randomly selected three topics (d19 from DUC'01, d117i from DUC'02 and d30042 from DUC'04), and let both SPPI and our best-performing APRIL interact with PO for 10 rounds on these topics. The resulting 100-word summaries, shown in Figure 2, were presented to seven users, who had already read two background texts to familiarize with the topic. The users were asked to provide their preference on the presented

Topic d117i (DUC'02), SPPI: The Booker Prize is sponsored by Booker, an international food and agriculture business. The novel, a story of Scottish low-life narrated largely in Glaswegian dialect, is unlikely to prove a popular choice with booksellers, who have damned all six books shortlisted for the prize as boring, elitist and- worst of all- unsaleable. The shortlist of six for the Pounds 20,000 Booker Prize for fiction, announced yesterday, immediately prompted the question 'Who ? ' Japanese writer Kazuo Ishiguro won the 1989 Booker Prize, Britain's top literary award, for his novel "The Remains of the Day," judges announced Thursday. He didn't win.	**Topic d117i (DUC'02), APRIL**: Australian novelist Peter Carey was awarded the coveted Booker Prize for fiction Tuesday night for his love story, "Oscar and Lucinda." The Booker Prize is sponsored by Booker, an international food and agriculture business, and administered by The Book Trust. British publishers can submit three new novels by British and Commonwealth writers. Six novels have been nominated for the Booker Prize, Britain's most prestigious fiction award, and bookmakers say the favorite is "The Remains of the Day" by Japanese author Kazuo Ishiguro. On the day of the Big Event, Ladbroke, the large British betting agency, posted the final odds.
Topic d19 (DUC'01), SPPI: The issue cuts across partisan lines in the Senate, with Minority Leader Bob Dole (R-Kan.) arguing against the White House position on grounds that including illegal aliens in the census is unfair to American citizens.. Loss of Seats Cited. Shelby's amendment says only that the secretary is to "make such adjustments in total population figures as may be necessary, using such methods and procedures as the secretary determines feasible and appropriate" to keep illegal aliens from being counted in congressional reapportionment. "Some states will lose congressional seats because of illegal aliens," Dole argued. But there's nothing simple about it.	**Topic d19 (DUC'01), APRIL**: In a blow to California and other states with large immigrant populations, the Senate voted Friday to bar the Census Bureau from counting illegal aliens in the 1990 population count. But the Senate already has voted to force the Census Bureau to exclude illegal immigrants in preparing tallies for congressional reapportionment. said that Georgia and Indiana both lost House seats after the 1980 Census, and California and New York- centers of illegal immigration- each gained seats. A majority of the members of the House of Representatives has signaled support. The national head count will be taken April 1, 1990.

Figure 2: Summaries generated by SPPI and APRIL used in the human evaluation experiments.

summary pairs and rate the summaries on a 5-point Likert scale with higher scores for better summaries. All users are fluent in English.

In all three topics, all users prefer the APRIL-generated summaries over the SPPI-generated summaries. Table 5 shows the users' ratings. The APRIL-generated summaries consistently receive higher ratings. These results are consistent with our simulation experiments and confirm the significant advantage of APRIL over SPPI.

8 Conclusion

We propose a novel preference-based interactive learning formulation named APRIL (Active Preference ReInforcement Learning), which is able to make structured predictions without referring to the gold standard data. Instead, APRIL learns from preference-based feedback. We designed a novel objective function for APRIL, which naturally splits APRIL into an *active preference learning* (APL) phase and a *reinforcement learning* (RL) phase, enabling us to leverage a wide spectrum of active learning, preference learning and RL algorithms to maximise the output quality with a limited number of interaction rounds. We applied APRIL to the Extractive Multi-Document Summarisation (EMDS) problem, simulated the users' preference-giving behaviour using multiple user-response models, and compared the performance of multiple APL and RL techniques. Simulation experiments indicated that APRIL significantly improved the summary quality with just 10 rounds of interaction (even with high-noise oracles), and significantly outperformed SPPI in terms of both sample complexity and noise robustness. Human evaluation results suggested that real users preferred the APRIL-generated summaries over the SPPI-generated ones.

We identify two major lines of future work. On the technical side, we plan to employ more advanced APL and RL algorithms in APRIL, such as sample-efficient Bayesian-based APL algorithms (e.g., Simpson and Gurevych, 2018) and neural RL algorithms (e.g. Mnih et al., 2015) to further reduce the sample complexity of APRIL. On the experimental side, a logical next step is to implement an interactive user interface for APRIL and conduct a larger evaluation study comparing the summary quality before and after the interaction. We also plan to apply APRIL to more NLP applications, including machine translation, information exploration and semantic parsing.

Abstract

Generating a text abstract from a set of documents remains a challenging task. The neural encoder-decoder framework has recently been exploited to summarize single documents, but its success can in part be attributed to the availability of large parallel data automatically acquired from the Web. In contrast, parallel data for multi-document summarization are scarce and costly to obtain. There is a pressing need to adapt an encoder-decoder model trained on single-document summarization data to work with multiple-document input. In this paper, we present an initial investigation into a novel adaptation method. It exploits the maximal marginal relevance method to select representative sentences from multi-document input, and leverages an abstractive encoder-decoder model to fuse disparate sentences to an abstractive summary. The adaptation method is robust and itself requires no training data. Our system compares favorably to state-of-the-art extractive and abstractive approaches judged by automatic metrics and human assessors.

1 Introduction

Neural abstractive summarization has primarily focused on summarizing short texts written by single authors. For example, *sentence summarization* seeks to reduce the first sentence of a news article to a title-like summary (Rush et al., 2015; Nallapati et al., 2016; Takase et al., 2016; Song et al., 2018); *single-document summarization* (**SDS**) focuses on condensing a news article to a handful of bullet points (Paulus et al., 2017; See et al., 2017). These summarization studies are empowered by large parallel datasets automatically harvested from online news outlets, including Gigaword (Rush et al., 2015), CNN/Daily Mail (Hermann et al., 2015), NYT (Sandhaus, 2008), and Newsroom (Grusky et al., 2018).

To date, *multi-document summarization* (**MDS**) has not yet fully benefited from the development of neural encoder-decoder models. MDS seeks to condense a set of documents likely written by multiple authors to a short and informative summary. It has practical applications, such as summarizing product reviews (Gerani et al., 2014), student responses to post-class questionnaires (Luo and Litman, 2015; Luo et al., 2016), and sets of news articles discussing certain topics (Hong et al., 2014). State-of-the-art MDS systems are mostly extractive (Nenkova and McKeown, 2011). Despite their promising results, such systems cannot perform text abstraction, e.g., paraphrasing, generalization, and sentence fusion (Jing and McKeown, 1999). Further, annotated MDS datasets are often scarce, containing only hundreds of training pairs (see Table 1). The cost to create ground-truth summaries from multiple-document inputs can be prohibitive. The MDS datasets are thus too small to be used to train neural encoder-decoder models with millions of parameters without overfitting.

DATASET	SOURCE	SUMMARY	#PAIRS
Gigaword (Rush et al., 2015)	**the first sentence** of a news article	**8.3 words** title-like	**4 Million**
CNN/Daily Mail (Hermann et al., 2015)	**a news article**	**56 words** multi-sent	**312 K**
TAC (08-11) (Dang et al., 2008)	**10 news articles** related to a topic	**100 words** multi-sent	**728**
DUC (03-04) (Over and Yen, 2004)	**10 news articles** related to a topic	**100 words** multi-sent	**320**

Table 1: A comparison of datasets available for sent. summarization (Gigaword), single-doc (CNN/DM) and multi-doc summarization (DUC/TAC). The labelled data for multi-doc summarization are much less.

A promising route to generating an abstractive summary from a multi-document input is to apply a neural encoder-decoder model trained for single-document summarization to a "*mega-document*" created by concatenating all documents in the set at test time. Nonetheless, such a model may not scale well for two reasons. First, identifying important text pieces from a mega-document can be challenging for the encoder-decoder model, which is trained on single-document summarization data

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4131–4141
Brussels, Belgium, October 31 - November 4, 2018.

where the summary-worthy content is often contained in the first few sentences of an article. This is not the case for a mega-document. Second, redundant text pieces in a mega-document can be repeatedly used for summary generation under the current framework. The attention mechanism of an encoder-decoder model (Bahdanau et al., 2014) is position-based and lacks an awareness of semantics. If a text piece has been attended to during summary generation, it is unlikely to be used again. However, the attention value assigned to a similar text piece in a different position is not affected. The same content can thus be repeatedly used for summary generation. These issues may be alleviated by improving the encoder-decoder architecture and its attention mechanism (Cheng and Lapata, 2016; Tan et al., 2017). However, in these cases the model has to be re-trained on large-scale MDS datasets that are not available at the current stage. There is thus an increasing need for a lightweight adaptation of an encoder-decoder model trained on SDS datasets to work with multi-document inputs at test time.

In this paper, we present a novel adaptation method, named PG-MMR, to generate abstracts from multi-document inputs. The method is robust and requires no MDS training data. It combines a recent neural encoder-decoder model (PG for Pointer-Generator networks; See et al., 2017) that generates abstractive summaries from single-document inputs with a strong extractive summarization algorithm (MMR for Maximal Marginal Relevance; Carbonell and Goldstein, 1998) that identifies important source sentences from multi-document inputs. The PG-MMR algorithm iteratively performs the following. It identifies a handful of the most important sentences from the mega-document. The attention weights of the PG model are directly modified to focus on these important sentences when generating a summary sentence. Next, the system re-identifies a number of important sentences, but the likelihood of choosing certain sentences is reduced based on their similarity to the partially-generated summary, thereby reducing redundancy. Our research contributions include the following:

- we present an investigation into a novel adaptation method of the encoder-decoder framework from single- to multi-document summarization. To the best of our knowledge, this is the first attempt to couple the maximal marginal relevance algorithm with pointer-generator networks for multi-document summarization;
- we demonstrate the effectiveness of the proposed method through extensive experiments on standard MDS datasets. Our system compares favorably to state-of-the-art extractive and abstractive summarization systems measured by both automatic metrics and human judgments.

2 Related Work

Popular methods for multi-document summarization have been extractive. Important sentences are extracted from a set of source documents and optionally compressed to form a summary (Daume III and Marcu, 2002; Zajic et al., 2007; Gillick and Favre, 2009; Galanis and Androutsopoulos, 2010; Berg-Kirkpatrick et al., 2011; Li et al., 2013; Thadani and McKeown, 2013; Wang et al., 2013; Yogatama et al., 2015; Filippova et al., 2015; Durrett et al., 2016). In recent years neural networks have been exploited to learn word/sentence representations for single- and multi-document summarization (Cheng and Lapata, 2016; Cao et al., 2017; Isonuma et al., 2017; Yasunaga et al., 2017; Narayan et al., 2018). These approaches remain extractive; and despite encouraging results, summarizing a large quantity of texts still requires sophisticated abstraction capabilities such as generalization, paraphrasing and sentence fusion.

Prior to deep learning, abstractive summarization has been investigated (Barzilay et al., 1999; Carenini and Cheung, 2008; Ganesan et al., 2010; Gerani et al., 2014; Fabbrizio et al., 2014; Pighin et al., 2014; Bing et al., 2015; Liu et al., 2015; Liao et al., 2018). These approaches construct domain templates using a text planner or an open-IE system and employ a natural language generator for surface realization. Limited by the availability of labelled data, experiments are often performed on small domain-specific datasets.

Neural abstractive summarization utilizing the encoder-decoder architecture has shown promising results but studies focus primarily on single-document summarization (Nallapati et al., 2016; Kikuchi et al., 2016; Chen et al., 2016; Miao and Blunsom, 2016; Tan et al., 2017; Zeng et al., 2017; Zhou et al., 2017; Paulus et al., 2017; See et al., 2017; Gehrmann et al., 2018). The pointing mechanism (Gulcehre et al., 2016; Gu et al., 2016) allows a summarization system to both copy words from the source text and generate new words from the vocabulary. Reinforcement learning is exploited to directly optimize evaluation metrics (Paulus et al., 2017; Kryściński et al., 2018; Chen and Bansal, 2018). These studies focus on summarizing single documents in part because the training data are abundant.

The work of Baumel et al. (2018) and Zhang et al. (2018) are related to ours. In particular, Baumel et al. (2018) propose to extend an abstractive summarization system to generate query-focused summaries; Zhang et al. (2018) add a document set encoder to their hierarchical summarization framework. With these few exceptions, little research has been dedicated to investigate the feasibility of extending the encoder-decoder framework to generate abstractive summaries from multi-document inputs, where available training data are scarce.

This paper presents some first steps towards the goal of extending the encoder-decoder model to a multi-document setting. We introduce an adaptation method combining the pointer-generator (PG) networks (See et al., 2017) and the maximal marginal relevance (MMR) algorithm (Carbonell and Goldstein, 1998). The PG model, trained on SDS data and detailed in Section §3, is capable of generating document abstracts by performing text abstraction and sentence fusion. However, if the model is applied at test time to summarize multi-document inputs, there will be limitations. Our PG-MMR algorithm, presented in Section §4, teaches the PG model to effectively recognize important content from the input documents, hence improving the quality of abstractive summaries, all without requiring any training on multi-document inputs.

3 Limits of the Encoder-Decoder Model

The encoder-decoder architecture has become the *de facto* standard for neural abstractive summarization (Rush et al., 2015). The encoder is often a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) converting the input text to a set of hidden states $\{\mathbf{h}_i^e\}$, one for each input word, indexed by i. The decoder is a unidirectional LSTM that generates a summary by predicting one word at a time. The decoder hidden states are represented by $\{\mathbf{h}_t^d\}$, indexed by t. For sentence and single-document summarization (Nallapati et al., 2016; Paulus et al., 2017; See et al., 2017), the input text is treated as a sequence of words, and the model is expected to capture the source syntax inherently.

$$e_{t,i} = \mathbf{v}^\top \tanh(\mathbf{W}^e[\mathbf{h}_t^d||\mathbf{h}_i^e||\widetilde{\alpha}_{t,i}] + \mathbf{b}^e) \quad (1)$$
$$\alpha_{t,i} = \text{softmax}(e_{t,i}) \quad (2)$$
$$\widetilde{\alpha}_{t,i} = \textstyle\sum_{t'=0}^{t-1} \alpha_{t',i} \quad (3)$$

The attention weight $\alpha_{t,i}$ measures how important the i-th input word is to generating the t-th output word (Eq. (1-2)). Following (See et al., 2017), $\alpha_{t,i}$ is calculated by measuring the strength of interaction between the decoder hidden state $\mathbf{h}_t^d$, the encoder hidden state $\mathbf{h}_i^e$, and the *cumulative* attention $\widetilde{\alpha}_{t,i}$ (Eq. (3)). $\widetilde{\alpha}_{t,i}$ denotes the cumulative attention that the i-th input word receives up to time step t-1. A large value of $\widetilde{\alpha}_{t,i}$ indicates the i-th input word has been used prior to time t and it is unlikely to be used again for generating the t-th output word.

A context vector ($\mathbf{c}_t$) is constructed (Eq. (4)) to summarize the semantic meaning of the input; it is a weighted sum of the encoder hidden states. The context vector and the decoder hidden state ($[\mathbf{h}_t^d||\mathbf{c}_t]$) are then used to compute the vocabulary probability $P_{vcb}(w)$ measuring the likelihood of a vocabulary word w being selected as the t-th output word (Eq. (5)).[1]

$$\mathbf{c}_t = \textstyle\sum_i \alpha_{t,i}\mathbf{h}_i^e \quad (4)$$
$$P_{vcb}(w) = \text{softmax}(\mathbf{W}^y[\mathbf{h}_t^d||\mathbf{c}_t] + \mathbf{b}^y) \quad (5)$$

In many encoder-decoder models, a "switch" is estimated ($p_{gen} \in [0,1]$) to indicate whether the system has chosen to select a word from the vocabulary or to copy a word from the input text (Eq. (6)). The switch is computed using a feedforward layer with σ activation over $[\mathbf{h}_t^d||\mathbf{c}_t||\mathbf{y}_{t-1}]$, where $\mathbf{y}_{t-1}$ is the embedding of the output word at time t-1. The attention weights ($\alpha_{t,i}$) are used to compute the copy probability (Eq. (7)). If a word w appears once or more in the input text, its copy probability ($\sum_{i:w_i=w} \alpha_{t,i}$) is the sum of the attention weights over all its occurrences. The final probability $P(w)$ is a weighted combination of the vocabulary probability and the copy probability. A cross-entropy loss function can often be used to train the model end-to-end.

$$p_{gen}=\sigma(\mathbf{w}^z[\mathbf{h}_t^d||\mathbf{c}_t||\mathbf{y}_{t-1}])+b^z) \quad (6)$$
$$P(w)=p_{gen}P_{vcb}(w)+(1-p_{gen})\sum_{i:w_i=w}\alpha_{t,i} \quad (7)$$

To thoroughly understand the aforementioned encoder-decoder model, we divide its model parameters into four groups. They include

- parameters of the encoder and the decoder;
- $\{\mathbf{w}^z, b^z\}$ for calculating the "switch" (Eq. (6));

---

[1] Here $[\cdot||\cdot]$ represents the concatenation of two vectors. The pointer-generator networks (See et al., 2017) use two linear layers to produce the vocabulary distribution $P_{vcb}(w)$. We use $\mathbf{W}^y$ and $\mathbf{b}^y$ to denote parameters of both layers.

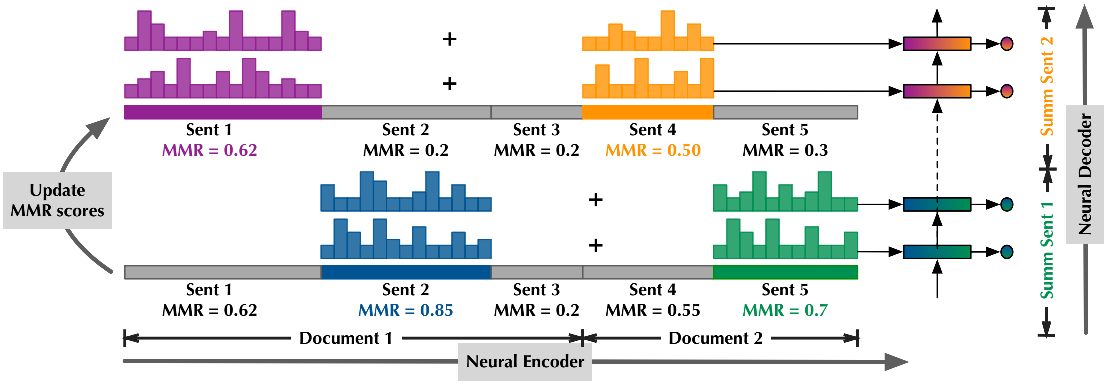

Figure 1: System framework. The PG-MMR system uses K highest-scored source sentences (in this case, K=2) to guide the PG model to generate a summary sentence. All other source sentences are "muted" in this process. Best viewed in color.

- $\{\mathbf{W}^y, \mathbf{b}^y\}$ for calculating $P_{vcb}(w)$ (Eq. (5));
- $\{\mathbf{v}, \mathbf{W}^e, \mathbf{b}^e\}$ for attention weights (Eq. (1)).

By training the encoder-decoder model on single-document summarization (SDS) data containing a large collection of news articles paired with summaries (Hermann et al., 2015), these model parameters can be effectively learned.

However, at test time, we wish for the model to generate abstractive summaries from *multi-document inputs*. This brings up two issues. First, the parameters are ineffective at identifying salient content from multi-document inputs. Humans are very good at identifying representative sentences from a set of documents and fusing them into an abstract. However, this capability is not supported by the encoder-decoder model. Second, the attention mechanism is based on input word positions but not their semantics. It can lead to redundant content in the multi-document input being repeatedly used for summary generation. We conjecture that both aspects can be addressed by introducing an "external" model that selects representative sentences from multi-document inputs and dynamically adjusts the sentence importance to reduce summary redundancy. This external model is integrated with the encoder-decoder model to generate abstractive summaries using selected representative sentences. In the following section we present our adaptation method for multi-document summarization.

4 Our Method

Maximal marginal relevance. Our adaptation method incorporates the maximal marginal relevance algorithm (MMR; Carbonell and Goldstein, 1998) into pointer-generator networks (PG; See et al., 2017) by adjusting the network's attention values. MMR is one of the most successful extractive approaches and, despite its straightforwardness, performs on-par with state-of-the-art systems (Luo and Litman, 2015; Yogatama et al., 2015). At each iteration, MMR selects one sentence from the document (D) and includes it in the summary (S) until a length threshold is reached. The selected sentence (s_i) is the most important one amongst the remaining sentences and it has the least content overlap with the current summary. In the equation below, $\text{Sim}_1(s_i, D)$ measures the similarity of the sentence s_i to the document. It serves as a proxy of sentence importance, since important sentences usually show similarity to the centroid of the document. $\max_{s_j \in S} \text{Sim}_2(s_i, s_j)$ measures the maximum similarity of the sentence s_i to each of the summary sentences, acting as a proxy of redundancy. λ is a balancing factor.

$$\underset{s_i \in D \setminus S}{\text{argmax}} \Big[\underbrace{\lambda \text{Sim}_1(s_i, D)}_{\text{importance}} - \underbrace{(1-\lambda) \max_{s_j \in S} \text{Sim}_2(s_i, s_j)}_{\text{redundancy}} \Big]$$

Our PG-MMR describes an iterative framework for summarizing a multi-document input to a summary consisting of multiple sentences. At each iteration, PG-MMR follows the MMR principle to select the K highest-scored source sentences; they serve as the basis for PG to generate a summary sentence. After that, the scores of all source sentences are updated based on their importance and redundancy. Sentences that are highly similar to the partial summary receive lower scores. Selecting K sentences via the MMR algorithm helps the PG system to effectively identify salient source content that has not been included in the summary.

Muting. To allow the PG system to effectively utilize the K source sentences without retraining the neural model, we dynamically adjust the PG attention weights ($\alpha_{t,i}$) at test time. Let S_k represent a selected sentence. The attention weights of the words belonging to $\{\mathrm{S}_k\}_{k=1}^K$ are calculated as before (Eq. (2)). However, words in other sentences are forced to receive zero attention weights ($\alpha_{t,i}$=0), and all $\alpha_{t,i}$ are renormalized (Eq. (8)).

$$\alpha_{t,i}^{\text{new}} = \begin{cases} \alpha_{t,i} & i \in \{\mathrm{S}_k\}_{k=1}^K \\ 0 & \text{otherwise} \end{cases} \tag{8}$$

It means that the remaining sentences are "muted" in this process. In this variant, the sentence importance does not affect the original attention weights, other than muting.

In an alternative setting, the sentence salience is multiplied with the word salience and renormalized (Eq. (9)). PG uses the reweighted alpha values to predict the next summary word.

$$\alpha_{t,i}^{\text{new}} = \begin{cases} \alpha_{t,i}\text{MMR}(\mathrm{S}_k) & i \in \{\mathrm{S}_k\}_{k=1}^K \\ 0 & \text{otherwise} \end{cases} \tag{9}$$

Sentence Importance. To estimate sentence importance $\text{Sim}_1(s_i, D)$, we introduce a supervised regression model in this work. Importantly, the model is trained on single-document summarization datasets where training data are abundant. At test time, the model can be applied to identify important sentences from multi-document input. Our model determines sentence importance based on four indicators, inspired by how humans identify important sentences from a document set. They include (a) sentence length, (b) its absolute and relative position in the document, (c) sentence quality, and (d) how close the sentence is to the main topic of the document set. These features are considered to be important indicators in previous extractive summarization framework (Galanis and Androutsopoulos, 2010; Hong et al., 2014).

Regarding the sentence quality (c), we leverage the PG model to build the sentence representation. We use the bidirectional LSTM encoder to encode any source sentence to a vector representation. $[\overrightarrow{\mathbf{h}}_N^e || \overleftarrow{\mathbf{h}}_1^e]$ is the concatenation of the last hidden states of the forward and backward passes. A document vector is the average of all sentence vectors. We use the document vector and the cosine similarity between the document and sentence vectors as indicator (d). A support vector regression model is trained on (sentence, score) pairs where the training data are obtained from the CNN/Daily Mail dataset. The target importance score is the ROUGE-L recall of the sentence compared to the ground-truth summary. Our model architecture leverages neural representations of sentences and documents, they are data-driven and not restricted to a particular domain.

Algorithm 1 The PG-MMR algorithm for summarizing multi-document inputs.

```
Input: SDS data; MDS source sentences $\{\mathrm{S}_i\}$
Train the PG model on SDS data
▶ $\mathcal{I}(\mathrm{S}_i)$ and $\mathcal{R}(\mathrm{S}_i)$ are the importance and redundancy scores of the source sentence $\mathrm{S}_i$
$\mathcal{I}(\mathrm{S}_i) \leftarrow \text{SVR}(\mathrm{S}_i)$ for all source sentences
$\text{MMR}(\mathrm{S}_i) \leftarrow \lambda\mathcal{I}(\mathrm{S}_i)$ for all source sentences
Summary $\leftarrow \{\}$
$t \leftarrow$ index of summary words
while $t < L_{\text{max}}$ do
    Find $\{\mathrm{S}_k\}_{k=1}^K$ with highest MMR scores
    Compute $\alpha_{t,i}^{\text{new}}$ based on $\{\mathrm{S}_k\}_{k=1}^K$ (Eq. (8))
    Run PG decoder for one step to get $\{w_t\}$
    Summary $\leftarrow$ Summary + $\{w_t\}$
    if $w_t$ is the period symbol then
        $\mathcal{R}(\mathrm{S}_i) \leftarrow \text{Sim}(\mathrm{S}_i, \text{Summary}), \forall i$
        $\text{MMR}(\mathrm{S}_i) \leftarrow \lambda\mathcal{I}(\mathrm{S}_i) - (1-\lambda)\mathcal{R}(\mathrm{S}_i), \forall i$
    end if
end while
```

Sentence Redundancy. To calculate the redundancy of the sentence ($\max_{s_j \in S} \text{Sim}_2(s_i, s_j)$), we compute the ROUGE-L precision, which measures the longest common subsequence between a source sentence and the partial summary (consisting of all sentences generated thus far by the PG model), divided by the length of the source sentence. A source sentence yielding a high ROUGE-L precision is deemed to have significant content overlap with the partial summary. It will receive a low MMR score and hence is less likely to serve as basis for generating future summary sentences.

Alg. 1 provides an overview the PG-MMR algorithm and Fig. 1 is a graphical illustration. The MMR scores of source sentences are updated after each summary sentence is generated by the PG model. Next, a different set of highest-scored sentences are used to guide the PG model to generate the next summary sentence. "Muting" the remaining source sentences is important because it helps the PG model to focus its attention on the most significant source content. The code for our model is publicly available to further MDS research.[2]

5 Experimental Setup

Datasets. We investigate the effectiveness of the PG-MMR method by testing it on standard multi-document summarization datasets (Over and Yen,

---

[2] https://github.com/ucfnlp/multidoc_summarization

2004; Dang and Owczarzak, 2008). These include DUC-03, DUC-04, TAC-08, TAC-10, and TAC-11, containing 30/50/48/46/44 topics respectively. The summarization system is tasked with generating a concise, fluent summary of 100 words or less from a set of 10 documents discussing a topic. All documents in a set are chronologically ordered and concatenated to form a mega-document serving as input to the PG-MMR system. Sentences that start with a quotation mark or do not end with a period are excluded (Wong et al., 2008). Each system summary is compared against 4 human abstracts created by NIST assessors. Following convention, we report results on DUC-04 and TAC-11 datasets, which are standard test sets; DUC-03 and TAC-08/10 are used as a validation set for hyperparameter tuning.[3]

The PG model is trained for single-document summarization using the CNN/Daily Mail (Hermann et al., 2015) dataset, containing single news articles paired with summaries (human-written article highlights). The training set contains 287,226 articles. An article contains 781 tokens on average; and a summary contains 56 tokens (3.75 sentences). During training we use the hyperparameters provided by See et al. (2017). At test time, the maximum/minimum decoding steps are set to 120/100 words respectively, corresponding to the max/min lengths of the PG-MMR summaries. Because the focus of this work is on multi-document summarization (MDS), we do not report results for the CNN/Daily Mail dataset.

Baselines. We compare PG-MMR against a broad spectrum of baselines, including state-of-the-art extractive ('*ext-*') and abstractive ('*abs-*') systems. They are described below.[4]

- *ext-***SumBasic** (Vanderwende et al., 2007) is an extractive approach assuming words occurring frequently in a document set are more likely to be included in the summary;
- *ext-***KL-Sum** (Haghighi and Vanderwende, 2009) greedily adds source sentences to the summary if it leads to a decrease in KL divergence;
- *ext-***LexRank** (Erkan and Radev, 2004) uses a graph-based approach to compute sentence importance based on eigenvector centrality in a graph representation;
- *ext-***Centroid** (Hong et al., 2014) computes the importance of each source sentence based on its cosine similarity with the document centroid;
- *ext-***ICSISumm** (Gillick et al., 2009) leverages the ILP framework to identify a globally-optimal set of sentences covering the most important concepts in the document set;

System	DUC-04 R-1	R-2	R-SU4
SumBasic (Vanderwende et al., 2007)	29.48	4.25	8.64
KLSumm (Haghighi et al., 2009)	31.04	6.03	10.23
LexRank (Erkan and Radev, 2004)	34.44	7.11	11.19
Centroid (Hong et al., 2014)	35.49	7.80	12.02
ICSISumm (Gillick and Favre, 2009)	37.31	9.36	13.12
DPP (Taskar, 2012)	38.78	9.47	13.36
Extract+Rewrite (Song et al., 2018)	28.90	5.33	8.76
Opinosis (Ganesan et al., 2010)	27.07	5.03	8.63
PG-Original (See et al., 2017)	31.43	6.03	10.01
PG-MMR w/ SummRec	34.57	7.46	11.36
PG-MMR w/ SentAttn	36.52	8.52	12.57
PG-MMR w/ Cosine (*default*)	36.88	**8.73**	12.64
PG-MMR w/ BestSummRec	36.42	**9.36**	13.23

Table 2: ROUGE results on the DUC-04 dataset.

System	TAC-11 R-1	R-2	R-SU4
SumBasic (Vanderwende et al., 2007)	31.58	6.06	10.06
KLSumm (Haghighi et al., 2009)	31.23	7.07	10.56
LexRank (Erkan and Radev, 2004)	33.10	7.50	11.13
Extract+Rewrite (Song et al., 2018)	29.07	6.11	9.20
Opinosis (Ganesan et al., 2010)	25.15	5.12	8.12
PG-Original (See et al., 2017)	31.44	6.40	10.20
PG-MMR w/ SummRec	35.06	8.72	12.39
PG-MMR w/ SentAttn	37.01	10.43	13.85
PG-MMR w/ Cosine (*default*)	37.17	**10.92**	14.04
PG-MMR w/ BestSummRec	40.44	**14.93**	17.61

Table 3: ROUGE results on the TAC-11 dataset.

- *ext-***DPP** (Taskar, 2012) selects an optimal set of sentences per the determinantal point processes that balance the coverage of important information and the sentence diversity;
- *abs-***Opinosis** (Ganesan et al., 2010) generates abstractive summaries by searching for salient paths on a word co-occurrence graph created from source documents;
- *abs-***Extract+Rewrite** (Song et al., 2018) is a recent approach that scores sentences using LexRank and generates a title-like summary for each sentence using an encoder-decoder model trained on Gigaword data.
- *abs-***PG-Original** (See et al., 2017) introduces an encoder-decoder model that encourages the system to copy words from the source text via pointing, while retaining the ability to produce novel words through the generator.

6 Results

Having described the experimental setup, we next compare the PG-MMR method against the baselines on standard MDS datasets, evaluated by both automatic metrics and human assessors.

ROUGE (Lin, 2004). This automatic metric measures the overlap of unigrams (R-1), bigrams (R-2) and skip bigrams with a maximum distance of 4 words (R-SU4) between the system summary and a set of reference summaries. ROUGE scores of various systems are presented in Table 2 and 3 respectively for the DUC-04 and TAC-11 datasets.

We explore variants of the PG-MMR method.

---

[3] The hyperparameters for all PG-MMR variants are K=7 and λ=0.6; except for "w/ BestSummRec" where K=2.

[4] We are grateful to Hong et al. (2014) for providing the summaries generated by Centroid, ICSISumm, DPP systems. These are only available for the DUC-04 dataset.

They differ in how the importances of source sentences are estimated and how the sentence importance affects word attention weights. "***w/ Cosine***" computes the sentence importance as the cosine similarity score between the sentence and document vectors, both represented as sparse TF-IDF vectors under the vector space model. "***w/ SummRec***" estimates the sentence importance as the predicted R-L recall score between the sentence and the summary. A support vector regression model is trained on sentences from the CNN/Daily Mail datasets (≈33K) and applied to DUC/TAC sentences at test time (see §4). "***w/ BestSummRec***" obtains the best estimate of sentence importance by calculating the R-L recall score between the sentence and reference summaries. It serves as an upper bound for the performance of "w/ SummRec." For all variants, the sentence importance scores are normalized to the range of [0,1]. "***w/ SentAttn***" adjusts the attention weights using Eq. (9), so that words in important sentences are more likely to be used to generate the summary. The weights are otherwise computed using Eq. (8).

As seen in Table 2 and 3, our PG-MMR method surpasses all unsupervised extractive baselines, including SumBasic, KLSumm, and LexRank. On the DUC-04 dataset, ICSISumm and DPP show good performance, but these systems are trained directly on MDS datasets, which are not utilized by the PG-MMR method. PG-MMR exhibits superior performance compared to existing abstractive systems. It outperforms Opinosis and PG-Original by a large margin in terms of R-2 F-scores (5.03/6.03/**8.73** for DUC-04 and 5.12/6.40/**10.92** for TAC-11). In particular, ***PG-Original*** is the original pointer-generator networks with multi-document inputs at test time. Compared to it, PG-MMR is more effective at identifying summary-worthy content from the input. "w/ Cosine" is used as the default PG-MMR and it shows better results than "w/ SummRec." It suggests that the sentence and document representations obtained from the encoder-decoder model (trained on CNN/DM) are suboptimal, possibly due to a vocabulary mismatch, where certain words in the DUC/TAC datasets do not appear in CNN/DM and their embeddings are thus not learned during training. Finally, we observe that "w/ BestSummRec" yields the highest performance on both datasets. This finding suggests that there is a great potential for improvements of the PG-MMR method as its "extractive" and "abstractive" components can be separately optimized.

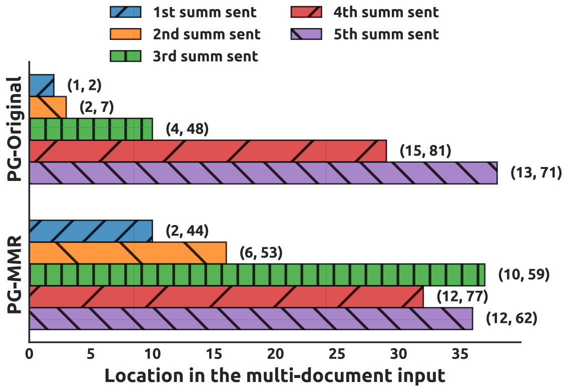

Figure 2: The median location of summary n-grams in the multi-document input (and the lower/higher quartiles). The n-grams come from the 1st/2nd/3rd/4th/5th summary sentence and the location is the source sentence index. (TAC-11)

System	1-grams	2-grams	3-grams	Sent
Extr+Rewrite	89.37	54.34	25.10	6.65
PG-Original	99.64	96.28	88.83	47.67
PG-MMR	99.74	97.64	91.57	59.13
Human Abst.	84.32	45.22	18.70	0.23

Table 4: Percentages of summary n-grams (or the entire sentences) appear in the multi-document input. (TAC-11)

Location of summary content. We are interested in understanding why PG-MMR outperforms PG-Original at identifying summary content from the multi-document input. We ask the question: where, in the source documents, does each system tend to look when generating their summaries? Our findings indicate that PG-Original gravitates towards early source sentences, while PG-MMR searches beyond the first few sentences.

In Figure 2 we show the median location of the first occurrences of summary n-grams, where the n-grams can come from the 1st to 5th summary sentence. For PG-Original summaries, n-grams of the 1st summary sentence frequently come from the 1st and 2nd source sentences, corresponding to the lower/higher quartiles of source sentence indices. Similarly, n-grams of the 2nd summary sentence come from the 2nd to 7th source sentences. For PG-MMR summaries, the patterns are different. The n-grams of the 1st and 2nd summary sentences come from source sentences of the range (2, 44) and (6, 53), respectively. Our findings suggest that PG-Original tends to treat the input as a single-document and identifies summary-worthy content from the beginning of the input, whereas PG-MMR can successfuly search a broader range of the input for summary content. This capability is crucial for multi-document input where important content can come from any article in the set.

Degree of extractiveness. Table 4 shows the

	Linguistic Quality			Rankings (%)			
System	Fluency	Inform.	NonRed.	1st	2nd	3rd	4th
Extract+Rewrite	2.03	2.19	1.88	5.6	11.6	11.6	**71.2**
LexRank	**3.29**	3.36	3.30	30.0	28.8	32.0	9.2
PG-Original	3.20	3.30	3.19	29.6	26.8	**32.8**	10.8
PG-MMR	3.24	**3.52**	**3.42**	**34.8**	**32.8**	23.6	8.8

Table 5: Linguistic quality and rankings of system summaries. (DUC-04)

Human Abstract	PG-Original Summary
• Boeing 737-400 plane with 102 people on board crashed into a mountain in the West Sulawesi province of Indonesia, on Monday, January 01, 2007, killing at least 90 passengers, with 12 possible survivors. • The plane was Adam Air flight KI-574, departing at 12:59 pm from Surabaya on Java bound for Manado in northeast Sulawesi. • The plane crashed in a mountainous region in Polewali, west Sulawesi province. • There were three Americans on board, it is not know if they survived. • The cause of the crash is not known at this time but it is possible bad weather was a factor.	• Adam Air Boeing 737-400 crashed Monday after vanishing off air traffic control radar screens between the Indonesian islands of Java and Sulawesi. • Up to 12 people were thought to have survived, with rescue teams racing to the crash site near Polewali in West Sulawesi , some 180 kilometres north of the South Sulawesi provincial capital Makassar. • It was the worst air disaster since Sept. 5, 2005, when a Mandala Airline's Boeing 737-200 crashed shortly after taking off from the North Sumatra's airport, killing 103 people. • Earlier on Friday, a ferry carrying 628 people sank off the Java coast.
Extract+Rewrite Summary	**PG-MMR Summary**
• Plane with 102 people on board crashes. • Three Americans among 102 on board plane in Indonesia. • Rescue team arrives in Indonesia after plane crash. • Plane with 102 crashes in West Sulawesi, killing at least 90. • No word on the fate of Boeing 737-400. • Plane carrying 96 passengers loses contact with Makassar. • Plane crashes in Indonesia , killing at least 90. • Indonesian navy sends two planes to carry bodies of five. • Indonesian plane carrying 102 missing. • Indonesian lawmaker criticises slow deployment of plane. • Hundreds of kilometers plane crash.	• The Adam Air Boeing 737-400 crashed Monday afternoon, but search and rescue teams only discovered the wreckage early Tuesday. • The Indonesian rescue team arrived at the mountainous area in West Sulawesi province where a passenger plane with 102 people onboard crashed into a mountain in Polewali, West Sulawesi province. • Air force rear commander Eddy Suyanto told-Shinta radio station that the plane – operated by local carrier Adam Air – had crashed in a mountainous region in Polewali province on Monday. • There was no word on the fate of the remaining 12 people on board the boeing 737-400.

Table 6: Example system summaries and human-written abstract. The sentences are manually de-tokenized for readability.

percentages of summary n-grams (or entire sentences) appearing in the multi-document input. PG-Original and PG-MMR summaries both show a high degree of extractiveness, and similar findings have been revealed by See et al. (2017). Because PG-MMR relies on a handful of representative source sentences and mutes the rest, it appears to be marginally more extractive than PG-Original. Both systems encourage generating summary sentences by stitching together source sentences, as about 52% and 41% of the summary sentences do not appear in the source, but about 90% the n-grams do. The Extract+Rewrite summaries (§5), generated by rewriting selected source sentences to title-like summary sentences, exhibits a high degree of abstraction, close to that of human abstracts.

Linguistic quality. To assess the linguistic quality of various system summaries, we employ Amazon Mechanical Turk human evaluators to judge the summary quality, including PG-MMR, LexRank, PG-Original, and Extract+Rewrite. A turker is asked to rate each system summary on a scale of 1 (worst) to 5 (best) based on three evaluation criteria: ***informativeness*** (to what extent is the meaning expressed in the ground-truth text preserved in the summary?), ***fluency*** (is the summary grammatical and well-formed?), and ***non-redundancy*** (does the summary successfully avoid repeating information?). Human summaries are used as the ground-truth. The turkers are also asked to provide an overall ranking for the four system summaries. Results are presented in Table 5. We observe that the LexRank summaries are highest-rated on fluency. This is because LexRank is an extractive approach, where summary sentences are directly taken from the input. PG-MMR is rated as the best on both informativeness and non-redundancy. Regarding overall system rankings, PG-MMR summaries are frequently ranked as the 1st- and 2nd-best summaries, outperforming the others.

Example summaries. In Table 6 we present example summaries generated by various systems. PG-Original cannot effectively identify important content from the multi-document input. Extract+Rewrite tends to generate short, title-like sentences that are less informative and carry substantial redundancy. This is because the system is trained on the Gigaword dataset (Rush et al., 2015) where the target summary length is 7 words. PG-MMR generates summaries that effectively condense the important source content.

7 Conclusion

We describe a novel adaptation method to generate abstractive summaries from multi-document inputs. Our method combines an extractive summarization algorithm (MMR) for sentence extraction and a recent abstractive model (PG) for fusing source sentences. The PG-MMR system demonstrates competitive results, outperforming strong extractive and abstractive baselines.

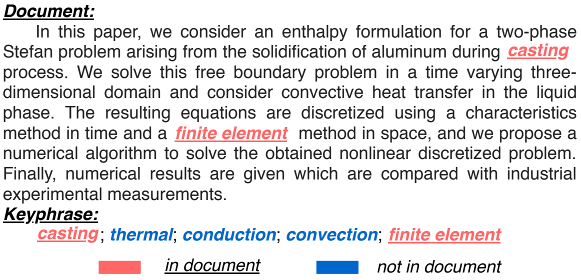
Abstract

We study the problem of generating keyphrases that summarize the key points for a given document. While sequence-to-sequence (seq2seq) models have achieved remarkable performance on this task (Meng et al., 2017), model training often relies on large amounts of labeled data, which is only applicable to resource-rich domains. In this paper, we propose semi-supervised keyphrase generation methods by leveraging both labeled data and large-scale unlabeled samples for learning. Two strategies are proposed. First, unlabeled documents are first tagged with synthetic keyphrases obtained from unsupervised keyphrase *extraction* methods or a self-learning algorithm, and then combined with labeled samples for training. Furthermore, we investigate a multi-task learning framework to jointly learn to generate keyphrases as well as the titles of the articles. Experimental results show that our semi-supervised learning-based methods outperform a state-of-the-art model trained with labeled data only.

1 Introduction

Keyphrase extraction concerns the task of selecting a set of phrases from a document that can indicate the main ideas expressed in the input (Turney, 2000; Hasan and Ng, 2014). It is an essential task for document understanding because accurate identification of keyphrases can be beneficial for a wide range of downstreaming natural language processing and information retrieval applications. For instance, keyphrases can be leveraged to improve text summarization systems (Zhang et al., 2004; Liu et al., 2009a; Wang and Cardie, 2013), facilitate sentiment analysis and opinion mining (Wilson et al., 2005; Berend, 2011), and help with document clustering (Hammouda et al., 2005). Though relatively easy to implement, extract-based approaches fail to generate keyphrases that do not appear in the source document, which are frequently produced by human annotators as shown in Figure 1. Recently, Meng et al. (2017) propose to use a sequence-to-sequence model (Sutskever et al., 2014) with copying mechanism for *keyphrase generation*, which is able to produce phrases that are not in the input documents.



Document:

In this paper, we consider an enthalpy formulation for a two-phase Stefan problem arising from the solidification of aluminum during ***casting*** process. We solve this free boundary problem in a time varying three-dimensional domain and consider convective heat transfer in the liquid phase. The resulting equations are discretized using a characteristics method in time and a ***finite element*** method in space, and we propose a numerical algorithm to solve the obtained nonlinear discretized problem. Finally, numerical results are given which are compared with industrial experimental measurements.

While seq2seq model demonstrates good performance on keyphrase generation (Meng et al., 2017), it heavily relies on massive amounts of labeled data for model training, which is often unavailable for new domains. To overcome this drawback, in this work, *we investigate semi-supervised learning for keyphrase generation, by leveraging abundant unlabeled documents along with limited labeled data*. Intuitively, additional documents, though unlabeled, can provide useful knowledge on universal linguistic features and discourse structure, such as context information for keyphrases and that keyphrases are likely to be noun phrases or main verbs. Furthermore, learning with unlabeled data can also mitigate the overfitting problem, which is often caused by small size of labeled training data, and thus improve model generalizability and enhance keyphrase generation performance on unseen data.

Concretely, two major approaches are proposed for leveraging unlabeled data. For the first method,

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4142–4153
Brussels, Belgium, October 31 - November 4, 2018.

unlabeled documents are first tagged with synthetic keyphrases, then mixed with labeled data for model pre-training. Synthetic keyphrases are acquired through existing unsupervised keyphrase *extraction* methods (e.g., TF-IDF or TextRank (Mihalcea and Tarau, 2004)) or a self-learning algorithm. The pre-trained model will further be fine-tuned on the labeled data only. For the second approach, we propose a multi-task learning (MTL) framework[1] by jointly learning the main task of keyphrase generation based on labeled samples, and an auxiliary task of title generation (Rush et al., 2015) on unlabeled documents. Here one encoder is shared among the two tasks. Importantly, we test our proposed methods on a seq2seq framework, however, we believe they can be easily adapted to other encoder-decoder-based systems.

Extensive experiments are conducted in scientific paper domain. Results on five different datasets show that all of our semi-supervised learning-based models can uniformly significantly outperform a state-of-the-art model (Meng et al., 2017) as well as several competitive unsupervised and supervised keyphrase extraction algorithms based on F_1 and recall scores. We further carry out a cross-domain study on generating keyphrases for news articles, where our models yield better F_1 than a model trained on labeled data only. Finally, we also show that training with unlabeled samples can further produce performance gain even when a large amount of labeled data is available.

2 Related Work

Keyphrase Extraction and Generation. Early work mostly focuses on the keyphrase extraction task, and a two-step strategy is typically designed. Specifically, a large pool of candidate phrases are first extracted according to predefined syntactic templates (Mihalcea and Tarau, 2004; Wan and Xiao, 2008; Liu et al., 2009b, 2011) or their estimated importance scores (Hulth, 2003). In the second step, re-ranking is applied to yield the final keyphrases, based on supervised learning (Frank et al., 1999; Witten et al., 1999; Hulth, 2003; Lopez and Romary, 2010; Kim and Kan, 2009), unsupervised graph algorithms (Mihalcea and Tarau, 2004; Wan and Xiao, 2008; Bougouin et al., 2013), or topic modelings (Liu et al., 2009c, 2010). Keyphrase generation is studied in more recent work. For instance, Liu et al. (2011) propose to use statistic machine translation model to learn word-alignments between documents and keyphrases, enabling the model to generate keyphrases which do not appear in the input. Meng et al. (2017) train seq2seq-based generation models (Sutskever et al., 2014) on large-scale labeled corpora, which may not be applicable to a new domain with minimal human labels.

Neural Semi-supervised Learning. As mentioned above, though significant success has been achieved by seq2seq model in many NLP tasks (Luong et al., 2015; See et al., 2017; Dong and Lapata, 2016; Wang and Ling, 2016; Ye et al., 2018), they often rely on large amounts of labeled data, which are expensive to get. In order to mitigate the problem, semi-supervised learning has been investigated to incorporate unlabeled data for modeling training (Dai and Le, 2015; Ramachandran et al., 2017). For example, neural machine translation community has studied the usage of source-side or target-side monolingual data to improve translation quality (Gülçehre et al., 2015), where generating synthetic data (Sennrich et al., 2016; Zhang and Zong, 2016), multi-task learning (Zhang and Zong, 2016), and autoencoder-based methods (Cheng et al., 2016) are shown to be effective. Multi-task learning is also examined for sequence labeling tasks (Rei, 2017; Liu et al., 2018). In our paper, we study semi-supervised learning for keyphrase generation based on seq2seq models, which has not been explored before. Besides, we focus on leveraging source-side unlabeled articles to enhance performance with synthetic keyphrase construction or multi-task learning.

3 Neural Keyphrase Generation Model

In this section, we describe the neural keyphrase generation model built on a sequence-to-sequence model (Sutskever et al., 2014) as illustrated in Figure 2. We denote the input source document as a sequence $\mathbf{x} = x_1 \cdots x_{|\mathbf{x}|}$ and its corresponding keyphrase set as $a = \{a_i\}_{i=1}^{|a|}$, with a_i as one keyphrase.

Keyphrase Sequence Formulation. Different from the setup by Meng et al. (2017), where input article is paired with each keyphrase a_i to consist a training sample, we concatenate the keyphrases in a into a keyphrase sequence $\mathbf{y} =$

---

[1] We use "semi-supervised learning" as a broad term to refer to the two methods proposed in this paper.

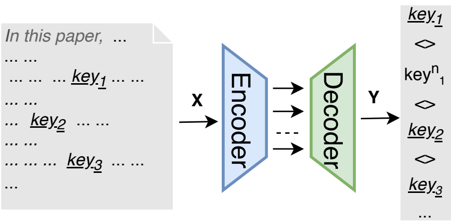

Figure 2: Neural keyphrase generation model built on sequence-to-sequence framework. Input is the document, and output is the keyphrase sequence consisting of phrases present (key_i) or absent (key_i^n) in the input.

$a_1 \diamondsuit a_2 \diamondsuit \cdots \diamondsuit a_{|a|}$, where $\diamondsuit$ is a segmenter to separate the keyphrases[2]. With this setup, the seq2seq model is capable to generate all possible keyphrases in one sequence as well as capture the contextual information between the keyphrases from the same sequence.

Seq2Seq Attentional Model. With source document $\mathbf{x}$ and its keyphrase sequence $\mathbf{y}$, an encoder encodes $\mathbf{x}$ into context vectors, from which a decoder then generates $\mathbf{y}$. We set the encoder as one-layer bi-directional LSTM model and the decoder as another one-layer LSTM model (Hochreiter and Schmidhuber, 1997). The probability of generating target sequence $p(\mathbf{y}|\mathbf{x})$ is formulated as:

$$p(\mathbf{y}|\mathbf{x}) = \prod_{t=1}^{|\mathbf{y}|} p(y_t|\mathbf{y}_{<t}, \mathbf{x}) \tag{1}$$

where $\mathbf{y}_{<t} = y_1 \cdots y_{t-1}$.

Let $\mathbf{h}_t = [\overrightarrow{\mathbf{h}}_t; \overleftarrow{\mathbf{h}}_t]$ denote the hidden state vector in the encoder at time step t, which is the concatenation of forward hidden vector $\overrightarrow{\mathbf{h}}_t$ and backward hidden vector $\overleftarrow{\mathbf{h}}_t$. Specifically, $\overrightarrow{\mathbf{h}}_t = \mathbf{f}_{\mathrm{LSTM_e}}(x_t, \overrightarrow{\mathbf{h}}_{t-1})$ and $\overleftarrow{\mathbf{h}}_t = \mathbf{f}_{\mathrm{LSTM_e}}(x_t, \overleftarrow{\mathbf{h}}_{t+1})$, where $\mathbf{f}_{\mathrm{LSTM_e}}$ is an LSTM unit in encoder.

Decoder hidden state is calculated as $\mathbf{s}_t = \mathbf{f}_{\mathrm{LSTM_d}}(y_{t-1}, \mathbf{s}_{t-1})$, where $\mathbf{f}_{\mathrm{LSTM_d}}$ is an LSTM unit in decoder. We apply global attention mechanism (Luong et al., 2015) to calculate the context vector:

$$\begin{aligned} \mathbf{c}_t &= \sum_{i=1}^{|\mathbf{x}|} \alpha_{t,i} \mathbf{h}_i \\ \alpha_{t,i} &= \frac{\exp(\mathbf{W}_{\mathrm{att}}[\mathbf{s}_t; \mathbf{h}_i])}{\sum_{k=1}^{|x|} \exp(\mathbf{W}_{\mathrm{att}}[\mathbf{s}_t \mathbf{h}_k])} \end{aligned} \tag{2}$$

Algorithm 1 Keyphrase Ranking

```
Input: Generated top R keyphrase sequences $\mathcal{S} = [\mathbf{y}_1, \cdots, \mathbf{y}_{\mathrm{R}}]$ ranked with generation possibility from high
    to low with beam search
Output: Ranked keyphrase set $\mathcal{A}$ with importance from
    high to low
    function KEY-RANK($\mathcal{S}$)
        $\mathcal{A} \leftarrow$ list()                    ▷ set $\mathcal{A}$ as a empty list.
        $\mathcal{Q} \leftarrow$ dict()      ▷ to skip keyword that is already in $\mathcal{A}$.
        for $\mathbf{y}_i \in \mathcal{S}$ do
            $y_i \leftarrow \mathbf{y}_i$.split("$\diamondsuit$");               ▷ split $\mathbf{y}_i$ by "$\diamondsuit$"
            for $a \in y_i$ do
                ▷ if $a$ has not been merged in $\mathcal{A}$, then keep it.
                if not $\mathcal{Q}$.has_key($a$) then
                    $\mathcal{A}$.append($a$)
                    $\mathcal{Q}$.update(dict({$a$ : ""}))
```

where $\alpha_{t,i}$ is the attention weight; $\mathbf{W}_{\mathrm{att}}$ contains learnable parameters. In this paper, we omit the bias variables to save space.

The probability to predict y_t in the decoder at time step t is factorized as:

$$\begin{aligned} p_{\mathrm{vocab}}(y_t|\mathbf{y}_{<t}, \mathbf{c}_t) = \mathbf{f}_{\mathrm{softmax}}(\mathbf{W}_{\mathrm{d_1}} \cdot \\ \tanh(\mathbf{W}_{\mathrm{d_2}}[\mathbf{s}_t; \mathbf{c}_t])) \end{aligned} \tag{3}$$

where $\mathbf{f}_{\mathrm{softmax}}$ is the softmax function and $\mathbf{W}_{\mathrm{d_1}}$ and $\mathbf{W}_{\mathrm{d_2}}$ are learnable parameters.

Pointer-generator Network. Similar to Meng et al. (2017), we utilize copying mechanism via pointer-generator network (See et al., 2017) to allow the decoder to directly copy words from input document, thus mitigating out-of-vocabulary (OOV) problem. At time step t, the generation probability p_{gen} is calculated as:

$$p_{\mathrm{gen}} = \mathbf{f}_{\mathrm{sigmoid}}(\mathbf{W}_{\mathrm{c}}\mathbf{c}_t + \mathbf{W}_{\mathrm{s}}\mathbf{s}_t + \mathbf{W}_{\mathrm{y}}y_t) \tag{4}$$

where $\mathbf{f}_{\mathrm{sigmoid}}$ is a sigmoid function; $\mathbf{W}_{\mathrm{c}}$, $\mathbf{W}_{\mathrm{s}}$ and $\mathbf{W}_{\mathrm{y}}$ are learnable parameters. p_{gen} plays a role of switcher to choose to generate a word from a fixed vocabulary with probability p_{vocab} or directly copy a word from the source document with the attention distribution α_t. With a combination of a fixed vocabulary and the extended source document vocabulary, the probability to predict y_t is:

$$p(y_t) = p_{\mathrm{gen}} p_{\mathrm{vocab}}(y_t|\mathbf{y}_{<t}, \mathbf{c}_t) + (1 - p_{\mathrm{gen}}) \sum_{i: y_i = y_t} \alpha_{t,i} \tag{5}$$

where if y_t does not appear in the fixed vocabulary, then the first term will be zero; and if y_t is outside source document, the second term will be zero.

---

[2] We concatenate keyphrases following the original keyphrase order in the corpora, and we set $\diamondsuit$ as ";" in our implementation. The effect of keyphrase ordering will be studied in the future work.

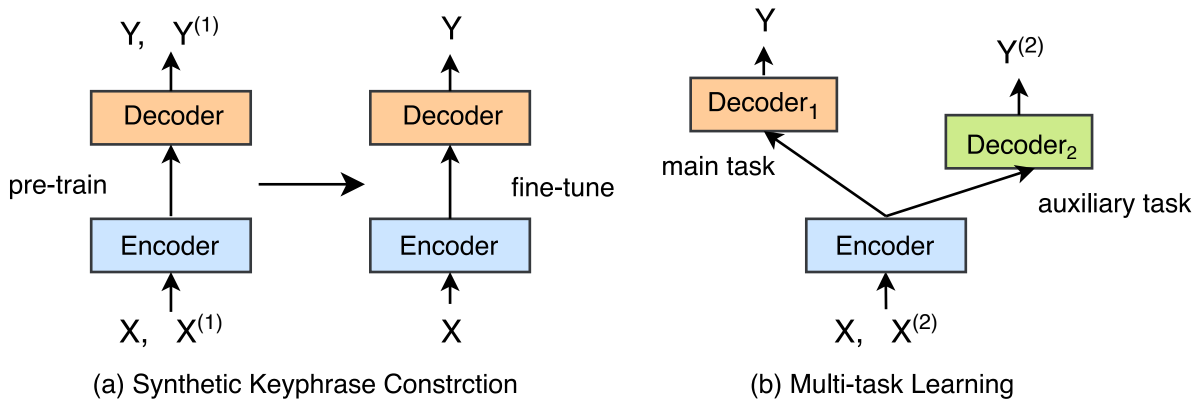

Figure 3: Our two semi-supervised learning methods which are based on (a) synthetic keyphrase construction, and (b) multi-task learning. (X, Y) represents labeled sample. $\mathrm{X}^{(1)}$ and $\mathrm{X}^{(2)}$ denotes unlabeled documents. $\mathrm{Y}^{(1)}$ refers to synthetic keyphrases of $\mathrm{X}^{(1)}$ and $\mathrm{Y}^{(2)}$ means the title of $\mathrm{X}^{(2)}$. For method of synthetic keyphrase construction, model will be pre-trained on the mixture of gold-standards and synthetic data, then fine-tuned on labeled data. For multi-task learning, model parameters of main task and auxiliary task will be jointly updated. Encoder parameters of the two tasks are shared.

Supervised Learning. With a labeled dataset $\mathcal{D}_p = \{\mathbf{x}_{(i)}, \mathbf{y}_{(i)}\}_{i=1}^N$, the loss function of seq2seq model is as follows:

$$\mathcal{L}(\theta) = -\sum_{i=1}^{N} \log p(\mathbf{y}_{(i)}|\mathbf{x}_{(i)}; \theta) \tag{6}$$

where θ contains all model parameters.

Keyphrase Inference and Ranking Strategy. Beam search is utilized for decoding, and the top R keyphrase sequences are leveraged for producing the final keyphrases. Here we use a beam size of 50, and R as 50. We propose a ranking strategy to collect the final set of keyphrases. Concretely, in sequence we collect unique keyphrases from the top ranked beams to lower ranked beams, and keyphrases in the same sequence are ordered as in the generation process. Intuitively, higher ranked sequences are likely of better quality. As for keyphrases in the same sequence, we find that more salient keyphrases are usually generated first. The ranking method is presented in Algorithm 1.

4 Semi-Supervised Learning for Keyphrase Generation

As illustrated in Figure 3, two methods are proposed to leverage abundant unlabeled data. The first is to provide synthetic keyphrases using unsupervised keyphrase extraction methods or self-learning algorithm, then mixed with labeled data for model training, which is described in Section 4.1. Furthermore, we introduce multi-task learning that jointly generates keyphrases and the title of the document (Section 4.2). We denote the large-scale unlabeled documents as $\mathcal{D}_u = \{\mathbf{x}'_{(i)}\}_{i=1}^M$ and labeled data as $\mathcal{D}_p = \{\mathbf{x}_{(i)}, \mathbf{y}_{(i)}\}_{i=1}^N$, where $M \gg N$.

4.1 Synthetic Keyphrase Construction

The first proposed technique is to construct synthetic labeled data by assigning keyphrases for unlabeled documents, and then mix the synthetic data with human labeled data for modeling training. Intuitively, adding training samples with synthetic keyphrases has two potentially benefits: (1) the encoder is exposed to more documents in training, and (2) the decoder also benefit from additional information from identifying contextual information for keyphrases. We propose and compare two methods to extract synthetic keyphrases.

Unsupervised Learning Methods. Unsupervised learning methods on keyphrase extraction have been long studied in previous work (Mihalcea and Tarau, 2004; Wan and Xiao, 2008). Here we select two effective and widely used methods to select keyphrases on unlabeled dataset $\mathcal{D}_u$, which are TF-IDF and TextRank (Mihalcea and Tarau, 2004). We combine the two methods into a hybrid approach, in which we first adopt the two methods to separately select top K keyphrases from the document, we then take the union with duplicate removal. To construct the keyphrase se-

Algorithm 2 Training Procedures for Synthetic Keyphrase Construction

```
Input: $\mathcal{D}_p$, $\mathcal{D}_s$, $\theta$
Output: $\theta$
  function PRE-TRAIN($\mathcal{D}_p$, $\mathcal{D}_s$, $\theta$)
      $\mathcal{D}_{p+s} \leftarrow \mathcal{D}_p \cup \mathcal{D}_s$
      Shuffle $\mathcal{D}_{p+s}$ randomly
      Update $\theta$ on $\mathcal{D}_{p+s}$ until converge
  function FINE-TUNE($\mathcal{D}_p$, $\theta$)
      Set $\theta$ as the best parameters from PRE-TRAIN
      Update $\theta$ on $\mathcal{D}_p$ until converge
```

quence, we concatenate the terms from TF-IDF and then from TextRank, following the corresponding ranking order. We set K as 5 in our experiments.

Self-learning Algorithm. Inspired by prior work (Zhang and Zong, 2016; Sennrich et al., 2016), we adopt self-learning algorithm to boost training data. Concretely, we first build a baseline model by training the seq2seq model on the labeled corpus $\mathcal{D}_p$. Then the trained baseline model is utilized to generate synthetic keyphrase sequence $\mathbf{y}'$ given a unlabeled document $\mathbf{x}'$. We adopt beam search to generate the synthetic keyphrase sequences and beam size is set as 10. The top one beam is selected.

Training Procedure. After the synthetic data $\mathcal{D}_s = \{\mathbf{x}'_{(i)}, \mathbf{y}'_{(i)}\}_{i=1}^{M}$ is obtained by either of the aforementioned methods, we mix labeled data $\mathcal{D}_p$ with $\mathcal{D}_s$ to train the seq2seq model. As described in Algorithm 2, we combine $\mathcal{D}_p$ with $\mathcal{D}_s$ into $\mathcal{D}_{p+s}$ and shuffle $\mathcal{D}_{p+s}$ randomly, then we pre-train the model on $\mathcal{D}_{p+s}$, in which no network parameters are frozen during the training process. The best performing model is selected based on validation set, then fine-tuned on $\mathcal{D}_p$ until converge.

4.2 Multi-task Learning with Auxiliary Task

The second approach to leverage unlabeled documents is to employ a multi-task learning framework which combines the main task of keyphrase generation with an auxiliary task through parameter sharing strategy. Similar to the model structure in Zhang and Zong (2016), our main task and the auxiliary task share an encoder network but have different decoders. Multi-task learning will benefit from the source-side information to improve the model generality of encoder.

In most domains such as scientific papers or news articles, a document usually contains a title that summarizes the core topics or ideas, with a similar spirit as keyphrases. We thus choose title generation as auxiliary task, which has been studied as a summarization problem (Rush et al., 2015; Colmenares et al., 2015). Let $\mathcal{D}'_u = \{\mathbf{x}'_{(i)}, \mathbf{q}_{(i)}\}_{i=1}^{M}$ denote the dataset which is assigned with titles for unlabeled data $\mathcal{D}_u$, the loss function of multi-task learning is factorized as:

Dataset	TRAIN	VALID
Small-scale		
Document-Keyphrase	40,000	5,000
Document-SyntheticKeyphrase	400,000	N/A
Document-Title	400,000	15,000
Large-scale		
Document-Keyphrase	130,000	5,000

Avg. #Tokens in Train	LABELED	SYN.	MTL
Small-scale			
Document	176.3	175.9	165.5
Keyphrase Sequence	23.3	23.5	N/A
Title	N/A	N/A	10.4

Table 1: Statistics of datasets used in our experiments.

$$\mathcal{L}(\theta^e, \theta_1^d, \theta_2^d) = -\sum_{i=1}^{N} \log p(\mathbf{y}_{(i)} | \mathbf{x}_{(i)}; \theta^e, \theta_1^d) - \sum_{i=1}^{M} \log p(\mathbf{q}_{(i)} | \mathbf{x}'_{(i)}; \theta^e, \theta_2^d) \quad (7)$$

where θ^e indicates encoder parameters; θ_1^d and θ_2^d are the decoder parameters.

Training Procedure. We adopt a simple alternating training strategy to switch training between the main task and the auxiliary task. Specifically, we first estimate parameters on auxiliary task with $\mathcal{D}'_u$ for one epoch, then train model on the main task with $\mathcal{D}_p$ (labeled dataset) for T epochs. We follow this training procedure for several times until the model of our main task converges. We set T as 3.

5 Experiments

5.1 Datasets

Our major experiments are conducted on scientific articles which have been studied in previous work (Hulth, 2003; Nguyen and Kan, 2007; Meng et al., 2017). We use the dataset from Meng et al. (2017) which is collected from various online digital libraries, e.g. ScienceDirect, ACM Digital Library, Wiley, and other portals.

As indicated in Table 1, we construct a relatively small-scale labeled dataset with 40K document-keyphrase[3] pairs, and a large-scale

Table 2: Results of *present* keyphrase generation with metrics F_1@5 and F_1@10. $*$ marks numbers that are significantly better than SEQ2SEQ-COPY ($p < 0.01$, F-test). Due to the high time perplexity, no result is reported by ExpandRank on KP20K, as done in Meng et al. (2017).

dataset of 400K unlabeled documents. Each document contains an abstract and a title of the paper. In multi-task learning setting, the auxiliary task is to generate the title from the abstract. For the validation set, we collect 5K document-keyphrase pairs for the process of pre-training and fine-tuning for methods based on synthetic data construction. For multi-task learning, we use the same 5K document-keyphrase pairs for the main task training, another 15K document-title pairs for the auxiliary task. We further conduct experiments on a 130K large-scale labeled dataset, which includes the small-scale labeled data.

Similar to Meng et al. (2017), we test our model on five widely used public datasets from the scientific domain: INSPEC (Hulth, 2003), NUS (Nguyen and Kan, 2007), KRAPIVIN (Krapivin et al., 2009), SEMEVAL-2010 (Kim et al., 2010) and KP20K (Meng et al., 2017).

5.2 Experimental Settings

Data preprocessing is implemented as in (Meng et al., 2017). The texts are first tokenized by NLTK (Bird and Loper, 2004) and lowercased, then the numbers are replaced with <digit>. We set maximal length of source text as 200, 40 for target text. Encoder and decoder both have a vocabulary size of 50K. The word embedding size is set to 128. Embeddings are randomly initialized and learned during training. The size of hidden vector is 512. Dropout rate is set as 0.3. Maximal gradient normalization is 2. Adagrad (Duchi et al., 2011) is adopted to train the model with learning rate of 0.15 and the initial accumulator rate is 0.1.

For synthetic data construction, we first use batch size of 64 for model pre-training and then reduce to 32 for model fine-tuning. For both training stages, after 8 epochs, learning rate be decreased with a rate of 0.5. For multi-task learning, batch size is set to 32 and learning rate is reduced to half after 20 training epochs. To build baseline seq2seq model, we set batch size as 32 and decrease learning rate after 8 epochs. For self-learning algorithm, beam size is set to 10 to generate target sequences for unlabeled data and the top one is retained.

5.3 Comparisons with Baselines

Evaluation Metrics. Following (Liu et al., 2011; Meng et al., 2017), we adopt top-N macro-averaged *precision*, *recall* and *F-measure* (F_1) for model evaluation. *Precision* means how many top-N extracted keywords are correct and *recall* means how many target keyphrases are extracted in top-N candidates. Porter Stemmer is applied before comparisons.

Baselines. We train a baseline seq2seq model on the small-scale labeled dataset. We further compare with four unsupervised learning methods: TF-IDF, TextRank (Mihalcea and Tarau, 2004), SingleRank (Wan and Xiao, 2008), ExpandRank (Wan and Xiao, 2008), and two supervised learning methods of Maui (Medelyan et al., 2009) and KEA (Witten et al., 1999). We follow Meng et al. (2017) for baselines setups.

Results. Here we show results for *present* and *absent* keyphrase generation separately[4]. From the results of present keyphrase generation as shown in Table 2, although trained on small-scale

---

[4] Recall that *present* means the keyphrase appears in the document, otherwise, it is *absent*.

labeled corpora, our baseline seq2seq model with copying mechanism still achieves better F_1@5 scores, compared to other baselines. This demonstrates that a baseline seq2seq model has learned the mapping patterns from source text to target keyphrases to some degree. However, small-scale labeled data still hinders the potential of seq2seq model according to the poor performance of F_1@10. By leveraging large-scale unlabeled data, our semi-supervised learning methods achieve siginifcant improvement over seq2seq baseline, as well as exhibit the best performance in both F_1@5 and F_1@10 on almost all datasets.

We further compare seq2seq based models on the task of generating keyphrases beyond input article vocabulary. Illustrated by Table 3, semi-supervised learning significantly improves the absent generation performance, compared to the baseline seq2seq. Among our models, the multi-task learning method is more effective at generating absent keyphrases than the two methods by leveraging synthetic data. The main reason may lie in that synthetic keyphrases potentially introduce noisy annotations, while the decoder in multi-task learning setting focuses on learning from gold-standard keyphrases. We can also see that the overall performances by all models are low, due to the intrinsic difficulty of absent keyphrase generation (Meng et al., 2017). Moreover, we only employ 40K labeled data for training, which is rather limited for training. Besides, we believe better evaluation methods should be used instead of exact match, e.g., by considering paraphrases. This will be studied in the future work.

5.4 Effect of Synthetic Keyphrase Quality

In this section, we conduct experiments to further study the effect of synthetic keyphrase quality on model performance. Two sets of experiments are undertaken, one for evaluating unsupervised learning and one for self-learning algorithm.

For self-learning algorithm, we further generate synthetic keyphrases using following options:

- Beam-size-3: Based on our baseline model trained with labeled data, we use beam search with a smaller beam size of 3 to generate synthetic data[5].

- Trained-model: We adopt the model which has been trained with self-learning algorithm on 40K labeled data and 400K unlabeled data, to generate the top one keyphrase sequence with beam size of 10.

For unsupervised learning method, we originally merge top-K (K = 5) keyphrases from TF-IDF and TextRank, here we use options where K is set as 1 or 10 to extract keyphrases:

- Top@1: Using TF-IDF or TextRank, we only keep top 1 extraction from each, then take the union of the two.

- Top@10: Similarly, we keep top 10 extracted terms from TF-IDF or TextRank, then take the union.

As illustrated in Figure 4, when models are pre-trained with synthetic keyphrases of better quality, results by "Trained-model" consistently produce better performance (i.e., lower perplexity). Similar phenomenon can be observed when "top@5" and "top@10" are applied for extraction in unsupervised learning setting. Furthermore, after models are pre-trained and then fine-tuned, the results in Figure 5 show that the difference among baselines becomes insignificant—the quality of synthetic keyphrases have limited effect on final scores. The reason might be that though synthetic

---

[5] We also experiment with greedy search (i.e. beam size of 1), however, unknown words are frequently generated.

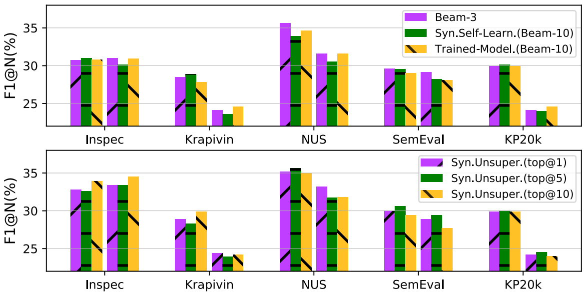

Figure 5: Effect of synthetic data quality on *present* keyphrase generation (models are pre-trained and fine-tuned) based on $F_1@5$ (left three columns) and $F_1@10$ (right three columns), on five datasets. The upper is for self-learning algorithm and the bottom is for unsupervised learning method.

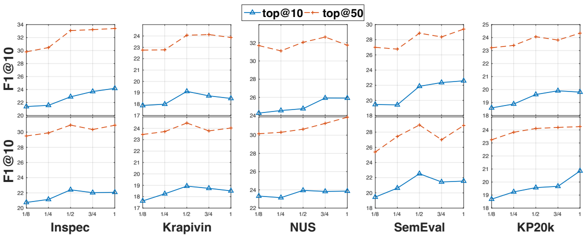

Figure 6: Effect of various amounts of unlabeled data for training on *present* keyphrase generation with $F_1@10$. Upper is for synthetic data construction method with unsupervised learning. Bottom is for multi-task learning algorithm.

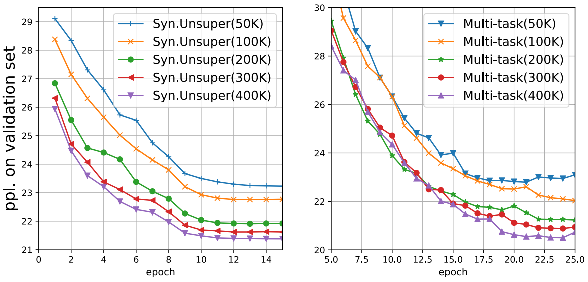

Figure 7: Perplexity on validation set with varying amounts of unlabeled data for training. Left is for fine-tuning procedure based on models trained with synthetic data constructed with unsupervised learning. Right is for multi-task learning procedure with performance on the main task.

Table 4: Results of keyphrase generation for news from DUC dataset with F_1. Results of unsupervised learning methods are adopted from Hasan and Ng (2010).

keyphrases potentially introduce noisy information for decoder training, the encoder is still well trained. In addition, after fine-tuning on labeled data, the decoder acquires additional knowledge, thus leading to better performance and minimal difference among the options.

5.5 Effect of Amount of Unlabeled Data

In this section, we further evaluate whether varying the amount of unlabeled data will affect model performance. We conduct experiments based on methods of synthetic data construction with unsupervised learning and multi-task learning. We further carry out experiments with randomly selected $50K(1/8)$, $100K(1/4)$, $200K(1/2)$ and $300K(3/4)$ unlabeled documents from the pool of $400K$ unlabeled data. After models being trained, we adopt beam search to generate keyphrase sequences with beam size of 50. We keep top N keyphrase sequences to yield the final keyphrases using Algorithm 1. $F_1@10$ is adopted to illustrate the model performances. N is set as 10 or 50.

The *present* keyphrase generation results are shown in Figure 6, from which we can see that when increasing the amount of unlabeled data, model performance is further improved. This is because additional unlabeled data can provide with more evidence on linguistic or context features and thus make the model, especially the encoder, have better generalizability. This finding echoes with the training procedure illustrated in Figure 7, where more unlabeled data uniformly leads to better performance. Therefore, we believe that leveraging more unlabeled data for model training can boost model performance.

5.6 A Pilot Study for Cross-Domain Test

Up to now, we have demonstrated the effectiveness of leveraging unlabeled data for in-domain experiments, but is it still effective when being tested on a different domain? We thus carry out a pilot cross-domain test on news articles. The widely used DUC dataset (Wan and Xiao, 2008) is utilized, consisting of 308 articles with 2,048 labeled keyphrases.

The experimental results are shown in Table 4 which indicate that: 1) though trained on scientific papers, our models still have the ability to gener-

ate keyphrases for news articles, illustrating that our models have learned some universal features between the two domains; and 2) semi-supervised learning by leveraging unlabeled data improves the generation performances more, indicating that our proposed method is reasonably effective when being tested on cross-domain data. Though unsupervised methods are still superior, for future work, we can leverage unlabeled out-of-domain corpora to improve cross-domain keyphrase generation performance, which could be a promising direction for domain adaption or transfer learning.

Table 6: Performance on *absent* keyphrase generation by Recall@10 with large-scale labeled training data.

5.7 Training on Large-scale Labeled Data

Finally, it would be interesting to study whether unlabeled data can still improve performance when the model is trained on a larger scaled labeled data. We conduct experiments on a larger labeled dataset with 130K pairs, along with the 400K unlabeled data. Here the baseline seq2seq model is built on the 130K dataset.

From the *present* keyphrase generation results in Table 5, it can be seen that unlabeled data is still helpful for model training on a large-scale labeled dataset. This implies that we can also leverage unlabeled data to enhance generation performance even in a resource-rich setting. Referring to the *absent* keyphrase generation results shown in Table 6, semi-supervised learning also boosts the scores. From Table 6, training on large-scale labeled data, *absent* generation is significantly improved, compared to being trained on a small-scale labeled data (see Table 3).

6 Conclusion and Future Work

In this paper, we presented a semi-supervised learning framework that leverages unlabeled data for keyphrase generation built upon seq2seq models. We introduced synthetic keyphrases construction algorithm and multi-task learning to effectively leverage abundant unlabeled documents. Extensive experiments demonstrated the effectiveness of our methods, even in scenario where large-scale labeled data is available.

For future work, we will 1) leverage unlabeled data to study domain adaptation or transfer learning for keyphrase generation; and 2) investigate novel models to improve *absent* keyphrase generation when limited labeled data is available based on semi-supervised learning.

Abstract

Multimodal summarization has drawn much attention due to the rapid growth of multimedia data. The output of the current multimodal summarization systems is usually represented in texts. However, we have found through experiments that multimodal output can significantly improve user satisfaction for informativeness of summaries. In this paper, we propose a novel task, multimodal summarization with multimodal output (MSMO). To handle this task, we first collect a large-scale dataset for MSMO research. We then propose a multimodal attention model to jointly generate text and select the most relevant image from the multimodal input. Finally, to evaluate multimodal outputs, we construct a novel multimodal automatic evaluation (MMAE) method which considers both intramodality salience and intermodality relevance. The experimental results show the effectiveness of MMAE.

1 Introduction

Text summarization is to extract the important information from source documents. With the increase of multimedia data on the internet, some researchers (Li et al., 2016b; Shah et al., 2016; Li et al., 2017) focus on multimodal summarization in recent years. Existing experiments (Li et al., 2017, 2018a) have proven that, compared to text summarization, multimodal summarization can improve the quality of generated summary by using information in visual modality.

However, the output of existing multimodal summarization systems is usually represented in a single modality, such as textual or visual (Li et al., 2017; Evangelopoulos et al., 2013; Mademlis et al., 2016). In this paper, we argue that multimodal output[1] is necessary for the following three reasons: 1) It is much easier and faster for users to get critical information from the images (Li et al., 2017). 2) According to our experiments, the multimodal output (text+image) increases users' satisfaction by 12.4% compared to the single-modality output (text) (more details can be found in Sec. 4.2). 3) Images help users to grasp events while texts provide more details related to the events. Thus the images and text can complement each other, assisting users to gain a more visualized understanding of events (Bian et al., 2013). We give an example in Fig. 1 to illustrate this phenomenon. For the output with only the text summary, user will be confused about the description of "four-legged creatures"; while with a relevant image, user will have a clearer understanding of the text.

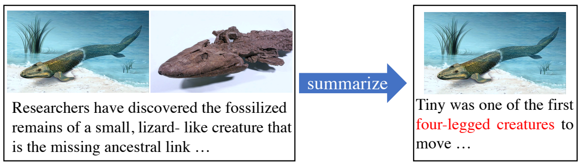

Figure 1: The illustration of our proposed task – Multimodal Summarization with Multimodal Output (MSMO). The image can help better understand the text in the red font.

In recent years, some researchers(Bian et al., 2013, 2015; Wang et al., 2016) focus on incorporating multimedia contents into the output of summarization which all treat the image-text pair as a basic summarization unit. But in our work, our input comes from a document and a collection of images where there is no alignment between texts and images. So our biggest challenge is how to bridge the semantic gaps between texts and images. Based on the above discussion, in this work, we propose a novel task which we refer to as Multimodal Summarization with Multimodal Output (MSMO). To explore this task, we focus on the

---

[1] Note that in this work, the multimodal output refers to a pictorial summary which contains one image (for the sake of simplicity, we first consider only one image) and a piece of text. We leave the other multimodal content (like videos) as future work.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4154–4164
Brussels, Belgium, October 31 - November 4, 2018.

following three questions: 1) how to acquire the relevant data; 2) how to generate the multimodal output; 3) how to automatically evaluate the quality of the multimodal output in MSMO.

For the first question, similar to Hermann et al. (2015), we collect a large-scale multimodal dataset[2] from *Daily Mail* website and annotate some pictorial summaries. For the second question, we propose a multimodal attention model to jointly generate text and the most relevant image, in which the importance of images is determined by the visual coverage vector. For the last question, we construct a novel multimodal automatic evaluation (MMAE) which jointly considers salience of text, salience of image, and image-text relevance.

Our main contributions are as follows:

- We present a novel multimodal summarization task, which takes the news with images as input, and finally outputs a pictorial summary. We construct a large-scale corpus for MSMO studying.
- We propose an abstractive multimodal summarization model to jointly generate summary and the most relevant image.
- We propose a multimodal automatic evaluation (MMAE) method which mainly considers three aspects: salience of text, salience of image, and relevance between text and image.

2 Our Models

2.1 Overview

We begin by defining the MSMO task. The input of the task is a document and a collection of images and the output is a pictorial summary. As shown in Fig. 2, our proposed model consists of four modules: text encoder, image encoder, multimodal attention layer, and summary decoder. The text encoder is a BiLSTM used to encode text. Our image encoder is VGG19[3] pretrained on ImageNet (Simonyan and Zisserman, 2015) used to extract global or local features. The multimodal attention layer aims to fuse textual and visual information during decoding. Our summary decoder, which is a unidirectional LSTM, makes use of information from two modalities to generate the text summary and select the most relevant image according to visual coverage vector. Our text encoder and summary decoder are based on pointer-generator network which we will describe in Sec. 2.2. We then describe image encoder and multimodal attention layer in our multimodal attention model (Sec. 2.3).

2.2 Pointer-Generator Network

See et al. (2017) propose a pointer-generator network which allows both copying words from the source text and generating words from a fixed vocabulary, achieving the best performance on *CNN/Daily mail* dataset. Their model consists of an encoder (a single-layer bidirectional LSTM) and an attentive decoder (a unidirectional LSTM). The encoder maps the article to a sequence of encoder hidden states h_i. During decoding, the decoder receives the embedding of the previous word and reaches a new decoder state s_t. Then the context vector c_t is computed by the attention mechanism (Bahdanau et al., 2015; Luong et al., 2015) as calculated in Eq. 1 and 2. To alleviate the problem of repetition, See et al. (2017) maintain a coverage vector cov^t, which is the sum of attention distributions over all previous decoding timesteps (initialized to zero vector at timestep 0): $cov^t = \sum_{\tilde{t}=0}^{t-1} \alpha^{\tilde{t}}$. The coverage vector is used as an extra input to the attention vector (Eq. 1) and is also used to calculate the coverage loss (Eq. 6). Next, the attention distribution is used to calculate the context vector as follows.

$$e_i^t = v^T \tanh(\mathbf{W}_h h_i + \mathbf{W}_s s_t + \mathbf{W}_c cov^t) \quad (1)$$

$$\alpha^t = \mathrm{softmax}(e^t) \quad (2)$$

$$c_t = \sum_i \alpha_i^t h_i \quad (3)$$

The important part in this model is the calculation of the generation probability p_g. It represents the probability of generating a word from the vocabulary distribution p_v, and $(1 - p_g)$ represents the probability of copying a word from the source by sampling from the attention distribution α^t. p_g is determined by c_t, s_t, and the decoder input x_t in Eq. 4. The final probability distribution over the extended vocabulary, which denotes the union of the vocabulary and all words in the source, is calculated in Eq. 5. Finally, the loss for timestep t is the sum of the negative log likelihood of the target

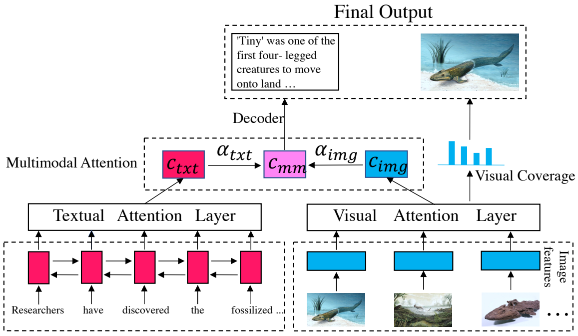

Figure 2: The framework of our model.

word w_t^* and the coverage loss (Eq. 6):

$$p_g = \sigma(\mathbf{W}_h^* c_t + \mathbf{W}_s^* s_t + \mathbf{W}_x x_t) \quad (4)$$

$$p_w = p_g p_v(w) + (1 - p_g) \sum_{w_i = w} \alpha_i^t \quad (5)$$

$$L_t = -\mathrm{log} p_{w_t^*} + \sum_i \min(\alpha_i^t, cov_i^t) \quad (6)$$

2.3 Multimodal Attention Model

We incorporate visual information into the pointer-generator network and propose a novel multimodal attention model. As shown in Fig. 2, there are three main differences between our model and pointer-generator network: 1) We have an extra image encoder and a corresponding visual attention layer; 2) To achieve the fusion of textual and visual information, we introduce a multimodal attention mechanism; 3) We add a visual coverage (Li et al., 2018a) to both alleviate visual repetition and measure the salience of image. More details are as follows.

Image Encoder. We apply the VGG19 to extract global and local image feature vectors for all images. The global features g are 4096-dimensional activations of the pre-softmax fully-connected layer `fc7`. The local features l are the $7 \times 7 \times 512$ feature maps of the last pooling layer (`pool5`). We flatten the local feature into a matrix $\mathbf{A} = (a_1, \cdots, a_L)(L = 49)$ where $a_l \in \mathbb{R}^{512}$ corresponds to a patch of an image.

Visual Attention. The attention mechanism is learned to focus on different parts of input text while decoding. Attention mechanisms have also shown to work with other modalities, like images, where they can learn to attend the salient parts of an image (Xu et al., 2015). We then explore to use images with a visual attention to learn text-image alignment. Concretely, we extend attention mechanism (Bahdanau et al., 2015; Luong et al., 2015) to visual attention mechanisms, which attend visual signals. There are three variants of our visual attention mechanisms: 1) attention on global features (ATG), 2) attention on local features (ATL), and 3) hierarchical visual attention on local features (HAN). We take the calculation of ATG as an example. To attend to the salient parts of a collection of images with size M, we flatten the global feature set g into a matrix $g\prime = (g_1, \cdots, g_M)$. In addition to calculating the text context vector in Sec. 2.2, we also obtain a visual context vector. We first project the image feature into the same dimension as the text context vector. The visual attention is calculated as follows:

$$g^* = \mathbf{W}_I^2(\mathbf{W}_I^1 g + b_I^1) + b_I^2 \quad (7)$$

$$e_a^t = v_a^T \tanh(\mathbf{W}_a g_i^* + \mathbf{U}_a s_t + cov_a^t) \quad (8)$$

$$\alpha_a^t = \mathrm{softmax}(e_a^t) \quad (9)$$

where $\mathbf{W}_I^1 \in \mathbb{R}^{4096 \times 4096}$ and $\mathbf{W}_I^2 \in \mathbb{R}^{4096 \times d_h}$ are the image transformation matrices, $b_I^1 \in \mathbb{R}^{4096}$ and $b_I^2 \in \mathbb{R}^{d_h}$ are bias vectors, and cov_a^t denotes the visual coverage vector and is initialized to zero vector in the beginning. Then the visual attention distribution α_a^t is used to obtain the visual context vector c_{img}^t through $c_{img}^t = \sum_i \alpha_{a,i}^t g_i^*$. Similar is the ATL, we flatten the local feature set A into a matrix $A' = (a_1, \cdots, a_{M \times 49})$. The calculation of attention in ATL is the same as in ATG. There is a bit difference in the HAN model, which first attend to the 49 image patches and get an intermediate visual context vector to represent the image, and then attend to the intermediate visual context vectors to get the visual context vector.

Multimodal Attention. To fuse the text and visual context information, we add a multimodal attention layer (Li et al., 2018a), as shown in Fig. 2. And the attention distribution is calculated as follows:

$$e_{txt}^t = v_{txt}^T(\mathbf{W}_{txt} c_{txt}^t + \mathbf{U}_{txt} s_t) \quad (10)$$

$$e_{img}^t = v_{img}^T(\mathbf{W}_{img} c_{img}^t + \mathbf{U}_{img} s_t) \quad (11)$$

$$\alpha_{txt}^t = \mathrm{softmax}(e_{txt}^t) \quad (12)$$

$$\alpha_{img}^t = \mathrm{softmax}(e_{img}^t) \quad (13)$$

$$c_{mm}^t = \alpha_{txt}^t c_{txt}^t + \alpha_{img}^t c_{img}^t \quad (14)$$

where α_{txt}^t is the attention weight for text context vector and α_{img}^t is the attention weight for visual context vector.

Visual Coverage. In addition to the calculation of the text coverage vector as in Sec. 2.2, we also obtain a visual coverage vector cov_{img}^t, which is the sum of visual attention distributions. To help reduce repeated attention to multimodal information, we incorporate a text coverage loss and a visual coverage loss into the loss function. The final loss function is as follows:

$$L_t = -\log p_{w_t^*} + \sum_i \min(\alpha_i^t, cov_i^t) + \sum_j \min(\alpha_j^t, cov_{img,j}^t) \quad (15)$$

The attention mechanism can attend the salient parts of texts or images. Meanwhile, the coverage mechanism sums up all the historical attention distributions. Therefore, we regard the coverage vector as a global salience measure of the source being attended. We then use the visual coverage vector in the last decoding timestep to select the most relevant image. Concretely, we choose the image whose coverage score is the largest. The process is a bit different for the local features. An image corresponds to 49 patches, the coverage scores of these patches are summed up to get the salience score of the image as follows:

$$\mathrm{S}_j = \sum_{patch} cov_{patch,j}^{t^*} \quad (16)$$

where $\mathrm{S_j}$ denotes the salience of the j-th image and $cov_{patch,j}^{t^*}$ denotes the coverage score of each corresponding image patch in the last decoding timestep $t*$. For the HAN, we introduce an extra coverage vector for the image patches attention and calculate coverage loss for it as follows:

$$L_t = -\log p_{w_t^*} + \sum_k \min(\alpha_k^t, cov_{patch,k}^t) + \sum_i \min(\alpha_i^t, cov_i^t) + \sum_j \min(\alpha_j^t, cov_{img,j}^t) \quad (17)$$

3 Multimodal Automatic Evaluation

To evaluate the quality of a pictorial summary, we propose the MMAE method which is defined as $y = f(m_1, m_2, m_3)$. In this definition, m_1, m_2, and m_3 denote scores measured by three metrics which consider salience of text (Sec. 3.1), salience of image (Sec. 3.2), and image-text relevance (Sec. 3.3) respectively, $f(\cdot)$ denotes a mapping function, and y denotes the score of the pictorial summary.

In our experiments, the reference pictorial summary consists of a text summary and a reference image set[4] $\mathrm{ref}_{\mathrm{img}}$. In MMAE, m_1 is obtained by comparing the text summary in reference with that in model output, m_2 is obtained by comparing the image set in reference with the image in model output, and m_3 considers the image-text similarity in model output. To learn MMAE, we choose three simple methods to fit y with human judgment scores. These methods include Linear Regression (LR), and two nonlinear methods: Logistic Regression (Logis), and Multilayer Perceptron (MLP).

3.1 Salience of Text

ROUGE (Lin, 2004b) is widely used to automatically assess the quality of text summarization systems. It has been shown that ROUGE correlates well with human judgments (Lin, 2004a; Owczarzak et al., 2012; Over and Yen, 2004). Therefore, we directly apply ROUGE to assess the salience of the text units.

3.2 Salience of Image

We propose a metric, namely, image precision (**IP**), to measure the salience of image. The image precision is defined as follows:

$$\mathrm{IP} = \frac{|\{\mathrm{ref}_{\mathrm{img}}\} \cap \{\mathrm{rec}_{\mathrm{img}}\}|}{|\{\mathrm{rec}_{\mathrm{img}}\}|} \quad (18)$$

where ref_{img}, rec_{img} denote reference images and recommended images by MSMO systems respectively. The reasons for this metric are as follows.

A good summary should have good coverage of the events for both texts and images. The image in the output should be closely related to the events. So we formulate the image selection process as an image recommendation —instead of recommending items to users as in a recommendation system, we recommend the most salient image to an event. It can also be viewed as an image retrieval task, which retrieves the image most relevant to an event. Precision and recall are commonly used to evaluate recommendation systems (Karypis, 2001) and information retrieval task (Zuva and Zuva, 2012). However, we only care about whether the image appears in the reference image set. Thus in our case, we are only interested in calculating precision metric. Therefore, we adapt the precision here as **IP** to measure image salience.

---

[4] More details can be found in Sec. 4.1

3.3 Image-Text Relevance

A prerequisite for a pictorial summary to help users accurately acquire information is that the image must be related to the text. Therefore, we regard the image-text relevance as one of metrics to measure the quality of the pictorial summary. We consider using visual-semantic embedding (Faghri et al., 2018; Wang et al., 2018) to calculate the cosine similarity between visual feature and textual feature, which we use as image-text relevance. Visual-semantic embedding has been widely used in cross-modal retrieval (Kiros et al., 2014) and image captioning (Karpathy and Fei-Fei, 2015).

We apply VSE0 model of Faghri et al. (2018), which achieves state-of-the-art performance for image-caption retrieval task on the Flickr30K dataset (Young et al., 2014). The difference is that instead of training a CNN model to encode the image, we use the pretrained VGG19 to extract global features. The text is encoded by a unidirectional Gated Recurrent Unit (GRU) to a sequence of vector representations. Then we apply the max-over-time pooling (Collobert et al., 2011) to get a single vector representation. Next, the visual features and text features are projected to a joint semantic space by two feed-forward neural networks. The whole network is trained using a max-margin loss:

$$\begin{aligned} L = \sum_{\hat{c}} \max(\beta - s(i,c) + s(i,\hat{c}), 0) \\ + \sum_{\hat{i}} \max(\beta - s(i,c) + s(\hat{i},c), 0) \end{aligned} \quad (19)$$

The loss comprises two symmetric terms, with i and c being images and captions repectively. The first term is taken over negative captions $\hat{c}$ image i in a batch. The second is over negative images $\hat{i}$ given caption c. If i and c are closer to each other in the joint embedding space than to any other negative pairs, by a margin β, the loss is zero. We choose to use image-caption pairs in our dataset to train the VSE0 model.

4 Experiments

We conduct the following five sets of experiments: 1) To verify our motivation of the multimodal output (pictorial summary), we design an experiment for user satisfaction test (Sec. 4.2); 2) We compare our multimodal summarization with text summarization from both ROUGE score and manual evaluation (Sec. 4.3); 3) To verify the effectiveness of our evaluation metrics, we calculate the correlation between these metrics and human judgments (Sec. 4.4); 4) We conduct two experiments to show the effectiveness of our proposed MMAE and the generalization of MMAE respectively (Sec. 4.5); 5) Finally, we evaluate our multimodal attention model with MMAE (Sec. 4.6).

The hyperparameters in our model are similar to See et al. (2017), except that we set the maximum number of images to 10, 7, and 7 for ATG, ATL, and HAN respectively, because different articles have the image collection of different sizes. The images are sorted in the order of the position in the article.

4.1 Dataset

There is no large-scale benchmark dataset for MSMO. We follow Hermann et al. (2015) to construct a corpus from *Daily Mail* website[5]. Similar to Hermann et al. (2015), we use the manually-written highlights offered by *Daily Mail* as a reference text summary. From *Daily Mail*, we randomly select articles within a week and find that 2,917 out of 2,930 articles contain images. More details are illustrated in Table 1.

	train	valid	test
#Documents	293,965	10,355	10,261
#ImgCaps	1,928,356	68,520	71,509
#AvgTokens(S)	720.87	766.08	730.80
#AvgTokens(R)	70.12	70.02	72.16
#AvgCapTokens	22.07	22.64	22.34
#AvgImgCaps	6.56	6.62	6.97

Table 1: Corpus statistics. Each image on the website is paired with a caption. *#ImgCaps* denotes the number of image-caption pairs. *#AvgTokens(S)*, *#AvgTokens(R)* and *#AvgCapTokens* denote the average number of tokens in articles, highlights, and captions respectively.

To get the pictorial reference, we employ 10 graduate students to select the relevant images from the article for each reference text summary. We allow annotators to select up to three images to reduce the difference between different annotators. If the annotators find that there is no relevant image, they will select none of them. Each article is annotated by at least two students[6]. Since we use the text reference to guide the generation of the pictorial summary, we do not use the reference image during training. Therefore, we only conduct the annotation on the test set.

---

[5] `http://www.dailymail.co.uk`

[6] A third annotator will be asked to decide the final annotation for the case of divergence for the first two annotators.

4.2 User Satisfaction Test

We conduct an experiment to investigate whether a pictorial summary can improve the user satisfaction for the informativeness of the summary. For a fair comparison, we propose a novel strategy to compare text summaries and pictorial summaries. We take an example to illustrate our strategy. Given 100 source news pages, we have their corresponding reference text summaries and pictorial summaries. We divide them into two parts of the same size, part 1 and part 2. In part 1, human annotator A evaluates the text summaries according to the input news, and human annotator B evaluates the pictorial summaries. In part 2, annotator A evaluates the pictorial summaries and annotator B evaluates the text summaries. All annotators will give a score of 1 to 5. The input news is the same for annotator A and annotator B.

Format	$\text{Annotator}_{\text{A}}$	$\text{Annotator}_{\text{B}}$	Overall
Text	3.67	3.75	3.71
Pictorial	4.14	4.20	4.17

Table 2: User satisfaction test results. In total, we use the strategy mentioned in Section 4.2 to evaluate 400 randomly selected source news pages. *Overall* denotes the average score on these 400 samples.

Table 2 shows our results for user satisfaction test. User ratings of pictorial summaries are 12.4% higher than text summaries. It shows that users prefer this way of presenting information. It also confirms our motivation for MSMO.

4.3 Comparison with Text Summarization

Our user satisfaction test in Sec. 4.2 is done in an ideal situation, comparing the text reference with the pictorial reference. To show the effectiveness of our model, we also compare our model with text summarization from ROUGE and human judgment scores. We compare several abstractive summarization methods with our multimodal summarization methods. **PGC**[7] (See et al., 2017) refers to the pointer-generator network (Sec. 2.2). **AED** (Nallapati et al., 2016) uses an attentional encoder-decoder framework and adds some linguistic features such as POS, named-entities, and TF-IDF into the encoder. We also implement a seq2seq model with attention (**S2S+attn**). To compare the multimodal output with our multimodal model, we propose an extractive method based on GuideRank (**GR**) (Li et al., 2016a, 2018b). GuideRank applies LexRank (Erkan and Radev, 2004) with guidance strategy. In this strategy, captions recommend the sentences related to them. The rankings of sentences and captions are obtained through GR; we extract sentences that satisfy the length limit as a text summary according to the ranking of text. We select an image whose caption ranks the first in the captions. And finally, the pictorial summary is obtained. We evaluate different summarization models with the standard ROUGE metric, reporting the F1 scores for ROUGE-1, ROUGE-2, and ROUGE-L. Our ROUGE results are given in Table 3, and human judgment scores are given in Table 4.

	Model	ROUGE-1	ROUGE-2	ROUGE-L
Base	S2S+attn	32.32	12.44	29.65
	AED	34.78	13.10	32.24
	PGC	**41.11**	**18.31**	**37.74**
MM	ATG	40.63	18.12	37.53
	ATL	**40.86**	18.27	**37.75**
	HAN	40.82	**18.30**	37.70
	GR	37.13	15.03	30.21

Table 3: ROUGE F1 scores on our test set. All our ROUGE scores are reported by official ROUGE script.

Model	PGC	ATG	ATL	HAN
HS	3.07	3.30	3.22	3.20

Table 4: Human judgment scores for our multimodal model and PGC. We randomly select 400 articles and use the same strategy as Sec. 4.2. HS denotes the average human judgment scores.

From Table 3, all multimodal models lead to a decrease in ROUGE scores which can attribute to the following reasons. There are 6.56 images on average in each article and not every image is closely related to the event of the article. In other words, some images are noise. On the other hand, our text input is long text, and it contains enough information for text generation. In Table 4, multimodal models are better than text model in human judgments. It further illustrates our motivation, and also proves the effectiveness of our models.

4.4 Correlation Test

To illustrate the effectiveness of our evaluation metrics, we conduct an experiment on correlations between these metrics and human judgment scores. Human annotators give a score which ranges from 1 to 5 to a pictorial summary accord-

---

[7] `https://github.com/abisee/pointer-generator`

ing to the reference[8]. The reference consists of a text summary and up to three relevant images selected by humans. We randomly extract the pictorial summaries from the output of different systems. In response to the three aspects we proposed in Section 3, we propose some related metrics respectively. For text salience, we apply **ROUGE-1**, **ROUGE-2**, **ROUGE-L**, and **BLEU**. For image-text relevance of candidate pictorial summaries, we propose two ways. One is to calculate the similarity (**Img-Sum**) between the image and the whole text summary. The other is to calculate the similarities between the image and each sentence in the text summary. Then we take the maximum and average values as two metrics: **MAX$_{\text{sim}}$** and **AVG$_{\text{sim}}$**. For image salience, in addition to the **IP** metric mentioned in Section 3.2, we try to calculate the similarity between the candidate image and each reference image in three ways: 1) **I-I**: similarities between the global `fc7` features, 2) **Hist**: Bhattacharyya distance[9] for histogram comparison (Bhattacharyya, 1943), and 3) **Temp**: Fourier Analysis template matching (Briechle and Hanebeck, 2001).

We employ annotators to evaluate 600 samples (randomly selected from the outputs of each model on the validation set). Each sample is scored by two persons and we take the average score as the final score. We use 450 of them as training set to train the MMAE model in Sec. 4.5, the rest is used as test set. The scores calculated by each evaluation metric are then tested on the training set to see how well they correlate with human judgments. The correlation is evaluated with three metrics, including 1) Pearson correlation coefficient (r), 2) Spearman rank coefficient (ρ), and 3) Kendall rank coefficient (τ). Our results of correlation test are given in Table 5.

As shown in Table 5, **IP** (Image Precision) correlates best with human assessments according to the three correlation coefficients. It illustrates that people pay more attention to images when assessing pictorial summaries. If we choose the right image for the summary, people are more likely to assign a high score. We also note that the correlation score of **IP** is significantly higher than four text metrics. Because it is easy for a person to judge the importance of images based on reference, such as to see whether the image appears in reference. However, measuring the semantic similarity of two texts is difficult. The four metrics all measure the degree of n-gram overlap which cannot accurately measure semantic similarity.

	Metric	r	ρ	τ
Text	BLEU	.1949	.1542	.1198
	ROUGE-1	.3006	.2941	.2152
	ROUGE-2	.2735	.2742	.2002
	ROUGE-L	**.3144**	**.3087**	**.2272**
Image-Text	AVG$_{\text{sim}}$	.2662	.2388	.1774
	MAX$_{\text{sim}}$	**.2849**	**.2749**	**.2033**
	Img-Sum	.2380	.2075	.1556
Image	I-I (max)	.0169	.0258	.0196
	I-I (avg)	-.0262	-.0140	-.0113
	Hist$_{\text{avg}}$	.4688	.5077	.3725
	Hist$_{\text{max}}$	.5974	.6388	.5149
	Temp$_{\text{avg}}$	.4913	.4944	.3631
	Temp$_{\text{max}}$	.5967	.6435	.5080
	IP	**.6407**	**.6482**	**.5789**

Table 5: Correlation with human judgment scores (training set), measured with Pearson r, Spearman ρ, and Kendall τ coefficients. The max and avg denote the maximum and average value of the scores.

For the image-text relevance, **MAX$_{\text{sim}}$** performs best and is comparable to the several ROUGE metrics. It shows that in a good pictorial summary, the image and text should be relevant. In some cases, even though the generated text is not so important, the image is closely related to the text. At this time, people can also be satisfied. On the other hand, our VSE0 (Sec. 3.3) model can capture some fluency of sentences by adopting GRU. Compare **MAX$_{\text{sim}}$**, **AVG$_{\text{sim}}$**, and **Img-Sum**, this is very intuitive. Once people find a sentence (or a part) relevant to the image, they will think the image is related to the text. Besides, the worst performance of **Img-Sum** metric is probably because the average length of captions used to train VSE0 model is about 22, far less than the length of the summary. We find the **I-I (max)** and **I-I (avg)** nearly do not correlate with human assessments. It shows that the visual features extracted from VGG19 are not suitable for calculating the similarity between news images. The analysis of **Hist (Temp)$_{\text{avg}}$** and **Hist (Temp)$_{\text{max}}$** is similar to the analysis of **MAX$_{\text{sim}}$** and **AVG$_{\text{sim}}$** above.

4.5 Effectiveness and Generalization of MMAE

We then select the best-performing metrics separately from the three sets of metrics, namely

---

[8] Some articles are annotated with no relevant images (about 3.9%), we directly skipped these articles without manual scoring

[9] In statistics, the Bhattacharyya distance measures the similarity of two discrete or continuous probability distributions. For a distance d, we take $(1-d)$ as the similarity.

ROUGE-L, **MAX$_{\text{sim}}$**, and **IP**. We apply LR, MLP, and Logis to learn our MMAE model that combines the three metrics. We calculate the three coefficients for the three metrics on the test set as a comparison. The correlation results are given in Table 6.

Metric	r	ρ	τ
ROUGE-L	.3488	.3554	.2669
MAX$_{\text{sim}}$	.2541	.2339	.1773
IP	**.5982**	**.5966**	**.5485**
MMAE$_{\text{LR}}$	**.6646**	.6644	.5265
MMAE$_{\text{MLP}}$	.6632	.6646	.5265
MMAE$_{\text{Logis}}$	.6630	**.6653**	**.5277**

Table 6: Correlation with human judgment scores (test set).

As shown in Table 6, the MMAE learned by three methods correlates better with human judgments. Although MMAE$_{\text{Logis}}$ gets a slightly higher correlation score according to Spearman and Kendall coefficients, we choose the MMAE$_{\text{LR}}$[10] as our final MMAE model due to Occam's Razor[11].

It is crucial that MMAE can generalize for a previously unseen system. To test the generalization of MMAE, we use MMAE to evaluate a new system and calculate the correlation with human judgment scores. The new system is a naive model which applies LexRank to extract sentences and randomly select an image from source. We can observe that MMAE still correlates well with human judgment scores, as shown in Table 7. It illustrates that MMAE generalize well for a new model. We give some examples of MMAE in supplementary material.

Metric	r	ρ	τ
ROUGE-L	.3223	.3514	.2615
MMAE	.6352	.6318	.4728

Table 7: Correlation results for the new model on the same 150 test samples as in Sec. 4.4.

4.6 Model Performances

According to our analyses above, we have proved MMAE can evaluate multimodal output. In this section, we report the MMAE scores for our proposed multimodal attention model, as shown in Table 8.

Model	ROUGE-L	MAX$_{\text{sim}}$	IP	MMAE
ATG	40.76	25.82	59.28	**3.35**
ATL	40.80	13.26	**62.44**	3.26
HAN	**40.82**	12.22	61.83	3.25
GR	30.20	**26.60**	61.70	3.20

Table 8: Results evaluated by our MMAE method. We skipped the articles that are labeled as no relevant images. Finally, only 9,851 of the 10,261 articles are left.

Surprisingly, the model ATG achieves the highest MMAE score despite the mediocre performance in three individual metrics. The **MAX$_{\text{sim}}$** score of ATG is much higher than ATL and HAN. It shows the global features can help to learn better image-text alignments. Since GR itself makes use of the image-caption pairs, it is natural to get a high image-text relevance score. Our proposed multimodal attention models all achieves higher performance than the extractive baseline GR, which further indicate the effectiveness of our models.

5 Related Work

Different from text summarization (Wan and Yang, 2006; Rush et al., 2015; Zhu et al., 2017; See et al., 2017; Celikyilmaz et al., 2018; Paulus et al., 2018), Multimodal Summarization is a task to generate a condensed text summary or a few keyframes to help acquire the gist of multimedia data. One of the most significant advantages of the task is that it does not rely solely on text information, but it can also utilize the rich visual content from the images.

In recent years, much work has focused on multimodal summarization. Evangelopoulos et al. (2013) detect salient events in a movie based on the saliency of individual features for aural, visual, and linguistic representations. Li et al. (2017) generate the text summary from an asynchronous collection of text, image, audio, and video. There has also been some work (Bian et al., 2013, 2015; Wang et al., 2016; Qian et al., 2016) focused on producing multimodal output for summarization. Bian et al. (2013, 2015) aim to produce a visualized summary for microblogs. Wang et al. (2016) generate a pictorial storyline for summarization. Qian et al. (2016) generate the multimedia topics for social events. But these researches all treat image-text pairs, in which texts and images are aligned, as a basic summarization unit. For example, the images are aligned with the text in a mi-

---

[10] The weight for ROUGE-L, MAX$_{\text{sim}}$, and IP is 1.641, 0.854, 0.806 respectively and the intercept is 1.978.

[11] `https://en.wikipedia.org/wiki/Occam%27s_razor`

croblog post; Wang et al. (2016) obtain the image-text pairs by using image search engine. None of the above works focuses on generating multimodal output from a collection of texts and images that are not explicitly aligned. This is one of the goals in this paper. Another difference is that they separately evaluate texts and images when evaluating the final results. In our work, we propose a new automatic evaluation which jointly considers two aspects of textual and visual modalities.

6 Conclusion

In this paper, we focus on a novel task which aims to automatically generate a multimodal summary from multimodal news, where the images and the texts are not explicitly aligned. We provide a multimodal summarization method to jointly generate text and the most relevant image, which can be referred as the baseline for further study. Our proposed metrics have been proved to be effective in evaluating the multimodal output. Moreover, the idea of constructing our MMAE can be easily extended to other modalities. That is, we both consider the intramodality salience and the intermodality relevance.

Frustratingly Easy Model Ensemble for Abstractive Summarization

Hayato Kobayashi
Yahoo Japan Corporation / RIKEN AIP
`hakobaya@yahoo-corp.jp`

Abstract

Ensemble methods, which combine multiple models at decoding time, are now widely known to be effective for text-generation tasks. However, they generally increase computational costs, and thus, there have been many studies on compressing or distilling ensemble models. In this paper, we propose an alternative, simple but effective unsupervised ensemble method, *post-ensemble*, that combines multiple models by selecting a majority-like output in post-processing. We theoretically prove that our method is closely related to kernel density estimation based on the von Mises-Fisher kernel. Experimental results on a news-headline-generation task show that the proposed method performs better than the current ensemble methods.

1 Introduction

Recent success in deep learning, especially encoder-decoder models (Sutskever et al., 2014; Bahdanau et al., 2015), has dramatically improved the performance of various text-generation tasks, such as translation (Johnson et al., 2017), summarization (Ayana et al., 2017), question-answering (Choi et al., 2017), and dialogue response generation (Dhingra et al., 2017). In these studies on neural text generation, it has been known that a model-ensemble method, which predicts output text by averaging multiple text-generation models at decoding time, is effective even for text-generation tasks, and many state-of-the-art results have been obtained with ensemble models. However, an ensemble method has a clear drawback in that it increases computational costs, i.e., the increase in time as the number of models increases, since it averages the word-prediction probabilities of all models in each decoding step. Therefore, there have been many studies on model compression or distillation for ensemble methods, each of which has successfully shrunk an ensemble model (Hinton et al., 2015; Chebotar and Waters, 2016; Kuncoro et al., 2016; Kim and Rush, 2016; Stahlberg and Byrne, 2017; Freitag et al., 2017).

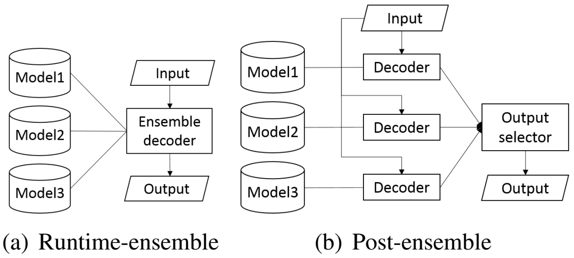

Figure 1: Flow charts of current runtime-ensemble (a) and our proposed post-ensemble (b).

In this paper, we propose an alternative method for model ensemble inspired by the majority vote in classification tasks (Littlestone and Warmuth, 1994). Majority vote is a method that selects the most frequent label from the predicted labels of multiple classifiers in post-processing. Similarly, our method involves selecting a majority-like output from the generated outputs of multiple text-generation models in post-processing as in Fig. 1(b), instead of averaging models at decoding time as in Fig. 1(a). The difference between a classification task and text-generation task is that we need to consider a sequence of labels for each model output in a text-generation task, although we consider only one label in a classification task. This means a majority output may not exist since each output will be basically different from other outputs, which are generated from different models. To overcome this problem, we propose an unsupervised method for selecting a majority-like output close to the other outputs by using cosine similarity. The idea is quite simple, but experiments showed that our method is more effective than the current ensemble methods.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4165–4176
Brussels, Belgium, October 31 - November 4, 2018.

Our work can open up a new direction for two research communities: model ensemble and hypotheses reranking (see Sec. 6 for detailed descriptions of the related studies). For the first, we suggest a new category of ensemble algorithms that corresponds to the output selection in classification tasks. In classification tasks, there are roughly three approaches for model ensemble: model selection in preprocessing, model average at runtime, and output selection in post-processing. In text generation studies, model selection by cross-validation and model average with an ensemble decoder have been frequently used, but output selection as typified by majority vote has received less attention because of the fact that a majority output may not exist, as described above. Therefore, there is enough room to study this direction in the future. Since our algorithm in this paper is quite simple, we expect that more sophisticated methods can improve the results even over our approach.

For the hypotheses reranking research community, we suggest a new category of reranking tasks, where we need to select the best output from the generated outputs of multiple models, instead of the N-best hypotheses of a single model. Hypotheses reranking for a text-generation model is related to our task, but in this case, a reranking method based on a language model is frequently used and is basically enough to correct the scoring of a beam search with a single model (Chen et al., 2006; Vaswani et al., 2013; Luong and Popescu-Belis, 2016) since the purpose is to obtain a fluent output and remove erroneous outputs, assuming the model can generate good outputs. A clear difference between our task and the reranking task is that we should consider all outputs to decide the goodness of an output because a fluent output is not always appropriate in this task. This is similar to extractive summarization (Erkan and Radev, 2004) but is significantly different from our task in that our output candidates have almost the same meaning.

Our contributions in this paper are as follows.

- We propose a simple, fast, and effective method for unsupervised ensembles of text generation models, where (i) the implementation is "frustratingly easy" without any modification of model code (Alg. 1), (ii) the computational time is enough for practical use (Sec. 5.3), i.e., an ensemble time of 3.7 ms per sentence against a decoding time of 44 ms, and (iii) the performance is competitive with the state-of-the-art results (Sec. 5.2), i.e., our method (ensemble of 32 models) for 37.52 ROUGE-1 against the state-of-the-art method (single model) for 37.27 ROUGE-1 on a news-headline-generation task.
- We prove that our method is an approximation of finding the maximum density point by kernel density estimation based on the von Mises-Fisher kernel (Sec. 4). In addition, we derive a formula of the error bound of this approximation.
- We will release the 128 prepared models used in this paper (Sec. 5.1), each of which was trained for more than two days, as a new dataset to improve ensemble methods.

2 Preliminaries

In Sec. 2.1, we briefly explain an encoder-decoder model for text generation, and in Sec. 2.2, we discuss the current ensemble methods for combining multiple text generation models at decoding time.

2.1 Encoder-Decoder Model

An encoder-decoder model is a conditional language generation model, which can learn rules for generating an appropriate output sequence corresponding to an input sequence by using the statistics of many correct pairs of input and output sequences, e.g., news articles and their headlines. When training this model, we calculate a conditional likelihood,

$$p(y \mid x) = \prod_{t=1}^{T-1} p(y_{t+1} \mid y_{\le t}, x), \qquad (1)$$

with respect to each pair (x, y) of input sequence $x = x_1 \cdots x_S$ and output sequence $y = y_1 \cdots y_T$, where $y_{\le t} = y_1 \cdots y_t$, and maximize its mean. The model $p(y \mid x)$ in Eq. (1) is achieved by combining two recurrent neural networks, called an *encoder* and *decoder*. The former reads an input sequence x to recognize its content, and the latter predicts an output sequence y corresponding to the content.

After training, we can obtain an output y from an input x by using a learned model $p(y \mid x)$. Since the calculation of an optimal output is clearly intractable, most studies used a beam search, which is a greedy search algorithm that keeps a limited number of best partial solutions, whose size is called the *beam size*. Formally, a set of best partial solutions of beam size b at step t is represented as $Y^b_{\le t}$, which is recursively defined as the top b elements with respect to $p(y_{\leq t} \mid x)$, where $y_{\leq t} \in Y^b_{\leq t-1} \times Y$. The Y is a set of available elements for y_i, or a target dictionary. Let start and goal meta symbols be <s> and </s>, respectively. A beam search procedure starts from $Y_{\leq 0} = \{$<s>$\}$ and finishes when the last symbols of all elements in $Y^b_{\leq t}$ are the goal element </s> or when its length t becomes larger than some threshold.

2.2 Runtime-Ensemble

In a text-generation task, model ensemble is a method of predicting a next word by averaging the word-prediction probabilities of multiple text-generation models at decoding time. Fig. 1(a) shows a flow chart of the current ensemble methods, which we call *runtime-ensemble* to distinguish them from our method. There are mainly two variants of runtime-ensemble using arithmetic mean $\overline{p}_{\mathrm{a}}$ and geometric mean $\overline{p}_{\mathrm{g}}$, which are defined as

$$\overline{p}_{\mathrm{a}}(y_{\leq t} \mid x) = \tfrac{1}{|M|} \textstyle\sum_{p \in M} p(y_{\leq t} \mid x), \tag{2}$$

$$\overline{p}_{\mathrm{g}}(y_{\leq t} \mid x) = \left(\textstyle\prod_{p \in M} p(y_{\leq t} \mid x)\right)^{\frac{1}{|M|}}, \tag{3}$$

where M is a set of learned models. We call the former `EnsSum` and the latter `EnsMul`. Although there have been no comparative experiments, `EnsMul` is usually used since most decoding programs keep $\log p$ and calculating $\sum_{p \in M} \log p$ is enough to obtain the top b words with respect to $\overline{p}_{\mathrm{g}}$ for a beam search procedure.

3 Post-Ensemble

Our alternative ensemble method combines multiple text-generation models by selecting a majority-like output close to the other outputs, which is calculated with a similarity function such as cosine similarity. We call this method *post-ensemble* since it is executed in post-processing, i.e., after a decoding process. Fig. 1(b) shows a flow chart of post-ensemble, and Alg. 1 shows its algorithm. When our method receives an input x, a normal decoder calculates the output s of each model p from the input in parallel (lines 2–4), and the output selector selects the majority-like output y from all outputs (lines 6–9). In line 7, we calculate the score c of each output s by using a similarity function K, where $K(s, s')$ represents the similarity between s and s'. A higher score means that the output s is in a denser part in the output space since the score c means the average similarity in other outputs.

```
   Input: Input text $x$, set $M$ of learned models, and
          similarity function $K$, such as cos.
   Output: Output prediction $y$.
1  $S \leftarrow \emptyset$;
2  foreach $p \in M$ do
3      $s \leftarrow$ output of model $p$ for input $x$;
4      $S \leftarrow S \cup \{s\}$;
5  $C \leftarrow \{\}$; // as a hash map
6  foreach $s \in S$ do
7      $c \leftarrow \frac{1}{|S|} \sum_{s' \in S} K(s, s')$;
8      $C[s] \leftarrow c$;
9  $y = \mathrm{argmax}_{s \in S}\, C[s]$;
10 return $y$
```

Algorithm 1: Post-ensemble procedure.

The post-ensemble procedure has two main advantages compared with the current runtime-ensemble procedure. One is that we do not need to develop an ensemble decoder by modifying a decoding program on a deep learning framework. The concept of runtime-ensemble is simple, but its implementation is not that simple in recent sophisticated open source software. For example, we need to modify about 100 lines to add an ensemble feature to the decoding program of an open source neural machine translator, OpenNMT[1], which requires understanding the overall mechanism of the software. The other advantage is that we can easily parallelize decoding processes in our method since each output can be calculated by using a single model. If we have a server program for text generation, we can improve its performance with all our machine resources (ideally) by assigning a server to each model and allowing the output selector to communicate with it.

One drawback of our method is that its expressive power is basically the same as that of each single model. However, this alternatively means that the lower bound of the quality of each output is guaranteed with the worst case of the outputs of single models, while the current runtime-ensemble method can perform worse than each single model for the worst case input. Furthermore, experiments showed our post-ensemble method is more effective than the current runtime-ensemble methods.

4 Theoretical Analysis

In this section, we prove that when $K(s, s') = \cos(s, s')$, Alg. 1 is an approximation of find-

---

[1] https://github.com/OpenNMT/OpenNMT-py

ing the maximum density point by kernel density estimation based on the von Mises-Fisher kernel. First, we briefly explain kernel density estimation and how to apply it to our method in Sec. 4.1. Then, we introduce the von Mises-Fisher kernel used in this analysis and later experiments in Sec. 4.2. Finally, we prove a theorem that guarantees the approximation error in Sec. 4.3.

4.1 Kernel Density Estimation

Kernel density estimation is a non-parametric method for estimating the probability density function of a random variable. Let $(X_1, \cdots, X_n)$ be an independent and identically distributed (i.i.d.) sample that was drawn from a distribution with an unknown density function f. The kernel density estimator based on the sample is defined as

$$\tilde{f}(X) = \tfrac{1}{n} \textstyle\sum_{i=1}^{n} K(X, X_i). \tag{4}$$

Using an appropriate kernel such as the Gaussian kernel, this estimator $\tilde{f}$ converges to the true density f, and it can be proved that there is no non-parametric estimator that converges faster than this kernel density estimator (Wahba, 1975).

Here, let us consider our outputs $(s_1, \cdots, s_n)$, which correspond to S in Alg. 1. They are generated from text generation models $(p_1, \cdots, p_n)$, which correspond to M in Alg. 1. We assume that these models are trained with randomly initialized parameters $(\theta_1, \cdots, \theta_n)$, each of which includes a random seed for the optimizer, and the other settings are deterministic. In this case, we can construct a function $F : P \to O$ that maps the parameter space P onto the output space O. In other words, if each parameter θ_i is an i.i.d. random variable, the corresponding output $s_i = F(\theta_i)$ is also an i.i.d. random variable. Therefore, Eq. (4) can be directly used for line 7 in Alg. 1.

Our method can be regarded as a heuristic approach based on the characteristics of our encoder-decoder model, where there are many local solutions for optimization. We expect that our method can be applied to other models on the basis of a theoretical study (Kawaguchi, 2016), that showed that deep neural networks can have many local optima, but there are no poor local optima (formally, every local minimum of deep neural networks is a global minimum under a certain condition). We do not consider this direction since theoretical justification is beyond our scope.

4.2 von Mises-Fisher Kernel

The von Mises-Fisher kernel (Hall et al., 1987) is a natural extension of the Gaussian kernel to a unit hypersphere. This kernel is especially useful for directional or angular statistics, so it is expected to be compatible with the cosine similarity frequently used in natural language processing. The definition is

$$K_{\text{vmf}}(s, s') = C_q(\kappa) \exp(\kappa \cos(s, s')), \tag{5}$$

where κ is a smoothing factor called the *concentration parameter*, and cos is a cosine similarity, i.e., $\cos(s, s') = \frac{s \cdot s'}{||s||_2 ||s'||_2}$. $C_q(\kappa)$ is the normalization constant, which is defined as

$$C_q(\kappa) = \left(\kappa^{\frac{q-1}{2}}\right) \Big/ \left((2\pi)^{\frac{q+1}{2}} \mathcal{I}_{\frac{q-1}{2}}(\kappa)\right), \tag{6}$$

where $\mathcal{I}_v$ is the modified Bessel function of the first kind at order v, and q is the dimension of directional data (angular expression of data).

In the experiments described later, we implemented Alg. 1 with this kernel by using the log-sum-exp trick (Nielsen and Sun, 2016) to avoid overflow/underflow problems since $\text{argmax} \sum \exp(x) = \text{argmax} \log \sum \exp(x)$. In addition, we used Garcia-Portugues's rule (Garcia-Portugues, 2013) to adjust the concentration parameter $\kappa = \hat{h}^{-2}$, defined as

$$\hat{h} = \left(\frac{4\pi^{\frac{1}{2}} \mathcal{I}_{\frac{q-1}{2}}(\tilde{\kappa})^2}{\tilde{\kappa}^{\frac{q+1}{2}} \left(2q \mathcal{I}_{\frac{q+1}{2}}(2\tilde{\kappa}) + (2+q)\tilde{\kappa} \mathcal{I}_{\frac{q+3}{2}}(2\tilde{\kappa}) \right) n} \right)^{\frac{1}{4+q}} \tag{7}$$

where $\tilde{\kappa}$ is an approximation of κ derived from the maximum likelihood estimation (Sra, 2012), defined as $\tilde{\kappa} = \frac{\tilde{\mu}(q-\tilde{\mu})}{1-\tilde{\mu}^2}$, where $\tilde{\mu}$ is the sample mean of the directional data in a unit hypersphere.

4.3 Approximation Error Analysis

We prove an approximation error bound of Alg. 1 when $K(s, s') = \cos(s, s')$, as shown in the following theorem.

Theorem 1. The output y of Alg. 1 with $K(s, s') = \cos(s, s')$ is equivalent to the maximization of the first order Taylor series approximation $\tilde{p}$ of the kernel density estimator p based on the von Mises-Fisher kernel, i.e.,

$$\tilde{p}(y) = \max\nolimits_{s \in S} \tilde{p}(s), \tag{8}$$

where the approximation error R^* of the output y with respect to the true density estimator p, i.e,. $R^* = \max_{s \in S} p(s) - p(y)$, is bounded by

$$R^* \leq C_q(\kappa) \kappa^2 \exp(\kappa) (\sigma^2 + \mu^2), \tag{9}$$

where $\mu = \max_{s \in S} \mathbb{E}_{s'}[\cos(s, s')]$, and $\sigma^2 = \max_{s \in S} \mathbb{V}_{s'}[\cos(s, s')]$.

Proof sketch. Eq. (8) can be obtained by using the first order Taylor series approximation at 0 of $\exp(x)$, i.e., $\exp(x) \approx 1 + x$, and the nature of argmax, i,e., $\operatorname{argmax}(1 + \kappa x) = \operatorname{argmax} x$. Eq. (9) can be derived by the Lagrange error bound $\tilde{R}(x)$ for $\exp(x) \approx 1+x$, where $x = \kappa \cos(s, s')$, and $-\kappa \le x \le \kappa$, as

$$\tilde{R}(x) = \frac{\max_{x'} \exp(x')}{2!} x^2 \le \frac{\exp(\kappa)}{2} x^2. \quad (10)$$

See Appendix A for the complete proof. ☐

This theorem implies that the approximation error becomes smaller as κ becomes smaller. Since κ is the concentration parameter, the shape of the density estimation will be smooth when κ is small, while it will be a peak when κ is large. This means that, when κ is large, the density estimation is almost the same as the majority vote. Therefore, we can naturally choose a small value for κ for our purpose. In fact, the concentration parameter was set as $\kappa = 0.69$ by using Garcia-Portugues's rule in our experiments. The normalization constant using κ was calculated as $C_q(\kappa) = 0.14$, and the average values of μ and σ with respect to the set S of output candidates were $\mathbb{E}_S[\sigma] = 0.30$ and $\mathbb{E}_S[\mu] = 0.78$, respectively. In this case, the theoretical average approximation error was calculated as $\mathbb{E}_S[R^*] \le 0.093 = 0.14 \times 0.69^2 \times \exp(0.69) \times (0.78^2 + 0.30^2)$. This is quite small in view of the approximation error for a probability. In addition, the actual average approximation error can be much smaller, and it was about 1.95×10^{-7} in our experiments. The accuracy defined by the rate at which the approximate maximum is the true maximum, i.e., $p(y) = \max_{s \in S} p(s)$, was 96.36%. Detail on the settings of our experiments will be given in the next section.

5 Experiments

We first explain the basic settings of our experiments in Sec. 5.1 and report a comparative experiment and analysis on the news-headline-generation task in Sec. 5.2. Then, we discuss the change in some of the settings to conduct an experiment by changing the number of models and the settings of model preparation in Sec. 5.3 and Sec. 5.4, respectively.

5.1 Basic Settings

Dataset: We used a well-known dataset `Gigaword` of a news-headline-generation task, which was prepared by Rush et al. (2015). This dataset has been extensively used in recent studies on abstractive summarization (Takase et al., 2016; Chopra et al., 2016; Kiyono et al., 2017; Zhou et al., 2017; Suzuki and Nagata, 2017; Cao et al., 2018). The `Gigaword` dataset was created from the English Gigaword corpus[2], in which the input is the first sentence in a news article, and the output is the headline of the article. The training, validation, and test sets included 3.8M, 189K, and 2K sentences, respectively. The preprocessed data are publicly available[3]. The dataset is also used to train official pretrained models of OpenNMT[4].

Model and Training: We basically used the default PyTorch implementation of OpenNMT[5] on June 11, 2017 throughout our experiments, but the unidirectional long short-term memory (LSTM) for the encoder was replaced with a bidirectional one to obtain nearly state-of-the-art results. The basic settings are as follows. Our model consisted of a bidirectional LSTM for the encoder and a stacked LSTM with input feeding for the decoder. These LSTMs had two layers with 500-dimensional hidden layers whose dropout rates were 0.3, and their input vectors were created by a 500-dimensional word-embedding layer.

The model was trained with a stochastic gradient descent method with a learning rate of 1.0, where the mini-batch size was set to 64. The learning process ended in 13 epochs, decaying the learning rate with a decay factor of 0.5 in each epoch after 8 epochs. These training settings are the same as the training of the official pretrained models of OpenNMT, and we confirmed that these settings performed better than training with Adam (Kingma and Ba, 2014) in our preliminary experiments. We prepared 10 learned models by random initialization for the ensemble methods in our experiments.

Decoding and Evaluation: When decoding input sequences, we used a beam-search algorithm with a beam width of 5. The maximum size of decoded sequences was 100. The generated unknown token <unk> was replaced by the source word with the highest attention weight.

To evaluate decoded sequences, we calculated ROUGE-1, ROUGE-2, and ROUGE-L (Lin, 2004), mainly used in the headline-generation-task (Rush et al., 2015). ROUGE-1 and ROUGE-

2 are the co-occurrence rates of unigrams and bigrams, respectively, between a generated headline and its reference. ROUGE-L is the rate of the longest common subsequence between them to the reference length. We used a Python wrapper of the ROUGE-1.5.5.pl script[6] and took the average value of 10 times, each of which used 10 models.

Compared Methods: We compared the following methods. `Single` is a baseline with a single model. `EnsSum` and `EnsMul` are strong baselines with runtime-ensemble. `MaxLik` and `MajVote` are weak baselines with naive post-processing. `LexRank` and `LMRank` are simple unsupervised methods from two other related tasks, extractive summarization and hypotheses reranking, respectively. `PostCosE` and `PostCosB` are variants of the proposed method with post-ensemble. `PostVmfE` and `PostVmfB` are true density estimators corresponding to `PostCosE` and `PostCosB`, respectively. Their descriptions are listed below in detail.

- `Single` decodes an output by using the best single model with respect to the word level accuracy on a validation set.
- `EnsSum` and `EnsMul` decode an output averaging multiple models with Eq. (2) and Eq. (3), respectively.
- `MaxLik` selects an output with the maximum likelihood, which is calculated by the corresponding model p in Alg. 1, from candidate outputs generated by multiple models.
- `MajVote` selects an output by majority vote based on exact matching, i.e., $y = \mathrm{argmax}_{s \in S} |\{s' \in S \mid s = s'\}|$.
- `LexRank` selects an output with the LexRank algorithm (Erkan and Radev, 2004). We used a Python implementation[7], where a graph is constructed on the basis of cosine similarities between the tf-idf vectors (without stop-words) of candidate outputs. The idf weights are calculated from the training set.
- `LMRank` selects an output that maximizes the likelihood of a (non-conditional) language model p_{LM}, i.e., $y = \mathrm{argmax}_{s \in S}\, p_{\mathrm{LM}}(s)$, as in (Vaswani et al., 2013). We used the decoder part of the encoder-decoder model described in Sec. 5.1, which was trained with both source and target sentences in the training set. This allows this model to learn the fluency in both normal and headline-like sentences.
- `PostCosE` and `PostVmfE` select an output on the basis of Alg. 1 with the cosine similarity i.e., $K(s, s') = \cos(s, s')$, and the von Mises-Fisher kernel, i.e., $K(s, s') = K_{\mathrm{vmf}}(s, s')$ in Eq. (5), respectively. The feature of each output is the average of pretrained 300-dimensional word embeddings[8].
- `PostCosB` and `PostVmfB` are variants of `PostCosE` and `PostVmfE` with simple bag-of-words features (sparse vectors), respectively.

In addition, we used the following measurements for analysis. `MaxRef` represents the upper bound for the performance of our method. `Mean`, `Max`, and `Min` represent the performance statistics of the single models.

- `MaxRef` selects the best output with respect to ROUGE-1, which is calculated by using the references in the test set.
- `Mean`, `Max`, and `Min` are the mean, maximum, and minimum of the (non-ensemble) ROUGE-1 values for the 10 models, respectively. The difference between `Single` and `Max` is that the former uses the validation set, while the latter uses the test set.

5.2 Main Results

We conducted a comparative experiment on the news-headline-generation task to verify the effectiveness of our post-ensemble method compared with the current runtime-ensemble methods.

Tab. 1 shows the experimental results for the `Gigaword` dataset, including the results of our method with 32 models and other previous results. First of all, we can see that the variant of our post-ensemble method, `PostCosB`, clearly outperformed the runtime-ensemble methods (strong baselines), `EnsSum` and `EnsMul`, and the other baselines. The differences between our best method `PostCosB` and the best baseline `EnsSum` were all statistically significant on the basis of a one-tailed, paired t-test ($p < 0.05$). Comparing with the recent results of Cao et al. (2018) obtained with open information extraction and dependency parse technologies and the other previous results[9], our method with 32 models also performed better, although the algorithm of our

Table 1: F-measure ROUGE-1, ROUGE-2, and ROUGE-L scores (%) for news-headline-generation task. Bold and underlined scores represent best scores for ensembles of 10 models and all methods excluding measurements with "$*$," respectively. Results with "♯" are taken from corresponding papers.

method is quite simple. Note that our method can be easily applied to their models to improve their results. Looking at the row for `MaxRef`, the results imply that our post-ensemble method still has room for improvement without any changes to model structure. Although we also conducted an experiment by changing the settings of model preparation, the results had a similar tendency to those of the main results (see Sec. 5.4).

Fig. 2 illustrates how our method worked with kernel density estimation (see the figure caption for detailed descriptions). The left scatter-plot shows a two-dimensional visualization of 10 outputs generated from the 10 models and the estimated densities (represented by color intensity in the right bar). Looking at the center part of the plot, we can see that there are many good outputs with high ROUGE-1 results (noted in brackets in the plot) in the dense part. The right list shows the corresponding outputs of the points in the left plot, where these outputs are sorted by the estimated density. The list shows that our method successfully obtained the majority-like output (model ID of 0) in the dense part of the output space, although there are no exact match outputs. Looking at the bottom part of the list, we can see that our method clearly eliminated unpromising outputs (model ID of 7, 8, and 9) with less information, since they are scattered.

5.3 Effect of Number of Models

We compared the effect of changing the number of models on the performance of our best method `PostCosB` and the best baseline `EnsSum`. We pre-

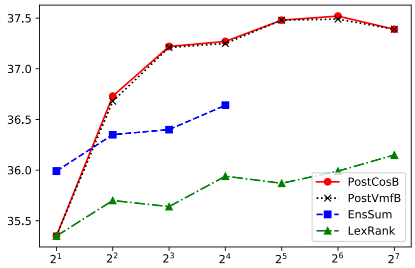

Figure 3: F-measure ROUGE-1 performance (%) vs. number of models for news-headline-generation task. X-axis is log scale (2^1–2^7).

pared 128 models, in which each training took more than two days. The ROUGE-1 performance was measured by varying the number of models, i.e., 2, 4, $\cdots$, 128.

Fig. 3 shows the performance of our best method `PostCosB`, the corresponding true estimator `PostVmfB`, the best baseline `EnsMul`, and the most widely-used baseline `LexRank` versus the number of models. Note that we could not calculate the results of `EnsMul` for more than 16 models due to out of memory errors. The figure shows that `PostCosB` performed better than `EnsMul` even for these 16 models. We obtained a 37.48 ROUGE-1 score with 32 models, which was better than the state-of-the-art results in Tab. 1, but the performance seems to be saturated with more than 32 models. Looking at `PostCosB` and `PostVmfB`, we can see that the performances are almost the same, which also supports our theoretical analysis in Sec. 4. `LexRank` did not work well even though the number of models was large.

The complexity of the post-ensemble procedure in Alg. 1 is $O(\beta\nu+\delta\nu^2)$, where ν is the number of models, δ is the dimension of the output space, and β is the number of operations of the beam-search. We can reduce it to $O(\beta+\delta\nu)$ by simply parallelizing lines 2–4 and 6–8 in Alg. 1 without any change to the model code on the deep learning framework. Since the operations of β includes all matrix calculations in the model, we can basically assume $\beta \gg \delta\nu$. In fact, the actual calculation times of `PostCosE` and `PostCosB` with a naive implementation in Python were 0.0097 and 0.0037 seconds per sentence when $\nu = 32$, respectively. They are enough for practical use in comparison with the decoding speeds of 0.044 (GPU) and 0.49 (CPU) seconds per sentence. In addition, the complexity of the runtime-ensemble is $O(\beta\nu)$, which cannot be parallelized without modifying more than a hundred lines of code after understanding a whole system.

	Random	Self	Hetero	Bagging
`Single`	35.57	35.34	35.67	34.87
`EnsSum`	36.55	35.46	36.42	36.25

`Min`*	35.00	33.43	34.49	34.36

Table 2: F-measure ROUGE-1 scores (%) of random-ensemble (Random), self-ensemble (Self), hetero-ensemble (Hetero), and bagging-ensemble (Bagging) for news-headline-generation task. Bold scores represent best scores for all methods excluding measurements with “$*$.”

5.4 Effect of Model Preparation

We conducted experiments to verify the effect of changing the model preparation on post-ensemble performance. In addition to random initialization (*random-ensemble*), we address three variations of model preparation: *self-ensemble*, *hetero-ensemble*, and *bagging-ensemble*. The first one, self-ensemble, is a method of extracting models from “checkpoints” saved in each epoch in a training. We prepared the models of self-ensemble by using 10 checkpoints from 4–13 epochs. The second one, hetero-ensemble, is a method of training models varying in model structure. We prepared 10 models for hetero-ensemble, consisting of 8 models prepared by changing the number of layers in the LSTM encoder/decoder in $\{2, 3\}$, the size of LSTM hidden states in $\{250, 500\}$, and the size of word embedding in $\{250, 500\}$, and two models prepared by replacing the bidirectional encoder with a unidirectional encoder and a bidirectional encoder with a different merge action, i.e., summation instead of concatenation. The third one, bagging-ensemble, is a method of training models by bagging of training data. We randomly extracted 80% of the training data 10 times and prepared 10 models for bagging-ensemble. We used the same dictionary of the original data for these models, since the runtime-ensemble methods, `EnsSum` and `EnsMul`, failed to average the models with different dictionaries.

Note that the outputs for self-ensemble and hetero-ensemble cannot be regarded as i.i.d samples, but we believe the basic idea can be practically applied.

Tab. 2 shows the F-measure ROUGE-1 scores for the `Gigaword` dataset of the above three variations, self-, hetero-, and bagging-ensembles, as well as random-ensemble. The table indicates that all variants of our post-ensemble method performed better than the current runtime-ensemble methods, `EnsSum` and `EnsMul`, for all variations of model preparation. Looking at the row for `PostCosE`, random-ensemble was the most effective, while self-ensemble was the worst, as expected. Bagging-ensemble was relatively effective for post-ensemble according to the relative improvement from `Single`, despite the fact that we trained the models with 80% of the training data. Hetero-ensemble performed worse than random-ensemble for these settings, but we expect that if the model structure can be randomly chosen, hetero-ensemble will perform better.

6 Related Work

Distillation techniques for an ensemble of multiple models have been widely studied (Kuncoro et al., 2016; Chebotar and Waters, 2016; Kim and Rush, 2016; Freitag et al., 2017; Stahlberg and Byrne, 2017), especially after a study by Hinton et al. (2015). Kuncoro et al. (2016) and Chebotar and Waters (2016) studied distillation techniques for ensembles of multiple dependency parsers and speech recognition models, respectively. There are several ensemble methods for ensembles of machine translation models (Kim and Rush, 2016; Freitag et al., 2017; Stahlberg and Byrne, 2017). For example, Stahlberg and Byrne (2017) proposed a method of unfolding an ensemble of multiple translation models into a single large model once and shrinking it down to a small one. However, all methods require extra implementation on a deep-learning framework, and it is not easy to apply them to other models. Our post-ensemble method does not require such coding skills. In addition, since the predictions of post-ensemble can be regarded as a teacher model, these distillation techniques should be combined with a teacher model based on post-ensemble.

Hypotheses reranking of language generation has been extensively studied, but most studies focused on discriminative training using costly annotated data (Shen et al., 2004; White and Rajkumar, 2009; Duh et al., 2010; Kim and Mooney, 2013; Mizumoto and Matsumoto, 2016). The main stream of our focused unsupervised approach was a reranking method based on a language model (Chen et al., 2006; Vaswani et al., 2013; Luong and Popescu-Belis, 2016), and other approaches include reranking methods based on key phrase extraction (Boudin and Morin, 2013), dependency analysis (Hasan et al., 2010), and search results (Peng et al., 2013). All of the above described studies were not used for model ensemble. Tomeh et al. (2013) used an ensemble learning, but the purpose was to improve the performance of the reranking model for hypotheses reranking of a single model. Li et al. (2009), which work is the most related one, proposed a reranking algorithm for model ensemble. However, their method was constructed to perform at decoding time, so it can be regarded as runtime-ensemble.

The term "frustratingly easy" in this paper is borrowed from "frustratingly easy" papers (Daumé III, 2007; Daumé III et al., 2010; Tommasi and Caputo, 2013; Sun et al., 2016; Kim et al., 2016).

7 Conclusion

We proposed a simple but effective model-ensemble method, called *post-ensemble*, for abstractive-summarization models, i.e., encoder-decoder models. We verified the effectiveness of our method on the news-headline-generation task.

We will release the 128 prepared models used in this paper[10], each of which was trained for more than two days, as a new dataset for improving ensemble methods. For example, future research includes applying learning-to-rank regarding all outputs as features, conducting active learning to select a new model setting online, and developing boosting-like-ensemble based on the bagging of training data.

Abstract

This paper tackles automation of the pyramid method, a reliable manual evaluation framework. To construct a pyramid, we transform human-made reference summaries into extractive reference summaries that consist of Elementary Discourse Units (EDUs) obtained from source documents and then weight every EDU by counting the number of extractive reference summaries that contain the EDU. A summary is scored by the correspondences between EDUs in the summary and those in the pyramid. Experiments on DUC and TAC data sets show that our methods strongly correlate with various manual evaluations.

1 Introduction

To develop high quality summarization systems, we need accurate automatic content evaluation. Although, various evaluation measures have been proposed, ROUGE-N (Lin, 2004), Basic Elements (BE) (Hovy et al., 2006) remain the de facto standard measures since they strongly correlate with various manual evaluations and are easy to use. However, the evaluation scores computed by these automatic measures are not so useful for improving system performance because they merely confirm if the summary contains small textual fragments and so they do not address semantic correctness.

The pyramid method was proposed as a manual evaluation that well supports the improvement of summarization systems (Nenkova and Passonneau, 2004; Nenkova et al., 2007). First, the method identifies conceptual contents, Summary Content Units (SCUs), in reference summaries and then constructs a pyramid by collecting semantically equivalent SCUs. The weight of an SCU in the pyramid is defined as the number of reference summaries that contain the SCU. Thus, an SCU shared by many reference summaries is given higher weight. Second, a system summary is scored by the correspondences between SCUs in the summary and the pyramid. Its results are very useful for system improvement, *i.e.*, we can know which important SCUs the system could or could not include in the summary. Although the pyramid method is reliable, it requires considerable cost and effort.

To address the weaknesses, automatic pyramid evaluation, Pyramid Evaluation via Automated Knowledge Extraction (PEAK) was proposed (Yang et al., 2016). Since SCU is the conceptual content of the text, it is difficult to automatically extract them from reference summaries by systems. Thus, PEAK regards subject-predicate-object triples as alternatives to SCUs and constructs a pyramid by clustering semantically equivalent triples. However, the performance of subject-predicate-object triples extraction is not satisfying for the practical demands and semantic similarity utilized for clustering the triples does not correlate well with human judgment (see Section 2). As a result, the resultant pyramid is unreliable. Actually, PEAK is significantly inferior to ROUGE and BE (see Section 4.3) in terms of correlation.

To cope with the above problems, this paper proposes yet another automatic pyramid evaluation method. Its key feature is constructing a pyramid that consists of Elementary Discourse Units (EDUs), clause-like text units introduced in Rhetorical Structure Theory (Mann, William Charles and Thompson, Sandra Annear, 1988), in the source documents. In other words, we regard EDUs as alternatives to SCUs. To construct the pyramid, we transform human-made reference summaries into EDU-based extractive reference summaries and then weight every EDU by counting the number of the extractive reference summaries that contain the EDU. The rea-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4177–4186
Brussels, Belgium, October 31 - November 4, 2018.

son why we derive extractive reference summaries whose SCUs are EDUs is as follows. First, Li et al. (2016) reported that EDUs are very similar to SCUs. Second, the performance of EDU segmenter is sufficient to satisfy practical requirements (see Section 2). Third, we do not need measure any semantic similarity to identify EDUs common to the extractive reference summaries. We also examine two types of extractive reference summary. One is based on the alignment between EDUs in reference summary and source documents. The other is based on the *extractive oracle summary* (Hirao et al., 2017). We conducted experiments on the Document Understanding Conference (DUC) 2003 to 2007 data sets and Text Analysis Conference (TAC) 2008 to 2011 data sets. The results showed that our methods exhibit strong correlation with manual evaluations.

2 Background and Related Work

The pyramid method (Nenkova and Passonneau, 2004; Nenkova et al., 2007), a manual evaluation framework, was developed to measure the content coverage of summaries. The pyramid method consists of two steps: (1) pyramid construction, and (2) summary scoring based on the pyramid. First, human annotators identify Summary Content Units (SCUs), conceptual content units in the reference summaries. They then construct a pyramid by clustering and weighting SCUs. The weight of an SCU is defined as the number of reference summaries that contain the SCU. As a result, if there are K reference summaries, the upper bound weight of an SCU in the pyramid is K and the lower bound is 1. Second, the score for a summary is determined by the correspondences between SCUs in the summary and those in the pyramid. Thus, the score is defined as the sum of weights of SCUs that correspond to those in the pyramid in the summary divided by the sum of SCU weight possible for an average-length reference summary. The pyramid method has two advantages over conventional manual evaluations: (1) the score is not intuitive but is systematically computed, *i.e.*, the score can be explained as the sum of weights of SCUs in the pyramid, (2) the correspondences between the SCUs in a summary and the pyramid tell us whether the summary contains important SCUs or not. Thus, the results explicitly tell us why a summary was given a good or bad score.

During the past few years, studies have focused on the automatic scoring of summaries based on manually generated pyramids. Harnly et al. (2005) proposed a scoring method that matches SCUs in the pyramid with possible textual fragments in the summary. They enumerate all possible textual fragments within a sentence in the summary and compute similarity scores between the fragments and the SCUs in the pyramid based on unigram overlap. Then, they find the optimal correspondences between SCUs and the fragments that maximize the sum of similarity scores. Passonneau et al. (2013) extended the method by introducing distributional semantics to compute the similarity scores between SCUs and the fragments.

Recently, Yang et al. (2016) proposed the first automatic pyramid method, Pyramid Evaluation via Automated Knowledge Extraction (PEAK). PEAK employs subject-predicate-object triples extracted by ClausIE (Del Corro and Gemulla, 2013) as SCUs, and constructs pyramids by cutting a graph whose vertices represent the triples and whose edges represent semantic similarity scores between the triples computed by Align, Disambiguate and Walk (ADW) (Pilehvar et al., 2013). When evaluating a summary, PEAK constructs a weighted bipartite graph whose vertices represent subject-predicate-object triples extracted from the pyramid and the summary, respectively; the edges represent the similarity scores between the triples as computed by ADW. It scores the summary by solving the Linear Assignment Problem which involves maximizing the sum of the similarity scores on the bipartite graph.

The major difference between PEAK and our method is that the former regards the reference summary as a set of subject-predicate-object triples while the latter regards a reference summary as a set of EDUs obtained from the source documents. Thus, to construct high quality pyramids, PEAK is required to not only accurately extract the triples but also measure the semantic similarity between them accurately. However, in general, both extracting the triples and measuring the semantic similarity are still challenging NLP tasks. The performances are not always achieved in practical use. Actually, the F-measure of ClausIE is around 0.6 (Del Corro and Gemulla, 2013) and the correlation coefficients between the semantic similarity obtained from ADW and human judgment lie in the range of 0.55 to 0.88

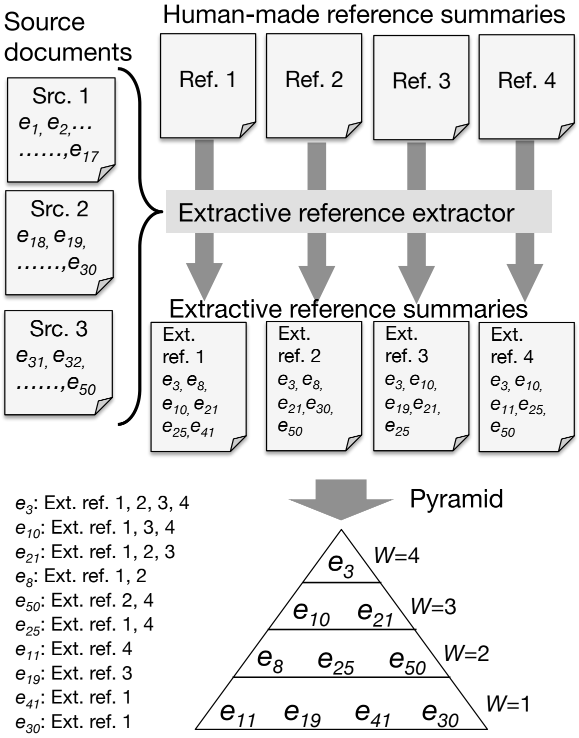

Figure 1: Overview of our pyramid construction.

(Pilehvar et al., 2013). As a result, the resultant pyramids have insufficient quality to be practical. Clearly, further improvement is necessary.

While our method is required to decompose a document into EDUs accurately, the EDU segmenter offers accurate decomposition performance; existing EDU boundary detection methods have F-measures over 0.9 (Fisher and Roark, 2007; Feng and Hirst, 2014). Moreover, since extractive reference summaries are set of EDUs from the source documents, we do not need semantic similarity to identify EDUs that have the same meaning. Thus, we can easily construct a pyramid by simply counting the number of extractive reference summaries that contains each EDU.

3 Automatic Pyramid Evaluation

First, we transform human-made reference summaries into extractive reference summaries; the EDUs in the source documents are used as the atomic units. Second, we construct a pyramid by weighting EDUs in the extractive reference summaries. EDU weights are defined as the number of reference summaries that contain each EDU (see Figure 1). In addition, we propose two techniques for deriving the extractive reference summaries.

3.1 Extractive Reference Summaries based on Alignment between EDUs

When similarity scores between EDUs in a reference summary and those in the source documents are available, we can regard extractive reference summary derivation as an optimal alignment problem with a length constraint, an extension of Linear Assignment Problem. We assume that a bipartite graph in which the vertices represent EDUs in the reference summary and source documents, and the edges represent similarity scores between the EDUs. The optimal alignment is obtained by solving following ILP problem:

$$\text{maximize} \sum_{j=1}^{|\mathcal{E}|} \sum_{k=1}^{|\mathcal{M}|} \phi(e_j, m_k) a_{j,k} \tag{1}$$

$$\text{s.t.} \quad \sum_{j=1}^{|\mathcal{E}|} \sum_{k=1}^{|\mathcal{M}|} \ell(e_j) a_{j,k} \leq L_{\max} \tag{2}$$

$$\sum_{j=1}^{|\mathcal{E}|} a_{j,k} \leq 1 \qquad \forall k \tag{3}$$

$$\sum_{k=1}^{|\mathcal{M}|} a_{j,k} \leq 1 \qquad \forall j \tag{4}$$

$$a_{j,k} \in \{0, 1\} \qquad \forall j, k. \tag{5}$$

$\mathcal{E}$ is the set of all EDUs in the source documents and $\mathcal{M}$ is the set of all EDUs in the reference summary. $\ell()$ returns the length (the number of words) of a textual unit. $\phi(e_j, m_k)$ returns the similarity score between the j-th EDU in the source documents and the k-th EDU in the reference summary as follows:

$$\phi(e_j, m_k) = \frac{\ell(\text{LCS}(e_j, m_k))}{\ell(m_k)}. \tag{6}$$

LCS$(\cdot, \cdot)$ returns the Longest Common Subsequence between e_j and m_k. $a_{j,k}$ is a binary indicator, and $a_{j,k} = 1$ denotes that the j-th EDU e_j in the source documents is aligned to the k-th EDU in the reference summary, *i.e.*, e_j is included in the extractive reference summary. Equation (2) ensures the the length of the extractive reference summary is less than $L_{\max}$, the length of the human-made reference summary. After solving the ILP problem, we can obtain the extractive reference summaries by collecting EDUs according to $a_{j,k} = 1$.

3.2 Extractive Reference Summaries based on Extractive Oracle Summaries

As another extractive reference summary, we can utilize extractive oracle summary (Hirao et al., 2017). The extractive oracle summary is defined as the set of consequential textual fragments within a sentence obtained from the source documents that has the maximum automatic evaluation score. Since we regard EDUs as SCUs and employ ROUGE/BE as an automatic evaluation measure, an extractive reference summary is a summary that consists of EDUs in the source documents and has maximum ROUGE/BE score.

For a given reference summary R , the extractive oracle summary is defined as follows:

$$\begin{aligned} O = &\mathop{\arg\max}_{E \subseteq \mathcal{E}} f(R, S) \\ \text{s.t.} \quad & \ell(S) \leq L_{\max}. \end{aligned} \tag{7}$$

$f()$ denotes an automatic evaluation measure (ROUGE/BE) and is defined as follows:

$$f(R, S) = \frac{\sum_{i=1}^{|U|} \min\{N(u_i, R), N(u_i, S)\}}{\sum_{i=1}^{|U|} N(u_i, R)}. \tag{8}$$

S is a system summary and U is the set of all atomic units in the reference summary. N-grams are utilized as the units used in computing ROUGE and head-modifier-relation triples are utilized in computing BE. $N(u_i, R)$; $N(u_i, S)$ returns the number of occurrences of the units in the reference and system summary, respectively.

Since the extractive oracle summaries in Hirao et al. (2017) are based on sentences, we extend the method to obtain EDU-based extractive oracle summaries. The ILP formulation that returns an extractive oracle summary is defined as follows:

$$\text{maximize} \sum_{i=1}^{|U|} z_i - \sum_{m=1}^{|S|} s_m \tag{9}$$

$$\text{s.t.} \quad \sum_{j=1}^{|\mathcal{E}|} \ell(e_j) x_j \leq L_{\max} \tag{10}$$

$$N(u_i, R) \geq z_i \qquad \forall i \tag{11}$$

$$\sum_{n \in V_i} d_n \geq z_i \qquad \forall i \tag{12}$$

$$x_{\text{left}(n)} \geq d_n \qquad \forall n \tag{13}$$

$$x_{\text{right}(n)} \geq d_n \qquad \forall n \tag{14}$$

$$s_{\text{c}(j)} \geq x_j \qquad \forall j \tag{15}$$

$$d_n \in \{0, 1\} \qquad \forall n \tag{16}$$

$$x_j \in \{0, 1\} \qquad \forall j \tag{17}$$

$$z_i \in \mathbb{Z}_+ \qquad \forall i. \tag{18}$$

z_i is the count of the i-th unit in the oracle summary. x_j is a binary indicator, $x_j = 1$ denotes that the j-th EDU, e_j, is included in the oracle summary. s_m is a binary indicator, $s_m = 1$ denotes that EDU(s) in m-th sentence is included in the oracle summary. The value of $\sum_{m=1}^{|S|} s_m$ is equal to the number of sentence whose EDU(s) is used in oracle summary. Thus, an oracle summary that consist of fewer sentences tends to obtain a higher objective value. Therefore, we can avoid generating fragmented oracle summaries with low readability. This objective function is inspired by the work of compressive summarization method (Morita et al., 2013). V_i is the set of indices indicating the position of the i-th unit, and d_n is a binary indicator indicating whether the n-th unit is contained in the oracle summary or not. Function left($\cdot$) and right($\cdot$) return the index of EDU that contains a word on the left in the unit, and the index of EDU that contains a word on the right in the unit, respectively. Function c($\cdot$) returns the index of sentence that contains j-th EDU.

Figure 2 shows examples. Suppose that the 10-th triple in U is "<has,computer,rcmod>". From the figure, the indices of the triple corresponding to "<has,computer,rcmod>" are 6 and 21. Thus, $V_{10} = \{6, 21\}$. The word on the left in the triples is "computer" and the word on the right is "has". For the first triple, the index of the EDU that contains "computer" is 1 and the index of the EDU that contains "has" is 2. For the second triple, the index of the EDU that corresponds to "computer" is 4, while that of "has" is 5. Thus, $\text{left}(6) = 1$ and $\text{right}(6) = 2$, $\text{left}(21) = 4$, and $\text{right}(21) = 5$.

After solving the ILP problem, we construct the extractive oracle summary by collecting EDUs according to $x_j = 1$.

3.3 Pyramid Construction: EDU Weighting

By deriving extractive references, we can easily construct a pyramid. The weight of an EDU is defined as the number of extractive references that contain the EDU. Here, $\mathcal{P}$ is a complete set of all EDUs in K extractive reference summaries, *i.e.*, $\mathcal{P} = \bigcup_{i=1}^{K} E_i$. E_i is the set of EDUs obtained from the i-th extractive reference summary. The weight

Figure 2: Examples of head-modifier-relation triples.

of the j-th EDU in $\mathcal{P}$ is defined as follows:

$$w_j = C(p_j). \quad (19)$$

$C()$ returns the number of extractive reference summaries that contain p_j, *i.e.*, the maximum score of $C(p_j)$ is K and its minimum score is 1. Since all EDUs in the source documents are assigned an integer score in the range of 0[1] to K, the scoring can be regard as a variant of relative utility score (Radev and Tam, 2003).

3.4 Automatic Scoring of Summaries

Based on the pyramid, we compute a score for a summary by aligning EDUs in the pyramid and EDUs in the system summary. By following PEAK, we find the optimal alignment by solving the Linear Assignment Problem. That is, we compute all similarity scores between EDUs in the summary and pyramid and then find the maximal score so that each EDU in the system summary is matched to at most one EDU in the pyramid. The ILP formulation of the problem is as follows:

$$\text{maximize} \quad \sum_{i=1}^{|\mathcal{C}|} \sum_{j=1}^{|\mathcal{P}|} g(c_i, p_j) w_j \alpha_{i,j} \quad (20)$$

$$\text{s.t.} \quad \sum_{i=1}^{|\mathcal{C}|} \alpha_{i,j} \leq 1 \quad \forall i \quad (21)$$

$$\sum_{j=1}^{|\mathcal{P}|} \alpha_{i,j} \leq 1 \quad \forall j \quad (22)$$

$$\alpha_{i,j} \in \{0, 1\} \quad \forall i, j (23)$$

$\mathcal{C}$ is the set of EDUs in the system summary. Function $g()$ indicates a binary function based on the similarity score between EDUs as follows:

$$g(c, p) = \begin{cases} 1 & \phi(c, p) \geq t \\ 0 & \text{otherwise.} \end{cases} \quad (24)$$

We set $t = 0.55$ in our experiments (Section 4).

$\alpha_{i,j}$ is a binary indicator, $\alpha_{i,j} = 1$ denotes that the i-th EDU in the system summary is aligned to j-th EDU in the pyramid.

The optimal solution of the objective function in the ILP problem (19)-(22) is not normalized. Since the unnormalized score is not suitable for comparing systems, we propose a normalization method. To normalize the score to satisfy the range of 0 to 1, we divide the score by the maximum score of sum of the EDU weights. Since every EDU in the pyramid has both length (the number of the word) and weight, the maximum score is derived by solving the *knapsack problem*:

$$\text{maximize} \quad \sum_{j=1}^{|\mathcal{P}|} w_j x_j \quad (25)$$

$$\text{s.t.} \quad \sum_{j=1}^{|\mathcal{P}|} \ell(p_j) \leq L_{\max} \quad (26)$$

---

[1] The EDUs that are not included in pyramid have scores of zero.

x_j is a binary indicator, and $x_j = 1$ denotes that the j-th EDU is included in the *knapsack*.

Finally, the score is defined as $\mathrm{Pyramid}(\mathcal{P}, S) = \mathrm{OTP}_{\mathrm{LAP}}/\mathrm{OPT}_{\mathrm{KP}}$. $\mathrm{OPT}_{\mathrm{LAP}}$ and $\mathrm{OPT}_{\mathrm{LAP}}$ denote maximum score of Equation (20) and maximum score of Equation (25), respectively.

4 Experiments

To investigate the effectiveness of our automatic evaluation method, we compare the correlation coefficients yielded by our methods with those obtained from strong baselines, ROUGE-2, ROUGE-SU4 and BE. We employ ROUGE toolkit version 1.5.5 to compute ROUGE/BE scores and Stanford Parser (de Marneffe et al., 2006) to obtain head-modifier-relation triples. In addition, we examine two types of oracle summaries for our method. One is ROUGE-2-based, the other is BE-based.

We evaluate automatic evaluation measures by Pearson's correlation r, Spearman's rank correlation ρ and Kendall's rank correlation τ. Correlation coefficients are computed by average automatic score and average manual evaluation score for all topics.

4.1 Data Sets

We conducted experiments on the data sets developed for multi document summarization tasks in DUC-2003 to 2007 and TAC-2008 to 2011. Table 1 and Table 2 show the statistics of the data sets.

DUC-2003 and 2004 were used for a generic summarization task with 100 word limit; mean coverage was used in a manual evaluation. DUC-2005 to 2007 were used for a query-focused summarization task with 250 word limit; responsiveness was used in a manual evaluation. The number of topics varied from 30 to 50 and the participating systems from 16 to 35. Note that the pyramid method was applied to small sets of topics in DUC-2006 and 2007.

TAC-2008 and 2009 were used for an update summarization task while TAC-2010 and 2011 were employed for a guided summarization task. For both tasks, the participating systems required two types of summaries, *initial summary* and *update summary* with 100 word limit. Both pyramid method and responsiveness were used in manual evaluations. In particular, TAC-2008 to 2011 have large numbers of participating systems, from 44 to 48.

4.2 EDU Segmenter

We regard decomposing a sentence into EDUs as a sequential tagging problem and implement a neural EDU segmenter that classifies each word in a sentence as the boundary of EDU or not based on 3-layer bi-LSTM (Wang et al., 2015). The size of word embeddings and hidden layers of the LSTM were set to 100 and 256, respectively. To handle low-frequency words, all words are encoded to 40 dimension hidden state by using character-based bi-LSTM (Lample et al., 2016). To utilize entire words in a corpus, we integrated word dropout (Iyyer et al., 2015) into our models with smoothing rate, 1.0. Moreover, to avoid overfitting the training data, dropout layer was adopted to the input of the LSTMs with the ratio 0.3.

The segmenter was trained by utilizing the training data of RST Discourse Treebank corpus (Carlson et al., 2001). The macro-averaged F-measure of boundary detection on the test data of the corpus is 0.917. The source documents, system summaries and reference summaries utilized

in our experiments were decomposed into EDUs by the segmenter.

4.3 Results and Discussion

Table 3 and 4 list the correlation coefficients between manual evaluation and automatic evaluation for DUC-2003 to 2007 and TAC-2008 to 2011, respectively. In the tables, the coefficients are written in the order "Pearson's r/ Spearman's ρ/ Kendall's τ". The rows of Prop(BE), Prop(ROUGE) and Prop(AL) denote our method with BE-based oracle summaries as extractive reference summaries, with ROUGE-2-based oracle summaries, and with extractive reference summaries based on alignment, respectively. "Cov.", "Resp." and "Pyr." denote mean coverage, responsiveness and manual pyramid, respectively.

With regard to mean coverage on DUC-2003 to 2004, Prop(BE) achieved the best correlation coefficients. The correlation coefficients indicate very strong correlation with the manual evaluation. Prop(ROUGE) and Prop(AL) attained comparable correlation coefficients with the baseline methods. The correlation coefficients still indicate strong correlation.

With regard to responsiveness, our methods achieved lower correlation coefficients on DUC-2005 to 2007 than on DUC-2003 to 2004. Although our methods are outperformed by the baseline methods, both r and ρ of Prop(BE) still exceed 0.8 except for responsiveness on DUC-2006. Since our methods mimic manual pyramid evaluation, correlation coefficients against manual pyramid on DUC-2006 to 2007 are better than those against responsiveness and the scores are comparable to those of the baselines.

Moreover, we compare our methods with PEAK on the DUC-2006 data set. For manual pyramid, r and ρ are 0.508 and 0.538, respectively, while for responsiveness they are 0.617 and 0.640, respectively. These scores are significantly lower than those attained by our methods and baselines. Note that these results are obtained by running the code from the author's web page `http://www.larayang.com/peak/`. The results demonstrated that our methods are superior to PEAK.

For manual pyramid on TAC-2008 to 2011, all methods attained quite strong correlation. The scores achieved were around 0.9 and better than those on DUC-2003 to 2007. In particular, Prop(BE) achieved the best scores in some cases. Although, responsiveness yielded lower correlation coefficients than manual pyramid, Prop(BE) still retains strong correlation , e.g., ρ are in the range of 0.857 to 0.932 against manual pyramid, 0.810 to 0.913 against responsiveness. The average correlation coefficients across all data sets on TAC are shown in Table 5. The average correlation coefficients of Prop(BE) slightly lower than those of ROUGE-2 and BE against manual pyramid. On the ohter hand, Prop(BE) achieved the best correlation coefficients against responsiveness. The results imply that Prop(BE) achieves comparable performance to baseline methods.

In a comparison of our methods, Prop(BE) attained the best results while Prop(ROUGE) showed better results than Prop(AL) in many cases. These results imply that extractive oracle summaries are helpful as extractive reference summaries and BE is better objective function to generate them.

In addition, we show SCUs and corresponding EDUs obtained from a human-made pyramid and Prop(BE) in Figure 3. They are obtained from topic "Earthquake Sichuan (ID:D1110B)" from TAC-2011 Guided Summarization Task, the topic type is categorized as "Accidents and Natural Disasters". Summarizers are required to generate a summary that includes following aspects: (1) WHAT: what happend, (2) WHEN: date, time, other temporal placement makers, (3) WHERE: physical location, (4) WHY: reasons for accident/disaster, (5) WHO_AFFECTED: casualties (death, injury), or individuals otherwise negatively affected by the accident/disaster, (6) DAMAGES: damages caused by the accident/disaster, (7) COUNTERMEASURES: countermeasures, rescue efforts, prevention efforts, other reactions to the accident/disaster. From the figure, we can see that the EDUs are not always identical to human-generated SCUs at word-level but are identical at concept-level.

	Pyr.	Resp.
ROUGE-2	.932/.900/.752	.868/.847/.685
ROUGE-SU4	.923/.893/.741	.861/.841/.675
BE	.921/.910/.764	.842/.834/.663
Prop(BE)	.911/.899/.742	.903/.861/.694
Prop(ROUGE)	.905/.880/.713	.890/.837/.668
Prop(AL)	.894/.856/.678	.877/.824/.656

Table 5: Average correlation coefficients across data sets (TAC-2008 to TAC-2011)

In short, these results imply that our methods have at least comparable performance to the baselines. Although our methods are outperformed by the baselines in some cases, the correlation coefficients are high enough against manual evaluation. Moreover, our methods have a significant advantage over the baselines methods because our methods clearly indicate whether the output of the text summarization system failed to include important SCUs. Thus, our automatic pyramid method enhanced with extractive oracle summaries is helpful for further improvement of summarization systems.

5 Conclusion

This paper proposed an automatic pyramid evaluation method that allows us to scrutinize the failure analysis of systems. To construct a pyramid, we transform human-made reference summaries into extractive reference summaries whose atomic units are EDUs obtained from the source documents. Then, we weight every EDU by counting the number of extractive reference summaries that contain the EDU. When evaluating a summary, we determine the correspondences between EDUs in the pyramid to those in the summary by solving Linear Assignment Problem and give a score to the summary based on the correspondences. We also proposed two types of extractive reference summaries. The first is the alignment-based extractive reference summary. The second is the extractive

SCUs obtained from human-made pyramid

$w = 4$ The 7.8-magnitude earthquake struck
$w = 4$ Sichuan Province of China
$w = 4$ No warning signs detected
$w = 4$ Over 8,500 killed
$w = 4$ China allocated 200 million yuan ($29 Million) disaster relief
$w = 1$ Rain is forecast, could hamper relief efforts
$w = 1$ Quake also affected Gansu, Shaanxi provinces, and Chongqing municipality

EDUs obtained from pyramid of Prop(BE)

$w = 1$ The 7.8-magnitude earthquake struck Sichuan province shortly before 2:30 pm
$w = 2$ in aid for earthquake victims in Sichuan Province of China
$w = 4$ Chinese authorities did not detect any warning signs ahead of Monday's earthquake
$w = 1$ leaving at least 12,000 people died
$w = 2$ China has allocated 200 million yuan
$w = 1$ Rain in the coming days in Sichuan is expected to hamper earthquake relief efforts, as well as increase risks of landslides
$w = 1$ 50 in the municipality of Chongqing, 61 in Shaanxi province, and one in southwestern Yunnan

Figure 3: Examples of SCUs obtained from pyramids.

oracle summary.

To demonstrate the effectiveness of our methods, we conducted experiments on DUC-2003 to 2007 and TAC-2008 to 2011 data sets. The results demonstrated that our method yielded results that well correlated with various manual evaluations. The correlation coefficients are at least comparable to those obtained from strong baselines, ROUGE-2, ROUGE-SU and BE and significantly higher than those obtained from previous automatic pyramid evaluation, PEAK.

Learning to Encode Text as Human-Readable Summaries using Generative Adversarial Networks

Abstract

Auto-encoders compress input data into a latent-space representation and reconstruct the original data from the representation. This latent representation is not easily interpreted by humans. In this paper, we propose training an auto-encoder that encodes input text into human-readable sentences, and unpaired abstractive summarization is thereby achieved. The auto-encoder is composed of a generator and a reconstructor. The generator encodes the input text into a shorter word sequence, and the reconstructor recovers the generator input from the generator output. To make the generator output human-readable, a discriminator restricts the output of the generator to resemble human-written sentences. By taking the generator output as the summary of the input text, abstractive summarization is achieved without document-summary pairs as training data. Promising results are shown on both English and Chinese corpora.

1 Introduction

When it comes to learning data representations, a popular approach involves the auto-encoder architecture, which compresses the data into a latent representation without supervision. In this paper we focus on learning text representations. Because text is a sequence of words, to encode a sequence, a sequence-to-sequence (seq2seq) auto-encoder (Li et al., 2015; Kiros et al., 2015) is usually used, in which a RNN is used to encode the input sequence into a fixed-length representation, after which another RNN is used to decode the original input sequence given this representation.

Although the latent representation learned by the seq2seq auto-encoder can be used in downstream applications, it is usually not human-readable. A human-readable representation should comply the rule of human grammar and can be comprehended by human. Therefore, in this work, we use comprehensible natural language as a latent representation of the input source text in an auto-encoder architecture. This human-readable latent representation is shorter than the source text; in order to reconstruct the source text, it must reflect the core idea of the source text. Intuitively, the latent representation can be considered a summary of the text, so unpaired abstractive summarization is thereby achieved.

The idea that using human comprehensible language as a latent representation has been explored on text summarization, but only in a semi-supervised scenario. Previous work (Miao and Blunsom, 2016) uses a prior distribution from a pre-trained language model to constrain the generated sequence to natural language. However, to teach the compressor network to generate text summaries, the model is trained using labeled data. In contrast, in this work we need no labeled data to learn the representation.

As shown in Fig. 1, the proposed model is composed of three components: a generator, a discriminator, and a reconstructor. Together, the generator and reconstructor form a text auto-encoder. The generator acts as an encoder in generating the latent representation from the input text. Instead of using a vector as latent representation, however, the generator generates a word sequence much shorter than the input text. From the shorter text, the reconstructor reconstructs the original input of the generator. By minimizing the reconstruction loss, the generator learns to generate short text segments that contain the main information in the original input. We use the seq2seq model in modeling the generator and reconstructor because both have input and output sequences with different lengths.

However, it is very possible that the generator's output word sequence can only be processed and recognized by the reconstructor but is

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4187–4195
Brussels, Belgium, October 31 - November 4, 2018.

not readable by humans. Here, instead of regularizing the generator output with a pre-trained language model (Miao and Blunsom, 2016), we borrow from adversarial auto-encoders (Makhzani et al., 2015) and cycle GAN (Zhu et al., 2017) and introduce a third component – the discriminator – to regularize the generator's output word sequence. The discriminator and the generator form a generative adversarial network (GAN) (Goodfellow et al., 2014). The discriminator discriminates between the generator output and human-written sentences, and the generator produces output as similar as possible to human-written sentences to confuse the discriminator. With the GAN framework, the discriminator teaches the generator how to create human-like summary sentences as a latent representation. However, due to the non-differential property of discrete distributions, generating discrete distributions by GAN is challenging. To tackle this problem, in this work, we proposed a new kind of method on language generation by GAN.

By achieving unpaired abstractive text summarization, machine is able to unsupervisedly extract the core idea of the documents. This approach has many potential applications. For example, the output of the generator can be used for the downstream tasks like document classification and sentiment classification. In this study, we evaluate the results on an abstractive text summarization task. The output word sequence of the generator is regarded as the summaries of the input text. The model is learned from a set of documents without summaries. As most documents are not paired with summaries, for example the movie reviews or lecture recordings, this technique makes it possible to learn summarizer to generate summaries for these documents. The results show that the generator generates summaries with reasonable quality on both English and Chinese corpora.

2 Related Work

Abstractive Text Summarization

Recent model architectures for abstractive text summarization basically use the sequence-to-sequence (Sutskever et al., 2014) framework in combination with various novel mechanisms. One popular mechanism is attention (Bahdanau et al., 2015), which has been shown helpful for summarization (Nallapati et al., 2016; Rush et al., 2015; Chopra et al., 2016). It is also possible to directly optimize evaluation metrics such as ROUGE (Lin, 2004) with reinforcement learning (Ranzato et al., 2016; Paulus et al., 2017; Bahdanau et al., 2016). The hybrid pointer-generator network (See et al., 2017) selects words from the original text with a pointer (Vinyals et al., 2015) or from the whole vocabulary with a trained weight. In order to eliminate repetition, a coverage vector (Tu et al., 2016) can be used to keep track of attended words, and coverage loss (See et al., 2017) can be used to encourage model focus on diverse words. While most papers focus on supervised learning with novel mechanisms, in this paper, we explore unsupervised training models.

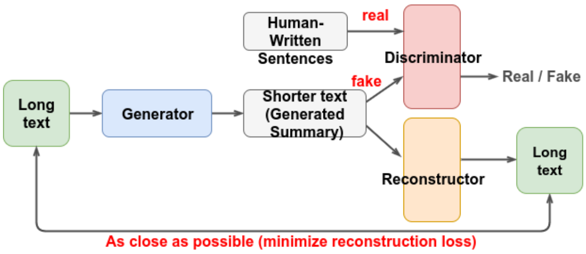

Figure 1: Proposed model. Given long text, the generator produces a shorter text as a summary. The generator is learned by minimizing the reconstruction loss together with the reconstructor and making discriminator regard its output as human-written text.

GAN for Language Generation

In this paper, we borrow the idea of GAN to make the generator output human-readable. The major challenge in applying GAN to sentence generation is the discrete nature of natural language. To generate a word sequence, the generator usually has non-differential parts such as *argmax* or other sample functions which cause the original GAN to fail.

In (Gulrajani et al., 2017), instead of feeding a discrete word sequence, the authors directly feed the generator output layer to the discriminator. This method works because they use the earth mover's distance on GAN as proposed in (Arjovsky et al., 2017), which is able to evaluate the distance between a discrete and a continuous distribution. SeqGAN (Yu et al., 2017) tackles the sequence generation problem with reinforcement learning. Here, we refer to this approach as adversarial REINFORCE. However, the discriminator only measures the quality of whole sequence, and thus the rewards are extremely sparse and the rewards assigned to all the generation steps are all the same. MC search (Yu et al., 2017) is proposed to evaluate the approximate reward at each time step, but this method suffers from high time complexity. Following this idea, (Li et al., 2017) proposes partial evaluation approach to evaluate the expected reward at each time step. In this paper, we propose the self-critical adversarial REINFORCE algorithm as another way to evaluate the expected reward at each time step. The performance between original WGAN and proposed adversarial REINFORCE is compared in experiment.

3 Proposed Method

The overview of the proposed model is shown in Fig. 2. The model is composed of three components: generator G, discriminator D, and reconstructor R. Both G and R are seq2seq hybrid pointer-generator networks (See et al., 2017) which can decide to copy words from encoder input text via pointing or generate from vocabulary. They both take a word sequence as input and output a sequence of word distributions. Discriminator D, on the other hand, takes a sequence as input and outputs a scalar. The model is learned from a set of documents x and human-written sentences y^{real}.

To train the model, a training document $x = \{x_1, x_2, ..., x_t, ..., x_T\}$, where x_t represents a word, is fed to G, which outputs a sequence of word distributions $G(x) = \{y_1, y_2, ..., y_n, ..., y_N\}$, where y_n is a distribution over all words in the lexicon. Then we randomly sample a word y_n^s from each distribution y_n, and a word sequence $y^s = \{y_1^s, y_2^s, ..., y_N^s\}$ is obtained according to $G(x)$. We feed the sampled word sequence y^s to reconstructor R, which outputs another sequence of word distributions $\hat{x}$. The reconstructor R reconstructs the original text x from y^s. That is, we seek an output of reconstructor $\hat{x}$ that is as close to the original text x as possible; hence the loss for training the reconstructor, R_{loss}, is defined as

$$R_{loss} = \sum_{k=1}^{K} l_s(x, \hat{x}), \tag{1}$$

where the reconstruction loss $l_s(x, \hat{x})$ is the cross-entropy loss computed between the reconstructor output sequence $\hat{x}$ and the source text x, or the negative conditional log-likelihood of source text x given word sequence y^s sampled from $G(x)$. The reconstructor output sequence $\hat{x}$ is teacher-forced by source text x. The subscript $_s$ in $l_s(x, \hat{x})$ indicates that $\hat{x}$ is reconstructed from y^s. K is the number of training documents, and (1) is the summation of the cross-entropy loss over all the training documents x.

In the proposed model, the generator G and reconstructor R form an auto-encoder. However, the reconstructor R does not directly take the generator output distribution $G(x)$ as input [1]. Instead, the reconstructor takes a sampled discrete sequence y^s as input. Due to the non-differentiable property of discrete sequences, we apply the REINFORCE algorithm, which is described in Section 4.

In addition to reconstruction, we need the discriminator D to discriminate between the real sequence y^{real} and the generated sequence y^s to regularize the generated sequence satisfying the summary distribution. D learns to give y^{real} higher scores while giving y^s lower scores. The loss for training the discriminator D is denoted as D_{loss}; this is further described in Section 5.

G learns to minimize the reconstruction loss R_{loss}, while maximizing the loss of the discriminator D by generating a summary sequence y^s that cannot be differentiated by D from the real thing. The loss for the generator G_{loss} is

$$G_{loss} = \alpha R_{loss} - D'_{loss} \tag{2}$$

where D'_{loss} is highly related to D_{loss} – but not necessary the same[2] – and α is a hyper-parameter. After obtaining the optimal generator by minimizing (2), we use it to generate summaries.

Generator G and discriminator D together form a GAN. We use two different adversarial training methods to train D and G; as shown in Fig. 2, these two methods have their own discriminators 1 and 2. Discriminator 1 takes the generator output layer $G(x)$ as input, whereas discriminator 2 takes the sampled discrete word sequence y^s as input. The two methods are described respectively in Sections 5.1 and 5.2.

4 Minimizing Reconstruction Loss

Because discrete sequences are non-differentiable, we use the REINFORCE algorithm. The generator is seen as an agent whose reward given the source text x is $-l_s(x, \hat{x})$. Maximizing the reward is equivalent to minimizing the reconstruction loss R_{loss} in (1). However, the reconstruction

---

[1] We found that if the reconstructor R directly takes $G(x)$ as input, the generator G learns to put the information about the input text in the distribution of $G(x)$, making it difficult to sample meaningful sentences from $G(x)$.

[2] D'_{loss} has different formulations in different approaches. This will be clear in Sections 5.1 and 5.2.

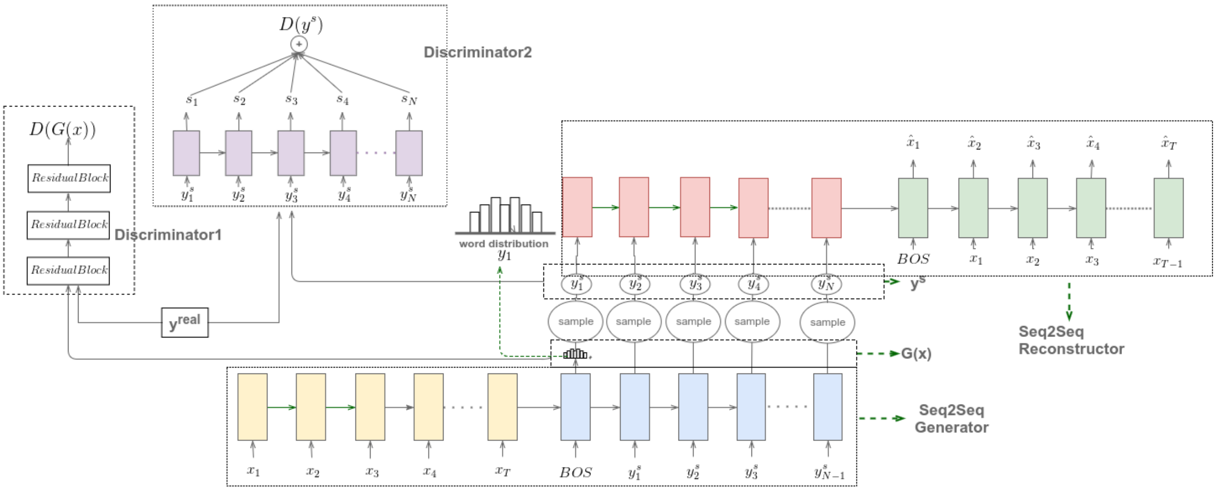

Figure 2: Architecture of proposed model. The generator network and reconstructor network are a seq2seq hybrid pointer-generator network, but for simplicity, we omit the pointer and the attention parts.

loss varies widely from sample to sample, and thus the rewards to the generator are not stable either. Hence we add a baseline to reduce their difference. We apply self-critical sequence training (Rennie et al., 2017); the modified reward $r^R(x, \hat{x})$ from reconstructor R with the baseline for the generator is

$$r^R(x, \hat{x}) = -l_s(x, \hat{x}) - (-l_a(x, \hat{x}) - b) \quad (3)$$

where $-l_a(x, \hat{x}) - b$ is the baseline. $l_a(x, \hat{x})$ is also the same cross-entropy reconstruction loss as $l_s(x, \hat{x})$, except that $\hat{x}$ is obtained from y^a instead of y^s. y^a is a word sequence $\{y_1^a, y_2^a, ..., y_n^a, ..., y_N^a\}$, where y_n^a is selected using the *argmax* function from the output distribution of generator y_n. As in the early training stage, the sequence y^s barely yields higher reward than sequence y^a, to encourage exploration we introduce the second baseline score b, which gradually decreases to zero. Then, the generator is updated using the REINFORCE algorithm with reward $r^R(x, \hat{x})$ to minimize R_{loss}.

5 GAN Training

With adversarial training, the generator learns to produce sentences as similar to the human-written sentences as possible. Here, we conduct experiments on two kinds of methods of language generation with GAN. In Section 5.1 we directly feed the generator output probability distributions to the discriminator and use a Wasserstein GAN (WGAN) with a gradient penalty. In Section 5.2, we explore adversarial REINFORCE, which feeds sampled discrete word sequences to the discriminator and evaluates the quality of the sequence from the discriminator for use as a reward signal to the generator.

5.1 Method 1: Wasserstein GAN

In the lower left of Fig. 2, the discriminator model of this method is shown as **discriminator1** D_1. D_1 is a deep CNN with residual blocks, which takes a sequence of word distributions as input and outputs a score. The discriminator loss D_{loss} is

$$D_{loss} = \frac{1}{K}\sum_{k=1}^{K} D_1(G(x^{(k)})) - \frac{1}{K}\sum_{k=1}^{K} D_1(y^{real(k)}) + \beta_1 \frac{1}{K}\sum_{k=1}^{K}(\Delta_{y^{i(k)}} D_1(y^{i(k)}) - 1)^2,$$

where K denotes the number of training examples in a batch, and k denotes the k-th example. The last term is the gradient penalty (Gulrajani et al., 2017). We interpolate the generator output layer $G(x)$ and the real sample y^{real}, and apply the gradient penalty to the interpolated sequence y^i. β_1 determines the gradient penalty scale. In Equation (2), for WGAN, the generator maximizes D'_{loss}:

$$D'_{loss} = \frac{1}{K}\sum_{k=1}^{K} D_1(G(x^{(k)})). \quad (4)$$

5.2 Method 2: Self-Critic Adversarial REINFORCE

In this section, we describe in detail the proposed adversarial REINFORCE method. The core idea is we use the LSTM discriminator to evaluate the current quality of the generated sequence

$\{y_1^s, y_2^s, ..., y_i^s\}$ at each time step i. The generator knows that compared to the last time step, as the generated sentence either improves or worsens, it can easily find the problematic generation step in a long sequence, and thus fix the problem easily.

5.2.1 Discriminator 2

As shown in Fig. 2, the **discriminator2** D_2 is a unidirectional LSTM network which takes a discrete word sequence as input. At time step i, given input word y_i^s it predicts the current score s_i based on the sequence $\{y_1, y_2, ..., y_i\}$. The score is viewed as the quality of the current sequence. An example of discriminator regularized by weight clipping(Arjovsky et al., 2017) is shown in Fig. 3.

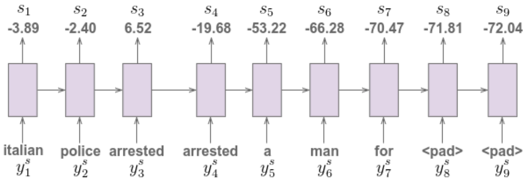

Figure 3: When the second *arrested* appears, as the sentence becomes ungrammatical, the discriminator determines that this example comes from the generator. Hence, after this time-step, it outputs low scores.

In order to compute the discriminator loss D_{loss}, we sum the scores $\{s_1, s_2, ..., s_N\}$ of the whole sequence y^s to yield

$$D_2(y^s) = \frac{1}{N}\sum_{n=1}^{N} s_n.$$

where N denotes the generated sequence length. Then, the loss of discriminator is

$$D_{loss} = \frac{1}{K}\sum_{k=1}^{K} D_2(y^{s(k)}) - \frac{1}{K}\sum_{k=1}^{K} D_2(y^{real(k)})$$
$$+\beta_2 \frac{1}{K}\sum_{k=1}^{K}(\Delta_{y^{i(k)}} D_2(y^{i(k)}) - 1)^2,$$

Similar to previous section, the last term is gradient penalty term. With the loss mentioned above, the discriminator attempts to quickly determine whether the current sequence is real or fake. The earlier the timestep discriminator determines whether the current sequence is real or fake, the lower its loss.

5.2.2 Self-Critical Generator

Since we feed a discrete sequence y^s to the discriminator, the gradient from the discriminator cannot directly back-propagate to the generator. Here, we use the policy gradient method. At timestep i, we use the $i-1$ timestep score s_{i-1} from the discriminator as its self-critical baseline. The reward r_i^D evaluates whether the quality of sequence in timestep i is better or worse than that in timestep $i-1$. The generator reward r_i^D from D_2 is

$$r_i^D = \begin{cases} s_i & \text{if i = 1} \\ s_i - s_{i-1} & \text{otherwise.} \end{cases}$$

However, some sentences may be judged as bad sentences at the previous timestep, but at later timesteps judged as good sentences, and vice versa. Hence we use the discounted expected reward d with discount factor γ to calculate the discounted reward d_i at time step i as

$$d_i = \sum_{j=i}^{N} \gamma^{j-i} r_j^D.$$

To maximize the expected discounted reward d_i, the loss of generator is:

$$G'_{loss} = -E_{y_i^s \sim p_G(y_i^s|y_1^s,...,y_{i-1}^s,x)}[d_i]. \qquad (5)$$

We use the likelihood ratio trick to approximate the gradient to minimize (5).

6 Experiment

Our model was evaluated on the English/Chinese Gigaword datasets and CNN/Daily Mail dataset. In Section 6.1,6.2 and 6.4, the experiments were conducted on English Gigaword, while the experiments were conducted on CNN/Daily Mail dataset and Chinese Gigaword dataset respectively in Sections 6.3 and 6.6. We used ROUGE(Lin, 2004) as our evaluation metric.[3] During testing, when using the generator to generate summaries, we used beam search with beam size=5, and we eliminated repetition. We provide the details of the implementation and corpus re-processing respectively in Appendix A and B.

Before jointly training the whole model, we pre-trained the three major components – generator, discriminator, and reconstructor – separately. First, we pre-trained the generator in an unsupervised manner so that the generator would be able to somewhat grasp the semantic meaning of the source text. The details of the pre-training are in Appendix C. We pre-trained the discriminator and reconstructor respectively with the pre-trained generator's output to ensure that these two critic networks provide good feedback to the generator.

---

[3] We used pyrouge package with option -m -n 2 -w 1.2 to compute ROUGE score for all experiments.

Table 1: Average F1 ROUGE scores on English Gigaword. R-1, R-2 and R-L refers to ROUGE 1, ROUGE 2 and ROUGE L respectively. Results marked with † are obtained from corresponding papers. In part (A), the model was trained supervisedly. In row (B-1), we select the article's first eight words as its summary. Part (C) are the results obtained without paired data. In part (D), we trained our model with few labeled data. In part (E), we pre-trained generator on CNN/Diary and used the summaries from CNN/Diary as real data for the discriminator.

6.1 English Gigaword

The English Gigaword is a sentence summarization dataset which contains the first sentence of each article and its corresponding headlines. The preprocessed corpus contains 3.8M training pairs and 400K validation pairs. We trained our model on part of or fully unparalleled data on 3.8M training set. To have fair comparison with previous works, the following experiments were evaluated on the 2K testing set same as (Rush et al., 2015; Miao and Blunsom, 2016). We used the sentences in article headlines as real data for discriminator[4]. As shown in the following experiments, the headlines can even come from another set of documents not related to the training documents.

The results on English Gigaword are shown in Table 1. WGAN and adversarial REINFORCE refer to the adversarial training methods mentioned in Sections 5.1 and 5.2 respectively. Results trained by full labeled data are in part (A). In row (A-1), We trained our generator by supervised training. Compared with the previous work (Zhou et al., 2017), we used simpler model and smaller vocabulary size. We did not try to achieve the state-of-the-art results because the focus of this work is unsupervised learning, and the proposed approach is independent to the summarization models used. In row (B-1), we simply took the first eight words in a document as its summary.

The results for the pre-trained generator with method mentioned in Appendix.C is shown in row (C-1). In part (C), we directly took the sentences in the summaries of Gigaword as the training data of discriminator. Compared with the pre-trained generator and the trivial baseline , the proposed approach (rows (C-2) and (C-3)) showed good improvement. In Fig. 4, we provide a real example. More examples can be found in the Appendix.D.

6.2 Semi-Supervised Learning

In semi-supervised training, generator was pre-trained with few available labeled data. During training, we conducted teacher-forcing with labeled data on generator after several updates without labeled data. With 10K, 500K and 1M la-

---

[4] Instead of using general sentences as real data for discriminator, we chose sentences from headlines because they have their own unique distribution.

beled data, the teacher-forcing was conducted every 25, 5 and 3 updates without paired data, respectively. In teacher-forcing, given source text as input, the generator was teacher-forced to predict the human-written summary of source text. Teacher-forcing can be regarded as regularization of unpaired training that prevents generator from producing unreasonable summaries of source text. We found that if we teacher-forced generator too frequently, generator would overfit on training data since we only used very few labeled data on semi-supervised training.

The performance of semi-supervised model in English Gigaword regarding available labeled data is shown in Table 1 part (D). We compared our results with (Miao and Blunsom, 2016) which was the previous state-of-the-art method on semi-supervised summarization task under the same amount of labeled data. With both 500K and 1M labeled data, our method performed better. Furthermore, with only 1M labeled data, using adversarial REINFORCE even outperformed supervised training in Table 1 (A-1) with the whole 3.8M labeled data.

6.3 CNN/Daily Mail dataset

The CNN/Daily Mail dataset is a long text summarization dataset which is composed of news articles paired with summaries. We evaluated our model on this dataset because it's a popular benchmark dataset, and we want to know whether the proposed model works on long input and long output sequences. The details of corpus preprocessing can be found in Appendix.B . In unpaired training, to prevent the model from directly matching the input articles to its corresponding summaries, we split the training pairs into two equal sets, one set only supplied articles and the other set only supplied summaries.

The results are shown in Table 2. For supervised approaches in part (A), although our seq2seq model was similar to (See et al., 2017), due to the smaller vocabulary size (we didn't tackle out-of-vocabulary words), simpler model architecture, shorter output length of generated summaries, there was a performance gap between our model and the scores reported in (See et al., 2017). Compared to the lead-3 baseline in part (B) which took the first three sentences of articles as summaries, the seq2seq models fell behind. That was because news writers often put the most important information in the first few sentences, and thus even the best abstractive summarization model only slightly beat the lead-3 baseline on ROUGE scores. However, during pre-training or training we didn't make assumption that the most important sentences are in first few sentences.

We observed that our unpaired model yielded decent ROUGE-1 score, but it yielded lower ROUGE-2 and ROUGE-L score. That was probably because the length of our generated sequence was shorter than ground truth, and our vocabulary size was small. Another reason was that the generator was good at selecting the most important words from the articles, but sometimes failed to combine them into reasonable sentences because it's still difficult for GAN to generate long sequence. In addition, since the reconstructor only evaluated the reconstruction loss of whole sequence, as the generated sequence became long, the reconstruction reward for generator became extremely sparse. However, compared to pre-trained generator (rows (C-2), (C-3) v.s. (C-1)), our model still enhanced the ROUGE score. An real example of generated summary can be found at Appendix.D Fig.11 .

6.4 Transfer Learning

The experiments conducted up to this point required headlines unpaired to the documents but in the same domain to train discriminator. In this subsection, we generated the summaries from English Gigaword (target domain), but the summaries for discriminator were from CNN/Daily Mail dataset (source domain).

The results of transfer learning are shown in Table. 1 part (E). Table 1 (E-1) is the result of pre-

trained generator and the poor pre-training result indicates that the data distributions of two datasets are quite different. We find that using sentences from another dataset yields lower ROUGE scores on the target testing set (parts (E) v.s. (C)) due to the mismatch word distributions between the summaries of the source and target domains. However, the discriminator still regularizes the generated word sequence. After unpaired training, the model enhanced the ROUGE scores of the pre-trained model (rows (E-2), (E-3) v.s. (E-1)) and it also surpassed the trivial baselines in part (B).

6.5 GAN Training

In this section, we discuss the performance of two GAN training methods. As shown in the Table 1, in English Gigaword, our proposed adversarial REINFORCE method performed better than WGAN. However, in Table 2, our proposed method slightly outperformed by WGAN. In addition, we find that when training with WGAN, convergence is faster. Because WGAN directly evaluates the distance between the continuous distribution from generator and the discrete distribution from real data, the distribution was sharpened at an early stage in training. This caused generator to converge to a relatively poor place. On the other hand, when training with REINFORCE, generator keeps seeking the network parameters that can better fool discriminator. We believe that training GAN on language generation with this method is worth exploring.

6.6 Chinese Gigaword

The Chinese Gigaword is a long text summarization dataset composed of paired headlines and news. Unlike the input news in English Gigaword, the news in Chinese Gigaword consists of several sentences. The results are shown in Table 3. Row (A) lists the results using 1.1M document-summary pairs to directly train the generator without the reconstructor and discriminator: this is the upper bound of the proposed approach. In row (B), we simply took the first fifteen words in a document as its summary. The number of words was chosen to optimize the evaluation metrics. Part (C) are the results obtained in the scenario without paired data. The discriminator took the summaries in the training set as real data. We show the results of the pre-trained generator in row (C-1); rows (C-2) and (C-3) are the results for the two GAN training methods respectively. We find that despite the performance gap between the unpaired and supervised methods (rows (C-2), (C-3) v.s. (A)), the proposed method yielded much better performance than the trivial baselines (rows (C-2), (C-3) v.s. (B)).

7 Conclusion and Future Work

Using GAN, we propose a model that encodes text as a human-readable summary, learned without document-summary pairs. In future work, we hope to use extra discriminators to control the style and sentiment of the generated summaries.

Abstract

We address jointly two important tasks for Question Answering in community forums: given a new question, (*i*) *find related existing questions*, and (*ii*) *find relevant answers to this new question*. We further use an auxiliary task to complement the previous two, i.e., (*iii*) *find good answers with respect to the thread question in a question-comment thread*. We use deep neural networks (DNNs) to learn meaningful task-specific embeddings, which we then incorporate into a conditional random field (CRF) model for the multitask setting, performing joint learning over a complex graph structure. While DNNs alone achieve competitive results when trained to produce the embeddings, the CRF, which makes use of the embeddings and the dependencies between the tasks, improves the results significantly and consistently across a variety of evaluation metrics, thus showing the complementarity of DNNs and structured learning.

1 Introduction and Motivation

Question answering web forums such as StackOverflow, Quora, and Yahoo! Answers usually organize their content in topically-defined forums containing multiple *question–comment threads*, where a question posed by a user is often followed by a possibly very long list of comments by other users, supposedly intended to answer the question. Many forums are not moderated, which often results in noisy and redundant content.

Within community Question Answering (cQA) forums, two subtasks are of special relevance when a user poses a new question to the website (Hoogeveen et al., 2018; Lai et al., 2018): (*i*) finding similar questions (*question-question relatedness*), and (*ii*) finding relevant answers to the new question, if they already exist (*answer selection*).

Both subtasks have been the focus of recent research as they result in end-user applications. The former is interesting for a user who wants to explore the space of similar questions in the forum and to decide whether to post a new question. It can also be relevant for the forum owners as it can help detect redundancy, eliminate question duplicates, and improve the overall forum structure. Subtask (*ii*) on the other hand is useful for a user who just wants a quick answer to a specific question, without the need of digging through the long answer threads and winnowing good from bad comments or without having to post a question and then wait for an answer.

Obviously, the two subtasks are interrelated as the information needed to answer a new question is usually found in the threads of highly related questions. Here, we focus on jointly solving the two subtasks with the help of yet another related subtask, i.e., determining whether a comment within a question-comment thread is a good answer to the question heading that thread.

An example is shown in Figure 1. A new question q is posed for which several potentially related questions are identified in the forum (e.g., by using an information retrieval system); q_i in the example is one of these existing questions. Each retrieved question comes with an associated thread of comments; c^i_m represents one comment from the thread of question q_i. Here, c^i_m is a *good* answer for q_i, q_i is indeed a question *related* to q, and consequently c^i_m is a *relevant* answer for the new question q. This is the setting of SemEval-2016 Task 3, and we use its benchmark datasets.

Our approach has two steps. First, a deep neural network (DNN) in the form of a feed-forward neural network is trained to solve each of the three subtasks separately, and the subtask-specific hidden layer activations are taken as embedded feature representations to be used in the second step.

q: **"How can I extend a family visit visa?"**

q_i: "Dear All; I wonder if anyone knows the procedure how I can extend the family visit visa for my wife beyond 6 months. I already extended it for 5 months and is 6 months running. I would like to get it extended for couple of months more.Any suggestion is highly appreciable.Thanks"

c_m^i: "You can get just another month's extension before she completes 6 months by presenting to immigration office a confirmed booking of her return ticket which must not exceed 7 months."

Figure 1: Example of the three pieces of information in the cQA problems addressed in this paper.

Then, a conditional random field (CRF) model uses these embeddings and performs joint learning with global inference to exploit the dependencies between the subtasks.

A key strength of DNNs is their ability to learn nonlinear interactions between underlying features through specifically-designed hidden layers, and also to learn the features (e.g., vectors for words and documents) automatically. This capability has led to gains in many unstructured output problems. DNNs are also powerful for structured output problems. Previous work has mostly relied on recurrent or recursive architectures to propagate information through hidden layers, but has been disregarding the modeling strength of structured conditional models, which use global inference to model consistency in the output structure (i.e., the class labels of all nodes in a graph). In this work, we explore the idea that combining simple DNNs with structured conditional models can be an effective and efficient approach for cQA subtasks that offers the best of both worlds.

Our experimental results show that: (*i*) DNNs already perform very well on the question-question similarity and answer selection subtasks; (*ii*) strong dependencies exist between the subtasks under study, especially answer-goodness and question-question-relatedness influence answer-selection significantly; (*iii*) the CRFs exploit the dependencies between subtasks, providing sizeably better results that are on par or above the state of the art. In summary, we demonstrate the effectiveness of this marriage of DNNs and structured conditional models for cQA subtasks, where a feed-forward DNN is first used to build vectors for each individual subtask, which are then "reconciled" in a multitask CRF.

2 Related Work

Various neural models have been applied to cQA tasks such as *question-question similarity* (dos Santos et al., 2015; Lei et al., 2016; Wang et al., 2018) and *answer selection* (Wang and Nyberg, 2015; Qiu and Huang, 2015; Tan et al., 2015; Chen and Bunescu, 2017; Wu et al., 2018). Most of this work used advanced neural network architectures based on convolutional neural networks (CNN), long short-term memory (LSTM) units, attention mechanism, etc. For instance, dos Santos et al. (2015) combined CNN and bag of words for comparing questions. Tan et al. (2015) adopted an attention mechanism over bidirectional LSTMs to generate better answer representations, and Lei et al. (2016) combined recurrent and CNN models for question representation. In contrast, here we use a simple DNN model, i.e., a feed-forward neural network, which we only use to generate task-specific embeddings, and we defer the joint learning with global inference to the structured model.

From the perspective of modeling cQA subtasks as structured learning problems, there is a lot of research trying to exploit the correlations between the comments in a question–comment thread. This has been done from a feature engineering perspective, by modeling a comment in the context of the entire thread (Barrón-Cedeño et al., 2015), but more interestingly by considering a thread as a structured object, where comments are to be classified as *good* or *bad* answers collectively. For example, Zhou et al. (2015) treated the answer selection task as a sequence labeling problem and used recurrent convolutional neural networks and LSTMs. Joty et al. (2015) modeled the relations between pairs of comments at any distance in the thread, and combined the predictions of local classifiers using graph-cut and Integer Linear Programming. In a follow up work, Joty et al. (2016) also modeled the relations between all pairs of comments in a thread, but using a fully-connected pairwise CRF model, which is a joint model that integrates inference within the learning process using global normalization. Unlike these models, we use DNNs to induce task-specific embeddings, and, more importantly, we perform multitask learning of three different cQA subtasks, thus enriching the relational structure of the graphical model.

We solve the three cQA subtasks jointly, in a multitask learning framework. We do this using the datasets from the SemEval-2016 Task 3 on *Community Question Answering* (Nakov et al., 2016b), which are annotated for the three subtasks, and we compare against the systems that participated in that competition. In fact, most of these systems did not try to exploit the interaction between the subtasks or did so only as a pipeline. For example, the top two systems, SUPER TEAM (Mihaylova et al., 2016) and KELP (Filice et al., 2016), stacked the predicted labels from two subtasks in order to solve the main answer selection subtask using SVMs. In contrast, our approach is neural, it is based on joint learning and task-specific embeddings, and it is also lighter in terms of features.

In work following the competition, Nakov et al. (2016a) used a triangulation approach to answer ranking in cQA, modeling the three types of similarities occurring in the triangle formed by the original question, the related question, and an answer to the related comment. However, theirs is a pairwise ranking model, while we have a joint model. Moreover, they focus on one task only, while we use multitask learning. Bonadiman et al. (2017) proposed a multitask neural architecture where the three tasks are trained together with the same representation. However, they do not model comment-comment interactions in the same question-comment thread nor do they train task-specific embeddings, as we do.

The general idea of combining DNNs and structured models has been explored recently for other NLP tasks. Collobert et al. (2011) used Viterbi inference to train their DNN models to capture dependencies between word-level tags for a number of sequence labeling tasks: part-of-speech tagging, chunking, named entity recognition, and semantic role labeling. Huang et al. (2015) proposed an LSTM-CRF framework for such tasks. Ma and Hovy (2016) included a CNN in the framework to compute word representations from character-level embeddings. While these studies consider tasks related to constituents in a sentence, e.g., words and phrases, we focus on methods to represent comments and to model dependencies between comment-level tags. We also experiment with arbitrary graph structures in our CRF model to model dependencies at different levels.

3 Learning Approach

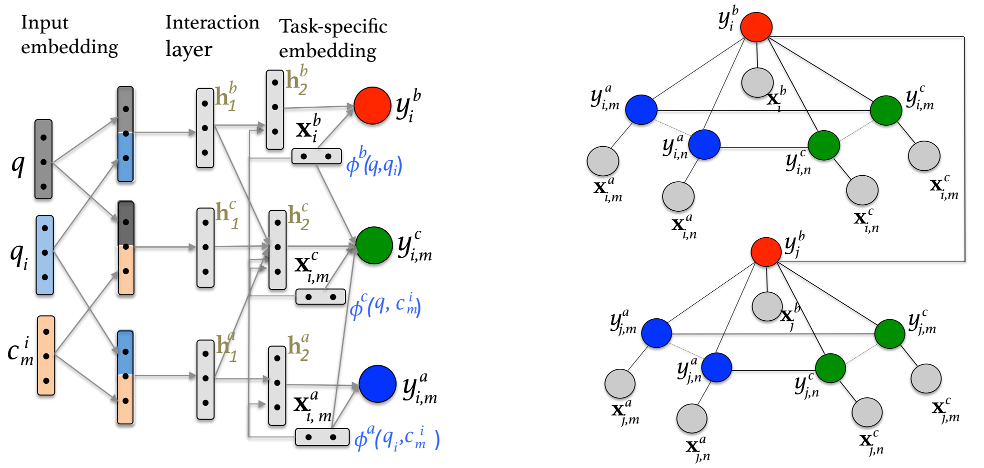
Let q be a newly-posed question, and c_m^i denote the m-th comment ($m \in \{1, 2, \ldots, M\}$) in the answer thread for the i-th potentially related question q_i ($i \in \{1, 2, \ldots, I\}$) retrieved from the forum. We can define three cQA subtasks: (*A*) classify each comment c_m^i in the thread for question q_i as *Good* vs. *Bad* with respect to q_i; (*B*) determine, for each retrieved question q_i, whether it is *Related* to the new question q in the sense that a good answer to q_i might also be a good answer to q; and finally, (*C*) classify each comment c_m^i in each answer thread as either *Relevant* or *Irrelevant* with respect to the new question q.

Let $y_{i,m}^a \in \{Good, Bad\}$, $y_i^b \in \{Related, Not\text{-}related\}$, and $y_{i,m}^c \in \{Relevant, Irrelevant\}$ denote the corresponding output labels for subtasks A, B, and C, respectively. As argued before, subtask C depends on the other two subtasks. Intuitively, if c_m^i is a good comment with respect to the existing question q_i, and q_i is related to the new question q (subtask A), then c_m^i is likely to be a relevant answer to q. Similarly, subtask B can benefit from subtask C: if comment c_m^i in the answer thread of q_i is relevant with respect to q, then q_i is likely to be related to q.

We propose to exploit these inherent correlations between the cQA subtasks as follows: (*i*) by modeling their interactions in the input representations, i.e., in the feature space of (q, q_i, c_m^i), and more importantly, (*ii*) by capturing the dependencies between the output variables $(y_{i,m}^a, y_i^b, y_{i,m}^c)$. Moreover, we cast each cQA subtask as a structured prediction problem in order to model the dependencies between output variables of the same type. Our intuition is that if two comments c_m^i and c_n^i in the same thread are similar, then they are likely to have the same labels for both subtask A and subtask C, i.e., $y_{i,m}^a \approx y_{i,n}^a$, and $y_{i,m}^c \approx y_{i,n}^c$. Similarly, if two pre-existing questions q_i and q_j are similar, they are also likely to have the same labels, i.e., $y_i^b \approx y_j^b$.

Our framework works in two steps. First, we use a DNN, specifically, a feed-forward NN, to learn task-specific embeddings for the three subtasks, i.e., output embeddings $\mathbf{x}_{i,m}^a$, $\mathbf{x}_i^b$ and $\mathbf{x}_{i,m}^c$ for subtasks A, B and C (Figure 2a). The DNN uses syntactic and semantic embeddings of the input elements, their interactions, and other similarity features between them and, as a by-product, learns the output embeddings for each subtask.

In the second step, a structured conditional model operates on subtask-specific embeddings from the DNNs and captures the dependencies between the



(a) Our feed-forward neural networks

(b) Our globally normalized joint conditional model

Figure 2: Graphical representation of our cQA framework. On the left (a), we have three feed-forward neural networks to learn task-specific embeddings for the three cQA subtasks. On the right (b), a global conditional random field (CRF) models intra- and inter-subtask dependencies.

subtasks, between existing questions, and between comments for an existing question (Figure 2b). Below, we describe the two steps in detail.

3.1 Neural Models for cQA Subtasks

Figure 2a depicts our complete neural framework for the three subtasks. The input is a tuple (q, q_i, c^i_m) consisting of a new question q, a retrieved question q_i, and a comment c^i_m from q_i's answer thread. We first map the input elements to fixed-length vectors $(\mathbf{z}_q, \mathbf{z}_{q_i}, \mathbf{z}_{c^i_m})$ using their syntactic and semantic *embeddings*. Depending on the requirements of the subtasks, the network then models the interactions between the inputs by passing their embeddings through non-linear hidden layers $\nu(\cdot)$. Additionally, the network also considers *pairwise* similarity features $\phi(\cdot)$ between two input elements that go directly to the output layer, and also through the last hidden layer. The pairwise features together with the activations at the final hidden layer constitute the task-specific embeddings for each subtask t: $\mathbf{x}^t_i = [\nu^t(\cdot), \phi^t(\cdot)]$. The final layer defines a Bernoulli distribution for each subtask $t \in \{a, b, c\}$:

$$p(y^t_i|q, q_i, c^i_m, \theta) = \mathrm{Ber}(y^t_i|\,\mathrm{sig}(\mathbf{w}^T_t \mathbf{x}^t_i)) \qquad (1)$$

where $\mathbf{x}^t_i$, $\mathbf{w}_t$, and y^t_i are the task-specific embedding, the output layer weights, and the prediction variable for subtask t, respectively, and $\mathrm{sig}(\cdot)$ refers to the sigmoid function.

We train the models by minimizing the cross-entropy between the predicted distribution and the gold labels. The main difference between the models is how they compute the task-specific embeddings $\mathbf{x}^t_i$ for subtask t.

Neural Model for Subtask A. The feed-forward network for subtask A is shown in the lower part of Figure 2a. To determine whether a comment c^i_m is *good* with respect to the thread question q_i, we model the interactions between c^i_m and q_i by merging their embeddings $\mathbf{z}_{c^i_m}$ and $\mathbf{z}_{q_i}$, and passing them through a hidden layer:

$$\mathbf{h}^a_1 = f(U^a[\mathbf{z}_{q_i}, \mathbf{z}_{c^i_m}]) \qquad (2)$$

where U^a is the weight matrix from the inputs to the first hidden units, f is a non-linear activation function. The activations are then fed to a final subtask-specific hidden layer, which combines these signals with the pairwise similarity features $\phi^a(q_i, c^i_m)$. Formally,

$$\mathbf{h}^a_2 = f(V^a[\mathbf{h}^a_1, \phi^a(q_i, c^i_m)]) \qquad (3)$$

where V^a is the weight matrix. The task-specific output embedding is formed by merging $\mathbf{h}^a_2$ and $\phi^a(q_i, c^i_m)$; $\mathbf{x}^a_{i,m} = [\mathbf{h}^a_2, \phi^a(q_i, c^i_m)]$.

Neural Model for Subtask B. To determine whether an existing question q_i is *related* to the new question q, we model the interactions between q and q_i using their embeddings and pairwise similarity features similarly to subtask A.

The upper part of Figure 2a shows the network. The transformation is defined as follows:

$$\mathbf{h}^b_1 = f(U^b[\mathbf{z}_q, \mathbf{z}_{q_i}]); \mathbf{h}^b_2 = f(V^b[\mathbf{h}^b_1, \phi^b(q, q_i)])$$

where U^b and V^b are the weight matrices in the first and second hidden layer. The task-specific embedding is formed by $\mathbf{x}_i^b = [\mathbf{h}_2^b, \phi^b(q, q_i)]$.

Neural Model for Subtask C. The network for subtask C is shown in the middle of Figure 2a. To decide if a comment c_m^i in the thread of q_i is *relevant* to q, we consider how related q_i is to q, and how useful c_m^i is to answer q_i. Again, we model the direct interactions between q and c_m^i using pairwise features $\phi^c(q, c_m^i)$ and a hidden layer transformation $\mathbf{h}_1^c = f(U^c[\mathbf{z}_q, \mathbf{z}_{c_m^i}])$, where U^c is a weight matrix. We then include a second hidden layer to combine the activations from different inputs and pairwise similarity features. Formally,

$$\mathbf{h}_2^c = f(V^c[\mathbf{h}_1^a, \mathbf{h}_1^b, \mathbf{h}_1^c, \phi^a(q_i, c_m^i), \phi^b(q, q_i), \phi^c(q, c_m^i)])$$

The final task-specific embedding for subtask C is formed as $\mathbf{x}_i^c = [\mathbf{h}_2^c, \phi^a(q_i, c_m^i), \phi^b(q, q_i), \phi^c(q, c_m^i)]$.

3.2 Joint Learning with Global Inference

One simple way to exploit the interdependencies between the subtask-specific embeddings ($\mathbf{x}_{i,m}^a$, $\mathbf{x}_i^b$, $\mathbf{x}_{i,m}^c$) is to precompute the predictions for some subtasks (A and B), and then to use the predictions as features for the other subtask (C). However, as shown later in Section 6, such a *pipeline* approach propagates errors from one subtask to the subsequent ones. A more robust way is to build a joint model for all subtasks.

We could use the full DNN network in Figure 2a to learn the classification functions for the three subtasks *jointly* as follows:

$$p(y_{i,m}^a, y_i^b, y_{i,m}^c|\theta) = p(y_{i,m}^a|\theta_a)p(y_i^b|\theta_b)p(y_{i,m}^c|\theta_c) \tag{4}$$

where $\theta = [\theta_a, \theta_b, \theta_c]$ are the model parameters.

However, this has two key limitations: (*i*) it assumes conditional independence between the subtasks given the parameters; (*ii*) the scores are normalized locally, which leads to the so-called *label bias* problem (Lafferty et al., 2001), i.e., the features for one subtask would have no influence on the other subtasks.

Thus, we model the dependencies between the output variables by learning (globally normalized) node and edge factor functions that jointly optimize a global performance criterion. In particular, we represent the cQA setting as a large undirected graph $G{=}(V, E){=}(V_a{\cup}V_b{\cup}V_c, E_{aa}{\cup}E_{bb}{\cup}E_{cc}{\cup}E_{ac}{\cup}E_{bc}{\cup}E_{ab})$. As shown in Figure 2b, the graph contains six subgraphs: $G_a{=}(V_a, E_{aa})$, $G_b{=}(V_b, E_{bb})$ and $G_c{=}(V_c, E_{cc})$ are associated with the three subtasks, while the bipartite subgraphs $G_{ac}{=}(V_a \cup V_c, E_{ac})$, $G_{bc}{=}(V_b \cup V_c, E_{bc})$ and $G_{ab}{=}(V_a \cup V_b, E_{ab})$ connect nodes across tasks.

We associate each node $u \in V_t$ with an input vector $\mathbf{x}_u$, representing the embedding for subtask t, and an output variable y_u, representing the class label for subtask t. Similarly, each edge $(u, v) \in E_{st}$ is associated with an input feature vector $\mu(\mathbf{x}_u, \mathbf{x}_v)$, derived from the node-level features, and an output variable $y_{uv} \in \{1, 2, \cdots, L\}$, representing the state transitions for the pair of nodes.[1] For notational simplicity, here we do not distinguish between comment and question nodes, rather we use u and v as general indices. We define the following joint conditional distribution:

$$p(\mathbf{y}|\theta, \mathbf{x}) = \frac{1}{Z(\theta, \mathbf{x})} \prod_{t \in \tau} \Big[\prod_{u \in V_t} \psi_n(y_u|\mathbf{x}, \mathbf{w}_n^t) \Big] \prod_{(s,t) \in \tau \times \tau} \Big[\prod_{(u,v) \in E_{st}} \psi_e(y_{uv}|\mathbf{x}, \mathbf{w}_e^{st}) \Big] \tag{5}$$

where $\tau = \{a, b, c\}$, $\psi_n(\cdot)$ and $\psi_e(\cdot)$ are node and edge *factors*, respectively, and $Z(\cdot)$ is a global normalization constant. We use log-linear factors:

$$\psi_n(y_u|\mathbf{x}, \mathbf{w}_n^t) = \exp(\sigma(y_u, \mathbf{x})^T \mathbf{w}_n^t) \tag{6}$$

$$\psi_e(y_{uv}|\mathbf{x}, \mathbf{w}_e^{st}) = \exp(\sigma(y_{uv}, \mathbf{x})^T \mathbf{w}_e^{st}) \tag{7}$$

where $\sigma(\cdot)$ is a feature vector derived from the inputs and the labels.

This model is essentially a pairwise conditional random field (Murphy, 2012). The global normalization allows CRFs to surmount the *label bias* problem, allowing them to take long-range interactions into account. The objective in Equation 5 is a convex function, and thus we can use gradient-based methods to find the global optimum. The gradients have the following form:

$$f'(\mathbf{w}_n^t) = \sum_{u \in V_t} \sigma(y_u, \mathbf{x}) - \mathbb{E}[\sigma(y_u, \mathbf{x})] \tag{8}$$

$$f'(\mathbf{w}_e^{st}) = \sum_{(u,v) \in E_{st}} \sigma(y_{uv}, \mathbf{x}) - \mathbb{E}[\sigma(y_{uv}, \mathbf{x})] \tag{9}$$

where $\mathbb{E}[\phi(\cdot)]$ is the expected feature vector.

Training and Inference. Traditionally, CRFs have been trained using offline methods like LBFGS (Murphy, 2012). Online training using

---

[1] To avoid visual clutter, the input features and the output variables for the edges are not shown in Figure 2b.

first-order methods such as stochastic gradient descent was proposed by Vishwanathan et al. (2006). Since our DNNs are trained with the RMSprop online adaptive algorithm (Tieleman and Hinton, 2012), in order to compare our two models, we use RMSprop to train our CRFs as well.

For our CRF models, we use Belief Propagation, or BP, (Pearl, 1988) for inference. BP converges to an exact solution for trees. However, exact inference is intractable for graphs with loops. Despite this, Pearl (1988) advocated for the use of BP in loopy graphs as an approximation. Even though BP only gives approximate solutions, it often works well in practice for loopy graphs (Murphy et al., 1999), outperforming other methods such as mean field (Weiss, 2001).

Variations of Graph Structures. A crucial advantage of our CRFs is that we can use arbitrary graph structures, which allows us to capture dependencies between different types of variables: (*i*) *intra-subtask*, for variables of the same subtask, e.g., y_i^b and y_j^b in Figure 2b, and (*ii*) *across-subtask*, for variables of different subtasks.

For intra-subtask, we explore *null* (i.e., no connection between nodes) and *fully-connected* relations. For subtasks A and C, the intra-subtask connections are restricted to the nodes inside a thread, e.g., we do not connect $y_{i,m}^c$ and $y_{j,m}^c$ in Figure 2b.

For across-subtask, we explored three types of connections depending on the subtasks involved: (*i*) *null* or no connection between subtasks, (*ii*) *1:1* connection for A-C, where the corresponding nodes of the two subtasks in a thread are connected, e.g., $y_{i,m}^a$ and $y_{i,m}^c$ in Figure 2b, and (*iii*) *M:1* connection to B, where we connect all the nodes of C or A to the thread-level B node. Each configuration of intra- and across-connections yields a different CRF model. Figure 2b shows one such model for two threads each containing two comments, where all subtasks have fully-connected intra-subtask links, 1:1 connection for A-C, and M:1 for C-B and A-B.

4 Features for the DNN Models

We have two types of features: (*i*) *input embeddings*, for q, q_i and c_m^i, and (*ii*) *pairwise features*, for (q, q_i), (q, c_m^i), and (q_i, c_m^i) — see Figure 2a.

4.1 Input Embeddings

We use three types of pre-trained vectors to represent a question (q or q_i) or a comment (c_m^i):

GOOGLE VECTORS. 300-dimensional embedding vectors, trained on 100 billion words from Google News (Mikolov et al., 2013). The embedding for a question (or comment) is the average of the word embeddings it is composed of.

SYNTAX. We parse the question (or comment) using the Stanford neural parser (Socher et al., 2013), and we use the final 25-dimensional vector produced internally as a by-product of parsing.

QL VECTORS. We use fine-tuned word embeddings pretrained on all the available in-domain Qatar Living data (Mihaylov and Nakov, 2016).

4.2 Pairwise Features

We extract pairwise features for each of (q, q_i), (q, c_m^i), and (q_i, c_m^i) pairs. These include:

COSINES. We compute cosines using the above vectors: $\cos(q, q_i)$, $\cos(q, c_m^i)$ and $\cos(q_i, c_m^i)$.

MT FEATURES. We use the following machine translation evaluation metrics: (1) BLEU (Papineni et al., 2002); (2) NIST (Doddington, 2002); (3) TER v0.7.25 (Snover et al., 2006); (4) METEOR v1.4 (Lavie and Denkowski, 2009); (5) Unigram PRECISION; (6) Unigram RECALL.

BLEU COMPONENTS. We further use various components involved in the computation of BLEU:[2] n-gram precisions, n-gram matches, total number of n-grams (n=1,2,3,4), lengths of the hypotheses and of the reference, length ratio between them, and BLEU's brevity penalty.

QUESTION-COMMENT RATIO. (1) question-to-comment count ratio in terms of sentences/tokens/nouns/verbs/adjectives/adverbs/pronouns; (2) question-to-comment count ratio of words that are not in WORD2VEC's Google News vocabulary.

4.3 Node Features

COMMENT FEATURES. These include number of (1) nouns/verbs/adjectives/adverbs/pronouns, (2) URLs/images/emails/phone numbers, (3) tokens/sentences, (4) positive/negative smileys, (5) single/double/triple exclamation/interrogation symbols, (6) interrogative sentences, (7) 'thank' mentions, (8) words that are not in WORD2VEC's Google News vocabulary. Also, (9) average number of tokens, and (10) word type-to-token ratio.

META FEATURES. (1) is the person answering the question the one who asked it; (2) reciprocal rank of comment c_m^i in the thread of q_i, i.e., $1/m$;

---

[2] BLEU FEATURES and BLEU COMPONENTS (Guzmán et al., 2016a,b) are ported from an MT evaluation framework (Guzmán et al., 2015; Guzmán et al., 2017) to cQA.

Table 2: Results for our DNN models on all cQA subtasks, compared to the top-2 systems from SemEval-2016 Task 3. Inter-subtask dependencies are explored using gold output labels.

(3) reciprocal rank of c_m^i in the list of comments for q, i.e., $1/[m+10\times(i-1)]$; and (4) reciprocal rank of question q_i in the list for q, i.e., $1/i$.

5 Data and Settings

We experiment with the data from SemEval-2016 Task 3 (Nakov et al., 2016b). Consistently with our notation from Section 3, it features three subtasks: subtask A (i.e., whether a comment c_m^i is a good answer to the question q_i in the thread), subtask B (i.e., whether the retrieved question q_i is related to the new question q), and subtask C (i.e., whether the comment c_m^i is a relevant answer for the new question q). Note that the two main subtasks we are interested in are B and C.

DNN Setting. We preprocess the data using min-max scaling. We use RMSprop[3] for learning, with parameters set to the values suggested by Tieleman and Hinton (2012). We use up to 100 epochs with patience of 25, rectified linear units (ReLU) as activation functions, l_2 regularization on weights, and dropout (Srivastava et al., 2014) of hidden units. See Table 1 for more detail.

CRF Setting. For the CRF model, we initialize the node-level weights from the output layer weights of the DNNs, and we set the edge-level weights to 0. Then, we train using RMSprop with loopy BP. We regularize the node parameters according to the best settings of the DNN: 0.001, 0.05, and 0.0001 for A, B, and C, respectively.

6 Results and Discussion

Below, we first present the evaluation results using DNN models (Section 6.1). Then, we discuss the performance of the joint models (Section 6.2).

6.1 Results for the DNN Models

Table 2 shows the results for our individual DNN models (rows in boldface) for subtasks A, B and C on the TEST set.

We report three ranking-based measures that are commonly accepted in the IR community: mean average precision (MAP), which was the official evaluation measure of SemEval-2016, average recall (AvgRec), and mean reciprocal rank (MRR).

For each subtask, we show two baselines and the results of the top-2 systems at SemEval. The first baseline is a random ordering of the questions/comments, assuming no knowledge about the subtask. The second baseline keeps the chronological order of the comments for subtask A, of the question ranking from the IR engine for subtask B, and both for subtask C.

We can see that the individual DNN models for subtasks B and C are very competitive, falling between the first and the second best at SemEval-2016. For subtask A, our model is weaker, but, as we will see below, it can help improve the results for subtasks B and C, which are our focus here.

Looking at the results for subtask C, we can see that sizeable gains are possible when using gold labels for subtasks A and B as features to DNN$_C$, e.g., adding gold A labels yields +6.90 MAP points.

Similarly, using gold labels for subtask B adds +2.05 MAP points absolute. Moreover, the gain is cumulative: using the two gold labels together

---

[3] Other adaptive algorithms such as ADAM (Kingma and Ba, 2014) or ADADELTA (Zeiler, 2012) were slightly worse.

yields +9.25 MAP points. The same behavior is observed for the other evaluation measures. Of course, as we use gold labels, this is an upper bound on performance, but it justifies our efforts towards a joint multitask learning model.

6.2 Results for the Joint Model

Below we discuss the evaluation results for the joint model. We focus on subtasks B and C, which are the main target of our study.

Results for Subtask C. Table 3 compares several variants of the CRF model for joint learning, which we described in Section 3.2 above.

Row 1 shows the results for our individual DNN_C model. The following rows 2–4 present a *pipeline* approach, where we first predict labels for subtasks A and B and then we add these predictions as features to DNN_C. This is prone to error propagation, and improvements are moderate and inconsistent across the evaluation measures.

The remaining rows correspond to variants of our CRF model with different graph structures. Overall, the improvements over DNN_C are more sizeable than for the pipeline approach (with one single exception out of 24 cases); they are also more consistent across the evaluation measures, and the improvements in MAP over the baseline range from +0.96 to +1.76 points absolute.

Rows 5–8 show the impact of adding connections to subtasks A and B when solving subtask C (see Figure 2b). Interestingly, we observe the same pattern as with the gold labels: the A-C and B-C connections help individually and in combination, with A-C being more helpful. Yet, further adding A-B does not improve the results (row 8).

Note that the locally normalized joint model in Eq. 4 yields much lower results than the globally normalized CRF_{all} (row 8): 54.32, 59.87, and 61.76 in MAP, AvgRec and MRR (figures not included in the table for brevity). This evinces the problems with the conditional independence assumption and the local normalization in the model.

Finally, rows 9–12 explore variants of the best system from the previous set (row 7), which has connections between subtasks only. Rows 9–12 show the results when using subgraphs for A, B and C that are fully connected (i.e., for all pairs).
We can see that none of these variants yields improvements over the model from row 7, i.e., the fine-grained relations between comments in the threads and between the different related questions do not seem to help solve subtask C in the joint model. Note that our scores from row 7 are better than the best results achieved by a system at SemEval-2016 Task 3 subtask C: 56.00 vs. 55.41 on MAP, and 63.25 vs. 61.48 on MRR.

Results for Subtask B. Next, we present in Table 4 similar experiments, but this time with subtask B as the target, and we show some more measures (accuracy, precision, recall, and F_1).

Given the insights from Table 2 (where we used gold labels), we did not expect to see much improvements for subtask B. Indeed, as rows 2–4 show, using the pipeline approach, the IR measures are basically unaltered. However, classification accuracy improves by almost one point absolute, recall is also higher (trading for lower precision), and F_1 is better by a sizeable margin.

Coming to the joint models (rows 6–9), we can see that the IR measures improve consistently over the pipeline approach, even though not by much. The effect on accuracy-P-R-F_1 is the same as observed with the pipeline approach but with larger differences.[4] In particular, accuracy improves by more than two points absolute, and recall increases, which boosts F_1 to almost 60.

Row 5 is a special case where we only consider subtask B, but we do the learning and the inference over the set of ten related questions, exploiting their relations. This yields a slight increase in all measures; more importantly, it is crucial for obtaining better results with the joint models.

Rows 6–9 show results for various variants of the A-C and B-C architecture with fully connected B nodes, playing with the fine-grained connection of the A and C nodes. The best results are in this block, with increases over DNN_B in MAP (+0.61), AvgRec (+0.69) and MRR (+1.05), and especially in accuracy (+2.18) and F_1 (+11.25 points). This is remarkable given the low expectation we had about improving subtask B.

Note that the best architecture for subtask C from Table 3 (A-C and B-C with no fully connected B layer) does not yield good results for subtask B.
We speculate that subtask B is overlooked by the architecture, which has many more connections and parameters on the nodes for subtasks A and C (ten comments are to be classified for both subtask

---

[4] Note that we have a classification approach, which favors accuracy-P-R-F_1; if we want to improve the ranking measures, we should optimize for them directly.

Table 4: Performance of the *pipeline* and of the joint models on subtask B (best results in boldface).

A and C, while only one decision is to be made for the related question B).

Finally, note that our best results for subtask B are also slightly better than those for the best system at SemEval-2016 Task 3, especially on MRR.

7 Conclusion

We have presented a framework for multitask learning of two community Question Answering problems: question-question relatedness and answer selection. We further used a third, auxiliary one, i.e., finding the good comments in a question-comment thread. We proposed a two-step framework based on deep neural networks and structured conditional models, with a feed-forward neural network to learn task-specific embeddings, which are then used in a pairwise CRF as part of a multitask model for all three subtasks.

The DNN model has its strength in generating compact embedded representations for the subtasks by modeling interactions between different input elements.

On the other hand, the CRF is able to perform global inference over arbitrary graph structures accounting for the dependencies between subtasks to provide globally good solutions. The experimental results have proven the suitability of combining the two approaches. The DNNs alone already yielded competitive results, but the CRF was able to exploit the task-specific embeddings and the dependencies between subtasks to improve the results consistently across a variety of evaluation metrics, yielding state-of-the-art results.

In future work, we plan to model text complexity (Mihaylova et al., 2016), veracity (Mihaylova et al., 2018), speech act (Joty and Hoque, 2016), user profile (Mihaylov et al., 2015), trollness (Mihaylov et al., 2018), and goodness polarity (Balchev et al., 2016; Mihaylov et al., 2017). From a modeling perspective, we want to strongly couple CRF and DNN, so that the global errors are backpropagated from the CRF down to the DNN layers. It would be also interesting to extend the framework to a cross-domain (Shah et al., 2018) or a cross-language setting (Da San Martino et al., 2017; Joty et al., 2017). Trying an ensemble of neural networks with different initial seeds is another possible research direction.

Abstract

A challenge in creating a dataset for machine reading comprehension (MRC) is to collect questions that require a sophisticated understanding of language to answer beyond using superficial cues. In this work, we investigate what makes questions easier across recent 12 MRC datasets with three question styles (answer extraction, description, and multiple choice). We propose to employ simple heuristics to split each dataset into *easy* and *hard* subsets and examine the performance of two baseline models for each of the subsets. We then manually annotate questions sampled from each subset with both validity and requisite reasoning skills to investigate which skills explain the difference between easy and hard questions. From this study, we observed that (i) the baseline performances for the hard subsets remarkably degrade compared to those of entire datasets, (ii) hard questions require knowledge inference and multiple-sentence reasoning in comparison with easy questions, and (iii) multiple-choice questions tend to require a broader range of reasoning skills than answer extraction and description questions. These results suggest that one might overestimate recent advances in MRC.

Article: Spectre (2015 film) on Wikipedia
Context: (s_1) In *November 2014*, **Sony Pictures** Entertainment was targeted by **hackers** who released details of confidential **e-mails** between **Sony** executives regarding [...]. (s_2) Included within these were several memos relating to the production [...]. (s_3) Eon Productions later issued a statement [...].
Question: When $_{(k=1)}$ did hackers get into the Sony Pictures e-mail system?
Prediction for the full question: *November 2014*
Prediction for the $k = 1$ question: *November 2014*
Uni-gram overlaps between s_i and the question:
s_1: 5, s_2: 0, s_3: 0

Figure 1: Example from the SQuAD dataset (Rajpurkar et al., 2016). The baseline system can answer the token-limited question and, even if there are other candidate answers, it can easily attend to the answer-contained sentence (s_1) by watching word overlaps.

1 Introduction

Evaluating natural language understanding (NLU) systems is a long-established problem in AI (Levesque, 2014). One approach to doing so is the machine reading comprehension (MRC) task, in which a system answers questions about given texts (Hirschman et al., 1999). Although recent studies have made advances (Yu et al., 2018), it is still unclear to what precise extent questions require understanding of texts (Jia and Liang, 2017).

In this study, we examine MRC datasets and discuss what is needed to create datasets suitable for the detailed testing of NLU. Our motivation originates from studies that demonstrated unintended biases in the sourcing of other NLU tasks, in which questions contain simple patterns and systems can recognize these patterns to answer them (Gururangan et al., 2018; Mostafazadeh et al., 2017).

We conjecture that a situation similar to this occurs in MRC datasets. Consider the question shown in Figure 1, for example. Although the question, starting with *when*, requires an answer that is expressed as a moment in time, there is only one such expression (i.e., *November 2014*) in the given text (we refer to the text as the *context*). In other words, the question has only a single candidate answer. The system can solve it merely by *recognizing the entity type* required by *when*. In addition to this, even if another expression of time appears in other sentences, only one sentence (i.e., s_1) appears to be related to the question; thus, the system can easily determine the correct answer by *attention*, that is, by matching the words appearing both in the context and the ques-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4208–4219
Brussels, Belgium, October 31 - November 4, 2018.

tion. Therefore, this kind of question does not require a complex understanding of language—e.g., multiple-sentence reasoning, which is known as a more challenging task (Richardson et al., 2013).

In Section 3, we define two heuristics, namely *entity-type recognition* and *attention*. We specifically analyze the differences in the performance of baseline systems for the following two configurations: (i) questions answerable or unanswerable with the first k tokens; and (ii) questions whose correct answer appears or does not appear in the context sentence that is most similar to the question (henceforth referred to as *the most similar sentence*). Although similar heuristics are proposed by Weissenborn et al. (2017), ours are utilized for question filtering, rather than system development; Using these simple heuristics, we split each dataset into *easy* and *hard* subsets for further investigation of the baseline performance.

After conducting the experiments, we analyze the following two points in Section 4. First, we consider which questions are valid for testing, i.e., reasonably solvable. Second, we consider what reasoning skills are required and whether this exposes any differences among the subsets. To investigate these two concerns, we manually annotate sample questions from each subset in terms of validity and required reasoning skills, such as word matching, knowledge inference, and multiple sentence reasoning.

We examine 12 recently proposed MRC datasets (Table 1), which include answer extraction, description, and multiple-choice styles. We also observe differences based on these styles. For our baselines, we use two neural-based systems, namely, the Bidirectional Attention Flow (Seo et al., 2017) and the Gated-Attention Reader (Dhingra et al., 2017).

In Section 5, we describe the advantages and disadvantages of different question styles with regard to evaluating NLU systems. We also interpret our heuristics for constructing realistic MRC datasets.

Our contributions are as follows:

- This study is the first large-scale investigation across recent 12 MRC datasets with three question styles.
- We propose to employ simple heuristics to split each dataset into *easy* and *hard* subsets and examine the performance of two baseline models for each of the subsets.
- We manually annotate questions sampled from each subset with both validity and requisite reasoning skills to investigate which skills explain the difference between easy and hard questions.

Answer extraction (select a context span)
1. SQuAD (v1.1) (Rajpurkar et al., 2016)
2. AddSent (Jia and Liang, 2017)
3. NewsQA (Trischler et al., 2017)
4. TriviaQA (Wikipedia set) (Joshi et al., 2017)
5. QAngaroo (WikiHop) (Welbl et al., 2018)

6. MS MARCO (v2) (Nguyen et al., 2016)
7. NarrativeQA (summary) (Kočiský et al., 2018)
Multiple choice (choose from multiple options)
8. MCTest (160 + 500) (Richardson et al., 2013)
9. RACE (middle + high) (Lai et al., 2017)
10. MCScript (Ostermann et al., 2018)
11. ARC Easy (ARC-E) (Clark et al., 2018)
12. ARC Challenge (ARC-C) (Clark et al., 2018)

Table 1: Examined datasets.

We observed the following:

- The baseline performances for the hard subsets remarkably degrade compared to those of entire datasets.
- Our annotation study shows that hard questions require knowledge inference and multiple-sentence reasoning in comparison with easy questions.
- Compared to questions with answer extraction and description styles, multiple-choice questions tend to require a broader range of reasoning skills while exhibiting answerability, multiple answer candidates, and unambiguity.

These findings suggest that one might overestimate recent advances in MRC systems. They also emphasize the importance of considering simple answer-seeking heuristics when sourcing questions, in that a dataset could be easily biased unless such heuristics are employed.[1]

2 Examined Datasets and Baselines

2.1 Datasets

We analyzed 12 MRC datasets with three question styles: answer extraction, description, and

---

[1] All scripts used in this study, along with the subsets of the datasets and the annotation results, are available at `https://github.com/Alab-NII/mrc-heuristics`.

multiple choice (Table 1). Our aim was to select datasets varying in terms of corpus genre, context length, and question sourcing methods.[2] Other datasets that are not covered in our study, but can be analyzed using the same method, include: QA4MRE (Sutcliffe et al., 2013), CNN/Daily Mail (Hermann et al., 2015), Children's Book Test (Hill et al., 2016), bAbI (Weston et al., 2015), WikiReading (Hewlett et al., 2016), LAMBADA (Paperno et al., 2016), Who-did-What (Onishi et al., 2016), ProPara (Dalvi et al., 2018), MultiRC (Khashabi et al., 2018), CliCR (Suster and Daelemans, 2018), SQuAD (v2.0) (Rajpurkar et al., 2018), and DuoRC (Saha et al., 2018).

2.2 Baseline Systems

We employed the following two widely used baselines.

Bidirectional Attention Flow (BiDAF) (Seo et al., 2017) was used for the answer extraction and description datasets. BiDAF models bi-directional attention between the context and question. It achieved state-of-the-art performance on the SQuAD dataset.

Gated-Attentive Reader (GA) (Dhingra et al., 2017) was used for the multiple-choice datasets. GA has a multi-hop architecture with an attention mechanism. It achieved state-of-the-art-performance on the CNN/Daily Mail and Who-did-What datasets.

Why we used different baseline systems: The multiple-choice style can be transformed to answer extraction, as mentioned in Clark et al. (2018). However, in some datasets, many questions have no textual overlap to determine the correct answer span in the context. Therefore, in order to avoid underestimating the baseline performance of those datasets, we used the GA system which is applicable to multiple choice questions.

We scored the performance using exact match (EM)/F1 (Rajpurkar et al., 2016), Rouge-L (Lin, 2004), and accuracy for the answer extraction, description, and multiple-choice datasets, respectively (henceforth, we refer to these collectively as the *score*, for simplicity). For the description datasets, we determined in advance the answer span of the context that gives the highest Rouge-L score to the human-generated gold answer. We computed the Rouge-L score between the predicted span and the gold answer.[3]

Reproduction of the baseline performance: We used the same architecture as the official baseline systems unless specified otherwise. All systems were trained on the training set and tested on the development/test set of each dataset. We also used different hyperparameters for each dataset according to characteristics such as context length (see Appendix A for details). We show the baseline performance of both the official results and those from our implementations in Tables 2 and 3. Our implementations outperformed or showed comparable performance to the official baseline on most datasets. However, in TriviaQA, MCTest, RACE, and ARC-E, our baseline performance did not reach that of the official baseline, due to differences in architecture or the absence of reported hyperparameters in the literature.

3 Two Filtering Heuristics

The first goal of this paper is to determine whether there are unintended biases of the kind exposed in Figure 1 in MRC datasets. We examined the influence of the two filtering heuristics: (i) entity type recognition (Section 3.1) and (ii) attention (Section 3.2). We then investigated the performance of the baseline systems on the questions filtered by the defined heuristics (Section 3.3).

3.1 Entity Type-based Heuristic

The aim of this heuristic was to detect questions that can be solved based on (i) the existence of a single candidate answer that is restricted by expressions such as "wh-" and "how many," and (ii) lexical patterns that appear around the correct answer. Because the query styles are not uniform across datasets (e.g., MARCO uses search engine queries), we could not directly use interrogatives. Instead, we simply provided the first k tokens of questions to the baseline systems. We chose smaller values for k than the (macro) average of the question length across the datasets (= 12.2 tokens). For example, for $k = 4$ of the question *will I qualify for OSAP if I'm new in Canada* (excerpted from MARCO), we use *will I qualify for*. Even if the tokens do not have an interrogative, the system may recognize lexical patterns around the correct answer. Questions that can be solved

---

[2] The ARC Easy and Challenge were collected using different methods; hence, we treated them as different datasets (see Clark et al. (2018) for further details).

[3] We used the official evaluation scripts of SQuAD and MS MARCO to compute the EM/F1 and Rouge-L, respectively.

	Dataset	SQuAD	AddSent	NewsQA	TriviaQA	QAngaroo	MARCO	NarraQA

Table 2: Statistics from the answer extraction and description datasets and their baselines. *Dev* represents a development set. *Ans in sim sent* refers to questions whose answer appears in the sentence that is most similar to the question. [1]The questions are not complete sentences and may start with more specific words than interrogatives. [2]Verified set. [3]No answer questions were removed. [4]The Passage Ranking model (Nguyen et al., 2016).

by examining these patterns were also of interest when filtering.

Results: Tables 2 and 3 present the results for $k = 1, 2, 4$. In addition, to know the exact ratio of the questions that are solved rather than the scores for the answer extraction and description styles, we counted questions with $k = 2$ that achieved the score ≥ 0.5.[4] As k decreased, so too did the baseline performance on all datasets in Table 2 except QAngaroo. By contrast, in QAngaroo and the multiple-choice datasets, the performance did not degrade so strongly. In particular, the difference between the scores on the full and $k = 1$ questions in QAngaroo was 1.8. Because the questions in QAngaroo are not complete sentences, but rather knowledge-base entries that have a blank, such as *country_of_citizenship Henry VI of England,* this result implies that the baseline system can infer the answer merely by the first token of questions, i.e., the type of knowledge-base entry.

In most multiple-choice datasets, the $k = 1$ scores were significantly higher than random-choice scores. Given that multiple-choice questions offer multiple options that are of valid entity/event types, this gap was not necessarily caused by the limited number of candidate answers, as in the case with the answer extraction datasets. Therefore, we inferred that in the solved questions, incorrect options appeared less than the correct option did or did not appear at all in the context (such questions were regarded as solvable exclusively using the word match skill, which we analyzed in Section 4). Remarkably, although we failed to achieve a higher baseline performance, the score for the complete questions in MCTest was lower than that of the $k = 1$ questions. This result showed that the MCTest questions were sufficiently difficult such that it was not especially useful for the baseline system to consider the entire question statement.

3.2 Attention-based Heuristic

Next, we examined in each dataset (i) how many questions have their correct answers in the most similar sentence and (ii) whether a performance gap exists for such questions (i.e., whether such questions are easier than the others).

We used uni-gram overlap as a similarity mea-

---

[4] We considered that this threshold is sufficient to judge that the system attends to the correct span because of the potential ambiguity of these styles (see Section 4).

	Dataset	MCTest	RACE	MCScript	ARC-E	ARC-C

	% of *hard*	**62.4**	**58.8**	**27.1**	**53.9**	**66.4**

Table 3: Statistics from the multiple-choice datasets and their baselines. [1]The Attentive Reader (Hermann et al., 2015) from Yin et al. (2016). [2]An information retrieval system from Clark et al. (2018).

sure.[5] We counted how many times question words appeared in each sentence, where question words were stemmed and stopwords were dropped. We then checked whether the correct answer appeared in the most similar sentence. For the multiple-choice datasets, we selected the text span that provided the highest Rouge-L score with the correct option as the correct answer.

Results: Tables 2 and 3 show the results. Considering the average number of context sentences, most datasets contained a significantly high proportion of questions whose answers were in the most similar sentence.

In the answer extraction and description datasets, except QAngaroo, the baseline performance improved when the correct answer appeared in the most similar sentence, and gaps were found between the performances on these questions and the others. These gaps indicated that the dataset may lack balance for testing NLU. If these questions tend to require the word matching skill exclusively, attending the other portion is useful in studying a more realistic NLU, e.g., common-sense reasoning and discourse understanding. Therefore, we investigated whether these questions merely require word matching (see Section 4).

Meanwhile, in the first three multiple-choice datasets, the performance differences were marginal or inversed, implying that although the baseline performance was not especially high, the difficulty of these questions for the baseline system was not affected by whether their correct answers appeared in the most similar sentence.

We further analyzed the baseline performance after removing the context and leaving only the most similar sentence. In AddSent and QAngaroo, the scores remarkably improved (>20 F1). From this result, we can infer that on these datasets the baseline systems were distracted by other sentences in the context. This observation was supported by the results from the AddSent dataset (Jia and Liang, 2017), which contains manually injected distracting sentences (i.e., adversarial examples).

3.3 Performance on *Hard* Subsets

In the previous two sections, we observed that in the examined datasets (i) some questions were solved by the baseline systems merely with the first k tokens and/or (ii) the baseline performances increased for questions whose answers were in the most similar sentence. We were concerned that these two will become dominant factors in measuring the baseline performance using the datasets; Hence, we split each development/test set into *easy* and *hard* subsets for further investigation.

***Hard* subsets:** A *hard* subset comprised questions (i) whose score is not positive when $k = 2$ *and* (ii) whose correct answer does not appear in the most similar sentence. The easy subsets comprised the remaining questions. We aimed to investigate the gap of the performance values between the *easy* and *hard* subsets. If the gap is large, the dataset may be strongly biased toward questions that are solved by recognizing entity types or lexical patterns and may not be suitable for measuring the system's ability for complex reasoning.

Results and clarification: The bottom row of Tables 2 and 3 shows that the baseline performances on the *hard* subset remarkably decreased in almost all examined datasets. These results revealed that we may overestimate the ability of the baseline systems previously perceived. How-

---

[5] Although there are other similarity measures, we used this basic measure to obtain an intuitive result.

ever, we clarify that our intention is not to remove the questions solved or mitigated by our defined heuristics to create a new *hard* subset because this may generate new biases as indicated in Gururangan et al. (2018). Rather, we would like to emphasize the importance of the defined heuristics when sourcing questions. Indeed, ill attention to these heuristics can lead to unintended biases.

4 Annotating Question Validity and Required Skills

4.1 Annotation Specifications

Objectives: To complement the observations in the previous sections, we annotated sampled questions from each subset of the datasets. Our motivation can be summarized as follows: (i) How many questions are valid in each dataset? That is, the *hard* questions may not in fact be hard, but just unsolvable, as indicated in Chen et al. (2016). (ii) What kinds of reasoning skills explain the *easy*/*hard* questions? (iii) Are there any differences among the datasets and the question styles?

We annotated the minimum skills required to choose the correct answer among other candidates. We assumed that the solver knows what type of entity or event is entailed by the question.

Annotation labels: Our annotation labels (Table 4) were inspired by previous works such as Chen et al. (2016), Trischler et al. (2017), and Lai et al. (2017). The major modifications were twofold: (i) detailed question validity, including a number of reasonable candidate answers and answer ambiguity, and (ii) posing multiple-sentence reasoning as a skill compatible with other skills.

Reasoning types indeed have other classifications. For instance, Lai et al. (2017) defined five reasoning types, including *attitude analysis* and *whole-picture reasoning*. We incorporated them into the *knowledge* and *meta/whole* classes. Clark et al. (2018) proposed detailed knowledge and reasoning types, but these were specific to science exams and, thus, omitted from our study.

Independent of the abovementioned reasoning types, we checked whether the question required multiple-sentence reasoning to answer the questions. As another modification, we extended the notion of "sentence" in our annotation and considered a subordinate clause as a sentence. This modification was intended to deal with the internal complexity of a sentence with multiple clauses, which can also render a question difficult.

Validity

1. *Unsolvable* – the context coupled with the question does not reasonably give the answer.
2. *Single candidate* – the question does not have multiple candidate answers.
3. *Ambiguous* – the question does not have a unique, decidable answer, or, multiple possible answers are not covered by the gold answers.

Reasoning skill

4. *Word matching* – matching the context and question words.
5. *Paraphrasing* – using lexical and grammatical knowledge.
6. *Knowledge* – inference using commonsense and/or world knowledge.
7. *Meta/Whole* – understanding meta terms, such as "author" and "writer," and comprehending the general context.
8. *Math/Logic* – using mathematical and logical knowledge, includeing multiple-choice questions that ask "which option is not true."

Multiple-sentence reasoning

9. (i) coreference (ii) causal relation (iii) spatial–temporal relations (iv) none – gathering cues from multiple sentences/clauses.

Table 4: Annotation labels. One of the reasoning skills is annotated with the questions that are "no" in all validity labels. Multiple sentence reasoning is independent of reasoning skills and annotated with all valid questions.

Settings: For each subset of the datasets, 30 questions were annotated. Therefore we obtained annotations for $30 \times 2 \times 12 = 720$ questions. The annotation was performed by the authors. The annotator was given the context, question, and candidate answers for multiple-choice questions along with the correct answer. To reduce bias, the annotator did not know which *easy* or *hard* subset the questions were in, and was not told the predictions and scores of the respective baseline systems.

4.2 Annotation Results

Tables 5 and 6 show the annotation results.

Validity: TriviaQA, QAngaroo, and ARCs revealed a relatively high *unsolvability*, which seemed to be caused by the unrelatedness between the questions and their context. For example, QAngaroo's context was gathered from Wikipedia articles that were not necessarily related to the questions.[6] The context passages in ARCs were

---

[6] Nonetheless, it is remarkable that even though the dataset was automatically constructed, the remaining valid *hard*

curated from textbooks that may not provide sufficient information to answer the questions.[7] Note that it is possible for unsolvable questions to be permitted, and that the system must indicate them in some datasets, such as QA4MRE, NewsQA, MARCO, and SQuAD (v2.0).

However, for *single candidate*, we found that few questions had only single-candidate answers. Furthermore, there were even fewer single-candidate answers in AddSent than in SQuAD. This result supported the claim that the adversarial examples augmented the number of possible candidate answers, thereby degrading the baseline performance.

In our annotation, *ambiguous* questions were

---

questions were difficult for the baseline system.

[7] Our analysis was not intended to undermine the quality of these questions. We refer readers to Clark et al. (2018).

ID: ./cnn/stories/4ca29639845a40551a62d10212a46aec7caf3369.story-2
Context: [...] This plot of land is scheduled to house the permanent United Airlines Flight 93 memorial. [...]
Question: What was the name of the flight?
Answer: 93
Possible answers: United Airlines Flight 93, Flight 93

Figure 2: Example of an *ambiguous* question from NewsQA (Trischler et al., 2017).

found to be those with multiple correct spans. Figure 2 shows an example. In this case, several answers aside from "93" were correct. Ambiguity is an important feature insofar because it can lead to unstable scoring in EM/F1.

The multiple-choice datasets mostly comprised valid questions, with the exception of the unsolvable questions in the ARC datasets.

Reasoning skills: We can see that *word matching* was more important in the *easy* subsets, and *knowledge* was more pertinent to the *hard* subsets in 10 of the 12 datasets. These results confirmed that the manner by which we split the subsets was successful at filtering questions that were relatively easy in terms of reasoning skills. However, we did not observe this trend with *paraphrasing*, which seemed difficult to distinguish from *word matching* and *knowledge*. With regard to *meta/whole* and *math/logic*, we can see that these skills were needed less in the answer extraction and description datasets. They were more pertinent to the multiple-choice datasets.

Multiple-sentence reasoning: Multiple-sentence reasoning was more correlated with the *hard* subsets in 10 of the 12 datasets. Although NewsQA showed the inverse tendency for *word matching*, *knowledge*, and *multiple-sentence reasoning*, we suspect that this was caused by annotation variance and filtering a large portion of ambiguous questions. For relational types, we did not see a significant trend in any particular type.

Correlation of labels and baseline scores: Across all examined datasets, we analyzed the correlations between the annotation labels and the scores of each baseline system in Table 7. In spite of the small size of the annotated samples, we derived statistically significant correlations for six labels. These results confirmed that BiDAF performed well for the *word matching* questions and relatively poorly with the *knowledge* questions. By contrast, we did not observe this trend in GA.

5 Discussion

In this section, we discuss the advantages and disadvantages of the question styles. We also interpret the defined heuristics in terms of constructing more realistic MRC datasets.

Differences among the question styles: The biggest advantage to the answer extraction style is its ease in generating questions, which enables us to produce large-scale datasets. In contrast, a disadvantage to this style is that it rarely demands *meta/whole* and *math/logic* skills, which can require answers not contained in the context. Moreover, as observed in Section 4, it seems difficult to guarantee that all possible answer spans are given as the correct answers. By contrast, the description and multiple-choice styles have the advantage of having no such restrictions on the appearance of candidate answers (Kočiský et al., 2018; Khashabi et al., 2018). Nonetheless, the description style is difficult to evaluate because the Rouge-L and BLEU scores are insufficient for testing NLU. Whereas it is easy to evaluate the performance on multiple-choice questions, generating multiple reasonable options requires considerable effort.

Interpretation of our heuristics: When we regard the MRC task as recognizing textual entailment (RTE) (Dagan et al., 2006), the task requires the reader to construct one or more premises from the context and form the most reasonable hypothesis from the question and candidate answer (Sachan et al., 2015). Thus, easier questions are those (i) where the reader needs to generate only one hypothesis, and (ii) where the premises directly describe the correct hypothesis. Our two heuristics can also be seen as the formalizations of these criteria. Therefore, to make questions more realistic, we need to create multiple hypotheses that require complex reasoning to be distinguished. Moreover, the integration of premises should be complemented by external knowledge to provide sufficient information to verify the correct hypothesis.

6 Related Work

Our heuristics and annotation were motivated by *unintended biases* (Levesque, 2014) and *evaluation overfitting* (Whiteson et al., 2011), respectively.

Unintended biases: The MRC task tests a reading process that involves retrieving stored information and performing inferences (Sutcliffe et al., 2013). However, constructing datasets that comprehensively require those skills is difficult. As Levesque (2014) discussed as a desideratum for testing AI, we should avoid creating questions that can be solved by matching patterns, using unintended biases, and selectional restrictions. For the unintended biases, one suggestive example is the Story Cloze Test (Mostafazadeh et al., 2016), in which a system chooses a sentence among candidates to conclude a given paragraph of the story. A recent attempt at this task showed that recognizing superficial features in the correct candidate is critical to achieve the state of the art (Schwartz et al., 2017).

Similarly, in MRC, Weissenborn et al. (2017) proposed *context/type matching heuristic* to develop a simple neural system. Min et al. (2018) observed that, in SQuAD, 92% of answerable questions can be answered only using a single context sentence. In visual question answering, Agrawal et al. (2016) analyzed the behavior of models with the variable length of the first question words. Khashabi et al. (2018) more recently proposed a dataset with questions for multi-sentence reasoning.

Evaluation overfitting: The theory behind evaluating AI distinguishes between task- and skill-oriented approaches (Hernández-Orallo, 2017). In the task-oriented approach, we usually develop a system and test it on a specific dataset. The developed system sometimes lacks generality but achieves the state of the art for that specific dataset. Further, it becomes difficult to verify and explain the solution to tasks. The situation in which we are biased to the specific tasks is called evaluation overfitting (Whiteson et al., 2011). By contrast, with the skill-oriented approach, we aim to interpret the relationships between tasks and skills. This orientation can encourage the development of more realistic NLU systems.

As One of our goals was to investigate whether easy questions are dominant in recent datasets, it did not necessarily require a detailed classification of reasoning types. Nonetheless, we recognize there are more fine-grained classifications of the required skills for NLU. For example, Weston et al. (2015) defined 20 skills as a set of toy tasks. Sugawara et al. (2017) also organized 10 prerequisite skills for MRC. LoBue and Yates (2011) and Sammons et al. (2010) analyzed entailment phenomena using detailed classifications in RTE. For the ARC dataset, Boratko et al. (2018) proposed knowledge and reasoning types.

7 Conclusion

This study examined MRC questions from 12 datasets to determine what makes such questions easier to answer. We defined two heuristics that limit candidate answers and thereby mitigate the difficulty of questions. Using these heuristics, the datasets were split into easy and hard subsets. We further annotated the questions with their validity and the reasoning skills needed to answer them. Our experiments revealed that the baseline performance degraded with the hard questions, which required knowledge inference and multiple-sentence reasoning compared to easy questions. These results suggest that one might overestimate the ability of the baseline systems. They also emphasize the importance of analyzing and reporting the properties of new datasets when released. One limitation of this work was the heavy cost of the annotation. In future research, we plan to explore a method for automatically classifying reasoning types. This will enable us to evaluate systems through a detailed organization of the datasets.

A Hyperparameters of the Baseline Systems

We used different hyperparameters for each dataset because of the different characteristics of the datasets, e.g., the context length. Tables 8 and 9 show the hyperparameters.

Dataset	b	h	q	d
SQuAD	60	100	400	20
AddSent	60	100	400	20
NewsQA	32	100	1000	20
TriviaQA	32	100	400	20
QAngaroo	16	50	4096	20
MARCO	20	40	1600	30
NarrativeQA	60	50	1000	20

Table 8: Hyperparameters (batch size b, hidden layer size h, document size threshold d, question size threshold q) of the Bidirectional Attention Flow (Seo et al., 2017) for each dataset. The other settings basically followed the original implementation. In TriviaQA, we followed a method for the dataset preparation used in Joshi et al. (2017).

Dataset	b	h	n	dr	lr
MCTest	10	32	1	0.5	0.01
RACE	32	128	1	0.2	0.1
MCScript	25	64	1	0.5	0.2
ARC-E	32	256	1	0.5	0.3
ARC-C	32	256	1	0.5	0.3

Table 9: Hyperparameters (batch size b, hidden layer size h, number of attention layers n, dropout rate dr, learning rate lr) of the Gated-Attentive Reader (Dhingra et al., 2017) for each dataset. The other settings basically followed the implementation in Lai et al. (2017).

Commonsense for Generative Multi-Hop Question Answering Tasks

Abstract

Reading comprehension QA tasks have seen a recent surge in popularity, yet most works have focused on fact-finding extractive QA. We instead focus on a more challenging multi-hop generative task (NarrativeQA), which requires the model to reason, gather, and synthesize disjoint pieces of information within the context to generate an answer. This type of multi-step reasoning also often requires understanding implicit relations, which humans resolve via external, background commonsense knowledge. We first present a strong generative baseline that uses a multi-attention mechanism to perform multiple hops of reasoning and a pointer-generator decoder to synthesize the answer. This model performs substantially better than previous generative models, and is competitive with current state-of-the-art span prediction models. We next introduce a novel system for selecting grounded multi-hop relational commonsense information from ConceptNet via a pointwise mutual information and term-frequency based scoring function. Finally, we effectively use this extracted commonsense information to fill in gaps of reasoning between context hops, using a selectively-gated attention mechanism. This boosts the model's performance significantly (also verified via human evaluation), establishing a new state-of-the-art for the task. We also show that our background knowledge enhancements are generalizable and improve performance on QAngaroo-WikiHop, another multi-hop reasoning dataset.

1 Introduction

In this paper, we explore the task of machine reading comprehension (MRC) based QA. This task tests a model's natural language understanding capabilities by asking it to answer a question based on a passage of relevant content. Much progress has been made in reasoning-based MRC-QA on the bAbI dataset (Weston et al., 2016), which contains questions that require the combination of multiple disjoint pieces of evidence in the context. However, due to its synthetic nature, bAbI evidences have smaller lexicons and simpler passage structures when compared to human-generated text.

There also have been several attempts at the MRC-QA task on human-generated text. Large scale datasets such as CNN/DM (Hermann et al., 2015) and SQuAD (Rajpurkar et al., 2016) have made the training of end-to-end neural models possible. However, these datasets are fact-based and do not place heavy emphasis on multi-hop reasoning capabilities. More recent datasets such as QAngaroo (Welbl et al., 2018) have prompted a strong focus on multi-hop reasoning in very long texts. However, QAngaroo is an extractive dataset where answers are guaranteed to be spans within the context; hence, this is more focused on fact finding and linking, and does not require models to synthesize and generate new information.

We focus on the recently published NarrativeQA generative dataset (Kočiský et al., 2018) that contains questions requiring multi-hop reasoning for long, complex stories and other narratives, which requires the model to go beyond fact linking and to synthesize non-span answers. Hence, models that perform well on previous reasoning tasks (Dhingra et al., 2018) have had limited success on this dataset. In this paper, we first propose the Multi-Hop Pointer-Generator Model (MHPGM), a strong baseline model that uses multiple hops of bidirectional attention, self-attention, and a pointer-generator decoder to effectively read and reason within a long passage and synthesize a coherent response. Our model achieves 41.49 Rouge-L and 17.33 METEOR on the summary

subtask of NarrativeQA, substantially better than the performance of previous generative models.

Next, to address the issue that understanding human-generated text and performing long-distance reasoning on it often involves intermittent access to missing hops of external commonsense (background) knowledge, we present an algorithm for selecting useful, grounded multi-hop relational knowledge paths from ConceptNet (Speer and Havasi, 2012) via a pointwise mutual information (PMI) and term-frequency-based scoring function. We then present a novel method of inserting these selected commonsense paths between the hops of document-context reasoning within our model, via the Necessary and Optional Information Cell (NOIC), which employs a selectively-gated attention mechanism that utilizes commonsense information to effectively fill in gaps of inference. With these additions, we further improve performance on the NarrativeQA dataset, achieving 44.16 Rouge-L and 19.03 METEOR (also verified via human evaluation). We also provide manual analysis on the effectiveness of our commonsense selection algorithm.

Finally, to show the effectiveness and generalizability of our multi-hop reasoning and commonsense methods, we also tested our MHPGM and MHPGM+NOIC models on QAngaroo-WikiHop (Welbl et al., 2018), which is an extractive dataset for multi-hop reasoning on human-generated documents. We found that our background commonsense knowledge enhanced model achieved 1.5% higher accuracy than our strong baseline.

2 Related Work

Machine Reading Comprehension: MRC has long been a task used to assess a model's ability to understand and reason about language. Large scale datasets such as CNN/Daily Mail (Hermann et al., 2015) and SQuAD (Rajpurkar et al., 2016) have encouraged the development of many advanced, high performing attention-based neural models (Seo et al., 2017; Dhingra et al., 2017). Concurrently, datasets such as bAbI (Weston et al., 2016) have focused specifically on multi-step reasoning by requiring the model to reason with disjoint pieces of information. On this task, it has been shown that iteratively updating the query representation with information from the context can effectively emulate multi-step reasoning (Sukhbaatar et al., 2015).

More recently, there has been an increase in multi-paragraph, multi-hop inference QA datasets such as QAngaroo (Welbl et al., 2018) and NarrativeQA (Kočiskỳ et al., 2018). These datasets have much longer contexts than previous datasets, and answering a question often requires the synthesis of multiple discontiguous pieces of evidence. It has been shown that models designed for previous tasks (Seo et al., 2017; Kadlec et al., 2016) have limited success on these new datasets. In our work, we expand upon Gated Attention Network (Dhingra et al., 2017) to create a baseline model better suited for complex MRC datasets such as NarrativeQA by improving its attention and gating mechanisms, expanding its generation capabilities, and allowing access to external commonsense for connecting implicit relations.

Commonsense/Background Knowledge: Commonsense or background knowledge has been used for several tasks including opinion mining (Cambria et al., 2010), sentiment analysis (Poria et al., 2015, 2016), handwritten text recognition (Wang et al., 2013), and more recently, dialogue (Young et al., 2018; Ghazvininejad et al., 2018). These approaches add commonsense knowledge as relation triples or features from external databases. Recently, large-scale graphical commonsense databases such as ConceptNet (Speer and Havasi, 2012) use graphical structure to express intricate relations between concepts, but effective goal-oriented graph traversal has not been extensively used in previous commonsense incorporation efforts. Knowledge-base QA is a task in which systems are asked to find answers to questions by traversing knowledge graphs (Bollacker et al., 2008). Knowledge path extraction has been shown to be effective at the task (Bordes et al., 2014; Bao et al., 2016). We apply these techniques to MRC-QA by using them to extract useful commonsense knowledge paths that fully utilize the graphical nature of databases such as ConceptNet (Speer and Havasi, 2012).

Incorporation of External Knowledge: There have been several attempts at using external knowledge to boost model performance on a variety of tasks: Chen et al. (2018) showed that adding lexical information from semantic databases such as WordNet improves performance on NLI; Xu et al. (2017) used a gated recall-LSTM mechanism to incorporate commonsense information into token representations in dialogue.

In MRC, Weissenborn et al. (2017) integrated external background knowledge into an NLU model by using contextually-refined word embeddings which integrated information from ConceptNet (single-hop relations mapped to unstructured text) via a single layer bidirectional LSTM. Concurrently to our work, Mihaylov and Frank (2018) showed improvements on a cloze-style task by incorporating commonsense knowledge via a context-to-commonsense attention, where commonsense relations were extracted as triples. This work represented commonsense relations as key-value pairs and combined context representation and commonsense via a static gate.

Differing from previous works, we employ multi-hop commonsense paths (multiple connected edges within ConceptNet graph that give us information beyond a single relationship triple) to help with our MRC model. Moreover, we use this in tandem with our multi-hop reasoning architecture to incorporate different aspects of the commonsense relationship path at each hop, in order to bridge different inference gaps in the multi-hop QA task. Additionally, our model performs synthesis with its external, background knowledge as it generates, rather than extracts, its answer.

3 Methods

3.1 Multi-Hop Pointer-Generator Baseline

We first rigorously state the problem of generative QA as follows: given two sequences of input tokens: the context, $X^C = \{w_1^C, w_2^C, \ldots, w_n^C\}$ and the query, $X^Q = \{w_1^Q, w_2^Q, \ldots, w_m^Q\}$, the system should generate a series of answer tokens $X^a = \{w_1^a, w_2^a, \ldots, w_p^a\}$. As outlined in previous sections, an effective generative QA model needs to be able to perform several hops of reasoning over long and complex passages. It would also need to be able to generate coherent statements to answer complex questions while having the ability to copy rare words such as specific entities from the reading context. With these in mind, we propose the Multi-Hop Pointer-Generator Model (MHPGM) baseline, a novel combination of previous works with the following major components:

- **Embedding Layer**: The tokens are embedded into both learned word embeddings and pretrained context-aware embeddings (ELMo (Peters et al., 2018)).
- **Reasoning Layer**: The embedded context is then passed through k reasoning cells, each of which iteratively updates the context representation with information from the query via BiDAF attention (Seo et al., 2017), emulating a single reasoning step within the multi-step reasoning process.
- **Self-Attention Layer**: The context representation is passed through a layer of self-attention (Cheng et al., 2016) to resolve long-term dependencies and co-reference within the context.
- **Pointer-Generator Decoding Layer**: A attention-pointer-generator decoder (See et al., 2017) that attends on and potentially copies from the context is used to create the answer.

The overall model is illustrated in Fig. 1, and the layers are described in further detail below.

Embedding layer: We embed each word from the context and question with a learned embedding space of dimension d. We also obtain context-aware embeddings for each word via the pretrained embedding from language models (ELMo) (1024 dimensions). The embedded representation for each word in the context or question, $\mathbf{e}_i^C$ or $\mathbf{e}_i^Q \in \mathbb{R}^{d+1024}$, is the concatenation of its learned word embedding and ELMo embedding.

Reasoning layer: Our reasoning layer is composed of k reasoning cells (see Fig. 1), where each incrementally updates the context representation. The t^{th} reasoning cell's inputs are the previous step's output ($\{\mathbf{c}_i^{t-1}\}_{i=1}^n$) and the embedded question ($\{\mathbf{e}_i^Q\}_{i=1}^m$). It first creates step-specific context and query encodings via cell-specific bidirectional LSTMs:

$$\mathbf{u}^t = \text{BiLSTM}(\mathbf{c}^{t-1}); \qquad \mathbf{v}^t = \text{BiLSTM}(\mathbf{e}^Q)$$

Then, we use bidirectional attention (Seo et al., 2017) to emulate a hop of reasoning by focusing on relevant aspects of the context. Specifically, we first compute context-to-query attention:

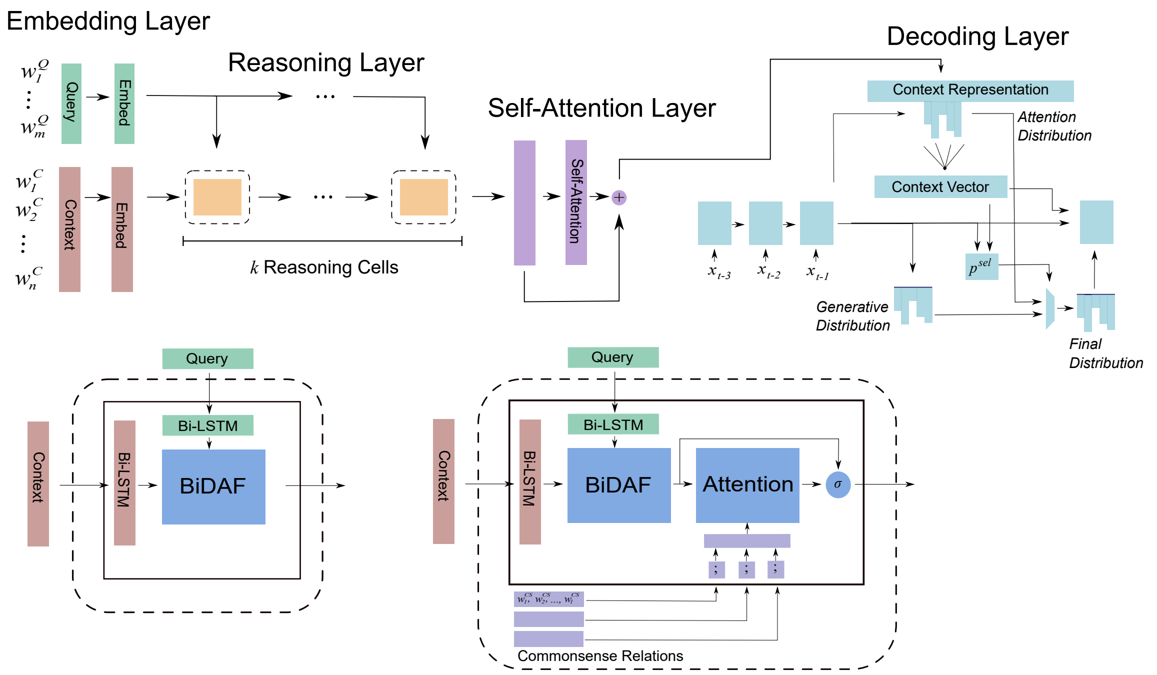
$$S_{ij}^t = W_1^t \mathbf{u}_i^t + W_2^t \mathbf{v}_j^t + W_3^t(\mathbf{u}_i^t \odot \mathbf{v}_j^t)$$

$$p_{ij}^t = \frac{\exp(S_{ij}^t)}{\sum_{k=1}^m \exp(S_{ik}^t)}$$

$$(\mathbf{c_q})_i^t = \sum_{j=1}^m p_{ij}^t \mathbf{v}_j^t$$

where W_1^t, W_2^t, W_3^t are trainable parameters, and $\odot$ is elementwise multiplication. We then compute a query-to-context attention vector:

$$m_i^t = \max_{1 \leq j \leq m} S_{ij}^t$$



Baseline Reasoning Cell

NOIC Reasoning Cell

Figure 1: Architecture for our Multi-Hop Pointer-Generator Model, and the NOIC commonsense reasoning cell.

$$p_i^t = \frac{\exp(m_i^t)}{\sum_{j=1}^{n} \exp(m_j^t)}$$

$$\mathbf{q_c}^t = \sum_{i=1}^{n} p_i^t \mathbf{u}_i^t$$

We then obtain the updated context representation:

$$\mathbf{c}_i^t = [\mathbf{u}_i^t; (\mathbf{c_q})_i^t; \mathbf{u}_i^t \odot (\mathbf{c_q})_i^t; \mathbf{q_c}^t \odot (\mathbf{c_q})_i^t]$$

where ; is concatenation, $\mathbf{c}^t$ is the cell's output.

The initial input of the reasoning layer is the embedded context representation, i.e., $\mathbf{c}^0 = \mathbf{e}^C$, and the final output of the reasoning layer is the output of the last cell, $\mathbf{c}^k$.

Self-Attention Layer: As the final layer before answer generation, we utilize a residual static self-attention mechanism (Clark and Gardner, 2018) to help the model process long contexts with long-term dependencies. The input of this layer is the output of the last reasoning cell, $\mathbf{c}^k$. We first pass this representation through a fully-connected layer and then a bi-directional LSTM to obtain another representation of the context $\mathbf{c}^{SA}$. We obtain the self attention representation $\mathbf{c}'$:

$$S_{ij}^{SA} = W_4\mathbf{c}_i^{SA} + W_5\mathbf{c}_j^{SA} + W_6(\mathbf{c}_i^{SA} \odot \mathbf{c}_j^{SA})$$

$$p_{ij}^{SA} = \frac{\exp(S_{ij}^{SA})}{\sum_{k=1}^{n} \exp(S_{ik}^{SA})}$$

$$\mathbf{c}'_i = \sum_{j=1}^{n} p_{ij}^{SA}\mathbf{c}_j^{SA}$$

where W_4, W_5, and W_6 are trainable parameters.

The output of the self-attention layer is generated by another layer of bidirectional LSTM.

$$\mathbf{c}'' = \text{BiLSTM}([\mathbf{c}'; \mathbf{c}^{SA}; \mathbf{c}' \odot \mathbf{c}^{SA}])$$

Finally, we add this residually to $\mathbf{c}^k$ to obtain the encoded context $\mathbf{c} = \mathbf{c}^k + \mathbf{c}''$.

Pointer-Generator Decoding Layer: Similar to the work of See et al. (2017), we use a pointer-generator model attending on (and potentially copying from) the context.

At decoding step t, the decoder receives the input $\mathbf{x}_t$ (embedded representation of last timestep's output), the last time step's hidden state $\mathbf{s}_{t-1}$ and context vector $\mathbf{a}_{t-1}$. The decoder computes the current hidden state $\mathbf{s}_t$ as:

$$\mathbf{s}_t = \text{LSTM}([\mathbf{x}_t; \mathbf{a}_{t-1}], \mathbf{s}_{t-1})$$

This hidden state is then used to compute a probability distribution over the generative vocabulary:

$$P_{gen} = \text{softmax}(W_{gen}\mathbf{s}_t + \mathbf{b}_{gen})$$

We employ Bahdanau attention mechanism (Bahdanau et al., 2015) to attend over the context ($\mathbf{c}$ being the output of self-attention layer):

$$\alpha_i = \mathbf{v}^\intercal \tanh(W_c\mathbf{c}_i + W_s\mathbf{s}_t + b_{attn})$$

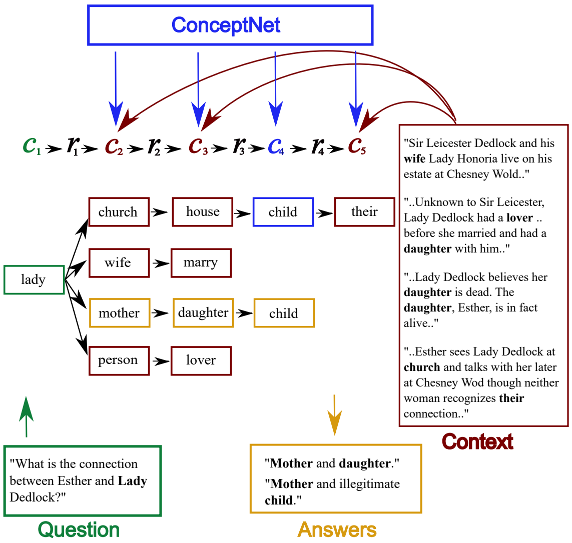


Figure 2: Commonsense selection approach.

$$\hat{\alpha}_i = \frac{\exp(\alpha_i)}{\sum_{j=1}^{n} \exp(\alpha_j)}$$

$$\mathbf{a}_t = \sum_{i=1}^{n} \hat{\alpha}_i \mathbf{c}_i$$

We utilize a pointer mechanism that allows the decoder to directly copy tokens from the context based on $\hat{\alpha}_i$. We calculate a selection distribution $\mathbf{p}^{sel} \in \mathbb{R}^2$, where p_1^{sel} is the probability of generating a token from P_{gen} and p_2^{sel} is the probability of copying a word from the context:

$$\mathbf{o} = \sigma(W_a \mathbf{a}_t + W_x \mathbf{x}_t + W_s \mathbf{s}_t + b_{ptr})$$

$$\mathbf{p}^{sel} = \text{softmax}(\mathbf{o})$$

Our final output distribution at timestep t is a weighted sum of the generative distribution and the copy distribution:

$$P_t(w) = p_1^{sel} P_{gen}(w) + p_2^{sel} \sum_{i:w_i^C = w} \hat{\alpha}_i$$

3.2 Commonsense Selection and Representation

In QA tasks that require multiple hops of reasoning, the model often needs knowledge of relations not directly stated in the context to reach the correct conclusion. In the datasets we consider, manual analysis shows that external knowledge is frequently needed for inference (see Table 1).

Dataset	Outside Knowledge Required
WikiHop	11%
NarrativeQA	42%

Table 1: Qualitative analysis of commonsense requirements. WikiHop results are from Welbl et al. (2018); NarrativeQA results are from our manual analysis (on the validation set).

Even with a large amount of training data, it is very unlikely that a model is able to learn every nuanced relation between concepts and apply the correct ones (as in Fig. 2) when reasoning about a question. We remedy this issue by introducing *grounded* commonsense (background) information using relations between concepts from ConceptNet (Speer and Havasi, 2012)[1] that help inference by introducing useful connections between concepts in the context and question.

Due to the size of the semantic network and the large amount of unnecessary information, we need an effective way of selecting relations which provides novel information while being grounded by the context-query pair. Our commonsense selection strategy is twofold: (1) collect potentially relevant concepts via a tree construction method aimed at selecting with high recall candidate reasoning paths, and (2) rank and filter these paths to ensure both the quality and variety of added information via a 3-step scoring strategy (initial node scoring, cumulative node scoring, and path selection). We will refer to Fig. 2 as a running example throughout this section.[2]

3.2.1 Tree Construction

Given context C and question Q, we want to construct paths grounded in the pair that emulate reasoning steps required to answer the question. In this section, we build 'prototype' paths by constructing trees rooted in concepts in the query with the following branching steps[3] to emulate multi-hop reasoning process. For each concept c_1 in the question, we do:

Direct Interaction: In the first level, we select relations r_1 from ConceptNet that directly link c_1 to a concept within the context, $c_2 \in C$, e.g., in Fig. 2, we have *lady* → *church*, *lady* → *mother*, *lady* → *person*.

Multi-Hop: We then select relations in ConceptNet r_2 that link c_2 to another concept in the context, $c_3 \in C$. This emulates a potential reason-

---

[1] A semantic network where the nodes are individual concepts (words or phrases) and the edges describe directed relations between them (e.g., ⟨island, UsedFor, vacation⟩).

[2] We release all our commonsense extraction code and the extracted commonsense data at: `https://github.com/yicheng-w/CommonSenseMultiHopQA`

[3] If we are unable to find a relation that satisfies the condition, we keep the steps up to and including the node.

ing hop within the context of the MRC task, e.g., *church* $\rightarrow$ *house*, *mother* $\rightarrow$ *daughter*, *person* $\rightarrow$ *lover*.

Outside Knowledge: We then allow an unconstrained hop into c_3's neighbors in ConceptNet, getting to $c_4 \in \text{nbh}(c_3)$ via r_3 ($\text{nbh}(v)$ is the set of nodes that can be reached from v in one hop). This emulates the gathering of useful external information to complete paths within the context, e.g., *house* $\rightarrow$ *child*, *daughter* $\rightarrow$ *child*.

Context-Grounding: To ensure that the external knowledge is indeed helpful to the task, and also to explicitly link 2nd degree neighbor concepts within the context, we finish the process by grounding it again into context by connecting c_4 to $c_5 \in C$ via r_4, e.g., *child* $\rightarrow$ *their*.

3.2.2 Rank and Filter

This tree building process collects a large number of potentially relevant and useful paths. However, this step also introduces a large amount of noise. For example, given the question and full context (not depicted in the figure) in Fig. 2, we obtain the path "*between* $\rightarrow$ *hard* $\rightarrow$ *being* $\rightarrow$ *cottage* $\rightarrow$ *country*" using our tree building method, which is not relevant to our question. Therefore, to improve the precision of useful concepts, we rank these knowledge paths by their relevance and filter out noise using the following 3-step scoring method:

Initial Node Scoring: We want to select paths with nodes that are important to the context, in order to provide the most useful commonsense relations. We approximate importance and saliency for concepts in the context by their term-frequency, under the heuristic that important concepts occur more frequently. Thus we score $c \in \{c_2, c_3, c_5\}$ by: $\text{score}(c) = \text{count}(c)/|C|$, where $|C|$ is the context length and count() is the number of times a concept appears in the context. In Fig. 2, this ensures that concepts like *daughter* are scored highly due to their frequency in the context.

For c_4, we use a special scoring function as it is an unconstrained hop into ConceptNet. We want c_4 to be a logically consistent next step in reasoning following the path of c_1 to c_3, e.g., in Fig. 2, we see that *child* is a logically consistent next step after the partial path of *mother* $\rightarrow$ *daughter*. We approximate this based on the heuristic that logically consistent paths occur more frequently. Therefore, we score this node via Pointwise Mutual Information (PMI) between the partial path c_{1-3} and c_4: $\text{PMI}(c_4, c_{1-3}) = \log(\mathbb{P}(c_4, c_{1-3})/\mathbb{P}(c_4)\mathbb{P}(c_{1-3}))$, where

$$\mathbb{P}(c_4, c_{1-3}) = \frac{\text{\# of paths connecting } c_1, c_2, c_3, c_4}{\text{\# of distinct paths of length 4}}$$

$$\mathbb{P}(c_4) = \frac{\text{\# of nodes that can reach } c_4}{|\text{ConceptNet}|}$$

$$\mathbb{P}(c_{1-3}) = \frac{\text{\# of paths connecting } c_1, c_2, c_3}{\text{\# of paths of length 3}}$$

Further, it is well known that PMI has high sensitivity to low-frequency values, thus we use normalized PMI (NPMI) (Bouma, 2009): $\text{score}(c_4) = \text{PMI}(c_4, c_{1-3})/(-\log \mathbb{P}(c_4, c_{1-3}))$.

Since the branching at each juncture represents a hop in the multi-hop reasoning process, and hops at different levels or with different parent nodes do not 'compete' with each other, we normalize each node's score against its siblings:

$$\text{n-score}(c) = \text{softmax}_{\text{siblings}(c)}(\text{score}(c)).$$

Cumulative Node Scoring: We want to add commonsense paths consisting of multiple hops of relevant information, thus we re-score each node based not only on its relevance and saliency but also that of its tree descendants.

We do this by computing a cumulative node score from the bottom up, where at the leaf nodes, we have c-score $=$ n-score, and for c_l not a leaf node, we have $\text{c-score}(c_l) = \text{n-score}(c_l) + f(c_l)$ where f of a node is the average of the c-scores of its top 2 highest scoring children.

For example, given the paths *lady* $\rightarrow$ *mother* $\rightarrow$ *daughter*, *lady* $\rightarrow$ *mother* $\rightarrow$ *married*, and *lady* $\rightarrow$ *mother* $\rightarrow$ *book*, we start the cumulative scoring at the leaf nodes, which in this case are *daughter*, *married*, and *book*, where *daughter* and *married* are scored much higher than *book* due to their more frequent occurrences. Then, to cumulatively score $mother$, we would take the average score of its two highest scoring children (in this case *married* and *daughter*) and compound that with the score of *mother* itself. Note that the poor scoring of the irrelevant concept *book* does not affect the scoring of *mother*, which is quite high due to the concept's frequent occurrence and the relevance of its top scoring children.

Path Selection: We select paths in a top-down breath-first fashion in order to add information relevant to different parts of the context. Starting at the root, we recursively take two of its children with the highest cumulative scores until we reach a leaf, selecting up to $2^4 = 16$ paths. For example, if we were at node *mother*, this allows us to select the child node *daughter* and *married* over the child node *book*. These selected paths, as well as their partial sub-paths, are what we add as external information to the QA model, i.e., we add the complete path ⟨lady, AtLocation, church, RelatedTo, house, RelatedTo, child, RelatedTo, their⟩, but also truncated versions of the path, including ⟨lady, AtLocation, church, RelatedTo, house, RelatedTo, child⟩. We directly give these paths to the model as sequences of tokens.[4]

Overall, our sampling strategy provides the knowledge that a *lady* can be a *mother* and that *mother* is connected to *daughter*. This creates a logical connection between *lady* and *daughter* which helps highlight the importance of our second piece of evidence (see Fig. 2). Likewise, the commonsense information we extracted create a similar connection in our third piece of evidence, which states the explicit connection between *daughter* and *Esther*. We also successfully extract a more story context-centric connection, in which commonsense provides the knowledge that a *lady* is at the location *church*, which directs to another piece of evidence in the context. Additionally, this path also encodes a relation between *lady* and *child*, by way of *church*, which is how *lady* and *Esther* are explicitly connected in the story.

3.3 Commonsense Model Incorporation

Given the list of commonsense logic paths as sequences of words: $X^{CS} = \{w_1^{CS}, w_2^{CS}, \dots, w_l^{CS}\}$ where w_i^{CS} represents the list of tokens that make up a single path, we first embed these commonsense tokens into the learned embedding space used by the model, giving us the embedded commonsense tokens, $\mathbf{e}_{ij}^{CS} \in \mathbb{R}^d$. We want to use these commonsense paths to fill in the gaps of reasoning between hops of inference. Thus, we propose Necessary and Optional Information Cell (NOIC), a variation of our base reasoning cell used in the reasoning layer that is capable of incorporating optional helpful information.

NOIC This cell is an extension to the base reasoning cell that allows the model to use commonsense information to fill in gaps of reasoning. An example of this is on the bottom left of Fig. 1, where we see that the cell first performs the operations done in the base reasoning cell and then adds optional, commonsense information.

At reasoning step t, after obtaining the output of the base reasoning cell, $\mathbf{c}^t$, we create a cell-specific representation for commonsense information by concatenating the embedded commonsense paths so that each path has a single vector representation, $\mathbf{u}_i^{CS}$. We then project it to the same dimension as $\mathbf{c}_i^t$: $\mathbf{v}_i^{CS} = \text{ReLU}(W\mathbf{u}_i^{CS} + b)$ where W and b are trainable parameters.

We use an attention layer to model the interaction between commonsense and the context:

$$S_{ij}^{CS} = W_1^{CS}\mathbf{c}_i^t + W_2^{CS}\mathbf{v}_j^{CS} + W_3^{CS}(\mathbf{c}_i^t \odot \mathbf{v}_j^{CS})$$

$$p_{ij}^{CS} = \frac{\exp(S_{ij}^{CS})}{\sum_{k=1}^{l}\exp(S_{ij}^{CS})}$$

$$\mathbf{c}_i^{CS} = \sum_{j=1}^{l} p_{ij}^{CS}\mathbf{v}_j^{CS}$$

Finally, we combine this commonsense-aware context representation with the original $\mathbf{c}_i^t$ via a sigmoid gate, since commonsense information is often not necessary at every step of inference:

$$\mathbf{z}_i = \sigma(W_z[\mathbf{c}_i^{CS}; \mathbf{c}_i^t] + b_z)$$

$$(\mathbf{c_o})_i^t = \mathbf{z}_i \odot \mathbf{c}_i^t + (1 - \mathbf{z}_i) \odot \mathbf{c}_i^{CS}$$

We use ${\mathbf{c_o}}^t$ as the output of the current reasoning step instead of $\mathbf{c}^t$. As we replace each base reasoning cell with NOIC, we selectively incorporate commonsense at every step of inference.

4 Experimental Setup

Datasets: We report results on two multi-hop reasoning datasets: generative NarrativeQA (Kočiský et al., 2018) (summary subtask) and extractive QAngaroo WikiHop (Welbl et al., 2018). For multiple-choice WikiHop, we rank candidate responses by their generation probability. Similar to previous works (Dhingra et al., 2018), we use the non-oracle, unmasked and not-validated dataset.

Evaluation Metrics: We evaluate NarrativeQA on the metrics proposed by its original authors: Bleu-1, Bleu-4 (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005) and Rouge-L (Lin, 2004). We also evaluate on CIDEr (Vedantam et al., 2015) which emphasizes annotator consensus. For WikiHop, we evaluate on accuracy.[5]

More dataset, metric, and all other training details are in the supplementary.

---

[4] In cases where more than one relation can be used to make a hop, we pick one at random.

[5] Due to the 2-week evaluation wait-time on the non-public test set, we instead train our model on a sub-section of the training set, pick hyperparameters based on a small

Model	BLEU-1	BLEU-4	METEOR	Rouge-L	CIDEr
Seq2Seq (Kočiskỳ et al., 2018)	15.89	1.26	4.08	13.15	-

5 Results

5.1 Main Experiment

The results of our model on both NarrativeQA and WikiHop with and without commonsense incorporation are shown in Table 2 and Table 3. We see empirically that our model outperforms all generative models on NarrativeQA, and is competitive with the top span prediction models. Furthermore, with the NOIC commonsense integration, we were able to further improve performance ($p < 0.001$ on all metrics[6]), establishing a new state-of-the-art for the task. We also see that our model performs well on WikiHop,[7] and is further improved via the addition of commonsense ($p < 0.001$), demonstrating the generalizability of both our model and commonsense addition techniques.[8]

5.2 Model Ablations

We also tested the effectiveness of each component of our architecture as well as the effectiveness of adding commonsense information on the NarrativeQA validation set, with results shown in Table 4. Experiment 1 and 5 are our models presented in Table 2. Experiment 2 demonstrates the importance of multi-hop attention by showing that if we only allow one hop of attention (even with all other components of the model, including ELMo embeddings) the model's performance decreases by over 12 Rouge-L points. Experiment 3 and 4 demonstrate the effectiveness of other parts of our model. We see that ELMo embeddings (Peters et al., 2018) were also important for the model's performance and that self-attention is able to contribute significantly to performance on top of other components of the model. Finally, we see that effectively introducing external knowledge via our commonsense selection algorithm and NOIC can improve performance even further on top of our strong baseline.

5.3 Commonsense Ablations

We also conducted experiments testing the effectiveness of our commonsense selection and incorporation techniques. We first tried to naively add ConceptNet information by initializing the word embeddings with the ConceptNet-trained embeddings, NumberBatch (Speer and Havasi, 2012) (we also change embedding size from 256 to 300). Then, to verify the effectiveness of our commonsense selection and grounding algorithm, we test our best model on in-domain noise by giving each context-query pair a set of random relations grounded in other context-query pairs. This should teach the model about general commonsense relations present in the domain of NarrativeQA but does not provide grounding that fills in specific hops of inference. We also experimented with a simpler commonsense extraction method of using a single hop from the query to the context. The results of these are shown in Table 5, where we see that neither NumberBatch nor random-relationships nor single-hop commonsense offer statistically significant improvements[9],

---

(500 examples) held-out part of the training set, and test on the original validation set (by treating it as an unseen test set). We will promptly include the non-public test set results in the next version and at: `https://github.com/yicheng-w/CommonSenseMultiHopQA`

[6] Stat. significance computed using bootstrap test with 100K iterations (Noreen, 1989; Efron and Tibshirani, 1994).

[7] Note that we compare our model's performance to other models' tuned performance on the development set and ours is still equal or better.

[8] All results here are for the standard (non-oracle) unmasked and not-validated dataset. Welbl et al. (2018) has reported higher numbers on different data settings which are not comparable to our results.

[9] The improvement in Rouge-L and METEOR for all three ablation approaches have $p \geq 0.15$ with the bootstrap test.

whereas our commonsense selection and incorporation mechanism improves performance significantly across all metrics. We also present several examples of extracted commonsense and its model attention visualization in the supplementary.

6 Human Evaluation Analysis

We also conduct human evaluation analysis on both the quality of the selected commonsense relations, as well as the performance of our final model.

Commonsense Selection: We conducted manual analysis on a 50 sample subset of the NarrativeQA test set to check the effectiveness of our commonsense selection algorithm. Specifically, given a context-query pair, as well as the commonsense selected by our algorithm, we conduct two independent evaluations: (1) was any external commonsense knowledge necessary for answering the question?; (2) were the commonsense relations provided by our algorithm relevant to the question? The result for these two evaluations as well as how they overlap with each other are shown in Table 6, where we see that 50% of the cases required external commonsense knowledge, and on a majority (34%) of those cases our algorithm was able to select the correct/relevant commonsense information to fill in gaps of inference. We also see that in general, our algorithm was able to provide useful commonsense 48% of the time.

Model Performance: We also conduct human evaluation to verify that our commonsense incorporated model was indeed better than MHPGM. We randomly selected 100 examples from the NarrativeQA test set, along with both models' predicted answers, and for each datapoint, we asked 3 external human evaluators (fluent English speakers) to decide (without knowing which model produced each response) if one is strictly better than the other, or that they were similar in quality (both-good or both-bad). As shown in Table 7, we see that the human evaluation results are in agreement with that of the automatic evaluation metrics: our commonsense incorporation has a reasonable impact on the overall correctness of the model. The inter-annotator agreement had a Fleiss $\kappa = 0.831$, indicating 'almost-perfect' agreement between the annotators (Landis and Koch, 1977).

7 Conclusion

We present an effective reasoning-generative QA architecture that is a novel combination of previous work, which uses multiple hops of bidirectional attention and a pointer-generator decoder to effectively perform multi-hop reasoning and synthesize a coherent and correct answer. Further, we introduce an algorithm to select grounded, useful paths of commonsense knowledge to fill in the gaps of inference required for QA, as well a Necessary and Optional Information Cell (NOIC) which successfully incorporates this information during multi-hop reasoning to achieve the new state-of-the-art on NarrativeQA.

Abstract

Open Domain Question Answering (QA) is evolving from complex pipelined systems to end-to-end deep neural networks. Specialized neural models have been developed for extracting answers from either text alone or Knowledge Bases (KBs) alone. In this paper we look at a more practical setting, namely QA over the combination of a KB and entity-linked text, which is appropriate when an *incomplete* KB is available with a large text corpus. Building on recent advances in graph representation learning we propose a novel model, GRAFT-Net, for extracting answers from a question-specific subgraph containing text and KB entities and relations. We construct a suite of benchmark tasks for this problem, varying the difficulty of questions, the amount of training data, and KB completeness. We show that GRAFT-Net is competitive with the state-of-the-art when tested using either KBs or text alone, and vastly outperforms existing methods in the combined setting.

1 Introduction

Open domain Question Answering (QA) is the task of finding answers to questions posed in natural language. Historically, this required a specialized pipeline consisting of multiple machine-learned and hand-crafted modules (Ferrucci et al., 2010). Recently, the paradigm has shifted towards training end-to-end deep neural network models for the task (Chen et al., 2017; Liang et al., 2017; Raison et al., 2018; Talmor and Berant, 2018; Iyyer et al., 2017). Most existing models, however, answer questions using a *single* information source, usually either text from an encyclopedia, or a single knowledge base (KB).

Intuitively, the suitability of an information source for QA depends on both its *coverage* and the *difficulty* of extracting answers from it. A large text corpus has high coverage, but the information is expressed using many different text patterns. As a result, models which operate on these patterns (e.g. BiDAF (Seo et al., 2017)) do not generalize beyond their training domains (Wiese et al., 2017; Dhingra et al., 2018) or to novel types of reasoning (Welbl et al., 2018; Talmor and Berant, 2018). KBs, on the other hand, suffer from low coverage due to their inevitable incompleteness and restricted schema (Min et al., 2013), but are easier to extract answers from, since they are constructed precisely for the purpose of being queried.

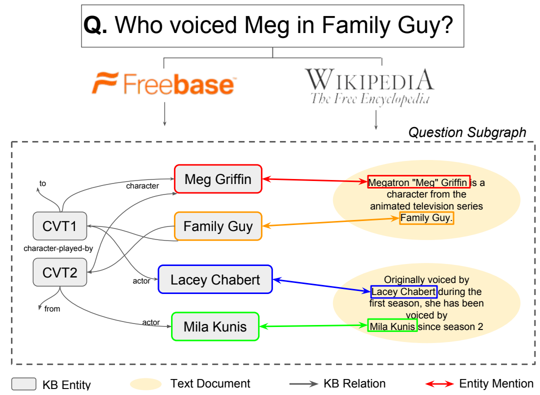

Figure 1: To answer a question posed in natural language, GRAFT-Net considers a heterogeneous graph constructed from text and KB facts, and thus can leverage the rich relational structure between the two information sources.

In practice, some questions are best answered using text, while others are best answered using KBs. A natural question, then, is how to effectively combine both types of information. Surprisingly little prior work has looked at this problem. In this paper we focus on a scenario in which a large-scale KB (Bollacker et al., 2008; Auer et al., 2007) and a text corpus are available, but neither is sufficient alone for answering all questions.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4231–4242
Brussels, Belgium, October 31 - November 4, 2018.

A naïve option, in such a setting, is to take state-of-the-art QA systems developed for each source, and aggregate their predictions using some heuristic (Ferrucci et al., 2010; Baudiš, 2015). We call this approach *late fusion*, and show that it can be sub-optimal, as models have limited ability to aggregate evidence across the different sources (§ 5.4). Instead, we focus on an *early fusion* strategy, where a single model is trained to extract answers from a *question subgraph* (Fig 1) containing relevant KB facts as well as text sentences. Early fusion allows more flexibility in combining information from multiple sources.

To enable early fusion, in this paper we propose a novel graph convolution based neural network, called GRAFT-Net (Graphs of Relations Among Facts and Text Networks), specifically designed to operate over heterogeneous graphs of KB facts and text sentences. We build upon recent work on graph representation learning (Kipf and Welling, 2016; Schlichtkrull et al., 2017), but propose two key modifications to adopt them for the task of QA. First, we propose *heterogeneous update rules* that handle KB nodes differently from the text nodes: for instance, LSTM-based updates are used to propagate information into and out of text nodes (§ 3.2). Second, we introduce a *directed propagation method*, inspired by personalized Pagerank in IR (Haveliwala, 2002), which constrains the propagation of embeddings in the graph to follow paths starting from seed nodes linked to the question (§ 3.3). Empirically, we show that both these extensions are crucial for the task of QA.

We evaluate these methods on a new suite of benchmark tasks for testing QA models when both KB and text are present. Using WikiMovies (Miller et al., 2016) and WebQuestionsSP (Yih et al., 2016), we construct datasets with a varying amount of training supervision and KB completeness, and with a varying degree of question complexity. We report baselines for future comparison, including Key Value Memory Networks (Miller et al., 2016; Das et al., 2017c), and show that our proposed GRAFT-Nets have superior performance across a wide range of conditions (§ 5). We also show that GRAFT-Nets are competitive with the state-of-the-art methods developed specifically for text-only QA, and state-of-the art methods developed for KB-only QA (§ 5.4)[1].

2 Task Setup

2.1 Description

A knowledge base is denoted as $\mathcal{K} = (\mathcal{V}, \mathcal{E}, \mathcal{R})$, where $\mathcal{V}$ is the set of entities in the KB, and the edges $\mathcal{E}$ are triplets (s, r, o) which denote that relation $r \in \mathcal{R}$ holds between the subject $s \in \mathcal{V}$ and object $o \in \mathcal{V}$. A text corpus $\mathcal{D}$ is a set of documents $\{d_1, \dots, d_{|\mathcal{D}|}\}$ where each document is a sequence of words $d_i = (w_1, \dots, w_{|d_i|})$. We further assume that an (imperfect) entity linking system has been run on the collection of documents whose output is a set $\mathcal{L}$ of links (v, d_p) connecting an entity $v \in \mathcal{V}$ with a word at position p in document d, and we denote with $\mathcal{L}_d$ the set of all entity links in document d. For entity mentions spanning multiple words in d, we include links to all the words in the mention in $\mathcal{L}$.

The task is, given a natural language question $q = (w_1, \dots, w_{|q|})$, extract its answers $\{a\}_q$ from $\mathcal{G} = (\mathcal{K}, \mathcal{D}, \mathcal{L})$. There may be multiple correct answers for a question. In this paper, we assume that the answers are entities from either the documents or the KB. We are interested in a wide range of settings, where the KB $\mathcal{K}$ varies from highly incomplete to complete for answering the questions, and we will introduce datasets for testing our models under these settings.

To solve this task we proceed in two steps. First, we extract a subgraph $\mathcal{G}_q \subset \mathcal{G}$ which contains the answer to the question with high probability. The goal for this step is to ensure high recall for answers while producing a graph small enough to fit into GPU memory for gradient-based learning. Next, we use our proposed model GRAFT-Net to learn node representations in $\mathcal{G}_q$, conditioned on q, which are used to classify each node as being an answer or not. Training data for the second step is generated using distant supervision. The entire process mimics the search-and-read paradigm for text-based QA (Dhingra et al., 2017).

2.2 Question Subgraph Retrieval

We retrieve the subgraph $\mathcal{G}_q$ using two parallel pipelines – one over the KB $\mathcal{K}$ which returns a set of entities, and the other over the corpus $\mathcal{D}$ which returns a set of documents. The retrieved entities and documents are then combined with entity links to produce a fully-connected graph.

KB Retrieval. To retrieve relevant entities from the KB we first perform entity linking on the ques-

---

[1] Source code and data are available at `https://github.com/OceanskySun/GraftNet`

tion q, producing a set of *seed entities*, denoted S_q. Next we run the Personalized PageRank (PPR) method (Haveliwala, 2002) around these seeds to identify other entities which might be an answer to the question. The edge-weights around S_q are distributed equally among all edges of the same type, and they are weighted such that edges relevant to the question receive a higher weight than those which are not. Specifically, we average word vectors to compute a relation vector $v(r)$ from the surface form of the relation, and a question vector $v(q)$ from the words in the question, and use cosine similarity between these as the edge weights. After running PPR we retain the top E entities $v_1, \ldots, v_E$ by PPR score, along with any edges between them, and add them to $\mathcal{G}_q$.

Text Retrieval. We use Wikipedia as the corpus and retrieve text at the sentence level, i.e. documents in $\mathcal{D}$ are defined along sentences boundaries[2]. We perform text retrieval in two steps: first we retrieve the top 5 most relevant Wikipedia articles, using the weighted bag-of-words model from DrQA (Chen et al., 2017); then we populate a Lucene[3] index with sentences from these articles, and retrieve the top ranking ones $d_1, \ldots, d_D$, based on the words in the question. For the sentence-retrieval step, we found it beneficial to include the title of the article as an additional field in the Lucene index. As most sentences in an article talk about the title entity, this helps in retrieving relevant sentences that do not explicitly mention the entity in the question. We add the retrieved documents, along with any entities linked to them, to the subgraph $\mathcal{G}_q$.

The final question subgraph is $\mathcal{G}_q = (\mathcal{V}_q, \mathcal{E}_q, \mathcal{R}^+)$, where the vertices $\mathcal{V}_q$ consist of all the retrieved entities and documents, i.e. $\mathcal{V}_q = \{v_1, \ldots, v_E\} \cup \{d_1, \ldots, d_D\}$. The edges are all relations from $\mathcal{K}$ among these entities, plus the entity-links between documents and entities, i.e.

$$\begin{aligned}\mathcal{E}_q = &\{(s, o, r) \in \mathcal{E} : s, o \in \mathcal{V}_q, r \in \mathcal{R}\} \\ &\cup \{(v, d_p, r_L) : (v, d_p) \in \mathcal{L}_d, d \in \mathcal{V}_q\},\end{aligned}$$

where r_L denotes a special "linking" relation. $\mathcal{R}^+ = \mathcal{R} \cup \{r_L\}$ is the set of all edge types in the subgraph.

3 GRAFT-Nets

The question q and its answers $\{a\}_q$ induce a labeling of the nodes in $\mathcal{V}_q$: we let $y_v = 1$ if $v \in \{a\}_q$ and $y_v = 0$ otherwise for all $v \in \mathcal{V}_q$. The task of QA then reduces to performing binary classification over the nodes of the graph $\mathcal{G}_q$. Several graph-propagation based models have been proposed in the literature which learn node representations and then perform classification of the nodes (Kipf and Welling, 2016; Schlichtkrull et al., 2017). Such models follow the standard gather-apply-scatter paradigm to learn the node representation with homogeneous updates, i.e. treating all neighbors equally.

The basic recipe for these models is as follows:

1. Initialize node representations $h_v^{(0)}$.
2. For $l = 1, \ldots, L$ update node representations

$$h_v^{(l)} = \phi\left(h_v^{(l-1)}, \sum_{v' \in N_r(v)} h_{v'}^{(l-1)}\right),$$

where $N_r(v)$ denotes the neighbours of v along incoming edges of type r, and ϕ is a neural network layer.

Here L is the number of *layers* in the model and corresponds to the maximum length of the paths along which information should be propagated in the graph. Once the propagation is complete the final layer representations $h_v^{(L)}$ are used to perform the desired task, for example link prediction in knowledge bases (Schlichtkrull et al., 2017).

However, there are two differences in our setting from previously studied graph-based classification tasks. The first difference is that, in our case, the graph $\mathcal{G}_q$ consists of *heterogeneous* nodes. Some nodes in the graph correspond to KB entities which represent symbolic objects, whereas other nodes represent textual documents which are variable length sequences of words. The second difference is that we want to condition the representation of nodes in the graph on the natural language question q. In §3.2 we introduce heterogeneous updates to address the first difference, and in §3.3 we introduce mechanisms for conditioning on the question (and its entities) for the second.

3.1 Node Initialization

Nodes corresponding to entities are initialized using fixed-size vectors $h_v^{(0)} = x_v \in \mathbb{R}^n$, where

---

[2] The term *document* will always refer to a sentence in the rest of this paper.

[3] `https://lucene.apache.org/`

x_v can be pre-trained KB embeddings or random, and n is the embedding size. Document nodes in the graph describe a variable length sequence of text. Since multiple entities might link to different positions in the document, we maintain a variable length representation of the document in each layer. This is denoted by $H_d^{(l)} \in \mathbb{R}^{|d| \times n}$. Given the words in the document $(w_1, \ldots, w_{|d|})$, we initialize its hidden representation as:

$$H_d^{(0)} = \text{LSTM}(w_1, w_2, \ldots),$$

where LSTM refers to a long short-term memory unit. We denote the p-th row of $H_d^{(l)}$, corresponding to the embedding of p-th word in the document d at layer l, as $H_{d,p}^{(l)}$.

3.2 Heterogeneous Updates

Figure 2 shows the update rules for entities and documents, which we describe in detail here.

Entities. Let $M(v) = \{(d,p)\}$ be the set of positions p in documents d which correspond to a mention of entity v. The update for entity nodes involves a single-layer feed-forward network (FFN) over the concatenation of four states:

$$h_v^{(l)} = \text{FFN}\left(\begin{bmatrix} h_v^{(l-1)} \\ h_q^{(l-1)} \\ \sum_r \sum_{v' \in N_r(v)} \alpha_r^{v'} \psi_r(h_{v'}^{(l-1)}) \\ \sum_{(d,p) \in M(v)} H_{d,p}^{(l-1)} \end{bmatrix}\right). \quad (1)$$

The first two terms correspond to the entity representation and question representation (details below), respectively, from the previous layer.

The third term aggregates the states from the entity neighbours of the current node, $N_r(v)$, after scaling with an attention weight $\alpha_r^{v'}$ (described in the next section), and applying relation specific transformations ψ_r. Previous work on Relational-Graph Convolution Networks (Schlichtkrull et al., 2017) used a linear projection for ψ_r. For a batched implementation, this results in matrices of size $O(B|\mathcal{R}_q||\mathcal{E}_q|n)$, where B is the batch size, which can be prohibitively large for large subgraphs[4]. Hence in this work we use *relation vectors* x_r for $r \in \mathcal{R}_q$ instead of matrices, and compute the update along an edge as:

$$\psi_r(h_{v'}^{(l-1)}) = pr_{v'}^{(l-1)} \text{FFN}\left(x_r, h_{v'}^{(l-1)}\right). \quad (2)$$

Here $pr_{v'}^{(l-1)}$ is a PageRank score used to control the propagation of embeddings along paths starting from the seed nodes, which we describe in detail in the next section. The memory complexity of the above is $O(B(|\mathcal{F}_q| + |\mathcal{E}_q|)n)$, where $|\mathcal{F}_q|$ is the number of facts in the subgraph $\mathcal{G}_q$.

The last term aggregates the states of all tokens that correspond to mentions of the entity v among the documents in the subgraph. Note that the update depends on the positions of entities in their containing document.

Documents. Let $L(d,p)$ be the set of all entities linked to the word at position p in document d. The document update proceeds in two steps. First we aggregate over the entity states coming in at each position separately:

$$\tilde{H}_{d,p}^{(l)} = \text{FFN}\left(H_{d,p}^{(l-1)}, \sum_{v \in L(d,p)} h_v^{(l-1)}\right). \quad \text{(3a)}$$

Here $h_v^{(l-1)}$ are normalized by the number of outgoing edges at v. Next we aggregate states within the document using an LSTM:

$$H_d^{(l)} = \text{LSTM}(\tilde{H}_d^{(l)}). \quad \text{(3b)}$$

3.3 Conditioning on the Question

For the parts described thus far, the graph learner is largely agnostic of the question. We introduce dependence on question in two ways: by attention over relations, and by personalized propagation.

To represent q, let $w_1^q, \ldots, w_{|q|}^q$ be the words in the question. The initial representation is computed as:

$$h_q^{(0)} = \text{LSTM}(w_1^q, \ldots, w_{|q|}^q)_{|q|} \in \mathbb{R}^n, \quad (4)$$

where we extract the final state from the output of the LSTM. In subsequent layers the question representation is updated as $h_q^{(l)} = \text{FFN}\left(\sum_{v \in S_q} h_v^{(l)}\right)$, where S_q denotes the seed entities mentioned in the question.

Attention over Relations. The attention weight in the third term of Eq. (1) is computed using the question and relation embeddings:

$$\alpha_r^{v'} = \text{softmax}(x_r^T h_q^{(l-1)}),$$

where the softmax normalization is over all outgoing edges from v', and x_r is the relation vector for relation r. This ensures that embeddings are propagated more along edges relevant to the question.

---

[4] This is because we have to use adjacency matrices of size $|\mathcal{R}_q| \times |\mathcal{E}_q| \times |\mathcal{E}_q|$ to aggregate embeddings from neighbours of all nodes simultaneously.

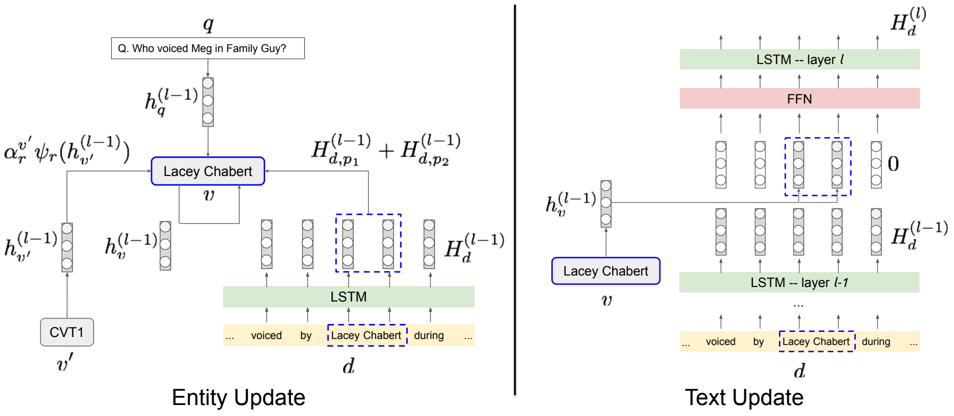

Figure 2: Illustration of the heterogeneous update rules for entities (**left**) and text documents (**right**)

Directed Propagation. Many questions require multi-hop reasoning, which follows a path from a seed node mentioned in the question to the target answer node. To encourage such a behaviour when propagating embeddings, we develop a technique inspired from personalized PageRank in IR (Haveliwala, 2002). The propagation starts at the seed entities S_q mentioned in the question. In addition to the vector embeddings $h_v^{(l)}$ at the nodes, we also maintain scalar "PageRank" scores $pr_v^{(l)}$ which measure the total weight of paths from a seed entity to the current node, as follows:

$$pr_v^{(0)} = \begin{cases} \frac{1}{|S_q|} & \text{if} \quad v \in S_q \\ 0 & \text{o.w.} \end{cases},$$

$$pr_v^{(l)} = (1-\lambda)pr_v^{(l-1)} + \lambda \sum_r \sum_{v' \in N_r(v)} \alpha_r^{v'} pr_{v'}^{(l-1)}.$$

Notice that we reuse the attention weights $\alpha_r^{v'}$ when propagating PageRank, to ensure that nodes along paths relevant to the question receive a high weight. The PageRank score is used as a scaling factor when propagating embeddings along the edges in Eq. (2). For $l = 1$, the PageRank score will be 0 for all entities except the seed entities, and hence propagation will only happen outward from these nodes. For $l = 2$, it will be non-zero for the seed entities and their 1-hop neighbors, and propagation will only happen along these edges. Figure 3 illustrates this process.

3.4 Answer Selection

The final representations $h_v^{(L)} \in \mathbb{R}^n$, are used for binary classification to select the answers:

$$\Pr\left(v \in \{a\}_q | \mathcal{G}_q, q\right) = \sigma(w^T h_v^{(L)} + b), \tag{5}$$

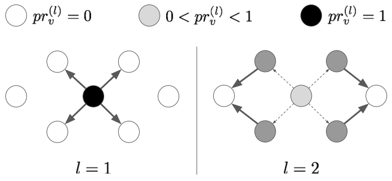

Figure 3: Directed propagation of embeddings in GRAFT-Net. A scalar *PageRank* score $pr_v^{(l)}$ is maintained for each node v across layers, which spreads out from the seed node. Embeddings are only propagated from nodes with $pr_v^{(l)} > 0$.

where σ is the sigmoid function. Training uses binary cross-entropy loss over these probabilities.

3.5 Regularization via Fact Dropout

To encourage the model to learn a robust classifier, which exploits all available sources of information, we randomly drop edges from the graph during training with probability p_0. We call this *fact-dropout*. It is usually easier to extract answers from the KB than from the documents, so the model tends to rely on the former, especially when the KB is complete. This method is similar to DropConnect (Wan et al., 2013).

4 Related Work

The work of Das et al. (2017c) attempts an early fusion strategy for QA over KB facts and text. Their approach is based on Key-Value Memory Networks (KV-MemNNs) (Miller et al., 2016) coupled with a universal schema (Riedel et al., 2013) to populate a memory module with representations of KB triples and text snippets independently. The key limitation for this model is that it ignores the rich relational structure between the facts and text snippets. Our graph-based method, on the other hand, explicitly uses this structure for the propagation of embeddings. We compare the two approaches in our experiments (§5), and show that GRAFT-Nets outperform KV-MemNNs over all tasks.

Non-deep learning approaches have been also attempted for QA over both text assertions and KB facts. Gardner and Krishnamurthy (2017) use traditional feature extraction methods of open-vocabulary semantic parsing for the task. Ryu et al. (2014) use a pipelined system aggregating evidence from both unstructured and semi-structured sources for open-domain QA.

Another line of work has looked at learning combined representations of KBs and text for relation extraction and Knowledge Base Completion (KBC) (Lao et al., 2012; Riedel et al., 2013; Toutanova et al., 2015; Verga et al., 2016; Das et al., 2017b; Han et al., 2016). The key difference in QA compared to KBC is that in QA the inference process on the knowledge source has to be conditioned on the question, so different questions induce different representations of the KB and warrant a different inference process. Furthermore, KBC operates under the fixed schema defined by the KB before-hand, whereas natural language questions might not adhere to this schema.

The GRAFT-Net model itself is motivated from the large body of work on graph representation learning (Scarselli et al., 2009; Li et al., 2016; Kipf and Welling, 2016; Atwood and Towsley, 2016; Schlichtkrull et al., 2017). Like most other graph-based models, GRAFT-Nets can also be viewed as an instantiation of the Message Passing Neural Network (MPNN) framework of Gilmer et al. (2017). GRAFT-Nets are also *inductive* representation learners like GraphSAGE (Hamilton et al., 2017), but operate on a heterogeneous mixture of nodes and use retrieval for getting a subgraph instead of random sampling. The recently proposed Walk-Steered Convolution model uses random walks for learning graph representations (Jiang et al., 2018). Our personalization technique also borrows from such random walk literature, but uses it to localize propagation of embeddings.

Tremendous progress on QA over KB has been made with deep learning based approaches like memory networks (Bordes et al., 2015; Jain, 2016) and reinforcement learning (Liang et al., 2017; Das et al., 2017a). But extending them with text, which is our main focus, is non-trivial. In another direction, there is also work on producing parsimonious graphical representations of textual data (Krause et al., 2016; Lu et al., 2017); however in this paper we use a simple sequential representation augmented with entity links to the KB which works well.

For QA over text only, a major focus has been on the task of reading comprehension (Seo et al., 2017; Gong and Bowman, 2017; Hu et al., 2017; Shen et al., 2017; Yu et al., 2018) since the introduction of SQuAD (Rajpurkar et al., 2016). These systems assume that the answer-containing passage is known apriori, but there has been progress when this assumption is relaxed (Chen et al., 2017; Raison et al., 2018; Dhingra et al., 2017; Wang et al., 2018, 2017; Watanabe et al., 2017). We work in the latter setting, where relevant information must be retrieved from large information sources, but we also incorporate KBs into this process.

5 Experiments & Results

5.1 Datasets

WikiMovies-10K consists of $10K$ randomly sampled training questions from the WikiMovies dataset (Miller et al., 2016), along with the original test and validation sets. We sample the training questions to create a more difficult setting, since the original dataset has $100K$ questions over only 8 different relation types, which is unrealistic in our opinion. In § 5.4 we also compare to the existing state-of-the-art using the full training set.

We use the KB and text corpus constructed from Wikipedia released by Miller et al. (2016). For entity linking we use simple surface level matches, and retrieve the top 50 entities around the seeds to create the question subgraph. We further add the top 50 sentences (along with their article titles) to the subgraph using Lucene search over the text corpus. The overall answer recall in our constructed subgraphs is 99.6%.

WebQuestionsSP (Yih et al., 2016) consists of 4737 natural language questions posed over Freebase entities, split up into 3098 training and 1639 test questions. We reserve 250 training questions for model development and early stopping. We use the entity linking outputs from S-MART[5] and retrieve 500 entities from the neighbourhood around the question seeds in Freebase to populate the

---

[5] `https://github.com/scottyih/STAGG`

question subgraphs[6]. We further retrieve the top 50 sentences from Wikipedia with the two-stage process described in §2. The overall recall of answers among the subgraphs is 94.0%.

Table 1 shows the combined statistics of all the retreived subgraphs for the questions in each dataset. These two datasets present varying levels of difficulty. While all questions in WikiMovies correspond to a single KB relation, for WebQuestionsSP the model needs to aggregate over two KB facts for ∼30% of the questions, and also requires reasoning over constraints for ∼7% of the questions (Liang et al., 2017). For maximum portability, QA systems need to be robust across several degrees of KB availability since different domains might contain different amounts of structured data; and KB completeness may also vary over time. Hence, we construct an additional 3 datasets each from the above two, with the number of KB facts downsampled to 10%, 30% and 50% of the original to simulate settings where the KB is incomplete. We repeat the retrieval process for each sampled KB.

5.2 Compared Models

KV-KB is the Key Value Memory Networks model from Miller et al. (2016); Das et al. (2017c) but using only KB and ignoring the text. **KV-EF** (early fusion) is the same model with access to both KB and text as memories. For text we use a BiLSTM over the entire sentence as keys, and entity mentions as values. This re-implementation shows better performance on the text-only and KB-only WikiMovies tasks than the results reported previously[7] (see Table 4). **GN-KB** is the GRAFT-Net model ignoring the text. **GN-LF** is a late fusion version of the GRAFT-Net model: we train two separate models, one using text only and the other using KB only, and then ensemble the two[8]. **GN-EF** is our main GRAFT-Net model with early fusion. **GN-EF+LF** is an ensemble over the GN-EF and GN-LF models, with the same ensembling method as GN-LF. We report Hits@1, which is the accuracy of the top-predicted answer from the model, and the F1 score. To compute the F1 score we tune a threshold on the development set to select answers based on binary probabilities for each node in the subgraph.

5.3 Main Results

Table 2 presents a comparison of the above models across all datasets. GRAFT-Nets (GN) shows consistent improvement over KV-MemNNs on both datasets in all settings, including KB only (-KB), text only (-EF, Text Only column), and early fusion (-EF). Interestingly, we observe a larger relative gap between the Hits and F1 scores for the KV models than we do for our GN models. We believe this is because the attention for KV is normalized over the memories, which are KB facts (or text sentences): hence the model is unable to assign high probabilities to multiple facts at the same time. On the other hand, in GN, we normalize the attention over *types of relations* outgoing from a node, and hence can assign high weights to all the correct answers.

We also see a consistent improvement of early fusion over late fusion (-LF), and by ensembling them together we see the best performance across all the models. In Table 2 (right), we further show the improvement for KV-EF over KV-KB, and GN-LF and GN-EF over GN-KB, as the amount of KB is increased. This measures how effective these approaches are in utilizing text plus a KB. For KV-EF we see improvements when the KB is highly incomplete, but in the full KB setting, the performance of the fused approach is worse. A similar trend holds for GN-LF. On the other hand, GN-EF with text improves over the KB-only approach in all settings. As we would expect, though, the benefit of adding text decreases as the KB becomes more and more complete.

5.4 Comparison to Specialized Methods

In Table 4 we compare GRAFT-Nets to state-of-the-art models that are specifically designed and tuned for QA using either only KB or only text. For this experiment we use the full WikiMovies dataset to enable direct comparison to previously reported numbers. For DrQA (Chen et al., 2017), following the original paper, we restrict answer spans for WebQuestionsSP to match an entity in Freebase. In each case we also train GRAFT-Nets using only KB facts or only text sentences. In three out of the four cases, we find that GRAFT-Nets ei-

---

[6] A total of 13 questions had no detected entities. These were ignored during training and considered as incorrect during evaluation.

[7] For all KV models we tuned the number of layers $\{1, 2, 3\}$, batch size $\{10, 30, 50\}$, model dimension $\{50, 80\}$. We also use fact dropout regularization in the KB+Text setting tuned between $\{0, 0.2, 0.4\}$.

[8] For ensembles we take a weighted combination of the answer probabilities produced by the models, with the weights tuned on the dev set. For answers only in text or only in KB, we use the probability as is.

Table 2: **Left:** Hits@1 / F1 scores of GRAFT-Nets (GN) compared to KV-MemNN (KV) in KB only (-KB), early fusion (-EF), and late fusion (-LF) settings. **Right:** Improvement of early fusion (-EF) and late fusion (-LF) over KB only (-KB) settings as KB completeness increases.

ther match or outperform the existing state-of-the-art models. We emphasize that the latter have no mechanism for dealing with the fused setting.

The one exception is the KB-only case for WebQuestionsSP where GRAFT-Net does 6.2% F1 points worse than Neural Symbolic Machines (Liang et al., 2017). Analysis suggested three explanations: (1) In the KB-only setting, the recall of subgraph retrieval is only 90.2%, which limits overall performance. In an oracle setting where we ensure the answers are part of the subgraph, the F1 score increases by 4.8%. (2) We use the same probability threshold for all questions, even though the number of answers may vary significantly. Models which parse the query into a symbolic form do not suffer from this problem since answers are retrieved in a deterministic fashion. If we tune separate thresholds for each question the F1 score improves by 7.6%. (3) GRAFT-Nets perform poorly in the few cases where there is a constraint involved in picking out the answer (for example, "who *first* voiced Meg in Family Guy"). If we ignore such constraints, and consider all entities with the same sequence of relations to the seed as correct, the performance improves by 3.8% F1. Heuristics such as those used by Yu et al. (2017) can be used to improve these cases. Figure 3 shows examples where GRAFT-Net fails to predict the correct answer set exactly.

5.5 Effect of Model Components

Heterogeneous Updates. We tested a non-heterogeneous version of our model, where instead of using fine-grained entity linking information for updating the node representations ($M(v)$ and $L(d,p)$ in Eqs. 1, 3a), we aggregate the document states across all its positions as $\sum_p H_{d,p}^{(l)}$ and use this combined state for all updates. Without the heterogeneous update, all entities $v \in L(d,\cdot)$ will receive the same update from document d. Therefore, the model cannot disambiguate different entities mentioned in the same document. The result in Table 5 shows that this version is consistently worse than the heterogeneous model.

Conditioning on the Question. We performed an ablation test on the directed propagation method and attention over relations. We observe that both components lead to better performance. Such effects are observed in both complete and incomplete KB scenarios, e.g. on WebQuestionsSP dataset, as shown in Figure 4 (left).

Fact Dropout. Figure 4 (right) compares the performance of the early fusion model as we vary

the rate of fact dropout. Moderate levels of fact dropout improve performance on both datasets. The performance increases as the fact dropout rate increases until the model is unable to learn the inference chain from KB.

6 Conclusion

In this paper we investigate QA using text combined with an incomplete KB, a task which has received limited attention in the past. We introduce several benchmark problems for this task by modifying existing question-answering datasets, and discuss two broad approaches to solving this problem—"late fusion" and "early fusion". We show that early fusion approaches perform better.

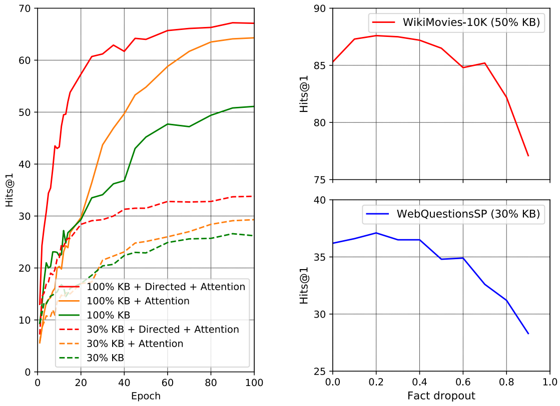

Figure 4: **Left:** Effect of directed propagation and query-based attention over relations for the WebQuestionsSP dataset with 30% KB and 100% KB. **Right:** Hits@1 with different rates of fact-dropout on and WikiMovies and WebQuestionsSP.

We also introduce a novel early-fusion model, called GRAFT-Net, for classifying nodes in subgraph consisting of both KB entities and text documents. GRAFT-Net builds on recent advances in graph representation learning but includes several innovations which improve performance on this task. GRAFT-Nets are a single model which achieve performance competitive to state-of-the-art methods in both text-only and KB-only settings, and outperform baseline models when using text combined with an incomplete KB. Current directions for future work include – (1) extending GRAFT-Nets to pick spans of text as answers, rather than only entities and (2) improving the subgraph retrieval process.

A Nil-Aware Answer Extraction Framework for Question Answering

Souvik Kundu and **Hwee Tou Ng**
Department of Computer Science
National University of Singapore
`{souvik, nght}@comp.nus.edu.sg`

Abstract

Recently, there has been a surge of interest in reading comprehension-based (RC) question answering (QA). However, current approaches suffer from an impractical assumption that every question has a valid answer in the associated passage. A practical QA system must possess the ability to determine whether a valid answer exists in a given text passage. In this paper, we focus on developing QA systems that can extract an answer for a question if and only if the associated passage contains an answer. If the associated passage does not contain any valid answer, the QA system will correctly return *Nil*. We propose a nil-aware answer span extraction framework that is capable of returning *Nil* or a text span from the associated passage as an answer in a single step. We show that our proposed framework can be easily integrated with several recently proposed QA models developed for reading comprehension and can be trained in an end-to-end fashion. Our proposed nil-aware answer extraction neural network decomposes pieces of evidence into relevant and irrelevant parts and then combines them to infer the existence of any answer. Experiments on the NewsQA dataset show that the integration of our proposed framework significantly outperforms several strong baseline systems that use pipeline or threshold-based approaches.

1 Introduction

Machine comprehension (MC) systems mimic the process of reading comprehension (RC) by answering questions after understanding natural language text. Several datasets and resources have been developed recently. Richardson et al. (2013) developed a small-scale multiple-choice question answering (QA) dataset. Hermann et al. (2015) created a large cloze-style MC dataset based on CNN and Daily Mail news article summaries. However, Chen et al. (2016) reported that the task is not challenging enough and hence, advanced models had to be evaluated on more realistic datasets. Subsequently, SQuAD (Rajpurkar et al., 2016) was released, where, unlike previous datasets, the answers to different questions can vary in length.

In previous datasets, questions and answers are formulated given text passages. Hence, a valid answer can always be found in the associated passage for every question created. Trischler et al. (2017) proposed a more challenging and realistic dataset, NewsQA, where the questions were formed using CNN article summaries without accessing the original full texts. As such, some questions have no valid answers in the associated passages (referred to as nil questions).

Recently, several neural models for answer span extraction have been proposed (Wang and Jiang, 2017; Seo et al., 2017; Yang et al., 2017; Xiong et al., 2017; Weissenborn et al., 2017; Wang et al., 2017; Shen et al., 2017b; Chen et al., 2017; Kundu and Ng, 2018). However, none of the models considered nil questions, although it is crucial for a practical QA system to be able to determine whether a text passage contains a valid answer for a question. In this paper, we focus on developing QA systems that extract an answer for a question if and only if the associated passage contains a valid answer. Otherwise, they are expected to return *Nil* as answer. We propose a nil-aware answer extraction framework which returns *Nil* or a span of text as answer, when integrated with end-to-end neural MC models. Our proposed framework is based on evidence decomposition-aggregation, where the evidence vectors derived by a higher level encoding layer are first decomposed into relevant and irrelevant components and later aggregated to infer the existence of a valid answer. In addition, we develop several baseline models with pipeline and threshold-based approaches. In a

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4243–4252
Brussels, Belgium, October 31 - November 4, 2018.

pipeline model, detection of nil questions is carried out separately before answer span extraction. In a threshold-based model, the answer span extraction model is entirely trained on questions that have valid answers, and *Nil* is returned based on a confidence threshold.

The contributions of this paper are as follows: (1) We propose a nil-aware answer span extraction framework to return *Nil* or an exact answer span to a question, in a single step, depending on the existence of a valid answer. (2) Our proposed framework can be readily integrated with many recently proposed neural machine comprehension models. In this paper, we extend four machine comprehension models, namely BiDAF (Seo et al., 2017), R-Net (Wang et al., 2017), DrQA (Chen et al., 2017), and AMANDA (Kundu and Ng, 2018), with our proposed framework, and show that they achieve significantly better results compared to the corresponding pipeline and threshold-based models on the NewsQA dataset.

2 Task Definition

Given a passage and a question, we propose models that can extract an answer if and only if the passage contains an answer. When the passage does not contain any answer, the models return *Nil* as the answer. A valid answer is denoted as two pointers in the passage, representing the start and end tokens of the answer span. Let $\mathcal{P}$ be a passage with tokens $(\mathcal{P}_1, \mathcal{P}_2, \ldots, \mathcal{P}_T)$ and $\mathcal{Q}$ be a question with tokens $(\mathcal{Q}_1, \mathcal{Q}_2, \ldots, \mathcal{Q}_U)$, where T and U are the length of the passage and question respectively. A system needs to determine whether the answer is *Nil* or comprises two pointers, b and e, such that $1 \leq b \leq e \leq T$.

3 Proposed Framework

In this section, we first describe our proposed evidence decomposition-aggregation framework for nil-aware answer extraction. Then, we provide a detailed description of how we extend a state-of-the-art model AMANDA (Kundu and Ng, 2018) to NAMANDA[1] (nil-aware AMANDA). We also provide brief descriptions of how we integrate our proposed framework with the other three models.

3.1 Nil-Aware Answer Extraction

Decomposition of lexical semantics over sentences has been successfully used in the past for sentence similarity learning (Wang et al., 2016). Most of the recently proposed machine reading comprehension models can be generalized based on a common pattern observed in their network architecture. They have a question-passage joint encoding layer (also known as question-aware passage encoding layer) followed by an evidence encoding layer. In this work, we decompose the evidence vectors for each passage word obtained from the evidence encoding layer with respect to question-passage joint encoding vectors to derive semantically relevant and irrelevant components. We decompose the evidence vectors for each passage word, because passage vectors can be partially supported by the corresponding question-passage joint encoding vectors, and based on the level of support, it either increases or decreases the chance of finding a valid answer. When we aggregate the orthogonally decomposed evidence vectors, it combines both the supportive and unsupportive pieces of evidence for a particular passage word. To obtain the most impactful portions, we perform a max-pooling operation over all the aggregated vectors. The resulting vector is denoted as the Nil vector. As the training set contains both nil questions (with no valid answers) and non-nil questions (with valid answers), the model automatically learns when to pool unsupportive (for nil questions) and supportive (for non-nil questions) portions to construct the Nil vector. In this way, the model is able to induce a strong bias towards the nil pointer when there is no answer present due to the dominance of unsupportive components in the nil vector.

The proposed method in Wang et al. (2016) was developed for sentence similarity learning tasks, such as answer sentence selection. They decompose an answer sentence with respect to a question and vice versa. The decomposed vectors are then aggregated to obtain a single vector which is used to derive the similarity score. Although our proposed method (developed for the more complex task of answer span extraction) is inspired from the idea of lexical decomposition and composition, one major difference is that we decompose the evidence vectors with respect to question-passage joint encoding vectors. Another important advance is how it is adopted to return nil or a span

---

[1] Our source code is available at `https://github.com/nusnlp/namanda`

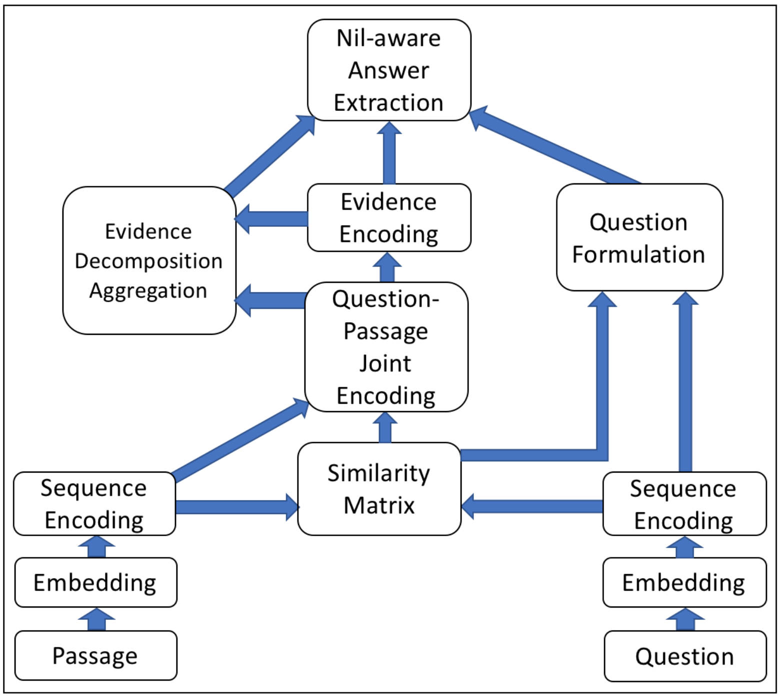

Figure 1: Overview of the architecture of Nil-aware AMANDA (NAMANDA).

of text from the passage in a single step.

3.2 Nil-Aware AMANDA

The architecture of Nil-aware AMANDA (NAMANDA) is given in Figure 1.

3.2.1 Embeddings

To obtain the embeddings, we concatenate word and character-level embedding vectors. We use pre-trained vectors from GloVe (Pennington et al., 2014) for word-level embeddings. For character embeddings, a trainable character-based lookup table is used followed by a convolutional neural network (CNN) and max-pooling (Kim, 2014).

3.2.2 Sequence Encoding

We use bi-directional LSTM (BiLSTM) (Hochreiter and Schmidhuber, 1997) on the embedding vectors to incorporate contextual information. We represent the outputs as $\mathbf{D} \in \mathbb{R}^{T \times H}$ and $\mathbf{Q} \in \mathbb{R}^{U \times H}$ for passage and question respectively. H is the number of hidden units of the BiLSTMs.

3.2.3 Similarity Matrix

The similarity matrix is obtained by computing the dot product of passage and question sequence-level encoding vectors. The similarity matrix $\mathbf{A} \in \mathbb{R}^{T \times U}$ can be expressed as $\mathbf{A} = \mathbf{D}\ \mathbf{Q}^{\top}$, where $A_{i,j}$ is the similarity between the ith passage word and the jth question word.

3.2.4 Question Formulation

To aggregate the most relevant parts of the question, column-wise maximum values of $\mathbf{A}$ are normalized using a softmax function to obtain $\mathbf{k} \in \mathbb{R}^{U}$. Then, the question vectors in $\mathbf{Q}$ are aggregated by $\mathbf{q}_{ma} = \mathbf{k}\ \mathbf{Q}$. The question type information is incorporated via $\mathbf{q}_f \in \mathbb{R}^{2H}$, by concatenating the sequence-level question encoding vectors of the first wh-word $\mathbf{q}_{t_{wh}}$ and its following word $\mathbf{q}_{t_{wh}+1}$. It can be given as $\mathbf{q}_f = \mathbf{q}_{t_{wh}} \,||\, \mathbf{q}_{t_{wh}+1}$, where $||$ denotes the concatenation operation. The set of wh-words we used is $\{$*what, who, how, when, which, where, why*$\}$. The final question representation, $\tilde{\mathbf{q}} \in \mathbb{R}^{H}$, is formulated by applying a feed-forward neural network on the concatenated representation of $\mathbf{q}_{ma}$ and $\mathbf{q}_f$.

3.2.5 Question-Passage Joint Encoding

In this step, we jointly encode the passage and question. We apply a row-wise softmax function on $\mathbf{A}$ to obtain $\mathbf{R} \in \mathbb{R}^{T \times U}$. Now, for all the passage words, the aggregated question representation $\mathbf{G} \in \mathbb{R}^{T \times H}$ is computed by $\mathbf{G} = \mathbf{R}\ \mathbf{Q}$. The aggregated question vectors corresponding to the passage words are then concatenated with the sequence-level passage vectors to obtain $\mathbf{S} \in \mathbb{R}^{T \times 2H}$. We apply another BiLSTM to obtain a combined representation $\mathbf{V} \in \mathbb{R}^{T \times H}$.

3.2.6 Evidence Decomposition-Aggregation

First, multi-factor self-attentive encoding is applied to accumulate evidence from the entire passage. The use of multiple factors while calculating self attention helps to obtain meaningful information from a long context with fine-grained inference. If m represents the number of factors, multi-factor attention $\mathbf{F}^{[1:m]} \in \mathbb{R}^{T \times m \times T}$ is formulated as:

$$\mathbf{F}^{[1:m]} = \mathbf{V}\, \mathbf{W}_f^{[1:m]}\, \mathbf{V}^\top \ , \tag{1}$$

where $\mathbf{W}_f^{[1:m]} \in \mathbb{R}^{H \times m \times H}$ is a 3-way tensor. Now, to refine the evidence, a max-pooling operation is performed on $\mathbf{F}^{[1:m]}$ over the number of factors, resulting in the self-attention matrix $\mathbf{F} \in \mathbb{R}^{T \times T}$. We normalize $\mathbf{F}$ by applying a row-wise softmax function, resulting in $\tilde{\mathbf{F}} \in \mathbb{R}^{T \times T}$. Now the self-attentive encoding $\mathbf{M} \in \mathbb{R}^{T \times H}$ can be given as $\mathbf{M} = \tilde{\mathbf{F}}\ \mathbf{V}$. The self-attentive encoding vectors are then concatenated with the question-dependent passage word encoding vectors ($\mathbf{V}$), and a feed-forward neural network-based gating is applied to control the overall impact, resulting in $\mathbf{Y} \in \mathbb{R}^{T \times 2H}$.

Then we decompose the evidence vector for every passage word with orthogonal decomposition. Each row of $\mathbf{Y}$, $\mathbf{y}_t \in \mathbb{R}^{2H}$, is decomposed into its parallel and perpendicular components with respect to the corresponding question-passage joint encoding ($\mathbf{S}$) vector, $\mathbf{s}_t \in \mathbb{R}^{2H}$. The parallel components represent the relevant parts of the accumulated evidence and the orthogonal components represent the irrelevant counterparts. If the parallel component of $\mathbf{y}_t$ is represented as $\mathbf{y}_t^{=} \in \mathbb{R}^{2H}$ and the perpendicular component is represented as $\mathbf{y}_t^{\perp} \in \mathbb{R}^{2H}$, then

$$\mathbf{y}_t^{=} = \frac{\mathbf{y}_t\, \mathbf{s}_t^\top}{\mathbf{s}_t\, \mathbf{s}_t^\top}\, \mathbf{s}_t \tag{2}$$

$$\mathbf{y}_t^{\perp} = \mathbf{y}_t - \mathbf{y}_t^{=} \tag{3}$$

Similarly, we derive the parallel and orthogonal vectors for all the passage words. We denote parallel components with $\mathbf{Y}^{=} \in \mathbb{R}^{T \times 2H}$ and perpendicular components with $\mathbf{Y}^{\perp} \in \mathbb{R}^{T \times 2H}$.

In the aggregation step, the parallel and orthogonal components are fed to a feed-forward linear layer. $\mathbf{Y}^a \in \mathbb{R}^{T \times H}$ denotes the output of the linear layer and $\mathbf{y}_t^a \in \mathbb{R}^H$ is its tth row:

$$\mathbf{y}_t^a = \tanh(\mathbf{y}_t^{=}\mathbf{W}_a + \mathbf{y}_t^{\perp}\mathbf{W}_a + \mathbf{b}_a) \ , \tag{4}$$

where $\mathbf{W}_a \in \mathbb{R}^{2H \times H}$ and $\mathbf{b}_a \in \mathbb{R}^H$ are the weight matrix and bias vector respectively. Then we apply a max-pooling operation over all the words to obtain the *Nil* vector representation denoted as $\hat{\mathbf{n}}$. Now we derive the score for the *Nil* pointer which will be shared for normalizing the beginning and ending pointers later. The *Nil* pointer score is given as:

$$n_s = \hat{\mathbf{n}}\mathbf{w}_n^\top \ , \tag{5}$$

where $\mathbf{w}_n \in \mathbb{R}^H$ is a learnable weight vector.

3.2.7 Nil-Aware Pointing

Two stacked BiLSTMs are used on top of $\mathbf{Y}$ to determine the beginning and ending pointers. Let the hidden unit representations of these two BiLSTMs be $\mathbf{B} \in \mathbb{R}^{T \times H}$ and $\mathbf{E} \in \mathbb{R}^{T \times H}$. We measure the similarity scores between the previously derived question vector $\tilde{\mathbf{q}}$ and the contextual encoding vectors in $\mathbf{B}$ and $\mathbf{E}$. If $\mathbf{s}_b \in \mathbb{R}^T$ and $\mathbf{s}_e \in \mathbb{R}^T$ are the scores for the beginning and ending pointers, then

$$\mathbf{s}_b = \tilde{\mathbf{q}}\, \mathbf{B}^\top \ , \ \mathbf{s}_e = \tilde{\mathbf{q}}\, \mathbf{E}^\top \tag{6}$$

We prepend the *nil* score n_s to $\mathbf{s}_b$ and $\mathbf{s}_e$ for shared normalization. The updated scores $\hat{\mathbf{s}}_b \in \mathbb{R}^{T+1}$ and $\hat{\mathbf{s}}_e \in \mathbb{R}^{T+1}$ can be represented as:

$$\hat{\mathbf{s}}_b = [n_s, \mathbf{s}_b] \ , \ \hat{\mathbf{s}}_e = [n_s, \mathbf{s}_e] \tag{7}$$

The beginning and ending pointer probability distributions for a given passage $\mathcal{P}$ and a question $\mathcal{Q}$ is given as:

$$\begin{aligned} \Pr(b \mid \mathcal{P}, \mathcal{Q}) &= \text{softmax}(\hat{\mathbf{s}}_b) \\ \Pr(e \mid \mathcal{P}, \mathcal{Q}) &= \text{softmax}(\hat{\mathbf{s}}_e) \end{aligned} \tag{8}$$

The joint probability distribution for answer a is given as:

$$\Pr(a \mid \mathcal{P}, \mathcal{Q}) = \Pr(b \mid \mathcal{P}, \mathcal{Q})\, \Pr(e \mid \mathcal{P}, \mathcal{Q}) \tag{9}$$

For training, we minimize the cross entropy loss summing over all training instances. During prediction, we select the locations in the passage for which the product of $\Pr(b)$ and $\Pr(e)$ is maximized, where $1 \le b \le e \le T + 1$. If the value of b is 1, we assign the answer as *Nil*.

3.3 Nil-Aware DrQA

We extend DrQA (Chen et al., 2017) to NDrQA by integrating our proposed nil-aware answer extraction framework. In DrQA, the embeddings of passage tokens consist of pretrained word vectors from Glove, several syntactic features, and passage-question joint embedding (aligned question embedding). The syntactic features include exact match of passage words with question in surface, lowercase, and lemma form. They also used part-of-speech tags, named entity tags, and term frequency values for each passage word. Subsequently, a stack of BiLSTMs is used for encoding. The outputs of the stacked BilSTMs are used as evidence vectors to help extract the answer span. We decompose those stacked BiLSTM output vectors with respect to the passage embedding and generate the *nil* pointer score as given in Eqs (2–5). The question vector formulation in DrQA is performed by applying a stack of BilSTMs on question embedding. The nil-aware pointing mechanism is the same as that given in Section 3.2.7 except an additional bi-linear term is used for each $\mathbf{s}_b$ and $\mathbf{s}_e$ in Eq (6).

3.4 Nil-Aware R-Net

In R-Net (Wang et al., 2017), after embedding and encoding of the passage and question words, a gated recurrent network is used to obtain the question-passage joint representation. Subsequently, a self-matching attentive encoding is used to accumulate evidence from the entire passage. In the output layer, an answer recurrent pointer network is used to predict the boundary of an answer span. To extend R-Net to nil-aware R-Net (NR-Net), we decompose the output vectors of the self-matching layer with respect to the question-passage joint encoding vectors, and then aggregate them to obtain the *nil* pointer score as illustrated in Eqs (2–5). In the output layer, we combine the *nil* pointer score to the beginning and ending pointer unnormalized scores, and jointly normalize them using softmax function as given in Eqs (7–8).

3.5 Nil-Aware BiDAF

In BiDAF (Seo et al., 2017), an attention flow layer is used to jointly encode the passage and question. Then, a modeling layer is used to capture the interaction among the question-aware passage vectors. The output of the modeling layer serves as evidence to help extract the answer span in the output layer. To extend the BiDAF model to nil-aware BiDAF (NBiDAF), we decompose the output of the modeling layer with respect to the question-passage joint encoding vectors, and then aggregate them to derive the *nil* pointer score (similar to Eqs (2–5). Similar to the other nil-aware models, we concatenate the *nil* pointer score to the start and end pointer unnormalized scores derived in the output layer, and then jointly normalize them.

4 Baseline Models

For comparison, we propose two types of baseline approaches for nil-aware answer extraction.

4.1 Pipeline Approach

Here, two models are used in a pipeline:

Nil detector: Given a pair of passage and question, a nil detector model determines whether a valid answer is present in the passage.

Answer span extractor: If the nil detector model predicts the presence of a valid answer, the answer span extractor then extracts the answer.

For nil detection, we developed a logistic regression (LR) model with manually defined features and four neural models. For the LR model, we extract four different features which capture the similarity between a passage and a question. Let $\mathcal{P}$ be the passage and $\mathcal{Q}$ be the question (consisting of U' tokens excluding stop words). If $f(\mathcal{P}, \mathcal{Q}_i)$ is the frequency of the ith question word in passage $\mathcal{P}$, then the first feature η is defined as:

$$\eta = \sum_{i=1}^{U'} \log(1 + f(\mathcal{P}, \mathcal{Q}_i)) \qquad (10)$$

The second feature is the same as η, except that the lemma form is considered for both passage and question tokens instead of the surface form. Additionally, we include word overlap count features in both surface and lemma forms.

We also develop several advanced neural network architectures for nil detection. After embedding (the same as Section 3.2.1), we apply sequence-level encoding with either BiLSTM or CNN. For CNN, we use equal numbers of unigram, bigram, and trigram filters and the outputs are concatenated to obtain the final encoding. Next, we apply either global max-pooling (MP) or attentive pooling (AP) over all the sequence vectors to obtain an aggregated vector representation. Let the sequence encoding of a passage be $\mathbf{P}^{nd} \in \mathbb{R}^{T\times H}$, and $\mathbf{p}_t^{nd}$ be the tth row of $\mathbf{P}^{nd}$. The aggregated vector $\tilde{\mathbf{p}}_{nd} \in \mathbb{R}^{H}$ for AP can be obtained as:

$$a_t^{nd} \propto \exp(\mathbf{p}_t^{nd} \mathbf{w}^\top) \tag{11}$$

$$\tilde{\mathbf{p}}_{nd} = \mathbf{a}^{nd} \mathbf{P}^{nd} \ , \tag{12}$$

where $\mathbf{w} \in \mathbb{R}^H$ is a learnable vector. Similarly, we derive the aggregated question vector $\tilde{\mathbf{q}}_{nd}$. For nil detection, we compute the similarity score (s_{nd}) between the aggregated vectors:

$$s_{nd} = \text{sigmoid}(\tilde{\mathbf{p}}_{nd} \ \tilde{\mathbf{q}}_{nd}^\top) \tag{13}$$

We experimented with four state-of-the-art answer span extractor models, namely BiDAF (Seo et al., 2017), R-Net (Wang et al., 2017), DrQA (Chen et al., 2017), and AMANDA (Kundu and Ng, 2018). Note that the answer extraction models are trained entirely on passage-question pairs which always have valid answers.

4.2 Threshold-Based Approach

Here, we do not use any nil questions to train the neural answer span extraction model. This approach assumes that when there is a valid answer, the probability distributions of the beginning and ending pointers will have lower entropy. This results in a higher maximum joint probability of the beginning and ending pointers. In contrast, when an answer is not present in the associated passage, the output probability distributions have higher entropy, resulting in a lower value of maximum joint probability. We set the maximum joint probability *threshold* based on the best Nil F1 score on the nil questions in the development set. Now, for a given test passage and question, we first compute the maximum of all the joint probabilities associated with all the answer spans. Let a_{span} be the answer span with highest joint probability p_{max}. We assign the final *answer* as follows:

$$answer = \begin{cases} Nil, & \text{if } p_{max} \leq threshold \\ a_{span}, & \text{otherwise} \end{cases} \tag{14}$$

5 Experiments

5.1 Experimental Settings

We use the NewsQA dataset with nil questions (Trischler et al., 2017) in our experiments. Its training, development, and test sets consist of 10,938, 638, and 632 passages respectively and every passage is associated with some questions. In each subset, there are some questions which have no answers in the corresponding associated passages (i.e., the nil questions). The detailed statistics of the dataset are given in Table 1.

Dataset		#Passages	#Questions
Train	NewsQA	10,938	92,549
	+Nil Qs		107,673
Dev	NewsQA	638	5,166
	+Nil Qs		5,988
Test	NewsQA	632	5,126
	+Nil Qs		5,971

Table 1: Statistics of the NewsQA dataset.

We compute exact match (EM) and F1 score for questions with valid answers. For questions without any valid answers, we compute Nil precision, recall, and F1 scores as follows:

$$\text{Nil precision} = \frac{\#\text{Correctly predicted Nil}}{\#\text{predicted Nil}} \tag{15}$$

$$\text{Nil recall} = \frac{\#\text{Correctly predicted Nil}}{\#\text{Nil questions}} \tag{16}$$

$$\text{Nil F1} = 2 \times \frac{\text{Nil precision} \times \text{Nil recall}}{\text{Nil precision} + \text{Nil recall}} \tag{17}$$

To compute the overall EM and F1 scores, we consider *Nil* as correct for the questions which do not have any valid answers. All evaluation scores reported in this paper are in %.

All the neural network models are implemented in PyTorch[2]. We use the default hyper-parameters for all the answer span extractor models. We use the open source implementation of DrQA[3]. We use a third party implementation of R-Net[4] whose performance is very similar to the original scores. We reimplemented BiDAF[5] and AMANDA[6] to easily integrate our proposed nil-aware answer extraction framework and make the training faster. We integrate the nil-aware answer span extraction framework with each model keeping all the hyper-parameters unchanged. For nil-detection models, we use the same settings as (N)AMANDA. We use 300 hidden units for BiLSTMs and a total of 300 filters for the CNN-based models. We use dropout (Srivastava et al., 2014) with probability 0.3 for every trainable layer. We use binary cross-entropy loss and the Adam optimizer (Kingma and Ba, 2015) for training the nil-detection models.

Table 2: Performance Comparison with pipeline approaches on the NewsQA test set.

5.2 Results

Tables 2 and 3 compare results of the nil-aware answer span extractor models with several pipeline and threshold-based models, respectively. We also include the results of four standalone answer span extraction models on the test set without nil questions. Table 2 shows that the end-to-end nil-aware models achieve the highest overall EM and F1 scores compared to all the corresponding pipeline systems. Note that the MP-BiLSTM nil detection model achieves higher Nil F1 scores compared to LR and MP-CNN. This is because BiLSTM is able to capture long-range contextual information to infer the existence of valid answers. Furthermore, AP-based models perform better compared to MP-based models as the attention mechanism used in AP-based models inherently identifies important contextual information. Due to this, the performance gap between AP-CNN and AP-BiLSTM is lower than the performance gap between MP-CNN and MP-BiLSTM. In addition to achieving higher Nil F1 score than the strong nil detection baseline systems, nil-aware models manage to achieve competitive scores compared to the corresponding standalone answer span extractors on the test set where there are no nil questions.

Table 3 shows that the nil-aware models outperform the corresponding threshold-based models. Note that all four answer span extraction models, when used in a threshold-based approach for nil detection, produce low Nil precision and relatively higher Nil recall. The low precision significantly degrades performance on the test set without nil questions. These models often return *Nil* since it is critical to find suitable values for the required *threshold*. This is because NewsQA passages are often very long and as a result, probability distributions with higher entropy for answer pointer selection lead to irregular maximum joint probability *threshold* values.

We perform statistical significance tests using paired t-test and bootstrap resampling. Performances of all the nil-aware models (in terms of overall EM and F1) are significantly better ($p < 0.01$) than the corresponding best pipeline models and threshold-based approaches.

Answer Extractor	Nil Answer Handling	Test Set (w/o Nil Questions)		Test Set (with Nil Questions)				
		EM	F1	Nil Precision	Nil Recall	Nil F1	Overall EM	Overall F1
BiDAF	No	42.5	57.5	-	-	-	36.5	49.4
	Yes	37.9	48.3	25.8	60.2	36.1	41.0	50.0

	Yes	42.2	51.3	24.0	59.5	34.2	44.6	52.5
NAMANDA		48.6	62.2	57.1	56.7	56.9	49.7	61.5

Table 3: Performance comparison with threshold-based approaches on the NewsQA test set.

5.3 Analysis

For better understanding, we present further experiments and analysis of one of the proposed models, NAMANDA.

In addition to linear aggregation, we experiment with BiLSTM-based and CNN-based aggregation models. When we use BiLSTM aggregation, Eq. (4) is modified to $\mathbf{y}_t^a = \mathbf{h}_t^{=} + \mathbf{h}_t^{\perp}$, where

$$\begin{aligned} \mathbf{h}_t^{=} &= \text{BiLSTM}(\mathbf{y}_t^{=}, \mathbf{h}_{t-1}^{=}, \mathbf{h}_{t+1}^{=}) \quad (18) \\ \mathbf{h}_t^{\perp} &= \text{BiLSTM}(\mathbf{y}_t^{\perp}, \mathbf{h}_{t-1}^{\perp}, \mathbf{h}_{t+1}^{\perp}) \end{aligned}$$

We use equal numbers of unigram, bigram, and trigram filters for CNN-based aggregation. Similar to BiLSTM-based aggregation, we add the CNN outputs for $\mathbf{Y}^{=}$ and $\mathbf{Y}^{\perp}$. Table 4 shows that linear aggregation achieves the highest overall F1 score despite using the least number of parameters.

Table 5 shows the results of NAMANDA on the NewsQA development set when different components are removed such as character embeddings, question-passage joint encoding, and the second LSTM for the answer-ending pointer. When question-passage joint encoding is removed, self-attentive encoding is formed as well as decomposed with respect to sequence-level passage encoding. When we remove the second LSTM for the answer-ending pointer, a feed-forward network is used instead. It is clear from Table 5 that question-passage joint encoding has the highest impact.

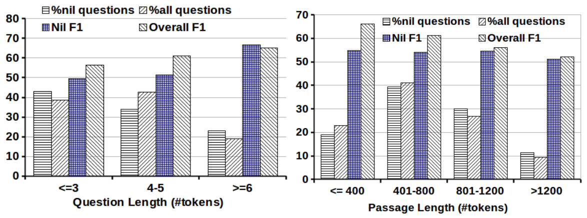
Aggregation Model	w/o Nil	with Nil	
	EM (F1)	Nil Prec/ Rec (F1)	Overall EM (F1)
BiLSTM	47.6 (60.9)	56.5/53.5 (55.0)	48.4 (59.9)
CNN	46.2 (60.0)	52.7/54.5 (53.6)	47.3 (59.2)
Linear (NAMANDA)	47.8 (60.5)	51.2/57.2 (54.0)	49.1 (60.0)

Table 4: Effect of different aggregation models on the NewsQA dev set.

Model	w/o Nil	with Nil	
	EM (F1)	Nil Prec/ Rec (F1)	Overall EM (F1)
– character embeddings	46.3 (59.2)	51.9/54.1 (53.0)	47.4 (58.5)
– q-passage joint encoding	32.5 (43.9)	41.4/58.8 (48.6)	36.1 (45.9)
– second LSTM	47.6 (60.3)	56.7/51.0 (53.7)	48.0 (59.0)
NAMANDA	47.8 (60.5)	51.2/57.2 (54.0)	49.1 (60.0)

Table 5: Ablation studies on the NewsQA dev set.

Figure 2(a) and Figure 2(b) show the results of NAMANDA on different question (excluding the stop words) and passage lengths respectively on the NewsQA development set. With increasing question length, the Nil F1 score also improves. This is because with more information in a question, it becomes easier to detect whether the associated passage contains a valid answer. Increasing Nil F1 scores also help to improve the overall F1 scores. However, the overall F1 score degrades with increasing length of the associated passage. When the associated passage is long, it is difficult for the answer span extractor to extract an answer for a question which has a valid answer, due to the increasing amount of potentially distracting information. The Nil F1 scores remain similar for passages consisting of not more than 1,200 tokens. Beyond that, the Nil F1 score degrades a little



(a) (b)

Figure 2: Results for different (a) question and (b) passage lengths on NewsQA dev set.

as it becomes very challenging to infer the existence of a valid answer accurately with increasing amount of potentially distracting information present in the passage.

Nil detection is itself a very challenging task. Performances of the nil-aware models are worse than the corresponding answer extractor models on the test set without nil questions as Nil precision is lower than 100%. We carried out an experiment to evaluate the performance of NAMANDA on development sets with varying number of nil questions. As the proportion of nil questions in a set increases, NAMANDA outperforms AMANDA by a larger margin on overall scores.

6 Related Work

In some years of the question answering track at the Text Retrieval Conference (TREC)[7], some questions were considered as nil questions for which no valid answers could be found in the entire corpus. Participating teams were required to return *Nil* as answer for those questions. Many teams used threshold-based methods to determine whether any of the retrieved answers for a given question was valid or not. If none of the answers had high confidence, *Nil* was returned as answer. To evaluate the performance on the nil questions, TREC used Nil precision, recall and F1 scores.

In recent years, research on question answering has witnessed substantial progress with rapid advances in neural network architectures. For example, on the answer sentence selection task, where a system has to choose the correct answer sentence from a pool of candidate sentences for a given question, the introduction of attention-based neural models has rapidly advanced the state of the art (Tan et al., 2015; Yang et al., 2016; dos Santos et al., 2016; Wang et al., 2016; Bian et al., 2017; Shen et al., 2017a).

However, in the answer sentence selection task, the answer is always a full sentence. Rajpurkar et al. (2016) released a reading comprehension-based QA dataset SQuAD, where given a passage and a question, a system needs to find the exact answer span rather than a sentence. Although SQuAD became very popular and served as a good test set to develop advanced end-to-end neural network architectures, it does not include any nil questions. In practical QA, it is critical to decide whether or not a passage contains a valid answer for a given question. Subsequently, the NewsQA (Trischler et al., 2017) dataset has been released which attempts to overcome this deficiency. However, all the proposed models for NewsQA so far have excluded nil questions during evaluation. Contrary to prior work, we focus on developing models for nil-aware answer span extraction. Very recently, Rajpurkar et al. (2018) released the SQUADRUN dataset by augmenting the SQuAD dataset with unanswerable questions. The unanswerable questions are written adversarially by crowdworkers to look similar to the answerable ones.

7 Conclusion

In this paper, we have focused on nil-aware answer span extraction for RC-based QA. A nil-aware QA system only extracts a span of text from the associated passage as an answer to a given question if and only if the passage contains a valid answer. We have proposed a nil-aware answer span extraction framework based on evidence decomposition and aggregation that can be easily integrated with several recently proposed neural answer span extraction models. We have also developed several pipeline and threshold-based models using advanced neural architectures for comparison. Experiments on the NewsQA dataset show that our proposed framework, when integrated with the answer span extraction models, achieves better performance compared to all the corresponding pipeline and threshold-based models. Employing such a nil-aware answer span extractor in practical IR-style QA tasks will be interesting future work.

Abstract

Advanced neural machine translation (NMT) models generally implement encoder and decoder as multiple layers, which allows systems to model complex functions and capture complicated linguistic structures. However, only the top layers of encoder and decoder are leveraged in the subsequent process, which misses the opportunity to exploit the useful information embedded in other layers. In this work, we propose to simultaneously expose all of these signals with layer aggregation and multi-layer attention mechanisms. In addition, we introduce an auxiliary regularization term to encourage different layers to capture diverse information. Experimental results on widely-used WMT14 English⇒German and WMT17 Chinese⇒English translation data demonstrate the effectiveness and universality of the proposed approach.

1 Introduction

Neural machine translation (NMT) models have advanced the machine translation community in recent years (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Sutskever et al., 2014). NMT models generally consist of two components: an *encoder* network to summarize the input sentence into sequential representations, based on which a *decoder* network generates target sentence word by word with an attention model (Bahdanau et al., 2015; Luong et al., 2015).

Nowadays, advanced NMT models generally implement encoder and decoder as multiple layers, regardless of the specific model architectures such as RNN (Zhou et al., 2016; Wu et al., 2016), CNN (Gehring et al., 2017), or Self-Attention Network (Vaswani et al., 2017; Chen et al., 2018). Several researchers have revealed that different layers are able to capture different types of syntax and semantic information (Shi et al., 2016; Peters et al., 2018; Anastasopoulos and Chiang, 2018). For example, Shi et al. (2016) find that both local and global source syntax are learned by the NMT encoder and different types of syntax are captured at different layers.

However, current NMT models only leverage the top layers of encoder and decoder in the subsequent process, which misses the opportunity to exploit useful information embedded in other layers. Recently, aggregating layers to better fuse semantic and spatial information has proven to be of profound value in computer vision tasks (Huang et al., 2017; Yu et al., 2018). In natural language processing community, Peters et al. (2018) have proven that simultaneously exposing all layer representations outperforms methods that utilize just the top layer for transfer learning tasks.

Inspired by these findings, we propose to exploit deep representations for NMT models. Specifically, we investigate two types of strategies to better fuse information across layers, ranging from layer aggregation to multi-layer attention. While layer aggregation strategies combine hidden states at the same position across different layers, multi-layer attention allows the model to combine information in different positions. In addition, we introduce an auxiliary objective to encourage different layers to capture diverse information, which we believe would make the deep representations more meaningful.

We evaluated our approach on two widely-used WMT14 English⇒German and WMT17 Chinese⇒English translation tasks. We employed TRANSFORMER (Vaswani et al., 2017) as the baseline system since it has proven to outperform other architectures on the two tasks (Vaswani et al., 2017; Hassan et al., 2018). Experimen-

tal results show that exploiting deep representations consistently improves translation performance over the vanilla TRANSFORMER model across language pairs. It is worth mentioning that TRANSFORMER-BASE with deep representations exploitation outperforms the vanilla TRANSFORMER-BIG model with only less than half of the parameters.

2 Background: Deep NMT

Deep representations have proven to be of profound value in machine translation (Meng et al., 2016; Zhou et al., 2016). Multiple-layer encoder and decoder are employed to perform the translation task through a series of nonlinear transformations from the representation of input sequences to final output sequences. The layer can be implemented as RNN (Wu et al., 2016), CNN (Gehring et al., 2017), or Self-Attention Network (Vaswani et al., 2017). In this work, we take the advanced Transformer as an example, which will be used in experiments later. However, we note that the proposed approach is generally applicable to any other type of NMT architectures.

Specifically, the encoder is composed of a stack of L identical layers, each of which has two sub-layers. The first sub-layer is a self-attention network, and the second one is a position-wise fully connected feed-forward network. A residual connection (He et al., 2016) is employed around each of the two sub-layers, followed by layer normalization (Ba et al., 2016). Formally, the output of the first sub-layer $\mathbf{C}_e^l$ and the second sub-layer $\mathbf{H}_e^l$ are calculated as

$$\begin{aligned}\mathbf{C}_e^l &= \textsc{Ln}\big(\textsc{Att}(\mathbf{Q}_e^l, \mathbf{K}_e^{l-1}, \mathbf{V}_e^{l-1}) + \mathbf{H}_e^{l-1}\big),\\ \mathbf{H}_e^l &= \textsc{Ln}\big(\textsc{Ffn}(\mathbf{C}_e^l) + \mathbf{C}_e^l\big),\end{aligned} \qquad (1)$$

where $\textsc{Att}(\cdot)$, $\textsc{Ln}(\cdot)$, and $\textsc{Ffn}(\cdot)$ are self-attention mechanism, layer normalization, and feed-forward networks with ReLU activation in between, respectively. $\{\mathbf{Q}_e^l, \mathbf{K}_e^{l-1}, \mathbf{V}_e^{l-1}\}$ are query, key and value vectors that are transformed from the (*l-1*)-th encoder layer $\mathbf{H}_e^{l-1}$.

The decoder is also composed of a stack of L identical layers. In addition to two sub-layers in each decoder layer, the decoder inserts a third sublayer $\mathbf{D}_d^l$ to perform attention over the output of the encoder stack $\mathbf{H}_e^L$:

$$\begin{aligned}\mathbf{C}_d^l &= \textsc{Ln}\big(\textsc{Att}(\mathbf{Q}_d^l, \mathbf{K}_d^{l-1}, \mathbf{V}_d^{l-1}) + \mathbf{H}_d^{l-1}\big),\\ \mathbf{D}_d^l &= \textsc{Ln}\big(\textsc{Att}(\mathbf{C}_d^l, \mathbf{K}_e^{L}, \mathbf{V}_e^{L}) + \mathbf{C}_d^{l}\big),\\ \mathbf{H}_d^l &= \textsc{Ln}\big(\textsc{Ffn}(\mathbf{D}_d^l) + \mathbf{D}_d^l\big),\end{aligned} \qquad (2)$$

where $\{\mathbf{Q}_d^l, \mathbf{K}_d^{l-1}, \mathbf{V}_d^{l-1}\}$ are transformed from the (*l-1*)-th decoder layer $\mathbf{H}_d^{l-1}$, and $\{\mathbf{K}_e^L, \mathbf{V}_e^L\}$ are transformed from the top layer of the encoder. The top layer of the decoder $\mathbf{H}_d^L$ is used to generate the final output sequence.

Multi-layer network can be considered as a strong feature extractor with extended receptive fields capable of linking salient features from the entire sequence (Chen et al., 2018). However, one potential problem about the vanilla Transformer, as shown in Figure 1a, is that both the encoder and decoder stack layers in sequence and only utilize the information in the top layer. While studies have shown deeper layers extract more semantic and more global features (Zeiler and Fergus, 2014; Peters et al., 2018), these do not prove that the last layer is the ultimate representation for any task. Although residual connections have been incorporated to combine layers, these connections have been "shallow" themselves, and only fuse by simple, one-step operations (Yu et al., 2018). We investigate here how to better fuse information across layers for NMT models.

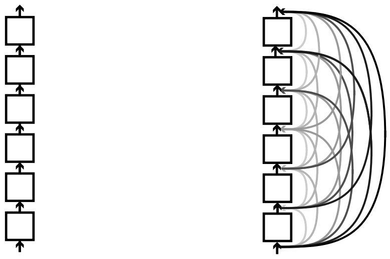
In the following sections, we simplify the equations to $\mathbf{H}^l = \textsc{Layer}(\mathbf{H}^{l-1})$ for brevity.

3 Proposed Approaches

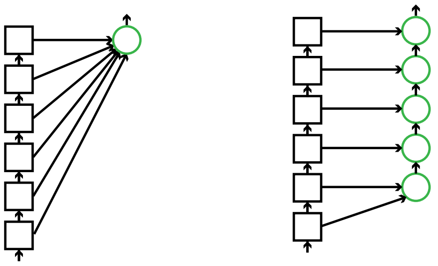
In this section, we first introduce how to exploit deep representations by simultaneously exposing all of the signals from all layers (Sec 3.1). Then, to explicitly encourage different layers to incorporate various information, we propose one way to measure the diversity between layers and add a regularization term to our objective function to maximize the diversity across layers (Sec 3.2).

3.1 Deep Representations

To exploit deep representations, we investigate two types of strategies to fuse information across layers, from layer aggregation to multi-layer attention. While layer aggregation strategies combine hidden states at the same position across different layers, multi-layer attention allows the model to combine information in different positions.



(a) Vanilla (b) Dense



(c) Linear (d) Iterative

Figure 1: Illustration of (a) vanilla model without any aggregation and (b,c,d) layer aggregation strategies. Aggregation nodes are represented by green circles.

3.1.1 Layer Aggregation

While the aggregation strategies are inspired by previous work, there are several differences since we have simplified and generalized from the original model, as described below.

Dense Connection. The first strategy is to allow all layers to directly access previous layers:

$$\mathbf{H}^l = f(\mathbf{H}^1, \ldots, \mathbf{H}^{l-1}). \tag{3}$$

In this work, we mainly investigate whether densely connected networks work for NMT, which have proven successful in computer vision tasks (Huang et al., 2017). The basic strategy of densely connected networks is to connect each layer to every previous layer with a residual connection:

$$\mathbf{H}^l = \text{Layer}(\mathbf{H}^{l-1}) + \sum_{i=1}^{l-1} \mathbf{H}^i. \tag{4}$$

Figure 1b illustrates the idea of this approach. Our implementation differs from (Huang et al., 2017) in that we use an addition instead of a concatenation operation in order to keep the state size constant. Another reason is that concatenation operation is computationally expensive, while residual connections are more efficient.

While dense connection directly feeds previous layers to the subsequent layers, the following mechanisms maintain additional layers to aggregate standard layers, from shallow linear combination, to deep non-linear aggregation.

Linear Combination. As shown in Figure 1c, an intuitive strategy is to linearly combine the outputs of all layers:

$$\widehat{\mathbf{H}} = \sum_{l=1}^{L} \mathbf{W}_l \mathbf{H}^l, \tag{5}$$

where $\{\mathbf{W}_1, \ldots, \mathbf{W}_L\}$ are trainable matrices. While the strategy is similar in spirit to (Peters et al., 2018), there are two main differences: (1) they use normalized weights while we directly use parameters that could be either positive or negative numbers, which may benefit from more modeling flexibility. (2) they use a scalar that is shared by all elements in the layer states, while we use learnable matrices. The latter offers a more precise control of the combination by allowing the model to be more expressive than scalars (Tu et al., 2017).

We also investigate strategies that *iteratively* and *hierarchically* merge layers by incorporating more depth and sharing, which have proven effective for computer vision tasks (Yu et al., 2018).

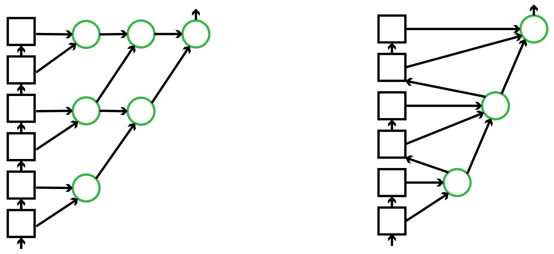
Iterative Aggregation. As illustrated in Figure 1d, iterative aggregation follows the iterated stacking of the backbone architecture. Aggregation begins at the shallowest, smallest scale and then iteratively merges deeper, larger scales. The iterative deep aggregation function I for a series of layers $\mathbf{H}_1^l = \{\mathbf{H}^1, \cdots, \mathbf{H}^l\}$ with increasingly deeper and semantic information is formulated as

$$\widehat{\mathbf{H}}^l = I(\mathbf{H}_1^l) = \textsc{Agg}(\mathbf{H}^l, \widehat{\mathbf{H}}^{l-1}), \tag{6}$$

where we set $\widehat{\mathbf{H}}^1 = \mathbf{H}^1$ and $\textsc{Agg}(\cdot, \cdot)$ is the aggregation function:

$$\textsc{Agg}(x, y) = \textsc{Ln}(\textsc{Ff}([x; y]) + x + y). \tag{7}$$

As seen, in this work, we first concatenate x and y into $z = [x; y]$, which is subsequently fed to a feed-forward network with a sigmoid activation in between. Residual connection and layer normalization are also employed. Specifically, both x and y have residual connections to the output. The choice of the aggregation function will be further studied in the experiment section.



(a) CNN-like tree (b) Hierarchical

Figure 2: Hierarchical aggregation (b) that aggregates layers through a tree structure (a).

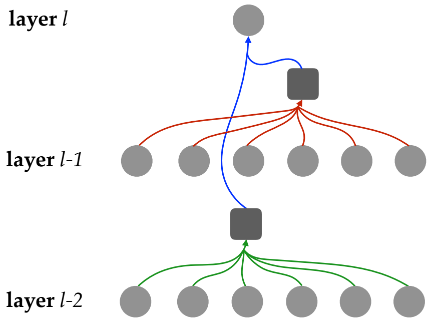


Figure 3: Multi-layer attention allows the model to attend multiple layers to construct each hidden state. We use two-layer attention for illustration, while the approach is applicable to any layers lower than l.

Hierarchical Aggregation. While iterative aggregation deeply combines states, it may still be insufficient to fuse the layers for its sequential architecture. Hierarchical aggregation, on the other hand, merges layers through a tree structure to preserve and combine feature channels, as shown in Figure 2. The original model proposed by Yu et al. (2018) requires the number of layers to be the power of two, which limits the applicability of these methods to a broader range of NMT architectures (e.g. six layers in (Vaswani et al., 2017)). To solve this problem, we introduce a CNN-like tree with the filter size being two, as shown in Figure 2a. Following (Yu et al., 2018), we first merge aggregation nodes of the same depth for efficiency so that there would be at most one aggregation node for each depth. Then, we further feed the output of an aggregation node back into the backbone as the input to the next sub-tree, instead of only routing intermediate aggregations further up the tree, as shown in Figure 2b. The interaction between aggregation and backbone nodes allows the model to better preserve features.

Formally, each aggregation node $\widehat{\mathbf{H}}^i$ is calculated as

$$\widehat{\mathbf{H}}^i = \begin{cases} \textsc{Agg}(\mathbf{H}^{2i-1}, \mathbf{H}^{2i}), & i = 1 \\ \textsc{Agg}(\mathbf{H}^{2i-1}, \mathbf{H}^{2i}, \widehat{\mathbf{H}}^{i-1}), & i = 2, 3 \end{cases}$$

where $\textsc{Agg}(\mathbf{H}^{2i-1}, \mathbf{H}^{2i})$ is computed via Eqn. 7, and $\textsc{Agg}(\mathbf{H}^{2i-1}, \mathbf{H}^{2i}, \widehat{\mathbf{H}}^{i-1})$ is computed as

$$\textsc{Agg}(x, y, z) = \textsc{Ln}(\textsc{Ff}([x; y; z]) + x + y + z).$$

The aggregation node at the top layer $\widehat{\mathbf{H}}^{L/2}$ serves as the final output of the network.

3.1.2 Multi-Layer Attention

Partially inspired by Meng et al. (2016), we also propose to introduce a multi-layer attention mechanism into deep NMT models, for more power of transforming information across layers. In other words, for constructing each hidden state in any layer-l, we allow the self-attention model to attend any layers lower than l, instead of just layer *l-1*:

$$\begin{aligned} \mathbf{C}^l_{-1} &= \textsc{Att}(\mathbf{Q}^l, \mathbf{K}^{l-1}, \mathbf{V}^{l-1}), \\ \mathbf{C}^l_{-2} &= \textsc{Att}(\mathbf{Q}^l, \mathbf{K}^{l-2}, \mathbf{V}^{l-2}), \\ &\dots \\ \mathbf{C}^l_{-k} &= \textsc{Att}(\mathbf{Q}^l, \mathbf{K}^{l-k}, \mathbf{V}^{l-k}), \\ \mathbf{C}^l &= \textsc{Agg}(\mathbf{C}^l_{-1}, \dots, \mathbf{C}^l_{-k}), \end{aligned} \tag{8}$$

where $\mathbf{C}^l_{-i}$ is sequential vectors queried from layer *l-i* using a separate attention model, and $\textsc{Agg}(\cdot)$ is similar to the pre-defined aggregation function to transform k vectors $\{\mathbf{C}^l_{-1}, \dots, \mathbf{C}^l_{-k}\}$ to a d-dimension vector, which is subsequently used to construct the encoder and decoder layers via Eqn. 1 and 2 respectively. Note that multi-layer attention only modifies the self-attention blocks in both encoder and decoder, while does not revises the encoder-decoder attention blocks.

3.2 Layer Diversity

Intuitively, combining layers would be more meaningful if different layers are able to capture diverse information. Therefore, we explicitly add a *regularization* term to encourage the diversities between layers:

$$\mathcal{L} = \mathcal{L}_{\text{likelihood}} + \lambda \mathcal{L}_{\text{diversity}}, \tag{9}$$

where λ is a hyper-parameter and is set to 1.0 in this paper. Specifically, the regularization term measures the average of the distance between every two adjacent layers:

$$\mathcal{L}_{diversity} = \frac{1}{L-1} \sum_{l=1}^{L-1} D(\mathbf{H}^l, \mathbf{H}^{l+1}). \qquad (10)$$

Here $D(\mathbf{H}^l, \mathbf{H}^{l+1})$ is the averaged *cosine-squared distance* between the states in layers $\mathbf{H}^l = \{\mathbf{h}_1^l, \ldots, \mathbf{h}_N^l\}$ and $\mathbf{H}^{l+1} = \{\mathbf{h}_1^{l+1}, \ldots, \mathbf{h}_N^{l+1}\}$:

$$D(\mathbf{H}^l, \mathbf{H}^{l+1}) = \frac{1}{N} \sum_{n=1}^{N} (1 - \cos^2(\mathbf{h}_n^l, \mathbf{h}_n^{l+1})).$$

The cosine-squared distance between two vectors is maximized when two vectors are linearly independent and minimized when two vectors are linearly dependent, which satisfies our goal.[1]

4 Experiments

4.1 Setup

Dataset. To compare with the results reported by previous work (Gehring et al., 2017; Vaswani et al., 2017; Hassan et al., 2018), we conducted experiments on both Chinese⇒English (Zh⇒En) and English⇒German (En⇒De) translation tasks. For the Zh⇒En task, we used all of the available parallel data with maximum length limited to 50, consisting of about 20.62 million sentence pairs. We used newsdev2017 as the development set and newstest2017 as the test set. For the En⇒De task, we trained on the widely-used WMT14 dataset consisting of about 4.56 million sentence pairs. We used newstest2013 as the development set and newstest2014 as the test set. Byte-pair encoding (BPE) was employed to alleviate the Out-of-Vocabulary problem (Sennrich et al., 2016) with 32K merge operations for both language pairs. We used 4-gram NIST BLEU score (Papineni et al., 2002) as the evaluation metric, and *sign-test* (Collins et al., 2005) to test for statistical significance.

Models. We evaluated the proposed approaches on advanced Transformer model (Vaswani et al., 2017), and implemented on top of an open-source toolkit – THUMT (Zhang et al., 2017). We followed Vaswani et al. (2017) to set the configurations and train the models, and have reproduced their reported results on the En⇒De task. The parameters of the proposed models were initialized by the pre-trained model. We tried $k = 2$ and $k = 3$ for the multi-layer attention model, which allows to attend to the lower two or three layers.

We have tested both *Base* and *Big* models, which differ at hidden size (512 vs. 1024), filter size (2048 vs. 4096) and the number of attention heads (8 vs. 16).[2] All the models were trained on eight NVIDIA P40 GPUs where each was allocated with a batch size of 4096 tokens. In consideration of computation cost, we studied model variations with *Base* model on En⇒De task, and evaluated overall performance with *Big* model on both Zh⇒En and En⇒De tasks.

4.2 Results

Table 1 shows the results on WMT14 En⇒De translation task. As seen, the proposed approaches improve the translation quality in all cases, although there are still considerable differences among different variations.

Model Complexity Except for dense connection, all other deep representation strategies introduce new parameters, ranging from 14.7M to 33.6M. Accordingly, the training speed decreases due to more efforts to train the new parameters. Layer aggregation mechanisms only marginally decrease decoding speed, while multi-layer attention decreases decoding speed by 21% due to an additional attention process for each layer.

Layer Aggregation (Rows 2-5): Although dense connection and linear combination only marginally improve translation performance, iterative and hierarchical aggregation strategies achieve more significant improvements, which are up to +0.99 BLEU points better than the baseline model. This indicates that deep aggregations outperform their shallow counterparts by incorporating more depth and sharing, which is consistent with the results in computer vision tasks (Yu et al., 2018).

Multi-Layer Attention (Rows 6-7): Benefiting from the power of attention models, multi-layer attention model can also significantly outperform baseline, although it only attends to one or two additional layers. However, increasing the number of lower layers to be attended from $k = 2$ to

---

[1] We use cosine-squared distance instead of cosine distance, since the latter is maximized when two vectors are in opposite directions. In such case, the two vectors are in fact linearly dependent, while we aim at encouraging the vectors independent from each other.

[2] Here “filter size” refers to the hidden size of the feed-forward network in the Transformer model.

Table 2: Comparing with existing NMT systems on WMT14 English⇒German and WMT17 Chinese⇒English tasks. "+ Deep Representations" denotes "+ Hierarchical Aggregation + $\mathcal{L}_{diversity}$". "†" indicates statistically significant difference ($p < 0.01$) from the Transformer baseline.

$k = 3$ only gains marginal improvement, at the cost of slower training and decoding speeds. In the following experiments, we set set $k = 2$ for the multi-layer attention model.

Layer Diversity (Rows 8-10): The introduced diversity regularization consistently improves performance in all cases by encouraging different layers to capture diverse information. Our best model outperforms the vanilla Transformer by +1.14 BLEU points. In the following experiments, we used hierarchical aggregation with diversity regularization (Row 8) as the default strategy.

Main Results Table 2 lists the results on both WMT17 Zh⇒En and WMT14 En⇒De translation tasks. As seen, exploiting deep representations consistently improves translation performance across model variations and language pairs, demonstrating the effectiveness and universality of the proposed approach. It is worth mentioning that Transformer-Base with deep representations exploitation outperforms the vanilla Transformer-Big model, with only less than half of the parameters.

4.3 Analysis

We conducted extensive analysis from different perspectives to better understand our model. All results are reported on the En⇒De task with Transformer-Base.

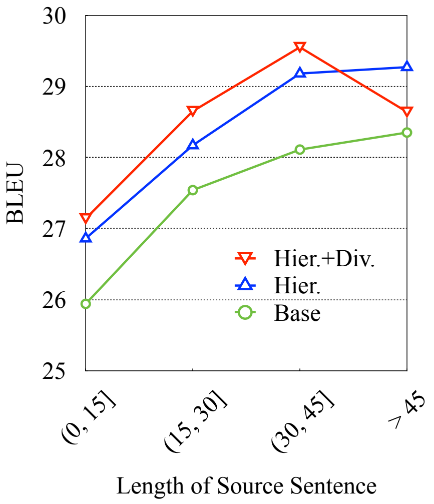

Figure 4: BLEU scores on the En⇒De test set with respect to various input sentence lengths. “Hier.” denotes hierarchical aggregation and “Div.” denotes diversity regularization.

4.3.1 Length Analysis

Following Bahdanau et al. (2015) and Tu et al. (2016), we grouped sentences of similar lengths together and computed the BLEU score for each group, as shown in Figure 4. Generally, the performance of TRANSFORMER-BASE goes up with the increase of input sentence lengths, which is superior to the performance of RNN-based NMT models on long sentences reported by (Bentivogli et al., 2016). We attribute this to the strength of self-attention mechanism to model global dependencies without regard to their distance.

Clearly, the proposed approaches outperform the baseline model in all length segments, while there are still considerable differences between the two variations. Hierarchical aggregation consistently outperforms the baseline model, and the improvement goes up on long sentences. One possible reason is that long sentences indeed require deep aggregation mechanisms. Introducing diversity regularization further improves performance on most sentences (e.g. ≤ 45), while the improvement degrades on long sentences (e.g. > 45). We conjecture that complex long sentences may need to store duplicate information across layers, which conflicts with the diversity objective.

4.3.2 Effect on Encoder and Decoder

Both encoder and decoder are composed of a stack of L layers, which may benefit from the proposed approach. In this experiment, we investigated how our models affect the two components, as shown in Table 3. Exploiting deep representations of encoder or decoder individually consistently outperforms the vanilla baseline model, and exploiting both components further improves the performance. These results provide support for the claim that exploiting deep representations is useful for both understanding input sequence and generating output sequence.

		RELU	26.56
		ATTENTION	26.54

Table 4: Impact of residual connections and aggregation functions for hierarchical layer aggregation.

As described in Section 3.1.1, the function of hierarchical layer aggregation is defined as

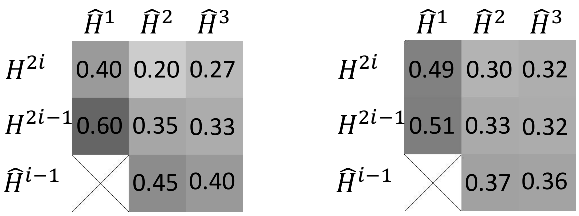
$$\mathrm{AGG}(x, y, z) = \mathrm{LN}(\mathrm{FF}([x; y; z]) + x + y + z),$$

where $\mathrm{FF}(\cdot)$ is a feed-forward network with a sigmoid activation in between. In addition, all the input layers $\{x, y, z\}$ have residual connections to the output. In this experiment, we evaluated the impact of residual connection options, as well as different choices for the aggregation function, as shown in Table 4.

Concerning residual connections, if none of the input layers are connected to the output layer (“None”), the performance would decrease. The translation performance is improved when the output is connected to only the top level of the input layers (“Top”), while connecting to all input layers (“All”) achieves the best performance. This indicates that cross-layer connections are necessary to avoid the gradient vanishing problem.

Besides the feed-forward network with sigmoid activation, we also tried two other aggregation functions for $\textsc{Ff}(\cdot)$: (1) A feed-forward network with a ReLU activation in between; and (2) multi-head self-attention layer that constitutes the encoder and decoder layers in the TRANSFORMER model. As seen, all the three functions consistently improve the translation performance, proving the robustness of the proposed approaches.

4.4 Visualization of Aggregation



(a) No regularization. (b) With regularization.

Figure 5: Visualization of the exploitation of input representations for hierarchical aggregation. x-axis is the aggregation node and y-axis is the input representation. $\widehat{H}^i$ denotes the i-th aggregation layer, and H^i denotes the i-th encoder layer. The rightmost and topmost position in x-axis and y-axis respectively represent the highest layer.

To investigate the impact of diversity regularization, we visualized the exploitation of the input representations for hierarchical aggregation in encoder side, as shown in Figure 5. Let $\mathbf{H}^i = \{H^{2i}, H^{2i-1}, \widehat{H}^{i-1}\}$ be the input representations, we calculated the exploitation of the j-th input as

$$s_j = \frac{\sum_{w \in W_j} |w|}{\sum_{H_{j'} \in \mathbf{H}} \{\sum_{w' \in W_{j'}} |w'|\}}, \qquad (11)$$

where W_j is the parameter matrix associated with the input H_j. The score s_j is a rough estimation of the contribution of H_j to the aggregation $\widehat{H}^i$.

We have two observations. First, the model tends to utilize the bottom layer more than the top one, indicating the necessity of fusing information across layers. Second, using the diversity regularization in Figure 5(b) can encourage each layer to contribute more equally to the aggregation. We hypothesize this is because of the diversity regularization term encouraging the different layers to contain diverse and equally important information.

5 Related Work

Representation learning is at the core of deep learning. Our work is inspired by technological advances in representation learning, specifically in the field of *deep representation learning* and *representation interpretation*.

Deep Representation Learning Deep neural networks have advanced the state of the art in various communities, such as computer vision and natural language processing. One key challenge of training deep networks lies in how to transform information across layers, especially when the network consists of hundreds of layers.

In response to this problem, ResNet (He et al., 2016) uses skip connections to combine layers by simple, one-step operations. Densely connected network (Huang et al., 2017) is designed to better propagate features and losses through skip connections that concatenate all the layers in stages. Yu et al. (2018) design structures iteratively and hierarchically merge the feature hierarchy to better fuse information in a deep fusion.

Concerning machine translation, Meng et al. (2016) and Zhou et al. (2016) have shown that deep networks with advanced connecting strategies outperform their shallow counterparts. Due to its simplicity and effectiveness, skip connection becomes a standard component of state-of-the-art NMT models (Wu et al., 2016; Gehring et al., 2017; Vaswani et al., 2017). In this work, we prove that deep representation exploitation can further improve performance over simply using skip connections.

Representation Interpretation Several researchers have tried to visualize the representation of each layer to help better understand what information each layer captures (Zeiler and Fergus, 2014; Li et al., 2016; Ding et al., 2017). Concerning natural language processing tasks, Shi et al. (2016) find that both local and global source syntax are learned by the NMT encoder and different types of syntax are captured at different layers. Anastasopoulos and Chiang (2018) show that higher level layers are more representative than lower level layers. Peters et al. (2018) demonstrate that higher-level layers capture context-dependent aspects of word meaning while lower-level layers model aspects of syntax. Inspired by these observations, we propose to expose all of these representations to better fuse information across layers. In addition, we introduce a regularization to encourage different layers to capture diverse information.

6 Conclusion

In this work, we propose to better exploit deep representations that are learned by multiple layers for neural machine translation. Specifically, the hierarchical aggregation with diversity regularization achieves the best performance by incorporating more depth and sharing across layers and by encouraging layers to capture different information. Experimental results on WMT14 English⇒German and WMT17 Chinese⇒English show that the proposed approach consistently outperforms the state-of-the-art TRANSFORMER baseline by +0.54 and +0.63 BLEU points, respectively. By visualizing the aggregation process, we find that our model indeed utilizes lower layers to effectively fuse the information across layers.

Future directions include validating our approach on other architectures such as RNN (Bahdanau et al., 2015) or CNN (Gehring et al., 2017) based NMT models, as well as combining with other advanced techniques (Shaw et al., 2018; Shen et al., 2018; Yang et al., 2018; Li et al., 2018) to further improve the performance of TRANSFORMER.

Abstract

Recently, non-recurrent architectures (convolutional, self-attentional) have outperformed RNNs in neural machine translation. CNNs and self-attentional networks can connect distant words via shorter network paths than RNNs, and it has been speculated that this improves their ability to model long-range dependencies. However, this theoretical argument has not been tested empirically, nor have alternative explanations for their strong performance been explored in-depth. We hypothesize that the strong performance of CNNs and self-attentional networks could also be due to their ability to extract semantic features from the source text, and we evaluate RNNs, CNNs and self-attention networks on two tasks: subject-verb agreement (where capturing long-range dependencies is required) and word sense disambiguation (where semantic feature extraction is required). Our experimental results show that: 1) self-attentional networks and CNNs do not outperform RNNs in modeling subject-verb agreement over long distances; 2) self-attentional networks perform distinctly better than RNNs and CNNs on word sense disambiguation.

1 Introduction

Different architectures have been shown to be effective for neural machine translation (NMT), ranging from recurrent architectures (Kalchbrenner and Blunsom, 2013; Bahdanau et al., 2015; Sutskever et al., 2014; Luong et al., 2015) to convolutional (Kalchbrenner and Blunsom, 2013; Gehring et al., 2017) and, most recently, fully self-attentional (Transformer) models (Vaswani et al., 2017). Since comparisons (Gehring et al., 2017; Vaswani et al., 2017; Hieber et al., 2017) are mainly carried out via BLEU (Papineni et al., 2002), it is inherently difficult to attribute gains in BLEU to architectural properties.

Recurrent neural networks (RNNs) (Elman, 1990) can easily deal with variable-length input sentences and thus are a natural choice for the encoder and decoder of NMT systems. Modern variants of RNNs, such as GRUs (Cho et al., 2014) and LSTMs (Hochreiter and Schmidhuber, 1997), address the difficulty of training recurrent networks with long-range dependencies. Gehring et al. (2017) introduce a neural architecture where both the encoder and decoder are based on CNNs, and report better BLEU scores than RNN-based NMT models. Moreover, the computation over all tokens can be fully parallelized during training, which increases efficiency. Vaswani et al. (2017) propose Transformer models, which are built entirely with attention layers, without convolution or recurrence. They report new state-of-art BLEU scores for EN→DE and EN→FR. Yet, the BLEU metric is quite coarse-grained, and offers no insight as to which aspects of translation are improved by different architectures.

To explain the observed improvements in BLEU, previous work has drawn on theoretical arguments. Both Gehring et al. (2017) and Vaswani et al. (2017) argue that the length of the paths in neural networks between co-dependent elements affects the ability to learn these dependencies: the shorter the path, the easier the model learns such dependencies. The papers argue that Transformers and CNNs are better suited than RNNs to capture long-range dependencies.

However, this claim is based on a theoretical argument and has not been empirically tested. We argue other abilities of non-recurrent networks could be responsible for their strong performance. Specifically, we hypothesize that the improvements in BLEU are due to CNNs and Transformers being strong semantic feature extractors.

---

[*] Work carried out during a visit to the machine translation group at the University of Edinburgh.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4263–4272
Brussels, Belgium, October 31 - November 4, 2018.

In this paper, we evaluate all three popular NMT architectures: models based on RNNs (referred to as *RNNS2S* in the remainder of the paper), based on CNNs (referred to as *ConvS2S*) and self-attentional models (referred to as Transformers). Motivated by the aforementioned theoretical claims regarding path length and semantic feature extraction, we evaluate their performance on a subject-verb agreement task (that requires modeling long-range dependencies) and a word sense disambiguation (WSD) task (that requires extracting semantic features). Both tasks build on test sets of contrastive translation pairs, *Lingeval97* (Sennrich, 2017) and *ContraWSD* (Rios et al., 2017).

The main contributions of this paper can be summarized as follows:

- We test the theoretical claims that architectures with shorter paths through networks are better at capturing long-range dependencies. Our experimental results on modeling subject-verb agreement over long distances do not show any evidence that Transformers or CNNs are superior to RNNs in this regard.
- We empirically show that the number of attention heads in Transformers impacts their ability to capture long-distance dependencies. Specifically, many-headed multi-head attention is essential for modeling long-distance phenomena with only self-attention.
- We empirically show that Transformers excel at WSD, indicating that they are strong semantic feature extractors.

2 Related work

Yin et al. (2017) are the first to compare CNNs, LSTMs and GRUs on several NLP tasks. They find that CNNs are better at tasks related to semantics, while RNNs are better at syntax-related tasks, especially for longer sentences.

Based on the work of Linzen et al. (2016), Bernardy and Lappin (2017) find that RNNs perform better than CNNs on a subject-verb agreement task, which is a good proxy for how well long-range dependencies are captured. Tran et al. (2018) find that a Transformer language model performs worse than an RNN language model on a subject-verb agreement task. They, too, note that this is especially true as the distance between subject and verb grows, even if RNNs resulted in a higher perplexity on the validation set. This result of Tran et al. (2018) is clearly in contrast to the general finding that Transformers are better than RNNs for NMT tasks.

Bai et al. (2018) evaluate CNNs and LSTMs on several sequence modeling tasks. They conclude that CNNs are better than RNNs for sequence modeling. However, their CNN models perform much worse than the state-of-art LSTM models on some sequence modeling tasks, as they themselves state in the appendix.

Tang et al. (2018) evaluate different RNN architectures and Transformer models on the task of historical spelling normalization which translates a historical spelling into its modern form. They find that Transformer models surpass RNN models only in high-resource conditions.

In contrast to previous studies, we focus on the machine translation task, where architecture comparisons so far are mostly based on BLEU.

3 Background

3.1 NMT Architectures

We evaluate three different NMT architectures: RNN-based models, CNN-based models, and Transformer-based models. All of them have a bipartite structure in the sense that they consist of an encoder and a decoder. The encoder and the decoder interact via a soft-attention mechanism (Bahdanau et al., 2015; Luong et al., 2015), with one or multiple attention layers.

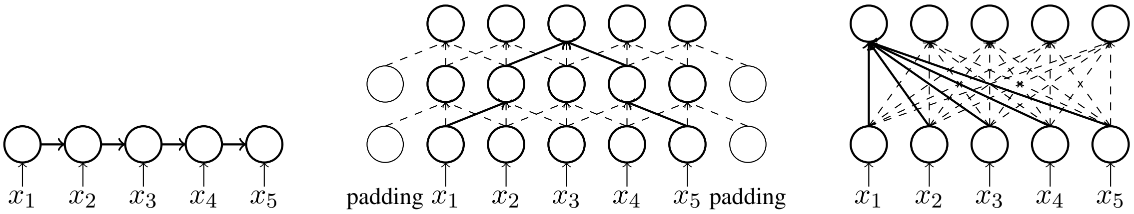
In the following sections, h_i^l is the hidden state at step i of layer l, h_{i-1}^l represents the hidden state at the previous step of layer l, h_i^{l-1} means the hidden state at i of $l-1$ layer, E_{x_i} represents the embedding of x_i, and $e_{pos,i}$ denotes the positional embedding at position i.

3.1.1 RNN-based NMT

RNNs are stateful networks that change as new inputs are fed to them, and each state has a direct connection only to the previous state. Thus, the path length of any two tokens with a distance of n in RNNs is exactly n. Figure 1 (a) shows an illustration of RNNs.

$$h_i^l = h_i^{l-1} + f_{rnn}(h_i^{l-1}, h_{i-1}^l) \tag{1}$$

In deep architectures, two adjacent layers are commonly connected with residual connections. In the lth encoder layer, h_i^l is generated by Equation 1,



(a) RNN (b) CNN (c) Self-attention

Figure 1: Architectures of different neural networks in NMT.

where f_{rnn} is the RNN (GRU or LSTM) function. In the first layer, $h_i^0 = f_{rnn}(E_{x_i}, h_{i-1}^0)$.

In addition to the connection between the encoder and decoder via attention, the initial state of the decoder is usually initialized with the average of the hidden states or the last hidden state of the encoder.

3.1.2 CNN-based NMT

CNNs are hierarchical networks, in that convolution layers capture local correlations. The local context size depends on the size of the kernel and the number of layers. In order to keep the output the same length as the input, CNN models add padding symbols to input sequences. Given an L-layer CNN with a kernel size k, the largest context size is $L(k-1)$. For any two tokens in a local context with a distance of n, the path between them is only $\lceil n/(k-1) \rceil$.

As Figure 1 (b) shows, a 2-layer CNN with kernel size 3 "sees" an effective local context of 5 tokens. The path between the first token and the fifth token is only 2 convolutions.[1] Since CNNs do not have a means to infer the position of elements in a sequence, positional embeddings are introduced.

$$h_i^l = h_i^{l-1} + f_{cnn}(W^l[h_{i-\lfloor k/2 \rfloor}^{l-1}; ...; h_{i+\lfloor k/2 \rfloor}^{l-1}] + b^l) \quad (2)$$

The hidden state h_i^l shown in Equation 2 is related to the hidden states in the same convolution and the hidden state h_i^{l-1} from the previous layer. k denotes the kernel size of CNNs and f_{cnn} is a nonlinearity. *ConvS2S* chooses Gated Linear Units (GLU) which can be viewed as a gated variation of ReLUs. W^l are called convolutional filters. In the input layer, $h_i^0 = E_{x_i} + e_{pos,i}$.

3.1.3 Transformer-based NMT

Transformers rely heavily on self-attention networks. Each token is connected to any other token in the same sentence directly via self-attention. Moreover, Transformers feature attention networks with multiple *attention heads*. Multi-head attention is more fine-grained, compared to conventional 1-head attention mechanisms. Figure 1 (c) illustrates that any two tokens are connected directly: the path length between the first and the fifth tokens is 1. Similar to CNNs, positional information is also preserved in positional embeddings.

The hidden state in the Transformer encoder is calculated from all hidden states of the previous layer. The hidden state h_i^l in a self-attention network is computed as in Equation 3.

$$h_i^l = h_i^{l-1} + f(\text{self-attention}(h_i^{l-1})) \quad (3)$$

where f represents a feedforward network with ReLU as the activation function and layer normalization. In the input layer, $h_i^0 = E_{x_i} + e_{pos,i}$. The decoder additionally has a multi-head attention over the encoder hidden states.

3.2 Contrastive Evaluation of Machine Translation

Since we evaluate different NMT architectures explicitly on subject-verb agreement and WSD (both happen implicitly during machine translation), BLEU as a measure of overall translation quality is not helpful. In order to conduct these targeted evaluations, we use contrastive test sets.

Sets of contrastive translations can be used to analyze specific types of errors. Human reference translations are paired with one or more contrastive variants, where a specific type of error is introduced automatically.

The evaluation procedure then exploits the fact that NMT models are conditional language models. By virtue of this, given any source sentence S

---

[1] Note that the decoder employs masking to avoid conditioning the model on future information, which reduces the effective context size to $L\frac{k-1}{2}$.

and target sentence T, any NMT model can assign to them a probability $P(T|S)$. If a model assigns a higher score to the correct target sentence than to a contrastive variant that contains an error, we consider it a correct decision. The accuracy of a model on such a test set is simply the percentage of cases where the correct target sentence is scored higher than all contrastive variants.

Contrastive evaluation tests the sensitivity of NMT models to specific translation errors. The contrastive examples are designed to capture specific translation errors rather than evaluating the global quality of NMT models. Although they do not replace metrics such as BLEU, they give further insights into the performance of models, on specific linguistic phenomena.

3.2.1 *Lingeval97*

Lingeval97 has over 97,000 English→German contrastive translation pairs featuring different linguistic phenomena, including subject-verb agreement, noun phrase agreement, separable verb-particle constructions, transliterations and polarity. In this paper, we are interested in evaluating the performance on long-range dependencies. Thus, we focus on the subject-verb agreement category which consists of 35,105 instances.

In German, verbs must agree with their subjects in both grammatical number and person. Therefore, in a contrastive translation, the grammatical number of a verb is swapped. Table 1 gives an example.

English:	[...] plan will be approved
German:	[...] **Plan** verabschiedet **wird**
Contrast:	[...] **Plan** verabschiedet **werden**

Table 1: An example of a contrastive pair in the subject-verb agreement category.

3.2.2 *ContraWSD*

In *ContraWSD*, given an ambiguous word in the source sentence, the correct translation is replaced by another meaning of the ambiguous word which is incorrect. For example, in a case where the English word *line* is the correct translation of the German source word *Schlange*, *ContraWSD* replaces *line* with the other translations of *Schlange*, such as *snake*, *serpent*, to generate contrastive translations.

For German→English, *ContraWSD* contains 84 different German word senses. It has 7,200 German→English lexical ambiguities, each lexical ambiguity instance has 3.5 contrastive translations on average. For German→French, it consists of 71 different German word senses. There are 6,700 German→French lexical ambiguities, with an average of 2.2 contrastive translations each lexical ambiguity instance. All the ambiguous words are nouns so that the disambiguation is not possible simply based on syntactic context.

4 Subject-verb Agreement

The subject-verb agreement task is the most popular choice for evaluating the ability to capture long-range dependencies and has been used in many studies (Linzen et al., 2016; Bernardy and Lappin, 2017; Sennrich, 2017; Tran et al., 2018). Thus, we also use this task to evaluate different NMT architectures on long-range dependencies.

4.1 Experimental Settings

Different architectures are hard to compare fairly because many factors affect performance. We aim to create a level playing field for the comparison by training with the same toolkit, *Sockeye* (Hieber et al., 2017) which is based on MXNet (Chen et al., 2015). In addition, different hyperparameters and training techniques (such as label smoothing or layer normalization) have been found to affect the performance (Chen et al., 2018). We apply the same hyperparameters and techniques for all architectures except the parameters of each specific architecture. Since the best hyperparameters for different architectures may be diverse, we verify our hyperparameter choice by comparing our results to those published previously. Our models achieve similar performance to that reported by Hieber et al. (2017) with the best available settings. In addition, we extend *Sockeye* with an interface that enables scoring of existing translations, which is required for contrastive evaluation.

All the models are trained with 2 GPUs. During training, each mini-batch contains 4096 tokens. A model checkpoint is saved every 4,000 updates. We use *Adam* (Kingma and Ba, 2015) as the optimizer. The initial learning rate is set to 0.0002. If the performance on the validation set has not improved for 8 checkpoints, the learning rate is multiplied by 0.7. We set the early stopping patience to 32 checkpoints. All the neural networks have 8 layers. For *RNNS2S*, the encoder has 1 bi-directional LSTM and 6 stacked uni-directional LSTMs, and the decoder is a stack of 8 uni-directional LSTMs. The size of embeddings and hidden states is 512. We apply layer normalization and label smoothing (0.1) in all models. We tie the source and target embeddings. The dropout rate of embeddings and Transformer blocks is set to 0.1. The dropout rate of RNNs and CNNs is 0.2. The kernel size of CNNs is 3. Transformers have an 8-head attention mechanism.

To test the robustness of our findings, we also test a different style of RNN architecture, from a different toolkit. We evaluate bi-deep transitional RNNs (Miceli Barone et al., 2017) which are state-of-art RNNs in machine translation. We use the bi-deep RNN-based model (*RNN-bideep*) implemented in *Marian* (Junczys-Dowmunt et al., 2018). Different from the previous settings, we use the Adam optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.98$, $\epsilon = 10^{-9}$. The initial learning rate is 0.0003. We tie target embeddings and output embeddings. Both the encoder and decoder have 4 layers of LSTM units, only the encoder layers are bi-directional. LSTM units consist of several cells (deep transition): 4 in the first layer of the decoder, 2 cells everywhere else.

We use training data from the WMT17 shared task.[2] We use *newstest2013* as the validation set, and use *newstest2014* and *newstest2017* as the test sets. All BLEU scores are computed with *SacreBLEU* (Post, 2018). There are about 5.9 million sentence pairs in the training set after preprocessing with Moses scripts. We learn a joint BPE model with 32,000 subword units (Sennrich et al., 2016). We employ the model that has the best perplexity on the validation set for the evaluation.

4.2 Overall Results

Table 2 reports the BLEU scores on *newstest2014* and *newstest2017*, the perplexity on the validation set, and the accuracy on long-range dependencies.[3] *Transformer* achieves the highest accuracy on this task and the highest BLEU scores on both *newstest2014* and *newstest2017*. Compared to *RNNS2S*, *ConvS2S* has slightly better results regarding BLEU scores, but a much lower accuracy on long-range dependencies. The *RNN-bideep* model achieves distinctly better BLEU scores and a higher accuracy on long-range dependencies. However, it still cannot outperform Transformers on any of the tasks.

Model	2014	2017	PPL	Acc(%)
RNNS2S	23.3	25.1	6.1	95.1
ConvS2S	23.9	25.2	7.0	84.9
Transformer	**26.7**	**27.5**	**4.5**	**97.1**
RNN-bideep	24.7	26.1	5.7	96.3

Table 2: The results of different NMT models, including the BLEU scores on *newstest2014* and *newstest2017*, the perplexity on the validation set, and the accuracy of long-range dependencies.

Figure 2 shows the performance of different architectures on the subject-verb agreement task. It is evident that *Transformer*, *RNNS2S*, and *RNN-bideep* perform much better than *ConvS2S* on long-range dependencies. However, *Transformer*, *RNNS2S*, and *RNN-bideep* are all robust over long distances. *Transformer* outperforms *RNN-bideep* for distances 11-12, but *RNN-bideep* performs equally or better for distance 13 or higher. Thus, we cannot conclude that Transformer models are particularly stronger than RNN models for long distances, despite achieving higher average accuracy on distances above 10.

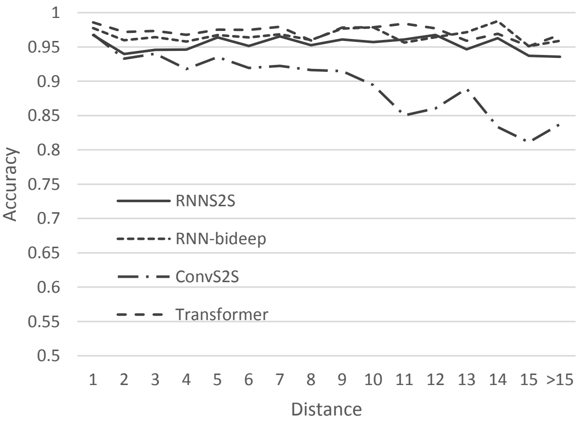


Figure 2: Accuracy of different NMT models on the subject-verb agreement task.

4.2.1 CNNs

Theoretically, the performance of CNNs will drop when the distance between the subject and the verb exceeds the local context size. However, *ConvS2S* is also clearly worse than *RNNS2S* for subject-verb agreement within the local context size.

In order to explore how the ability of *ConvS2S* to capture long-range dependencies depends on the local context size, we train additional systems,

---

[2] `http://www.statmt.org/wmt17/translation-task.html`

[3] We report average accuracy on instances where the distance between subject and verb is longer than 10 words.

varying the number of layers and kernel size. Table 3 shows the performance of different *ConvS2S* models. Figure 3 displays the performance of two 8-layer CNNs with kernel size 3 and 7, a 6-layer CNN with kernel size 3, and *RNNS2S*. The results indicate that the accuracy increases when the local context size becomes larger, but the BLEU score does not. Moreover, *ConvS2S* is still not as good as *RNNS2S* for subject-verb agreement.

Layer	K	Ctx	2014	2017	Acc(%)
4	3	4	22.9	24.2	81.1
6	3	6	23.6	25.0	82.5
8	3	8	**23.9**	**25.2**	84.9
8	5	16	23.5	24.7	89.7
8	7	24	23.3	24.6	**91.3**

Table 3: The performance of *ConvS2S* with different settings. *K* means the kernel size. The *ctx* column is the theoretical largest local context size in the masked decoder.

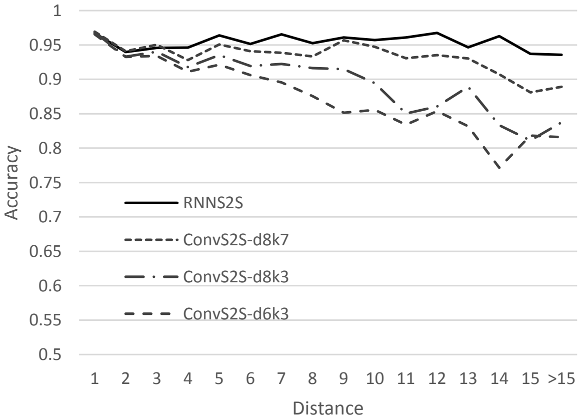

Figure 3: Results of *ConvS2S* models and the *RNNS2S* model at different distances.

Regarding the explanation for the poor performance of *ConvS2S*, we identify the limited context size as a major problem. One assumption to explain the remaining difference is that, scale invariance of CNNs is relatively poor (Xu et al., 2014). Scale-invariance is important in NLP, where the distance between arguments is flexible, and current recurrent or attentional architectures are better suited to handle this variance.

Our empirical results do not confirm the theoretical arguments in Gehring et al. (2017) that CNNs can capture long-range dependencies better with a shorter path. The BLEU score does not correlate well with the targeted evaluation of long-range distance interactions. This is due to the locality of BLEU, which only measures on the level of n-grams, but it may also indicate that there are other trade-offs between the modeling of different phenomena depending on hyperparameters. If we aim to get better performance on long-range dependencies, we can take this into account when optimizing hyperparameters.

4.2.2 RNNs vs. *Transformer*

Even though *Transformer* achieves much better BLEU scores than *RNNS2S* and *RNN-bideep*, the accuracies of these architectures on long-range dependencies are close to each other in Figure 2.

Our experimental result contrasts with the result from Tran et al. (2018). They find that Transformers perform worse than LSTMs on the subject-verb agreement task, especially when the distance between the subject and the verb becomes longer. We perform several experiments to analyze this discrepancy with Tran et al. (2018).

A first hypothesis is that this is caused by the amount of training data, since we used much larger datasets than Tran et al. (2018). We retrain all the models with a small amount of training data similar to the amount used by Tran et al. (2018), about 135K sentence pairs. The other training settings are the same as in Section 4.1. We do not see the expected degradation of *Transformer-s*, compared to *RNNS2S-s* (see Figure 4). In Table 4, the performance of *RNNS2S-s* and *Transformer-s* is similar, including the BLEU scores on *newstest2014, newstest2017*, the perplexity on the validation set, and the accuracy on the long-range dependencies.

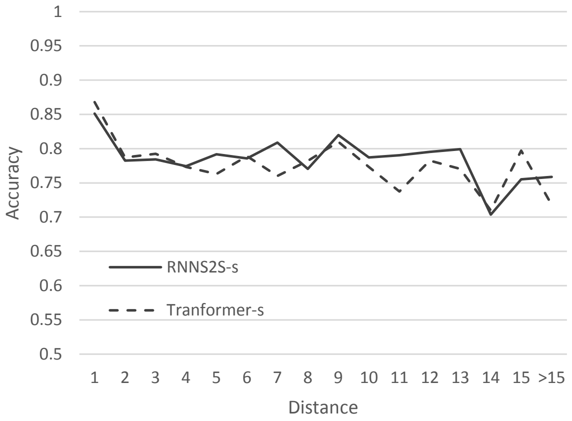

Figure 4: Results of a Transformer and *RNNS2S* model trained on a small dataset.

A second hypothesis is that the experimental settings lead to the different results. In order to investigate this, we do not only use a small training set, but also replicate the experimental settings of Tran et al. (2018). The main changes are neural network layers (8→4); embedding size (512→128); multi-head size (8→2); dropout rate (0.1→0.2); checkpoint save frequency (4,000→1,000), and initial learning rate (0.0002→0.001).

Model	2014	2017	PPL	Acc(%)
RNNS2S-s	7.3	7.8	47.8	77.3
Trans-s	7.2	8.0	44.6	74.6
RNNS2S-re	9.2	10.5	39.2	77.7
Trans-re-h2	9.6	10.7	36.9	71.9
Trans-re-h4	9.5	11.9	35.8	73.8
Trans-re-h8	9.4	10.4	36.0	75.3

Table 4: The results of different models with small training data and replicate settings. *Trans* is short for Transformer. Models with the suffix "*-s*" are models trained with small data set. Models with the suffix "*-re*" are models trained with replicate settings. "*h2, h4, h8*" indicates the number of attention heads for Transformer models.

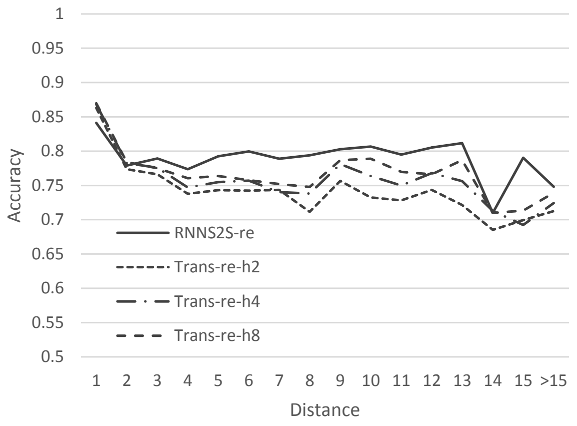

Figure 5: Results of the models with replicate settings, varying the number of attention heads for the Transformer models.

In the end, we get a result that is similar to Tran et al. (2018). In Figure 5, *Transformer-re-h2* performs clearly worse than *RNNS2S-re* on long-range dependencies. By increasing the number of heads in multi-head attention, subject-verb accuracy over long distances can be improved substantially, even though it remains below that of *RNNS2S-re*. Also, the effect on BLEU is small.

Our results suggest that the importance of multi-head attention with a large number of heads is larger than BLEU would suggest, especially for the modeling of long-distance phenomena, since multi-head attention provides a way for the model to attend to both local and distant context, whereas distant context may be overshadowed by local context in an attention mechanism with a single or few heads.

Although our study is not a replication of Tran et al. (2018), who work on a different task and a different test set, our results do suggest an alternative interpretation of their findings, namely that the poor performance of the Transformer in their experiments is due to hyperparameter choice. Rather than concluding that RNNs are superior to Transformers for the modeling of long-range dependency phenomena, we find that the number of heads in multi-head attention affects the ability of Transformers to model long-range dependencies in subject-verb agreement.

5 WSD

Our experimental results on the subject-verb agreement task demonstrate that CNNs and Transformer are not better at capturing long-range dependencies compared to RNNs, even though the paths in CNNs and Transformers are shorter. This finding is not in accord with the theoretical argument in both Gehring et al. (2017) and Vaswani et al. (2017). However, these architectures perform well empirically according to BLEU. Thus, we further evaluate these architectures on WSD, to test our hypothesis that non-recurrent architectures are better at extracting semantic features.

5.1 Experimental settings

We evaluate all architectures on *ContraWSD* on both DE→EN and DE→FR. We reuse the parameter settings in Section 4.1, except that: the initial learning rate of *ConvS2S* is reduced from 0.0003 to 0.0002 in DE→EN; the checkpoint saving frequency is changed from 4,000 to 1,000 in DE→FR because of the training data size.

For DE→EN, the training set, validation set, and test set are the same as the other direction EN→DE. For DE→FR, we use around 2.1 million sentence pairs from Europarl (v7) (Tiedemann, 2012)[4] and News Commentary (v11) cleaned by Rios et al. (2017)[5] as our training set. We use *newstest2013* as the evaluation set, and use *newstest2012* as the test set. All the data is preprocessed with Moses scripts.

Model	DE→EN				DE→FR		
	PPL	2014	2017	Acc(%)	PPL	2012	Acc(%)
RNNS2S	5.7	29.1	30.1	84.0	7.06	16.4	72.2
ConvS2S	6.3	29.1	30.4	82.3	7.93	16.8	72.7
Transformer	**4.3**	**32.7**	33.7	**90.3**	**4.9**	**18.7**	**76.7**
uedin-wmt17	–	–	**35.1**	87.9	–	–	–
TransRNN	5.2	30.5	31.9	86.1	6.3	17.6	74.2

Table 5: The results of different architectures on *newstest* sets and *ContraWSD*. *PPL* is the perplexity on the validation set. *Acc* means accuracy on the test set.

In addition, we also compare to the best result reported for DE→EN, achieved by *uedin-wmt17* (Sennrich et al., 2017), which is an ensemble of 4 different models and reranked with right-to-left models.[6] *uedin-wmt17* is based on the bi-deep RNNs (Miceli Barone et al., 2017) that we mentioned before. To the original 5.9 million sentence pairs in the training set, they add 10 million synthetic pairs with back-translation.

5.2 Overall Results

Table 5 gives the performance of all the architectures, including the perplexity on validation sets, the BLEU scores on *newstest*, and the accuracy on *ContraWSD*. Transformers distinctly outperform *RNNS2S* and *ConvS2S* models on DE→EN and DE→FR. Moreover, the Transformer model on DE→EN also achieves higher accuracy than *uedin-wmt17*, although the BLEU score on *newstest2017* is 1.4 lower than *uedin-wmt17*. We attribute this discrepancy between BLEU and WSD performance to the use of synthetic news training data in *uedin-wmt17*, which causes a large boost in BLEU due to better domain adaptation to *newstest*, but which is less helpful for ContraWSD, whose test set is drawn from a variety of domains.

For DE→EN, *RNNS2S* and *ConvS2S* have the same BLEU score on *newstest2014*, *ConvS2S* has a higher score on *newstest2017*. However, the WSD accuracy of *ConvS2S* is 1.7% lower than *RNNS2S*. For DE→FR, *ConvS2S* achieves slightly better results on both BLEU scores and accuracy than *RNNS2S*.

The Transformer model strongly outperforms the other architectures on this WSD task, with a gap of 4–8 percentage points. This affirms our hypothesis that Transformers are strong semantic features extractors.

5.3 Hybrid Encoder-Decoder Model

In recent work, Chen et al. (2018) find that hybrid architectures with a Transformer encoder and an RNN decoder can outperform a pure Transformer model. They speculate that the Transformer encoder is better at encoding or extracting features than the RNN encoder, whereas the RNN is better at conditional language modeling.

For WSD, it is unclear whether the most important component is the encoder, the decoder, or both. Following the hypothesis that Transformer encoders excel as semantic feature extractors, we train a hybrid encoder-decoder model (*TransRNN*) with a Transformer encoder and an RNN decoder.

The results (in Table 5) show that *TransRNN* performs better than *RNNS2S*, but worse than the pure Transformer, both in terms of BLEU and WSD accuracy. This indicates that WSD is not only done in the encoder, but that the decoder also affects WSD performance. We note that Chen et al. (2018); Domhan (2018) introduce the techniques in Transformers into RNN-based models, with reportedly higher BLEU. Thus, it would be interesting to see if the same result holds true with their architectures.

6 Conclusion

In this paper, we evaluate three popular NMT architectures, *RNNS2S*, *ConvS2S*, and Transformers, on subject-verb agreement and WSD by scoring contrastive translation pairs.

We test the theoretical claims that shorter path lengths make models better capture long-range dependencies. Our experimental results show that:

- There is no evidence that CNNs and Transformers, which have shorter paths through networks, are empirically superior to RNNs in modeling subject-verb agreement over long distances.

---

[6] `https://github.com/a-rios/ContraWSD/tree/master/baselines`

- The number of heads in multi-head attention affects the ability of a Transformer to model long-range dependencies in the subject-verb agreement task.
- Transformer models excel at another task, WSD, compared to the CNN and RNN architectures we tested.

Lastly, our findings suggest that assessing the performance of NMT architectures means finding their inherent trade-offs, rather than simply computing their overall BLEU score. A clear understanding of those strengths and weaknesses is important to guide further work. Specifically, given the idiosyncratic limitations of recurrent and self-attentional models, combining them is an exciting line of research. The apparent weakness of CNN architectures on long-distance phenomena is also a problem worth tackling, and we can find inspiration from related work in computer vision (Xu et al., 2014).

Abstract

In this paper, we propose an addition-subtraction twin-gated recurrent network (ATR) to simplify neural machine translation. The recurrent units of ATR are heavily simplified to have the smallest number of weight matrices among units of all existing gated RNNs. With the simple addition and subtraction operation, we introduce a twin-gated mechanism to build input and forget gates which are highly correlated. Despite this simplification, the essential non-linearities and capability of modeling long-distance dependencies are preserved. Additionally, the proposed ATR is more transparent than LSTM/GRU due to the simplification. Forward self-attention can be easily established in ATR, which makes the proposed network interpretable. Experiments on WMT14 translation tasks demonstrate that ATR-based neural machine translation can yield competitive performance on English-German and English-French language pairs in terms of both translation quality and speed. Further experiments on NIST Chinese-English translation, natural language inference and Chinese word segmentation verify the generality and applicability of ATR on different natural language processing tasks.

1 Introduction

Neural machine translation (NMT), typically with an attention-based encoder-decoder framework (Bahdanau et al., 2015), has recently become the dominant approach to machine translation and already been deployed for online translation services (Wu et al., 2016). Recurrent neural networks (RNN), e.g., LSTMs (Hochreiter and Schmidhuber, 1997) or GRUs (Chung et al., 2014), are widely used as the encoder and decoder for NMT. In order to alleviate the gradient vanishing issue found in simple recurrent neural networks (SRNN) (Elman, 1990), recurrent units in LSTMs or GRUs normally introduce different gates to create shotcuts for gradient information to pass through.

Notwithstanding the capability of these gated recurrent networks in learning long-distance dependencies, they use remarkably more matrix transformations (i.e., more parameters) than SRNN. And with many non-linear functions modeling inputs, hidden states and outputs, they are also less transparent than SRNN. These make NMT which is based on these gated RNNs suffer from not only inefficiency in training and inference due to recurrency and heavy computation in recurrent units (Vaswani et al., 2017) but also difficulty in producing interpretable models (Lee et al., 2017). These also hinder the deployment of NMT models particularly on memory- and computation-limited devices.

In this paper, our key interest is to simplify recurrent units in RNN-based NMT. In doing so, we want to investigate how further we can advance RNN-based NMT in terms of the number of parameters (i.e., memory consumption), running speed and interpretability. This simplification shall preserve the capability of modeling long-distance dependencies in LSTMs/GRUs and the expressive power of recurrent non-linearities in SRNN. The simplification shall also reduce computation load and physical memory consumption in recurrent units on the one hand and allow us to take a good look into the inner workings of RNNs on the other hand.

In order to achieve this goal, we propose an addition-subtraction twin-gated recurrent network (ATR) for NMT. In the recurrent units of ATR, we only keep the very essential weight matrices: one over the input and the other over the history (similar to SRNN). Comparing with previous

Brussels, Belgium, October 31 - November 4, 2018.

RNN variants (e.g., LSTM or GRU), we have the smallest number of weight matrices. This will reduce the computation load of matrix multiplication. ATR also uses gates to bypass the vanishing gradient problem so as to capture long-range dependencies. Specifically, we use the addition and subtraction operations between the weighted history and input to estimate an input and forget gate respectively. These add-sub operations not only distinguish the two gates so that we do not need to have different weight matrices for them, but also make the two gates dynamically correlate to each other. Finally, we remove some non-linearities in recurrent units.

Due to these simplifications, we can easily show that each new state in ATR is an unnormalized weighted sum of previous inputs, similar to recurrent additive networks (Lee et al., 2017). This property not only allows us to trace each state back to those inputs which contribute more but also establishes unnormalized forward self-attention between the current state and all its previous inputs. The self-attention mechanism has already proved very useful in non-recurrent NMT (Vaswani et al., 2017).

We build our NMT systems on the proposed ATR with a single-layer encoder and decoder. Experiments on WMT14 English-German and English-French translation tasks show that our model yields competitive results compared with GRU/LSTM-based NMT. When we integrate an orthogonal context-aware encoder (still single layer) into ATR-based NMT, our model (yielding 24.97 and 39.06 BLEU on English-German and English-French translation respectively) is even comparable to deep RNN and non-RNN NMT models which are all with multiple encoder/decoder layers. In-depth analyses demonstrate that ATR is more efficient than LSTM/GRU in terms of NMT training and decoding speed.

We adapt our model to other language translation and natural language processing tasks, including NIST Chinese-English translation, natural language inference and Chinese word segmentation. Our conclusions still hold on all these tasks.

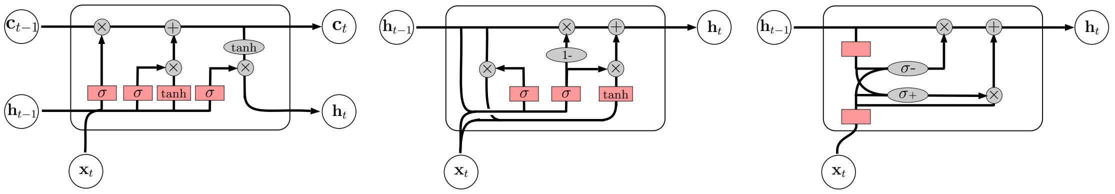
2 Related Work

The most widely used RNN models are LSTM (Hochreiter and Schmidhuber, 1997) and GRU (Chung et al., 2014), both of which are good at handling gradient vanishing problem, a notorious bottleneck of the simple RNN (Elman, 1990). The design of gates in our model follows the gate philosophy in LSTM/GRU.

Our work is closely related to the recurrent additive network (RAN) proposed by Lee et al. (2017). They empirically demonstrate that many non-linearities commonly used in RNN transition dynamics can be removed, and that recurrent hidden states computed as purely the weighted sum of input vectors can be quite efficient in language modeling. Our work follows the same spirit of simplifying recurrent units as they do. But our proposed ATR is significantly different from RAN in three aspects. First, ATR is simpler than RAN with even fewer parameters. There are only two weight matrices in ATR while four different weight matrices in the simplest version of RAN (two for each gate in RAN). Second, since the only difference between the input and forget gate in ATR is the addition/subtraction operation between the history and input, the two gates can be learned to be highly correlated as shown in our analysis. Finally, although RAN is verified effective in language modeling, our experiments show that ATR is better than RAN in machine translation in terms of both speed and translation quality.

To speed up RNN models, a line of work has attempted to remove recurrent connections. For example, Bradbury et al. (2016) propose the quasi-recurrent neural network (QRNN) which uses convolutional layers and a minimalist recurrent pooling function to improve parallelism. Very recently, Lei and Zhang (2017) propose a simple recurrent unit (SRU). With the cuDNN optimization, their RNN model can be trained as fast as CNNs. However, to obtain promising results, QRNN and SRU have to use deep architectures. In practice, 4-layer QRNN encoder and decoder are used to gain translation quality that is comparable to that of single-layer LSTM/GRU NMT. In particular, our one-layer model achieves significantly higher performance than a 10-layer SRU system.

Finally, our work is also related to the efforts in developing alternative architectures for NMT models. Zhou et al. (2016) introduce fast-forward connections between adjacent stacked RNN layers to ease gradient propagation. Wang et al. (2017a) propose a linear associate unit to reduce the gradient propagation length along layers in deep NMT. Gehring et al. (2017b) and Vaswani et al. (2017) explore purely convolutional and attentional archi-



(a) LSTM (b) GRU (c) ATR

tectures as alternatives to RNNs for neural translation. With careful configurations, their deep models achieve state-of-the-art performance on various datasets.

3 Addition-Subtraction Twin-Gated Recurrent Network

Given a sequence $\mathbf{x} = \{\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_T\}$, RNN updates the hidden state $\mathbf{h}_t$ recurrently as follows:

$$\mathbf{h}_t = \phi(\mathbf{h}_{t-1}, \mathbf{x}_t) \tag{1}$$

where $\mathbf{h}_{t-1}$ is the previous hidden state, which is considered to store information from all previous inputs, and $\mathbf{x}_t$ is the current input. The function $\phi(\cdot)$ is a non-linear recurrent function, abstracting away from details in recurrent units.

GRU can be considered as a simplified version of LSTM. In this paper, theoretically, we use GRU as our benchmark and propose a new recurrent unit to further simplify it. The GRU function is defined as follows (see Figure 1b):

$$\mathbf{z}_t = \sigma(\mathbf{W}_z\mathbf{x}_t + \mathbf{U}_z\mathbf{h}_{t-1}) \tag{2}$$
$$\mathbf{r}_t = \sigma(\mathbf{W}_r\mathbf{x}_t + \mathbf{U}_r\mathbf{h}_{t-1}) \tag{3}$$
$$\tilde{\mathbf{h}}_t = \tanh(\mathbf{W}_h\mathbf{x}_t + \mathbf{U}_h(\mathbf{r}_t \odot \mathbf{h}_{t-1})) \tag{4}$$
$$\mathbf{h}_t = \mathbf{z}_t \odot \mathbf{h}_{t-1} + (1 - \mathbf{z}_t) \odot \tilde{\mathbf{h}}_t \tag{5}$$

where $\odot$ denotes an element-wise multiplication. The *reset* gate $\mathbf{r}_t$ and *update* gate $\mathbf{z}_t$ enable manageable information flow from the history and the current input to the new state respectively. Despite the success of these two gates in handling gradient flow, they consume extensive matrix transformations and weight parameters.

We argue that many of these matrix transformations are not essential. We therefore propose an addition-subtraction twin-gated recurrent unit (ATR), formulated as follows (see Figure 1c):

$$\mathbf{p}_t = \mathbf{W}_h\mathbf{h}_{t-1}, \ \mathbf{q}_t = \mathbf{W}_x\mathbf{x}_t \tag{6}$$
$$\mathbf{i}_t = \sigma(\mathbf{p}_t + \mathbf{q}_t) \tag{7}$$
$$\mathbf{f}_t = \sigma(\mathbf{p}_t - \mathbf{q}_t) \tag{8}$$
$$\mathbf{h}_t = \mathbf{i}_t \odot \mathbf{q}_t + \mathbf{f}_t \odot \mathbf{h}_{t-1} \tag{9}$$

The hidden state $\mathbf{h}_t$ in ATR is a weighted mixture of both the current input $\mathbf{q}_t$ and the history $\mathbf{h}_{t-1}$ controlled by an *input* gate $\mathbf{i}_t$ and a *forget* gate $\mathbf{f}_t$ respectively. Notice that we use the transformed representation $\mathbf{q}_t$ for the current input rather than the raw vector $\mathbf{x}_t$ due to the potential mismatch in dimensions between $\mathbf{h}_t$ and $\mathbf{x}_t$.

Similar to GRU, we use gates, especially the forget gate, to control the back-propagated gradient flow to make sure gradients will neither vanish nor explode. We also preserve the non-linearities of SRNN in ATR but only in the two gates.

There are three significant differences of ATR from GRU. Some of these differences are due to the simplifications introduced in ATR. First, we squeeze the number of weight matrices in gate calculation from four to two (see Equation (2&3) and (7&8)). In all existing gated RNNs, the inputs to gates are weighted sum of the previous hidden state and input. In order to distinguish these gates, the weight matrices over the previous hidden state and the current input should be different for different gates. The number of different weight matrices in gates is therefore 2|#gates| in previous gated RNNs. Different from them, ATR introduces different operations (i.e., addition and subtraction) between the weighted history and input to distinguish the input and forget gate. Therefore, the weight matrices over the previous state/input in the two gates can be the same in ATR. Second, we keep the very essential non-linearities, only in the two gates. In ATR, the role of $\mathbf{q}_t$ is similar to that of $\tilde{\mathbf{h}}_t$ in GRU (see Equation (4)). However, we completely wipe out the recurrent non-linearity

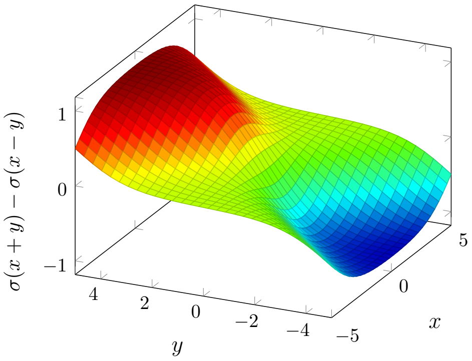

Figure 2: Visualization of the difference between $\sigma(x+y)$ (the input gate) and $\sigma(x-y)$ (the forget gate). Here, we set $x, y \in [-5, 5]$.

of $\tilde{\mathbf{h}}_t$ in $\mathbf{q}_t$ (i.e., $\mathbf{q}_t = \mathbf{W}_x\mathbf{x}_t$). Lee et al. (2017) show that this non-linearity is not necessary in language modeling. We further empirically demonstrate that it is neither essential in machine translation. Third, in GRU the gates for $\tilde{\mathbf{h}}_t$ and $\mathbf{h}_{t-1}$ are coupled and normalized to 1 while we do not explicitly associate the two gates in ATR. Instead, they can be learned to be correlated in an implicit way, as shown in the next subsection and our empirical analyis in Section 5.1.

3.1 Twin-Gated Mechanism

Unlike GRU, we use an addition and subtraction operation over the transformed current input $\mathbf{q}_t$ and history $\mathbf{p}_t$ to differentiate the two gates in ATR. As the two gates have the same weights for their input components with only a single difference in the operation between the input components, they act like twins. We term the two gates in ATR as twin gates and the procedure, shown in Equation (7&8), as the *twin-gated mechanism*. This mechanism endows our model with the following two advantages: 1) Both addition and subtraction operations are completely linear so that fast computation can be expected; and 2) No other weight parameters are introduced for gates so that our model is more memory-compact.

A practical question for the twin-gated mechanism is whether twin gates are really capable of dynamically weighting the input and history information. To this end, we plot the surface of one-dimensional $\sigma(x+y) - \sigma(x-y)$ in Figure 2. It is clear that both gates are highly non-linearly correlated, and that there are regions where $\sigma(x+y)$ is equal to, greater or smaller than $\sigma(x-y)$. In other words, by adapting the distribution of input and forget gates, the twin-gated mechanism has the potential to automatically seek suitable regions in Figure 2 to control its preference between the new and past information. We argue that the input and forget gates are negatively correlated after training, and empirically show their actual correlation in Section 5.1.

Model	**# WM**	**# MT**
LSTM	8	8
GRU	6	6
RAN	4	4
ATR	2	2

Table 1: Comparison of LSTM, GRU, RAN and ATR in terms of the number of weight matrices (WM) and matrix transformations (MT).

3.2 Computation Analysis

Here we provide a systematical comparison of computations in LSTM, GRU, RAN and our ATR with respect to the number of weight matrices and matrix transformations. Notice that all these units are building blocks of RNNs so that the total computational complexity and the minimum number of sequential operations required are unchanged, i.e. $\mathcal{O}(n \cdot d^2)$ and $\mathcal{O}(n)$ respectively where n is the sequence length and d is the dimensionality of hidden states. However, the actual number of matrix transformations in the unit indeed significantly affects the running speed of RNN in practice.

We summarize the results in Table 1. LSTM contains three different gates and a cell state, including 4 different neural layers with 8 weight matrices and transformations. GRU simplifies LSTM by removing a gate, but still involves two gates and a candidate hidden state. It includes 3 different neural layers with 6 weight matrices and transformations. RAN further simplifies GRU by removing the non-linearity in the state transition and therefore contains 4 weight matrices in its simplest version. Although our ATR also has two gates, however, there are only 2 weight matrices and transformations, accounting for only a third and a quarter of those in GRU and LSTM respectively. To the best of our knowledge, ATR has the smallest number of weight transformations in existing gated RNN units. We provide a detailed and empirical analysis on the speed in Section 5.2.

3.3 Interpretability Analysis of Hidden States

An appealing property of the proposed ATR is its interpretability. This can be demonstrated by rolling out Equation (9) as follows:

$$\begin{aligned}\mathbf{h}_t &= \mathbf{i}_t \odot \mathbf{q}_t + \mathbf{f}_t \odot \mathbf{h}_{t-1} \\ &= \mathbf{i}_t \odot \mathbf{W}_t \mathbf{x}_t + \sum_{k=1}^{t-1} \mathbf{i}_k \odot \left(\prod_{l=1}^{t-k} \mathbf{f}_{k+l} \right) \odot \mathbf{W}_x \mathbf{x}_k \\ &\approx \sum_{k=1}^{t} \mathbf{g}_k \odot \mathbf{W}_x \mathbf{x}_k \end{aligned} \tag{10}$$

where $\mathbf{g}_k$ can be considered as an approximate weight assigned to the k-th input. Similar to the RAN model (Lee et al., 2017), the hidden state in ATR is a component-wise weighted sum of the inputs. This not only enables ATR to build up essential dependencies between preceding inputs and the current hidden state, but also allows us to easily detect which previous words have the promising impacts on the current state. This desirable property obviously makes ATR highly interpretable.

Additionally, this form of weighted sum is also related to self-attention (Vaswani et al., 2017). It can be considered as a forward unnormalized self-attention where each hidden state attends to all its previous positions. As the self-attention mechanism has proved very useful in NMT (Vaswani et al., 2017), we conjecture that such property of ATR partially contributes to its success in machine translation as shown in our experiments. We visualize the dependencies captured by Equation (10) in Section 5.3.

4 Experiments

4.1 Setup

We conducted our main experiments on WMT14 English-German and English-French translation tasks. Translation quality is measured by case-sensitive BLEU-4 metric (Papineni et al., 2002). Details about each dataset are as follows:

English-German To compare with previous reported results (Luong et al., 2015b; Jean et al., 2015; Zhou et al., 2016; Wang et al., 2017a), we used the same training data of WMT 2014, which consist of 4.5M sentence pairs. We used the newstest2013 as our dev set, and the newstest2014 as our test set.

English-French We used the WMT 2014 training data. This corpora contain 12M selected sentence pairs. We used the concatenation of newstest2012 and newstest2013 as our dev set, and the newstest2014 as our test set.

The used NMT system is an attention-based encoder-decoder system, which employs a bidirectional recurrent network as its encoder and a two-layer hierarchical unidirectional recurrent network as its decoder, companied with an additive attention mechanism (Bahdanau et al., 2015). We replaced the recurrent unit with our proposed ATR model. More details are given in Appendix A.1.

We also conducted experiments on Chinese-English translation, natural language inference and Chinese word segmentation. Details and experiment results are provided in Appendix A.2.

4.2 Training

We set the maximum length of training instances to 80 words for both English-German and English-French task. We used the *byte pair encoding* compression algorithm (Sennrich et al., 2016) to reduce the vocabulary size as well as to deal with the issue of rich morphology. We set the vocabulary size of both source and target languages to 40K for all translation tasks. All out-of-vocabulary words were replaced with a token "*unk*".

We used 1000 hidden units for both encoder and decoder. All word embeddings had dimensionality 620. We initialized all model parameters randomly according to a uniform distribution ranging from -0.08 to 0.08. These tunable parameters were then optimized using Adam algorithm (Kingma and Ba, 2015) with the two momentum parameters set to 0.9 and 0.999 respectively. Gradient clipping 5.0 was applied to avoid the gradient explosion problem. We trained all models with a learning rate $5e^{-4}$ and batch size 80. We decayed the learning rate with a factor of 0.5 between each training epoch. Translations were generated by a beam search algorithm that was based on log-likelihood scores normalized by sentence length. We used a beam size of 10 in all the experiments. We also applied dropout for English-German and English-French tasks on the output layer to avoid over-fitting, and the dropout rate was set to 0.2.

To train deep NMT models, we adopted the GNMT architecture (Wu et al., 2016). We kept all the above settings, except the dimensionality

"*unk replace*" and "*PosUnk*" denotes the approach of handling rare words in Jean et al. (2015) and Luong et al. (2015a) respectively. "*RL*" and "*WPM*" is the reinforcement learning optimization and word piece model used in Wu et al. (2016). "*CA*" is the context-aware recurrent encoder (Zhang et al., 2017b). "*LAU*" and "*F-F*" denote the linear associative unit and the fast-forward architecture proposed by Wang et al. (2017a) and Zhou et al. (2016) respectively. "*aan*" denotes the average attention network proposed by Zhang et al. (2018a).

of word embedding and hidden state which we set to be 512.

4.3 Results on English-German Translation

The translation results are shown in Table 2. We also provide results of several existing systems that are trained with comparable experimental settings to ours. In particular, our single model yields a detokenized BLEU score of 21.99. In order to show that the proposed model can be orthogonal to previous methods that improve LSTM/GRU-based NMT, we integrate a single-layer context-aware (CA) encoder (Zhang et al., 2017b) into our system. The ATR+CA system further reaches 22.7 BLEU, outperforming the winner system (Buck et al., 2014) by a substantial improvement of 2 BLEU points. Enhanced with the deep GNMT architecture, the GNMT+ATR system yields a gain of 0.89 BLEU points over the RNNSearch+ATR+CA and 1.6 BLEU points over the RNNSearch + ATR. Notice that different from our system which was trained on the parallel corpus alone, the winner system used a huge monolingual text to enhance its language model.

Compared with the existing LSTM-based (Luong et al., 2015a) deep NMT system, our shallow/deep model achieves a gain of 2.41/3.26 tokenized BLEU points respectively. Under the same training condition, our ATR outperforms RAN by a margin of 0.34 tokenized BLEU points, and achieves competitive results against its GRU/LSTM counterpart. This suggests that although our ATR is much simpler than GRU, LSTM and RAN, it still possesses strong modeling capacity.

In comparison to several advanced deep NMT models, such as the Google NMT (8 layers, 24.61 tokenized BLEU) (Wu et al., 2016) and the LAU-connected NMT (4 layers, 23.80 tokenized BLEU) (Wang et al., 2017a), the performance of our shallow model (23.31) is competitive. Particularly, when replacing LSTM in the Google NMT with our ATR model, the GNMT+ATR system achieves a BLEU score of 24.16, merely 0.45 BLEU points lower. Notice that although all systems use the same training data of WMT14, the

	RNNSearch + ATR + CA + BPE + ensemble	40K	39.06	36.06

Table 3: Tokenized (*tok*) and detokenized (detok) case-sensitive BLEU scores on the WMT14 English-French translation task. "*12M data*" indicates the same training data as ours, while "*36M data*" is a significant larger dataset that contains the *12M data*.

tokenization of these work might be different from ours. However, the overall results can indicate the competitive strength of our model. In addition, SRU (Lei and Zhang, 2017), a recent proposed efficient recurrent unit, obtains a BLEU score of 20.70 with 10 layers, far more behind ATR's.

We further ensemble eight likelihood-trained models with different random initializations for the ATR+CA system. The variance in the tokenized BLEU scores of these models is 0.07. As can be seen from Table 2, the ensemble system achieves a tokenized and detokenized BLEU score of 24.97 and 24.33 respectively, obtaining a gain of 1.66 and 1.63 BLEU points over the single model. The final result of the ensemble system, to the best of our knowledge, is a very promising result that can be reached by single-layer NMT systems on WMT14 English-German translation.

4.4 Results on English-French Translation

Unlike the above translation task, the WMT14 English-French translation task provides a significant larger dataset. The full training data have approximately 36M sentence pairs, from which we only used 12M instances for experiments following previous work (Jean et al., 2015; Gehring et al., 2017a; Luong et al., 2015b; Wang et al., 2017a). We show the results in Table 3.

Our shallow model achieves a tokenized BLEU score of 36.89 and 37.88 when it is equipped with the CA encoder, outperforming almost all the listed systems, except the Google NMT (Wu et al., 2016), the ConvS2S (Gehring et al., 2017b) and the Transformer (Vaswani et al., 2017). Enhanced with the deep GNMT architecture, the GNMT+ATR system reaches a BLEU score of 38.59, which beats the base model version of the Transformer by a margin of 0.49 BLEU points. When we use four ensemble models (the variance in the tokenized BLEU scores of these ensemble models is 0.16), the ATR+CA system obtains another gain of 0.47 BLEU points, reaching a tokenized BLEU score of 39.06, which is comparable with several state-of-the-art systems.

5 Analysis

5.1 Analysis on Twin-Gated Mechanism

We provide an illustration of the actual relation between the learned input and forget gate in Figure 3. Clearly, these two gates show strong negative correlation. When the input gate opens with high values, the forget gate prefer to be close. Quantitatively, on the whole test set, the Pearson's r of the input and forget gate is -0.9819, indicating a high correlation.

5.2 Analysis on Speed and Model Parameters

As mentioned in Section 3.2, ATR has much fewer model parameters and matrix transformations. We

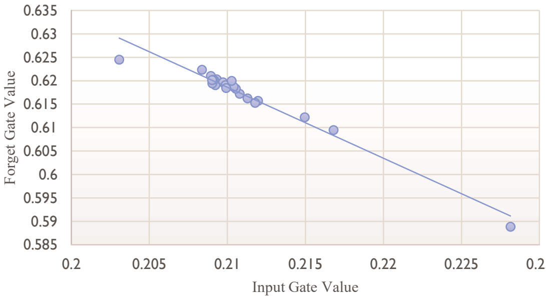

Figure 3: Visualization of correlation between the input and forget gate learned in Equation (13). For each gate, we record its mean value $(\frac{1}{d_h}\sum_i \mathbf{i}_{t,i}/\frac{1}{d_h}\sum_i \mathbf{f}_{t,i})$ with its position on newstest2014, and then average all gate values for each position over all test sentences. This figure illustrates the position-wise input and forget gate values.

Model	#PMs	Train	Test
RNNSearch+GRU	83.5M	1996	168 (0.133)
RNNSearch+LSTM	93.3M	1919	167 (0.139)
RNNSearch+RAN	79.5M	2192	170 (0.129)
DeepRNNSearch	143.0M	894	70 (0.318)
Transformer	70.2M	4961	44 (0.485)
RNNSearch+ATR	67.8M	2518	177 (0.123)
RNNSearch+ATR+CA	63.1M	3993	186 (0.118)

Table 4: Comparison on the training and decoding speed and the number of model parameters of different NMT models on WMT14 English-German translation task with beam size 1. **#PMs**: the number of model parameters. **Train/Test**: the number of words in one second processed during training/testing. The number in bracket indicates the average decoding time per source sentence (in seconds).

provide more details in this section by comparing against the following two NMT systems:

- *DeepRNNSearch (GRU)*: a deep GRU-equipped RNNSearch model (Wu et al., 2016) with 5 layers. We set the dimension of word embedding and hidden state to 620 and 1000 respectively.
- *Transformer*: a purely attentional translator (Vaswani et al., 2017). We set the dimension of word embedding and filter size to 512 and 2048 respectively. The model was trained with a minibatch size of 256.

We also compare with the GRU and LSTM-based RNNSearch. Without specific mention, all other experimental settings for all these models are the same as for our model. We implement all these models using the *Theano* library, and test the speed on one GeForce GTX TITAN X GPU card. We show the results on Table 4.

We observe that the Transformer achieves the best training speed, processing 4961 words per second. This is reasonable since the Transformer can be trained in full parallelization. On the contrary, DeepRNNSearch is the slowest system. As RNN performs sequentially, stacking more layers of RNNs inevitably reduces the training efficiency. However, this situation becomes the reverse when it comes to the decoding procedure. The Transformer merely generates 44 words per second while DeepRNNSearch reaches 70. This is because during decoding, all these beam search-based systems must generate translation one word after another. Therefore the parallelization advantage of the Transformer disappears. In comparison to DeepRNNSearch, the Transformer spends extra time on performing self-attention over all previous hidden states.

Our model with the CA structure, using only 63.1M parameters, processes 3993 words per second during training and generates 186 words per second during decoding, which yields substantial speed improvements over the GRU- and LSTM-equipped RNNSearch. This is due to the light matrix computation in recurrent units of ATR. Notice that the speed increase of ATR over GRU and LSTM does not reach 3x. This is because at each decoding step, there are mainly two types of computation: recurrent unit and softmax layer. The latter consumes the most calculation, which, however, is the same for different models (LSTM/GRU/ATR).

5.3 Analysis on Dependency Modeling

As shown in Section 3.3, a hidden state in our ATR can be formulated as a weighted sum of the previous inputs. In this section, we quantitatively analyze the weights $\mathbf{g}_k$ in Equation (10) induced from Equation (13). Inspired by Lee et al. (2017), we visualize the captured dependencies of an example in Figure 4 where we connect each word to the corresponding previous word with the highest weight $\mathbf{g}_k$.

Obviously, our model can discover strong local dependencies. For example, the token "*unglück@@*" and "*lichen*" should be a

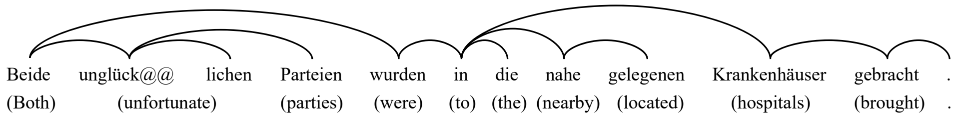

Figure 4: Visualization of dependencies on a target (German) sentence (selected from newstest2014). "@@" indicates a separator that splits one token into two pieces of sub-words.

single word. Our model successfully associates "*unglück@@*" closely to the generation of "*lichen*" during decoding. In addition, our model can also detect non-consecutive long-distance dependencies. Particularly, the prediction of "*Parteien*" relies heavily on the token "*unglücklichen*", which actually entails an *amod* linguistic dependency relationship. These captured dependencies make our model more interpretable than LSTM/GRU.

6 Conclusion and Future Work

This paper has presented a twin-gated recurrent network (ATR) to simplify neural machine translation. There are only two weight matrices and matrix transformations in recurrent units of ATR, making it efficient in physical memory usage and running speed. To avoid the gradient vanishing problem, ATR introduces a twin-gated mechanism to generate an input gate and forget gate through linear addition and subtraction operation respectively, without introducing any additional parameters. The simplifications allow ATR to produce interpretable results.

Experiments on English-German and English-French translation tasks demonstrate the effectiveness of our model. They also show that ATR can be orthogonal to and applied with methods that improve LSTM/GRU-based NMT, indicated by the promising performance of the ATR+CA system. Further analyses reveal that ATR can be trained more efficiently than GRU. It is also able to transparently model long-distance dependencies.

We also adapt our ATR to other natural language processing tasks. Experiments show encouraging performance of our model on Chinese-English translation, natural language inference and Chinese word segmentation, demonstrating its generality and applicability on various NLP tasks.

In the future, we will continue to examine the effectiveness of ATR on different neural models for NMT, such as the hierarchical NMT model (Su et al., 2018b) as well as the generative NMT model (Su et al., 2018a). We are also interested in adapting our ATR to summarization, semantic parsing etc.

Abstract

Although neural machine translation has achieved promising results, it suffers from slow translation speed. The direct consequence is that a trade-off has to be made between translation quality and speed, thus its performance can not come into full play. We apply cube pruning, a popular technique to speed up dynamic programming, into neural machine translation to speed up the translation. To construct the equivalence class, similar target hidden states are combined, leading to less RNN expansion operations on the target side and less $\mathrm{softmax}$ operations over the large target vocabulary. The experiments show that, at the same or even better translation quality, our method can translate faster compared with naive beam search by $3.3\times$ on GPUs and $3.5\times$ on CPUs.

1 Introduction

Neural machine translation (NMT) has shown promising results and drawn more attention recently (Kalchbrenner and Blunsom, 2013; Cho et al., 2014b; Bahdanau et al., 2015; Gehring et al., 2017a,b; Vaswani et al., 2017). A widely used architecture is the attention-based encoder-decoder framework (Cho et al., 2014b; Bahdanau et al., 2015) which assumes there is a common semantic space between the source and target language pairs. The encoder encodes the source sentence to a representation in the common space with the recurrent neural network (RNN) (Hochreiter and Schmidhuber, 1997) and the decoder decodes this representation to generate the target sentence word by word. To generate a target word, a probability distribution over the target vocabulary is drawn based on the attention over the entire source sequence and the target information rolled by another RNN. At the training time, the decoder is forced to generate the ground truth sentence, while at inference, it needs to employ the beam search algorithm to search through a constrained space due to the huge search space.

Even with beam search, NMT still suffers from slow translation speed, especially when it works not on GPUs, but on CPUs, which are more common practice. The first reason for the inefficiency is that the generation of each target word requires extensive computation to go through all the source words to calculate the attention. Worse still, due to the recurrence of RNNs, target words can only be generated *sequentially* rather than in parallel. The second reason is that large vocabulary on target side is employed to avoid unknown words (UNKs), which leads to a large number of normalization factors for the $\mathrm{softmax}$ operation when drawing the probability distribution. To accelerate the translation, the widely used method is to trade off between the translation quality and the decoding speed by reducing the size of vocabulary (Mi et al., 2016a) or/and the number of parameters, which can not realize the full potential of NMT.

In this paper, we borrow ideas from phrase-based and syntax-based machine translation where cube pruning has been successfully applied to speed up the decoding (Chiang, 2007; Huang and Chiang, 2007). Informally, cube pruning "coarsens" the search space by clustering similar states according to some equivalence relations. To apply this idea to NMT, however, is much more involved. Specifically, in the process of beam search, we cluster similar target hidden states to construct equivalence classes, the three dimensions of which are target words in the target vocabulary, part translations retained in the beam search and different combinations of similar target hidden states, respectively. The clustering operation

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4284–4294
Brussels, Belgium, October 31 - November 4, 2018.

can directly decrease the number of target hidden states in the following calculations, together with cube pruning, resulting in less RNN expansion operations to generate the next hidden state (related to the first reason) and less softmax operations over the target vocabulary (related to the second reason). The experiment results show that, when receiving the same or even better translation quality, our method can speed up the decoding speed by 3.3× on GPUs and 3.5× on CPUs.

2 Background

The proposed strategy can be adapted to optimize the beam search algorithm in the decoder of various NMT models. Without loss of generality, we take the attention-based NMT (Bahdanau et al., 2015) as an example to introduce our method. In this section, we first introduce the attention-based NMT model and then the cube pruning algorithm.

2.1 The Attention-based NMT Model

The attention-based NMT model follows the encoder-decoder framework with an extra attention module. In the following parts, we will introduce each of the three components. Assume the source sequence and the observed translation are $\mathbf{x} = \{x_1, \cdots, x_{|\mathbf{x}|}\}$ and $\mathbf{y} = \{y_1^*, \cdots, y_{|\mathbf{y}|}^*\}$.

Encoder The encoder uses a bidirectional GRU to obtain two sequences of hidden states. The final hidden state of each source word is got by concatenating the corresponding pair of hidden states in those sequences. Note that e_{x_i} is employed to represent the embedding vector of the word x_i.

$$\overrightarrow{h}_i = \overrightarrow{\mathbf{GRU}}\left(e_{x_i}, \overrightarrow{h}_{i-1}\right) \quad (1)$$

$$\overleftarrow{h}_i = \overleftarrow{\mathbf{GRU}}\left(e_{x_i}, \overleftarrow{h}_{i+1}\right) \quad (2)$$

$$h_i = \left[\overrightarrow{h}_i; \overleftarrow{h}_i\right] \quad (3)$$

Attention The attention module is designed to extract source information (called context vector) which is highly related to the generation of the next target word. At the j-th step, to get the context vector, the relevance between the target word y_j^* and the i-th source word is firstly evaluated as

$$r_{ij} = \mathbf{v}_a^T \tanh\left(\mathbf{W}_a s_{j-1} + \mathbf{U}_a h_i\right) \quad (4)$$

Then, the relevance is normalized over the source sequence, and all source hidden states are added weightedly to produce the context vector.

$$\alpha_{ij} = \frac{\exp\left(r_{ij}\right)}{\sum_{i'=1}^{|\mathbf{x}|} \exp\left(r_{i'j}\right)}; \; c_j = \sum\nolimits_{i=1}^{|\mathbf{x}|} \alpha_{ij} h_i \quad (5)$$

Decoder The decoder also employs a GRU to unroll the target information. The details are described in Bahdanau et al. (2015). At the j-th decoding step, the target hidden state s_j is given by

$$s_j = f\left(e_{y_{j-1}^*}, s_{j-1}, c_j\right) \quad (6)$$

The probability distribution $\mathcal{D}_j$ over all the words in the target vocabulary is predicted conditioned on the previous ground truth words, the context vector c_j and the unrolled target information s_j.

$$t_j = g\left(e_{y_{j-1}^*}, c_j, s_j\right) \quad (7)$$

$$o_j = \mathbf{W}_o t_j \quad (8)$$

$$\mathcal{D}_j = \mathrm{softmax}\left(o_j\right) \quad (9)$$

where g stands for a linear transformation, $\mathbf{W}_o$ is used to map t_j to o_j so that each target word has one corresponding dimension in o_j.

2.2 Cube Pruning

The cube pruning algorithm, proposed by Chiang (2007) based on the k-best parsing algorithm of Huang and Chiang (2005), is actually an accelerated extension based on the naive beam search algorithm. Beam search, a heuristic dynamic programming searching algorithm, explores a graph by expanding the most promising nodes in a limited set and searches approximate optimal results from candidates. For the sequence-to-sequence learning task, given a pre-trained model, the beam search algorithm finds a sequence that approximately maximizes the conditional probability (Graves, 2012; Boulanger-Lewandowski et al., 2013). Both Sutskever et al. (2014) and Bahdanau et al. (2015) employed the beam search algorithm into the NMT decoding to produce translations with relatively larger conditional probability with respect to the optimized model parameters. Remarkably, Huang and Chiang (2007) successfully applied the cube pruning algorithm to the decoding of SMT. They found that the beam search algorithm in SMT can be extended, and they utilized the cube pruning and some variants to optimize the search process in the decoding phase of phrase-based (Och and Ney, 2004) and syntax-based (Chiang, 2005; Galley et al., 2006) systems,

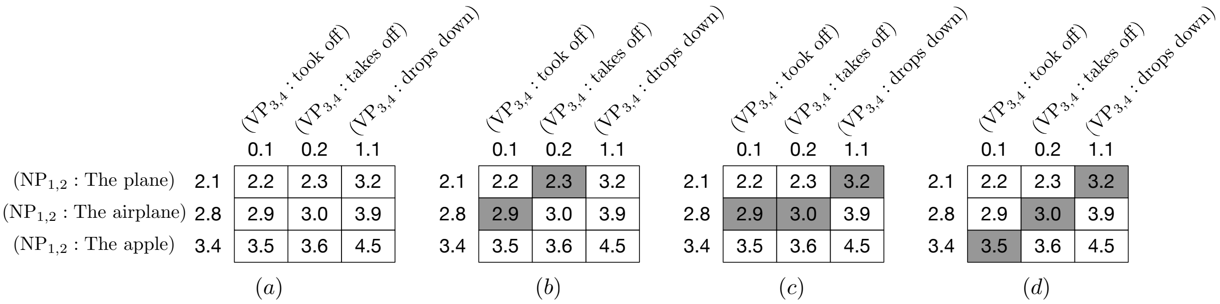

Figure 1: Cube pruning in SMT decoding. (a): the values in the grid denote the negative log-likelihood cost of the terminal combinations on both dimensions, and each dimension denotes a translation candidate in this example; (b)-(d): the process of popping the best candidate of top three items.

	GPU		**CPU**	
Calculation Units	**Time(s)**	**Percentage**	**Time(s)**	**Percentage**
Eq. (6): $s_j = f(e_{y^*_{j-1}}, s_{j-1}, c_j)$	551.07	75.73%	1370.92	19.42%
Eq. (7): $t_j = g(e_{y^*_{j-1}}, c_j, s_j)$	88.25	12.13%	277.76	3.93%
Eq. (8): $o_j = \mathbf{W}_o t_j$	25.33	3.48%	2342.53	33.18%
Eq. (9): $\mathcal{D}_j = \mathrm{softmax}(o_j)$	63.00	8.66%	3069.25	43.47%

Table 1: Time cost statistics for decoding the whole MT03 testset on GPUs and CPUs with beam size 10.

which decreased a mass of translation candidates and achieved a significant speed improvement by reducing the size of complicated search space, thereby making it possible to actualize the thought of improving the translation performance through increasing the beam size.

In the traditional SMT decoding, the cube pruning algorithm aims to prune a great number of partial translation hypotheses without computing and storing them. For each decoding step, those hypotheses with the same translation rule are grouped together, then the cube pruning algorithm is conducted over the hypotheses. We illustrate the detailed process in Figure 1.

3 NMT Decoder with Cube Pruning

3.1 Definitions

We define the related storage unit tuple of the i-th candidate word in the j-th beam as $n^i_j = (c^i_j, s^i_j, y^i_j, bp^i_j)$, where c^i_j is the negative log-likelihood (NLL) accumulation in the j-th beam, s^i_j is the decoder hidden state in the j-th beam, y^i_j is the index of the j-th target word in large vocabulary and bp^i_j is the backtracking pointer for the j-th decoding step. Note that, for each source sentence, we begin with calculating its encoded representation and the first hidden state s^0_0 in decoder, then searching from the initial tuple $(0.0, s^0_0, 0, 0)$ existing in the first beam[1].

It is a fact that Equation (9) produces the probability distribution of the predicted target words over the target vocabulary V. Cho et al. (2014b) indicated that whenever a target word is generated, the $\mathrm{softmax}$ function over V computes probabilities for all words in V, so the calculation is expensive when the target vocabulary is large. As such, Bahdanau et al. (2015) (and many others) only used the top-$30k$ frequent words as target vocabulary, and replaced others with UNK. However, the final normalization operation still brought high computation complexity for forward calculations.

3.2 Time Cost in Decoding

We conducted an experiment to explore how long each calculation unit in the decoder would take. We decoded the MT03 test dataset by using naive beam search with beam size of 10 and recorded the time consumed in the computation of Equation (6), (7), (8) and (9), respectively. The statistical results in Table 1 show that the recurrent calculation unit consumed the most time on GPUs, while

---

[1] The initial target word index y^0_0 equals to 0, which actually corresponds to the Beginning Of Sentence (BOS) token in target vocabulary.

the $\mathrm{softmax}$ computation also took lots of time. On CPUs, the most expensive computational time cost was caused by the $\mathrm{softmax}$ operation over the entire target vocabulary[2]. In order to avoid the time-consuming normalization operation in testing, we introduced *self-normalization* (denoted as **SN**) into the training.

3.3 Self-normalization

Self-normalization (Devlin et al., 2014) was designed to make the model scores which are produced by the output layer be approximated by the probability distribution over the target vocabulary without normalization operation. According to Equation (9), for an observed target sentence $\mathbf{y} = \{y_1^*, \cdots, y_{|\mathbf{y}|}^*\}$, the Cross-Entropy (CE) loss could be written as

$$\begin{aligned} \mathrm{L}_\theta &= -\sum_{j=1}^{|\mathbf{y}|} \log \mathcal{D}_j[y_j^*] \\ &= -\sum_{j=1}^{|\mathbf{y}|} \log \frac{\exp\left(o_j[y_j^*]\right)}{\sum_{y' \in V} \exp\left(o_j[y']\right)} \\ &= \sum_{j=1}^{|\mathbf{y}|} \log \sum_{y' \in V} \exp\left(o_j[y']\right) - o_j[y_j^*] \end{aligned} \tag{10}$$

where o_j is the model score generated by Equation (8) at the j-th step, we marked the $\mathrm{softmax}$ normalizer $\sum_{y' \in V} \exp\left(o_j[y']\right)$ as Z.

Following the work of Devlin et al. (2014), we modified the CE loss function into

$$\begin{aligned} \mathrm{L}_\theta &= -\sum_{j=1}^{|\mathbf{y}|} \left(\log \mathcal{D}_j[y_j^*] - \alpha(\log Z - 0)^2\right) \\ &= -\sum_{j=1}^{|\mathbf{y}|} \left(\log \mathcal{D}_j[y_j^*] - \alpha \log^2 Z\right) \end{aligned} \tag{11}$$

The objective function, shown in Equation (11), is optimized to make sure $\log Z$ is approximated to 0, equally, make Z close to 1 once it converges. We chose the value of α empirically. Because the $\mathrm{softmax}$ normalizer Z is converged to 1 in inference, we just need to ignore Z and predict the target word distribution at the j-th step only with o_j:

$$\mathcal{D}_j = o_j \tag{12}$$

3.4 Cube Pruning

Table 1 clearly shows that the equations in the NMT forward calculation take lots of time. Here, according to the idea behind the cube pruning algorithm, we tried to reduce the time of time-consuming calculations, e.g., Equation (6), and further decrease the search space by introducing the cube pruning algorithm.

3.4.1 Integrating into NMT Decoder

Extended from the naive beam search in the NMT decoder, cube pruning, treated as a pruning algorithm, attempts to reduce the search space and computation complexity by merging some similar items in a beam to accelerate the naive beam search, keeping the 1-best searching result almost unchanged or even better by increasing the beam size. Thus, it is a fast and effective algorithm to generate candidates.

Assume that T restores the set of the finished translations. For each step in naive beam search process, $\mathrm{beamsize}-|\mathrm{T}|$ times forward calculations are required to acquire $\mathrm{beamsize}-|\mathrm{T}|$ probability distributions corresponding to each item in the previous beam (Bahdanau et al., 2015). while for each step in cube pruning, in terms of some constraints, we merge all similar items in the previous beam into one *equivalence class* (called a sub-cube). The constraint we used here is that items being merged in the previous beam should have the same target words. Then, for the sub-cube, only one forward calculation is required to obtain the approximate predictions by using the loose hidden state. Elements in the sub-cube are sorted by previous accumulated NLL along the columns (the first dimension of beam size) and by the approximate predictions along the rows (the second dimension of vocabulary size). After merging, one beam may contain several sub-cubes (the third dimension), we start to search from item in the upper left corner of each sub-cube, which is the best one in the sub-cube, and continue to spread out until enough candidates are found. Once a item is selected, the exact hidden state will be used to calculate its exact NLL.

Through all above steps, the frequency of forward computations decreases. We give an example to dive into the details in Figure 2.

Assume that the beam size is 4. Given the 10^{th}

---

[2] Note that, identical to Bahdanau et al. (2015), we only used $30k$ as the vocabulary size.

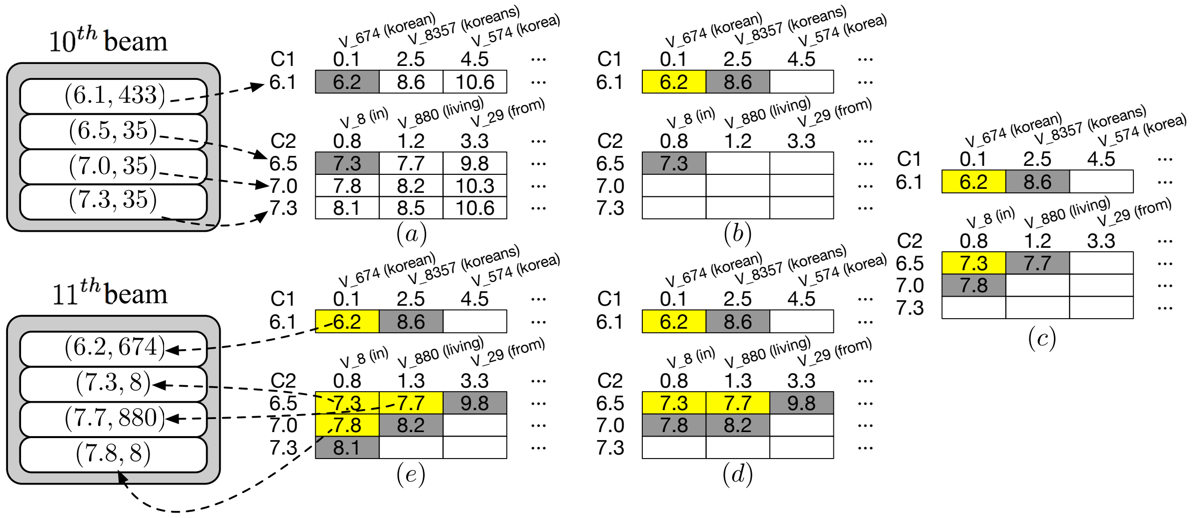

Figure 2: Cube pruning diagram in beam search process during NMT decoding. We only depict the accumulated NLL and the word-level candidate for each item in the beam (in the bracket). Assume the beam size is 4, we initialize a heap for the current step, elements in the 10^{th} beam are merged into two sub-cubes C1 and C2 according to the previous target words; (a) the two elements located in the upper-left corner of the two sub-cubes are pushed into the heap; (b) minimal element $(6.2, 674)$ is popped out, meanwhile, its neighbor $(8.6, 8357)$ is pushed into the heap; (c) minimal element $(7.3, 8)$ is popped out, its right-neighbor $(7.7, 880)$ and lower-neighbor $(7.8, 8)$ are pushed into the heap; (d) minimal element $(7.7, 880)$ is popped out, its right-neighbor $(9.8, 29)$ and down-neighbor $(8.2, 880)$ are pushed into the heap; (e) minimal element $(7.8, 8)$ is popped out, then its down-neighbor $(8.1, 8)$ is pushed into the heap. 4 elements have been popped out, we use them to construct the 11^{th} beam. Yellow boxes indicate the 4-best word-level candidates to be pushed into the 11^{th} beam.

beam, we generate the 11^{th} beam. Different from the naive beam search, we first group items in the previous beam into two sub-cubes C1 and C2 in term of the target word y_{j-1}. As shown in part (a) of Figure 2, $(6.1, 433)$ constructs the sub-cube C1; $(6.5, 35)$, $(7.0, 35)$ and $(7.3, 35)$ are put together to compose another sub-cube C2. Items in part (a) are ranked in ascending order along both row and column dimension according to the accumulated NLL. For each sub-cube, we use the first state vector in each sub-cube as the approximate one to produce the next probability distribution and the next state. At beginning, each upper-left corner element in each sub-cube is pushed into a minimum heap, after popping minimum element from the heap, we calculate and restore the exact NLL of the element, then push the right and lower ones alongside the minimum element into heap. At this rate, the searching continues just like the "diffusion" in the sub-cube until 4 elements are popped, which are ranked in terms of their exact NLLs to construct the 11^{th} beam. Note that once an element is popped, we calculate its exact NLL. From the step (e) in Figure 2, we can see that 4 elements have been popped from C1 and C2, and then ranked in terms of their exact NLLs to build the 11^{th} beam.

We refer above algorithm as the naive cube pruning algorithm (called **NCP**)

3.4.2 Accelerated Cube Pruning

In each step of the cube pruning algorithm, after merging the items in the previous beam, some similar candidates are grouped together into one or more sub-cube(s). We also try to predict the approximate distribution for each sub-cube only according to the top-1 state vector (the first row in the sub-cube in Figure 2), and select next candidates after ranking. The predicted probability distribution will be very similar to that of the naive beam search. Besides, Each sub-cube only requires one forward calculation. Thus, it could save more search space and further reduce the computation complexity for the decoder. Unlike the naive cube pruning algorithm, accelerated cube pruning pops each item, then still use the approximate NLL instead of the exact one. We denote this kind of accelerated cube pruning algorithm as **ACP**.

4 Experiments

We verified the effectiveness of proposed cube pruning algorithm on the Chinese-to-English (Zh-En) translation task.

4.1 Data Preparation

The Chinese-English training dataset consists of 1.25M sentence pairs[3]. We used the NIST 2002 (MT02) dataset as the validation set with 878 sentences, and the NIST 2003 (MT03) dataset as the test dataset, which contains 919 sentences.

The lengths of the sentences on both sides were limited up to 50 tokens, then actually 1.11M sentence pairs were left with 25.0M Chinese words and 27.0M English words. We extracted $30k$ most frequent words as the source and target vocabularies for both sides.

In all the experiments, case-insensitive 4-gram BLEU (Papineni et al., 2002) was employed for the automatic evaluation, we used the script *mteval-v11b.pl*[4] to calculate the BLEU score.

4.2 System

The system is an improved version of attention-based NMT system named RNNsearch (Bahdanau et al., 2015) where the decoder employs a conditional GRU layer with attention, consisting of two GRUs and an attention module for each step[5]. Specifically, Equation (6) is replaced with the following two equations:

$$\tilde{s}_j = \mathbf{GRU}_1(e_{y^*_{j-1}}, s_{j-1}) \tag{13}$$

$$s_j = \mathbf{GRU}_2(c_j, \tilde{s}_j) \tag{14}$$

Besides, for the calculation of relevance in Equation (4), s_{j-1} is replaced with $\tilde{s}_{j-1}$. The other components of the system keep the same as RNNsearch. Also, we re-implemented the beam search algorithm as the naive decoding method, and naive searching on the GPU and CPU server were conducted as two baselines.

4.3 Training Details

Specially, we employed a little different settings from Bahdanau et al. (2015): Word embedding sizes on both sides were set to 512, all hidden sizes in the GRUs of both encoder and decoder were also set to 512. All parameter matrices, including bias matrices, were initialized with the uniform distribution over $[-0.1, 0.1]$. Parameters were updated by using mini-batch Stochastic Gradient Descent (SGD) with batch size of 80 and the learning rate was adjusted by AdaDelta (Zeiler, 2012) with decay constant ρ=0.95 and denominator constant ϵ=1e-6. The gradients of all variables whose L2-norm are larger than a pre-defined threshold 1.0 were normalized to the threshold to avoid gradient explosion (Pascanu et al., 2013). Dropout was applied to the output layer with dropout rate of 0.5. We exploited length normalization (Cho et al., 2014a) strategy on candidate translations in beam search decoding.

The model whose BLEU score was the highest on the validation set was used to do testing. Maximal epoch number was set to 20. Training was conducted on a single Tesla K80 GPU, it took about 2 days to train a single NMT model on the Zh-En training data. For *self-normalization*, we empirically set α as 0.5 in Equation (11)[6].

4.4 Search Strategies

We conducted experiments to decode the MT03 test dataset on the GPU and CPU server respectively, then compared search quality and efficiency among following six search strategies under different beam sizes.

NBS-SN: Naive Beam Search without **SN**

NBS+SN: Naive Beam Search with **SN**

NCP-SN: Cube Pruning without **SN**

NCP+SN: Cube Pruning with **SN**

ACP-SN: Accelerated Cube Pruning without **SN**

ACP+SN: Accelerated Cube Pruning with **SN**

4.5 Comparison of Average Merging Rate

We first give the definition of the Average Merging Rate (denoted as AMR). Given a test dataset, we counted the total word-level candidates (noted as N_w) and the total sub-cubes (noted as N_c) during the whole decoding process, then the AMR can be simply computed as

$$\overline{m} = \mathrm{N}_w / \mathrm{N}_c \tag{15}$$

The MT03 test dataset was utilized to compare the trends of the AMR values under all

---

[3] These sentence pairs are mainly extracted from LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06

[4] `https://github.com/moses-smt/mosesdecoder/blob/master/scripts/generic/mteval-v11b.pl`

[5] `https://github.com/nyu-dl/dl4mt-tutorial/blob/master/docs/cgru.pdf`

[6] Following Devlin et al. (2014), we had tried 0.01, 0.1, 0.5 1.0 and 10.0 for the value of α, we found that 0.5 produced the best result.

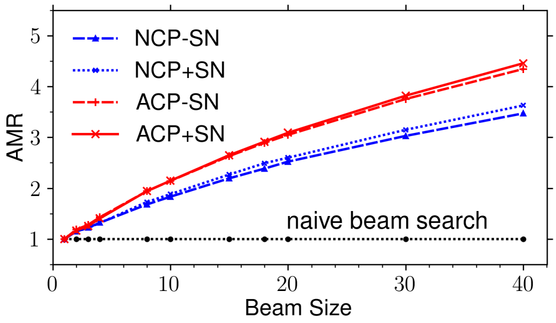

Figure 3: AMR comparison on the MT03 test dataset. Decoding the MT03 test dataset on a single GeForce GTX TITAN X GPU server under the different searching settings. y-axis represents the AMR on the test dataset in the whole searching process and x-axis indicates beam size. Unsurprisingly, we got exactly the same results on the CPU server, not shown here.

six methods. We used the pre-trained model to translate the test dataset on a single GeForce GTX TITAN X GPU server. Beam size varies from 1 to 40, values are included in the set $\{1, 2, 3, 4, 8, 10, 15, 18, 20, 30, 40\}$. For each beam size, six different searching settings were applied to translate the test dataset respectively. The curves of the AMRs during the decoding on the MT03 test dataset under the proposed methods are shown in Figure 3. Note that the AMR values of **NBS** are always 1 whether there is **SN** or not.

Comparing the curves in the Figure 3, we could observe that the naive beam search does not conduct any merging operation in the whole searching process, while the average merging rate in the cube pruning almost grows as the beam size increases. Comparing the red curves to the blue ones, we can conclude that, in any case of beam size, the AMR of the accelerated cube pruning surpasses the basic cube pruning by a large margin. Besides, self-normalization could produces the higher average merging rate comparing to the counterpart without self-normalization.

4.6 Comparison on the GPU Server

Intuitively, as the value of the AMR increases, the search space will be reduced and computation efficiency improves. We compare the two proposed searching strategies and the naive beam search in two conditions (with self-normalization and without self-normalization). Figure 4 demonstrates the results of comparison between the proposed searching methods and the naive beam search baseline in terms of search quality and search efficiency under different beam sizes.

By fixing the beam size and the dataset, we compared the changing trend of BLEU scores for the three distinct searching strategies under two conditions. Without self-normalization, Figure 4a shows the significant improvement of the search speed, however the BLEU score drops about 0.5 points. We then equipped the search algorithm with self-normalization. Figure 4b shows that the accelerated cube pruning search algorithm only spend about one-third of the time of the naive beam search to achieve the best BLEU score with beam size 30. Concretely, when the beam size is set to be 30, **ACP+SN** is 3.3 times faster than the baseline on the MT03 test dataset, and both performances are almost the same.

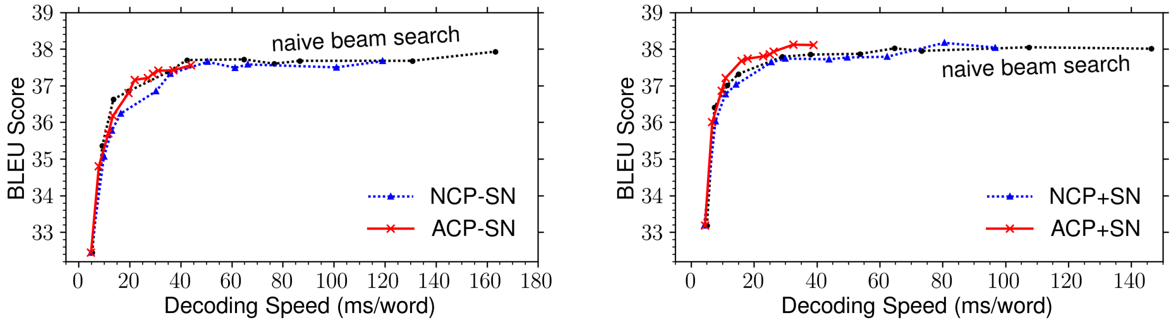
4.7 Comparison on the CPU Server

Similar to the experiments conducted on GPUs, we also translated the whole MT03 test dataset on the CPU server by using all six search strategies under different beam sizes. The trends of the BLEU scores over those strategies are shown in Figure 5.

The proposed search methods gain the similar superiority on CPUs to that on GPUs, and the decoding speed is obviously slower than that on GPUs. From the Figure 5a, we can also clearly see that, compared with the **NBS-SN**, **NCP-SN** only speeds up the decoder a little, **ACP-SN** produces much more acceleration. However, when we did not introduce self-normalization, the proposed search methods will also result in a loss of about 0.5 BLEU score. The self-normalization made the **ACP** strategy faster than the baseline by about 3.5×, in which condition the **NBS+SN** got the best BLEU score 38.05 with beam size 30 while the **ACP+SN** achieved the highest score 38.12 with beam size 30. The results could be observed in Figure 5b. Because our method is on the algorithmic level and platform-independent, it is reasonable that the proposed method can not only perform well on GPUs, but also accelerate the decoding significantly on CPUs. Thus, the accelerated cube pruning with self-normalization could improve the search quality and efficiency stably.

4.8 Decoding Time

In this section, we only focus on the consuming time of translating the entire MT03 test dataset.



(a) BLEU vs. decoding speed, without self-normalization

(b) BLEU vs. decoding speed, with self-normalization

Figure 4: Comparison among the decoding results of the MT03 test dataset on the single GeForce GTX TITAN X GPU server under the three different searching settings. y-axis represents the BLEU score of translations, x-axis indicates that how long it will take for translating one word on average.

Under the two conditions, we calculated the times spent on translating the entire test dataset for different beam sizes, then draw the curves in Figure 6 and 7. From the Figure 6a and 6b, we could observe that accelerated cube pruning algorithm speeds up the decoding by about 3.8× on GPUs when the beam size is set to 40. Figure 7a and 7b show that the accelerated cube pruning algorithm speeds up the decoding by about 4.2× on CPU server with the beam size 40.

5 Related Work

Recently, lots of works devoted to improve the efficiency of the NMT decoder. Some researchers employed the way of decreasing the target vocabulary size. Jean et al. (2015) improved the decoding efficiency even with the model using a very large target vocabulary but selecting only a small subset of the whole target vocabulary. Based on the work of Jean et al. (2015), Mi et al. (2016b) introduced sentence-level and batch-level vocabularies as a very small subset of the full output vocabulary, then predicted target words only on this small vocabulary, in this way, they only lost 0.1 BLEU points, but reduced target vocabulary substantially.

Some other researchers tried to raise the efficiency of decoding from other perspectives. Wu et al. (2016) introduced a coverage penalty α and length normalization β into beam search decoder to prune hypotheses and sped up the search process by 30%∼40% when running on CPUs. Hu et al. (2015) used a priority queue to choose the best hypothesis for the next search step, which drastically reduced search space.

Inspired by the works of Mi et al. (2016b) and Huang and Chiang (2007), we consider pruning hypothesis in NMT decoding by using cube pruning algorithm, but unlike traditional SMT decoding where dynamic programming was used to merge equivalent states (e.g., if we use phrase-

based decoding with trigram language model, we can merge states with same source-side coverage vector and same previous two target words). However, this is not appropriate for current NMT decoding, since the embedding of the previous target word is used as one input of the calculation unit of each step in the decoding process, we could group equivalence classes containing the same previous target word together.

6 Conclusions

We extended cube pruning algorithm into the decoder of the attention-based NMT. For each step in beam search, we grouped similar candidates in previous beam into one or more equivalence class(es), and bad hypotheses were pruned out. We started searching from the upper-left corner in each equivalence class and spread out until enough candidates were generated. Evaluations show that, compared with naive beam search, our method could improve the search quality and efficiency to a large extent, accelerating the NMT decoder by 3.3× and 3.5× on GPUs and CPUs, respectively. Also, the translation precision could be the same or even better in both situations. Besides, self-normalization is verified to be helpful to accelerate cube pruning even further.

Abstract

Translating characters instead of words or word-fragments has the potential to simplify the processing pipeline for neural machine translation (NMT), and improve results by eliminating hyper-parameters and manual feature engineering. However, it results in longer sequences in which each symbol contains less information, creating both modeling and computational challenges. In this paper, we show that the modeling problem can be solved by standard sequence-to-sequence architectures of sufficient depth, and that deep models operating at the character level outperform identical models operating over word fragments. This result implies that alternative architectures for handling character input are better viewed as methods for reducing computation time than as improved ways of modeling longer sequences. From this perspective, we evaluate several techniques for character-level NMT, verify that they do not match the performance of our deep character baseline model, and evaluate the performance versus computation time tradeoffs they offer. Within this framework, we also perform the first evaluation for NMT of conditional computation over time, in which the model learns which timesteps can be skipped, rather than having them be dictated by a fixed schedule specified before training begins.

1 Introduction

Neural Machine Translation (NMT) has largely replaced the complex pipeline of Phrase-Based MT with a single model that is trained end-to-end. However, NMT systems still typically rely on pre- and post-processing operations such as tokenization and word fragmentation through byte-pair encoding (BPE; Sennrich et al., 2016). Although these are effective, they involve hyperparameters that should ideally be tuned for each language pair and corpus, an expensive step that is frequently omitted. Even when properly tuned, the representation of the corpus generated by pipelined external processing is likely to be sub-optimal. For instance, it is easy to find examples of word fragmentations, such as *fling* → *fl* + *ing*, that are linguistically implausible. NMT systems are generally robust to such infelicities—and can be made more robust through subword regularization (Kudo, 2018)—but their effect on performance has not been carefully studied. The problem of finding optimal segmentations becomes more complex when an NMT system must handle multiple source and target languages, as in multilingual translation or zero-shot approaches (Johnson et al., 2017).

Translating characters instead of word fragments avoids these problems, and gives the system access to all available information about source and target sequences. However, it presents significant modeling and computational challenges. Longer sequences incur linear per-layer cost and quadratic attention cost, and require information to be retained over longer temporal spans. Finer temporal granularity also creates the potential for attention jitter (Gulcehre et al., 2017). Perhaps most significantly, since the meaning of a word is not a compositional function of its characters, the system must learn to memorize many character sequences, a different task from the (mostly) compositional operations it performs at higher levels of linguistic abstraction.

In this paper, we show that a standard LSTM sequence-to-sequence model works very well for characters, and given sufficient depth, consistently outperforms identical models operating over word fragments. This result suggests that a productive line of research on character-level models is to seek architectures that approximate standard sequence-to-sequence models while being compu-

Brussels, Belgium, October 31 - November 4, 2018.

tationally cheaper. One approach to this problem is *temporal compression*: reducing the number of state vectors required to represent input or output sequences. We evaluate various approaches for performing temporal compression, both according to a fixed schedule; and, more ambitiously, learning compression decisions with a Hierarchical Multiscale architecture (Chung et al., 2017). Following recent work by Lee et al. (2017), we focus on compressing the encoder.

Our contributions are as follows:

- The first large-scale empirical investigation of the translation quality of standard LSTM sequence-to-sequence architectures operating at the character level, demonstrating improvements in translation quality over word fragments, and quantifying the effect of corpus size and model capacity.
- A comparison of techniques to compress character sequences, assessing their ability to trade translation quality for increased speed.
- A first attempt to learn how to compress the source sequence during NMT training by using the Hierarchical Multiscale LSTM to dynamically shorten the source sequence as it passes through the encoder.

2 Related Work

Early work on modeling characters in NMT focused on solving the out-of-vocabulary and softmax bottleneck problems associated with word-level models (Ling et al., 2015; Costa-jussà and Fonollosa, 2016; Luong and Manning, 2016). These took the form of word-boundary-aware hierarchical models, with word-level models delegating to character-level models to generate representations in the encoder and words in the decoder. Our work will not assume fixed word boundaries are given in advance.

With the advent of word-fragment approaches, interest in character-level processing fell off, but has recently been reignited with the work of Lee et al. (2017). They propose a specialized character-level encoder, connected to an unmodified character-level RNN decoder. They address the modeling and efficiency challenges of long character sequences using a convolutional layer, max-pooling over time, and highway layers. We agree with their conclusion that character-level translation is effective, but revisit the question of whether their specific encoder produces a desirable speed-quality tradeoff in the context of a much stronger baseline translation system. We draw inspiration from their pooling solution for reducing sequence length, along with similar ideas from the speech community (Chan et al., 2016), when devising fixed-schedule reduction strategies in Section 3.3.

One of our primary contributions is an extensive invesigation of the efficacy of a typical LSTM-based NMT system when operating at the character-level. The vast majority of existing studies compare a specialized character-level architecture to a distinct word-level one. To the best of our knowledge, only a small number of papers have explored running NMT unmodified on character sequences; these include: Luong and Manning (2016) on WMT'15 English-Czech, Wu et al. (2016) on WMT'14 English-German, and Bradbury et al. (2016) on IWSLT German-English. All report scores that either trail behind or reach parity with word-level models. Only Wu et al. (2016) compare to word fragment models, which they show to outperform characters by a sizeable margin. We revisit the question of character- versus fragment-level NMT here, and reach quite different conclusions.

3 Methods

3.1 Baseline Sequence-to-Sequence Model

We adopt a simplified version of the LSTM architecture of Chen et al. (2018) that achieves state-of-the-art performance on the competitive WMT14 English-French and English-German benchmarks. This incorporates bidirectional LSTM (BiLSTM) layers in the encoder, concatenating the output from forward and backward directions before feeding the next layer. Output from the top encoder layer is projected down to the decoder dimension and used in an additive attention mechanism computed over the bottom decoder layer. The decoder consists of unidirectional layers, all of which use the encoder context vectors computed from attention weights over the bottom layer. For both encoder and decoder we use layer normalization (Ba et al., 2016) and residual connections beginning at the third layer. We do not apply a non-linearity to LSTM output. We regularize with dropout applied to embeddings and to the output of each LSTM layer.

In the interests of simplicity and reproducibility, we depart from Chen et al. (2018) in several ways: we do not use multi-headed attention, feed encoder context vectors to the softmax, regularize with label smoothing or weight decay, nor apply dropout to the attention mechanism.

Our baseline character models and BPE models both use this architecture, differing only in whether the source and target languages are tokenized into sequences of characters or BPE word fragments. We describe BPE briefly below.

3.2 Byte-Pair Encoding

Byte-Pair Encoding (BPE) offers a simple interpolation between word- and character-level representations (Sennrich et al., 2016). It creates a vocabulary of frequent words and word fragments in an iterative greedy merging process that begins with characters and ends when a desired vocabulary size is reached. The source and target language are typically processed together in order to exploit lexical similarities. Given a vocabulary, BPE re-tokenizes the corpus into word fragments in a greedy left-to-right fashion, selecting the longest possible vocabulary match, and backing off to characters when necessary.

Since each BPE token consists of one or more characters, BPE-tokenized sequences will be shorter than character sequences. Viewed as a mechanism to reduce sequence length, BPE differs from the solutions we will discuss subsequently in that it increases the vocabulary size, delegating the task of creating representations for word fragments to the embedding table. Also, despite being data-driven, its segmentation decisions are fixed before NMT training begins.

3.3 Fixed stride Temporal Pooling

We explore using fixed stride temporal pooling within the encoder to compress the source character sequence. These solutions are characterized by pooling the contents of two or more contiguous timesteps to create a single vector that summarizes them, and will replace them to shorten the sequence in the next layer. These approaches can learn to interpret the raw character sequence in service to their translation objective, but any such interepretation must fit into the pooling schedule that was specified during network construction. We evaluate two methods in this family: a re-implementation of Lee et al. (2017), and a version of our baseline with interspersed pooling layers.

As mentioned earlier, Lee et al. (2017) propose a specialized character encoder that combines convolutional layers to accumulate local context, max-pooling layers to reduce sequence lengths, highway layers to increase network capacity, followed by bidirectional GRU layers to generate globally aware contextual source representations. This strategy is particularly efficient because all reductions happen before the first recurrent layer. We re-implement their approach faithfully, with the exceptions of using LSTMs in place of GRUs,[1] and modifying the batch sizes to accomodate our multi-GPU training scheme.

While pooling based approaches are typically employed in association with convolutional layers, we can also intersperse pooling layers into our high capacity baseline encoder. This means that after each BiLSTM layer, we have the option to include a fixed-stride pooling layer to compress the sequence before it is processed by the next BiLSTM layer. This is similar to the pyramidal LSTM encoders used for neural speech recognition (Chan et al., 2016). This general strategy affords considerable flexibility to the network designer, leaving the type of pooling (concatenation, max, mean), and the strides with which to pool as design decisions that can be tuned to fit the task.

3.4 Learned Temporal Compression

It is unsatisfying to compress a sequence on a fixed schedule; after all, the characters in a sentence do not each carry an identical amount of information. The goal of this section is to explore data-driven reduction methods that are optimized to the NMT system's objective, and which learn to compress as a part of training.

Any strategy for performing temporal compression will necessarily make discrete decisions, since sentence length is discrete. Examples of such strategies include sparse attention (Raffel et al., 2017) and discrete auto-encoders (Kaiser et al., 2018). For our initial exploration, we chose the hierarchical multiscale (HM) architecture of Chung et al. (2017), which we briefly describe.

3.4.1 Hierarchical Multiscale LSTM

The HM is a bottom-up temporal subsampling approach, with each layer selecting the timesteps that will survive to the layer above. At a given timestep t and layer ℓ, the network makes a binary decision,

---

[1] Development experiments indicated that using LSTMs over GRUs resulted in a slight improvement.

z_t^ℓ, to determine whether or not it should send its output up to layer $\ell + 1$. The preactivation for this decision, $\tilde{z}_t^\ell$, is a function of the current node's inputs from below and from the previous hidden state, similar to an LSTM gate. However, z_t^ℓ's activation is a binary step function in the forward pass, to enable discrete decisions, and a hard sigmoid in the backward pass, to allow gradients to flow through the decision point.[2] The z_t^ℓ decision affects both the layer above, and the next timestep of the current layer:

- $z_t^\ell = 1$, *flow up*: the node above (t, ℓ+1) performs a normal LSTM update; the node to the right (t+1, ℓ) performs a modified update called a *flush*, which ignores the LSTM internal cell at (t, ℓ), and redirects the incoming LSTM hidden state from (t, ℓ) to (t, $\ell + 1$).
- $z_t^\ell = 0$, *flow right*: the node above (t, ℓ+1) simply copies the cell and hidden state values from ($t-1$, ℓ+1); the node to the right (t+1, ℓ) performs a normal LSTM update.

Conceptually, when $z_t^\ell = 0$, the node above it becomes a placeholder and is effectively removed from the sequence for that layer. Shorter upper layers save computation and facilitate the left-to-right flow of information for the surviving nodes.

Typically, one uses the top hidden state h_t^L from a stack of L RNNs to provide the representation for a timestep t. But for the HM, the top layer may be updated much less frequently than the layers below it. To enable tasks that need a distinct representation for each timestep, such as language modeling, the HM employs a *gated output module* to mix hidden states across layers. This learned module combines the states $h_t^1, h_t^2, \ldots, h_t^L$ using scaling and projection operators to produce a single output h_t.

3.4.2 Modifying the HM for NMT

We would like sequences to become progressively shorter as we move upward through the layers. As originally specified, the HM calculates z_t^ℓ independently for every t and ℓ, including copied nodes, meaning that a "removed" timestep could reappear in a higher layer when a copied node (t, ℓ) sets $z_t^\ell = 1$. This is easily addressed by locking $z_t^\ell = 0$ for copied nodes, creating a hierarchical structure in which upper layers never increase the amount of computation.

We also found that the flush component of the original architecture, which modifies the LSTM update at (t+1, ℓ) to discard the LSTM's internal cell, provided too much incentive to leave z_t^ℓ at 0, resulting in degenerate configurations which collapsed to having very few tokens in their upper layers. We addressed this by removing the notion of a flush from our architecture. The node to the right (t+1, ℓ) always performs a normal LSTM update, regardless of z_t^ℓ. This modification is similar to one proposed independently by Kádár et al. (2018), who simplified the flush operation by removing the connection to (t, $\ell + 1$).

We found it useful to change the initial value of the bias term used in the calculation of $\tilde{z}_t^\ell$, which we refer to as the z-bias. Setting z-bias to 1, which is the saturation point for the hard sigmoid with slope 1, improves training stability by encouraging the encoder to explore configurations where most timesteps survive through all layers, before starting to discard them.

Even with these modifications, we observed degenerate behavior in some settings. To discourage this, we added a compression loss component similar to that of Ke et al. (2018) to penalize z activation rates outside a specified range α_1, α_2: $\mathcal{L}_c = \sum_l \max(0,\ Z^l - \alpha_1 T,\ \alpha_2 T - Z^l)$, where T is source sequence length and $Z^l = \sum_{t=1}^{T} z_t^l$.

To incorporate the HM into our NMT encoder, we replace the lowest BiLSTM layer with unidirectional HM layers.[3] We adapt any remaining BiLSTM layers to copy or update according to the z-values calculated by the top HM layer.

4 Experimental Design

4.1 Corpora

We adopt the corpora used by Lee et al (2017), with the exception of WMT15 Russian-English.[4] To measure performance on an "easy" language pair, and to calibrate our results against recent benchmarks, we also included WMT14 English-French. Table 1 gives details of the corpora used. All corpora are preprocessed using Moses tools.[5]

---

[2] This disconnect between forward and backward activations is known as a straight-through estimator (Bengio et al., 2013).

[3] The flush operation makes the original HM inherently left-to-right. Since we have dropped flushes from our current version, it should be straightforward to devise a bidirectional variant, which we leave to future work.

[5] Scripts and arguments:
`remove-non-printing-char.perl`

corpus	train	dev	test
WMT15 Finnish-En	2.1M	1500	1370
WMT15 German-En	4.5M	3003	2169
WMT15 Czech-En	14.8M	3003	2056
WMT14 En-French	39.9M	3000	3003

Table 1: Corpora, with linecounts. Test sets are WMT14-15 newstest. Dev sets are newsdev 2015 (Fi) and newstest 2013 (De, Fr), and 2014 (Cs).

Dev and test corpora are tokenized, but not filtered or cleaned. Our character models use only the most frequent 496 characters across both source and target languages; similarly, BPE is run across both languages, with a vocabulary size of 32k.

4.2 Model sizes, training, and inference

Except where noted below, we used 6 bidirectional layers in the encoder, and 8 unidirectional layers in the decoder. All vector dimensions were 512.

Models were trained using sentence-level cross-entropy loss. Batch sizes are capped at 16,384 tokens, and each batch is divided among 16 NVIDIA P100s running synchronously.

Parameters were initialized with a uniform (0.04) distribution. We use the Adam optimizer, with $\beta_1 = 0.9$, $\beta_2 = 0.999$, and $\epsilon = 10^{-6}$ (Kingma and Ba, 2014). Gradient norm is clipped to 5.0. The initial learning rate is 0.0004, and we halve it whenever dev set perplexity has not decreased for 2k batches, with at least 2k batches between successive halvings. Training stops when dev set perplexity has not decreased for 8k batches.

Inference uses beam search with 8 hypotheses, coverage penalty of 0.2 (Tu et al., 2016), and length normalization of 0.2 (Wu et al., 2016).

4.3 Tuning and Evalution

When comparing character-level and BPE models, we tuned dropout independently for each setting, greedily exploring increments of 0.1 in the range 0.1–0.5, and selecting based on dev-set BLEU. This expensive strategy is crucial to obtaining valid conclusions, since optimal dropout values tend to be lower for character models.

Our main evaluation metric is Moses-tokenized case-sensitive BLEU score. We report test-set scores on the checkpoints having highest dev-set BLEU. To facilitate comparison with future work we also report SacreBLEU scores (Post, 2018) for key results, using the Moses detokenizer.

	Tokenized BLEU			SacreBLEU
Language	BPE	Char	Delta	Char

5 Results

5.1 Character-level translation

We begin with experiments to compare the standard RNN architecture from Section 3.1 at the character and BPE levels, using our full-scale model with 6 bidirectional encoder layers and 8 decoder layers. The primary results of our experiments are presented in Table 2, while Table 3 positions the same results with respect to recent points from the literature.

There are a number of observations we can draw from this data. First, from the EnFr results in Table 3, we are in line with GNMT (Wu et al., 2016), and within 2 BLEU points of the RNN and Transformer models investigated by Chen et al. (2018). So, while we are not working at the exact state-of-the-art, we are definitely in a range that should be relevant to most practitioners.

Also from Table 3, we compare quite favorably with Lee et al. (2017), exceeding their reported scores by 3-6 points, which we attribute to having employed much higher model capacity, as they use a single bidirectional layer in the encoder and a two-layer decoder. We investigate the impact of model capacity in Section 5.1.1.

Finally, Table 2 clearly shows the character-level systems outperforming BPE for all language pairs. The dominance of character-level methods in Table 2 indicates that RNN-based NMT architectures are not only capable of translating charac-

---

`tokenize.perl`

`clean-corpus-n.perl -ratio 9 1 100`

ter sequences, but actually benefit from them. This is in direct contradiction to the few previously reported results on this matter, which can in most cases be explained by our increased model capacity. The exception is GNMT (Wu et al., 2016), which had similar depth. In this case, possible explanations for the discrepancy include our use of a fully bidirectional encoder, our translating into English instead of German, and our model-specific tuning of dropout.

5.1.1 Effect of model capacity

Character-level NMT systems have a more difficult sequence-modeling task, as they need to infer the meaning of words from their constituent characters, where models with larger tokens instead delegate this task to the embedding table. Therefore, we hypothesize that increasing the model's capacity by adding layers will have a greater impact on character-level models. Figure 1 tests this hypothesis by measuring the impact of three model sizes on test BLEU score. For each of our four language pairs, the word-fragment model starts out ahead, and quickly loses ground as architecture size increases. For the languages with greater morphological complexity—German, Czech and Finnish—the slope of the character model's curve is notably steeper than that of the BPE system, indicating that these systems could benefit from yet more modeling capacity.

5.1.2 Effect of corpus size

One of the most compelling arguments for working with characters (and to a lesser extent, word-fragments) is improved generalization. Through morphological generalizations, the system can better handle low-frequency and previously unseen words. It stands to reason that as the training corpus increases in size, the importance of these generalization capabilities will decrease. We test this hypothesis by holding the language pair constant, and varying the training corpus size by downsampling the full training corpus. We choose EnFr because it has by far the most available data. We compare four sizes: 2M, 4M, 14M and 40M.

The results are shown in Figure 2. As expected, the gap between character and word-fragment modeling decreases as corpus size increases. From the slopes of the curves, we can infer that the advantage of character-level modeling will disappear completely as we reach 60-70M sentence pairs. However, there is reason to expect this break-even point to be much higher for more morphologically complex languages. It is also important to recall that relatively few language-pairs can assemble parallel corpora of this size.

5.1.3 Speed

The performance advantage of working with characters comes at a significant computational cost. With our full-sized architecture, character models trained roughly 8x more slowly than BPE models.[6] Figure 3 shows that training time grows linearly with number of layers in the model, and that character models have a much higher per-layer cost: roughly 0.38 msec/sentence versus 0.04 for BPE. We did not directly measure the difference in attention cost, but it cannot be greater than the difference in total cost for the smallest number of layers. Therefore, we can infer from Figure 3 that processing 5 layers in a character model incurs roughly the same time cost as attention. This is surprising given the quadratic cost of attention, and indicates that efforts to speed up character models cannot focus exclusively on attention.

5.1.4 Qualitative comparison

To make a qualitative comparison between word fragments (BPE) and characters for NMT, we examined 100 randomly selected sentence pairs from the DeEn test set. One author examined the sentences, using a display that showed the source[7] and the reference, along with the output of BPE and character models. Any differences between the two outputs were highlighted. They then assigned tags to both system outputs indicating broad error categories, such as lexical choice, word order and German compound handling.[8] Tags were restricted to cases where one system made a mistake that the other did not.

Of the 100 sentences, 47 were annotated as being identical or of roughly the same quality. The remaining 53 exhibited a large variety of differences. Table 4 summarizes the errors that were most easily characterized. BPE and character sys-

---

[6] Recall that we use batches containing 16,384 tokens—corresponding to a fixed memory budget—for both character and BPE models. Thus character models are slowed not only by having longer sentences, but also by parallelizing across fewer sentences in each batch.

[7] The annotating author does not speak German.

[8] Our annotator also looked specifically for agreement and negation errors, as studied by Sennrich (2017) for English-to-German character-level NMT. However, neither system exhibited these error types with sufficient frequency to draw meaningful conclusions.

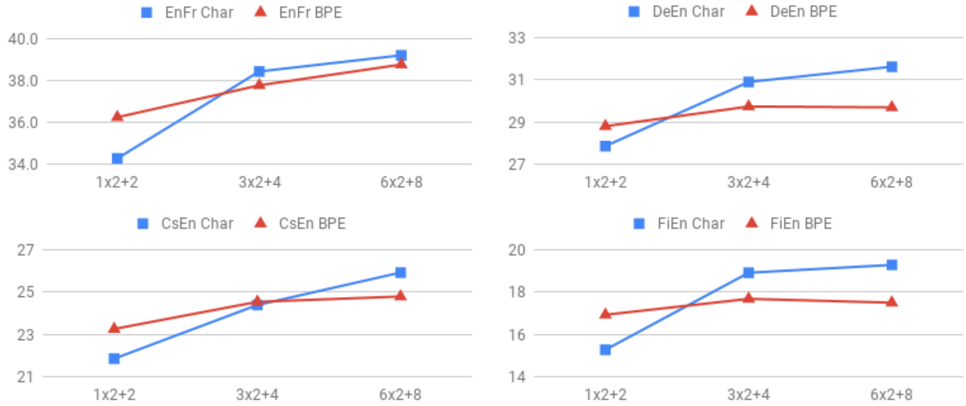

Figure 1: Test BLEU for character and BPE translation as architectures scale from 1 BiLSTM encoder layer and 2 LSTM decoder layers (1×2+2) to our standard 6×2+8. The y-axis spans 6 BLEU points for each language pair.

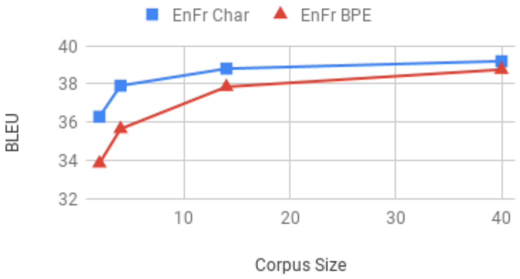

Figure 2: BLEU versus training corpus size in millions of sentence pairs, for the EnFr language-pair.

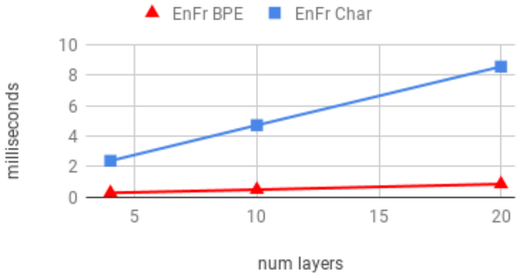

Figure 3: Training time per sentence versus total number of layers (encoder plus decoder) in the model.

Error Type	BPE	Char
Lexical Choice	19	8
Compounds	13	1
Proper Names	2	1
Morphological	2	2
Other lexical	2	4
Dropped Content	7	0

Table 4: Error counts out of 100 randomly sampled examples from the DeEn test set.

tems differ most in the number of lexical choice errors, and in the extent to which they drop content. The latter is surprising, and appears to be a side-effect of a general tendency of the character models to be more faithful to the source, verging on being overly literal. An example of dropped content is shown in Table 5 (top).

Regarding lexical choice, the two systems differ not only in the number of errors, but in the nature of those errors. In particular, the BPE model had more trouble handling German compound nouns. Table 5 (bottom) shows an example which exhibits two compound errors, including one where the character system is a strict improvement, translating *Bunsenbrenner* into *bunsen burner* instead of *bullets*. The second error follows another common pattern, where both systems mishandle the German compound (*Chemiestunden / chemistry lessons*), but the character system fails in a more useful way.

We also found that both systems occasionally mistranslate proper names. Both fail by attempting to translate when they should copy over, but the BPE system's errors are harder to understand as they involve semantic translation, rendering *Britta Hermann* as *Sir Leon*, and *Esme Nussbaum* as *smiling walnut*.[9] The character system's one observed error in this category was phonetic rather than semantic, rendering *Schotten* as *Scottland*.

Interestingly, we also observed several instances where the model correctly translates the German 24-hour clock into the English 12-hour clock; for example, *19.30* becomes *7:30 p.m.*. This deterministic transformation is potentially in reach for both models, but we observed it only for the character system in this sample.

---

[9] The BPE segmentations for these names were: `_Britt a _Herr mann` and `_Es me _N uss baum`

5.2 Compressing the Source Sequence

At this point we have established that character-level NMT benefits translation quality, but incurs a large computational cost. In this section, we evaluate the speed-quality tradeoffs of various techniques for reducing the number of state vectors required to represent the source sentence. All experiments are conducted on our DeEn language pair, chosen for having a good balance of morphological complexity and training corpus size.

5.2.1 Optimizing the BPE vocabulary

Recall that BPE interpolates between word- and character-level processing by tokenizing consecutive characters into word fragments; larger BPE vocabulary sizes result in larger fragments and shorter sequences. If character-level models outperform BPE with a vocabulary size of 32k, then is there a smaller BPE vocabulary size that reaps the benefits of character-level processing, while still substantially reducing the sequence length?

To answer this question, we test a number of BPE vocabularies, as shown in Table 6. For each vocabulary, we measure BLEU and sequence compression rate, defined as the average size of the source sequence in characters divided by its size in word fragments (the ratio for the target sequence was similar). Unfortunately, even at just 1k vocabulary items, BPE has already lost a BLEU point with respect to the character model. When comparing these results to the other methods in this section, it is important to recall that BPE is compressing both the source and target sequence (by approximately the same amount), doubling its effective compression rate.

Encoder	BPE Size	BLEU	Comp.
BiLSTM	Char	31.6	1.00
BiLSTM	1k	30.5	0.44
BiLSTM	2k	30.4	0.35
BiLSTM	4k	30.0	0.29
BiLSTM	8k	29.6	0.25
BiLSTM	16k	30.0	0.22
BiLSTM	32k	29.7	0.20
Lee et. al. reimpl	Char	28.0	0.20
BiLSTM + pooling	Char	30.0	0.47
HM, 3-layer	Char	31.2	0.77
HM, 2-layer	Char	30.9	0.89

Table 6: Compression results on WMT15 DeEn. The *Comp.* column shows the ratio of total computations carried out in the encoder.

5.2.2 Fixed Stride Compression

The goal of these experiments is to determine whether using fixed schedule compression is a feasible alternative to BPE. We evaluate our reimplementation of the pooling model of Lee et al. (2017) and our pooled BiLSTM encoder, both described in Section 3.3. For the pooled BiLSTM encoder, development experiments led us to introduce two mean-pooling layers, a stride 3 layer after the second BiLSTM, and a stride 2 layer after the third. Therefore, the final output of the encoder is compressed by a factor of 6.

The results are also shown in Table 6. Note that for the pooled BiLSTM, different encoder layers have different lengths: 2 full length layers, followed by 1 at $\frac{1}{3}$ length and 3 at $\frac{1}{6}$ length. Therefore, we report the average compression across layers here and for the HM in Section 5.2.3.

Our implementation of Lee et al. (2017) outperforms the original results by more than 2 BLEU

Model	BLEU	Comp.
LSTM	28.9	1.00
HM, no-fl	27.3	0.63
HM, no-fl, hier	28.5	0.65
HM, no-fl, hier, zb1, anneal	28.8	0.65

Table 7: HM small-scale results on WMT15 DeEn. The *Comp.* column is the proportion of layer-wise computation relative to the full LSTM.

points. We suspect most of these gains result from better optimization of the model with large batch training. However, our attempts to scale this encoder to larger depths, and therfore to the level of performance exhibited by our other systems, did not result in any significant improvements. This is possibly due to difficulties with optimizing a deeper stack of diverse layers.

Comparing the performance of our Pooled BiLSTM model against BPE, we notice that for a comparable level of compression (BPE size of 1k), BPE out-performs the pooled model by around 0.5 BLEU points. At a similar level of performance (BPE size of 4k), BPE has significantly shorter sequences. Although fixed-stride pooling does not yet match the performance of BPE, we remain optimistic about its potential. The appeal of these models derives from their simplicity; they are easy to optimize, perform reasonably well, and remove the complication of BPE preprocessing.

5.2.3 Hierarchical Multiscale Compression

We experimented with using the Hierarchical Multiscale (HM; Section 3.4.1) architecture to learn compression decisions for the encoder.

For initial exploration, we used a scaled-down architecture consisting of 3 unidirectional HM encoder layers and 2 LSTM decoder layers, attending over the HM's gated output module. Comparisons to an equivalent LSTM are shown in table 7. The first two HM lines justify the no-flush and hierarchical modifications described in Section 3.4.1, yielding incremental gains of 27.3 (the flush variant failed to converge), and 1.2 respectively. Initializing z-bias to 1 and annealing the slope of the hard binarizer from 1.0 to 5.0 over 80k minibatches gave further small gains, bringing the HM to parity with the LSTM while saving approximately 35% of layer-wise computations. Interestingly, we found that, over a wide range of training conditions, each layer tended to reduce computation by roughly 60% relative to the layer below.[10]

For full-scale experiments, we stacked 5 BiLSTM layers on top of 2 or 3 HM layers, as described in section 3.4.1, using only the top HM layer (rather than the gated output module) as input to the lowest BiLSTM layer. To stabilize the 3-HM configuration we used a compression penalty with a weight of 2, and α_1 and α_2 of 0.1 and 0.9. Given the tendency of HM layers to reduce computation by a roughly constant proportion, we expect fewer z-gates to be open in the 3-HM configuration, but this is achieved at the cost of one extra layer relative to our standard 12-layer encoder. As shown in table 6, the 3-HM configuration achieves much better compression even when this is accounted for, and also gives slightly better performance than 2-HM. In general, HM gating results in less compression but better performance than the fixed-stride techniques.

Although these preliminary results are promising, it should be emphasized that the speed gains they demonstrate are conceptual, and that realizing them in practice comes with significant engineering challenges.

6 Conclusion

We have demonstrated the translation quality of standard NMT architectures operating at the character-level. Our experiments show the surprising result that character NMT can substantially out-perform BPE tokenization for all but the largest training corpora sizes, and the less surprising result that doing so incurs a large computational cost. To address this cost, we have explored a number of methods for source-sequence compression, including the first application of the Hierarchical Multiscale LSTM to NMT, which allows us to learn to dynamically compress the source sequence.

We intend this paper as a call to action. Character-level translation is well worth doing, but we do not yet have the necessary techniques to benefit from this quality boost without suffering a disproportionate reduction in speed. We hope that these results will spur others to revisit the question of character-level translation as an interesting testbed for methods that can learn to process, summarize or compress long sequences.

---

[10] For instance, the 2nd and 3rd layer of the best configuration shown had on average 60% and 36% of z gates open, yielding the computation ratio of $(1 + 0.6 + 0.36)/3 = 0.65$.

Abstract

Narrative story generation is a challenging problem because it demands the generated sentences with tight semantic connections, which has not been well studied by most existing generative models. To address this problem, we propose a skeleton-based model to promote the coherence of generated stories. Different from traditional models that generate a complete sentence at a stroke, the proposed model first generates the most critical phrases, called skeleton, and then expands the skeleton to a complete and fluent sentence. The skeleton is not manually defined, but learned by a reinforcement learning method. Compared to the state-of-the-art models, our skeleton-based model can generate significantly more coherent text according to human evaluation and automatic evaluation. The G-score is improved by 20.1% in human evaluation.[1]

1 Introduction

We focus on the problem of narrative story generation, a special kind of story generation (Li et al., 2013). It requires systems to generate a narrative story based on a short description of a scene or an event, as shown in Table 1. In general, a narrative story is described with several inter-related scenes. Different from traditional text generation tasks, this task is more challenging because it demands the generated sentences with tight semantic connections. Currently, most state-of-the-art approaches (Jain et al., 2017; Liu et al., 2017; Fan et al., 2018; Ma et al., 2018a; Xu et al., 2018b) are largely based on Sequence-to-Sequence (Seq2Seq) models (Sutskever et al., 2014), which generate a sentence at a stroke in a left-to-right manner.

However, we find it hard for these approaches to model the semantic dependency among sentences, which causes low-quality generated stories where the scenes are irrelevant. In fact, as shown in Figure 1, we observe that the connection among sentences is mainly reflected through key phrases, such as predicates, subjects, objects and so on. In this work, we regard the phrases that express the key meanings of a sentence as a skeleton. The other words (e.g., modifiers) not only are redundant for understanding semantic dependency, but also make the dependency sparse. Therefore, generating all information at a stroke makes it difficult to learn the dependency of sentences. In contrast, the sentences written by humans are closely tied and the whole story is more coherent and fluent. It is mainly attributed to the way of human writing where we often first come up with a skeleton and then reorganize them into a fluent sentence.

Task Description
Input: A short description of a scene or an event. Output: A relevant narrative story following the input.
Examples
Input: *Fans came together to celebrate the opening of a new studio for an artist.* **Output**: *The artist provided champagne in flutes for everyone. Friends toasted and cheered the artist as she opened her new studio.*
Input: *Last week I attended a wedding for the first time.* **Output**: *There were a lot of families there. They were all taking pictures together. Everyone was very happy. The bride and groom got to ride in a limo that they rented.*

Table 1: An illustration of narrative story generation.

Therefore, motivated by the way of human writing, we propose a skeleton-based model to improve the coherence of generated text. The key idea is to first generate a skeleton and then expand the skeleton to a complete sentence. As a simplified sentence representation, the skeleton can help machines learn the dependency of sentences by avoiding the interference of irrelevant information. Our model contains two parts: a skeleton-

Brussels, Belgium, October 31 - November 4, 2018.

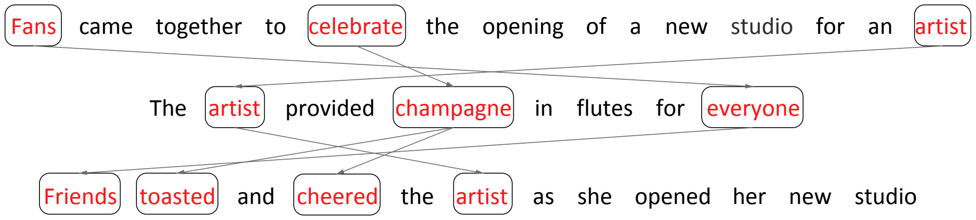

Figure 1: The semantic dependency among sentences in a narrative story. It can be seen that the connection among sentences is mainly reflected through key phrases (shown in red). In this work, we regard such key phrases as a skeleton.

based generative module and a skeleton extraction module.

The generative module consists of an input-to-skeleton component and a skeleton-to-sentence component. The input-to-skeleton component learns to associate inputs and skeletons, and the skeleton-to-sentence component learns to expand a skeleton to a sentence. In our model, a good skeleton that can capture key semantic information is a critical supervisory signal.

The skeleton extraction module is used to generate sentence skeletons. In real-world datasets, the human-annotated skeleton is usually unavailable. In addition, it is difficult to define the unified rules of extracting skeletons, because different sentences have different focuses. To address this problem, we build a skeleton extraction module to automatically explore sentence skeletons. Considering the discrete choice of skeleton words causes the loss function to be non-differentiable, we use a reinforcement learning method to build the connection between the skeleton extraction module and the generative module.

Our contributions are listed as follows:

- A skeleton-based model is proposed to promote the coherence of generated stories.
- The proposed model contains a skeleton-based generative module and a skeleton extraction module. Two modules are connected by a reinforcement learning method to automatically explore sentence skeletons.
- The experimental results on automatic evaluation and human evaluation show that our model can generate significantly more coherent text compared to the state-of-the-art models.

2 Related Work

Strictly speaking, the story generation task requires systems to generate a story from scratch without any external materials. However, for simplification, many existing story generation models rely on their given materials, such as short text descriptions (Harrison et al., 2017; Jain et al., 2017), visual images (Charles et al., 2001; Huang et al., 2016), and so on. Different from these studies, we get rid of external materials and consider the complete story generation task (McIntyre and Lapata, 2009). For this task, the widely used models are based on Seq2Seq models. However, although they can generate a fluent sentence (Xu et al., 2018a), these models still perform badly on generating inter-related sentences, which are necessary for a coherent story.

To address this problem, there are several models that build the mid-level sentence semantic representation to simplify the dependency among sentences. Clark et al. (2018) extract the entities in sentences, and combine the entity context and text context together when generating a target sentence. Cao et al. (2018) encode the words with specific pre-defined dependency labels to a mid-level sentence representation. Martin et al. (2018) use additional knowledge bases to get a generalized sentence representation. Ma et al. (2018b) use the bag-of-words which occur in all references as a representation of the correct translation. Luo et al. (2018) propose to use two auto-encoders to learn the semantic representation of utterance in dialogue. However, although these models reduce the dependency sparsity to some extent, the unified rules are non-flexible and tend to generate over-simplified representations, resulting in the loss of key information.

Different from these models, we use a reinforcement learning method to automatically extract sentence skeletons for simplifying the dependency of sentences, rather than manual rules. Therefore, our proposed skeleton-based model is more flexible and can adaptively determine the appropriate granularity of sentence representations for a balance between keeping key semantics and

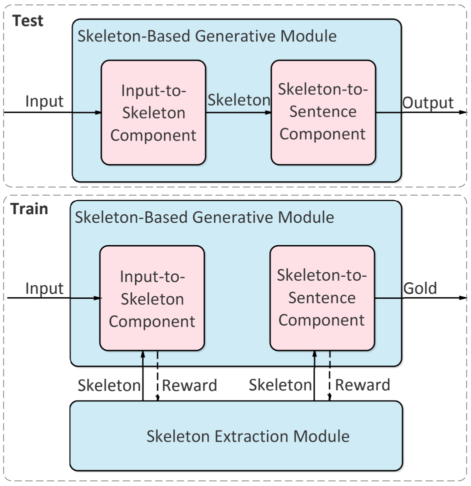

Figure 2: An illustration of the proposed model. Top: Testing. Bottom: Training. The "input" means the existing text, including the source input and the already generated text. The "skeleton" means the skeleton of the output. The skeleton extraction module first extracts skeletons from gold outputs. The pairs of input-skeleton and skeleton-gold are used to train the input-to-skeleton component and the skeleton-to-sentence component. In return, the generative module can be used to evaluate the quality of extracted skeletons. Therefore, we use the feedback of the generative module to reward extracted skeletons. By cooperation, the two modules can promote each other until convergence.

simplifying sentence representations.

3 Skeleton-Based Model

An overview of our proposed skeleton-based model is presented in Section 3.1. The details of the skeleton-based generative module and the skeleton extraction module are shown in Section 3.2 and Section 3.3. The reinforcement learning method is explained in Section 3.4.

3.1 Overview

As shown in Figure 2, our model consists of two parts, a skeleton-based generative module G_ϕ and a skeleton extraction module E_γ. The generative module consists of an input-to-skeleton component and a skeleton-to-sentence component.

The generative module generates a story sentence by sentence. When decoding a sentence, the input-to-skeleton component first generates a skeleton based on the existing text, including the source input and the already generated text, and then the skeleton-to-sentence component expands and reorganizes the skeleton into a complete sentence. We keep running this process until the generative module generates an ending symbol.

In the training process, we first use a weakly supervised method to assign the skeleton extraction module with initial extraction ability. Then, we use extracted skeletons to train the input-to-skeleton component and the skeleton-to-sentence component. In return, the generative module can be used to evaluate the quality of extracted skeletons. Therefore, we use the feedback of the generative module to reward extracted skeletons. The reward refines the skeleton extraction module. The improved skeleton extraction module further enhances the generative module. By cooperation, the two modules can promote each other until convergence.

3.2 Skeleton-Based Generative Module

The skeleton-based generative module G_ϕ consists of two parts: an input-to-skeleton component Q_α and a skeleton-to-sentence component D_θ.

3.2.1 Input-to-Skeleton Component

The input-to-skeleton component Q_α builds on a Seq2Seq structure with a hierarchical encoder (Li et al., 2015) and an attention-based decoder (Bahdanau et al., 2014). It is responsible for learning the dependency between inputs and skeletons. In the encoding process, we first obtain sentence representations via a word-level Long Short Term Memory (LSTM) network (Hochreiter and Schmidhuber, 1997), and then generate a compressed vector h via a sentence-level LSTM network. Finally, given the compressed vector h, the attention-based decoder is responsible for imagining a skeleton.

Given the training pair of input $\boldsymbol{c}$ and skeleton $\boldsymbol{s} = \{s_1, \cdots, s_i, \cdots, s_T\}$, the cross-entropy loss is computed as

$$L_\alpha = -\sum_{i=1}^{T} P_Q(s_i|\boldsymbol{c}, \alpha) \qquad (1)$$

where α refers to the parameters of the input-to-skeleton component. The skeleton $\boldsymbol{s}$ is extracted by the skeleton extraction module. The extracting details will be introduced in Section 3.3.

3.2.2 Skeleton-to-Sentence Component

The skeleton-to-sentence component D_θ builds on a Seq2Seq structure. Both the encoder and the decoder are one-layer LSTM networks with the attention mechanism. Given a skeleton $\boldsymbol{s}$, the encoder first generates a compressed representation, which is then used to generate a detailed and polished sentence via the decoder.

Given the training pair of skeleton $\boldsymbol{s}$ and target sentence $\boldsymbol{y} = \{y_1, \cdots, y_i, \cdots, y_M\}$, the cross-entropy loss is computed as
