Preface by the General Chair

Welcome to EMNLP 2018 in Brussels, Belgium! I hope that EMNLP 2018 will be a memorable experience filled with exciting research presentations, outstanding keynote speakers, and many stimulating conversations with colleagues and friends, both old and new. In the evenings, I hope that you will explore the wonderful city of Brussels! Admire the historic buildings, visit great museums, and enjoy the Belgian cuisine.

EMNLP 2018 will have an extensive technical program that includes 14 workshops, 6 tutorials, 3 invited speakers, 351 long paper presentations, 198 short paper presentations, 10 TACL paper presentations, and 29 demos. I want to give special thanks to the Program Co-Chairs: David Chiang, Julia Hockenmaier, and Jun'ichi Tsujii. EMNLP 2018 received a record-breaking 2,231 valid submissions, a 48% increase over EMNLP 2017! Despite the massive volume of submissions, the PC chairs put tremendous care into every decision, big and small, and gracefully handled numerous inquiries and requests. Their commitment to a high-quality program was inspiring. Of course, the PC Chairs did not handle the workload alone: we all owe an enormous debt of gratitude to the 60 Area Chairs and 1,436 reviewers (yes, 1,400+ reviewers!) who took on the critical responsibilities of reviewing paper submissions and providing feedback to the program chairs. Thank you all!

The Demo Co-Chairs, Eduardo Blanco and Wei Lu, also had to handle an usually high workload. EMNLP 2018 received 77 demo submissions, which was a 40% increase over EMNLP 2017. They recruited an additional 150+ reviewers to assess the demo submissions, and managed the review process seamlessly. Thank you, Eduardo and Wei!

The EMNLP 2018 Workshop Co-Chairs, Marieke van Erp and Vincent Ng, and the EMNLP 2018 Tutorial Co-Chairs, Mausam and Lu Wang, oversaw the selection of workshops and tutorials and coordinated planning with the organizers. Many thanks to Marieke, Vincent, Mausam, and Lu for orchestrating terrific workshop and tutorial programs! And I am thrilled to have three exceptional NLP researchers as our keynote speakers: Johan Bos, Julia Hirschberg, and Gideon Mann.

For EMNLP 2018, we added two new initiatives to provide financial support to conference participants. We introduced *childcare grants* that offer financial support for childcare expenses incurred to participate in the conference. These childcare grants give families broad flexibility to utilize many different types of childcare services and arrangements. A giant thank you to Swapna Somasundaran for navigating this new terrain and drafting the policy guidelines, and to both Swapna and Aoife Cahill for overseeing the application and decision processes.

EMNLP 2018 also introduced travel scholarships for non-students to attend the conference. The non-student travel scholarships provide support to people with financial need who might otherwise not be able to participate in the conference. We created this initiative with an eye toward supporting researchers from historically under-representated regions and young researchers or others with limited financial means. I want to thank Anna Rumshisky and Hugo Van hamme for managing these new non-student travel scholarships, along with the student travel scholarship and volunteer applications.

Nitin Madnani deserves special thanks for taking charge of *both* the EMNLP 2018 web site and conference app, and doing a fantastic job. Nitin was a pleasure to work with, and incredibly responsive, answering emails impossibly fast and accommodating every request. Thanks also to our Publicity Chair, Mohit Iyyer, for advertising the conference on social media and elsewhere, and our Video Chair, Bonan Min, for handling the video recordings.

Managing the conference proceedings and compiling the handbook are extremely time-consuming and tedious jobs, but less visible to conference attendees, who only see the final products. Enormous thanks to the Publication Chairs, Micha Elsner (junior chair) and Preethi Raghavan (senior chair), the Conference Handbook Chair, Kai-Wei Chang, the Handbook Advisor, Joachim Bingel, and the Handbook Proofreader, He He. They were truly a fantastic team!

And a huge thanks to the Local Organization Committee from KU Leuven: Marie-Francine Moens (chair), Dominique De Brabanter, Frieda Steurs, and Hugo Van hamme, as well as the Local Sponsorship Chair, Katrien Beuls from Vrije Universiteit Brussel. Their hard work and enthusiasm were key to making EMNLP 2018 a success! In addition, a large conference like EMNLP depends heavily on sponsorship, and I want to sincerely thank *all* of the EMNLP 2018 sponsors for their generous support!

I must also thank SIGDAT for their support throughout this past year. With extra thanks to Noah Smith, the SIGDAT Secretary-Treasurer and EMNLP liaison, for his support of our new initiatives, valuable feedback, and quick responses. Finally, I owe a huge debt of gratitude to Priscilla Rasmussen, who managed so many aspects of the conference that I can't even begin to name them. A heartfelt thanks to Priscilla for her hard work, sage advice, and for patiently answering an endless stream of questions from me, and many others.

And thanks to all of YOU for participating in EMNLP 2018! I hope you enjoy the conference and your time in Brussels!

EMNLP 2018 General Chair

Ellen Riloff, University of Utah, USA

Preface by the Program Committee Co-Chairs

Welcome to EMNLP 2018! This year's technical program consists of three invited talks, 224 oral presentations (including three papers appearing in the Transactions of the ACL), and 335 poster presentations (including seven papers appearing in TACL). To our knowledge, it's the largest NLP conference ever, and it would not have been possible without the help of our program committee members.

This year, we organized the program committee into eight broad areas. For each area, one of our amazing senior area chairs (Jordan Boyd-Graber, Xavier Carreras, Yejin Choi, Philipp Koehn, Alessandro Moschitti, Slav Petrov, Massimo Poesio, and Kam-Fai Wong) headed a team of several other area chairs (totaling 52 across all areas) and an army of reviewers (totaling 1,436 across all areas). We'd like to especially thank those reviewers who agreed to review a full load of papers, which turned out to be a bit heavier than expected!

2018 appears to have been the year of experimentation with new review forms, and EMNLP was no exception. We eliminated many of the traditional numerical ratings and divided up the free-form comments into a small number of separate free-response questions. We tried to make this new structure mirror the structure of a typical review, while encouraging more comprehensive reviewing.

Extrapolating exponentially from the past two years, we expected to receive about 1,800 submissions, but the eventual number exceeded our expectations at 2,231 (excluding empty and duplicate submissions). After removal of invalid submissions and some withdrawals, we sent 2,116 papers out for review. Despite the growing number of submissions, we tried to keep acceptance rates at the same level as past years. The acceptance statistics are shown below.

	Long	Short	Total	TACL
Submitted	1,376	855	2,231	–
Accepted as talk	140 (10.2%)	81 (9.5%)	221 (9.9%)	3
Accepted as poster	211 (15.3%)	117 (13.7%)	328 (14.7%)	7
Accepted (total)	351 (25.5%)	198 (23.2%)	549 (24.6%)	10

As in past years, three awards will be given for Best Long Paper, Best Short Paper, and Best Resource Paper. We solicited recommendations for awards from reviewers and area chairs. Following these recommendations, we sent 7 long papers, 5 short papers, and 5 resource papers to three committees chosen from among the area chairs. In the end, we selected two winners for Best Long Paper and one each for Best Short Paper and Best Resource Paper, all of which will be presented in a final plenary session.

We are delighted to have keynote addresses from three giants of our field: Johan Bos, on the future of computational semantics; Julia Hirschberg, on deception detection in speech; and Gideon Mann, on the use of NLP in finance.

In addition to our entire program committee, we would also like to give thanks to:

- Our general chair, Ellen Riloff,
- Priscilla Rasmussen,
- Last year's program chairs, Rebecca Hwa and Sebastian Riedel,
- Our local chair, Marie-Francine Moens, and the local organizing committee,
- Our web and publicity chairs, Nitin Madnani and Mohit Iyyer,
- Our publications chairs, Micha Elsner and Preethi Raghavan,
- Our handbook chair, Kai-Wei Chang,
- Rich Gerber and the technical support team at SoftConf.

Again, welcome! We hope that you enjoy this year's conference, and return home with new insights, ideas, and opportunities!

EMNLP 2018 Program Co-Chairs

David Chiang, University of Notre Dame, USA
Julia Hockenmaier, University of Illinois Urbana-Champaign, USA
Jun'ichi Tsujii, Artificial Intelligence Research Center, Japan

Organizing Committee

General Chair
Ellen Riloff, University of Utah, USA

Program Committee Co-chairs
David Chiang, University of Notre Dame, USA
Julia Hockenmaier, University of Illinois Urbana-Champaign, USA
Junichi Tsujii, Artificial Intelligence Research Center, Japan

Local Arrangements Committee
Marie-Francine Moens, KU Leuven, Belgium (chair)
Dominique De Brabanter, KU Leuven, Belgium
Frieda Steurs, KU Leuven, Belgium
Hugo Van hamme, KU Leuven, Belgium

Local Sponsorship Chair
Katrien Beuls, Vrije Universiteit Brussel, Belgium

Workshop Co-chairs
Marieke van Erp, KNAW Humanities Cluster, Netherlands
Vincent Ng, University of Texas at Dallas, USA

Tutorial Co-chairs
Mausam, Indian Institute of Technology Delhi, India
Lu Wang, Northeastern University, USA

Demos Co-chairs
Eduardo Blanco, University of North Texas, USA
Wei Lu, Singapore University of Technology and Design, Singapore

Publications Sr Chair
Preethi Raghavan, IBM, USA

Publications Jr Chair
Micha Elsner, Ohio State University, USA

Publicity Chair
Mohit Iyyer, University of Massachusetts at Amherst, USA

Video Chair
Bonan Min, BBN Technologies, USA

Website and Conference App Chair
Nitin Madnani, Educational Testing Service, USA

Conference Handbook Chair
Kai-Wei Chang, University of California at Los Angeles, USA

Conference Handbook Advisor
Joachim Bingel, University of Copenhagen, Denmark

Handbook Proofreader
He He, Stanford University, USA

Student Scholarship Co-chair and Student Volunteer Coordinator
Anna Rumshisky, University of Massachusetts at Lowell, USA
Hugo Van hamme, KU Leuven, Belgium

Childcare Policy and Grant Coordinator
Swapna Somasundaran, Educational Testing Service, USA
Aoife Cahill, Educational Testing Service, USA

Program Committee

Program Committee Co-chairs
David Chiang, University of Notre Dame, USA
Julia Hockenmaier, University of Illinois Urbana-Champaign, USA
Junichi Tsujii, Artificial Intelligence Research Center, Japan

Area Chairs
Information Extraction, Information Retrieval, and Question Answering
Jordan Boyd-Graber, University of Maryland, USA (senior chair)
Isabelle Augenstein, University of Copenhagen, Denmark
Ming-Wei Chang, Google, USA
Doug Downey, Northwestern University, USA
Ruihong Huang, Texas A&M University, USA
Mausam, IIT Delhi, India
Makoto Miwa, Toyota Technological Institute, Japan
William Wang, University of California at Santa Barbara, USA
Scott Yih, Allen Institute for Artificial Intelligence, USA

Text Mining and Information Retrieval
Alessandro Moschitti, University of Trento, Italy (senior chair)
Sophia Ananiadou, University of Manchester, United Kingdom
Hsin-Hsi Chen, National Taiwan University
Marius Pasca, Google, USA
Xiang Ren, University of Southern California, USA
Alan Ritter, Ohio State University, USA
David Smith, Northeastern University, USA

Social Media, Computational Social Science, and Sentiment/Opinion Analysis
Kam-Fai Wong, Chinese University of Hong Kong (senior chair)
Eiji Aramaki, Nara Institute of Science and Technology, Japan
Mona Diab, George Washington University, USA
Yulan He, Aston University, United Kingdom
Dirk Hovy, Bocconi University, Italy
Rada Mihalcea, University of Michigan, USA
Alice Oh, KAIST, Korea
Wei Xu, Ohio State University, USA

Morphology, Syntax, and Psycholinguistics
Slav Petrov, Google, USA (senior chair)
Liang Huang, Oregon State University, USA
Roger Levy, Massachusetts Institute of Technology, USA
Stephan Oepen, University of Oslo, Norway
Emily Pitler, Google, USA
Reut Tsarfaty, Open University of Isra

Semantics

Massimo Poesio, Queen Mary University of London, United Kingdom (senior chair)
Omri Abend, Hebrew University of Jerusalem, Israel
Raffaella Bernardi, University of Trento, Italy
Michael Lewis, Facebook, USA
Yulia Tsvetkov, Carnegie Mellon University, USA
Benjamin Van Durme, Johns Hopkins University, USA
Nianwen Xue, Brandeis University, USA

Discourse, Dialogue, Summarization, Generation, and Multimodal NLP

Yejin Choi, University of Washington, USA (senior chair)
Mohit Bansal, University of North Carolina, USA
Michel Galley, Microsoft, USA
Grzegorz Chrupała, Tilburg University, Netherlands
Haizhou Li, National University of Singapore
Fei Liu, University of Central Florida, USA
Karen Livescu, Toyota Technological Institute - Chicago, USA
Meg Mitchell, Google, USA
Rashmi Prasad, Interactions, USA
Xiaojun Wan, Peking University, China
Zhou Yu, University of California at Davis, USA

Machine Translation and Multilinguality

Philipp Koehn, Johns Hopkins University, USA (senior chair)
Arianna Bisazza, Leiden University, Netherlands
Qun Liu, Dublin City University, Ireland
Yang Liu, Tsinghua University, China
Zhaopeng Tu, Tencent, China
Taro Watanabe, Google, Japan

Machine Learning

Xavier Carreras, dMetrics, USA (senior chair)
Shay Cohen, University of Edinburgh, United Kingdom
Kevin Gimpel, Toyota Technological Institute - Chicago, USA
Stefan Riezler, Heidelberg University, Germany
Karl Stratos, Toyota Technological Institute - Chicago, USA
Jun Suzuki, Tohoku University, Japan

Reviewers

We would like to recognize the following 100 reviewers with the Best Reviewer Award.

Natalie Ahn, Emilia Apostolova, Miguel Ballesteros, Daniel Bauer, Yonatan Belinkov, Darina Benikova, Luciana Benotti, Robert Berwick, Chloé Braud, Hendrik Buschmeier, Jan Buys, Dallas Card, Asli Celikyilmaz, Arun Chaganty, Kai-Wei Chang, Colin Cherry, Maximin Coavoux, Zeyu Dai, Cedric De Boom, Miryam de Lhoneux, Mark Dredze, Greg Durrett, Ondrej Dusek, Jason Eisner, Michael Elhadad, M. Amin Farajian, Shi Feng, Simone Filice, Stefan L. Frank, Lea Frermann, Matthias Gallé, Ekaterina

Invited Speaker: Johan Bos, University of Groningen
The Moment of Meaning and the Future of Computational Semantics

Abstract: There are many recent advances in semantic parsing: we see a rising number of semantically annotated corpora and there is exciting technology (such as neural networks) to be explored. In this talk I will discuss what role computational semantics could play in future natural language processing applications (including fact checking and machine translation). I will argue that we should not just look at semantic parsing, but that things can get really interesting when we can use language-neutral meaning representations to draw (transparent) inferences. The main ideas will be exemplified by the parallel meaning bank, a new corpus comprising texts annotated with formal meaning representations for English, Dutch, German and Italian.

Bio: Johan Bos is Professor of Computational Semantics at the University of Groningen (Netherlands). He received his doctorate from the Computational Linguistics Department at the University of the Saarland (Germany) and held post-doc positions at the University of Edinburgh (UK) and the La Sapienza University in Rome (Italy). In 2010, he moved to his current position in Groningen, leading the computational semantics group. Bos is the developer of Boxer, a state-of-the-art wide-coverage semantic parser for English, initiator of the Groningen Meaning Bank, a large semantically-annotated corpus of texts, and inventor of Wordrobe, a game with a purpose for semantic annotation. Bos received a $1.5-million Vici grant from NWO (Netherlands Organisation for Scientific Research) in 2015 to investigate the role of meaning in human and machine translation. A concrete outcome of this project is the Parallel Meaning Bank containing detailed meaning representations for English, German, Dutch and Italian sentences.

Invited Speaker: Julia Hirschberg, Columbia University
Truth or Lie? Spoken Indicators of Deception in Speech

Abstract: Detecting deception from various forms of human behavior is a longstanding research goal which is of considerable interest to the military, law enforcement, corporate security, social services and mental health workers. However, both humans and polygraphs are very poor at this task. We describe more accurate methods we have developed to detect deception automatically from spoken language. Our classifiers are trained on the largest cleanly recorded corpus of within-subject deceptive and non-deceptive speech that has been collected. To distinguish truth from lie we make use of acoustic-prosodic, lexical, demographic, and personality features. We further examine differences in deceptive behavior based upon gender, personality, and native language (Mandarin Chinese vs. English), comparing our systems to human performance. We extend our studies to identify cues in trusted speech vs. mistrusted speech and how these features differ by speaker and by listener. Why does a listener believe a lie?

Bio: Julia Hirschberg is Percy K. and Vida L. W. Hudson Professor and Chair of Computer Science at Columbia University. She previously worked at Bell Laboratories and AT&T Labs where she created the HCI Research Department. She has been editor of Computational Linguistics and Speech Communication, is a fellow of AAAI, ISCA, ACL, ACM, and IEEE, and a member of the National Academy of Engineering. She received the IEEE James L. Flanagan Speech and Audio Processing Award and the ISCA Medal for Scientific Achievement. She currently serves on the IEEE Speech and Language Processing Technical Committee, is co-chair of the CRA-W Board, and has worked for diversity for many years at AT&T and Columbia. She works on spoken language processing and NLP, studying text-to-speech synthesis, spoken dialogue systems, entrainment in conversation, detection of deceptive and emotional speech, hedging behavior, and linguistic code-switching (language mixing).

Invited Speaker: Gideon Mann, Bloomberg L.P.

Understanding the News that Moves Markets

Abstract: Since the dawn of human civilization, finance and language technology have been connected. However, only recently have advances in statistical language understanding, and an ever-increasing thirst for market advantage, led to the widespread application of natural language technology across the global capital markets. This talk will review the ways in which language technology is enabling market participants to quickly understand and respond to major world events and breaking business news. It will outline the state of the art in applications of NLP to finance and highlight open problems that are being addressed by emerging research.

Bio: Gideon Mann is the Head of Data Science at Bloomberg L.P., where he guides the strategic direction for machine learning, natural language processing (NLP) and search across the company. He is part of the leadership team for the Office of the CTO. He served as a founding member of both the Data for Good Exchange (D4GX), an annual conference on data science applications for social good, and the Shift Commission on Work, Workers and Technology. He has also been active in academic research in fact extraction, weakly-supervised learning, and distributed optimization. Recently, he has also been interested in applications of machine learning to problems in software engineering. From 2007 to 2014, he worked at Google Research in New York City, and his team built core machine learning libraries, released the Google Prediction API, and developed Colaboratory. Mann graduated Brown University in 1999 and received a Ph.D. from The Johns Hopkins University in 2006.

Entity Linking within a Social Media Platform: A Case Study on Yelp
Hongliang Dai, Yangqiu Song, Liwei Qiu and Rijia Liu 2023

Annotation of a Large Clinical Entity Corpus
Pinal Patel, Disha Davey, Vishal Panchal and Parth Pathak 2033

Visual Supervision in Bootstrapped Information Extraction
Matthew Berger, Ajay Nagesh, Joshua Levine, Mihai Surdeanu and Helen Zhang 2043

Learning Named Entity Tagger using Domain-Specific Dictionary
Jingbo Shang, Liyuan Liu, Xiaotao Gu, Xiang Ren, Teng Ren and Jiawei Han 2054

Zero-Shot Open Entity Typing as Type-Compatible Grounding
Ben Zhou, Daniel Khashabi, Chen-Tse Tsai and Dan Roth 2065

Attention-Guided Answer Distillation for Machine Reading Comprehension
Minghao Hu, Yuxing Peng, Furu Wei, Zhen Huang, Dongsheng Li, Nan Yang and Ming Zhou2077

Interpretation of Natural Language Rules in Conversational Machine Reading
Marzieh Saeidi, Max Bartolo, Patrick Lewis, Sameer Singh, Tim Rocktäschel, Mike Sheldon, Guillaume Bouchard and Sebastian Riedel 2087

A State-transition Framework to Answer Complex Questions over Knowledge Base
Sen Hu, Lei Zou and Xinbo Zhang 2098

A Multi-answer Multi-task Framework for Real-world Machine Reading Comprehension
Jiahua Liu, Wan Wei, Maosong Sun, Hao Chen, Yantao Du and Dekang Lin 2109

Logician and Orator: Learning from the Duality between Language and Knowledge in Open Domain
Mingming Sun, Xu Li and Ping Li 2119

MemoReader: Large-Scale Reading Comprehension through Neural Memory Controller
Seohyun Back, Seunghak Yu, Sathish Reddy Indurthi, Jihie Kim and Jaegul Choo 2131

Multi-Granular Sequence Encoding via Dilated Compositional Units for Reading Comprehension
Yi Tay, Anh Tuan Luu and Siu Cheung Hui 2141

Neural Compositional Denotational Semantics for Question Answering
Nitish Gupta and Mike Lewis 2152

Cross-Pair Text Representations for Answer Sentence Selection
Kateryna Tymoshenko and Alessandro Moschitti 2162

QuAC: Question Answering in Context
Eunsol Choi, He He, Mohit Iyyer, Mark Yatskar, Wen-tau Yih, Yejin Choi, Percy Liang and Luke Zettlemoyer 2174

Knowledge Base Question Answering via Encoding of Complex Query Graphs
Kangqi Luo, Fengli Lin, Xusheng Luo and Kenny Zhu 2185

Neural Relation Extraction via Inner-Sentence Noise Reduction and Transfer Learning
Tianyi Liu, Xinsong Zhang, Wanhao Zhou and Weijia Jia 2195

Graph Convolution over Pruned Dependency Trees Improves Relation Extraction
Yuhao Zhang, Peng Qi and Christopher D. Manning 2205

Multi-Level Structured Self-Attentions for Distantly Supervised Relation Extraction
Jinhua Du, Jingguang Han, Andy Way and Dadong Wan 2216

N-ary Relation Extraction using Graph-State LSTM
Linfeng Song, Yue Zhang, Zhiguo Wang and Daniel Gildea 2226

Hierarchical Relation Extraction with Coarse-to-Fine Grained Attention
Xu Han, Pengfei Yu, Zhiyuan Liu, Maosong Sun and Peng Li 2236

Label-Free Distant Supervision for Relation Extraction via Knowledge Graph Embedding
Guanying Wang, Wen Zhang, Ruoxu Wang, Yalin Zhou, Xi Chen, Wei Zhang, Hai Zhu and Huajun Chen 2246

Extracting Entities and Relations with Joint Minimum Risk Training
Changzhi Sun, Yuanbin Wu, Man Lan, Shiliang Sun, Wenting Wang, Kuang-Chih Lee and Kewen Wu 2256

Large-scale Exploration of Neural Relation Classification Architectures
Hoang-Quynh Le, Duy-Cat Can, Sinh T. Vu, Thanh Hai Dang, Mohammad Taher Pilehvar and Nigel Collier 2266

Possessors Change Over Time: A Case Study with Artworks
Dhivya Chinnappa and Eduardo Blanco 2278

Using Lexical Alignment and Referring Ability to Address Data Sparsity in Situated Dialog Reference Resolution
Todd Shore and Gabriel Skantze 2288

Subgoal Discovery for Hierarchical Dialogue Policy Learning
Da Tang, Xiujun Li, Jianfeng Gao, Chong Wang, Lihong Li and Tony Jebara 2298

Supervised Clustering of Questions into Intents for Dialog System Applications
Iryna Haponchyk, Antonio Uva, Seunghak Yu, Olga Uryupina and Alessandro Moschitti 2310

Towards Exploiting Background Knowledge for Building Conversation Systems
Nikita Moghe, Siddhartha Arora, Suman Banerjee and Mitesh M. Khapra 2322

Decoupling Strategy and Generation in Negotiation Dialogues
He He, Derek Chen, Anusha Balakrishnan and Percy Liang 2333

Large-scale Cloze Test Dataset Created by Teachers
Qizhe Xie, Guokun Lai, Zihang Dai and Eduard Hovy 2344

emrQA: A Large Corpus for Question Answering on Electronic Medical Records
Anusri Pampari, Preethi Raghavan, Jennifer Liang and Jian Peng 2357

HotpotQA: A Dataset for Diverse, Explainable Multi-hop Question Answering
Zhilin Yang, Peng Qi, Saizheng Zhang, Yoshua Bengio, William Cohen, Ruslan Salakhutdinov and Christopher D. Manning 2369

Can a Suit of Armor Conduct Electricity? A New Dataset for Open Book Question Answering
Todor Mihaylov, Peter Clark, Tushar Khot and Ashish Sabharwal 2381

Evaluating Theory of Mind in Question Answering
Aida Nematzadeh, Kaylee Burns, Erin Grant, Alison Gopnik and Tom Griffiths 2392

A Unified Syntax-aware Framework for Semantic Role Labeling

On the Strength of Character Language Models for Multilingual Named Entity Recognition
Xiaodong Yu, Stephen Mayhew, Mark Sammons and Dan Roth 3073

Code-switched Language Models Using Dual RNNs and Same-Source Pretraining
Saurabh Garg, Tanmay Parekh and Preethi Jyothi 3078

Part-of-Speech Tagging for Code-Switched, Transliterated Texts without Explicit Language Identification
Kelsey Ball and Dan Garrette 3084

Zero-shot User Intent Detection via Capsule Neural Networks
Congying Xia, Chenwei Zhang, Xiaohui Yan, Yi Chang and Philip Yu 3090

Hierarchical Neural Networks for Sequential Sentence Classification in Medical Scientific Abstracts
Di Jin and Peter Szolovits 3100

Investigating Capsule Networks with Dynamic Routing for Text Classification
Min Yang, Wei Zhao, Jianbo Ye, Zeyang Lei, Zhou Zhao and Soufei Zhang 3110

Topic Memory Networks for Short Text Classification
Jichuan Zeng, Jing Li, Yan Song, Cuiyun Gao, Michael R. Lyu and Irwin King 3120

Few-Shot and Zero-Shot Multi-Label Learning for Structured Label Spaces
Anthony Rios and Ramakanth Kavuluru 3132

Automatic Poetry Generation with Mutual Reinforcement Learning
Xiaoyuan Yi, Maosong Sun, Ruoyu Li and Wenhao Li 3143

Variational Autoregressive Decoder for Neural Response Generation
Jiachen Du, Wenjie Li, Yulan He, Ruifeng Xu, Lidong Bing and Xuan Wang 3154

Integrating Transformer and Paraphrase Rules for Sentence Simplification
Sanqiang Zhao, Rui Meng, Daqing He, Andi Saptono and Bambang Parmanto 3164

Learning Neural Templates for Text Generation
Sam Wiseman, Stuart Shieber and Alexander Rush 3174

Multi-Reference Training with Pseudo-References for Neural Translation and Text Generation
Renjie Zheng, Mingbo Ma and Liang Huang 3188

Knowledge Graph Embedding with Hierarchical Relation Structure
Zhao Zhang, Fuzhen Zhuang, Meng Qu, Fen Lin and Qing He 3198

Embedding Multimodal Relational Data for Knowledge Base Completion
Pouya Pezeshkpour, Liyan Chen and Sameer Singh 3208

Multi-Task Identification of Entities, Relations, and Coreference for Scientific Knowledge Graph Construction
Yi Luan, Luheng He, Mari Ostendorf and Hannaneh Hajishirzi 3219

Playing 20 Question Game with Policy-Based Reinforcement Learning
Huang Hu, Xianchao Wu, Bingfeng Luo, Chongyang Tao, Can Xu, wei wu and Zhan Chen . . 3233

Multi-Hop Knowledge Graph Reasoning with Reward Shaping
Xi Victoria Lin, Richard Socher and Caiming Xiong 3243

Neural Transductive Learning and Beyond: Morphological Generation in the Minimal-Resource Setting
Katharina Kann and Hinrich Schütze 3254

Implicational Universals in Stochastic Constraint-Based Phonology
Giorgio Magri 3265

Explaining Character-Aware Neural Networks for Word-Level Prediction: Do They Discover Linguistic Rules?
Fréderic Godin, Kris Demuynck, Joni Dambre, Wesley De Neve and Thomas Demeester 3275

Adapting Word Embeddings to New Languages with Morphological and Phonological Subword Representations
Aditi Chaudhary, Chunting Zhou, Lori Levin, Graham Neubig, David R. Mortensen and Jaime Carbonell 3285

A Computational Exploration of Exaggeration
Enrica Troiano, Carlo Strapparava, Gözde Özbal and Serra Sinem Tekiroglu 3296

Building Context-aware Clause Representations for Situation Entity Type Classification
Zeyu Dai and Ruihong Huang 3305

Hierarchical Dirichlet Gaussian Marked Hawkes Process for Narrative Reconstruction in Continuous Time Domain
Yeon Seonwoo, Alice Oh and Sungjoon Park 3316

Investigating the Role of Argumentation in the Rhetorical Analysis of Scientific Publications with Neural Multi-Task Learning Models
Anne Lauscher, Goran Glavaš, Simone Paolo Ponzetto and Kai Eckert 3326

Neural Ranking Models for Temporal Dependency Structure Parsing
Yuchen Zhang and Nianwen Xue 3339

Causal Explanation Analysis on Social Media
Youngseo Son, Nipun Bayas and H. Andrew Schwartz 3350

LRMM: Learning to Recommend with Missing Modalities
Cheng Wang, Mathias Niepert and Hui Li 3360

Content Explorer: Recommending Novel Entities for a Document Writer
Michal Lukasik and Richard Zens 3371

A Genre-Aware Attention Model to Improve the Likability Prediction of Books
Suraj Maharjan, Manuel Montes, Fabio A. González and Thamar Solorio 3381

Thread Popularity Prediction and Tracking with a Permutation-invariant Model
Hou Pong Chan and Irwin King 3392

IARM: Inter-Aspect Relation Modeling with Memory Networks in Aspect-Based Sentiment Analysis
Navonil Majumder, Soujanya Poria, Alexander Gelbukh, Md Shad Akhtar, Erik Cambria and Asif Ekbal 3402

Limbic: Author-Based Sentiment Aspect Modeling Regularized with Word Embeddings and Discourse Relations
Zhe Zhang and Munindar Singh 3412

An Interpretable Neural Network with Topical Information for Relevant Emotion Ranking
Yang Yang, Deyu ZHOU and Yulan He 3423

Multi-grained Attention Network for Aspect-Level Sentiment Classification
Feifan Fan, Yansong Feng and Dongyan Zhao 3433

Attentive Gated Lexicon Reader with Contrastive Contextual Co-Attention for Sentiment Classification
Yi Tay, Anh Tuan Luu, Siu Cheung Hui and Jian Su 3443

Contextual Inter-modal Attention for Multi-modal Sentiment Analysis
Deepanway Ghosal, Md Shad Akhtar, Dushyant Chauhan, Soujanya Poria, Asif Ekbal and Pushpak Bhattacharyya 3454

Adaptive Semi-supervised Learning for Cross-domain Sentiment Classification
Ruidan He, Wee Sun Lee, Hwee Tou Ng and Daniel Dahlmeier 3467

ExtRA: Extracting Prominent Review Aspects from Customer Feedback
Zhiyi Luo, Shanshan Huang, Frank F. Xu, Bill Yuchen Lin, Hanyuan Shi and Kenny Zhu 3477

Cross-Lingual Cross-Platform Rumor Verification Pivoting on Multimedia Content
Weiming Wen, Songwen Su and Zhou Yu 3487

Extractive Adversarial Networks: High-Recall Explanations for Identifying Personal Attacks in Social Media Posts
Samuel Carton, Qiaozhu Mei and Paul Resnick 3497

Automatic Detection of Vague Words and Sentences in Privacy Policies
Logan Lebanoff and Fei Liu 3508

Multi-view Models for Political Ideology Detection of News Articles
Vivek Kulkarni, Junting Ye, Steve Skiena and William Yang Wang 3518

Predicting Factuality of Reporting and Bias of News Media Sources
Ramy Baly, Georgi Karadzhov, Dimitar Alexandrov, James Glass and Preslav Nakov 3528

Legal Judgment Prediction via Topological Learning
Haoxi Zhong, Guo Zhipeng, Cunchao Tu, Chaojun Xiao, Zhiyuan Liu and Maosong Sun 3540

Hierarchical CVAE for Fine-Grained Hate Speech Classification
Jing Qian, Mai ElSherief, Elizabeth Belding and William Yang Wang 3550

Residualized Factor Adaptation for Community Social Media Prediction Tasks
Mohammadzaman Zamani, H. Andrew Schwartz, Veronica Lynn, Salvatore Giorgi and Niranjan Balasubramanian 3560

Framing and Agenda-setting in Russian News: a Computational Analysis of Intricate Political Strategies
Anjalie Field, Doron Kliger, Shuly Wintner, Jennifer Pan, Dan Jurafsky and Yulia Tsvetkov . . 3570

Identifying the sentiment styles of YouTube's vloggers
Bennett Kleinberg, Maximilian Mozes and Isabelle van der Vegt 3581

Native Language Identification with User Generated Content
Gili Goldin, Ella Rabinovich and Shuly Wintner 3591

Beyond Error Propagation in Neural Machine Translation: Characteristics of Language Also Matter
Lijun Wu, Xu Tan, Di He, Fei Tian, Tao Qin, Jianhuang Lai and Tie-Yan Liu 3602

A Study of Reinforcement Learning for Neural Machine Translation
Lijun Wu, Fei Tian, Tao Qin, Jianhuang Lai and Tie-Yan Liu 3612

Meta-Learning for Low-Resource Neural Machine Translation
Jiatao Gu, Yong Wang, Yun Chen, Victor O. K. Li and Kyunghyun Cho 3622

Unsupervised Statistical Machine Translation
Mikel Artetxe, Gorka Labaka and Eneko Agirre 3632

A Visual Attention Grounding Neural Model for Multimodal Machine Translation
Mingyang Zhou, Runxiang Cheng, Yong Jae Lee and Zhou Yu 3643

Sentiment Classification towards Question-Answering with Hierarchical Matching Network
Chenlin Shen, Changlong Sun, Jingjing Wang, Yangyang Kang, Shoushan Li, Xiaozhong Liu, Luo Si, Min Zhang and Guodong Zhou 3654

Cross-topic Argument Mining from Heterogeneous Sources
Christian Stab, Tristan Miller, Benjamin Schiller, Pranav Rai and Iryna Gurevych 3664

Summarizing Opinions: Aspect Extraction Meets Sentiment Prediction and They Are Both Weakly Supervised
Stefanos Angelidis and Mirella Lapata 3675

CARER: Contextualized Affect Representations for Emotion Recognition
Elvis Saravia, Hsien-Chi Toby Liu, Yen-Hao Huang, Junlin Wu and Yi-Shin Chen 3687

Noise Contrastive Estimation and Negative Sampling for Conditional Models: Consistency and Statistical Efficiency
Zhuang Ma and Michael Collins 3698

CaLcs: Continuously Approximating Longest Common Subsequence for Sequence Level Optimization
Semih Yavuz, Chung-Cheng Chiu, Patrick Nguyen and Yonghui Wu 3708

Pathologies of Neural Models Make Interpretations Difficult
Shi Feng, Eric Wallace, Alvin Grissom II, Mohit Iyyer, Pedro Rodriguez and Jordan Boyd-Graber 3719

Phrase-level Self-Attention Networks for Universal Sentence Encoding
Wei Wu, Houfeng Wang, Tianyu Liu and Shuming Ma 3729

BanditSum: Extractive Summarization as a Contextual Bandit
Yue Dong, Yikang Shen, Eric Crawford, Herke van Hoof and Jackie Chi Kit Cheung 3739

A Word-Complexity Lexicon and A Neural Readability Ranking Model for Lexical Simplification
Mounica Maddela and Wei Xu 3749

Learning Latent Semantic Annotations for Grounding Natural Language to Structured Data
Guanghui Qin, Jin-Ge Yao, Xuening Wang, Jinpeng Wang and Chin-Yew Lin 3761

Syntactic Scaffolds for Semantic Structures
Swabha Swayamdipta, Sam Thomson, Kenton Lee, Luke Zettlemoyer, Chris Dyer and Noah A. Smith 3772

Hierarchical Quantized Representations for Script Generation
Noah Weber, Leena Shekhar, Niranjan Balasubramanian and Nate Chambers 3783

Semantic Role Labeling for Learner Chinese: the Importance of Syntactic Parsing and L2-L1 Parallel Data
Zi Lin, Yuguang Duan, Yuanyuan Zhao, Weiwei Sun and Xiaojun Wan 3793

A Teacher-Student Framework for Maintainable Dialog Manager
Weikang Wang, Jiajun Zhang, Han Zhang, Mei-Yuh Hwang, Chengqing Zong and Zhifei Li . 3803

Discriminative Deep Dyna-Q: Robust Planning for Dialogue Policy Learning
Shang-Yu Su, Xiujun Li, Jianfeng Gao, Jingjing Liu and Yun-Nung Chen 3813

A Self-Attentive Model with Gate Mechanism for Spoken Language Understanding
Changliang Li, Liang Li and Ji Qi 3824

Learning End-to-End Goal-Oriented Dialog with Multiple Answers
Janarthanan Rajendran, Jatin Ganhotra, Satinder Singh and Lazaros Polymenakos 3834

AirDialogue: An Environment for Goal-Oriented Dialogue Research
Wei Wei, Quoc Le, Andrew Dai and Jia Li 3844

QuaSE: Sequence Editing under Quantifiable Guidance
Yi Liao, Lidong Bing, Piji Li, Shuming Shi, Wai Lam and Tong Zhang 3855

Paraphrase Generation with Deep Reinforcement Learning
Zichao Li, Xin Jiang, Lifeng Shang and Hang Li 3865

Operation-guided Neural Networks for High Fidelity Data-To-Text Generation
Feng Nie, Jinpeng Wang, Jin-Ge Yao, Rong Pan and Chin-Yew Lin 3879

Generating Classical Chinese Poems via Conditional Variational Autoencoder and Adversarial Training
Juntao Li, Yan Song, Haisong Zhang, Dongmin Chen, Shuming Shi, Dongyan Zhao and Rui Yan 3890

Paragraph-level Neural Question Generation with Maxout Pointer and Gated Self-attention Networks
Yao Zhao, Xiaochuan Ni, Yuanyuan Ding and Qifa Ke 3901

Spider: A Large-Scale Human-Labeled Dataset for Complex and Cross-Domain Semantic Parsing and Text-to-SQL Task
Tao Yu, Rui Zhang, Kai Yang, Michihiro Yasunaga, Dongxu Wang, Zifan Li, James Ma, Irene Li, Qingning Yao, Shanelle Roman, Zilin Zhang and Dragomir Radev 3911

Unsupervised Natural Language Generation with Denoising Autoencoders
Markus Freitag and Scott Roy 3922

Answer-focused and Position-aware Neural Question Generation
Xingwu Sun, Jing Liu, Yajuan Lyu, Wei He, Yanjun Ma and Shi Wang 3930

Diversity-Promoting GAN: A Cross-Entropy Based Generative Adversarial Network for Diversified Text Generation
Jingjing Xu, Xuancheng Ren, Junyang Lin and Xu Sun 3940

Towards a Better Metric for Evaluating Question Generation Systems
Preksha Nema and Mitesh M. Khapra 3950

Stylistic Chinese Poetry Generation via Unsupervised Style Disentanglement
Cheng Yang, Maosong Sun, Xiaoyuan Yi and Wenhao Li 3960

Generating More Interesting Responses in Neural Conversation Models with Distributional Constraints
Ashutosh Baheti, Alan Ritter, Jiwei Li and Bill Dolan 3970

Better Conversations by Modeling, Filtering, and Optimizing for Coherence and Diversity
Xinnuo Xu, Ondřej Dušek, Ioannis Konstas and Verena Rieser 3981

Incorporating Background Knowledge into Video Description Generation
Spencer Whitehead, Heng Ji, Mohit Bansal, Shih-Fu Chang and Clare Voss 3992

Multimodal Differential Network for Visual Question Generation
Badri Narayana Patro, Sandeep Kumar, Vinod Kumar Kurmi and Vinay Namboodiri 4002

Entity-aware Image Caption Generation
Di Lu, Spencer Whitehead, Lifu Huang, Heng Ji and Shih-Fu Chang 4013

Learning to Describe Differences Between Pairs of Similar Images
Harsh Jhamtani and Taylor Berg-Kirkpatrick 4024

Object Hallucination in Image Captioning
Anna Rohrbach, Lisa Anne Hendricks, Kaylee Burns, Trevor Darrell and Kate Saenko 4035

Abstractive Text-Image Summarization Using Multi-Modal Attentional Hierarchical RNN
Jingqiang Chen and Hai Zhuge 4046

Keyphrase Generation with Correlation Constraints
Jun Chen, Xiaoming Zhang, Yu Wu, Zhao Yan and Zhoujun Li 4057

Closed-Book Training to Improve Summarization Encoder Memory
Yichen Jiang and Mohit Bansal 4067

Improving Neural Abstractive Document Summarization with Structural Regularization
Wei Li, Xinyan Xiao, Yajuan Lyu and Yuanzhuo Wang 4078

Iterative Document Representation Learning Towards Summarization with Polishing
Xiuying Chen, Shen Gao, Chongyang Tao, Yan Song, Dongyan Zhao and Rui Yan 4088

Bottom-Up Abstractive Summarization
Sebastian Gehrmann, Yuntian Deng and Alexander Rush 4098

Controlling Length in Abstractive Summarization Using a Convolutional Neural Network
Yizhu Liu, Zhiyi Luo and Kenny Zhu 4110

APRIL: Interactively Learning to Summarise by Combining Active Preference Learning and Reinforcement Learning
Yang Gao, Christian M. Meyer and Iryna Gurevych 4120

Adapting the Neural Encoder-Decoder Framework from Single to Multi-Document Summarization
Logan Lebanoff, Kaiqiang Song and Fei Liu 4131

Semi-Supervised Learning for Neural Keyphrase Generation
Hai Ye and Lu Wang 4142

MSMO: Multimodal Summarization with Multimodal Output
Junnan Zhu, Haoran Li, Tianshang Liu, Yu Zhou, Jiajun Zhang and Chengqing Zong 4154

Frustratingly Easy Model Ensemble for Abstractive Summarization
Hayato Kobayashi 4165

Automatic Pyramid Evaluation Exploiting EDU-based Extractive Reference Summaries
Tsutomu Hirao, Hidetaka Kamigaito and Masaaki Nagata 4177

Learning to Encode Text as Human-Readable Summaries using Generative Adversarial Networks
Yaushian Wang and Hung-yi Lee 4187

Joint Multitask Learning for Community Question Answering Using Task-Specific Embeddings
Shafiq Joty, Lluís Màrquez and Preslav Nakov 4196

What Makes Reading Comprehension Questions Easier?
Saku Sugawara, Kentaro Inui, Satoshi Sekine and Akiko Aizawa 4208

Commonsense for Generative Multi-Hop Question Answering Tasks
Lisa Bauer, Yicheng Wang and Mohit Bansal 4220

Open Domain Question Answering Using Early Fusion of Knowledge Bases and Text
Haitian Sun, Bhuwan Dhingra, Manzil Zaheer, Kathryn Mazaitis, Ruslan Salakhutdinov and William Cohen 4231

A Nil-Aware Answer Extraction Framework for Question Answering
Souvik Kundu and Hwee Tou Ng 4243

Exploiting Deep Representations for Neural Machine Translation
Zi-Yi Dou, Zhaopeng Tu, Xing Wang, Shuming Shi and Tong Zhang 4253

Why Self-Attention? A Targeted Evaluation of Neural Machine Translation Architectures
Gongbo Tang, Mathias Müller, Annette Rios and Rico Sennrich 4263

Simplifying Neural Machine Translation with Addition-Subtraction Twin-Gated Recurrent Networks
Biao Zhang, Deyi Xiong, jinsong su, Qian Lin and Huiji Zhang 4273

Speeding Up Neural Machine Translation Decoding by Cube Pruning
Wen Zhang, Liang Huang, Yang Feng, Lei Shen and Qun Liu 4284

Revisiting Character-Based Neural Machine Translation with Capacity and Compression
Colin Cherry, George Foster, Ankur Bapna, Orhan Firat and Wolfgang Macherey 4295

A Skeleton-Based Model for Promoting Coherence Among Sentences in Narrative Story Generation
Jingjing Xu, Xuancheng Ren, Yi Zhang, Qi Zeng, Xiaoyan Cai and Xu Sun 4306

NEXUS Network: Connecting the Preceding and the Following in Dialogue Generation
Xiaoyu Shen, Hui Su, Wenjie Li and Dietrich Klakow 4316

A Neural Local Coherence Model for Text Quality Assessment
Mohsen Mesgar and Michael Strube 4328

Deep Attentive Sentence Ordering Network
Baiyun Cui, Yingming Li, Ming Chen and Zhongfei Zhang 4340

Getting to "Hearer-old": Charting Referring Expressions Across Time
Ieva Staliūnaitė, Hannah Rohde, Bonnie Webber and Annie Louis 4350

Making "fetch" happen: The influence of social and linguistic context on nonstandard word growth and decline
Ian Stewart and Jacob Eisenstein 4360

Analyzing Correlated Evolution of Multiple Features Using Latent Representations
Yugo Murawaki 4371

Capturing Regional Variation with Distributed Place Representations and Geographic Retrofitting
Dirk Hovy and Christoph Purschke 4383

Characterizing Interactions and Relationships between People
Farzana Rashid and Eduardo Blanco 4395

Why Swear? Analyzing and Inferring the Intentions of Vulgar Expressions
Eric Holgate, Isabel Cachola, Daniel Preoţiuc-Pietro and Junyi Jessy Li 4405

Is it Time to Swish? Comparing Deep Learning Activation Functions Across NLP tasks
Steffen Eger, Paul Youssef and Iryna Gurevych 4415

Hard Non-Monotonic Attention for Character-Level Transduction
Shijie Wu, Pamela Shapiro and Ryan Cotterell 4425

Speed Reading: Learning to Read ForBackward via Shuttle
Tsu-Jui Fu and Wei-Yun Ma 4439

Modeling Localness for Self-Attention Networks
Baosong Yang, Zhaopeng Tu, Derek F. Wong, Fandong Meng, Lidia S. Chao and Tong Zhang 4449

Chargrid: Towards Understanding 2D Documents
Anoop R Katti, Christian Reisswig, Cordula Guder, Sebastian Brarda, Steffen Bickel, Johannes Höhne and Jean Baptiste Faddoul 4459

Simple Recurrent Units for Highly Parallelizable Recurrence
Tao Lei, Yu Zhang, Sida I. Wang, Hui Dai and Yoav Artzi 4470

NPRF: A Neural Pseudo Relevance Feedback Framework for Ad-hoc Information Retrieval
Canjia Li, Yingfei Sun, Ben He, Le Wang, Kai Hui, Andrew Yates, Le Sun and Jungang Xu . . 4482

Co-Stack Residual Affinity Networks with Multi-level Attention Refinement for Matching Text Sequences
Yi Tay, Anh Tuan Luu and Siu Cheung Hui 4492

Spherical Latent Spaces for Stable Variational Autoencoders
Jiacheng Xu and Greg Durrett 4503

Learning Universal Sentence Representations with Mean-Max Attention Autoencoder
Minghua Zhang, Yunfang Wu, Weikang Li and Wei Li 4514

Word Mover's Embedding: From Word2Vec to Document Embedding
Lingfei Wu, Ian En-Hsu Yen, Kun Xu, Fangli Xu, Avinash Balakrishnan, Pin-Yu Chen, Pradeep Ravikumar and Michael J. Witbrock 4524

Multilingual Clustering of Streaming News
Sebastião Miranda, Arturs Znotins, Shay B. Cohen and Guntis Barzdins 4535

Multi-Task Label Embedding for Text Classification
Honglun Zhang, Liqiang Xiao, Wenqing Chen, Yongkun Wang and Yaohui Jin 4545

Semantic-Unit-Based Dilated Convolution for Multi-Label Text Classification
Junyang Lin, Qi Su, Pengcheng Yang, Shuming Ma and Xu Sun 4554

MCapsNet: Capsule Network for Text with Multi-Task Learning
Liqiang Xiao, Honglun Zhang, Wenqing Chen, Yongkun Wang and Yaohui Jin 4565

Uncertainty-aware generative models for inferring document class prevalence
Katherine Keith and Brendan O'Connor 4575

Challenges of Using Text Classifiers for Causal Inference
Zach Wood-Doughty, Ilya Shpitser and Mark Dredze 4586

Direct Output Connection for a High-Rank Language Model
Sho Takase, Jun Suzuki and Masaaki Nagata 4599

Disfluency Detection using Auto-Correlational Neural Networks
Paria Jamshid Lou, Peter Anderson and Mark Johnson 4610

Pyramidal Recurrent Unit for Language Modeling
Sachin Mehta, Rik Koncel-Kedziorski, Mohammad Rastegari and Hannaneh Hajishirzi 4620

On Tree-Based Neural Sentence Modeling
Haoyue Shi, Hao Zhou, Jiaze Chen and Lei Li 4631

Language Modeling with Sparse Product of Sememe Experts
Yihong Gu, Jun Yan, Hao Zhu, Zhiyuan Liu, Ruobing Xie, Maosong Sun, Fen Lin and Leyu Lin 4642

Siamese Network-Based Supervised Topic Modeling
Minghui Huang, Yanghui Rao, Yuwei Liu, Haoran Xie and Fu Lee Wang 4652

GraphBTM: Graph Enhanced Autoencoded Variational Inference for Biterm Topic Model
Qile Zhu, Zheng Feng and Xiaolin Li 4663

Modeling Online Discourse with Coupled Distributed Topics
Akshay Srivatsan, Zachary Wojtowicz and Taylor Berg-Kirkpatrick 4673

Learning Disentangled Representations of Texts with Application to Biomedical Abstracts
Sarthak Jain, Edward Banner, Jan-Willem van de Meent, Iain J Marshall and Byron C. Wallace 4683

Multi-Source Domain Adaptation with Mixture of Experts
Jiang Guo, Darsh Shah and Regina Barzilay 4694

A Neural Model of Adaptation in Reading
Marten van Schijndel and Tal Linzen 4704

Understanding Deep Learning Performance through an Examination of Test Set Difficulty: A Psychometric Case Study
John Lalor, Hao Wu, Tsendsuren Munkhdalai and Hong Yu 4711

Lexicosyntactic Inference in Neural Models
Aaron Steven White, Rachel Rudinger, Kyle Rawlins and Benjamin Van Durme 4717

Dual Fixed-Size Ordinally Forgetting Encoding (FOFE) for Competitive Neural Language Models
Sedtawut Watcharawittayakul, Mingbin Xu and Hui Jiang 4725

The Importance of Being Recurrent for Modeling Hierarchical Structure
Ke Tran, Arianna Bisazza and Christof Monz 4731

Joint Learning for Targeted Sentiment Analysis
Dehong Ma, Sujian Li and Houfeng Wang 4737

Revisiting the Importance of Encoding Logic Rules in Sentiment Classification
Kalpesh Krishna, Preethi Jyothi and Mohit Iyyer 4743

A Co-Attention Neural Network Model for Emotion Cause Analysis with Emotional Context Awareness
Xiangju Li, Kaisong Song, Shi Feng, Daling Wang and Yifei Zhang 4752

Modeling Empathy and Distress in Reaction to News Stories
Sven Buechel, Anneke Buffone, Barry Slaff, Lyle Ungar and Joao Sedoc 4758

Interpretable Emoji Prediction via Label-Wise Attention LSTMs
Francesco Barbieri, Luis Espinosa Anke, Jose Camacho-Collados, Steven Schockaert and Horacio Saggion 4766

A Tree-based Decoder for Neural Machine Translation
Xinyi Wang, Hieu Pham, Pengcheng Yin and Graham Neubig 4772

Greedy Search with Probabilistic N-gram Matching for Neural Machine Translation
Chenze Shao, Xilin Chen and Yang Feng 4778

Exploring Recombination for Efficient Decoding of Neural Machine Translation
Zhisong Zhang, Rui Wang, Masao Utiyama, Eiichiro Sumita and Hai Zhao 4785

Has Machine Translation Achieved Human Parity? A Case for Document-level Evaluation
Samuel Läubli, Rico Sennrich and Martin Volk 4791

Automatic Reference-Based Evaluation of Pronoun Translation Misses the Point
Liane Guillou and Christian Hardmeier 4797

FewRel: A Large-Scale Supervised Few-Shot Relation Classification Dataset with State-of-the-Art Evaluation
Xu Han, Hao Zhu, Pengfei Yu, Ziyun Wang, Yuan Yao, Zhiyuan Liu and Maosong Sun 4803

A strong baseline for question relevancy ranking
Ana Gonzalez, Isabelle Augenstein and Anders Søgaard 4810

Learning Sequence Encoders for Temporal Knowledge Graph Completion
Alberto Garcia-Duran, Sebastijan Dumančić and Mathias Niepert 4816

Similar but not the Same: Word Sense Disambiguation Improves Event Detection via Neural Representation Matching
Weiyi Lu and Thien Huu Nguyen 4822

Learning Word Representations with Cross-Sentence Dependency for End-to-End Co-reference Resolution
Hongyin Luo and Jim Glass 4829

Word Relation Autoencoder for Unseen Hypernym Extraction Using Word Embeddings
Hong-You Chen, Cheng-Syuan Lee, Keng-Te Liao and Shou-de Lin 4834

Refining Pretrained Word Embeddings Using Layer-wise Relevance Propagation
Akira Utsumi 4840

Learning Gender-Neutral Word Embeddings
Jieyu Zhao, Yichao Zhou, Zeyu Li, Wei Wang and Kai-Wei Chang 4847

Learning Concept Abstractness Using Weak Supervision
Ella Rabinovich, Benjamin Sznajder, Artem Spector, Ilya Shnayderman, Ranit Aharonov, David Konopnicki and Noam Slonim 4854

Word Sense Induction with Neural biLM and Symmetric Patterns
Asaf Amrami and Yoav Goldberg 4860

InferLite: Simple Universal Sentence Representations from Natural Language Inference Data
Jamie Kiros and William Chan 4868

Similarity-Based Reconstruction Loss for Meaning Representation
Olga Kovaleva, Anna Rumshisky and Alexey Romanov 4875

What can we learn from Semantic Tagging?
Mostafa Abdou, Artur Kulmizev, Vinit Ravishankar, Lasha Abzianidze and Johan Bos 4881

Conditional Word Embedding and Hypothesis Testing via Bayes-by-Backprop
Rujun Han, Michael Gill, Arthur Spirling and Kyunghyun Cho 4890

Classifying Referential and Non-referential It Using Gaze
Victoria Yaneva, Le An Ha, Richard Evans and Ruslan Mitkov 4896

State-of-the-art Chinese Word Segmentation with Bi-LSTMs
Ji Ma, Kuzman Ganchev and David Weiss 4902

Sanskrit Sandhi Splitting using seq2(seq)2
Rahul Aralikatte, Neelamadhav Gantayat, Naveen Panwar, Anush Sankaran and Senthil Mani 4909

Unsupervised Neural Word Segmentation for Chinese via Segmental Language Modeling
Zhiqing Sun and Zhi-Hong Deng 4915

LemmaTag: Jointly Tagging and Lemmatizing for Morphologically Rich Languages with BRNNs
Daniel Kondratyuk, Tomáš Gavenčiak, Milan Straka and Jan Hajič 4921

Recovering Missing Characters in Old Hawaiian Writing
Brendan Shillingford and Oiwi Parker Jones 4929

When data permutations are pathological: the case of neural natural language inference
Natalie Schluter and Daniel Varab 4935

Bridging Knowledge Gaps in Neural Entailment via Symbolic Models
Dongyeop Kang, Tushar Khot, Ashish Sabharwal and Peter Clark 4940

The BQ Corpus: A Large-scale Domain-specific Chinese Corpus For Sentence Semantic Equivalence Identification
Jing Chen, Qingcai Chen, Xin Liu, Haijun Yang, Daohe Lu and Buzhou Tang 4946

Interpreting Recurrent and Attention-Based Neural Models: a Case Study on Natural Language Inference
Reza Ghaeini, Xiaoli Fern and Prasad Tadepalli 4952

Towards Semi-Supervised Learning for Deep Semantic Role Labeling
Sanket Vaibhav Mehta, Jay Yoon Lee and Jaime Carbonell 4958

Identifying Domain Adjacent Instances for Semantic Parsers
James Ferguson, Janara Christensen, Edward Li and Edgar Gonzàlez 4964

Mapping natural language commands to web elements
Panupong Pasupat, Tian-Shun Jiang, Evan Liu, Kelvin Guu and Percy Liang 4970

Wronging a Right: Generating Better Errors to Improve Grammatical Error Detection
Sudhanshu Kasewa, Pontus Stenetorp and Sebastian Riedel 4977

Modeling Input Uncertainty in Neural Network Dependency Parsing
Rob van der Goot and Gertjan van Noord 4984

Parameter sharing between dependency parsers for related languages
Miryam de Lhoneux, Johannes Bjerva, Isabelle Augenstein and Anders Søgaard 4992

Grammar Induction with Neural Language Models: An Unusual Replication
Phu Mon Htut, Kyunghyun Cho and Samuel Bowman 4998

Data Augmentation via Dependency Tree Morphing for Low-Resource Languages
Gozde Gul Sahin and Mark Steedman 5004

How Much Reading Does Reading Comprehension Require? A Critical Investigation of Popular Benchmarks
Divyansh Kaushik and Zachary C. Lipton 5010

MultiWOZ - A Large-Scale Multi-Domain Wizard-of-Oz Dataset for Task-Oriented Dialogue Modelling
Paweł Budzianowski, Tsung-Hsien Wen, Bo-Hsiang Tseng, Iñigo Casanueva, Stefan Ultes, Osman Ramadan and Milica Gasic 5016

Linguistically-Informed Self-Attention for Semantic Role Labeling
Emma Strubell, Patrick Verga, Daniel Andor, David Weiss and Andrew McCallum 5027

Phrase-Based & Neural Unsupervised Machine Translation
Guillaume Lample, Myle Ott, Alexis Conneau, Ludovic Denoyer and Marc'Aurelio Ranzato . 5039

Conference Program

Friday, November 2, 2018

09:00–09:30 ***Opening remarks (Gold Hall)***

09:30–10:30 ***Keynote I: Julia Hirschberg "Truth or Lie? Spoken Indicators of Deception in Speech" (Gold Hall)***

10:30–11:00 ***Coffee Break***

11:00–12:30 ***Long Papers and Demos (Orals and Posters) I***

Session 1A: Social Applications I (Gold Hall)

11:00–11:18 *Privacy-preserving Neural Representations of Text*
Maximin Coavoux, Shashi Narayan and Shay B. Cohen

11:18–11:36 *Adversarial Removal of Demographic Attributes from Text Data*
Yanai Elazar and Yoav Goldberg

11:36–11:54 *DeClarE: Debunking Fake News and False Claims using Evidence-Aware Deep Learning*
Kashyap Popat, Subhabrata Mukherjee, Andrew Yates and Gerhard Weikum

11:54–12:12 *It's going to be okay: Measuring Access to Support in Online Communities*
Zijian Wang and David Jurgens

12:12–12:30 *Detecting Gang-Involved Escalation on Social Media Using Context*
Serina Chang, Ruiqi Zhong, Ethan Adams, Fei-Tzin Lee, Siddharth Varia, Desmond Patton, William Frey, Chris Kedzie and Kathy McKeown

Friday, November 2, 2018 (continued)

Session 1B: Semantics I (Copper Hall)

11:00–11:18 *Reasoning about Actions and State Changes by Injecting Commonsense Knowledge*
Niket Tandon, Bhavana Dalvi, Joel Grus, Wen-tau Yih, Antoine Bosselut and Peter Clark

11:18–11:36 *Collecting Diverse Natural Language Inference Problems for Sentence Representation Evaluation*
Adam Poliak, Aparajita Haldar, Rachel Rudinger, J. Edward Hu, Ellie Pavlick, Aaron Steven White and Benjamin Van Durme

11:36–11:54 *Textual Analogy Parsing: What's Shared and What's Compared among Analogous Facts*
Matthew Lamm, Arun Chaganty, Christopher D. Manning, Dan Jurafsky and Percy Liang

11:54–12:12 *SWAG: A Large-Scale Adversarial Dataset for Grounded Commonsense Inference*
Rowan Zellers, Yonatan Bisk, Roy Schwartz and Yejin Choi

12:12–12:30 *TwoWingOS: A Two-Wing Optimization Strategy for Evidential Claim Verification*
Wenpeng Yin and Dan Roth

Session 1C: Vision (Silver Hall)

11:00–11:18 *Associative Multichannel Autoencoder for Multimodal Word Representation*
Shaonan Wang, Jiajun Zhang and Chengqing Zong

11:18–11:36 *Game-Based Video-Context Dialogue*
Ramakanth Pasunuru and Mohit Bansal

11:36–11:54 *simNet: Stepwise Image-Topic Merging Network for Generating Detailed and Comprehensive Image Captions*
Fenglin Liu, Xuancheng Ren, Yuanxin Liu, Houfeng Wang and Xu Sun

11:54–12:12 *Multimodal Language Analysis with Recurrent Multistage Fusion*
Paul Pu Liang, Ziyin Liu, AmirAli Bagher Zadeh and Louis-Philippe Morency

12:12–12:30 *Temporally Grounding Natural Sentence in Video*
Jingyuan Chen, Xinpeng Chen, Lin Ma, Zequn Jie and Tat-Seng Chua

Session 1D: Entities and Coreference (Hall 100)

11:00–11:18 *PreCo: A Large-scale Dataset in Preschool Vocabulary for Coreference Resolution*
Hong Chen, Zhenhua Fan, Hao Lu, Alan Yuille and Shu Rong

11:18–11:36 *Adversarial Transfer Learning for Chinese Named Entity Recognition with Self-Attention Mechanism*
Pengfei Cao, Yubo Chen, Kang Liu, Jun Zhao and Shengping Liu

11:36–11:54 *Using Linguistic Features to Improve the Generalization Capability of Neural Coreference Resolvers*
Nafise Sadat Moosavi and Michael Strube

11:54–12:12 *Neural Segmental Hypergraphs for Overlapping Mention Recognition*
Bailin Wang and Wei Lu

12:12–12:30 *Variational Sequential Labelers for Semi-Supervised Learning*
Mingda Chen, Qingming Tang, Karen Livescu and Kevin Gimpel

Session 1E: Machine Translation and Multilingual Methods (Posters and Demos, Grand Hall 2)

Joint Representation Learning of Cross-lingual Words and Entities via Attentive Distant Supervision
Yixin Cao, Lei Hou, Juanzi Li, Zhiyuan Liu, Chengjiang Li, Xu Chen and Tiansi Dong

Deep Pivot-Based Modeling for Cross-language Cross-domain Transfer with Minimal Guidance
Yftah Ziser and Roi Reichart

Multi-lingual Common Semantic Space Construction via Cluster-consistent Word Embedding
Lifu Huang, Kyunghyun Cho, Boliang Zhang, Heng Ji and Kevin Knight

Unsupervised Multilingual Word Embeddings
Xilun Chen and Claire Cardie

CLUSE: Cross-Lingual Unsupervised Sense Embeddings
Ta Chung Chi and Yun-Nung Chen

Adversarial Propagation and Zero-Shot Cross-Lingual Transfer of Word Vector Specialization
Edoardo Maria Ponti, Ivan Vulić, Goran Glavaš, Nikola Mrkšić and Anna Korhonen

Improving Cross-Lingual Word Embeddings by Meeting in the Middle
Yerai Doval, Jose Camacho-Collados, Luis Espinosa Anke and Steven Schockaert

WikiAtomicEdits: A Multilingual Corpus of Wikipedia Edits for Modeling Language and Discourse
Manaal Faruqui, Ellie Pavlick, Ian Tenney and Dipanjan Das

On the Relation between Linguistic Typology and (Limitations of) Multilingual Language Modeling
Daniela Gerz, Ivan Vulić, Edoardo Maria Ponti, Roi Reichart and Anna Korhonen

A Fast, Compact, Accurate Model for Language Identification of Codemixed Text
Yuan Zhang, Jason Riesa, Daniel Gillick, Anton Bakalov, Jason Baldridge and David Weiss

Personalized Microblog Sentiment Classification via Adversarial Cross-lingual Multi-task Learning
Weichao Wang, Shi Feng, Wei Gao, Daling Wang and Yifei Zhang

Cross-lingual Knowledge Graph Alignment via Graph Convolutional Networks
Zhichun Wang, Qingsong Lv, Xiaohan Lan and Yu Zhang

Cross-lingual Lexical Sememe Prediction
Fanchao Qi, Yankai Lin, Maosong Sun, Hao Zhu, Ruobing Xie and Zhiyuan Liu

Neural Cross-Lingual Named Entity Recognition with Minimal Resources
Jiateng Xie, Zhilin Yang, Graham Neubig, Noah A. Smith and Jaime Carbonell

A Stable and Effective Learning Strategy for Trainable Greedy Decoding
Yun Chen, Victor O.K. Li, Kyunghyun Cho and Samuel Bowman

Addressing Troublesome Words in Neural Machine Translation
Yang Zhao, Jiajun Zhang, Zhongjun He, Chengqing Zong and Hua Wu

Top-down Tree Structured Decoding with Syntactic Connections for Neural Machine Translation and Parsing
Jetic Gū, Hassan S. Shavarani and Anoop Sarkar

XL-NBT: A Cross-lingual Neural Belief Tracking Framework
Wenhu Chen, Jianshu Chen, Yu Su, Xin Wang, Dong Yu, Xifeng Yan and William Yang Wang

Contextual Parameter Generation for Universal Neural Machine Translation
Emmanouil Antonios Platanios, Mrinmaya Sachan, Graham Neubig and Tom Mitchell

Back-Translation Sampling by Targeting Difficult Words in Neural Machine Translation
Marzieh Fadaee and Christof Monz

Multi-Domain Neural Machine Translation with Word-Level Domain Context Discrimination
Jiali Zeng, Jinsong Su, Huating Wen, Yang Liu, Jun Xie, Yongjing Yin and Jianqiang Zhao

A Discriminative Latent-Variable Model for Bilingual Lexicon Induction
Sebastian Ruder, Ryan Cotterell, Yova Kementchedjhieva and Anders Søgaard

Non-Adversarial Unsupervised Word Translation
Yedid Hoshen and Lior Wolf

Semi-Autoregressive Neural Machine Translation
Chunqi Wang, Ji Zhang and Haiqing Chen

Understanding Back-Translation at Scale
Sergey Edunov, Myle Ott, Michael Auli and David Grangier

Bootstrapping Transliteration with Constrained Discovery for Low-Resource Languages
Shyam Upadhyay, Jordan Kodner and Dan Roth

NORMA: Neighborhood Sensitive Maps for Multilingual Word Embeddings
Ndapa Nakashole

Adaptive Multi-pass Decoder for Neural Machine Translation
Xinwei Geng, Xiaocheng Feng, Bing Qin and Ting Liu

Improving the Transformer Translation Model with Document-Level Context
Jiacheng Zhang, Huanbo Luan, Maosong Sun, Feifei Zhai, Jingfang Xu, Min Zhang and Yang Liu

MTNT: A Testbed for Machine Translation of Noisy Text
Paul Michel and Graham Neubig

Demo: CytonMT: an Efficient Neural Machine Translation Open-source Toolkit Implemented in C++
Xiaolin Wang, Masao Utiyama, and Eiichiro Sumita

Demo: SentencePiece: A simple and language independent subword tokenizer and detokenizer for Neural Text Processing
Taku Kudo and John Richardson

12:30–13:45 ***Lunch***

13:45–14:45 ***Short Papers (Orals and Posters) I***

Session 2A: Question Answering I (Gold Hall)

13:45–13:57 *SimpleQuestions Nearly Solved: A New Upperbound and Baseline Approach*
Michael Petrochuk and Luke Zettlemoyer

13:57–14:09 *Phrase-Indexed Question Answering: A New Challenge for Scalable Document Comprehension*
Minjoon Seo, Tom Kwiatkowski, Ankur Parikh, Ali Farhadi and Hannaneh Hajishirzi

14:09–14:21 *Ranking Paragraphs for Improving Answer Recall in Open-Domain Question Answering*
Jinhyuk Lee, Seongjun Yun, Hyunjae Kim, Miyoung Ko and Jaewoo Kang

14:21–14:33 *Cut to the Chase: A Context Zoom-in Network for Reading Comprehension*
Sathish Reddy Indurthi, Seunghak Yu, Seohyun Back and Heriberto Cuayahuitl

14:33–14:45 *Adaptive Document Retrieval for Deep Question Answering*
Bernhard Kratzwald and Stefan Feuerriegel

Session 2B: Semantics II (Copper Hall)

13:45–13:57 *Why is unsupervised alignment of English embeddings from different algorithms so hard?*
Mareike Hartmann, Yova Kementchedjhieva and Anders Søgaard

13:57–14:09 *Quantifying Context Overlap for Training Word Embeddings*
Yimeng Zhuang, Jinghui Xie, Yinhe Zheng and Xuan Zhu

14:09–14:21 *Neural Latent Relational Analysis to Capture Lexical Semantic Relations in a Vector Space*
Koki Washio and Tsuneaki Kato

14:21–14:33 *Generalizing Word Embeddings using Bag of Subwords*
Jinman Zhao, Sidharth Mudgal and Yingyu Liang

14:33–14:45 *Neural Metaphor Detection in Context*
Ge Gao, Eunsol Choi, Yejin Choi and Luke Zettlemoyer

Session 2C: Multilingual Methods I (Silver Hall)

13:45–13:57 *Distant Supervision from Disparate Sources for Low-Resource Part-of-Speech Tagging*
Barbara Plank and Željko Agić

13:57–14:09 *Unsupervised Bilingual Lexicon Induction via Latent Variable Models*
Zi-Yi Dou, Zhi-Hao Zhou and Shujian Huang

14:09–14:21 *Learning Unsupervised Word Translations Without Adversaries*
Tanmoy Mukherjee, Makoto Yamada and Timothy Hospedales

14:21–14:33 *Adversarial Training for Multi-task and Multi-lingual Joint Modeling of Utterance Intent Classification*
Ryo Masumura, Yusuke Shinohara, Ryuichiro Higashinaka and Yushi Aono

14:33–14:45 *Surprisingly Easy Hard-Attention for Sequence to Sequence Learning*
Shiv Shankar, Siddhant Garg and Sunita Sarawagi

Session 2D: Social Media (Hall 100)

13:45–13:57 *Joint Learning for Emotion Classification and Emotion Cause Detection*
Ying Chen, Wenjun Hou, Xiyao Cheng and Shoushan Li

13:57–14:09 *Exploring Optimism and Pessimism in Twitter Using Deep Learning*
Cornelia Caragea, Liviu P. Dinu and Bogdan Dumitru

14:09–14:21 *Predicting News Headline Popularity with Syntactic and Semantic Knowledge Using Multi-Task Learning*
Sotiris Lamprinidis, Daniel Hardt and Dirk Hovy

14:21–14:33 *Hybrid Neural Attention for Agreement/Disagreement Inference in Online Debates*
Di Chen, Jiachen Du, Lidong Bing and Ruifeng Xu

14:33–14:45 *Increasing In-Class Similarity by Retrofitting Embeddings with Demographic Information*
Dirk Hovy and Tommaso Fornaciari

Session 2E: Short Posters I (Grand Hall 2)

A Syntactically Constrained Bidirectional-Asynchronous Approach for Emotional Conversation Generation
Jingyuan Li and Xiao Sun

Auto-Dialabel: Labeling Dialogue Data with Unsupervised Learning
Chen Shi, Qi Chen, Lei Sha, Sujian Li, Xu Sun, Houfeng Wang and Lintao Zhang

Extending Neural Generative Conversational Model using External Knowledge Sources
Prasanna Parthasarathi and Joelle Pineau

Modeling Temporality of Human Intentions by Domain Adaptation
Xiaolei Huang, Lixing Liu, Kate Carey, Joshua Woolley, Stefan Scherer and Brian Borsari

An Auto-Encoder Matching Model for Learning Utterance-Level Semantic Dependency in Dialogue Generation
Liangchen Luo, Jingjing Xu, Junyang Lin, Qi Zeng and Xu Sun

A Dataset for Document Grounded Conversations
Kangyan Zhou, Shrimai Prabhumoye and Alan W Black

Out-of-domain Detection based on Generative Adversarial Network
Seonghan Ryu, Sangjun Koo, Hwanjo Yu and Gary Geunbae Lee

Listening Comprehension over Argumentative Content
Shachar Mirkin, Guy Moshkowich, Matan Orbach, Lili Kotlerman, Yoav Kantor, Tamar Lavee, Michal Jacovi, Yonatan Bilu, Ranit Aharonov and Noam Slonim

Using active learning to expand training data for implicit discourse relation recognition
Yang Xu, Yu Hong, Huibin Ruan, Jianmin Yao, Min Zhang and Guodong Zhou

Learning To Split and Rephrase From Wikipedia Edit History
Jan A. Botha, Manaal Faruqui, John Alex, Jason Baldridge and Dipanjan Das

BLEU is Not Suitable for the Evaluation of Text Simplification
Elior Sulem, Omri Abend and Ari Rappoport

S2SPMN: A Simple and Effective Framework for Response Generation with Relevant Information
Jiaxin Pei and Chenliang Li

Improving Reinforcement Learning Based Image Captioning with Natural Language Prior
Tszhang Guo, Shiyu Chang, Mo Yu and Kun Bai

Training for Diversity in Image Paragraph Captioning
Luke Melas-Kyriazi, Alexander Rush and George Han

A Graph-theoretic Summary Evaluation for ROUGE
Elaheh ShafieiBavani, Mohammad Ebrahimi, Raymond Wong and Fang Chen

Guided Neural Language Generation for Abstractive Summarization using Abstract Meaning Representation
Hardy Hardy and Andreas Vlachos

Evaluating Multiple System Summary Lengths: A Case Study
Ori Shapira, David Gabay, Hadar Ronen, Judit Bar-Ilan, Yael Amsterdamer, Ani Nenkova and Ido Dagan

Friday, November 2, 2018 (continued)

Neural Latent Extractive Document Summarization
Xingxing Zhang, Mirella Lapata, Furu Wei and Ming Zhou

On the Abstractiveness of Neural Document Summarization
Fangfang Zhang, Jin-ge Yao and Rui Yan

Automatic Essay Scoring Incorporating Rating Schema via Reinforcement Learning
Yucheng Wang, Zhongyu Wei, Yaqian Zhou and Xuanjing Huang

Identifying Well-formed Natural Language Questions
Manaal Faruqui and Dipanjan Das

15:00–15:12 *Self-Governing Neural Networks for On-Device Short Text Classification*
Sujith Ravi and Zornitsa Kozareva

HFT-CNN: Learning Hierarchical Category Structure for Multi-label Short Text Categorization
Kazuya Shimura, Jiyi Li and Fumiyo Fukumoto

A Hierarchical Neural Attention-based Text Classifier
Koustuv Sinha, Yue Dong, Jackie Chi Kit Cheung and Derek Ruths

Labeled Anchors and a Scalable, Transparent, and Interactive Classifier
Jeffrey Lund, Stephen Cowley, Wilson Fearn, Emily Hales and Kevin Seppi

Coherence-Aware Neural Topic Modeling
Ran Ding, Ramesh Nallapati and Bing Xiang

Utilizing Character and Word Embeddings for Text Normalization with Sequence-to-Sequence Models
Daniel Watson, Nasser Zalmout and Nizar Habash

Topic Intrusion for Automatic Topic Model Evaluation
Shraey Bhatia, Jey Han Lau and Timothy Baldwin

Supervised and Unsupervised Methods for Robust Separation of Section Titles and Prose Text in Web Documents
Abhijith Athreya Mysore Gopinath, Shomir Wilson and Norman Sadeh

Friday, November 2, 2018 (continued)

14:45–15:00 ***Mini-Break***

15:00–16:00 ***Short Papers (Orals and Posters) II***

Session 3A: Machine Translation I (Gold Hall)

15:00–15:12 *SwitchOut: an Efficient Data Augmentation Algorithm for Neural Machine Translation*
Xinyi Wang, Hieu Pham, Zihang Dai and Graham Neubig

15:12–15:24 *Improving Unsupervised Word-by-Word Translation with Language Model and Denoising Autoencoder*
Yunsu Kim, Jiahui Geng and Hermann Ney

15:24–15:36 *Decipherment of Substitution Ciphers with Neural Language Models*
Nishant Kambhatla, Anahita Mansouri Bigvand and Anoop Sarkar

15:36–15:48 *Rapid Adaptation of Neural Machine Translation to New Languages*
Graham Neubig and Junjie Hu

15:48–16:00 *Compact Personalized Models for Neural Machine Translation*
Joern Wuebker, Patrick Simianer and John DeNero

Session 3B: Machine Learning I (Copper Hall)

15:00–15:12 *Self-Governing Neural Networks for On-Device Short Text Classification*
Sujith Ravi and Zornitsa Kozareva

15:12–15:24 *Supervised Domain Enablement Attention for Personalized Domain Classification*
Joo-Kyung Kim and Young-Bum Kim

15:24–15:36 *A Deep Neural Network Sentence Level Classification Method with Context Information*
Xingyi Song, Johann Petrak and Angus Roberts

15:36–15:48 *Towards Dynamic Computation Graphs via Sparse Latent Structure*
Vlad Niculae, André F. T. Martins and Claire Cardie

15:48–16:00 *Convolutional Neural Networks with Recurrent Neural Filters*
Yi Yang

Session 3C: Semantic Parsing / Generation (Silver Hall)

15:00–15:12 *Exploiting Rich Syntactic Information for Semantic Parsing with Graph-to-Sequence Model*
Kun Xu, Lingfei Wu, Zhiguo Wang, Mo Yu, Liwei Chen and Vadim Sheinin

15:12–15:24 *Retrieval-Based Neural Code Generation*
Shirley Anugrah Hayati, Raphael Olivier, Pravalika Avvaru, Pengcheng Yin, Anthony Tomasic and Graham Neubig

15:24–15:36 *SQL-to-Text Generation with Graph-to-Sequence Model*
Kun Xu, Lingfei Wu, Zhiguo Wang, Yansong Feng and Vadim Sheinin

15:36–15:48 *Generating Syntactic Paraphrases*
Emilie Colin and Claire Gardent

15:48–16:00 *Neural-Davidsonian Semantic Proto-role Labeling*
Rachel Rudinger, Adam Teichert, Ryan Culkin, Sheng Zhang and Benjamin Van Durme

Session 3D: Vision / Discourse (Hall 100)

15:00–15:12 *Conversational Decision-Making Model for Predicting the King's Decision in the Annals of the Joseon Dynasty*
JinYeong Bak and Alice Oh

15:12–15:24 *Toward Fast and Accurate Neural Discourse Segmentation*
Yizhong Wang, Sujian Li and Jingfeng Yang

15:24–15:36 *A Dataset for Telling the Stories of Social Media Videos*
Spandana Gella, Mike Lewis and Marcus Rohrbach

15:36–15:48 *Cascaded Mutual Modulation for Visual Reasoning*
Yiqun Yao, Jiaming Xu, Feng Wang and Bo Xu

15:48–16:00 *How agents see things: On visual representations in an emergent language game*
Diane Bouchacourt and Marco Baroni

Session 3E: Short Posters II (Grand Hall 2)

Attention-Based Capsule Networks with Dynamic Routing for Relation Extraction
Ningyu Zhang, Shumin Deng, Zhanling Sun, Xi Chen, Wei Zhang and Huajun Chen

Put It Back: Entity Typing with Language Model Enhancement
Ji Xin, Hao Zhu, Xu Han, Zhiyuan Liu and Maosong Sun

Event Detection with Neural Networks: A Rigorous Empirical Evaluation
Walker Orr, Prasad Tadepalli and Xiaoli Fern

PubSE: A Hierarchical Model for Publication Extraction from Academic Homepages
Yiqing Zhang, Jianzhong Qi, Rui Zhang and Chuandong Yin

A Neural Transition-based Model for Nested Mention Recognition
Bailin Wang, Wei Lu, Yu Wang and Hongxia Jin

Genre Separation Network with Adversarial Training for Cross-genre Relation Extraction
Ge Shi, Chong Feng, Lifu Huang, Boliang Zhang, Heng Ji, Lejian Liao and Heyan Huang

Effective Use of Context in Noisy Entity Linking
David Mueller and Greg Durrett

Exploiting Contextual Information via Dynamic Memory Network for Event Detection
Shaobo Liu, Rui Cheng, Xiaoming Yu and Xueqi Cheng

Do explanations make VQA models more predictable to a human?
Arjun Chandrasekaran, Viraj Prabhu, Deshraj Yadav, Prithvijit Chattopadhyay and Devi Parikh

Facts That Matter
Marco Ponza, Luciano Del Corro and Gerhard Weikum

Entity Tracking Improves Cloze-style Reading Comprehension
Luong Hoang, Sam Wiseman and Alexander Rush

Adversarial Domain Adaptation for Duplicate Question Detection
Darsh Shah, Tao Lei, Alessandro Moschitti, Salvatore Romeo and Preslav Nakov

Translating a Math Word Problem to a Expression Tree
Lei Wang, Yan Wang, Deng Cai, Dongxiang Zhang and Xiaojiang Liu

Semantic Linking in Convolutional Neural Networks for Answer Sentence Selection
Massimo Nicosia and Alessandro Moschitti

A dataset and baselines for sequential open-domain question answering
Ahmed Elgohary, Chen Zhao and Jordan Boyd-Graber

Improving the results of string kernels in sentiment analysis and Arabic dialect identification by adapting them to your test set
Radu Tudor Ionescu and Andrei M. Butnaru

Parameterized Convolutional Neural Networks for Aspect Level Sentiment Classification
Binxuan Huang and Kathleen Carley

Improving Multi-label Emotion Classification via Sentiment Classification with Dual Attention Transfer Network
Jianfei Yu, Luis Marujo, Jing Jiang, Pradeep Karuturi and William Brendel

Learning Sentiment Memories for Sentiment Modification without Parallel Data
Yi Zhang, Jingjing Xu, Pengcheng Yang and Xu Sun

Joint Aspect and Polarity Classification for Aspect-based Sentiment Analysis with End-to-End Neural Networks
Martin Schmitt, Simon Steinheber, Konrad Schreiber and Benjamin Roth

Representing Social Media Users for Sarcasm Detection
Y. Alex Kolchinski and Christopher Potts

Syntactical Analysis of the Weaknesses of Sentiment Analyzers
Rohil Verma, Samuel Kim and David Walter

Is Nike female? Exploring the role of sound symbolism in predicting brand name gender
Sridhar Moorthy, Ruth Pogacar, Samin Khan and Yang Xu

Improving Large-Scale Fact-Checking using Decomposable Attention Models and Lexical Tagging
Nayeon Lee, Chien-Sheng Wu and Pascale Fung

Harnessing Popularity in Social Media for Extractive Summarization of Online Conversations
Ryuji Kano, Yasuhide Miura, Motoki Taniguchi, Yan-Ying Chen, Francine Chen and Tomoko Ohkuma

Identifying Locus of Control in Social Media Language
Masoud Rouhizadeh, Kokil Jaidka, Laura Smith, H. Andrew Schwartz, Anneke Buffone and Lyle Ungar

Somm: Into the Model
Shengli Hu

Fine-Grained Emotion Detection in Health-Related Online Posts
Hamed Khanpour and Cornelia Caragea

The Remarkable Benefit of User-Level Aggregation for Lexical-based Population-Level Predictions
Salvatore Giorgi, Daniel Preoţiuc-Pietro, Anneke Buffone, Daniel Rieman, Lyle Ungar and H. Andrew Schwartz

16:00–16:30 ***Coffee Break***

16:30–18:00 ***Long Papers and Demos (Orals and Posters) II***

Session 4A: Language Models (Gold Hall)

16:30–16:48 *Deterministic Non-Autoregressive Neural Sequence Modeling by Iterative Refinement*
Jason Lee, Elman Mansimov and Kyunghyun Cho

16:48–17:06 *Large Margin Neural Language Model*
Jiaji Huang, Yi Li, Wei Ping and Liang Huang

17:06–17:24 *Targeted Syntactic Evaluation of Language Models*
Rebecca Marvin and Tal Linzen

17:24–17:42 *Rational Recurrences*
Hao Peng, Roy Schwartz, Sam Thomson and Noah A. Smith

17:42–18:00 *Efficient Contextualized Representation: Language Model Pruning for Sequence Labeling*
Liyuan Liu, Xiang Ren, Jingbo Shang, Xiaotao Gu, Jian Peng and Jiawei Han

Session 4B: Information Extraction (Copper Hall)

16:30–16:48 *Automatic Event Salience Identification*
Zhengzhong Liu, Chenyan Xiong, Teruko Mitamura and Eduard Hovy

16:48–17:06 *Temporal Information Extraction by Predicting Relative Time-lines*
Artuur Leeuwenberg and Marie-Francine Moens

17:06–17:24 *Jointly Multiple Events Extraction via Attention-based Graph Information Aggregation*
Xiao Liu, Zhunchen Luo and Heyan Huang

17:24–17:42 *RESIDE: Improving Distantly-Supervised Neural Relation Extraction using Side Information*
Shikhar Vashishth, Rishabh Joshi, Sai Suman Prayaga, Chiranjib Bhattacharyya and Partha Talukdar

17:42–18:00 *Collective Event Detection via a Hierarchical and Bias Tagging Networks with Gated Multi-level Attention Mechanisms*
Yubo Chen, Hang Yang, Kang Liu, Jun Zhao and Yantao Jia

Session 4C: Syntactic Parsing (Silver Hall)

16:30–16:48 *Valency-Augmented Dependency Parsing*
Tianze Shi and Lillian Lee

16:48–17:06 *Unsupervised Learning of Syntactic Structure with Invertible Neural Projections*
Junxian He, Graham Neubig and Taylor Berg-Kirkpatrick

17:06–17:24 *Dynamic Oracles for Top-Down and In-Order Shift-Reduce Constituent Parsing*
Daniel Fernández-González and Carlos Gómez-Rodríguez

17:24–17:42 *Constituent Parsing as Sequence Labeling*
Carlos Gómez-Rodríguez and David Vilares

17:42–18:00 *Synthetic Data Made to Order: The Case of Parsing*
Dingquan Wang and Jason Eisner

Session 4D: Visual QA (Hall 100)

16:30–16:48 *Tell-and-Answer: Towards Explainable Visual Question Answering using Attributes and Captions*
Qing Li, Jianlong Fu, Dongfei Yu, Tao Mei and Jiebo Luo

16:48–17:06 *Learning a Policy for Opportunistic Active Learning*
Aishwarya Padmakumar, Peter Stone and Raymond Mooney

17:06–17:24 *RecipeQA: A Challenge Dataset for Multimodal Comprehension of Cooking Recipes*
Semih Yagcioglu, Aykut Erdem, Erkut Erdem and Nazli Ikizler-Cinbis

17:24–17:42 *TVQA: Localized, Compositional Video Question Answering*
Jie Lei, Licheng Yu, Mohit Bansal and Tamara Berg

17:42–18:00 *Localizing Moments in Video with Temporal Language*
Lisa Anne Hendricks, Oliver Wang, Eli Shechtman, Josef Sivic, Trevor Darrell and Bryan Russell

Session 4E: Semantics III (Posters and Demos, Grand Hall 2)

Card-660: Cambridge Rare Word Dataset - a Reliable Benchmark for Infrequent Word Representation Models
Mohammad Taher Pilehvar, Dimitri Kartsaklis, Victor Prokhorov and Nigel Collier

Leveraging Gloss Knowledge in Neural Word Sense Disambiguation by Hierarchical Co-Attention
Fuli Luo, Tianyu Liu, Zexue He, Qiaolin Xia, Zhifang Sui and Baobao Chang

Weeding out Conventionalized Metaphors: A Corpus of Novel Metaphor Annotations
Erik-Lân Do Dinh, Hannah Wieland and Iryna Gurevych

Streaming word similarity mining on the cheap
Olof Görnerup and Daniel Gillblad

Memory, Show the Way: Memory Based Few Shot Word Representation Learning
Jingyuan Sun, Shaonan Wang and Chengqing Zong

Disambiguated skip-gram model
Karol Grzegorczyk and Marcin Kurdziel

Picking Apart Story Salads
Su Wang, Eric Holgate, Greg Durrett and Katrin Erk

Dynamic Meta-Embeddings for Improved Sentence Representations
Douwe Kiela, Changhan Wang and Kyunghyun Cho

A Probabilistic Model for Joint Learning of Word Embeddings from Texts and Images
Melissa Ailem, Bowen Zhang, Aurélien Bellet, Pascal Denis and Fei Sha

Transfer and Multi-Task Learning for Noun–Noun Compound Interpretation
Murhaf Fares, Stephan Oepen and Erik Velldal

Dissecting Contextual Word Embeddings: Architecture and Representation
Matthew Peters, Mark Neumann, Luke Zettlemoyer and Wen-tau Yih

Preposition Sense Disambiguation and Representation
Hongyu Gong, Jiaqi Mu, Suma Bhat and Pramod Viswanath

Auto-Encoding Dictionary Definitions into Consistent Word Embeddings
Tom Bosc and Pascal Vincent

Spot the Odd Man Out: Exploring the Associative Power of Lexical Resources
Gabriel Stanovsky and Mark Hopkins

(TACL) Linear Algebraic Structure of Word Senses, with Applications to Polysemy
Sanjeev Arora, Yuanzhi Li, Yingyu Liang, Tengyu Ma, and Andrej Risteski

Neural Multitask Learning for Simile Recognition
Lizhen Liu, Xiao Hu, Wei Song, Ruiji Fu, Ting Liu and Guoping Hu

Structured Alignment Networks for Matching Sentences
Yang Liu, Matt Gardner and Mirella Lapata

Compare, Compress and Propagate: Enhancing Neural Architectures with Alignment Factorization for Natural Language Inference
Yi Tay, Anh Tuan Luu and Siu Cheung Hui

Convolutional Interaction Network for Natural Language Inference
Jingjing Gong, Xipeng Qiu, Xinchi Chen, Dong Liang and Xuanjing Huang

Lessons from Natural Language Inference in the Clinical Domain
Alexey Romanov and Chaitanya Shivade

Question Generation from SQL Queries Improves Neural Semantic Parsing
Daya Guo, Yibo Sun, Duyu Tang, Nan Duan, Jian Yin, Hong Chi, James Cao, Peng Chen and Ming Zhou

SemRegex: A Semantics-Based Approach for Generating Regular Expressions from Natural Language Specifications
Zexuan Zhong, Jiaqi Guo, Wei Yang, Jian Peng, Tao Xie, Jian-Guang Lou, Ting Liu and Dongmei Zhang

Decoupling Structure and Lexicon for Zero-Shot Semantic Parsing
Jonathan Herzig and Jonathan Berant

A Span Selection Model for Semantic Role Labeling
Hiroki Ouchi, Hiroyuki Shindo and Yuji Matsumoto

Mapping Language to Code in Programmatic Context
Srinivasan Iyer, Ioannis Konstas, Alvin Cheung and Luke Zettlemoyer

SyntaxSQLNet: Syntax Tree Networks for Complex and Cross-Domain Text-to-SQL Task
Tao Yu, Michihiro Yasunaga, Kai Yang, Rui Zhang, Dongxu Wang, Zifan Li and Dragomir Radev

Cross-lingual Decompositional Semantic Parsing
Sheng Zhang, Xutai Ma, Rachel Rudinger, Kevin Duh and Benjamin Van Durme

Learning to Learn Semantic Parsers from Natural Language Supervision
Igor Labutov, Bishan Yang and Tom Mitchell

DeepCx: A transition-based approach for shallow semantic parsing with complex constructional triggers
Jesse Dunietz, Jaime Carbonell and Lori Levin

What It Takes to Achieve 100% Condition Accuracy on WikiSQL
Semih Yavuz, Izzeddin Gur, Yu Su and Xifeng Yan

Better Transition-Based AMR Parsing with a Refined Search Space
Zhijiang Guo and Wei Lu

Demo: TRANX: A Transition-based Neural Abstract Syntax Parser for Semantic Parsing and Code Generation
Xiaolin Wang, Masao Utiyama, and Eiichiro Sumita

Demo: Visual Interrogation of Attention-Based Models for Natural Language Inference and Machine Comprehension
Shusen Liu, Tao Li, Zhimin Liu, Vivek Srikumar, Valerio Pascucci, and Peer-Timo Bremer

Demo: Magnitude: A Fast, Efficient Universal Vector Embedding Utility Package
Ajay Patel, Alexander Sands, Chris Callison-Burch, and Marianna Apidianaki

Demo: Universal Sentence Encoder for English
Daniel Cer, Yinfei Yang, Sheng-yi Kong, Nan Hua, Nicole Limtiaco, Rhomni St. John, Noah Constant, Mario Guajardo-Cespedes, Steve Yuan, Chris Tar, Brian Strope, and Ray Kurzweil

Saturday, November 3, 2018

09:00–10:30 ***Long Papers and Demos (Orals and Posters) III***

Session 5A: Semantics IV (Gold Hall)

09:00–09:18 *Heuristically Informed Unsupervised Idiom Usage Recognition*
Changsheng Liu and Rebecca Hwa

09:18–09:36 *Coming to Your Senses: on Controls and Evaluation Sets in Polysemy Research*
Haim Dubossarsky, Eitan Grossman and Daphna Weinshall

09:36–09:54 *Predicting Semantic Relations using Global Graph Properties*
Yuval Pinter and Jacob Eisenstein

09:54–10:12 *Learning Scalar Adjective Intensity from Paraphrases*
Anne Cocos, Veronica Wharton, Ellie Pavlick, Marianna Apidianaki and Chris Callison-Burch

10:12–10:30 *Pointwise HSIC: A Linear-Time Kernelized Co-occurrence Norm for Sparse Linguistic Expressions*
Sho Yokoi, Sosuke Kobayashi, Kenji Fukumizu, Jun Suzuki and Kentaro Inui

Session 5B: Summarization (Copper Hall)

09:00–09:18 *Neural Related Work Summarization with a Joint Context-driven Attention Mechanism*
Yongzhen Wang, Xiaozhong Liu and Zheng Gao

09:18–09:36 *Improving Neural Abstractive Document Summarization with Explicit Information Selection Modeling*
Wei Li, Xinyan Xiao, Yajuan Lyu and Yuanzhuo Wang

09:36–09:54 *Don't Give Me the Details, Just the Summary! Topic-Aware Convolutional Neural Networks for Extreme Summarization*
Shashi Narayan, Shay B. Cohen and Mirella Lapata

09:54–10:12 *Improving Abstraction in Text Summarization*
Wojciech Kryściński, Romain Paulus, Caiming Xiong and Richard Socher

10:12–10:30 *Content Selection in Deep Learning Models of Summarization*
Chris Kedzie, Kathleen McKeown and Hal Daume III

Session 5C: IR / Text Mining (Silver Hall)

09:00–09:18 *Improved Semantic-Aware Network Embedding with Fine-Grained Word Alignment*
Dinghan Shen, Xinyuan Zhang, Ricardo Henao and Lawrence Carin

09:18–09:36 *Learning Context-Sensitive Convolutional Filters for Text Processing*
Dinghan Shen, Martin Renqiang Min, Yitong Li and Lawrence Carin

09:36–09:54 *Deep Relevance Ranking Using Enhanced Document-Query Interactions*
Ryan McDonald, George Brokos and Ion Androutsopoulos

09:54–10:12 *Learning Neural Representation for CLIR with Adversarial Framework*
Bo Li and Ping Cheng

10:12–10:30 *AD3: Attentive Deep Document Dater*
Swayambhu Nath Ray, Shib Sankar Dasgupta and Partha Talukdar

Session 5D: Machine Learning II (Hall 100)

09:00–09:18 *Gromov-Wasserstein Alignment of Word Embedding Spaces*
David Alvarez-Melis and Tommi Jaakkola

09:18–09:36 *Deep Probabilistic Logic: A Unifying Framework for Indirect Supervision*
Hai Wang and Hoifung Poon

09:36–09:54 *Deriving Machine Attention from Human Rationales*
Yujia Bao, Shiyu Chang, Mo Yu and Regina Barzilay

09:54–10:12 *Semi-Supervised Sequence Modeling with Cross-View Training*
Kevin Clark, Minh-Thang Luong, Christopher D. Manning and Quoc Le

10:12–10:30 (TACL) Comparing Bayesian Models of Annotation
Silviu Paun, Bob Carpenter, Jon Chamberlain, Dirk Hovy, Udo Kruschwitz, and Massimo Poesio

Session 5E: Information Extraction, Question Answering (Posters and Demos, Grand Hall 2)

A Probabilistic Annotation Model for Crowdsourcing Coreference
Silviu Paun, Jon Chamberlain, Udo Kruschwitz, Juntao Yu and Massimo Poesio

A Deterministic Algorithm for Bridging Anaphora Resolution
Yufang Hou

A Knowledge Hunting Framework for Common Sense Reasoning
Ali Emami, Noelia De La Cruz, Adam Trischler, Kaheer Suleman and Jackie Chi Kit Cheung

Mapping Text to Knowledge Graph Entities using Multi-Sense LSTMs
Dimitri Kartsaklis, Mohammad Taher Pilehvar and Nigel Collier

Differentiating Concepts and Instances for Knowledge Graph Embedding
Xin Lv, Lei Hou, Juanzi Li and Zhiyuan Liu

One-Shot Relational Learning for Knowledge Graphs
Wenhan Xiong, Mo Yu, Shiyu Chang, Xiaoxiao Guo and William Yang Wang

Regular Expression Guided Entity Mention Mining from Noisy Web Data
Shanshan Zhang, Lihong He, Slobodan Vucetic and Eduard Dragut

HyTE: Hyperplane-based Temporally aware Knowledge Graph Embedding
Shib Sankar Dasgupta, Swayambhu Nath Ray and Partha Talukdar

Neural Adaptation Layers for Cross-domain Named Entity Recognition
Bill Yuchen Lin and Wei Lu

Entity Linking within a Social Media Platform: A Case Study on Yelp
Hongliang Dai, Yangqiu Song, Liwei Qiu and Rijia Liu

Annotation of a Large Clinical Entity Corpus
Pinal Patel, Disha Davey, Vishal Panchal and Parth Pathak

Visual Supervision in Bootstrapped Information Extraction
Matthew Berger, Ajay Nagesh, Joshua Levine, Mihai Surdeanu and Helen Zhang

Learning Named Entity Tagger using Domain-Specific Dictionary
Jingbo Shang, Liyuan Liu, Xiaotao Gu, Xiang Ren, Teng Ren and Jiawei Han

Zero-Shot Open Entity Typing as Type-Compatible Grounding
Ben Zhou, Daniel Khashabi, Chen-Tse Tsai and Dan Roth

Attention-Guided Answer Distillation for Machine Reading Comprehension
Minghao Hu, Yuxing Peng, Furu Wei, Zhen Huang, Dongsheng Li, Nan Yang and Ming Zhou

Interpretation of Natural Language Rules in Conversational Machine Reading
Marzieh Saeidi, Max Bartolo, Patrick Lewis, Sameer Singh, Tim Rocktäschel, Mike Sheldon, Guillaume Bouchard and Sebastian Riedel

A State-transition Framework to Answer Complex Questions over Knowledge Base
Sen Hu, Lei Zou and Xinbo Zhang

A Multi-answer Multi-task Framework for Real-world Machine Reading Comprehension
Jiahua Liu, Wan Wei, Maosong Sun, Hao Chen, Yantao Du and Dekang Lin

Logician and Orator: Learning from the Duality between Language and Knowledge in Open Domain
Mingming Sun, Xu Li and Ping Li

MemoReader: Large-Scale Reading Comprehension through Neural Memory Controller
Seohyun Back, Seunghak Yu, Sathish Reddy Indurthi, Jihie Kim and Jaegul Choo

Multi-Granular Sequence Encoding via Dilated Compositional Units for Reading Comprehension
Yi Tay, Anh Tuan Luu and Siu Cheung Hui

Neural Compositional Denotational Semantics for Question Answering
Nitish Gupta and Mike Lewis

Cross-Pair Text Representations for Answer Sentence Selection
Kateryna Tymoshenko and Alessandro Moschitti

QuAC: Question Answering in Context
Eunsol Choi, He He, Mohit Iyyer, Mark Yatskar, Wen-tau Yih, Yejin Choi, Percy Liang and Luke Zettlemoyer

Knowledge Base Question Answering via Encoding of Complex Query Graphs
Kangqi Luo, Fengli Lin, Xusheng Luo and Kenny Zhu

Neural Relation Extraction via Inner-Sentence Noise Reduction and Transfer Learning
Tianyi Liu, Xinsong Zhang, Wanhao Zhou and Weijia Jia

Graph Convolution over Pruned Dependency Trees Improves Relation Extraction
Yuhao Zhang, Peng Qi and Christopher D. Manning

Multi-Level Structured Self-Attentions for Distantly Supervised Relation Extraction
Jinhua Du, Jingguang Han, Andy Way and Dadong Wan

N-ary Relation Extraction using Graph-State LSTM
Linfeng Song, Yue Zhang, Zhiguo Wang and Daniel Gildea

Hierarchical Relation Extraction with Coarse-to-Fine Grained Attention
Xu Han, Pengfei Yu, Zhiyuan Liu, Maosong Sun and Peng Li

Label-Free Distant Supervision for Relation Extraction via Knowledge Graph Embedding
Guanying Wang, Wen Zhang, Ruoxu Wang, Yalin Zhou, Xi Chen, Wei Zhang, Hai Zhu and Huajun Chen

Extracting Entities and Relations with Joint Minimum Risk Training
Changzhi Sun, Yuanbin Wu, Man Lan, Shiliang Sun, Wenting Wang, Kuang-Chih Lee and Kewen Wu

Large-scale Exploration of Neural Relation Classification Architectures
Hoang-Quynh Le, Duy-Cat Can, Sinh T. Vu, Thanh Hai Dang, Mohammad Taher Pilehvar and Nigel Collier

Possessors Change Over Time: A Case Study with Artworks
Dhivya Chinnappa and Eduardo Blanco

Demo: CogCompTime: A Tool for Understanding Time in Natural Language
Qiang Ning, Ben Zhou, Zhili Feng, Haoruo Peng, and Dan Roth

Demo: DERE: A Task and Domain-Independent Slot Filling Framework for Declarative Relation Extraction
Heike Adel, Laura Ana Maria Bostan, Sean Papay, Sebastian Padó, and Roman Klinger

Demo: Integrating Knowledge-Supported Search into the INCEpTION Annotation Platform
Beto Boullosa, Richard Eckart de Castilho, Naveen Kumar, Jan-Christoph Klie, and Iryna Gurevych

Demo: OpenKE: An Open Toolkit for Knowledge Embedding
Xu Han, Shulin Cao, Xin Lv, Yankai Lin, Zhiyuan Liu, Maosong Sun, and Juanzi Li

Demo: An Interactive Web-Interface for Visualizing the Inner Workings of the Question Answering LSTM
Ekaterina Loginova and Günter Neumann

Demo: An Interface for Annotating Science Questions
Michael Boratko, Harshit Padigela, Divyendra Mikkilineni, Pritish Yuvraj, Rajarshi Das, Andrew McCallum, Maria Chang, Achille Fokoue, Pavan Kapanipathi, Nicholas Mattei, Ryan Musa, Kartik Talamadupula, and Michael Witbrock

Demo: Interactive Instance-based Evaluation of Knowledge Base Question Answering
Daniil Sorokin and Iryna Gurevych

10:30–11:00 ***Coffee Break***

11:00–12:30 ***Long Papers and Demos (Orals and Posters) IV***

Session 6A: Dialogue I (Gold Hall)

11:00–11:18 *Using Lexical Alignment and Referring Ability to Address Data Sparsity in Situated Dialog Reference Resolution*
Todd Shore and Gabriel Skantze

11:18–11:36 *Subgoal Discovery for Hierarchical Dialogue Policy Learning*
Da Tang, Xiujun Li, Jianfeng Gao, Chong Wang, Lihong Li and Tony Jebara

11:36–11:54 *Supervised Clustering of Questions into Intents for Dialog System Applications*
Iryna Haponchyk, Antonio Uva, Seunghak Yu, Olga Uryupina and Alessandro Moschitti

11:54–12:12 *Towards Exploiting Background Knowledge for Building Conversation Systems*
Nikita Moghe, Siddhartha Arora, Suman Banerjee and Mitesh M. Khapra

12:12–12:30 *Decoupling Strategy and Generation in Negotiation Dialogues*
He He, Derek Chen, Anusha Balakrishnan and Percy Liang

Session 6B: Question Answering II (Copper Hall)

11:00–11:18 *Large-scale Cloze Test Dataset Created by Teachers*
Qizhe Xie, Guokun Lai, Zihang Dai and Eduard Hovy

11:18–11:36 *emrQA: A Large Corpus for Question Answering on Electronic Medical Records*
Anusri Pampari, Preethi Raghavan, Jennifer Liang and Jian Peng

11:36–11:54 *HotpotQA: A Dataset for Diverse, Explainable Multi-hop Question Answering*
Zhilin Yang, Peng Qi, Saizheng Zhang, Yoshua Bengio, William Cohen, Ruslan Salakhutdinov and Christopher D. Manning

11:54–12:12 *Can a Suit of Armor Conduct Electricity? A New Dataset for Open Book Question Answering*
Todor Mihaylov, Peter Clark, Tushar Khot and Ashish Sabharwal

12:12–12:30 *Evaluating Theory of Mind in Question Answering*
Aida Nematzadeh, Kaylee Burns, Erin Grant, Alison Gopnik and Tom Griffiths

Session 6C: Semantics V (Silver Hall)

11:00–11:18 *A Unified Syntax-aware Framework for Semantic Role Labeling*
Zuchao Li, Shexia He, Jiaxun Cai, Zhuosheng Zhang, Hai Zhao, Gongshen Liu, Linlin Li and Luo Si

11:18–11:36 *Semantics as a Foreign Language*
Gabriel Stanovsky and Ido Dagan

11:36–11:54 *An AMR Aligner Tuned by Transition-based Parser*
Yijia Liu, Wanxiang Che, Bo Zheng, Bing Qin and Ting Liu

11:54–12:12 *Dependency-based Hybrid Trees for Semantic Parsing*
Zhanming Jie and Wei Lu

12:12–12:30 *Policy Shaping and Generalized Update Equations for Semantic Parsing from Denotations*
Dipendra Misra, Ming-Wei Chang, Xiaodong He and Wen-tau Yih

Session 6D: Multilingual Methods II (Hall 100)

11:00–11:18 *Sentence Compression for Arbitrary Languages via Multilingual Pivoting*
Jonathan Mallinson, Rico Sennrich and Mirella Lapata

11:18–11:36 *Unsupervised Cross-lingual Transfer of Word Embedding Spaces*
Ruochen Xu, Yiming Yang, Naoki Otani and Yuexin Wu

11:36–11:54 *XNLI: Evaluating Cross-lingual Sentence Representations*
Alexis Conneau, Ruty Rinott, Guillaume Lample, Adina Williams, Samuel Bowman, Holger Schwenk and Veselin Stoyanov

11:54–12:12 *Joint Multilingual Supervision for Cross-lingual Entity Linking*
Shyam Upadhyay, Nitish Gupta and Dan Roth

12:12–12:30 *Fine-grained Coordinated Cross-lingual Text Stream Alignment for Endless Language Knowledge Acquisition*
Tao Ge, Qing Dou, Heng Ji, Lei Cui, Baobao Chang, Zhifang Sui, Furu Wei and Ming Zhou

Session 6E: Syntax, Morphology, Vision and Language I (Posters and Demos, Grand Hall 2)

WECA:A WordNet-Encoded Collocation-Attention Network for Homographic Pun Recognition
Yufeng Diao, Hongfei Lin, Di Wu, Liang Yang, Kan Xu, Zhihao Yang, Jian Wang, Shaowu Zhang, Bo Xu and Dongyu Zhang

A Hybrid Approach to Automatic Corpus Generation for Chinese Spelling Check
Dingmin Wang, Yan Song, Jing Li, Jialong Han and Haisong Zhang

Neural Quality Estimation of Grammatical Error Correction
Shamil Chollampatt and Hwee Tou Ng

Transferring from Formal Newswire Domain with Hypernet for Twitter POS Tagging
Tao Gui, Qi Zhang, Jingjing Gong, Minlong Peng, di liang, Keyu Ding and Xuanjing Huang

Free as in Free Word Order: An Energy Based Model for Word Segmentation and Morphological Tagging in Sanskrit
Amrith Krishna, Bishal Santra, Sasi Prasanth Bandaru, Gaurav Sahu, Vishnu Dutt Sharma, Pavankumar Satuluri and Pawan Goyal

A Challenge Set and Methods for Noun-Verb Ambiguity
Ali Elkahky, Kellie Webster, Daniel Andor and Emily Pitler

What do character-level models learn about morphology? The case of dependency parsing
Clara Vania, Andreas Grivas and Adam Lopez

Learning Better Internal Structure of Words for Sequence Labeling
Yingwei Xin, Ethan Hart, Vibhuti Mahajan and Jean David Ruvini

ICON: Interactive Conversational Memory Network for Multimodal Emotion Detection
Devamanyu Hazarika, Soujanya Poria, Rada Mihalcea, Erik Cambria and Roger Zimmermann

Discriminative Learning of Open-Vocabulary Object Retrieval and Localization by Negative Phrase Augmentation
Ryota Hinami and Shin'ichi Satoh

Grounding Semantic Roles in Images
Carina Silberer and Manfred Pinkal

Commonsense Justification for Action Explanation
Shaohua Yang, Qiaozi Gao, Sari Sadiya and Joyce Chai

Learning Personas from Dialogue with Attentive Memory Networks
Eric Chu, Prashanth Vijayaraghavan and Deb Roy

Grounding language acquisition by training semantic parsers using captioned videos
Candace Ross, Andrei Barbu, Yevgeni Berzak, Battushig Myanganbayar and Boris Katz

Translating Navigation Instructions in Natural Language to a High-Level Plan for Behavioral Robot Navigation
Xiaoxue Zang, Ashwini Pokle, Marynel Vázquez, Kevin Chen, Juan Carlos Niebles, Alvaro Soto and Silvio Savarese

Mapping Instructions to Actions in 3D Environments with Visual Goal Prediction
Dipendra Misra, Andrew Bennett, Valts Blukis, Eyvind Niklasson, Max Shatkhin and Yoav Artzi

Deconvolutional Time Series Regression: A Technique for Modeling Temporally Diffuse Effects
Cory Shain and William Schuler

Is this Sentence Difficult? Do you Agree?
Dominique Brunato, Lorenzo De Mattei, Felice Dell'Orletta, Benedetta Iavarone and Giulia Venturi

Neural Transition Based Parsing of Web Queries: An Entity Based Approach
Rivka Malca and Roi Reichart

An Investigation of the Interactions Between Pre-Trained Word Embeddings, Character Models and POS Tags in Dependency Parsing
Aaron Smith, Miryam de Lhoneux, Sara Stymne and Joakim Nivre

Depth-bounding is effective: Improvements and evaluation of unsupervised PCFG induction
Lifeng Jin, Finale Doshi-Velez, Timothy Miller, William Schuler and Lane Schwartz

(TACL) In-Order Transition-based Constituent Parsing
Jiangming Liu and Yue Zhang

(TACL) Surface Statistics of an Unknown Language Indicate How to Parse It
Dingquan Wang and Jason Eisner

Incremental Computation of Infix Probabilities for Probabilistic Finite Automata
Marco Cognetta, Yo-Sub Han and Soon Chan Kwon

Syntax Encoding with Application in Authorship Attribution
Richong Zhang, Zhiyuan Hu, Hongyu Guo and Yongyi Mao

Sanskrit Word Segmentation Using Character-level Recurrent and Convolutional Neural Networks
Oliver Hellwig and Sebastian Nehrdich

(TACL) Universal Word Segmentation: Implementation and Interpretation
Yan Shao, Christian Hardmeier, and Joakim Nivre

Demo: MorAz: an Open-source Morphological Analyzer for Azerbaijani Turkish
Berke Özenç, Razieh Ehsani, and Ercan Solak

Demo: Juman++: A Morphological Analysis Toolkit for Scriptio Continua
Arseny Tolmachev, Daisuke Kawahara, and Sadao Kurohashi

12:30–13:45 ***Lunch***

13:45–14:45 ***Short Papers (Orals and Posters) III***

Saturday, November 3, 2018 (continued)

Session 7A: Dialogue II (Gold Hall)

13:45–13:57 *Session-level Language Modeling for Conversational Speech*
Wayne Xiong, Lingfeng Wu, Jun Zhang and Andreas Stolcke

13:57–14:09 *Towards Less Generic Responses in Neural Conversation Models: A Statistical Re-weighting Method*
Yahui Liu, Wei Bi, Jun Gao, Xiaojiang Liu, Jian Yao and Shuming Shi

14:09–14:21 *Training Millions of Personalized Dialogue Agents*
Pierre-Emmanuel Mazare, Samuel Humeau, Martin Raison and Antoine Bordes

14:21–14:33 *Towards Universal Dialogue State Tracking*
Liliang Ren, Kaige Xie, Lu Chen and Kai Yu

14:33–14:45 *Semantic Parsing for Task Oriented Dialog using Hierarchical Representations*
Sonal Gupta, Rushin Shah, Mrinal Mohit, Anuj Kumar and Mike Lewis

Session 7B: Social Applications II (Copper Hall)

13:45–13:57 *The glass ceiling in NLP*
Natalie Schluter

13:57–14:09 *Reducing Gender Bias in Abusive Language Detection*
Ji Ho Park, Jamin Shin and Pascale Fung

14:09–14:21 *SafeCity: Understanding Diverse Forms of Sexual Harassment Personal Stories*
Sweta Karlekar and Mohit Bansal

14:21–14:33 *Learning multiview embeddings for assessing dementia*
Chloé Pou-Prom and Frank Rudzicz

14:33–14:45 *WikiConv: A Corpus of the Complete Conversational History of a Large Online Collaborative Community*
Yiqing Hua, Cristian Danescu-Niculescu-Mizil, Dario Taraborelli, Nithum Thain, Jeffery Sorensen and Lucas Dixon

Session 7C: NER (Silver Hall)

13:45–13:57 *Marginal Likelihood Training of BiLSTM-CRF for Biomedical Named Entity Recognition from Disjoint Label Sets*
Nathan Greenberg, Trapit Bansal, Patrick Verga and Andrew McCallum

13:57–14:09 *Adversarial training for multi-context joint entity and relation extraction*
Giannis Bekoulis, Johannes Deleu, Thomas Demeester and Chris Develder

14:09–14:21 *Structured Multi-Label Biomedical Text Tagging via Attentive Neural Tree Decoding*
Gaurav Singh, James Thomas, Iain Marshall, John Shawe-Taylor and Byron C. Wallace

14:21–14:33 *Deep Exhaustive Model for Nested Named Entity Recognition*
Mohammad Golam Sohrab and Makoto Miwa

14:33–14:45 *Evaluating the Utility of Hand-crafted Features in Sequence Labelling*
Minghao Wu, Fei Liu and Trevor Cohn

Session 7D: Morphology / Parsing (Hall 100)

13:45–13:57 *Improved Dependency Parsing using Implicit Word Connections Learned from Unlabeled Data*
Wenhui Wang, Baobao Chang and Mairgup Mansur

13:57–14:09 *A Framework for Understanding the Role of Morphology in Universal Dependency Parsing*
Mathieu Dehouck and Pascal Denis

14:09–14:21 *The Lazy Encoder: A Fine-Grained Analysis of the Role of Morphology in Neural Machine Translation*
Arianna Bisazza and Clara Tump

14:21–14:33 *Imitation Learning for Neural Morphological String Transduction*
Peter Makarov and Simon Clematide

14:33–14:45 *An Encoder-Decoder Approach to the Paradigm Cell Filling Problem*
Miikka Silfverberg and Mans Hulden

Session 7E: Short Posters III (Grand Hall 2)

Generating Natural Language Adversarial Examples
Moustafa Alzantot, Yash Sharma, Ahmed Elgohary, Bo-Jhang Ho, Mani Srivastava and Kai-Wei Chang

Multi-Head Attention with Disagreement Regularization
Jian Li, Zhaopeng Tu, Baosong Yang, Michael R. Lyu and Tong Zhang

Deep Bayesian Active Learning for Natural Language Processing: Results of a Large-Scale Empirical Study
Aditya Siddhant and Zachary C. Lipton

Bayesian Compression for Natural Language Processing
Nadezhda Chirkova, Ekaterina Lobacheva and Dmitry Vetrov

Multimodal neural pronunciation modeling for spoken languages with logographic origin
Minh Nguyen, Gia H Ngo and Nancy Chen

Chinese Pinyin Aided IME, Input What You Have Not Keystroked Yet
Yafang Huang and Hai Zhao

Estimating Marginal Probabilities of n-grams for Recurrent Neural Language Models
Thanapon Noraset, Doug Downey and Lidong Bing

How to represent a word and predict it, too: Improving tied architectures for language modelling
Kristina Gulordava, Laura Aina and Gemma Boleda

The Importance of Generation Order in Language Modeling
Nicolas Ford, Daniel Duckworth, Mohammad Norouzi and George Dahl

Document-Level Neural Machine Translation with Hierarchical Attention Networks
Lesly Miculicich, Dhananjay Ram, Nikolaos Pappas and James Henderson

Three Strategies to Improve One-to-Many Multilingual Translation
Yining Wang, Jiajun Zhang, Feifei Zhai, Jingfang Xu and Chengqing Zong

Multi-Source Syntactic Neural Machine Translation
Anna Currey and Kenneth Heafield

Fixing Translation Divergences in Parallel Corpora for Neural MT
Minh Quang Pham, Josep Crego, Jean Senellart and François Yvon

Adversarial Evaluation of Multimodal Machine Translation
Desmond Elliott

Loss in Translation: Learning Bilingual Word Mapping with a Retrieval Criterion
Armand Joulin, Piotr Bojanowski, Tomas Mikolov, Hervé Jégou and Edouard Grave

Learning When to Concentrate or Divert Attention: Self-Adaptive Attention Temperature for Neural Machine Translation
Junyang Lin, Xu Sun, Xuancheng Ren, Muyu Li and Qi Su

Accelerating Asynchronous Stochastic Gradient Descent for Neural Machine Translation
Nikolay Bogoychev, Kenneth Heafield, Alham Fikri Aji and Marcin Junczys-Dowmunt

Learning to Jointly Translate and Predict Dropped Pronouns with a Shared Reconstruction Mechanism
Longyue Wang, Zhaopeng Tu, Andy Way and Qun Liu

Getting Gender Right in Neural Machine Translation
Eva Vanmassenhove, Christian Hardmeier and Andy Way

Towards Two-Dimensional Sequence to Sequence Model in Neural Machine Translation
Parnia Bahar, Christopher Brix and Hermann Ney

End-to-End Non-Autoregressive Neural Machine Translation with Connectionist Temporal Classification
Jindřich Libovický and Jindřich Helcl

Prediction Improves Simultaneous Neural Machine Translation
Ashkan Alinejad, Maryam Siahbani and Anoop Sarkar

Training Deeper Neural Machine Translation Models with Transparent Attention
Ankur Bapna, Mia Chen, Orhan Firat, Yuan Cao and Yonghui Wu

Context and Copying in Neural Machine Translation
Rebecca Knowles and Philipp Koehn

Encoding Gated Translation Memory into Neural Machine Translation
Qian Cao and Deyi Xiong

Automatic Post-Editing of Machine Translation: A Neural Programmer-Interpreter Approach
Thuy-Trang Vu and Gholamreza Haffari

Breaking the Beam Search Curse: A Study of (Re-)Scoring Methods and Stopping Criteria for Neural Machine Translation
Yilin Yang, Liang Huang and Mingbo Ma

Multi-Multi-View Learning: Multilingual and Multi-Representation Entity Typing
Yadollah Yaghoobzadeh and Hinrich Schütze

Word Embeddings for Code-Mixed Language Processing
Adithya Pratapa, Monojit Choudhury and Sunayana Sitaram

On the Strength of Character Language Models for Multilingual Named Entity Recognition
Xiaodong Yu, Stephen Mayhew, Mark Sammons and Dan Roth

Code-switched Language Models Using Dual RNNs and Same-Source Pretraining
Saurabh Garg, Tanmay Parekh and Preethi Jyothi

Part-of-Speech Tagging for Code-Switched, Transliterated Texts without Explicit Language Identification
Kelsey Ball and Dan Garrette

14:45–15:00 ***Mini-Break***

15:00–16:00 ***Keynote II: Gideon Mann "Understanding the News that Moves Markets" (Gold Hall)***

16:00–16:30 ***Coffee Break***

16:30–18:00 *Long Papers and Demos (Orals and Posters) V*

Session 8A: Text Categorization (Gold Hall)

16:30–16:48 *Zero-shot User Intent Detection via Capsule Neural Networks*
Congying Xia, Chenwei Zhang, Xiaohui Yan, Yi Chang and Philip Yu

16:48–17:06 *Hierarchical Neural Networks for Sequential Sentence Classification in Medical Scientific Abstracts*
Di Jin and Peter Szolovits

17:06–17:24 *Investigating Capsule Networks with Dynamic Routing for Text Classification*
Min Yang, Wei Zhao, Jianbo Ye, Zeyang Lei, Zhou Zhao and Soufei Zhang

17:24–17:42 *Topic Memory Networks for Short Text Classification*
Jichuan Zeng, Jing Li, Yan Song, Cuiyun Gao, Michael R. Lyu and Irwin King

17:42–18:00 *Few-Shot and Zero-Shot Multi-Label Learning for Structured Label Spaces*
Anthony Rios and Ramakanth Kavuluru

Session 8B: Generation (Copper Hall)

16:30–16:48 *Automatic Poetry Generation with Mutual Reinforcement Learning*
Xiaoyuan Yi, Maosong Sun, Ruoyu Li and Wenhao Li

16:48–17:06 *Variational Autoregressive Decoder for Neural Response Generation*
Jiachen Du, Wenjie Li, Yulan He, Ruifeng Xu, Lidong Bing and Xuan Wang

17:06–17:24 *Integrating Transformer and Paraphrase Rules for Sentence Simplification*
Sanqiang Zhao, Rui Meng, Daqing He, Andi Saptono and Bambang Parmanto

17:24–17:42 *Learning Neural Templates for Text Generation*
Sam Wiseman, Stuart Shieber and Alexander Rush

17:42–18:00 *Multi-Reference Training with Pseudo-References for Neural Translation and Text Generation*
Renjie Zheng, Mingbo Ma and Liang Huang

Session 8C: Knowledge Graphs (Silver Hall)

16:30–16:48 *Knowledge Graph Embedding with Hierarchical Relation Structure*
Zhao Zhang, Fuzhen Zhuang, Meng Qu, Fen Lin and Qing He

16:48–17:06 *Embedding Multimodal Relational Data for Knowledge Base Completion*
Pouya Pezeshkpour, Liyan Chen and Sameer Singh

17:06–17:24 *Multi-Task Identification of Entities, Relations, and Coreference for Scientific Knowledge Graph Construction*
Yi Luan, Luheng He, Mari Ostendorf and Hannaneh Hajishirzi

17:24–17:42 *Playing 20 Question Game with Policy-Based Reinforcement Learning*
Huang Hu, Xianchao Wu, Bingfeng Luo, Chongyang Tao, Can Xu, wei wu and Zhan Chen

17:42–18:00 *Multi-Hop Knowledge Graph Reasoning with Reward Shaping*
Xi Victoria Lin, Richard Socher and Caiming Xiong

Session 8D: Morphology / Phonology (Hall 100)

16:30–16:48 *Neural Transductive Learning and Beyond: Morphological Generation in the Minimal-Resource Setting*
Katharina Kann and Hinrich Schütze

16:48–17:06 *Implicational Universals in Stochastic Constraint-Based Phonology*
Giorgio Magri

17:06–17:24 *Explaining Character-Aware Neural Networks for Word-Level Prediction: Do They Discover Linguistic Rules?*
Fréderic Godin, Kris Demuynck, Joni Dambre, Wesley De Neve and Thomas Demeester

17:24–17:42 *Adapting Word Embeddings to New Languages with Morphological and Phonological Subword Representations*
Aditi Chaudhary, Chunting Zhou, Lori Levin, Graham Neubig, David R. Mortensen and Jaime Carbonell

17:42–18:00 (TACL) Recurrent Neural Networks in Linguistic Theory: Revisiting Pinker and Prince (1988) and the Past Tense Debate
Christo Kirov and Ryan Cotterell

Session 8E: Sentiment, Social Applications, Multimodal Semantics, Discourse (Posters and Demos, Grand Hall 2)

A Computational Exploration of Exaggeration
Enrica Troiano, Carlo Strapparava, Gözde Özbal and Serra Sinem Tekiroglu

Building Context-aware Clause Representations for Situation Entity Type Classification
Zeyu Dai and Ruihong Huang

Hierarchical Dirichlet Gaussian Marked Hawkes Process for Narrative Reconstruction in Continuous Time Domain
Yeon Seonwoo, Alice Oh and Sungjoon Park

Investigating the Role of Argumentation in the Rhetorical Analysis of Scientific Publications with Neural Multi-Task Learning Models
Anne Lauscher, Goran Glavaš, Simone Paolo Ponzetto and Kai Eckert

Neural Ranking Models for Temporal Dependency Structure Parsing
Yuchen Zhang and Nianwen Xue

Causal Explanation Analysis on Social Media
Youngseo Son, Nipun Bayas and H. Andrew Schwartz

LRMM: Learning to Recommend with Missing Modalities
Cheng Wang, Mathias Niepert and Hui Li

Content Explorer: Recommending Novel Entities for a Document Writer
Michal Lukasik and Richard Zens

A Genre-Aware Attention Model to Improve the Likability Prediction of Books
Suraj Maharjan, Manuel Montes, Fabio A. González and Thamar Solorio

Thread Popularity Prediction and Tracking with a Permutation-invariant Model
Hou Pong Chan and Irwin King

IARM: Inter-Aspect Relation Modeling with Memory Networks in Aspect-Based Sentiment Analysis
Navonil Majumder, Soujanya Poria, Alexander Gelbukh, Md Shad Akhtar, Erik Cambria and Asif Ekbal

Limbic: Author-Based Sentiment Aspect Modeling Regularized with Word Embeddings and Discourse Relations
Zhe Zhang and Munindar Singh

An Interpretable Neural Network with Topical Information for Relevant Emotion Ranking
Yang Yang, Deyu ZHOU and Yulan He

Multi-grained Attention Network for Aspect-Level Sentiment Classification
Feifan Fan, Yansong Feng and Dongyan Zhao

Attentive Gated Lexicon Reader with Contrastive Contextual Co-Attention for Sentiment Classification
Yi Tay, Anh Tuan Luu, Siu Cheung Hui and Jian Su

Contextual Inter-modal Attention for Multi-modal Sentiment Analysis
Deepanway Ghosal, Md Shad Akhtar, Dushyant Chauhan, Soujanya Poria, Asif Ekbal and Pushpak Bhattacharyya

Adaptive Semi-supervised Learning for Cross-domain Sentiment Classification
Ruidan He, Wee Sun Lee, Hwee Tou Ng and Daniel Dahlmeier

ExtRA: Extracting Prominent Review Aspects from Customer Feedback
Zhiyi Luo, Shanshan Huang, Frank F. Xu, Bill Yuchen Lin, Hanyuan Shi and Kenny Zhu

Cross-Lingual Cross-Platform Rumor Verification Pivoting on Multimedia Content
Weiming Wen, Songwen Su and Zhou Yu

Extractive Adversarial Networks: High-Recall Explanations for Identifying Personal Attacks in Social Media Posts
Samuel Carton, Qiaozhu Mei and Paul Resnick

Automatic Detection of Vague Words and Sentences in Privacy Policies
Logan Lebanoff and Fei Liu

Multi-view Models for Political Ideology Detection of News Articles
Vivek Kulkarni, Junting Ye, Steve Skiena and William Yang Wang

Saturday, November 3, 2018 (continued)

Predicting Factuality of Reporting and Bias of News Media Sources
Ramy Baly, Georgi Karadzhov, Dimitar Alexandrov, James Glass and Preslav Nakov

Legal Judgment Prediction via Topological Learning
Haoxi Zhong, Guo Zhipeng, Cunchao Tu, Chaojun Xiao, Zhiyuan Liu and Maosong Sun

Hierarchical CVAE for Fine-Grained Hate Speech Classification
Jing Qian, Mai ElSherief, Elizabeth Belding and William Yang Wang

Residualized Factor Adaptation for Community Social Media Prediction Tasks
Mohammadzaman Zamani, H. Andrew Schwartz, Veronica Lynn, Salvatore Giorgi and Niranjan Balasubramanian

Framing and Agenda-setting in Russian News: a Computational Analysis of Intricate Political Strategies
Anjalie Field, Doron Kliger, Shuly Wintner, Jennifer Pan, Dan Jurafsky and Yulia Tsvetkov

Identifying the sentiment styles of YouTube's vloggers
Bennett Kleinberg, Maximilian Mozes and Isabelle van der Vegt

Native Language Identification with User Generated Content
Gili Goldin, Ella Rabinovich and Shuly Wintner

Demo: Visualization of the Topic Space of Argument Search Results in args.me
Yamen Ajjour, Henning Wachsmuth, Dora Kiesel, Patrick Riehmann, Fan Fan, Giuliano Castiglia, Rosemary Adejoh, Bernd Fröhlich, and Benno Stein

Saturday, November 3, 2018 (continued)

Demo: A Multilingual Information Extraction Pipeline for Investigative Journalism
Gregor Wiedemann, Seid Muhie Yimam, and Chris Biemann

Demo: When science journalism meets artificial intelligence : An interactive demonstration
Raghuram Vadapalli, Bakhtiyar Syed, Nishant Prabhu, Balaji Vasan Srinivasan, and Vasudeva Varma

19:00–22:00 ***Social Event (Royal Museums of Fine Arts of Belgium)***

Sunday, November 4, 2018

09:00–10:30 ***Long Papers and Demos (Orals and Posters) VI***

Session 9A: Machine Translation II (Gold Hall)

09:00–09:18 *Beyond Error Propagation in Neural Machine Translation: Characteristics of Language Also Matter*
Lijun Wu, Xu Tan, Di He, Fei Tian, Tao Qin, Jianhuang Lai and Tie-Yan Liu

09:18–09:36 *A Study of Reinforcement Learning for Neural Machine Translation*
Lijun Wu, Fei Tian, Tao Qin, Jianhuang Lai and Tie-Yan Liu

09:36–09:54 *Meta-Learning for Low-Resource Neural Machine Translation*
Jiatao Gu, Yong Wang, Yun Chen, Victor O. K. Li and Kyunghyun Cho

09:54–10:12 *Unsupervised Statistical Machine Translation*
Mikel Artetxe, Gorka Labaka and Eneko Agirre

10:12–10:30 *A Visual Attention Grounding Neural Model for Multimodal Machine Translation*
Mingyang Zhou, Runxiang Cheng, Yong Jae Lee and Zhou Yu

Sunday, November 4, 2018 (continued)

Session 9B: Sentiment I (Copper Hall)

09:00–09:18 *Sentiment Classification towards Question-Answering with Hierarchical Matching Network*
Chenlin Shen, Changlong Sun, Jingjing Wang, Yangyang Kang, Shoushan Li, Xiaozhong Liu, Luo Si, Min Zhang and Guodong Zhou

09:18–09:36 *Cross-topic Argument Mining from Heterogeneous Sources*
Christian Stab, Tristan Miller, Benjamin Schiller, Pranav Rai and Iryna Gurevych

09:36–09:54 *Summarizing Opinions: Aspect Extraction Meets Sentiment Prediction and They Are Both Weakly Supervised*
Stefanos Angelidis and Mirella Lapata

09:54–10:12 *CARER: Contextualized Affect Representations for Emotion Recognition*
Elvis Saravia, Hsien-Chi Toby Liu, Yen-Hao Huang, Junlin Wu and Yi-Shin Chen

10:12–10:30 (TACL) Adversarial Deep Averaging Networks for Cross-Lingual Sentiment Classification
Xilun Chen, Yu Sun, Ben Athiwaratkun, Claire Cardie, and Kilian Weinberger

Session 9C: Machine Learning III (Silver Hall)

09:00–09:18 *Noise Contrastive Estimation and Negative Sampling for Conditional Models: Consistency and Statistical Efficiency*
Zhuang Ma and Michael Collins

09:18–09:36 *CaLcs: Continuously Approximating Longest Common Subsequence for Sequence Level Optimization*
Semih Yavuz, Chung-Cheng Chiu, Patrick Nguyen and Yonghui Wu

09:36–09:54 *Pathologies of Neural Models Make Interpretations Difficult*
Shi Feng, Eric Wallace, Alvin Grissom II, Mohit Iyyer, Pedro Rodriguez and Jordan Boyd-Graber

09:54–10:12 *Phrase-level Self-Attention Networks for Universal Sentence Encoding*
Wei Wu, Houfeng Wang, Tianyu Liu and Shuming Ma

10:12–10:30 *BanditSum: Extractive Summarization as a Contextual Bandit*
Yue Dong, Yikang Shen, Eric Crawford, Herke van Hoof and Jackie Chi Kit Cheung

Session 9D: Semantics VI (Hall 100)

09:00–09:18 *A Word-Complexity Lexicon and A Neural Readability Ranking Model for Lexical Simplification*
Mounica Maddela and Wei Xu

09:18–09:36 *Learning Latent Semantic Annotations for Grounding Natural Language to Structured Data*
Guanghui Qin, Jin-Ge Yao, Xuening Wang, Jinpeng Wang and Chin-Yew Lin

09:36–09:54 *Syntactic Scaffolds for Semantic Structures*
Swabha Swayamdipta, Sam Thomson, Kenton Lee, Luke Zettlemoyer, Chris Dyer and Noah A. Smith

09:54–10:12 *Hierarchical Quantized Representations for Script Generation*
Noah Weber, Leena Shekhar, Niranjan Balasubramanian and Nate Chambers

10:12–10:30 *Semantic Role Labeling for Learner Chinese: the Importance of Syntactic Parsing and L2-L1 Parallel Data*
Zi Lin, Yuguang Duan, Yuanyuan Zhao, Weiwei Sun and Xiaojun Wan

Session 9E: Generation, Dialog, Summarization; Vision and Language II (Posters and Demos, Grand Hall 2)

A Teacher-Student Framework for Maintainable Dialog Manager
Weikang Wang, Jiajun Zhang, Han Zhang, Mei-Yuh Hwang, Chengqing Zong and Zhifei Li

Discriminative Deep Dyna-Q: Robust Planning for Dialogue Policy Learning
Shang-Yu Su, Xiujun Li, Jianfeng Gao, Jingjing Liu and Yun-Nung Chen

A Self-Attentive Model with Gate Mechanism for Spoken Language Understanding
Changliang Li, Liang Li and Ji Qi

Learning End-to-End Goal-Oriented Dialog with Multiple Answers
Janarthanan Rajendran, Jatin Ganhotra, Satinder Singh and Lazaros Polymenakos

AirDialogue: An Environment for Goal-Oriented Dialogue Research
Wei Wei, Quoc Le, Andrew Dai and Jia Li

(TACL) Polite Dialogue Generation Without Parallel Data
Tong Niu and Mohit Bansal

QuaSE: Sequence Editing under Quantifiable Guidance
Yi Liao, Lidong Bing, Piji Li, Shuming Shi, Wai Lam and Tong Zhang

Paraphrase Generation with Deep Reinforcement Learning
Zichao Li, Xin Jiang, Lifeng Shang and Hang Li

Operation-guided Neural Networks for High Fidelity Data-To-Text Generation
Feng Nie, Jinpeng Wang, Jin-Ge Yao, Rong Pan and Chin-Yew Lin

Generating Classical Chinese Poems via Conditional Variational Autoencoder and Adversarial Training
Juntao Li, Yan Song, Haisong Zhang, Dongmin Chen, Shuming Shi, Dongyan Zhao and Rui Yan

Paragraph-level Neural Question Generation with Maxout Pointer and Gated Self-attention Networks
Yao Zhao, Xiaochuan Ni, Yuanyuan Ding and Qifa Ke

Spider: A Large-Scale Human-Labeled Dataset for Complex and Cross-Domain Semantic Parsing and Text-to-SQL Task
Tao Yu, Rui Zhang, Kai Yang, Michihiro Yasunaga, Dongxu Wang, Zifan Li, James Ma, Irene Li, Qingning Yao, Shanelle Roman, Zilin Zhang and Dragomir Radev

Unsupervised Natural Language Generation with Denoising Autoencoders
Markus Freitag and Scott Roy

Answer-focused and Position-aware Neural Question Generation
Xingwu Sun, Jing Liu, Yajuan Lyu, Wei He, Yanjun Ma and Shi Wang

Diversity-Promoting GAN: A Cross-Entropy Based Generative Adversarial Network for Diversified Text Generation
Jingjing Xu, Xuancheng Ren, Junyang Lin and Xu Sun

Towards a Better Metric for Evaluating Question Generation Systems
Preksha Nema and Mitesh M. Khapra

Stylistic Chinese Poetry Generation via Unsupervised Style Disentanglement
Cheng Yang, Maosong Sun, Xiaoyuan Yi and Wenhao Li

Generating More Interesting Responses in Neural Conversation Models with Distributional Constraints
Ashutosh Baheti, Alan Ritter, Jiwei Li and Bill Dolan

Better Conversations by Modeling, Filtering, and Optimizing for Coherence and Diversity
Xinnuo Xu, Ondřej Dušek, Ioannis Konstas and Verena Rieser

Incorporating Background Knowledge into Video Description Generation
Spencer Whitehead, Heng Ji, Mohit Bansal, Shih-Fu Chang and Clare Voss

Multimodal Differential Network for Visual Question Generation
Badri Narayana Patro, Sandeep Kumar, Vinod Kumar Kurmi and Vinay Namboodiri

Entity-aware Image Caption Generation
Di Lu, Spencer Whitehead, Lifu Huang, Heng Ji and Shih-Fu Chang

Learning to Describe Differences Between Pairs of Similar Images
Harsh Jhamtani and Taylor Berg-Kirkpatrick

Object Hallucination in Image Captioning
Anna Rohrbach, Lisa Anne Hendricks, Kaylee Burns, Trevor Darrell and Kate Saenko

Abstractive Text-Image Summarization Using Multi-Modal Attentional Hierarchical RNN
Jingqiang Chen and Hai Zhuge

Keyphrase Generation with Correlation Constraints
Jun Chen, Xiaoming Zhang, Yu Wu, Zhao Yan and Zhoujun Li

Closed-Book Training to Improve Summarization Encoder Memory
Yichen Jiang and Mohit Bansal

Improving Neural Abstractive Document Summarization with Structural Regularization
Wei Li, Xinyan Xiao, Yajuan Lyu and Yuanzhuo Wang

Iterative Document Representation Learning Towards Summarization with Polishing
Xiuying Chen, Shen Gao, Chongyang Tao, Yan Song, Dongyan Zhao and Rui Yan

Bottom-Up Abstractive Summarization
Sebastian Gehrmann, Yuntian Deng and Alexander Rush

Controlling Length in Abstractive Summarization Using a Convolutional Neural Network
Yizhu Liu, Zhiyi Luo and Kenny Zhu

APRIL: Interactively Learning to Summarise by Combining Active Preference Learning and Reinforcement Learning
Yang Gao, Christian M. Meyer and Iryna Gurevych

Adapting the Neural Encoder-Decoder Framework from Single to Multi-Document Summarization
Logan Lebanoff, Kaiqiang Song and Fei Liu

Semi-Supervised Learning for Neural Keyphrase Generation
Hai Ye and Lu Wang

MSMO: Multimodal Summarization with Multimodal Output
Junnan Zhu, Haoran Li, Tianshang Liu, Yu Zhou, Jiajun Zhang and Chengqing Zong

Frustratingly Easy Model Ensemble for Abstractive Summarization
Hayato Kobayashi

Automatic Pyramid Evaluation Exploiting EDU-based Extractive Reference Summaries
Tsutomu Hirao, Hidetaka Kamigaito and Masaaki Nagata

Learning to Encode Text as Human-Readable Summaries using Generative Adversarial Networks
Yaushian Wang and Hung-yi Lee

Demo: Visualizing Group Dynamics based on Multiparty Meeting Understanding
Ni Zhang, Tongtao Zhang, Indrani Bhattacharya, Heng Ji, and Rich Radke

Demo: PizzaPal: Conversational Pizza Ordering using a High-Density Conversational AI Platform
Antoine Raux, Yi Ma, Paul Yang, and Felicia Wong

Demo: Developing Production-Level Conversational Interfaces with Shallow Semantic Parsing
Arushi Raghuvanshi, Lucien Carroll, and Karthik Raghunathan

Demo: SyntaViz: Visualizing Voice Queries through a Syntax-Driven Hierarchical Ontology
Md Iftekhar Tanveer and Ferhan Ture

Demo: LIA: A Natural Language Programmable Personal Assistant
Igor Labutov, Shashank Srivastava, and Tom Mitchell

Demo: Data2Text Studio: Automated Text Generation from Structured Data
Longxu Dou, Guanghui Qin, Jinpeng Wang, Jin-Ge Yao, and Chin-Yew Lin

Demo: Demonstrating Par4Sem - A Semantic Writing Aid with Adaptive Paraphrasing
Seid Muhie Yimam and Chris Biemann

10:30–11:00 ***Coffee Break***

11:00–12:30 ***Long Papers and Demos (Orals and Posters) VII***

Sunday, November 4, 2018 (continued)

Session 10A: Question Answering III (Gold Hall)

11:00–11:18 *Joint Multitask Learning for Community Question Answering Using Task-Specific Embeddings*
Shafiq Joty, Lluís Màrquez and Preslav Nakov

11:18–11:36 *What Makes Reading Comprehension Questions Easier?*
Saku Sugawara, Kentaro Inui, Satoshi Sekine and Akiko Aizawa

11:36–11:54 *Commonsense for Generative Multi-Hop Question Answering Tasks*
Lisa Bauer, Yicheng Wang and Mohit Bansal

11:54–12:12 *Open Domain Question Answering Using Early Fusion of Knowledge Bases and Text*
Haitian Sun, Bhuwan Dhingra, Manzil Zaheer, Kathryn Mazaitis, Ruslan Salakhutdinov and William Cohen

12:12–12:30 *A Nil-Aware Answer Extraction Framework for Question Answering*
Souvik Kundu and Hwee Tou Ng

Session 10B: Machine Translation III (Copper Hall)

11:00–11:18 *Exploiting Deep Representations for Neural Machine Translation*
Zi-Yi Dou, Zhaopeng Tu, Xing Wang, Shuming Shi and Tong Zhang

11:18–11:36 *Why Self-Attention? A Targeted Evaluation of Neural Machine Translation Architectures*
Gongbo Tang, Mathias Müller, Annette Rios and Rico Sennrich

11:36–11:54 *Simplifying Neural Machine Translation with Addition-Subtraction Twin-Gated Recurrent Networks*
Biao Zhang, Deyi Xiong, jinsong su, Qian Lin and Huiji Zhang

11:54–12:12 *Speeding Up Neural Machine Translation Decoding by Cube Pruning*
Wen Zhang, Liang Huang, Yang Feng, Lei Shen and Qun Liu

12:12–12:30 *Revisiting Character-Based Neural Machine Translation with Capacity and Compression*
Colin Cherry, George Foster, Ankur Bapna, Orhan Firat and Wolfgang Macherey

Session 10C: Discourse (Silver Hall)

11:00–11:18 *A Skeleton-Based Model for Promoting Coherence Among Sentences in Narrative Story Generation*
Jingjing Xu, Xuancheng Ren, Yi Zhang, Qi Zeng, Xiaoyan Cai and Xu Sun

11:18–11:36 *NEXUS Network: Connecting the Preceding and the Following in Dialogue Generation*
Xiaoyu Shen, Hui Su, Wenjie Li and Dietrich Klakow

11:36–11:54 *A Neural Local Coherence Model for Text Quality Assessment*
Mohsen Mesgar and Michael Strube

11:54–12:12 *Deep Attentive Sentence Ordering Network*
Baiyun Cui, Yingming Li, Ming Chen and Zhongfei Zhang

12:12–12:30 *Getting to "Hearer-old": Charting Referring Expressions Across Time*
Ieva Staliūnaitė, Hannah Rohde, Bonnie Webber and Annie Louis

Session 10D: Evolution / Sociolinguistics (Hall 100)

11:00–11:18 *Making "fetch" happen: The influence of social and linguistic context on nonstandard word growth and decline*
Ian Stewart and Jacob Eisenstein

11:18–11:36 *Analyzing Correlated Evolution of Multiple Features Using Latent Representations*
Yugo Murawaki

11:36–11:54 *Capturing Regional Variation with Distributed Place Representations and Geographic Retrofitting*
Dirk Hovy and Christoph Purschke

11:54–12:12 *Characterizing Interactions and Relationships between People*
Farzana Rashid and Eduardo Blanco

12:12–12:30 *Why Swear? Analyzing and Inferring the Intentions of Vulgar Expressions*
Eric Holgate, Isabel Cachola, Daniel Preoţiuc-Pietro and Junyi Jessy Li

Session 10E: Machine Learning (Posters and Demos, Grand Hall 2)

Is it Time to Swish? Comparing Deep Learning Activation Functions Across NLP tasks
Steffen Eger, Paul Youssef and Iryna Gurevych

Hard Non-Monotonic Attention for Character-Level Transduction
Shijie Wu, Pamela Shapiro and Ryan Cotterell

Speed Reading: Learning to Read ForBackward via Shuttle
Tsu-Jui Fu and Wei-Yun Ma

Modeling Localness for Self-Attention Networks
Baosong Yang, Zhaopeng Tu, Derek F. Wong, Fandong Meng, Lidia S. Chao and Tong Zhang

Chargrid: Towards Understanding 2D Documents
Anoop R Katti, Christian Reisswig, Cordula Guder, Sebastian Brarda, Steffen Bickel, Johannes Höhne and Jean Baptiste Faddoul

Simple Recurrent Units for Highly Parallelizable Recurrence
Tao Lei, Yu Zhang, Sida I. Wang, Hui Dai and Yoav Artzi

NPRF: A Neural Pseudo Relevance Feedback Framework for Ad-hoc Information Retrieval
Canjia Li, Yingfei Sun, Ben He, Le Wang, Kai Hui, Andrew Yates, Le Sun and Jungang Xu

Co-Stack Residual Affinity Networks with Multi-level Attention Refinement for Matching Text Sequences
Yi Tay, Anh Tuan Luu and Siu Cheung Hui

Spherical Latent Spaces for Stable Variational Autoencoders
Jiacheng Xu and Greg Durrett

Learning Universal Sentence Representations with Mean-Max Attention Autoencoder
Minghua Zhang, Yunfang Wu, Weikang Li and Wei Li

Word Mover's Embedding: From Word2Vec to Document Embedding
Lingfei Wu, Ian En-Hsu Yen, Kun Xu, Fangli Xu, Avinash Balakrishnan, Pin-Yu Chen, Pradeep Ravikumar and Michael J. Witbrock

Sunday, November 4, 2018 (continued)

Multilingual Clustering of Streaming News
Sebastião Miranda, Arturs Znotins, Shay B. Cohen and Guntis Barzdins

Multi-Task Label Embedding for Text Classification
Honglun Zhang, Liqiang Xiao, Wenqing Chen, Yongkun Wang and Yaohui Jin

Semantic-Unit-Based Dilated Convolution for Multi-Label Text Classification
Junyang Lin, Qi Su, Pengcheng Yang, Shuming Ma and Xu Sun

MCapsNet: Capsule Network for Text with Multi-Task Learning
Liqiang Xiao, Honglun Zhang, Wenqing Chen, Yongkun Wang and Yaohui Jin

Uncertainty-aware generative models for inferring document class prevalence
Katherine Keith and Brendan O'Connor

12:30–13:45 ***Lunch***

13:00–13:45 ***Business Meeting***

13:45–14:45 ***Short Papers (Orals and Posters) IV***

Session 11A: Analyzing Models (Gold Hall)

13:45–13:57 *A Neural Model of Adaptation in Reading*
Marten van Schijndel and Tal Linzen

13:57–14:09 *Understanding Deep Learning Performance through an Examination of Test Set Difficulty: A Psychometric Case Study*
John Lalor, Hao Wu, Tsendsuren Munkhdalai and Hong Yu

14:09–14:21 *Lexicosyntactic Inference in Neural Models*
Aaron Steven White, Rachel Rudinger, Kyle Rawlins and Benjamin Van Durme

14:21–14:33 *Dual Fixed-Size Ordinally Forgetting Encoding (FOFE) for Competitive Neural Language Models*
Sedtawut Watcharawittayakul, Mingbin Xu and Hui Jiang

14:33–14:45 *The Importance of Being Recurrent for Modeling Hierarchical Structure*
Ke Tran, Arianna Bisazza and Christof Monz

Session 11B: Sentiment II (Copper Hall)

13:45–13:57 *Joint Learning for Targeted Sentiment Analysis*
Dehong Ma, Sujian Li and Houfeng Wang

13:57–14:09 *Revisiting the Importance of Encoding Logic Rules in Sentiment Classification*
Kalpesh Krishna, Preethi Jyothi and Mohit Iyyer

14:09–14:21 *A Co-Attention Neural Network Model for Emotion Cause Analysis with Emotional Context Awareness*
Xiangju Li, Kaisong Song, Shi Feng, Daling Wang and Yifei Zhang

14:21–14:33 *Modeling Empathy and Distress in Reaction to News Stories*
Sven Buechel, Anneke Buffone, Barry Slaff, Lyle Ungar and Joao Sedoc

14:33–14:45 *Interpretable Emoji Prediction via Label-Wise Attention LSTMs*
Francesco Barbieri, Luis Espinosa Anke, Jose Camacho-Collados, Steven Schockaert and Horacio Saggion

Session 11C: Machine Translation IV (Silver Hall)

13:45–13:57 *A Tree-based Decoder for Neural Machine Translation*
Xinyi Wang, Hieu Pham, Pengcheng Yin and Graham Neubig

13:57–14:09 *Greedy Search with Probabilistic N-gram Matching for Neural Machine Translation*
Chenze Shao, Xilin Chen and Yang Feng

14:09–14:21 *Exploring Recombination for Efficient Decoding of Neural Machine Translation*
Zhisong Zhang, Rui Wang, Masao Utiyama, Eiichiro Sumita and Hai Zhao

14:21–14:33 *Has Machine Translation Achieved Human Parity? A Case for Document-level Evaluation*
Samuel Läubli, Rico Sennrich and Martin Volk

14:33–14:45 *Automatic Reference-Based Evaluation of Pronoun Translation Misses the Point*
Liane Guillou and Christian Hardmeier

Session 11D: QA / Knowledge Graphs (Hall 100)

13:45–13:57 *FewRel: A Large-Scale Supervised Few-Shot Relation Classification Dataset with State-of-the-Art Evaluation*
Xu Han, Hao Zhu, Pengfei Yu, Ziyun Wang, Yuan Yao, Zhiyuan Liu and Maosong Sun

13:57–14:09 *A strong baseline for question relevancy ranking*
Ana Gonzalez, Isabelle Augenstein and Anders Søgaard

14:09–14:21 *Learning Sequence Encoders for Temporal Knowledge Graph Completion*
Alberto Garcia-Duran, Sebastijan Dumančić and Mathias Niepert

14:21–14:33 *Similar but not the Same: Word Sense Disambiguation Improves Event Detection via Neural Representation Matching*
Weiyi Lu and Thien Huu Nguyen

14:33–14:45 *Learning Word Representations with Cross-Sentence Dependency for End-to-End Co-reference Resolution*
Hongyin Luo and Jim Glass

Session 11E: Short Posters IV (Grand Hall 2)

Word Relation Autoencoder for Unseen Hypernym Extraction Using Word Embeddings
Hong-You Chen, Cheng-Syuan Lee, Keng-Te Liao and Shou-de Lin

Refining Pretrained Word Embeddings Using Layer-wise Relevance Propagation

Abstract

This article deals with adversarial attacks towards deep learning systems for Natural Language Processing (NLP), in the context of privacy protection. We study a specific type of attack: an attacker eavesdrops on the hidden representations of a neural text classifier and tries to recover information about the input text. Such scenario may arise in situations when the computation of a neural network is shared across multiple devices, e.g. some hidden representation is computed by a user's device and sent to a cloud-based model. We measure the privacy of a hidden representation by the ability of an attacker to predict accurately specific private information from it and characterize the tradeoff between the privacy and the utility of neural representations. Finally, we propose several defense methods based on modified training objectives and show that they improve the privacy of neural representations.

1 Introduction

This article presents an adversarial scenario meant at characterizing the privacy of neural representations for NLP tasks, as well as defense methods designed to improve the privacy of those representations. A deep neural network constructs intermediate hidden representations to extract features from its input. Such representations are trained to predict a label, and therefore should contain useful features for the final prediction. However, they might also encode information about the input that a user wants to keep private (e.g. personal data) and can be exploited for adversarial usages.

We study a specific type of attack on neural representations: an attacker eavesdrops on the hidden representations of novel input examples (that are not in the training set) and tries to recover information about the content of the input text (Figure 1). A typical scenario where such attacks would occur is when the computation of a deep neural net is shared between several devices (Li et al., 2017). For example, a user's device computes a representation of a textual input, and sends it a to cloud-based neural network to obtain, e.g. the topic of the text or its sentiment. The scenario is illustrated in Figure 1.

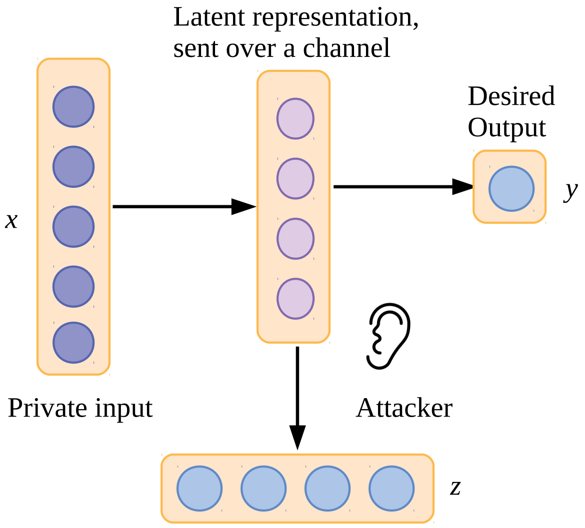

Figure 1: General setting illustration. The main classifier predicts a label y from a text x, the attacker tries to recover some private information $\mathbf{z}$ contained in x from the latent representation used by the main classifier.

Private information can take the form of key phrases *explicitly* contained in the text. However, it can also be *implicit*. For example, demographic information about the author of a text can be predicted with above chance accuracy from linguistic cues in the text itself (Rosenthal and McKeown, 2011; Preoţiuc-Pietro et al., 2015).

Independently of its explicitness, some of this private information correlates with the output labels, and therefore will be learned by the network. In such a case, there is a tradeoff between the utility of the representation (measured by the accuracy of the network) and its privacy. It might be

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1–10
Brussels, Belgium, October 31 - November 4, 2018.

necessary to sacrifice some accuracy in order to satisfy privacy requirements.

However, this is not the case of all private information, since some of it is not relevant for the prediction of the text label. Still, private information might be learned incidentally. This non-intentional and incidental learning also raises privacy concerns, since an attacker with an access to the hidden representations, may exploit them to recover information about the input.

In this paper we explore the following situation: (i) a *main classifier* uses a deep network to predict a label from textual data; (ii) an *attacker* eavesdrops on the hidden layers of the network and tries to recover information about the input text of unseen examples. In contrast to previous work about neural networks and privacy (Papernot et al., 2016; Carlini et al., 2018) we do not protect the privacy of examples from the training set, but the privacy of unseen examples provided, e.g., by a user.

An example of a potential application would be a spam detection service with the following constraints: the service provider does not access verbatim emails sent to users, only their vector representations. Theses vector representations should not be usable to gather information about the user's contacts or correspondents, i.e. protect the user from profiling.

This paper makes the following contributions:[1]

- We propose a metric to measure the privacy of the neural representation of an input for Natural Language Processing tasks. The metric is based on the ability of an attacker to recover information about the input from the latent representation only.
- We present defense methods designed against this type of attack. The methods are based on modified training objectives and lead to an improved privacy-accuracy tradeoff.

2 Adversarial Scenario

In the scenario we propose, each example consists of a triple $(x, y, \mathbf{z})$, where x is a natural language text, y is a single label (e.g. topic or sentiment), and $\mathbf{z}$ is a vector of private information contained in x. Our base setting has two entities: (i) a *main classifier* whose role is to learn to predict y from x, (ii) an *attacker* who learns to predict $\mathbf{z}$ from the latent representation of x used by the main classifier. We illustrate this setting in Figure 1.

In order to evaluate the utility and privacy of a specific model, we proceed in three phases:

Phase 1. Training of the main classifier on (x, y) pairs and evaluation of its accuracy;

Phase 2. Generation of a dataset of pairs $(\mathbf{r}(x), \mathbf{z})$ for the attacker, $\mathbf{r}$ is the representation function of the main classifier ($\mathbf{r}$ is defined in Section 2.1);

Phase 3. Training of the attacker's network and evaluation of its performance for measuring privacy.

In the remainder of this section, we describe the main classifier (Section 2.1), and the attacker's model (Section 2.2).

2.1 Text Classifier

As our base model, we chose a standard LSTM architecture (Hochreiter and Schmidhuber, 1997) for sequence classification. LSTM-based architectures have been applied to many NLP tasks, including sentiment classification (Wang et al., 2016) and text classification (Zhou et al., 2016).

First, an LSTM encoder computes a fixed-size representation $\mathbf{r}(x)$ from a sequence of tokens $x = (x_1, x_2, \ldots, x_n)$ projected to an embedding space. We use $\boldsymbol{\theta}_r$ to denote the parameters used to construct $\mathbf{r}$. They include the parameters of the LSTM, as well as the word embeddings. Then, the encoder output $\mathbf{r}(x)$ is fed as input to a feedforward network with parameters $\boldsymbol{\theta}_p$ that predicts the label y of the text, with a softmax output activation. In the standard setting, the model is trained to minimize the negative log-likelihood of y labels:

$$\mathcal{L}_m(\boldsymbol{\theta}_r, \boldsymbol{\theta}_p) = \sum_{i=1}^{N} - \log P(y^{(i)}|x^{(i)}; \boldsymbol{\theta}_r, \boldsymbol{\theta}_p),$$

where N is the number of training examples.

2.2 Attacker's Classifier

Once the main model has been trained, we assume that its parameters $\boldsymbol{\theta}_r$ and $\boldsymbol{\theta}_p$ are fixed. We generate a new dataset made of pairs $(\mathbf{r}(x), \mathbf{z}(x))$, where $\mathbf{r}(x)$ is the hidden representation used by the main model and $\mathbf{z}(x)$ is a vector of private categorical variables. In practice, $\mathbf{z}$ is a vector of binary variables, (representing e.g. demographic information about the author). In our experiments, we use the same training examples x for the main

---

[1] The source code used for the experiments described in this paper is available at `https://github.com/mcoavoux/pnet`.

classifier and the classifier of the attacker. However, since the attacker has access to the representation function $\mathbf{r}$ parameterized by $\boldsymbol{\theta}_r$, they can generate a dataset from any corpus containing the private variables they want to recover. In other words, it is not necessary that they have access to the original training corpus to train their classifier.

The attacker trains a second feedforward network on the new dataset $\{(\mathbf{r}(x^{(i)}), \mathbf{z}^{(i)})\}_{i \leq N}$. This classifier uses a sigmoid output activation to compute the probabilities of each binary variable in $\mathbf{z}$:

$$P(\mathbf{z}|\mathbf{r}(x); \boldsymbol{\theta}_a) = \sigma(\text{FeedForward}(\mathbf{r}(x))).$$

It is trained to minimize the negative log-likelihood of $\mathbf{z}$:

$$\begin{aligned}\mathcal{L}_a(\boldsymbol{\theta}_a) &= \sum_{i=1}^{N} -\log P(\mathbf{z}^{(i)}|\mathbf{r}(x^{(i)}); \boldsymbol{\theta}_a) \\ &= \sum_{i=1}^{N}\sum_{j=1}^{K} -\log P(\mathbf{z}_j^{(i)}|\mathbf{r}(x^{(i)}); \boldsymbol{\theta}_a),\end{aligned}$$

assuming that the K variables in $\mathbf{z}$ are independent. Since the parameters used to construct $\mathbf{r}$ are fixed, the attacker only acts upon its own parameters $\boldsymbol{\theta}_a$ to optimize this loss.

We use the performance of the attacker's classifier as a proxy for privacy. If its accuracy is high, then an eavesdropper can easily recover information about the input document. In contrast, if its accuracy is low (i.e. close to that of a most-frequent label baseline), then we may reasonably conclude that $\mathbf{r}$ does not encode enough information to reconstruct x, and mainly contains information that is useful to predict y.

In general, the performance of a single attacker does not provide sufficient evidence to conclude that the input representation $\mathbf{r}$ is robust to an attack. It should be robust to any type of reconstruction method. In the scope of this paper though, we only experiment with a feedforward network reconstructor, i.e. a powerful learner.

In the following sections, we propose several training method modifications aimed at obfuscating private information from the hidden representation $\mathbf{r}(x)$. Intuitively, the aim of these modifications is to minimize some measure of information between $\mathbf{r}$ and $\mathbf{z}$ to make the prediction of $\mathbf{z}$ hard. An obvious choice for that measure would be the Mutual Information (MI) between $\mathbf{r}$ and $\mathbf{z}$. However, MI is hard to compute due to the continuous distribution of $\mathbf{r}$ and does not lend itself well to stochastic optimization.

3 Defenses Against Adversarial Attacks

In this section, we present three training methods designed as defenses against the type of attack we described in Section 2.2. The first two methods are based on two neural networks with rival objective functions (Section 3.1). The last method is meant at discouraging the model to cluster together training examples with similar private variables $\mathbf{z}$ (Section 3.2).

3.1 Adversarial Training

First, we propose to frame the training of the main classifier as a two-agent process: the main agent and an adversarial generator, exploiting a setting similar to Generative Adversarial Networks (GAN, Goodfellow et al., 2014). The generator learns to reconstruct examples from the hidden representation, whereas the main agent learns (i) to perform its main task (ii) to make the task of the generator difficult.

We experiment with two types of generators: a classifier that predicts the binary attributes $\mathbf{z}(x)$ used as a proxy for the reconstruction of x (Section 3.1.1) and a character-based language model that directly optimizes the likelihood of the training examples (Section 3.1.2).

3.1.1 Adversarial Classification: Multidetasking

In order not to make $\mathbf{r}(x)$ a good representation for reconstructing $\mathbf{z}$, we make two modifications to the training setup of the main model (Phase 1):

- We use a duplicate adversarial classifier, with parameters $\boldsymbol{\theta}'_a$, that tries to predict $\mathbf{z}$ from $\mathbf{r}(x)$. It is trained simultaneously with the main classifier. Its training examples are generated on the fly, and change overtime as the main classifier updates its own parameters. This classifier simulates an attack during training.
- We modify the objective function of the main classifier to incorporate a penalty when the adversarial classifier is good at reconstructing $\mathbf{z}$. In other words, the main classifier tries to update its parameters so as to confuse the duplicate attacker.

Formally, for a single data point $(x, y, \mathbf{z})$, the adversarial classifier optimizes:

$$\mathcal{L}_{a'}(x, y, \mathbf{z}; \boldsymbol{\theta}'_a)_= -\log P(\mathbf{z}|\mathbf{r}(x); \boldsymbol{\theta}'_a),$$

whereas the main classifier optimizes:

$$\begin{aligned}\mathcal{L}_m(x, y, \mathbf{z}; \boldsymbol{\theta}_r, \boldsymbol{\theta}_p) = & -\alpha \log P(y|x; \boldsymbol{\theta}_r, \boldsymbol{\theta}_p) \\ & -\beta \log P(\neg\mathbf{z}|\mathbf{r}(x); \boldsymbol{\theta}'_a).\end{aligned}$$

The first term of this equation is the log-likelihood of the y labels. The second term is designed to deceive the adversary. The hyperparameters $\alpha > 0$ and $\beta > 0$ control the relative importance of both terms.

As in a GAN, the losses of both classifiers are interdependent, but their parameters are distinct: the adversary can only update $\boldsymbol{\theta}'_a$ and the main classifier can only update $\boldsymbol{\theta}_r$ and $\boldsymbol{\theta}_p$.

The duplicate adversarial classifier is identical to the classifier used to evaluate privacy after the main model has been trained and its parameters are fixed. However, both classifiers are completely distinct: the former is used during the training of the main model (Phase 1) to take privacy into account whereas the latter is used to evaluate the privacy of the final model (Phase 3), as is described in Section 2.

3.1.2 Adversarial Generation

The second type of generator we use is a character-based LSTM language model that is trained to reconstruct full training examples. For a single example $(x; y)$, the hidden state of the LSTM is initialized with $\mathbf{r}(x)$, computed by the main model. The generator optimizes:

$$\begin{aligned}\mathcal{L}_g(x, y; \boldsymbol{\theta}_\ell; \boldsymbol{\theta}_r) &= -\log P(x|\mathbf{r}(x); \boldsymbol{\theta}_\ell) \\ &= -\sum_{i=1}^{C} \log P(x_i|x_1^{i-1}, \mathbf{r}(x); \boldsymbol{\theta}_\ell),\end{aligned}$$

where $\boldsymbol{\theta}_\ell$ is the set of parameters of the LSTM generator, x_i is the i^{th} character in the document, and C is the length of the document in number of characters. The generator has no control over $\mathbf{r}(x)$, and optimizes the objective only by updating its own parameters $\boldsymbol{\theta}_\ell$.

Conversely, the loss of the main model is modified as follows:

$$\begin{aligned}\mathcal{L}_m(x, y; \boldsymbol{\theta}_r, \boldsymbol{\theta}_p) = & -\alpha \log P(y|x; \boldsymbol{\theta}_r, \boldsymbol{\theta}_p) \\ & -\beta \mathcal{L}_g(x, y; \boldsymbol{\theta}_\ell, \boldsymbol{\theta}_r).\end{aligned}$$

The first term maximizes the likelihood of the y labels whereas the second term is meant at making the reconstruction difficult by maximizing the loss of the generator. As in the loss function described in the previous section, α and β control the relative importance of both terms. Once again, the main classifier can optimize the second term only by updating $\boldsymbol{\theta}_r$, since it has no control over the parameters of the adversarial generator.

A key property of this defense method is that it has no awareness of what the private variables $\mathbf{z}$ are. Therefore, it has the potential to protect the neural representation against an attack on any private information. From a broader perspective, the goal of this defense method is to specialize the hidden representation $\mathbf{r}(x)$ to the task at hand (sentiment or topic prediction) and to avoid learning anything not relevant to it.

3.2 Declustering

The last strategy we employ to make the task of the attacker harder is based on the intuition that private variables $\mathbf{z}$ are easier to predict from $\mathbf{r}$ when the main model learns implicitly to cluster examples with similar $\mathbf{z}$ in the same regions of the representation space.

In order to avoid such implicit clustering, we add a term to the training objective of the main model that penalizes pairs of examples (x, x') that (i) have similar reconstructions $\mathbf{z}(x) \approx \mathbf{z}(x')$ (ii) have hidden representations $\mathbf{r}(x)$ and $\mathbf{r}(x')$ in the same region of space. We use the following modified loss for a single example:

$$\begin{aligned}\mathcal{L}_m(x, y, \mathbf{z}; \boldsymbol{\theta}_r, \boldsymbol{\theta}_p) &= -\log P(y|x; \boldsymbol{\theta}_r, \boldsymbol{\theta}_p) \\ &+\alpha(0.5 - \ell(\mathbf{z}, \mathbf{z}'))||\mathbf{r}(x) - \mathbf{r}(x')||_2^2,\end{aligned}$$

where $(x', \mathbf{z}')$ is another example sampled uniformly from the training set, α is a hyperparameter controlling the importance of the second term, and $\ell(\cdot, \cdot) \in [0, 1]$ is the normalized Hamming distance.

4 Experiments

Our experiments are meant to characterize the privacy-utility tradeoff of neural representations on text classification tasks, and evaluating if the proposed defense methods have a positive impact on it. We first describe the datasets we used (Section 4.1) and the experimental protocol (Section 4.2), then we discuss the results (Section 4.3). We found that in the normal training regime, where no defense is taken into account, the adversary can recover private information with higher accuracy than a most frequent class baseline. Furthermore, we found that the de-

fenses we implemented have a positive effect on the accuracy-privacy tradeoff.

4.1 Datasets

We experiment with two text classification tasks: sentiment analysis (Section 4.1.1) and topic classification (Section 4.1.2). The sizes of each dataset are summarized in Table 1.

4.1.1 Sentiment Analysis

We use the Trustpilot dataset (Hovy et al., 2015) for sentiment analysis. This corpus contains reviews associated with a sentiment score on a five point scale, and self-reported information about the users. We use the five subcorpora corresponding to five areas (Denmark, France, Germany, United Kingdom, United States).

We filter examples containing both the birth year and gender of the author of the review and use these variables as the private information. As in previous work on this dataset (Hovy, 2015; Hovy and Søgaard, 2015), we bin the age of the author into two categories (‘under 35’ and ‘over 45’). Finally, we randomly split each subcorpus into a training set (80%), a development set (10%) and a test (10%).

As an additional experimental setting, we use both demographic variables (gender and age) as input to the main model. We do so by adding two additional tokens at the beginning of the input text, one for each variable. It has been shown that those variables can be used to improve text classification (Hovy, 2015). Also, we would like to evaluate whether the attacker’s task is easier when the variables to predict are *explicitly* in the input, compared to when these information are only potentially and implicitly in the input. In other words, this setting simulates the case where private information may be used by the model to improve classification, but should not be exposed too obviously. In the rest of this section, we use RAW to denote the setting where only the raw text is used as input and +DEMO, the setting where the demographic variables are also used as input.

4.1.2 Topic Classification

We perform topic classification on two genres of documents: news articles and blog posts.

News article For topic classification of news article, we use two datasets: the AG news corpus[2] (Del Corso et al., 2005) and the English part of the Deutsche Welle (DW) news corpus (Pappas and Popescu-Belis, 2017).

For the AG corpus, following Zhang et al. (2015), we construct the dataset by extracting documents belonging to the four most frequent topics, and use the concatenation of the ‘title’ and ‘description’ fields as the input to the classifier. We randomly split the corpus into a training set (80%), a development set (10%) and a test set (10%). For the DW dataset, we use the ‘text’ field as input, and the standard split. We kept only documents belonging to the 20 most frequent topics.

The attacker tries to detect which named entities appear in the input text (each coefficient in $\mathbf{z}(x)$ indicates whether a specific named entity occurs in the text). For both datasets, we used the named entity recognition system from the NLTK package (Bird et al., 2009) to associate each example with the list of named entities that occur in it. We select the five most frequent named entities with type ‘person’, and only keep examples containing at least one of these named entities. This filtering is necessary to avoid a very unbalanced dataset (since each selected named entity appears usually in very few articles).

Blog posts We used the blog authorship corpus presented by Schler et al. (2006), a collection of blog posts associated with the age and gender of the authors, as provided by the authors themselves. Since the blog posts have no topic annotation, we ran the LDA algorithm (Blei et al., 2003) on the whole collection (with 10 topics). The LDA outputs a distribution on topics for each blog post. We selected posts with a single dominating topic ($> 80\%$) and discarded the other posts. We binned age into two category (under 20 and over 30). We

used the age and gender of the author as the private variables. These variables have a very unbalanced distribution in the dataset, we randomly select examples to obtain uniform distributions of private variables. Finally, we split the corpus into a training set (80%), a validation set and a test set (10% each).

4.2 Protocol

Evaluation For the main task, we report a single accuracy measure. For measuring the privacy of a representation, we compute the following metrics:

- For demographic variables (sentiment analysis and blog post topic classification): $1 - X$, where X is the average of the accuracy of the attacker on the prediction of gender and age;
- For named entities (news topic classification): $1 - F$, where F is an F-score computed over the set of binary variables in $\mathbf{z}$ that indicate the presence of named entities in the input example.

Training protocol We implemented our model using Dynet (Neubig et al., 2017). The feedforward components (both of the main model and of the attacker) have a single hidden layer of 64 units with a ReLU activation. Word embeddings have 32 units. The LSTM encoder has a single layer of varying sizes, since it is expected that the amount of information that can be learned depends on the size of these representations. We used the Adam optimizer (Kingma and Ba, 2014) with the default learning rate, and 0.2 dropout rate for the LSTM. We used $\alpha = 0.1$ for the declustering method, based on preliminary experiments. For the other defense methods, we used $\alpha = \beta = 1$ and did not experiment with other values.

For each dataset, and each LSTM state dimension ($\{8, 16, 32, 64, 128\}$), we train the main model for 8 epochs (sentiment classification) or 16 epochs (topic classification), and select the model with the best accuracy on the development set. Then, we generate the dataset for the attacker, train the adversarial model for 16 epochs and select the model with the worst privacy on the development set (i.e. the most successful attacker).

It has to be noted that we select the models that implement defenses on their accuracy, rather than their privacy or a combination thereof. In practice, we could also base the selection strategy on a privacy budget: selecting the most accurate model with privacy above a certain threshold.

4.3 Results

This section discusses results for the sentiment analysis task (Section 4.3.1) and the topic classification task (Section 4.3.2).

4.3.1 Sentiment Analysis

How private are neural representations? Before discussing the effect of proposed defense methods, we motivate empirically our approach by showing that adversarial models can recover private information with reasonable accuracy when the attack is targeted towards a model that implements none of the presented defense methods.

To do so, we compare the accuracy of adversarial models to two types of baselines:

- As a lower bound, we use the most frequent class baseline.
- As an upper bound, we trained a classifier that can optimize the hidden representations ($\mathbf{r}$) for the attacker's tasks. In other words, this baseline is trained to predict de-

mographic variables from x, as if it were the main task.

In Table 2, we compare both baselines to the best adversary in the two settings (RAW and +DEMO) among the models trained with no defenses. First of all, we observe that apart from gender on the German dataset, the trained baseline outperforms the most frequent class baseline by a wide margin (8 to 25 absolute difference). Second of all, the attacker is able to outperform the most frequent class baseline overall, even in the RAW setting. In more details, for age, the adversary is well over the baseline in all cases except US. On the other hand, gender seems harder to predict: the adversary outperforms the most frequent class baseline only in the +DEMO setting.

The same pattern is visible for the blog post dataset, also presented in the last line of Table 2: the best adversaries are 14 points over the baseline for gender and 5 points for age, i.e. almost as good as a model that can fine tune the hidden representations.

These results justify our approach, since they demonstrate that hidden representations learn private information about the input, and can be exploited to recover this information with reasonable accuracy.

Effect of defenses We report results for the main task accuracy and the representation privacy in Table 3 for the +DEMO setting and in Table 4 for the RAW setting. Recall that the privacy measure (Priv.) is computed by $1 - X$ where X is the average accuracy of the attacker on gender and age predictions. When this privacy metric is higher, it is more difficult to exploit the hidden representation of the network to recover information about x. The 'Standard' columns contain the accuracy and privacy of the base model described in Section 2. The next columns present the absolute variation in accuracy and privacy for the three defense methods presented in Section 3: Multidetasking, Adversarial Generation, and Declustering. We also report for each corpus the most frequent class baseline for the main task accuracy, and the privacy of the most frequent class baselines on private variables (i.e. the upper bound for privacy).

The three modified training methods designed as defenses have a positive effect on privacy. Despite a model selection based on accuracy, they lead to an improvement in privacy on all datasets, except on the France subcorpus. In most cases, we observe only a small decrease in accuracy, or even an improvement at times (e.g. multidetasking on the Germany dataset, RAW setting), thus improving the tradeoff between the utility and the privacy of the text representations.

4.3.2 Topic Classification

We report results on topic classification in Table 5.

News articles For the news corpora, the privacy metric is based on the F-score on the binary variables $\mathbf{z}$ indicating the presence or absence of a named entity in the text. First of all, we observe that defense methods that explicitly use $\mathbf{z}$ (i.e. multidetasking and declustering), have a very positive effect on privacy, but also a detrimental effect on the main task. We hypothesize that this is due to the strong correlations between the main task labels y and the private information $\mathbf{z}$. As a result, improving the privacy of the neural representations comes at a cost in accuracy.

In contrast, the adversarial generation defense method lead to an improvement in accuracy, that is quite substantial for the DW corpus. We speculate that this is due to the secondary term in the objective function of the main model (Section 3.1.2) that helps avoiding overfitting the main task or learning spurious features.

Blog posts On the blog post dataset, the effects are smaller, which we attribute to the nature of the task of the attacker. The defense methods consistently improve privacy and, in one case, accuracy. The best effects on the tradeoff are achieved with the multidetasking and adversarial generation methods.

5 Discussion

The main result of our experiments is that the defenses we propose improve privacy with usually a small effect, either positive or negative, on accuracy, thus improving the tradeoff between the utility and the privacy of neural representations.

An important direction for future work is the choice of a strategy for model selection. The tradeoff between utility and privacy can be controlled in many ways. For example, the importance of both terms in the loss functions in Section 3.1 can be controlled to favor either privacy or utility. In the scope of this paper, we did not perform thorough hyperparameter tuning, but believe that doing so is important for achieving better results, since the effects of defense method can be more drastic than desired in some cases, as exemplified on the news corpora (Table 5).

Overall, we found that the multidetasking approach lead to the more stable improvements and should be preferred in most cases, since it is also the less computationnally expensive defense. On the other hand, the adversarial generation method does not require the specification of private variables, and thus is a more general approach.

6 Related Work

The deployment of machine learning in both academic and industrial contexts raises concerns about adversarial uses of machine learning, as well as concerns about attacks specifically targeted at these algorithms that often rely on large amounts of data, including personal data.

More generally, the framework of differential privacy (Dwork, 2006) provides privacy guarantees for the problem of releasing information without compromising confidential data, and usually involves adding noise in the released information. It has been applied to the training of deep learning models (Abadi et al., 2016; Papernot et al., 2016; Papernot et al., 2018), and Bayesian topic models (Schein et al., 2018).

The notion of privacy is particularly crucial to NLP, since it deals with textual data, oftentimes user-generated data, that contain a lot of private information. For example, textual data contain a lot of signal about authors (Hovy and Spruit, 2016). and can be leveraged to predict demographic variables (Rosenthal and McKeown, 2011; Preoţiuc-Pietro et al., 2015). Oftentimes, this information is not explicit in the text but latent and related to the usage of various linguistic traits. Our work is based on a stronger hypothesis: this latent information is still present in vectorial representations of texts, even if the representations have not been supervised by these latent variables.

Li et al. (2017) study the privacy of unsupervised representations of images, and measures their privacy with the peak signal to noise ratio between an original image and its reconstruction by an attacker. They find a tradeoff between the privacy of the learned representations and the accuracy of an image classification model that uses these representations as inputs. Our setting is complementary since it is applied to NLP tasks, but explores a similar problem in the case of representations learned with a task supervision.

A related problem is the unintended memorization of private data from the training set and has been addressed by Carlini et al. (2018). They tackle this problem in the context of text generation (machine translation, language modelling).

If an attacker has access to e.g. a trained language model, they are likely to be able to generate sentences from the training set, since the language model is trained to assign high probabilities to those sentences. Such memorization is problematic when the training data contains private information and personal data. The experimental setting we explore is different from these works: we assume that the attacker has access to a hidden layer of the network and tries to recover information about an input example that is not in the training set.

In a recent study, Li et al. (2018) proposed a method based on GAN designed to improve the robustness and privacy of neural representations, applied to part-of-speech tagging and sentiment analysis. They use a training scheme with two agents similar to our multidetasking strategy (Section 3.1.1), and found that it made neural representations more robust and accurate. However, they only use a single adversary to alter the training of the main model and to evaluate the privacy of the representations, with the risk of overestimating privacy. In contrast, once the parameters of our main model are fixed, we train a new classifier from scratch to evaluate privacy.

7 Conclusion

We have presented an adversarial scenario and used it to measure the privacy of hidden representations in the context of two NLP tasks: sentiment analysis and topic classification of news article and blog posts. We have shown that in general, it is possible for an attacker to recover private variables with higher than chance accuracy, using only hidden representations. In order to improve the privacy of hidden representations, we have proposed defense methods based on modifications of the training objective of the main model. Empirically, the proposed defenses lead to models with a better privacy.

Adversarial Removal of Demographic Attributes from Text Data

Abstract

Recent advances in Representation Learning and Adversarial Training seem to succeed in removing unwanted features from the learned representation. We show that demographic information of authors is encoded in—and can be recovered from—the intermediate representations learned by text-based neural classifiers. The implication is that decisions of classifiers trained on textual data are not agnostic to—and likely condition on—demographic attributes. When attempting to remove such demographic information using adversarial training, we find that while the adversarial component achieves chance-level development-set accuracy during training, a post-hoc classifier, trained on the encoded sentences from the first part, still manages to reach substantially higher classification accuracies on the same data. This behavior is consistent across several tasks, demographic properties and datasets. We explore several techniques to improve the effectiveness of the adversarial component. Our main conclusion is a cautionary one: do not rely on the adversarial training to achieve invariant representation to sensitive features.

1 Introduction

Consider automated systems that are used for determining credit ratings, setting insurance policy rates, or helping in hiring decisions about individuals. We would like such decisions to not take into account factors such as the gender or the race of the individual, or any other factor which we deem to be irrelevant to the decision. We refer to such irrelevant factors as *protected attributes*. The naive solution of not including protected attributes in the features to a Machine Learning system is insufficient: other features may be highly correlated with—and thus predictive of—the protected attributes (Pedreshi et al., 2008). For example, in Credit Score modeling, text might help in credit score decisions (Ghailan et al., 2016). By using the raw text as is, a discrimination issue might arise, as textual information can be predictive of some demographic factors (Hovy et al., 2015) and author's attributes might correlate with target variables (Zhao et al., 2017).

In this paper we are interested in language-based features. It is well established that textual information can be predictive of age, race, gender, and many other social factors of the author (Koppel et al., 2002; Burger et al., 2011; Nguyen et al., 2013; Weren et al., 2014; Verhoeven and Daelemans, 2014; Rangel et al., 2016; Verhoeven et al., 2016; Blodgett et al., 2016), or even the audience of the text (Voigt et al., 2018).

Thus, any system that incorporates raw text into its decision process is at risk of indirectly conditioning on such signals. Recent advances in representation learning suggest *adversarial training* as a mean to hide the protected attributes from the decision function (Section 2). We perform a series of experiments and show that: (1) Information about race, gender and age is indeed encoded into intermediate representations of neural networks, even when training for seemingly unrelated tasks and the training data is balanced in terms of the protected attributes (Section 4); (2) The adversarial training method is indeed effective for reducing the amount of protected encoded information... (3) ...but in some cases even though the adversarial component seems to be doing a perfect job, a fair amount of protected information still remains, and can be extracted from the encoded representations (Section 5.1).

This suggests that when working with text data it is very easy to condition on sensitive properties by mistake. Even when explicitly using the adversarial training method to remove such properties, one should not blindly trust the adversary, and be careful to ensure the protected attributes are in-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 11–21
Brussels, Belgium, October 31 - November 4, 2018.

deed fully removed. We explore means for improving the effectiveness of the adversarial training procedure (section 5.2).[1]

However, while successful to some extent, none of the methods fully succeed in removing all demographic information. Our main message, then, remains cautionary: **if the goal is to ensure fairness or invariant representation, do not trust adversarial removal of features from text inputs for achieving it.**

2 Learning Setup

We follow a setup in which we have some labeled data D composed of documents $x_1, ..., x_n$ and task labels $y_1, ..., y_n$. We wish to train a classifier f that accurately predicts the main task labels y_i. Each data point x_i is also associated with a *protected attribute* z_i, and we want the decision $y_i = f(x_i)$ to be oblivious to z_i. Following (Ganin and Lempitsky, 2015; Xie et al., 2017), we structure f as an encoder $h(x)$ that maps x into a representation vector $\mathbf{h}_x$, and a classifier $c(h(x))$ that is used for predicting y based on $\mathbf{h}_x$. If $\mathbf{h}_{x_i}$ is not predictive of z_i, then the main task prediction $f(x_i) = c(h(x_i))$ does not depend on z_i.

We say that a protected attribute z has *leaked* if we can train a classifier $c'(\mathbf{h}_{x_i})$ to predict z_i with an accuracy beyond chance level, and that the protected attribute is *guarded* if we cannot train such a classifier. We say that a classifier $f(x) = c(h(x))$ is *guarded* if z is guarded, and that it is *leaky* with respect to z if z leaked.

Adversarial Training In order to make f oblivious to z, we follow the adversarial training setup (Goodfellow et al., 2014; Ganin and Lempitsky, 2015; Beutel et al., 2017; Xie et al., 2017). During training, an adversarial classifier $adv(\mathbf{h}_x)$ is trained to predict z, while the encoder h is trained to make adv fail. Concretely, the training procedure tries to jointly optimize both quantities:

$$\begin{aligned} &\arg\min_{adv} && L(adv(h(x_i)), z_i) \\ &\arg\min_{h,c} && L(c(h(x_i)), y_i) - L(adv(h(x_i)), z_i) \end{aligned}$$

where $L(y', y)$ is the loss function (in our case, cross entropy). This objective results in creating the representation $\mathbf{h}_x$ s.t. it's maximally informative for the main task, while at the same time minimally informative of the protected attribute. The optimization is performed in practice using the gradient-reversal layer (GRL) method (Ganin and Lempitsky, 2015). The GRL is a layer g_λ that is inserted between the encoded vector $\mathbf{h}_x$ and the adversarial classifier adv. During the forward pass the layer acts as the identity, while during backpropagation it scales the gradients passed through it by $-\lambda$, causing the encoder to receive the opposite gradients from the adversary. The metaparameter λ controls the intensity of the reversal layer. This results in the objective:

$$\arg\min_{h,c,adv} L(c(h(x_i)), y_i) + L(adv(g_\lambda(h(x_i))), z_i)$$

Attacker Network To test the effectiveness of the adversarial training, we use an *attacker network* $att(\mathbf{h}_x)$. After the classifier $c(h(x))$ is fully trained, we use the encoder to obtain representations $\mathbf{h}$, and train the attacker network to predict z based on $\mathbf{h}$, without access to the encoder or to the original inputs x that resulted in $\mathbf{h}$. If, after training, the attacker can predict z on unseen examples with an accuracy of beyond chance level, then the attribute z leaked to the representation, and the classifier is *not guarded.*

Network Architecture In our setup, an example x_i is a sequence of tokens $w_1, ..., w_{m_i}$ and the encoder is a one layer LSTM network that reads in the associated embedding vectors and returns the final state: $\mathbf{h} = LSTM(\mathbf{w}_{1:m})$. The classifier c and the adversarial adv are both multi-layer perceptrons with one hidden layer, sharing the same hidden layer size and activation function (tanh).[2]

3 Data, Tasks, and Protected Attributes

To perform our experiments, we need a reasonably large dataset in which the data-points x contain textual information, and for which we have both main-task labels y and protected attribute labels z. While our motivating example used prediction tasks for credit rating, insurance rates or hiring decisions, to the best of our knowledge there are no publicly available datasets for these sensitive tasks that meet our criteria. We thus opted to use much less sensitive main-tasks, for which we can obtain the needed data. We focus on Twitter messages, and our protected attributes are binary-race (non-hispanic Whites vs. non-hispanic Blacks),

---

[1] The code and data acquisition are available in: `https://github.com/yanaiela/demog-text-removal`

[2] Further details regarding the architecture and training parameters can be found in the supplementary materials.

binary-gender (Male vs. Female)[3] and binary-age (18-34 vs. 35+). As main tasks we chose *binary emoji-based sentiment prediction* and *binary tweet-mention prediction*. Both the sentiment and the mention prediction tasks are not inherently correlated with race, gender or age. Protected attributes leakage in these seemingly benign main-tasks is a strong indicator that such leakage is likely to occur also in more sensitive tasks.

Main Tasks: Sentiment and Mention-detection Both tasks can be derived automatically from twitter data. We construct a binary "sentiment" task by identifying a subset of emojis which are associated with positive and negative sentiment,[4] identifying tweets containing these emojis, assigning them with the corresponding sentiment and removing the emojis. Tweets containing emojis from both sentiment lists are discarded. The binary mention task is to determine if a tweet mentions another user, i.e, classifying conversational vs. non-conversational tweets. We derive this dataset by identifying tweets that include @mentions tokens, and removing all such tokens from the tweets.

Protected: Race The race annotation is based on the dialectal tweets (DIAL) corpus from (Blodgett et al., 2016), consisting of 59.2 million tweets by 2.8 million users. Each tweet is associated with predicted "race" information which was predicted using a technique that takes into account the geolocation of the author and the words in the tweet. We focus on the AAE (African-American English) and SAE (Standard American English) categories, which we use as proxies for non-Hispanic blacks and non-Hispanic whites.

We chose only annotations with confidence (the probability of the authors' race) of above 80%. Due to its construction, the race annotations in this dataset are highly correlated with the language being used. As such, the data reflects an extreme case in which the underlying language is very predictive of the protected attribute.

Protected: Age and Gender We use data from the PAN16 dataset (Rangel et al., 2016), containing manually annotated Age and Gender information of 436 Twitter users, along with up to 1k tweets for each user. User annotation was performed by consulting the user's LinkedIn profile. Gender was determined by considering the user's name and photograph, discarding unclear cases. Age range was determined by birth-date which was published on the user's profile, or by mapping their degree starting date.

Data-splits From the DIAL corpus we extracted 166K and 10K tweets for training and development purpose respectively (after cleaning and extracting relevant tweets), whereas for the PAN16 dataset we collected 160K tweets for training and 10K for development. The train/development split in both phases of the training (*task-training* and *attacker-training*) is the same. This is the worst possible scenario for the attacker, as it is training on the exact representations the adversary attempted to remove the protected attribute from. Each split is balanced with respect to both the main and the protected labels: a random prediction of each variable is likely to result in 50% accuracy.

Metrics Throughout this paper, we measure leakage using accuracy. We say that the protected attribute has leaked if an *attacker* manages to predict the protected attribute with better than 50% accuracy, which is always the probability of that attribute ($P(Z) = 0.5$). In Appendix A we relate our metric to more standard fairness metrics, and prove that in our setup a guarded predictor guarantees demographic parity, equality of odds, and equality of opportunity. Note however that we also show empirically that such guarded predictors are very hard to attain in practice.

4 Baselines and Data Leakage

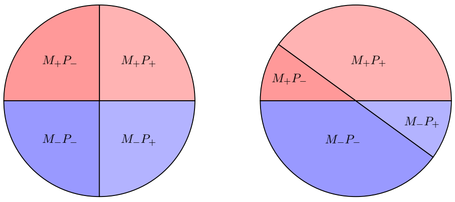
In-dataset Accuracy Upper-bounds We begin by examining how well can we perform on each task (both main-tasks and protected attributes) when training the encoder and classifier directly on that task, without any adversarial component. This provides an upper bound on the protected attribute leakage for the main tasks results. The results in Table 1 indicate that the classifiers achieve reasonable accuracies for the main tasks.[5] For

---

[3] While gender is a non-binary construct, many decisions in the real-world are unfortunately still influenced by hard binary gender categories. We thus consider binary-gender to be a useful approximation in our context.

[4] Complete list is available in Appendix C

[5] While the sentiment score may seem low, we manually verified the erroneous predictions and found out that many of them are indeed ambiguous with respect to sentiment, e.g. sentences like "I can't take Amanda seriously 😂" and "You make me so angry, yet you make me so happy. 😩" which were predicted negative and positive respectively, but their gold label was the opposite.



(a) balanced (b) unbalanced

Figure 1: Balanced (a) vs. Unbalanced (b) dataset. **Red(M+)/Blue(M-)**: Main Task. **Light(P+)/Dark(P-)**: Protected attribute. Each class is globally balanced, but in (b) the proportion of the protected attribute within each main task split is unbalanced.

the protected attributes, *race* is highly predictable (83.9%) while *age* and *gender* can also be recovered at above 64% accuracy.

Data	Task	Accuracy
DIAL	Sentiment	67.4
	Mention	81.2
	Race	83.9
PAN16	Mention	77.5
	Gender	67.7
	Age	64.8

Table 1: Accuracies when training directly towards a single task.

Leakage When training directly for the protected attributes, we can recover them with relatively high accuracies. But is information about them being encoded when we train on the main tasks? In this set of experiments, we encode the training and validation sets using the encoder trained on the main task, and train the attacker network to predict the protected attributes based on these vectors. This experiment suggests an upper bound on the amount of leakage of protected attributes when we do not actively attempt to prevent it. The Balanced section in Table 2 summarizes the validation-set accuracies. While the numbers are lower than when training directly (Table 1), they are still high enough to extract meaningful and possibly highly sensitive information (e.g. DIAL Race direct prediction is 83.9% while DIAL Race leakage on the balanced Sentiment task is 64.5%).

Leakage: Unbalanced Data The datasets we considered were perfectly balanced with respect to both main task and protected attribute labels (Figure 1a). Such extreme case is not representative of real-world datasets, in which a dataset may be well balanced w.r.t. the main task labels but not the protected attribute. For example, when training a classifier to predict a fit for managerial position based on Curriculum Vitae (CV) of candidates, the CV dataset may be perfectly balanced according to the managerial / non-managerial variable, but, because of existing social biases, CVs of females might be under-represented in the managerial category and over-represented in the non-managerial one. In such a situation, the classifier may perpetuate the bias by learning to favor males over females for managerial positions. We simulate this more realistic scenario by constructing unbalanced datasets in which the main tasks (sentiment/mention) remain balanced but the protected class proportions within each main class are not, as demonstrated in Figure 1b. For example, in the sentiment/gender case, we set the positive-sentiment class to contain 80% male and 20% female tweets, while the negative-sentiment class contains 20% male and 80% female tweets. We then follow the leakage experiment on the unbalanced datasets. The attacker is trained and tested on a balanced dataset. Otherwise, the attacker can perform quite well on the male/female task simply by learning to predict sentiment, which does not reflect leakage of gender data to the representation. When training the attacker on balanced data, its decisions cannot rely on the sentiment information encoded in the vectors, and must look for encoded information about the protected attributes. The results in Table 2 indicate that both task accuracy and attribute leakage are stronger in the unbalanced case.

Leakage: Real-world Example The above experiments used artificially constructed datasets. Here, we demonstrate leakage using a popular encoder trained for emotion detection: the DeepMoji encoder (Felbo et al., 2017) trained to predict the most suitable emoji usage for a sentence (one of 64 in total), based on 1.2 billion tweets. The model is advertised as a good encoder for encoding sentences into a representation that is highly predictive of sentiment, mood, emotion and sarcasm. Does it also capture *protected attributes*? We encode the sentences of the different *protected attributes* using the DeepMoji encoder and train three different *attackers* to predict race, gender and age. The best scores on the development set are 84.7%, 67.2% and 67.1% respectively. This should not come as a surprise, as indeed some

			Balanced		Unbalanced	
Data	Task	Protected Attribute	Task Acc	Leakage	Task Acc	Leakage
DIAL	Sentiment	Race	67.4	64.5	79.5	73.5
	Mention	Race	81.2	71.5	86.0	73.8
PAN16	Mention	Gender	77.5	60.1	76.8	64.0
		Age	74.7	59.4	77.5	59.7

Table 2: Protected attribute leakage: balanced & unbalanced data splits.

emoji usage is highly correlated with these properties.

5 Mitigating Data Leakage

Leakage of protected attributes information into the internal representation of the network when training on seemingly unrelated tasks is very common. We explore the means of mitigating such leakage.

5.1 Adversarial Training

We repeat the experiments in Table 2 with an adversarial component (Ganin and Lempitsky, 2015) as described in Section 2, in order to actively remove the protected attribute information from the encoded representation during training. Note that the adversarial objective is in odds with the main-task one: by removing the protected attribute information from the encoder, we may also hurt its ability to encode information about the main task.

Figure 2 shows the main task and adversary prediction accuracies on the development set as training progresses, for the Sentiment/Race pair.

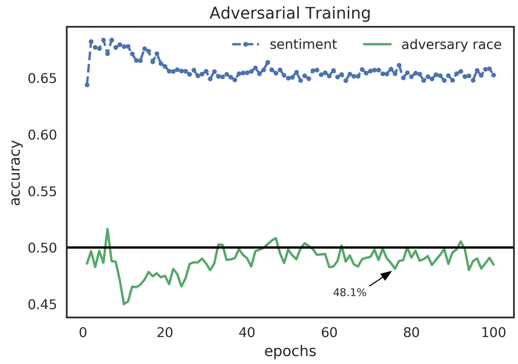


Figure 2: Main task and Adversary accuracy curves for Sentiment/Race.

After an initial peak in task prediction accuracy, the adversary prediction drops and starts to fluctuate around chance level (50%), as desired, along with a drop in main task accuracy as well. The adversary's accuracy remain around chance level throughout the entire training process, suggesting that the adversarial training is indeed effective for removing the protected attribute information from the encoded representation. These trends are persistent for all main-task/protected-attribute pairs we tried.

However, training the attacker network on the resulting encoder vectors reveals a different story. For example, when considering the encoder after 50 training epochs (adversary accuracy of 49.0%), the attacker reaches 56.0% accuracy: substantially higher than the adversarial's success rate, despite sharing the exact same architecture, and being trained and tested on the exact same dataset.

Table 3 summarizes the attacker's recovery rate on the adversarialy-trained encoders for the different settings. In all cases, the adversarial's success rate is around 50%, while the attacker's rate is substantially higher. The attacker's rates are lower than in Table 1, indicating the adversarial training is effective in removing *some* of the protected attribute. However, **a substantial amount of information managed to leak past the adversary, despite its seemingly perfect performance**.

Data	Task	Protected Attribute	Task Acc	Leakage	Δ
DIAL	Sentiment	Race	64.7	56.0	5.0
	Mention	Race	81.5	63.1	9.2
PAN16	Mention	Gender	75.6	58.5	8.0
	Mention	Age	72.5	57.3	6.9

Table 3: Performances on different datasets with an adversarial training. Δ is the difference between the attacker score and the corresponding adversary's accuracy.

Attacker's Accuracy on Unseen Data We verify that the attacker's recovery accuracy persists also on the more realistic scenario in which the attacker is applied to encoded sentences that did not participate in the adversarial training. We constructed an additional dataset of 166K completely unseen samples from the Sentiment/Race case. As expected, the attacker works even better in this case, reaching an accuracy of 59.7% Vs. 56.0% on the original development set.

5.2 Strengthening the Adversarial Component

We explore means of strengthening the adversarial component, by tuning its capacity and its weight, as well as by using a novel adversarial-ensemble configuration.

Capacity We increase the capacity of the adversarial component by increasing its hidden dimension, while keeping the attacker's hidden dimension constant at 300 dimensions. We try hidden dimensions of size 500, 1000, 2000, 5000 and 8000.

Weight We experiment with different weighting of the adversarial component during training by tuning the λ parameter, trying the values 0.5, 1.0 (default), 1.5, 2, 3, 5 (with values above 5 the main task training became extremely unstable, not raising above 50%).

Ensemble An alternative to using larger λ values is to introduce several adversaries. The potential benefit of this approach is that rather than focusing harder on removing a single feature, here the different adversaries could each focus on a different aspect of the representation. This approach is potentially better suited to deal with language variability. Concretely, we suggest the following adaptation to the adversarial loss to incorporate k adversaries with different random initializations:

$$L_y(c(h(x)), y) + \sum_{j=1}^{k} L_z(adv_j(g_\lambda(h(x))), z)$$

Other Attempts We also experienced with several other techniques: reinitializing the adversarial weights every t epochs; training the adversary without propagating the error to the encoder components for t epochs and only then starting to propagate; using adversaries with more hidden layers; adding dropout on the encoded vectors and within the encoder. None of these yielded improvements over the above methods.

Results All methods are effective to some extent, Table 4 summarizes the results.

Increasing the capacity of the adversarial network helped reduce the protected attribute's leakage, though different capacities work best on each setup. On the Sentiment/Race task, none of the higher dimensional adversaries worked better than the 300-dim one, on the PAN16 dataset it did. On PAN16/Gender the 8000-dim adversary performed best, and on PAN16/Age, the 500-dim one.

Increasing the weight of the adversary through the λ parameter also has a positive effect on the result (except on the Sentiment/Race pair). However, too large λ values make training unstable, and require many more epochs for the main-task to stabilize around a satisfying accuracy.

The adversarial ensemble method with 2 adversaries achieves 57.4% on Sentiment/Race, as opposed to 56.0% with a single one, but when using 5 different adversaries, we achieve 54.8%. On the PAN16 dataset larger ensembles are more effective. However, a potential issue with the ensemble method is that larger ensembles reduces training stability, similar to increasing the λ value. For example, with 5 adversaries, the main-task accuracy remained at random for 5 epochs, and only begun rising at the 6th epoch. Using 10 adversaries, the main task could not be trained.

To summarize, while all methods are effective to some extent, it appears that (a) no method and parameter setting performs equally well across the different setups; and (b) no method succeeds in completely preventing the leakage of the protected attributes. Combining the different methods (ensembles of larger networks, larger networks with larger λ, etc.) did not improve the results.

Unbalanced Data Results We repeated the same set of experiments on the unbalanced Sentiment/Race corpus (Table 5). In this setup, the results are somewhat similar: increasing the adversarial capacity and λ is ineffective, and even increases the attacker's recovery rate. However, using an ensemble of 5 adversaries does manage to reduce the leakage, but it is still far from a satisfying result.

6 Analysis

The gap between the adversary's dev-set accuracy and the after-the-fact attacker accuracy on the same data is surprising. To better understand the phenomenon, we perform further analysis on the Sentiment/Race pair with the default single adversary.

Embedding Vs. RNN Recall that the *attacker network* tries to extract as much information from

		DIAL			PAN16

the encoder's output as possible. The encoder consists of two components: (1) Embedding Matrix and (2) an RNN. Therefore, the leakage can be caused due to one of them (or due to their combination).

We conduct the following experiment to determine which part affects the leakage more: we create a new encoder by composing 2 existing encoders: an encoder with high leakage (*Leaky*, using the baseline encoder) and an encoder with low leakage (*Guarded*, using the 5-Ensemble adversary). We fuse the two encoders by combining the embedding matrix of the *Leaky* encoder with the RNN module of the *Guarded* encoder, and vice versa. This yields two new encoders: an encoder with a "leaky" Embedding Matrix module and a "strong" RNN module (*Leaky-EMB*), and an encoder with a "strong" Embedding Matrix module and a "leaky" RNN module (*Leaky-RNN*). We compare encoders *Leaky-EMB* and *Leaky-RNN* to gauge which module has a greater contribution to the data leakage. We train attacker-networks over the encoders' output to predict the protected attributes.

		Embedding	
		Leaky	Guarded
RNN	Leaky	64.5	67.8
	Guarded	59.3	54.8

Table 6: Accuracies of the protected attribute with different encoders.

Table 6 summarize the results, implying that the leakage is caused mainly by the RNN, and less by the Embedding Matrix.[6]

---

[6] A discrepancy exists to some extent in the new encoders, as their parts originate from different models that were trained separately. To test if the fusion is valid, we train a different classifier on top of the new encoders to predict the main task. The combination of the leaked RNN with the guarded embeddings results in 65.4% on the sentiment task and the other combination results in 60.9% as opposed to 67.5% and 63.8% on the leaked and guarded models, respectively. As the new models are on par with the original ones, we conclude that the new encoders are valid.

Consistent Leakage: Examples Inspection We are interested in tweets whose protected attribute (race) is correctly predicted by the adversary. However, at accuracy rates below 60%, many of the correct predictions could be attributed to chance. To identify the relevant examples, we repeated the Sentiment/Race default adversary experiment 10 times with different random seeds. We then trained 10 attacker networks, and used each of them to label all examples in the development set. We then looked for tweets which are consistently and correctly classified by at least 9 attackers.[7] Table 7 shows some of these cases. Many of them include tokens (*Naw*, *Bestfrand*, *tan*) and syntactic structures (*Going over Bae house*) which are indeed predictive, though not the most salient features.

Leakage via Embeddings Even though we found out the RNN is much more responsible to the leakage then the Embedding, those still contribute to the leakage and are easier to inspect. Therefore, we turn to inspect the encoders' Embedding. We hypothesize that a possible reason for the adversarial network's inability to completely remove the protected race information is word frequency. Namely, rare words, which might be strongly identified with one group, didn't get enough updates during training and therefore remained predictive towards one of the groups. To quantify this, we compared two vocabularies: words appearing in tweets where the predictions were consistently predicted (9 or 10 out of 10 times) by the different attackers, and words appearing in tweets that were randomly distributed (50%) between the attackers. If our hypothesis is correct, we expect words from the second group to be more frequent than words in the first group. We discard words appearing in both groups, and associate each word with its training set frequency. One-tailed Mann-Whitney U test (Mann and Whitney, 1947) showed the effect is highly significant with $p < e^{-12}$.

Data Overfitting? Standard ML setups often suffer from overfitting on the training data, especially when using neural-networks which tend to memorize the data they encounter. In the adversarial setup, the overfitting could result in the encoder-adversary pair working together to perfectly clean the attributes from the training data, without generalization. Such overfitting could explain the attacker success. Is this what happened? We test this hypothesis by using the same *attacker networks* experiments solely on the training data. We train the *attackers* on 90% of the training data while using the rest 10% as held-out. If overfitting has occurred, the accuracy is likely to result in 50% accuracy. Alas, this is not the case. Table 8 summarize the training accuracies of the *attacker network*. The Mention/Race task achieves the highest score of 64.3% whereas the Mention/Gender task achieves the lowest - 58.1%. Even though when trained directly to predict these attributes without the adversarial setup, the training accuracies are much higher, a substantial amount of signal is still left, even in the training data.

7 Related Work

The fact that intermediary vector representations that are trained for one task are predictive of another is not surprising: it is at the core of the success of NLP methods for deriving "generic" word and sentence representations (e.g. Word2vec (Mikolov et al., 2013), Skip-thought vectors (Kiros et al., 2015), Contextualized Word Representations (Melamud et al., 2016; Peters et al., 2018) etc.). While usually considered a positive feature, it can often have undesired consequences one should be aware of and potentially control for. Several works document biases and stereotypes that are captured by unsupervised word embeddings (Bolukbasi et al., 2016; Caliskan et al., 2017) and ways of mitigating them (Bolukbasi et al., 2016; Zhang et al., 2018). Bias and stereotyping were also documented on a common NLP dataset (Rudinger et al., 2017). While these work are concerned with the learned representations encoding unwanted biases about the world, our concern is with capturing potentially sensitive demographic information about individual authors of the text.

Removing sensitive attributes (demographic or otherwise) from intermediate representations in order to achieve fair classification has been explored by solving an optimization problem (Zemel et al., 2013), as well as by employing adversarial training (Edwards and Storkey, 2015; Louizos et al., 2015; Xie et al., 2017; Zhang et al., 2018), focusing on structured features. Adversarial training was also applied for Image anonymization

(Edwards and Storkey, 2015; Feutry et al., 2018). In contrast, we consider features that are based on short user-authored text.

Several works apply adversarial training to textual data, in order to learn encoders that are invariant to some properties of the text (Chen et al., 2016; Conneau et al., 2017; Zhang et al., 2017; Xie et al., 2017). As their main motivation is to remove information about domain or language in order to improve transfer learning, domain adaptation, or end task accuracy, they were less concerned with the ability to recover information from the resulting representation, and did not evaluate it directly as we do here.

Recent work on creating private representation in the text domain (Li et al., 2018) share our motivation of removing unintended demographic attributes from the learned representation using adversarial training. However, they report only the discrimination accuracies of the adversarial component, and do not train another classifier to verify that the representations are indeed clear of the protected attribute. As our work shows, trusting the adversary is insufficient, and external verification is crucial.

Finally, our work is motivated by the desire for fairness. We use a definition in which a fair classification is one that does not condition on a certain attribute (*fairness by blindness*), and evaluate the ability to achieve text-derived representations that are blind to a property we wish to protect. Many other definitions of fairness exist, including *demographic parity*, *equality of odds* and *equality of opportunity* (see e.g. discussion in (Hardt et al., 2016; Beutel et al., 2017)). Under our setup, blindness guarantees these metrics (Appendix A).

8 Conclusions

We show that demographic information leaks into intermediate representations of neural networks trained on text data. Systems that train on text data and do not want to condition on demographic information must take active steps against accidental conditioning. Our experiments suggest that:
(1) Adversarial training is effective for mitigating protected attribute leakage, but, when dealing with text data, may fail to remove it completely.
(2) When using the adversarial training method, the adversary score during training *cannot be trusted*, and must be verified with an externally-trained attacker, preferably on unseen data.
(3) Tuning the capacity and weight of the adversary, as well as using an ensemble of several adversaries, can improve the results. However, no single method is the most effective in all cases.

Abstract

Misinformation such as fake news is one of the big challenges of our society. Research on automated fact-checking has proposed methods based on supervised learning, but these approaches do not consider external evidence apart from labeled training instances. Recent approaches counter this deficit by considering external sources related to a claim. However, these methods require substantial feature modeling and rich lexicons. This paper overcomes these limitations of prior work with an end-to-end model for evidence-aware credibility assessment of arbitrary textual claims, without any human intervention. It presents a neural network model that judiciously aggregates signals from external evidence articles, the language of these articles and the trustworthiness of their sources. It also derives informative features for generating user-comprehensible explanations that makes the neural network predictions transparent to the end-user. Experiments with four datasets and ablation studies show the strength of our method.

1 Introduction

Motivation: Modern media (e.g., news feeds, microblogs, etc.) exhibit an increasing fraction of misleading and manipulative content, from questionable claims and “alternative facts” to completely faked news. The media landscape is becoming a twilight zone and battleground. This societal challenge has led to the rise of fact-checking and debunking websites, such as *Snopes.com* and *PolitiFact.com*, where people research claims, manually assess their credibility, and present their verdict along with evidence (e.g., background articles, quotations, etc.). However, this manual verification is time-consuming. To keep up with the scale and speed at which misinformation spreads, we need tools to automate this debunking process.

State of the Art and Limitations: Prior work on “truth discovery” (see Li et al. (2016) for survey)[1] largely focused on structured facts, typically in the form of subject-predicate-object triples, or on social media platforms like Twitter, Sina Weibo, etc. Recently, methods have been proposed to assess the credibility of claims in natural language form (Popat et al., 2017; Rashkin et al., 2017; Wang, 2017), such as news headlines, quotes from speeches, blog posts, etc.

The methods geared for general text input address the problem in different ways. On the one hand, methods like Rashkin et al. (2017); Wang (2017) train neural networks on labeled claims from sites like *PolitiFact.com*, providing credibility assessments without any explicit feature modeling. However, they use only the text of questionable claims and no external evidence or interactions that provide limited context for credibility analysis. These approaches also do not offer any explanation of their verdicts. On the other hand, Popat et al. (2017) considers external evidence in the form of other articles (retrieved from the Web) that confirm or refute a claim, and jointly assesses the language style (using subjectivity lexicons), the trustworthiness of the sources, and the credibility of the claim. This is achieved via a pipeline of supervised classifiers. On the upside, this method generates user-interpretable explanations by pointing to informative snippets of evidence articles. On the downside, it requires substantial feature modeling and rich lexicons to detect bias and subjectivity in the language style.

Approach and Contribution: To overcome the limitations of the prior works, we present *DeClarE*[2], an end-to-end neural network model for assessing and explaining the credibility of arbi-

---

[1] As fully objective and unarguable truth is often elusive or ill-defined, we use the term *credibility* rather than “truth”.

[2] Debunking Claims with Interpretable Evidence

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 22–32
Brussels, Belgium, October 31 - November 4, 2018.

trary claims in natural-language text form. Our approach combines the best of both families of prior methods. Similar to Popat et al. (2017), DeClarE incorporates external evidence or counter-evidence from the Web as well as signals from the language style and the trustworthiness of the underlying sources. However, our method does not require any feature engineering, lexicons, or other manual intervention. Rashkin et al. (2017); Wang (2017) also develop an end-to-end model, but DeClarE goes far beyond in terms of considering external evidence and joint interactions between several factors, and also in its ability to generate user-interpretable explanations in addition to highly accurate assessments. For example, given the natural-language input claim *"the gun epidemic is the leading cause of death of young African-American men, more than the next nine causes put together"* by Hillary Clinton, DeClarE draws on evidence from the Web to arrive at its verdict *credible*, and returns annotated snippets like the one in Table 6 as explanation. These snippets, which contain evidence in the form of statistics and assertions, are automatically extracted from web articles from sources of varying credibility.

Given an input claim, DeClarE searches for web articles related to the claim. It considers the *context* of the claim via word embeddings and the (language of) web articles captured via a bidirectional LSTM (biLSTM), while using an *attention* mechanism to focus on parts of the articles according to their relevance to the claim. DeClarE then aggregates all the information about claim source, web article contexts, attention weights, and trustworthiness of the underlying sources to assess the claim. It also derives informative features for interpretability, like source embeddings that capture trustworthiness and salient words captured via attention. Key contributions of this paper are:

- **Model:** An end-to-end neural network model which automatically assesses the credibility of natural-language claims, without any hand-crafted features or lexicons.
- **Interpretability:** An *attention* mechanism in our model that generates user-comprehensible explanations, making credibility verdicts transparent and interpretable.
- **Experiments:** Extensive experiments on four datasets and ablation studies, demonstrating effectiveness of our method over state-of-the-art baselines.

2 End-to-end Framework for Credibility Analysis

Consider a set of N claims $\langle C_n \rangle$ from the respective origins/sources $\langle CS_n \rangle$, where $n \in [1, N]$. Each claim C_n is reported by a set of M articles $\langle A_{m,n} \rangle$ along with their respective sources $\langle AS_{m,n} \rangle$, where $m \in [1, M]$. Each corresponding tuple of claim and its origin, reporting articles and article sources – $\langle C_n, CS_n, A_{m,n}, AS_{m,n} \rangle$ forms a training instance in our setting, along with the credibility label of the claim used as ground-truth during network training. Figure 1 gives a pictorial overview of our model. In the following sections, we provide a detailed description of our approach.

2.1 Input Representations

The input claim C_n of length l is represented as $[c_1, c_2, ..., c_l]$ where $c_l \in \Re^d$ is the d-dimensional word embedding of the l-th word in the input claim. The source/origin of the claim CS_n is represented by a d_s-dimensional embedding vector $cs_n \in \Re^{d_s}$.

A reporting article $A_{m,n}$ consisting of k tokens is represented by $[a_{m,n,1}, a_{m,n,2}, ..., a_{m,n,k}]$, where $a_{m,n,k} \in \Re^d$ is the d-dimensional word embedding vector for the k-th word in the reporting article $A_{m,n}$. The claim and article word embeddings have shared parameters. The source of the reporting article $AS_{m,n}$ is represented as a d_s-dimensional vector, $as_{m,n} \in \Re^{d_s}$. For the sake of brevity, we drop the notation subscripts n and m in the following sections by considering only a single training instance – the input claim C_n from source CS_n, the corresponding article $A_{m,n}$ and its sources $AS_{m,n}$ given by: $\langle C, CS, A, AS \rangle$.

2.2 Article Representation

To create a representation of an article, which may capture task-specific features such as whether it contains objective language, we use a bidirectional Long Short-Term Memory (LSTM) network as proposed by Graves et al. (2005). A basic LSTM cell consists of various gates to control the flow of information through timesteps in a sequence, making LSTMs suitable for capturing long and short range dependencies in text that may be difficult to capture with standard recurrent neural networks (RNNs). Given an input word embedding of tokens $\langle a_k \rangle$, an LSTM cell performs various non-linear transformations to generate a hidden vector state h_k for each token at each timestep k.

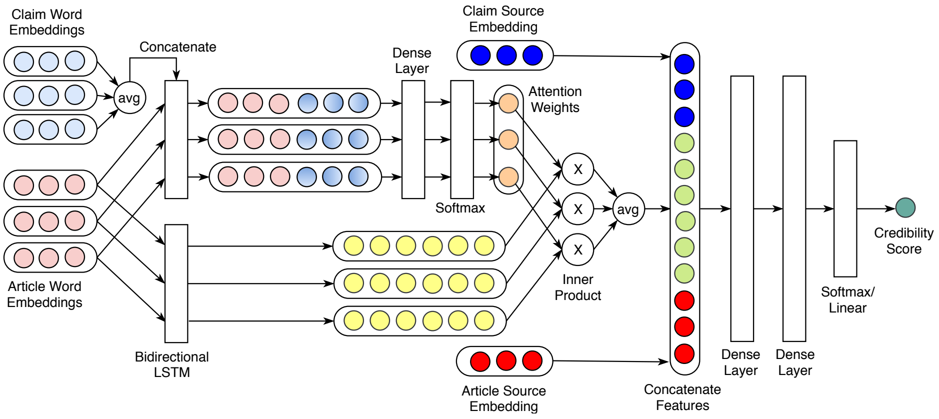

Figure 1: Framework for credibility assessment. Upper part of the pipeline combines the article and claim embeddings to get the claim specific attention weights. Lower part of the pipeline captures the article representation through biLSTM. Attention focused article representation along with the source embeddings are passed through dense layers to predict the credibility score of the claim.

We use bidirectional LSTMs in place of standard LSTMs. Bidirectional LSTMs capture both the previous timesteps (past features) and the future timesteps (future features) via forward and backward states respectively. Correspondingly, there are two hidden states that capture past and future information that are concatenated to form the final output as: $h_k = [\overrightarrow{h_k}, \overleftarrow{h_k}]$.

2.3 Claim Specific Attention

As we previously discussed, it is important to consider the relevance of an article with respect to the claim; specifically, focusing or *attending* to parts of the article that discuss the claim. This is in contrast to prior works (Popat et al., 2017; Rashkin et al., 2017; Wang, 2017) that ignore either the article or the claim, and therefore miss out on this important interaction.

We propose an attention mechanism to help our model focus on salient words in the article with respect to the claim. To this end, we compute the importance of each term in an article with respect to an overall representation of the corresponding claim. Additionally, incorporating attention helps in making our model transparent and interpretable, because it provides a way to generate the most salient words in an article as evidence of our model's verdict.

Following Wieting et al. (2015), the overall representation of an input claim is generated by taking an average of the word embeddings of all the words therein:

$$\bar{c} = \frac{1}{l}\sum_{l} c_l$$

We combine this overall representation of the claim with each article term:

$$\hat{a}_k = a_k \oplus \bar{c}$$

where, $\hat{a}_k \in \Re^{d+d}$ and $\oplus$ denotes the concatenate operation. We then perform a transformation to obtain claim-specific representations of each article term:

$$a'_k = \mathbf{f}(W_a \hat{a}_k + b_a)$$

where W_a and b_a are the corresponding weight matrix and bias terms, and $\mathbf{f}$ is an activation function[3], such as $ReLU$, $tanh$, or the identity function. Following this, we use a softmax activation to calculate an attention score α_k for each word in the article capturing its relevance to the claim context:

$$\alpha_k = \frac{\exp(a'_k)}{\sum_k \exp(a'_k)} \quad (1)$$

2.4 Per-Article Credibility Score of Claim

Now that we have article term representations given by $\langle h_k \rangle$ and their relevance to the claim given by $\langle \alpha_k \rangle$, we need to combine them to predict the claim's credibility. In order to create an

---

[3] In our model, the *tanh* activation function gives best results.

attention-focused representation of the article considering both the claim and the article's language, we calculate a weighted average of the hidden state representations for all article tokens based on their corresponding attention scores:

$$g = \frac{1}{k} \sum_{k} \alpha_k \cdot h_k \tag{2}$$

We then combine all the different feature representations: the claim source embedding (cs), the attention-focused article representation (g), and the article source embedding (as). In order to merge the different representations and capture their joint interactions, we process them with two fully connected layers with non-linear activations.

$$\begin{aligned} d_1 &= relu(W_c(g \oplus cs \oplus as) + b_c) \\ d_2 &= relu(W_d d_1 + b_d) \end{aligned}$$

where, W and b are the corresponding weight matrix and bias terms.

Finally, to generate the overall credibility label of the article for classification tasks, or credibility score for regression tasks, we process the final representation with a final fully connected layer:

$$\text{Classification:} \quad s = sigmoid(d_2) \tag{3}$$

$$\text{Regression:} \quad s = linear(d_2) \tag{4}$$

2.5 Credibility Aggregation

The credibility score in the above step is obtained considering a single reporting article. As previously discussed, we have M reporting articles per claim. Therefore, once we have the per-article credibility scores from our model, we take an average of these scores to generate the overall credibility score for the claim:

$$cred(C) = \frac{1}{M} \sum_{m} s_m \tag{5}$$

This aggregation is done after the model is trained.

3 Datasets

We evaluate our approach and demonstrate its generality by performing experiments on four different datasets: a general fact-checking website, a political fact-checking website, a news review community, and a SemEval Twitter rumour dataset.

3.1 Snopes

Snopes (`www.snopes.com`) is a general fact-checking website where editors manually investigate various kinds of rumors reported on the Internet. We used the Snopes dataset provided by Popat et al. (2017). This dataset consists of rumors analyzed on the Snopes website along with their credibility labels (*true* or *false*), sets of reporting articles, and their respective web sources.

3.2 PolitiFact

PolitiFact is a political fact-checking website (`www.politifact.com`) in which editors rate the credibility of claims made by various political figures in US politics. We extract all articles from PolitiFact published before December 2017. Each article includes a claim, the speaker (political figure) who made the claim, and the claim's credibility rating provided by the editors.

PolitiFact assigns each claim to one of six possible ratings: *true, mostly true, half true, mostly false, false* and *pants-on-fire*. Following Rashkin et al. (2017), we combine *true, mostly true* and *half true* ratings into the class label *true* and the rest as *false* – hence considering only binary credibility labels. To retrieve the reporting articles for each claim (similar to Popat et al. (2017)), we issue each claim as a query to a search engine[4] and retrieve the top 30 search results with their respective web sources.

3.3 NewsTrust

NewsTrust is a news review community in which members review the credibility of news articles. We use the NewsTrust dataset made available by Mukherjee and Weikum (2015). This dataset contains NewsTrust stories from May 2006 to May 2014. Each story consists of a news article along with its source, and a set of reviews and ratings by community members. NewsTrust aggregates these ratings and assigns an overall credibility score (on a scale of 1 to 5) to the posted article. We map the attributes in this data to the inputs expected by DeClarE as follows: the title and the web source of the posted (news) article are mapped to the input claim and claim source, respectively. Reviews and their corresponding user identities are mapped to reporting articles and article sources, respectively. We use this dataset for the regression task of predicting the credibility score of the posted article.

---

[4] We use the Bing search API.

Dataset	SN	PF	NT	SE
Total claims	4341	3568	5344	272
True claims	1164	1867	-	127
False claims	3177	1701	-	50
Unverified claims	-	-	-	95
Claim sources	-	95	161	10
Articles	29242	29556	25128	3717
Article sources	336	336	251	89

Table 1: Data statistics (SN: Snopes, PF: PolitiFact, NT: NewsTrust, SE: SemEval).

3.4 SemEval-2017 Task 8

As the fourth dataset, we consider the benchmark dataset released by SemEval-2017 for the task of determining credibility and stance of social media content (Twitter) (Derczynski et al., 2017). The objective of this task is to predict the credibility of a questionable tweet (*true*, *false* or *unverified*) along with a confidence score from the model. It has two sub-tasks: (i) a *closed* variant in which models only consider the questionable tweet, and (ii) an *open* variant in which models consider both the questionable tweet and additional context consisting of snapshots of relevant sources retrieved immediately before the rumor was reported, a snapshot of an associated Wikipedia article, news articles from digital news outlets, and preceding tweets about the same event. Testing and development datasets provided by organizers have 28 tweets (1021 reply tweets) and 25 tweets (256 reply tweets), respectively.

3.5 Data Processing

In order to have a minimum support for training, claim sources with less than 5 claims in the dataset are grouped into a single dummy claim source, and article sources with less than 10 articles are grouped similarly (5 articles for SemEval as it is a smaller dataset).

For Snopes and PolitiFact, we need to extract relevant snippets from the reporting articles for a claim. Therefore, we extract snippets of 100 words from each reporting article having the maximum relevance score: $sim = sim_{\text{bow}} \times sim_{\text{semantic}}$ where sim_{bow} is the fraction of claim words that are present in the snippet, and sim_{semantic} represents the cosine similarity between the average of claim word embeddings and snippet word embeddings. We also enforce a constraint that the sim score is at least δ. We varied δ from 0.2 to 0.8 and found 0.5 to give the optimal performance on a withheld dataset. We discard all articles related to Snopes and PolitiFact websites from our datasets to have an unbiased model. Statistics of the datasets after pre-processing is provided in Table 1. All the datasets are made publicly available at `https://www.mpi-inf.mpg.de/dl-cred-analysis/`.

Parameter	SN	PF	NT	SE
Word embedding length	100	100	300	100
Claim source embedding length	-	4	8	4
Article source embedding length	8	4	8	4
LSTM size (for each pass)	64	64	64	16
Size of fully connected layers	32	32	64	8
Dropout	0.5	0.5	0.3	0.3

Table 2: Model parameters used for each dataset (SN: Snopes, PF: PolitiFact, NT: NewsTrust, SE: SemEval).

4 Experiments

We evaluate our approach by conducting experiments on four datasets, as described in the previous section. We describe our experimental setup and report our results in the following sections.

4.1 Experimental Setup

When using the Snopes, PolitiFact and NewsTrust datasets, we reserve 10% of the data as validation data for parameter tuning. We report 10-fold cross validation results on the remaining 90% of the data; the model is trained on 9-folds and the remaining fold is used as test data. When using the SemEval dataset, we use the data splits provided by the task's organizers. The objective for Snopes, PolitiFact and SemEval experiments is binary (credibility) classification, while for NewsTrust the objective is to predict the credibility score of the input claim on a scale of 1 to 5 (i.e., credibility regression). We represent terms using pre-trained GloVe Wikipedia 6B word embeddings (Pennington et al., 2014). Since our training datasets are not very large, we do not tune the word embeddings during training. The remaining model parameters are tuned on the validation data; the parameters chosen are reported in Table 2. We use Keras with a Tensorflow backend to implement our system. All the models are trained using Adam optimizer (Kingma and Ba, 2014) (learning rate: 0.002) with categorical cross-entropy loss for classification and mean squared error loss for regression task. We use L2-regularizers with the

Dataset	**Configuration**	***True* Claims Accuracy (%)**	***False* Claims Accuracy (%)**	**Macro F1-Score**	**AUC**
Snopes	LSTM-text	64.65	64.21	0.66	0.70
	CNN-text	67.15	63.14	0.66	0.72
	Distant Supervision	**83.21**	**80.78**	**0.82**	**0.88**
	DeClarE (Plain)	74.37	78.57	0.78	0.83
	DeClarE (Plain+Attn)	78.34	78.91	0.79	0.85
	DeClarE (Plain+SrEmb)	77.43	79.80	0.79	0.85
	DeClarE (Full)	78.96	78.32	0.79	0.86
PolitiFact	LSTM-text	63.19	61.96	0.63	0.66
	CNN-text	63.67	63.31	0.64	0.67
	Distant Supervision	62.53	62.08	0.62	0.68
	DeClarE (Plain)	62.67	69.05	0.66	0.70
	DeClarE (Plain+Attn)	65.53	68.49	0.66	0.72
	DeClarE (Plain+SrEmb)	66.71	69.28	0.67	0.74
	DeClarE (Full)	**67.32**	**69.62**	**0.68**	**0.75**

Table 3: Comparison of various approaches for credibility classification on Snopes and PolitiFact datasets.

fully connected layers as well as dropout. For all the datasets, the model is trained using each claim-article pair as a separate training instance.

To evaluate and compare the performance of DeClarE with other state-of-the-art methods, we report the following measures:

- Credibility Classification (Snopes, PolitiFact and SemEval): accuracy of the models in classifying *true* and *false* claims separately, macro F1-score and Area-Under-Curve (AUC) for the ROC (Receiver Operating Characteristic) curve.
- Credibility Regression (NewsTrust): Mean Square Error (MSE) between the predicted and true credibility scores.

4.2 Results: Snopes and Politifact

We compare our approach with the following state-of-the-art models: (i) LSTM-text, a recent approach proposed by Rashkin et al. (2017). (ii) CNN-text: a CNN based approach proposed by Wang (2017). (iii) Distant Supervision: state-of-the-art distant supervision based approach proposed by Popat et al. (2017). (iv) DeClare (Plain): our approach with only biLSTM (no attention and source embeddings). (v) DeClarE (Plain+Attn): our approach with only biLSTM and attention (no source embeddings). (vi) DeClarE (Plain+SrEmb): our approach with only biLSTM and source embeddings (no attention). (vii) DeClarE (Full): end-to-end system with biLSTM, attention and source embeddings.

The results when performing credibility classification on the Snopes and PolitiFact datasets are shown in Table 3. DeClarE outperforms LSTM-text and CNN-text models by a large margin on both datasets. On the other hand, for the Snopes dataset, performance of DeClarE (Full) is slightly lower than the Distant Supervision configuration (p-value of 0.04 with a pairwise t-test). However, the advantage of DeClarE over Distant Supervision approach is that it does not rely on hand crafted features and lexicons, and can generalize well to arbitrary domains without requiring any seed vocabulary. It is also to be noted that both of these approaches use external evidence in the form of reporting articles discussing the claim, which are not available to the LSTM-text and CNN-text baselines. This demonstrates the value of external evidence for credibility assessment.

On the PolitiFact dataset, DeClarE outperforms all the baseline models by a margin of 7-9% AUC (p-value of $9.12e{-}05$ with a pairwise t-test) with similar improvements in terms of Macro F1. A performance comparison of DeClarE's various configurations indicates the contribution of each component of our model, i.e, biLSTM capturing article representations, attention mechanism and source embeddings. The additions of both the attention mechanism and source embeddings improve performance over the plain configuration in all cases when measured by Macro F1 or AUC.

4.3 Results: NewsTrust

When performing credibility regression on the NewsTrust dataset, we evaluate the models in terms of mean squared error (MSE; lower is better) for credibility rating prediction. We use the

Configuration	**MSE**
CNN-text	0.53
CCRF+SVR	0.36
LSTM-text	0.35
DistantSup	0.35
DeClarE (Plain)	0.34
DeClarE (Full)	**0.29**

Table 4: Comparison of various approaches for credibility regression on NewsTrust dataset.

first three models described in Section 4.2 as baselines. For CNN-text and LSTM-text, we add a linear fully connected layer as the final layer of the model to support regression. Additionally, we also consider the state-of-the-art CCRF+SVR model based on Continuous Conditional Random Field (CCRF) and Support Vector Regression (SVR) proposed by Mukherjee and Weikum (2015). The results are shown in Table 4. We observe that DeClarE (Full) outperforms all four baselines, with a 17% decrease in MSE compared to the best-performing baselines (i.e., LSTM-text and Distant Supervision). The DeClarE (Plain) model performs substantially worse than the full model, illustrating the value of including attention and source embeddings. CNN-text performs substantially worse than the other baselines.

4.4 Results: SemEval

On the SemEval dataset, the objective is to perform credibility classification of a tweet while also producing a classification confidence score. We compare the following approaches and consider both variants of the SemEval task: (i) *NileTMRG* (Enayet and El-Beltagy, 2017): the best performing approach for the *close* variant of the task, (ii) *IITP* (Singh et al., 2017): the best performing approach for the *open* variant of the task, (iii) DeClare (Plain): our approach with only biLSTM (no attention and source embeddings), and (iv) DeClarE (Full): our end-to-end system with biLSTM, attention and source embeddings.

We use the evaluation measure proposed by the task's organizers: macro F1-score for overall classification and Root-Mean-Square Error (RMSE) over confidence scores. Results are shown in Table 5. We observe that DeClarE (Full) outperforms all the other approaches — thereby, re-affirming its power in harnessing external evidence.

Configuration	**Macro Accuracy**	**RMSE**
IITP (Open)	0.39	0.746
NileTMRG (Close)	0.54	0.673
DeClarE (Plain)	0.46	0.687
DeClarE (Full)	**0.57**	**0.604**

Table 5: Comparison of various approaches for credibility classification on SemEval dataset.

5 Discussion

5.1 Analyzing Article Representations

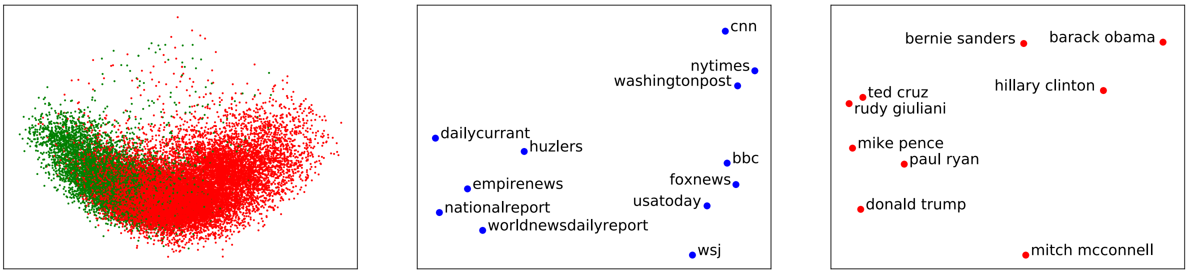
In order to assess how our model separates articles reporting false claims from those reporting true ones, we employ dimensionality reduction using Principal Component Analysis (PCA) to project the article representations (g in Equation 2) from a high dimensional space to a 2d plane. The projections are shown in Figure 2a. We observe that DeClarE obtains clear separability between credible versus non-credible articles in Snopes dataset.

5.2 Analyzing Source Embeddings

Similar to the treatment of article representations, we perform an analysis with the claim and article source embeddings by employing PCA and plotting the projections. We sample a few popular news sources from Snopes and claim sources from PolitiFact. These news sources and claim sources are displayed in Figure 2b and Figure 2c, respectively. From Figure 2b we observe that DeClarE clearly separates fake news sources like *nationalreport*, *empirenews*, *huzlers*, etc. from mainstream news sources like *nytimes*, *cnn*, *wsj*, *foxnews*, *washingtonpost*, etc. Similarly, from Figure 2c we observe that DeClarE locates politicians with similar ideologies and opinions close to each other in the embedding space.

5.3 Analyzing Attention Weights

Attention weights help understand what DeClarE focuses on during learning and how it affects its decisions – thereby, making our model transparent to the end-users. Table 6 illustrates some interesting claims and salient words (highlighted) that DeClarE focused on during learning. Darker shades indicate higher weights given to the corresponding words. As illustrated in the table, DeClarE gives more attention to important words in the reporting article that are relevant to the claim and also



(a) Projections of article representations using PCA; DeClarE obtains clear separation between representations of non-credible articles (*red*) vs. true ones (*green*).

(b) Projections of article source representations using PCA; DeClarE clearly separates fake news sources from authentic ones.

(c) Projections of claim source representations using PCA; DeClarE clusters politicians of similar ideologies close to each other in the embedding space.

Figure 2: Dissecting the article, article source and claim source representations learned by DeClarE.

Table 6: Interpretation via attention (weights) ([*True*]/[*False*] indicates the verdict from DeClarE).

play a major role in deciding the corresponding claim's credibility. In the first example on Table 6, highlighted words such as "..*barely true*..." and "..*sketchy evidence*..." help our system to identify the claim as *not credible*. On the other hand, highlighted words in the last example, like, "..*reveal*..." and "..*documenting reports*..." help our system to assess the claim as *credible*.

6 Related Work

Our work is closely related to the following areas:

Credibility analysis of Web claims: Our work builds upon approaches for performing credibility analysis of natural language claims in an open-domain Web setting. The approach proposed in Popat et al. (2016, 2017) employs stylistic language features and the stance of articles to assess the credibility of the natural language claims. However, their model heavily relies on hand-crafted language features. Rashkin et al. (2017); Wang (2017) propose neural network based approaches for determining the credibility of a textual claim, but it does not consider external sources like web evidence and claim sources. These can be important evidence sources for credibility analysis. The method proposed by Samadi et al. (2016) uses the Probabilistic Soft Logic (PSL) framework to estimate source reliability and claim correctness. Vydiswaran et al. (2011) proposes an iterative algorithm which jointly learns the veracity of textual claims and trustworthiness of the sources. These approaches do not consider the deeper semantic aspects of language, however. Wiebe and Riloff (2005); Lin et al. (2011); Recasens et al. (2013) study the problem of detecting bias in language, but do not consider credibility.

Truth discovery: Prior approaches for truth discovery (Yin et al., 2008; Dong et al., 2009, 2015; Li et al., 2011, 2014, 2015; Pasternack and Roth, 2011, 2013; Ma et al., 2015; Zhi et al., 2015; Gao et al., 2015; Lyu et al., 2017) have focused on structured data with the goal of addressing the problem of conflict resolution amongst multi-source data. Nakashole and Mitchell (2014) proposed a method to extract conflicting values from the Web in the form of Subject-Predicate-Object (SPO) triplets and uses language objectivity analysis to determine the true value. Like the other truth discovery approaches, however, this approach is mainly suitable for use with structured data.

Credibility analysis in social media: Mukherjee et al. (2014); Mukherjee and Weikum (2015) propose PGM based approaches to jointly infer a statement's credibility and the reliability of sources using language specific features. Approaches like (Castillo et al., 2011; Qazvinian et al., 2011; Yang et al., 2012; Xu and Zhao, 2012; Gupta et al., 2013; Zhao et al., 2015; Volkova et al., 2017) propose supervised methods for detecting deceptive content in social media platforms like Twitter, Sina Weibo, etc. Similarly, approaches like Ma et al. (2016); Ruchansky et al. (2017) use neural network methods to identify fake news and rumors on social media. Kumar et al. (2016) studies the problem of detecting hoax articles on Wikipedia. All these rely on domain-specific and community-specific features like retweets, likes, upvotes, etc.

7 Conclusion

In this work, we propose a completely automated end-to-end neural network model, DeClarE, for evidence-aware credibility assessment of natural language claims without requiring hand-crafted features or lexicons. DeClarE captures signals from external evidence articles and models joint interactions between various factors like the context of a claim, the language of reporting articles, and trustworthiness of their sources. Extensive experiments on real world datasets demonstrate our effectiveness over state-of-the-art baselines.

It's going to be okay:
Measuring Access to Support in Online Communities

Abstract

People use online platforms to seek out support for their informational and emotional needs. Here, we ask what effect does revealing one's gender have on receiving support. To answer this, we create (i) a new dataset and method for identifying supportive replies and (ii) new methods for inferring gender from text and name. We apply these methods to create a new massive corpus of 102M online interactions with gender-labeled users, each rated by degree of supportiveness. Our analysis shows wide-spread and consistent disparity in support: identifying as a woman is associated with higher rates of support—but also higher rates of disparagement.

1 Introduction

Despite substantial efforts to reduce gender disparities in online social contexts, gender gaps persist and, increasingly, negatively affect women through online harassment (Duggan, 2017). Online social platforms still serve a critical role for individuals as they seek to fill informational and emotional needs, frequently by interacting with others (Goswami et al., 2010; Chuang and Yang, 2012; Hether et al., 2016). The supportive replies of others help promote personal well-being (MacGeorge et al., 2011), yet unsupportive replies can not only lead to distress but discourage online engagement altogether. Given gender disparity in the receipt of anti-social behavior, to what degree does this disparity persist in individuals' receipt of support? We answer this question, illustrated in Figure 1, by examining supportive and unsupportive message rates across millions of online interactions, using a new computational model of support. Our work is motivated by an agenda of promoting supportive online platforms where people can participate equally.

Comment: `KatieZ22`: I'm nervous about my differential calculus exam next week. My current idea is work through problems on previous exams. But yiiiikes.
∟ **Reply**: `PizzaMagic`: You can ace that test! Your plan seems smart and you have plenty of time to prepare. :)

Figure 1: In this fictitious example, `KatieZ22` receives a supportive reply from `PizzaMagic`. In choosing their names, each user has chosen a particular gender performance, signaling female and gender-anonymity, respectively. In online settings, such gender performances evoke stereotypes that affect how others interact and provide access to online resources. Our study asks what effect does this gender signaling have on individuals receiving support and disparagement?

This work connects with the growing body of computational studies of gender disparity in online behavior (e.g., Lam et al., 2011; Magno and Weber, 2014; Garimella and Mihalcea, 2016; Li et al., 2018); our work here examines this disparity along a new dimension, support, and unlike prior work, examines disparity along the full spectrum of both pro-social (supportive) and anti-social (unsupportive) behaviors. Prior works have also examined the language of support in online support forums for health-related issues (Biyani et al., 2014; Wang et al., 2012; De Choudhury and De, 2014; Althoff et al., 2016; De Choudhury and Kiciman, 2017), often with the aim of improving people's access. Here, we aim to study support in general, everyday interactions, drawing upon theories of how support is expressed in language (Cutrona and Suhr, 1992; Wright et al., 2003).

Our investigation provides four main contributions. First, we introduce a new task of rating the supportiveness of a message and provide an accompanying dataset of 9,032 post-reply pairs with annotations (§2). Second, using this data, we develop a new computational model for automatically identifying supportive and unsupportive replies (§3), using theory-based features that operationalize linguistic strategies for giving support. Third, we develop a new state-of-the-art sys-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 33–45
Brussels, Belgium, October 31 - November 4, 2018. ©2018 Association for Computational Linguistics

tem for classifying the gender of a username (§4) and construct a massive dataset of over 102M post-reply pairs from three online platforms (§5), where participants are labeled by gender. Further, the text of each post is rated for its gender predictiveness, enabling studying gender performance at the name and textual levels. Finally, we apply our support classifier to our social interaction dataset to reveal wide-spread disparity on the basis of gender (§6). Our results show that when gender is performed, female performances are associated *both* with higher rates of supportive comments *and* with higher rates of unsupportive comments, highlighting that gender disparity is not just for negative behaviors online.

2 The Language of Support

Individuals engage in online platforms for a variety of reasons and supportive responses to this engagement can take many forms (Shumaker and Brownell, 1984; Vaux, 1985), from informational support like advice to emotional support like expressions of sympathy. Responders may choose from different linguistic support strategies depending on the speaker and context (Cutrona and Suhr, 1992). For example, given an individual commenting on a Wikipedia talk page about their idea for adding new content, a responder may point to an additional resource they can use, whereas given an individual posting to Reddit for relationship advice, a responder may express sympathy. Our goal is to study the language and behavior of *everyday* supportive or unsupportive interactions as they occur on three large social platforms: Reddit, StackExchange, and Wikipedia. These platforms represent common settings people seek out to engage in discussions and ask for help. Therefore, we annotate a dataset by degrees of support and analyze how linguistic expectations of support manifest in online interactions.

Data and Annotation Post and reply pairs were selected from the three platforms. Many of these interactions are short and therefore to increase diversity, annotated pairs were sampled by balancing by platform and the lengths of posts and replies seen in each.

As a social activity, support is often expressed by drawing upon other social strategies such as politeness (Feng et al., 2013). To help focus annotators' attention on support specifically and disentangle related social cues, we pair our support annotation with contrastive annotation questions for three other related phenomena: agreement (with the post's message), politeness, and offensiveness. Annotators were asked to rate support on a five-point Likert scale from very unsupportive and very supportive, with analogous questions each for agreement and politeness; offensiveness was rated on a five point scale from inoffensive to very offensive.

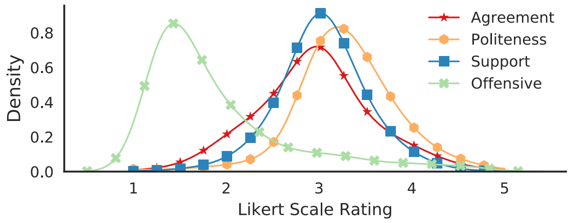

Figure 2: Annotators' rating distributions.

Rating	Example Reply
1.33	see your arse mate, stop talking out of it.
2.0	We dont like your kind.
3.0	I was referring to <link>
3.33	thanks chief.
3.66	Not many people, apparently, but I'm listening!
4.0	Im in as well! Meet up at the Tavern?!
4.33	I like your style!
4.66	Love this. Thank you, more please.

Table 1: Examples of annotator ratings of Support from 1 to 5. Additional examples are in Supplemental §2.

All data was annotated using CrowdFlower with detailed instructions and example replies for each level of the Likert scale. Each task presented five post-reply pairs and with detailed instructions that ask annotators to focus on rating each reply along these four dimensions. Annotators were required to pass a training phase where they had at least 70% agreement with a gold standard annotation on 10 items. After training, each task included one control question, which was used to remove annotators whose agreement with the gold standard fell below 70%.

In total, 9,032 instances were annotated by three annotators, who had a Krippendorff's α of 0.766, indicating substantial agreement on the data (Artstein and Poesio, 2008). Figure 2 shows the distribution of ratings. Support is positively correlated with agreement (r=0.71) and politeness (r=0.51), though annotators rated replies as having more politeness than support on average. Support annotation examples are shown in Table 1. Offensiveness was negatively correlated (r=-0.38) with support.

Analysis Supportive replies can use a variety of strategies for offering support, depending on need

	Strategy	Support	In Top-25%	Example
INFORMATIONAL	Suggestion advice	0.043	16.3%	You might try...
	Referral	0.091	1.3%	Please see [URL]
	Situational appraisal	-0.071^{**}	1.5%	Your situation sounds like...
	Teaching	-0.065^{***}	2.7%	The reason that's happening...
TANGIBLE	Direct offer to do something	-0.020	0.04%	Do you want me to?
	Willingness	0.266^{***}	1.6%	I could help you...
ESTEEM	Compliment	0.337^{***}	23.8%	Great idea!
	Validation	0.248^{***}	27.2%	You're right about...
	Relief of blame	0.490^{***}	1.2%	It's not your fault that...
	Companionship Reminder	-0.089^{*}	0.7%	Your friends and family still...
EMOTIONAL	Sympathy	0.041	0.1%	Sorry to hear that
	Listening	-0.104^{***}	3.1%	Why did you feel...
	Empathy	0.067	0.08%	I know how you feel...
	Encouragement	0.423^{***}	1.6%	Go for it
	Accommodation	0.035	74.7%	
	Emotion	0.081^{***}	27.2%	

Table 2: Support strategies and their presence in our data, as shown through the mean supportiveness rating (-2 to 2) for replies using that strategy and the percentage of posts in the top 25% of the most-supportive that employ the strategy. For supportiveness, posts are compared with all others not employing that strategy, with significance measured using the Mann-Whitney U test. Throughout the paper, *** denotes $p<0.001$, ** $p<0.01$, and * $p<0.05$.

and context. Cutrona and Suhr (1992) proposed a broad taxonomy of support strategies based on in-person interactions, such as offering an appraisal of the current situation or seeking to relieve the other person of blame. We examine to what degree are these strategies employed in online, relatively-anonymous settings and whether their usage online is associated with higher perceived support. To test this, support strategies were automatically identified using a combination of regular expressions for lexical patterns and dependency-parsed trees, together with specialized lexicons matching each strategy and rules for detecting negation. For example, suggestions were detected by identifying a second-person subject with a modal verb indicating possibility (Quirk et al., 1985, p. 219).

Many of the strategies suggested by Cutrona and Suhr (1992) for expressing support in person were also observed online; Table 2 shows the average supportiveness rating for replies containing each strategy, where supportiveness is centered to $[-2, 2]$. Further, their effect on perception of supportiveness, while small, is significant and positive for many. However, we do observe two notable negative trends. First informational support strategies of aiding a person by reassessing their situation (e.g., offering a new perspective) and by teaching were considered less supportive. We observed that in several cases these strategies were employed when an individual was not seeking support, in which case unrequested new information can appear condescending. Indeed, replies employing these two support strategies were still rated polite, 0.30 and 0.31 mean politeness respectively, suggesting the context in which new information is given weighs heavily on whether it is treated as supporting the individual.

Support can also be conveyed implicitly through unconscious stylistic choices. Rains (2016) notes linguistic accommodation is frequently observed in supportive responses, where individuals match the function word frequency of the original communication (Bucholtz and Hall, 2005; Danescu-Niculescu-Mizil et al., 2011). Shown in the bottom of Table 2, we observe only a weak non-significant positive association between support and accommodation (as measured using Danescu-Niculescu-Mizil et al. (2011)), though the single post-reply unit of analysis limits our ability to detect long-term accommodation across multiple dialog turns. Liviatan et al. (2008) and Li and Feng (2014) found that supportive replies often to contain more emotional language, which evokes a personal connection and intensity (Spottswood et al., 2013; Braithwaite et al., 1999). Shown in the bottom of Table 2, we find a significant and positive association where more emotive posts are viewed as more supportive.

Finally, we note that a few strategies suggested by Cutrona and Suhr (1992) were not seen in our annotated dataset. Strategies of offering to participate, using physical affection, assurances of confidentiality, material and financial loans, and prayer were not seen; a broader scan of our unannotated data did find these attested but rare in practice. We attribute this rareness to the public, online nature of the interactions, in contrast to the interpersonal setting studied by Cutrona and Suhr (1992).

3 Computational Model of Support

Our primary objective is to measure the relationship between identity and support in online social systems. Therefore, we next develop a classifier to automatically label replies with support.

Features As a social activity, the language of support draws upon multiple lexical and stylistic cues. We base on classifier on *theory-inspired* and data-driven features. The first set consists of the operationalized linguistic strategies for expressing support, shown in Table 2. Further, in constructing our feature set, we build upon past linguistic analyses of related social-situated language. Wellman and Wortley (1990) note that the availability of support is related to social distance, which is in part expressed linguistically through the degree of formality (Hovy, 1987; Sigley, 1997). Therefore, we include features from Pavlick and Tetreault (2016), which examined linguistic markers of formality. Advice giving is a core component of many theories of support (MacGeorge et al., 2011) and such advice is frequently wrapped in politeness language (Feng et al., 2013), e.g., hedging suggestions rather than imposing direction, which provides face-saving opportunities for the person receiving support (Clark and Schunk, 1980). Therefore, we include the feature set of Danescu-Niculescu-Mizil et al. (2013), which though focused on requests, provides many general lexical patterns for politeness.

Beyond these, we include features motivated by observational studies of support. In analyzing online support groups, Alpers et al. (2005) found that LIWC (Pennebaker and Stone, 2003) was valid as a construct for analyzing messages and compared similarly human judgments about the categories. To capture emotional language (Li and Feng, 2014; Liviatan et al., 2008), we include the NRC emotion lexicons of Mohammad and Turney (2013). Given the informational support strategy, we include lexicons from argumentation for capturing explanatory replies (Teufel, 2000).

Support may be given in response to stressors, which change in nature throughout a person's lifetime (Vaux, 1985; Segrin, 2003). To potentially capture variation in the language of support based on the posting individuals, we include features known to be associated with age such as elongation and capitalization (Goswami et al., 2009; Barbieri, 2008), grammatical differences in sentence construction and length (Hovy and Søgaard, 2015), and a lexicon for age of acquisition (Kuperman et al., 2012).

Data-driven features include (1) lexical features capturing the presence of n-grams, their relative frequency, (2) grammatical features from dependency-parsed triples, which are also backed off to parts of speech, (3) word lexicons for formality, sentiment, and subjectivity, (4) style features such as word and sentence length, complexity, and use of contractions, and (5) the average word vector for the sentence.

In total, our model includes 23,903 features, the bulk of which are n-grams and dependency triples. A detailed listing of all features is provided in Supplemental §1.

One notable feature that we did not include was the presence of self-disclosure in a reply, which has been linked to high-social support as a way of conveying connection and empathy (Wright et al., 2003). While computational models for self-disclosure have been proposed (Bak et al., 2014; De Choudhury and De, 2014), we were unable to scale these methods to the size of our analysis.

Task Setup Support ratings are discretized to create a ternary classification task with labels $\{-1, 0, 1\}$, denoting unsupportive, neutral, and supportive comments. Ratings were discretized by treating all those ratings $\leq$-0.67 as negative and those with a rating $\geq$0.67 as positive.

A Random Forest classifier was trained on all 23,903 features; random forests are robust to overfitting even with large numbers of features, making them suitable for this high-dimensional feature space (Fernández-Delgado et al., 2014). Furthermore, random forests are able to learn conjunctive features, allowing us to learn how combinations of strategies are employed to yield support. As the majority of posts are neutral, we mitigate the class imbalance using SMOTE (Chawla et al., 2002) to generate synthetic examples in the

Model	Macro-F1
Our Model	**0.52**
Bigram Features	0.43
Unigram Features	0.42
Support Features (Table 2)	0.40
Majority	0.29
Random	0.26

Table 3: Support classification performance

training fold using the 5 nearest neighbors, taking care to avoid contamination of the test set. The classifier is implemented using Scikit-learn (Pedregosa et al., 2011) and syntactic processing was done using spaCy (Honnibal and Johnson, 2015). Word vectors are the publicly released Google-News word2vec vectors (Mikolov et al., 2013).

Three works have examined related tasks where Biyani et al. (2014) and Khanpour et al. (2018) classify posts in online cancer support groups as providing informational or emotional support and Wang et al. (2012) classify the degree of support along these dimensions. Here, we solve a more general task that includes unsupportive comments and is in the general domain.

Evaluation We compare our full model for predicting support against three models: our 14 features for detecting support strategies from Table 2, a model trained on the subset of unigram features (4,352), and a model trained on bigram features (8,897), the latter of which is known to be a strong lexical baseline (Wang and Manning, 2012). All models were tested using five-fold cross-validation with Macro-F1 for evaluation and including baselines for labeling instances at random or choosing the most frequent.

Our full model obtains substantial improvements over all baselines and models, as shown in Table 3. Further, the simple support strategy features provide a large and statically-significant improvement over the two baselines. The model using support strategy features performs similarity to the unigram model, despite having two orders of magnitude fewer features. A follow-up analysis on cross-platform performance, described in Supplemental §1.2, showed that while within-platform performance was relatively high (0.54 Macro F1 for Reddit and 0.53 for Wikipedia), performance for the more technical StackExchange site was lower both within (0.44) and across (0.40 when trained on Reddit and 0.42 when on Wikipedia).

Examining our full model's most important features showed that the two support strategies for validation and compliments (cf. Table 2) were the most important features, followed closely by lexicons for emotion: Anger in LIWC, Disgust in NRC, and the positive sentiment in Liu et al. (2005), all of which were motivated by theory. These results confirm that our theory-inspired features are both salient for supportiveness and effective as features.

4 Inferring Gender

As a part of interacting, individuals present a view of themselves as an interlocutor, revealing aspects about themselves such as gender through explicit means (Marwick, 2013; Allen and Wiles, 2016), e.g., profile pictures, or through implicit—and potentially unconscious—cues such as stylistic choices in language (e.g., Eckert and McConnell-Ginet, 2003; Bamman et al., 2014). In the relatively anonymous and deindividuated online setting, these identity cues can have a profound impact on how other perceive and interact with them (e.g., Mickelson et al., 1995; Herring, 2003; Ammari et al., 2014; Megarry, 2014) and these minimal gender cues give rise to full-fledged social stereotypes and, potentially, the negative behavior that comes when treating someone as a stereotype (Kiesler et al., 1984; Lea and Spears, 1991; Postmes et al., 1998; Wang et al., 2009). Here, we develop methods for inferring gender from two signals: (1) names that users chose; and (2) implicit cues conveyed by linguistic features.

4.1 Gender from Names

Prior work has developed models for inferring gender from username alone (e.g., Tang et al., 2011; Liu and Ruths, 2013; Jaech and Ostendorf, 2015; Knowles et al., 2016). Here, we develop a new character-based neural model that incorporates rich gender-labeled username information for identifying additional gender-salience cues in usernames from roles and attributes, e.g., `SuperDad1` or `AspiringActress99`.

Data Individuals convey their gender in multiple ways beyond using gender-associated names. Therefore, to capture this variety, we collect usernames from two online platforms where users have self-declared their perceived gender. First, Twitter usernames and screen names were collected from a 10% sample from 2014 to 2017. Here, we identify usernames whose biography contains an explicit mention of their gender, e.g., by stating a gendered role "mom to two kids" or specifying pronoun preferences "he/him/his." Gendered profiles were collected for 4,900,250 individuals using a selection of lexical patterns with aggressive filtering to remove false positives. Second, we collect 283,427 usernames from Reddit identified through self-declarations of gender in /R/RELATIONSHIPS, e.g., "I [23F] need to talk to my boyfriend [27M]", and 84,068 usernames where the user has chosen a gender-indicating flair (a visual icon displayed within the subreddit). These two sources provide much-needed variation for gender in usernames beyond those mirroring full names.

Model Given a username, we infer gender using a character-based encoder consisting of three stacked LSTM networks (Hochreiter and Schmidhuber, 1997). Following platform restrictions on usernames, character sequences are restricted to being in ascii range and are embedded into 16 dimensional vectors as input. Adopting best practices (Ioffe and Szegedy, 2015), batch normalization is applied prior to the dense layer used to compute the gender prediction. LSTMs were sized at 256 after limited hyperparameter tuning on development data. We optimize with Adam (Kingma and Ba, 2014) with a learning rate of 0.002.

Training and Evaluation All data is partitioned into 80% train, 10% development, and 10% test splits. As some usernames are repeated in different communities, we keep only one unique instance prior to partitioning to avoid leakage between partitions.

Training mini-batches were balanced for both genders, which yielded better performance in tests on the development data. We compare the performance of our model on the test set against two current state-of-art systems available off the shelf for inferring gender from usernames, demographer (Knowles et al., 2016) and Jaech and Ostendorf (2015). Demographer is trained on names from the Social Security Administration and the method of Jaech and Ostendorf (2015) is trained on usernames from OkCupid and uses 3.5M Snapchat usernames for self-learning to improve accuracy.

As shown in Table 4, our model outperforms both systems by substantial margins for both Twitter and Reddit data. In tests on data from both papers reported in Supplemental §3, our model also outperforms their systems. High accuracy is not expected for these models in most domains, as many usernames do not signal gender.

Method	Twitter	Reddit
Our Model	**0.7785**	**0.6299**
Jaech and Ostendorf (2015)	0.7028	0.5935
Knowles et al. (2016)	0.6520	0.5216

Table 4: Gender inference (Macro-F1)

4.2 Gender from Text

Gender can also manifest through more subtle, stylistic cues (e.g., Schnoebelen, 2012; Flekova and Gurevych, 2013; Bamman et al., 2014; Volkova et al., 2015; Garimella and Mihalcea, 2016; Carpenter et al., 2016). Thus, even when a person chooses a neutral username, their linguistic style may reveal their gender. Therefore, we construct a regression model to infer the degree to which either gender is expressed through text.

Data and Model Gender-labeled post data was constructed using held-out data from our three platforms where posts were authored by a user with a high-confidence gender prediction. Posts were randomly sampled across forums (e.g., subreddits) from the held-out data to achieve gender parity with 555K posts for Wikipedia, and 58K for StackExchange; Reddit was subsampled to 1M posts total due to its size.

Features were selected by drawing upon prior work: (i) stylistic features like punctuation and number frequencies, casing, word length and (ii) content features including n-grams, sentiment, and specialized lexicons like LIWC. A full listing of features is reported in Supplemental §1.

Following prior work (Bamman et al., 2014), a logistic regression model was trained for each platform using L2 regression; we adopt separate models for each to better adapt to any platform-specific gender variation.

Evaluation Models were evaluated using AUC with five-fold cross validation, with 0.661 AUC for StackExchange, 0.700 for Wikipedia, and 0.661 for Reddit. The models perform substantially better than random choice (0.5) for the challenging task of inferring gender from a single post, as many posts contain no signal of gender. Additional analyses are reported in Supplemental §1.2.

5 Gender-Salient Interaction Data

To quantify the social support people receive online, we examine communications from three major online communities: Reddit, StackExchange, and Wikipedia. We refer to a communication between individuals as a *post* with a *reply*, defining

	Male	Female	Neutral
Reddit	1,017,455	213,849	1,211,813
SE	2,431,234	289,864	836,531
Wiki.	80,876	14,073	46,954

Table 5: Users with high-confidence or neutral gender

Gender: Female	**Gender: Male**	**Gender: Neutral**
Shanakitty	AdamMcAdamson	kazkeb
cassycas	ChipCarlson11	xuebin671
kelseylenae	BaBa_Dad	ConfigurationalYes
Mrs_BruceWayne	BarryCA67	thelizardof_Oz
madelaine00x	BenJewish	oibird
norma-gaspard	dojoguy	Merpageddon

Table 6: High-confidence and neutral name examples.

these for each platform next.

Reddit Reddit data was selected using a longitudinal sample of one month (July) per year, from 2006 to 2017, and a continuous sample of one full year's data in 2017. Our initial data consists of the top 10,000 subreddits ordered by the total number of posts in the data. From these communities we restrict our analysis to a comment and its first reply, which reduces confounds from multiparty communication. These post-reply pairs were further filtered to remove non-English posts using Google CLD2 (McCandless, 2010), yielding 434.29M candidate communications.

StackExchange StackExchange (SE) contains substantial social interaction in the comment to posts and replies (Ahn et al., 2013; Danescu-Niculescu-Mizil et al., 2013). These communications often expand beyond the immediate topic. Directed communication within these comments is frequently signaled using an explicit mention starting with an "@," which we use to identify pairs. In total, we collected post-reply pairs from the full history of all StackExchange, yielding 3.16M pairs across 162 sites.

Wikipedia Wikipedia features an active social component in its talk pages, with more personal communication–or even personal attacks–during debates around appropriateness or suggested changes (Bender et al., 2011). Similar to Reddit, we construct post-reply pairs by identifying each comment and its first response on a talk page, yielding 26.7M pairs from 387K talk pages.

Assigning Gender All post-reply pairs were labeled using our post classifier (§4.1). Posts with *high-confidence* gender predictions (softmax probability $>$ 0.9 or $<$ 0.1) were labeled with the predicted gender. To contrast the effects of having a gendered name, we construct a complementary dataset where the posting user's username is effectively gender *neutral*, e.g., `user1209`; these neutral names are chosen from those with near-chance probability in the output softmax $0.45 < p < 0.55$. The relative counts of high-confidence and neutral gender names in each platform are shown in Table 5, along with examples in Table 6.

Restricting the dataset to pairs where we have a salient identity, our final dataset for analysis consists of 49.58M, 0.72M, and 3.69M pairs for gender in Reddit, StackExchange, and Wikipedia; and 46.19M, 201.7K, and 1.60M for neutral in each, respectively. Where possible, we also record any high-salience identities for replying users.

6 Gender and Support

The gender cues provided through computer mediated communication provide enough information that a person will fill in the result with a stereotype (Lea and Spears, 1991; Spears and Lea, 1992). What effect might this stereotyping have for access to support? While establishing full causality for an answer is infeasible in our current observational study, we take the first step by quantifying whether disparity in support exists and examine what contextual factors may affect support giving. Using our classifier, we label the 102M post-reply pairs from our dataset (§5), which includes both high-confidence and gender-neutral users.

Model To quantify access to support, we construct separate mixed-effect logistic regression models for predicting the dependent variable of whether a post will receive a supportive reply and for whether it will receive an unsupportive reply. Random effects are added for each community within a platform, which capture the variance in support rates between communities, e.g., due to differences in community norms, topic, or size. As fixed effects, we include a categorical variable for name-inferred gender, always using the gender-neutral condition as the reference coding, which, critically, allows us to examine the changes of support for revealing gender relative to users whose identity is effectively anonymous. We include the predicted probability of a user's gender from their writing (§4.2), centered to $[-0.5, 0.5]$ such that 0 denotes a gender-neutral writing style. Finally, we include interaction terms for writing and names to capture effects of joint gender performance.

Results Three main results are observed. First,

	SUPPORTIVE			UNSUPPORTIVE		
	Reddit	**StackExchange**	**Wikipedia**	**Reddit**	**StackExchange**	**Wikipedia**
intercept	−2.3775***	−2.4729***	−2.9298***	−3.0232***	−4.3734***	−2.9787***
♀name	0.5480***	0.5409***	0.7376***	0.2927***	0.6071***	0.3543***
♂name	0.4652***	0.6639***	0.6422***	0.3230***	0.6445***	0.3313***
♀📝	1.1174***	−1.0778***	0.5261***	0.2520*	0.7398***	−0.1451**
♀name ∧ ♀📝	0.8802***	1.2751***	0.1155	0.2662*	0.0537	0.1695
♂name ∧ ♀📝	0.0535	0.8119***	−0.2070***	0.2016	0.3556*	0.4750***

Table 7: Logistic regression coefficients for predicting whether a post will receive a supportive reply (left) or unsupportive reply (right) on the basis of a gendered name and writing (denoted 📝), with coefficients for name and writing interactions. Name gender is categorical with the reference coding is neutral. The writing coefficient is center at 0 (neutral) with positive values being more female.

the use of a gender-conveying name is associated with both higher rates of supportive comments and unsupportive comments. Our results agree with those from the small scale study of Feng et al. (2013) who found that accounts with human pictures and person-sounding usernames receive higher social support. Indeed, while several studies have touted the benefits of anonymity online for discussing sensitive topics (Campbell and Wright, 2002; Wright, 2002a,b), our results suggest that selecting a gender neutral name may lead to lower support overall. Our findings also reinforce the observation that the personal-anonymity online does not lead to equal support due to cues about identity (Postmes and Spears, 2002).

Second, the rates of supportive and unsupportive comments are significantly associated with *both* kinds of gender performances (i.e., names and writing style). These results suggest that online audiences are sensitive to both kinds of overt and implicit gender displays and that even innocuous choices such as gendered usernames can shape our online interactions.

Third, when gender is performed in together name and writing, female performances are consistently associated across all three platforms with higher rates of receiving supportive replies and unsupportive replies. Note that this trend is seen in the cumulative effect on support after combining coefficients for the interactions term with the coefficients for writing and name. We illustrate this cumulative effect for two types of gender performances in Reddit, shown as separate axes in Figure 3. Indeed, when a user has a gendered username, the cumulative effect of male writing performance is consistently associated with fewer supportive replies. In small-scale interpersonal studies, Abbey et al. (1991) and Barbee et al. (1993) note men are more likely to receive unsupportive comments; however, we did not observe this disparity in our online setting.

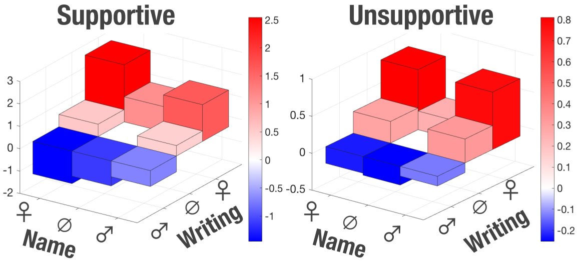

Figure 3: Cumulative effect of name and writing performances on the log-odds coefficients for receiving comments of each type in Reddit when the gender is maximally performed (cf. Table 7), excluding the intercept effect for clarity (∅ denotes neutral performance). Positive values (red) denote increased comment frequency and negative values (blue) show decreased frequency. This plot shows that as female performance becomes more salient (shown bottom to top visually), such users receive increasingly-higher rates of supportive and unsupportive replies in Reddit.

Does the replier's gender matter? Mickelson et al. (1995) note that men and women differ in *how* they receive support, with the gender composition of the interacting pair driving the kind of supportive behavior. Here, we examine whether men and women differ in the *rates* they give support to one another, using gendered names as a proxy for identity. Because only Reddit has sufficient data, we construct a mixed-effect regression model for Reddit using the 4.5M post-reply pairs where the replier has a high-confidence or neutral gender and include the replier's gender as a factor with interactions for the poster. The results shown in Table 8 reveal two main conclusions. First, men and women give supportive comments at different rates, with women being far more likely to leave supportive replies and less likely to leave unsupportive replies. Second, the interaction terms show that there is minimal dyadic interaction between the gender identities of the poster and replier with

	Sup.	Unsup.
intercept	-2.391^{***}	-3.107^{***}

P:♀name ∧ P:♀📝 ∧ R:♂name	0.329	0.312
P:♂name ∧ P:♀📝 ∧ R:♀name	0.067	0.178
P:♂name ∧ P:♀📝 ∧ R:♂name	0.024	0.203

Table 8: Regression coefficients for Reddit when the gender identity of the replier is known. The post author's identity is denoted with a P and replier's with R.

respect to rates of giving supportive or unsupportive comments. We only observe significant interactions indicating (1) replying users with female names are *less* likely to leave supportive replies to posting users with female names and (2) replying users with male names are *i*) *more* likely to leave supportive replies to other users with male names, *ii*) *less* likely to leave supportive comments if the writing appears more female, *iii*) *more* likely to leave unsupportive comments if the posters name is female, and *iv*) *less* likely to leave unsupportive comments if the writing appears more female.

Limitations The observations of our study should still be viewed within its practical limitations, of which we note two. First, in examining the content of replies, we do not control for potential direct or indirect requests for help in text that may ultimately affect the rates of support. This issue could be a potential confound, as the cultural norms for masculinity often promote self reliance (Addis and Mahalik, 2003), ultimately leading to gendered differences in requests. Second, this observational study cannot establish causality between gender displays and support; while the disparity is real, exogenous factors could potentially explain the disparity without finding gender displays as a cause, though the mixed effects still control for some contextual variability in the different support frequencies across communities. In spite of these limitations, we view this work as an important first step for demonstrating gender disparity in support—both positive and negative—and inviting future work to establish a causal explanation.

7 Ethical Considerations

The use of gender as a variable in NLP requires that we also discuss ethical considerations resulting from this work, as it directly relates to identity and the dignity of persons being studied. Following the guidelines of Larson (2017) for using gender in NLP, our use of gender is intentional and central to this study on gender disparities in received support. We base our notion of gender as one of linguistic performance (DeFrancisco et al., 2013), in which individuals adapt their style and name to emphasize or de-emphasize certain aspects of their gender identity (Eckert, 2008). Accordingly, we have opted represent gender performance along a graded scale, though we recognize that this representation does not capture non-binary gender identities.

The gender inference methods introduced here raise ethical considerations as they ultimately enable automatic identification of gender for any person on the basis of name or writing (Hamidi et al., 2018). Such technology could be used to unfairly identify and target persons of either gender for malicious behavior or may harm through misgendering individuals. Ultimately, we decided that such risk was acceptable given the positive impact of our study on revealing gender disparity. We hope to also use our method to better support privacy-preserving behavior (Allen and Wiles, 2016; Reddy and Knight, 2016) by helping individuals identify and change names or statements that would indicate a particular gender. Further, we hope that when used in combination with our support classifier and a larger context of gendered interactions (Voigt et al., 2018), these technologies can identify healthy communities that are supportive of all people.

8 Conclusion

Individuals use social media to support their informational and emotional needs. Our study has shown wide-spread disparity in the levels of support individuals receive on the basis of their perceived gender. Our results were made possible through the development of a new massive 102M post-reply dataset tagged with high-salience and neutral gender and the introduction of a new task, annotated dataset, and model for classifying supportive messages. All data, code, and annotation guidelines are publicly released at `https://github.com/davidjurgens/support`.

Acknowledgments

The authors would like to thank Sarita Schoenebeck, Eric Gilbert, and Libby Hemphill for their helpful feedback and the anonymous reviewers for their comments and suggestions. The authors gratefully acknowledge the Volkswagen Foundation for their support in part of this work.

Abstract

Gang-involved youth in cities such as Chicago have increasingly turned to social media to post about their experiences and intents online. In some situations, when they experience the *loss* of a loved one, their online expression of emotion may evolve into *aggression* towards rival gangs and ultimately into real-world violence. In this paper, we present a novel system for detecting Aggression and Loss in social media. Our system features the use of domain-specific resources automatically derived from a large unlabeled corpus, and contextual representations of the emotional and semantic content of the user's recent tweets as well as their interactions with other users. Incorporating context in our Convolutional Neural Network (CNN) leads to a significant improvement.

1 Introduction

In cities such as Chicago, gang-involved youth have increasingly turned to social media to post about their experience, often expressing grief when friends or family members are shot and killed. As grief turns to anger, their posts turn to retribution and ultimately to plans for revenge (Patton et al., 2018b). Research in this space has shown that online posts often affect life in the real world (Moule et al., 2013; Patton et al., 2013; Pyrooz et al., 2015; Patton et al., 2016, 2017a). In some communities, violence outreach workers manually scour online spaces to identify such possibilities and intervene to diffuse situations. A tool that identifies Aggression or Loss posts could help them filter irrelevant posts, but resources to develop a tool like this are scarce.

In this paper, we present automatic approaches for constructing resources and context features in this domain, and apply them to detecting Aggression and Loss in the social media posts of gang-involved youth in Chicago. We exploit both a small labeled dataset (4,936 posts) and a much larger unlabeled dataset (approximately 1 million posts), which we constructed using a method that enabled us to gather Twitter posts representative of the community we study. We incorporate our approaches into a CNN system, as well as a Support Vector Machine (SVM) to match the architecture of prior work, thus enabling analysis of the impact in different frameworks[1].

Key features of our system are the use of domain-specific word embeddings and a lexicon automatically induced from our unlabeled dataset. When classifying an individual tweet, our system considers the content and emotional impact of the tweets in the author's recent history. If applicable, our system additionally takes into account a model of the pairwise interactions between the author and other users in the tweet referenced via either retweet or mention.

We compare our approaches with previous work that used a smaller dataset (800 tweets) and hand-curated resources with an SVM (Blevins et al., 2016). By integrating our induced domain-specific and context information in a CNN, we achieve a significant increase over their reported results.

Our contributions include:

- A new labeled dataset, six times larger than that of prior work;
- Domain-specific resources, automatically induced from our constructed unlabeled dataset;
- Context features that capture semantic and emotion content in the user's recent posts as

well as their interactions with other users in the dataset.

Our approach brings us one step closer to building a useful tool that can help reduce gang violence in urban neighborhoods. In the remainder of the paper, we present related work, the dataset that we used, and our methodology. We conclude with an error analysis and a discussion of the impact of our contributions.

2 Related Work

Researchers have begun to explore how online data can be used to help prevent gun violence. Pavlick et al. 2016 are creating the Gun Violence Data Base by crowdsourcing annotations on newspaper articles that report on gun violence, labeling the sections of text that report on incidents, the shooter, and the victim. Researchers have also explored identifying deaths from police shootings with semi-supervised methods for both CNNs and logistic regression (Keith et al., 2017) and found that logistic regression using a soft-labeling approach gave the best results. Researchers studying gun control issues analyzed social media for posts related to any issue around guns in the year following the Sandy Hook elementary school shooting (Benton et al., 2016) and argued that online media can be used to understand trends in gun violence and gun-related behaviors (Ayers et al., 2016).

Closely related research aims to automatically identify gang members' Twitter profiles (Balasuriya et al., 2016). After collecting profiles using bootstrapping, they trained different classifiers on the tweets and meta-information about the authors. Further research analyzes the social networks of gangs (Radil et al., 2010) and predicts gang affiliation based on the analysis of graffiti style features (Piergallini et al., 2014).

The most relevant work in automatically analyzing social media posts by gang-involved youth is that of Blevins et al. 2016. The labeled dataset that Blevins and collaborators used is extremely challenging, in part due to its size, but also because it contains text in a particular dialect of English – African American English (AAE) – which has very little core NLP tool support. Other research investigating the development of tools for understanding AAE in social media (Blodgett et al., 2016) shows that existing tools (e.g., dependency parsers) perform poorly on this language. Previous work by Patton on a subset of our dataset notes that due to the linguistic style, tweets from gang-involved youth in Chicago can be challenging for outsiders to interpret and thus are often open to misinterpretation and potential criminalization (Patton et al., 2017b).

The challenges of interpreting our data are further compounded by the usual difficulties with Twitter data. Twitter data is sometimes handled by translating it to Standard American English (SAE) through the use of a phrasebook. The NoSlang Slang Translator (NoSlang, 2018b), and the accompanying NoSlang Drug Slang Translator (NoSlang, 2018a), have been used in other tasks to translate social media communication (Sarker et al., 2016), (Han and Baldwin, 2011).

To engineer features for an SVM classifier, Blevins et al. 2016 learned a part-of-speech (POS) tagger for their data and constructed a word level translation phrasebook to map emojis and slang to the Dictionary of Affect in Language (DAL) in order to identify their emotion.

In contrast to Blevins' translation approach, we leverage our large unlabeled dataset to automatically induce resources, such as word embeddings, that function well within the domain of our task. Previous research on domain-specific word embeddings includes work in cybersecurity (Roy et al., 2017), disease surveillance (Ghosh et al., 2016), and construction (Tixier et al., 2016). These domain-specific word embeddings tend to improve performance on tasks within that domain.

Context has been used in previous research on detecting hate speech in social media. Qian et al. 2018 found significant improvements by collecting the entire history of a user's tweets and feeding them to a encoder to create an intra-user representation, which was used as input to a Bidirectional LSTM. They also used a representation of tweets similar to the tweet being classified. While their approach captures a user profile based on everything the user has posted, in our approach we investigate how the recent history of tweets and interactions with others can improve classification. Others also make use of a user profile, though not one learned from unlabeled data (Dadvar et al., 2013).

3 Data

Our dataset consists of two parts: first, a collection of 4,936 tweets authored or retweeted by Gakirah Barnes, a powerful female Chicago gang member, and her top communicators, as well as additional Twitter users in the same demographic, annotated by social work researchers who have been studying Gakirah and the associated Chicago gangs. Second, we use a much larger collection of approximately one million unlabeled tweets automatically scraped from 279 users in the same social network. This social network is comprised of 214 users snowball-sampled from Gakirah Barnes' top 14 communicators. Traditionally, snowball sampling has been used to recruit hard-to-reach research subjects (Atkinson and Flint, 2001) and we have adapted it for social media. The remaining 65 users were added to this network by retaining those with the highest IQI score [2] from the full list of Gakirah's Twitter followers. Our tweets thus form a representative sample of Twitter dialogue between youth from Chicago neighborhoods with high levels of gang activity during that time period.

Table 1: Example tweets

No.	**Tweet Text**	**Label**
1	#FreeDaDommmmm [URL]	Loss
2	Damn juss peeped shorty on tha news out here @USER ..smh.. crazyy.. #RIPShorty	Loss
3	I'm smokin on Dat DMoney man Im high as fuck	Aggress
4	Lost Ty to Sum Fuck Shit dont Fuck around wit Fuck rounds n u a type of Niggas Ion fuck wit 👿💯	Loss
5	My bro Mooki thirsty he jus wana 👏 sum 💩 🔫 😈 💯	Aggress

The social work researchers performed a detailed, qualitative analysis of a subset of the dataset, with a focus on analyzing how context influences determination of a label. For example, they note that an aggressive tweet may reference a previous event, and will often use coded language to do so. Since much of the language used in our data differs significantly from standard American English, local youth active in similar environments served as consultants to answer questions about the language, as they were able to interpret the slang terms present in these tweets. The social work researchers conducted a fine-grained analysis using an online tool for annotation, identifying insults, threats, bragging, hypervigilance and challenges to authority, all of which were collapsed into a single category, Aggression. Posts including distress, sadness, loneliness and death were collapsed into the category Loss. The Other category includes discussion of other aspects of their life, such as friendships, relationships, drugs, general conversations, and happiness. We developed our system (as did Blevins et al. 2016) on the collapsed labels, as the task is difficult even with three-way categorization.

Each tweet in a subset of the entire dataset consisting of 3,000 tweets was reviewed by two different annotators. Inter-rater reliability between raters was tracked, with dissimilar annotations flagged for further review. Flagged tweets were further analyzed by the social work researchers, which included youth from Chicago who currently live in the same community as, or an adjacent one to, that in which the deceased Gakirah Barnes resided, to adjudicate disagreement. Among the set of tweets coded by two annotators, inter-annotator agreement on the Aggression class was high even before adjudication, with a Cohen's kappa coefficient of .94; agreement on the Loss class was somewhat lower, with a Cohen's kappa of .83. Examples of labeled Twitter posts from Gakirah and her followers are shown in Table 1 [3].

In order to mitigate potential issues with training and test data being drawn from different time periods or having different distributions of labels, we shuffled our data and drew stratified samples with equal distribution across classes for our training, validation, and test sets for each of the cross validation folds, using 64%, 16%, and 20% of our data for each respectively. The Aggression and Loss classes are relatively small, reflecting their low distribution in real life: we have only 329 Aggression tweets and 734 Loss tweets, with the Other class comprising the remaining 3,873 tweets.

4 Methods

We approach this classification task using a standard CNN classifier architecture (Kim, 2014; Collobert et al., 2011) as our starting point. We initially experimented with both character and word level CNNs but found the word level to be 1.6 macro-F1

---

[2] https://www.brookings.edu/wp-content/uploads/2016/06/isis_twitter_census_berger_morgan.pdf

[3] Our data was scraped from publicly available posts and was determined exempt by our organization's IRB. User names are replaced with USER in the table, and text has been modified to render tweets unsearchable.

points better than the character level, so we only include the word level here. We leveraged the unlabeled corpora by constructing domain-specific embeddings and a lexicon that better fit our unique and low-resource domain. We then integrated our domain-specific resources into the CNN to represent the given tweet as well as to represent context features. Our context features represent a window of the user's recent tweets as well as the interactions of the author with other users via references in their tweets.

4.1 Domain-Specific Resources

We exploited the large unlabeled corpus to build two domain-specific resources for this task: word embeddings and a task-specific lexicon.

4.1.1 Word Embeddings

Word embeddings have proven useful in representing the semantic content of sentences. The semantic representation of a word by its associated embedding, however, depends on its usage in the corpus the embedding was trained on, and so off-the-shelf word embeddings do not always adapt well to tasks with a unique domain (Roy et al., 2017), (Ghosh et al., 2016), (Tixier et al., 2016). Thus, we were motivated to use our unlabeled corpus to create domain-specific word embeddings. We used the Word2Vec (Mikolov et al., 2013) CBOW model to train the embeddings which is the default training algorithm available in Gensim [4]. We used a window size of 5 words with a minimum word count of 5 to train $w \in \mathbb{R}^{300}$. The CBOW model was trained for 20 epochs.

4.1.2 Computing a Lexicon of Aggression and Loss

Given the domain-specific nature of our users' language, we could not rely on standard NLP lexicons to represent emotion in their tweets. For our task, the two emotions of interest are Aggression and Loss. Previous work (Blevins et al., 2016) used a phrasebook to translate the domain-specific words of their corpus to Standard American English so that they could access emotion in the Dictionary of Affect in Language (DAL) (Whissell, 2009), but this approach does not generalize to capture new words.

We therefore adapted the SENTPROP algorithm (Hamilton et al., 2016) to automatically induce a lexicon of Aggression and Loss from our unlabeled corpus. The SENTPROP algorithm constructs a lexical graph out of the word embeddings, then propagates labels from the seed sets over the unlabeled nodes via a random walk method. The resulting output for each word indicates the probability of a random walk from the seed set landing on that node. We chose SENTPROP as an induction method because it performs especially well for domain-specific corpora, and it is resource-light and interpretable.

We created word embeddings by employing an SVD-based method that was reported by the SENTPROP authors to perform optimally with their algorithm. We first constructed the positive point-wise mutual information matrix, M^{PPMI}, over the unlabeled corpus, then computed singular value decomposition (SVD) to derive $M^{PPMI} = U\Sigma V^{\intercal}$. The word embedding for word w_i was thus given by U_i, truncated to a standard length of dimension 300. To construct our seed sets, we asked our annotators to consider words for Loss and Aggression which they associated most strongly with each class. They generated a set of 29 words for Aggression and a set of 40 words for Loss, which we include in our appendix.

We ran SENTPROP with our SVD-based embeddings and the seed sets from our annotators. We used the output probabilities from the random walks to map words to their association with Aggression and Loss, thus forming our lexicon of Aggression and Loss. Finally, we scaled the probabilities per class to mean 0 and variance 1.

4.2 Context Features

Our context features utilize the domain-specific resources that we induced from the unlabeled corpora. To capture context, we first considered the author's recent history, separately exploring representations by our domain-specific word embeddings and by the SENTPROP lexicon (SPLex). If applicable, we also considered the interactions between the author and other users who were referenced in the tweet, either via retweet or mention.

4.2.1 User History

To obtain the user's recent history, we ordered all the tweets chronologically and bucketed them by author. Thus, for any given tweet occurring at time t, a_t, we were able to retrieve previous tweets $a_{t-1}, a_{t-2}, \ldots$ by that user. We treated recent history as a sliding window and fetched tweets within

---

[4] `https://radimrehurek.com/gensim/models/word2vec.html`

the past d days from when the current tweet was tweeted, such that recent history tweets would be the set $\{a_{t-1}, \ldots, a_{t-k}\}$, where $t - k < d$.

To represent the tweets within the context of recent history, we first combined word level representations into tweet level, then tweet level representations into context level. At each stage of combination, we tried both summing and averaging. Thus, our recent history representations were built by aggregating either word embeddings or SPLex scores, which maintained their dimensionality of 300 or 2, respectively.

We also considered three types of tweets that would be relevant to a user. The user's own tweets (`SELF`) would always be relevant; we experimented with also including tweets where the user was retweeted (`RETWEET`) and tweets where the user was mentioned (`MENTION`). We included these parameters as additional sources of context because a user's tweet may be a response to a recent mention or retweet from another user.

We also experimented with weighting the most recent tweets more heavily than further tweets within the recent history window. This became especially important when we experimented with larger windows of a month or more, since tweets from a few days ago are more likely to be related to the current tweet than tweets from a few weeks ago. To model this diminishing relevance, we introduced a weighting protocol with a variable half-life where weights decay exponentially over time. The parameter we tuned was the half-life ratio r, which is the proportion of the window size d that corresponds to the window's half-life. Then, before combining tweet level representations into context level, we multiplied each tweet representation b_i by its weight, $2^{-\frac{\Delta t}{f}}$, where $\Delta t = t - i$ is the distance in days between the context tweet a_i and the current tweet a_t, and $f = d * r$ is the half life.

4.2.2 User Interactions

As an additional context feature, we modeled the pairwise interactions between users. To identify interactions, we iterated through our unlabeled and labeled corpora and checked which users were involved in each tweet. We counted a user as involved in a tweet if they posted the tweet or were referenced via retweet or mention. For each pair of users, we aggregated all their tweets of mutual involvement into one document and averaged the document's word embeddings to create a representation of their pairwise interactions in $\mathbb{R}^{300}$.

5 Experiments

We experimented with the efficacy of our domain-specific resources, the impact of different context parameters, and the contribution of context to predicting Aggression and Loss.

5.1 Corpus pre-processing

For word level models, we preprocess each tweet by: i) lowercasing every character, ii) replacing every user mention and url with special tokens "user" and "url", iii) considering each emoji an individual token, whether space separated or not, and iv) removing emoji modifiers to reduce sparsity, just as we used lowercasing. We select the top 40K tokens based on frequency, replacing the remaining tokens with "UNKNOWN". We zero-pad or trim tweets so that tweet length will be 50 when passed to our CNN model. Similarly, we only consider users who occur (as author, source of retweet, or in mention) in the labeled and unlabeled corpus at least twice, resulting in 35,656 users in total.

We extract the author of the tweets from metadata, and user mentions and original posters of retweets from the Twitter text, based on their Twitter display name. We used Twitter display name rather than user ID because we cannot collect user ID for interaction features.

5.2 CNN Architecture

For this 3-way classification task, we train two models; the first model predicts whether a tweet has the Aggression label and the second predicts for Loss. Each model maps a sequence of tokens to a probability value for a class. Here we define the architecture of our CNN model. Our input c is a token index sequence of length 50. We map each token index to a vector $\in \mathbb{R}^{300}$ with a trainable embedding matrix, followed by dropout 0.5. We apply a 1D Convolutional layer with kernel sizes 1 and 2, filter size 200 each, to the embedded token sequence, followed by ReLU activation, max pooling and dropout 0.5. We concatenate the output of max pooling for kernel sizes 1 and 2, stack another dense layer h with dimension 256, and connect the output of h to the final single output unit with sigmoid activation.

In the prediction phase, for each data point, we classify it as Aggression if the the first model produces the probability score above threshold t_A. If it is not predicted as Aggression, then we classify it as Loss if the second model produces a score above a threshold t_L. The remaining tweets are classified as Other. t_A and t_L are tuned on the validation set.

We incorporate context information into the neural network in the following way. Each type of context feature takes the form of a real vector: both word embedding user history and word embedding user interaction features are in $\mathbb{R}^{300}$, and SPLex user history features are in $\mathbb{R}^2$. We concatenate these feature vectors with the last layer h before the final classification output.

5.3 SVM Baseline

We used as our baseline method a linear-kernel SVM classifier as used by Blevins et al. 2016. We obtained code from the authors and trained on our larger dataset. In this method, after basic preprocessing is performed to replace urls and user mentions with special tokens, unigram, bigram, part-of-speech tag, and emotion features are extracted. Feature selection is performed to prune the feature space. The part-of-speech tagger used in Blevins et al. 2016 was developed for use on this domain; emotion features are computed using scores for each tweet word taken from the Dictionary of Affect in Language (DAL). We performed gridsearch to re-tune the loss function, the regularization penalty type, and the penalty parameter C, but found that the original settings for these parameters still performed best even on our new development set. We also tuned the class weights used: while the model performed best on the original data with balanced class weights, we found that less extreme balancing performed better here (weights 2, 1, and 0.12 for Aggression, Loss, and Other, respectively).

While we retrained the SVM on our new training set, we did not modify the additional components used for feature selection such as the phrase table or the specialized part-of-speech tagger, as we had no additional data available for this. This indicates the difficulty of generalizing to new data with unseen vocabulary, and is one of the disadvantages of using manually-created specialized feature sets such as these.

5.4 Domain Experiments

In order to test the efficacy of our domain-specific word embeddings, we compared them with a number of other embedding types. Our baseline method was Pennington et al. 2014's GloVe embeddings pretrained on a general Twitter dataset, available from their website[5]. We trained a parallel set of word embeddings on the African American English (AAE) corpus of around 1.1 million tweets provided by Blodgett et al. 2016, and another set on a corpus of a location-specific set of tweets that we scraped, drawn from users who posted from a specific area within the South Side of Chicago where the gangs we study are based. We also compared performance with a randomly initialized word embedding matrix.

5.5 Context Experiments

We first explored the impact of the user history parameters, tuning them separately for representations by our domain-specific word embeddings and by SPLex. We kept these representations separate because we expected them to capture different types of context: word embeddings should capture the semantic content of the user's history, while SPLex scores should capture something closer to the user's emotional state leading up to the tweet.

With each representation, we experimented with summing versus averaging word embeddings to yield a tweet level representation, and similarly experimented with summing and averaging from tweet embeddings to context level representations. We varied the size of the context window, d, trying 2 days, 1 week, 1 month, 2 months, and 3 months. We also varied the half-life ratio, r = .25, .5, .75, or no weighting. Lastly, we tried including different types of posts in the user history.

Once we tuned the user history parameters, we experimented with adding our context features (user history and user interactions) to the best tweet level model we could achieve without context. For our CNN, our best tweet level model used our domain-specific word embeddings as pretrained weights for the embedding layer (CNN-DS in Table 3). To evaluate the impact of our resources in different frameworks, we additionally experimented with the contribution of context in an SVM. The best tweet level SVM included the averaged domain-specific word embeddings and summed SPLex scores of the tokens in the tweet (SVM-DS).

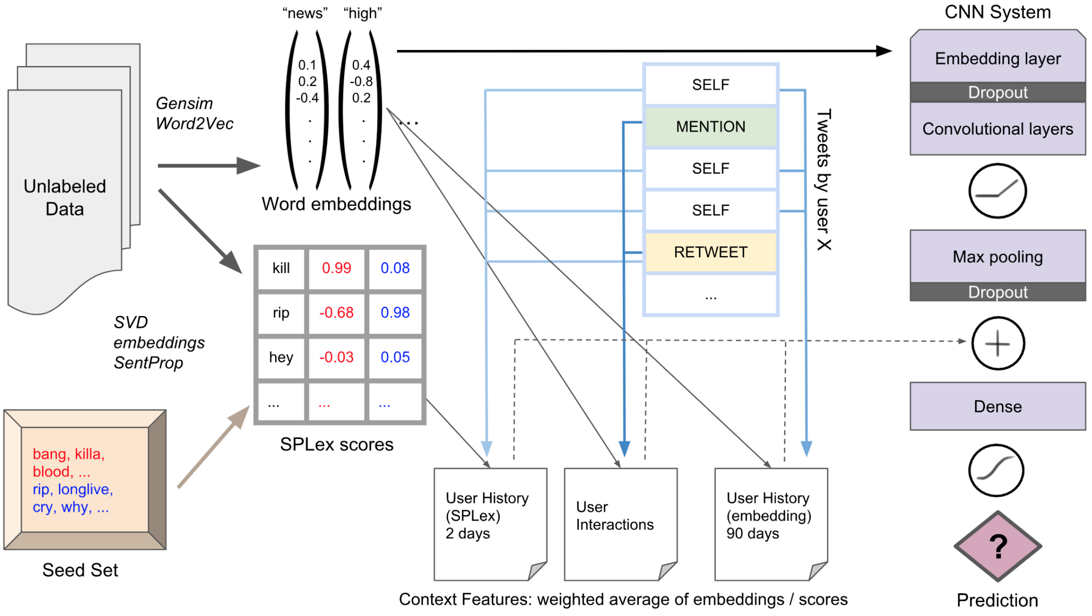
6 Results and Discussion

We report results comparing different embeddings and comparing parameters for context. We use the best results from these experiments to produce our

---

[5] `https://nlp.stanford.edu/projects/glove/`

Figure 1: Diagram of our steps to generate domain-specific and context features for our neural net system.



final systems in the SVM and CNN frameworks. The best resulting architecture for the CNN framework is illustrated in Fig. 1.

6.1 Comparison of Embeddings

Experiments were performed using five-fold cross-validation over the labeled data and were repeated five times for each fold to account for variance between runs. Reported F-scores, shown in Table 2, are averaged across runs and across folds.

Word embeddings trained on our unlabeled corpus outperformed other embeddings by over 4 points. Related datasets such as the location-specific or AAE corpus did not provide helpful semantic information, as their embeddings did not even beat random initialization. This was not an effect of corpus size, since these corpora contained 800,000 and 1.1 million tweets, respectively, compared to the 1 million in our unlabeled corpus. Thus, we attribute the difference to the importance of deriving embeddings directly from our community of interest, demonstrating that the language of our community is more specific than AAE in general and that our snowballing method was able to capture a better representation of user language than a location driven method.

6.2 User History Parameters

Experiments were performed using five-fold cross-validation and F-scores computed as in the word embedding experiments. We found that user history represented by domain-specific word embeddings performed optimally when we averaged from word to tweet level and from tweet to context level. The best window size was $d = 90$ days, including only `SELF` posts, and using a half-life ratio of $r = 0.25$. For user history represented by SPLex, we found the best method of combination to be summing, at both the word and tweet level. We hypothesize this is because summing captures not only the presence but also the number or density of highly indicative Aggression or Loss words posted by the user over the context window. The best window size was $d = 2$ days, including both `SELF` and `RETWEET` posts, without half-life weighting.

Our approach was designed to implement and

Table 2: Results comparing different embeddings with CNN. GN refers to Google News, LS to location specific embeddings, GT to Glove Twitter embeddings, and DS to our domain specific embeddings. A, L and O refer to Aggression, Loss, and Other respectively.

Embeddings Type	F1			Macro F1
	A	L	O	
GN	27.9	66.6	86.9	60.5
AAE	27.3	69.8	86.5	61.2
LS	31.3	68.3	87.9	62.5
Random Init.	29.3	70.5	88.9	62.9
GT	29.0	71.1	89.0	63.0
DS	**37.9**	**73.4**	**90.3**	**67.20**

Table 3: Comparison of different models. The below pairs of algorithms achieve statistical significance $p < 0.002$ for each class (the higher performing algorithm comes first): i) CNN-Context vs. CNN-DS; ii) CNN-DS vs. SVM-Retrained; iii) SVM-Context vs. SVM-DS. SVM-Context outperforms SVM-Retrained in the Aggression class by a robust margin (5 points).

Model	Aggression			Loss			Other			Macro F1
	P	R	F	P	R	F	P	R	F	
SVM-Retrained(baseline)	36.4	31.3	33.7	73.7	68.8	71.2	89.8	**92.0**	90.9	65.3
SVM-DS	32.4	38.9	35.4	66.9	72.9	69.8	90.8	87.7	89.2	64.8
SVM-Context	35.0	43.7	38.8	68.6	74.0	71.2	**91.6**	88.2	89.9	66.6
CNN-DS	35.7	41.1	38.2	**78.9**	70.3	74.3	90.7	91.4	91.0	67.9
CNN-Context	**38.3**	**46.4**	**42.0**	78.8	**73.2**	**75.9**	91.3	91.7	**91.5**	**69.8**

test previous insights about the domain, particularly that context plays a role in the interpretation of posts. The short time frame for SPLex user history corresponds with the 2 day window found in Patton et al. 2018b's research and reflects the fact that emotional states may fluctuate often and within a certain number of days. In contrast, word embeddings improved consistently as we extended the context window from 2 days to 90 days. Since word embedding user history is meant to capture the user's semantics, a larger window size means the representation can be drawn from more tweets, and thus reflects a more representative sample of the user's semantics around this time period.

6.3 Comparison of Best Systems

To develop a more stable measurement of comparison between different systems, we create four independent sets of 5-fold cross validation splits on our data set (altogether 20 folds); to account for randomness in neural net training, we train each neural net model 5 times and take the majority vote of the predictions. For each class, we calculate the statistical significance of F-score based on the predictions on the concatenated test sets of all 20 folds using the Approximate Randomization Test (Riezler and Maxwell 2005) with the Bonferroni correction for multiple comparisons. Results are shown in Table 3.

Adding context contributed to a significant improvement in both the CNN and SVM frameworks, demonstrating the independent value of our context features over domain-specific resources. For contrast, we also compared our context features with user profiles built from averaging the word embeddings in all of the user's tweets. Our pairwise and user history features outperformed user profiles by .7 points, demonstrating that it is valuable to provide dynamic representations of users that can adjust to their recent posts or their interactions with other users, as opposed to stereotyping their overall behavior.

Additionally, we compare the impact of our domain-specific resources to those used by Blevins et al. (2016). In particular, we expect that their emotion scores will not generalize to the new vocabulary in our large unlabeled corpus (see Section 4.1). Our domain-specific resources alone without context raise our SVM to comparable performance with the Blevins et al. retrained baseline, and the resources push our CNN without context over this baseline. This demonstrates that our automatic methods can do as well as if not better than phrasebook methods, and they are significantly more efficient to generate.

7 Error Analysis

In this section we provide an analysis of the tradeoffs of each classifier by analyzing some of the examples in Table 1.

Context vs non-context CNN. Our best CNN - a system which incorporated context - was able to correctly predict tweets 3 and 4, whereas our baseline using only our pretrained Word2Vec embeddings was not. Correctly classifying tweet 4 relies on the knowledge that the referenced user, DMoney, is a deceased member of a rival gang of the poster. In tweet 3, the poster is saying that he has seen Gakirah's death on the news; this is an expression of loss.

Domain-specific vocabulary. Our CNN trained on domain-specific word embeddings is able to correctly classify tweet 5, while the one trained on Twitter word embeddings did not pick up the aggressive content. This user is talking about how their friend is ready to kill someone. This tweet contains the word *thirsty* but in this domain-specific context it means being ready and having an urge (although it would not always refer to killing).

Hashtags and character sequences. Despite their strengths, both our best CNN and our best SVM classifiers were still unable to correctly classify some of the trickier cases. There were certain types of tweets they were categorically unable to recognize: tweet 1 features a hashtag that refers to an incarcerated acquaintance of the poster, but as both our CNN and SVM models operate at the word level, this tag would have appeared simply as a rare or unknown token to them.

Anger miscategorized as Aggression. At times, the classifier categorized posts that express anger as Aggression. For example, in tweet 4 the author uses profanity to express grief related to the loss of a friend. In addition, the devil face emoji, which is sometimes used to express aggression, is also used in the context of anger. While the best CNN model managed to correctly predict this as Loss, the SVM miscategorized it as Aggression.

8 Ethics

Our ethics guidelines include just treatment of the users who provide our data, removal of identifying information for publication, and the inclusion of Chicago-based community members as domain experts in the analysis and validation of our findings.

There are risks involved with detecting Aggression and Loss in social media data using automatic detection systems. These risks include possible misidentifications of tweets, increased police involvement, and loss of privacy, which all have the potential to harm marginalized communities and people. Our mitigation strategies begin by partnering with violence prevention organizations and incorporating domain experts (Frey et al., 2018) to ensure the highest ethical standards for interpreting social media posts and for the dissemination and use of our research for violence prevention. Through insights gained from these partnerships, we developed our own risk mitigation strategies: de-identifying each tweet and rendering it unsearchable through textual modification without altering meaning; encrypting our social media corpus to protect user identities; and relying on violence prevention organizations' expertise in deciding if and when to involve law enforcement to prevent the unethical use of our data (e.g., hyper-surveillance of communities of color).

9 Conclusion and Future Work

Our approach shows that integrating emotions and semantic content of a user's recent posts is an important component for the task of predicting Aggression and Loss in social media posts of gang-involved youth. Furthermore, using domain-specific embeddings and an Aggression-Loss lexicon induced from a corpus of language constructed to represent our specific community of users is also critical to success. Our experiments reveal that our snowballing technique is more effective than a location based approach and that fitting our community is more complex than resorting to their demographic, as captured in the AAE corpus of Blodgett et al. (2016).

Our work has real life implications for the use of machine learning to identify unique characteristics in social media data that may indicate the process by which gun violence may occur (Patton et al., 2018a). Our partnership between computer scientists, social work researchers and practitioners has advanced plans to create applications to help outreach workers in Chicago identify factors related to potential violence, potentially allowing them to prevent and intervene in aggressive online activity. The tool, which would be co-created with community stakeholders, would enable quick scanning of large quantities of social media posts that outreach workers would be unable to perform manually.

We expect our methods to be generalizable because we compute embeddings and lexicons from neighborhood-specific data and do not rely on large, hand-crafted resources such as dictionaries. However, we hope to test generalizability in future work by applying our methods to other gang-related corpora, because there is variation in language, local concepts, and behavior across gangs. In the future, we are also interested in further experimenting with the context features introduced in this work; for instance, by extending our pairwise interaction features to take into account direction between users. Finally, we intend to explore other types of context, such as reference to specific events that may trigger the emotions of either Aggression or Loss.

Reasoning about Actions and State Changes by Injecting Commonsense Knowledge

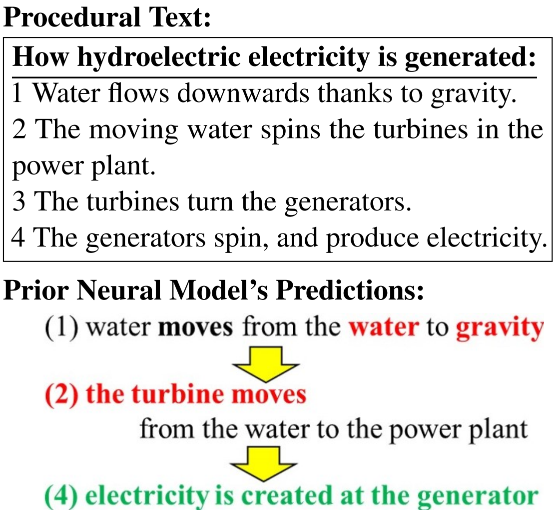
Abstract

Comprehending procedural text, e.g., a paragraph describing photosynthesis, requires modeling actions and the state changes they produce, so that questions about entities at different timepoints can be answered. Although several recent systems have shown impressive progress in this task, their predictions can be globally inconsistent or highly improbable. In this paper, we show how the predicted effects of actions in the context of a paragraph can be improved in two ways: (1) by incorporating global, commonsense constraints (e.g., a non-existent entity cannot be destroyed), and (2) by biasing reading with preferences from large-scale corpora (e.g., trees rarely move). Unlike earlier methods, we treat the problem as a neural structured prediction task, allowing hard and soft constraints to steer the model away from unlikely predictions. We show that the new model significantly outperforms earlier systems on a benchmark dataset for procedural text comprehension (+8% relative gain), and that it also avoids some of the nonsensical predictions that earlier systems make.



Procedural Text:

How hydroelectric electricity is generated:
1 Water flows downwards thanks to gravity.
2 The moving water spins the turbines in the power plant.
3 The turbines turn the generators.
4 The generators spin, and produce electricity.

Prior Neural Model's Predictions:

(1) water **moves** from the **water** to **gravity**

(2) the turbine moves from the water to the power plant

(4) electricity is created at the generator

Figure 1: Poor predictions (in red) made by a prior neural model (ProGlobal) applied to an (abbreviated) paragraph from the ProPara dataset. ProGlobal predicts entity locations at each sentence, but the implied movements violate commonsense constraints (e.g., an object cannot move from itself (1)) and corpus-based preferences (e.g., it is rare to see turbines move (2)).

1 Introduction

Procedural text is ubiquitous (e.g., scientific protocols, news articles, how-to guides, recipes), but is challenging to comprehend because of the dynamic nature of the world being described. Comprehending such text requires a model of the actions described in the text and the state changes they produce, so that questions about the states of entities at different timepoints can be answered (Bosselut et al., 2018).

Despite these challenges, substantial progress has been made recently in this task. Recent work – such as EntNet (Henaff et al., 2017), QRN (Seo et al., 2017b), ProLocal/ProGlobal (Dalvi et al., 2018), and NPN (Bosselut et al., 2018) – has focused on learning to predict individual entity states at various points in the text, thereby approximating the underlying dynamics of the world. However, while these models can learn to make local predictions with fair accuracy, their results are often globally unlikely or inconsistent. For example, in Figure 1, the neural ProGlobal model from Dalvi et al. (2018) learns to predict the impossible action of an object moving from itself (1), and the unlikely action of a turbine changing location (2). We observe similar mistakes in other neural models, indicating that these models have little notion of global consistency. Unsurprisingly, mistakes in local predictions compound as the process becomes longer, further reducing the plausibility of the overall result.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 57–66
Brussels, Belgium, October 31 - November 4, 2018.

To address this challenge, we treat process comprehension as a *structured prediction task* and apply hard and soft constraints during reading. During training, our model, called ProStruct, learns to search for the most likely action sequence that is consistent with global constraints (e.g., entities cannot be destroyed after they have already been destroyed) and priors from background knowledge (e.g., turbines rarely change location). The model is trained end-to-end, with gradients backpropagating through the search path. We find that this approach significantly outperforms existing approaches on a benchmark dataset for process comprehension, mainly by avoiding the nonsensical predictions that earlier systems make.

Our contributions are twofold. First, we reformulate procedural text comprehension in a novel way: as a (neural) structured prediction task. This lets hard and soft constraints steer the model away from unlikely and nonsensical predictions. Second, we present a novel, end-to-end model that integrates these constraints and achieves state-of-the-art performance on an existing process comprehension dataset (Dalvi et al., 2018).

2 Related Work

Our work builds off a recent body of work that focuses on using neural networks to explicitly track the states of entities while reading long texts. These works have focused on answering simple commonsense questions (Henaff et al., 2017), tracking entity states in scientific processes (Dalvi et al., 2018; Clark et al., 2018), tracking ingredients in cooking recipes (Bosselut et al., 2018), and tracking the emotional reactions and motivations of characters in simple stories (Rashkin et al., 2018). Our work extends these methods and addresses their most common issues by using background knowledge about entities to prune the set of state changes they can experience as the model reads new text.

Prior to these neural approaches, some earlier systems for process comprehension did make use of world knowledge, and motivated this work. Like us, the system ProRead (Berant et al., 2014; Scaria et al., 2013) also treated process comprehension as structure prediction, using an Integer Linear Programming (ILP) formalism to enforce global constraints (e.g., if the result of event1 is the agent of event2, then event1 must enable event2). Similarly, Kiddon et al. (2015) used corpus-based priors to guide extraction of an “action graph” from recipes. Our work here can viewed as incorporating these approaches within the neural paradigm.

Neural methods for structure prediction have been used extensively in other areas of NLP, and we leverage these methods here. In particular we use a neural encoder-decoder architecture with beam search decoding, representative of several current state-of-the-art systems (Bahdanau et al., 2014; Wiseman and Rush, 2016; Vinyals et al., 2015). As our model’s only supervision signal comes from the final prediction (of state changes), our work is similar to previous work in semantic parsing that extracts structured outputs from text with no intermediate supervision (Krishnamurthy et al., 2017).

State tracking also appears in other areas of AI, such as dialog. A typical dialog state tracking task (e.g., the DSTC competitions) involves gradually uncovering the user’s state (e.g., their constraints, preferences, and goals for booking a restaurant), until an answer can be provided. Although this context is somewhat different (the primary goal being state discovery from weak dialog evidence), state tracking techniques originally designed for procedural text have been successfully applied in this context also (Liu and Perez, 2017).

Finally, our model learns to search over the best candidate structures using hard constraints and soft KB priors. Previous work in Neural Machine Translation (NMT) has used sets of example-specific lexical constraints in beam search decoding to only produce translations that satisfy every constraint in the set (Hokamp and Liu, 2017). In contrast, our work uses a set of global example-free constraints to prune the set of possible paths the search algorithm can explore. Simultaneously, a recent body of work has explored encoding soft constraints as an additional loss term in the training objective for dialogue (Wen et al., 2015), machine translation (Tu et al., 2016), and recipe generation (Kiddon et al., 2016). Our work instead uses soft constraints to re-rank candidate structures and is not directly encoded in the loss function.

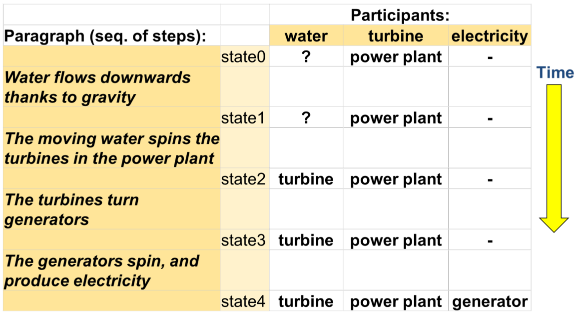
3 Problem Definition

We first define the general task that we are addressing, before presenting our approach.

3.1 General Formulation

We define the task as follows. **Given:**

- A **paragraph of procedural text** S = an ordered set of sentences $\{s_1, ..., s_T\}$ describing



Paragraph (seq. of steps):		Participants: water	turbine	electricity
	state0	?	power plant	-
Water flows downwards thanks to gravity				
	state1	?	power plant	-
The moving water spins the turbines in the power plant				
	state2	turbine	power plant	-
The turbines turn generators				
	state3	turbine	power plant	-
The generators spin, and produce electricity				
	state4	turbine	power plant	generator

Figure 2: How the (simplified) paragraph in Figure 1 is annotated in ProPara. Each filled row shows the location of entities between each step ("?" denotes "unknown", "-" denotes "does not exist"). For example, in the last line (state4), the water is at the turbine.

a sequence of **actions**[1] about a given **topic** (a word or phrase).

- A **set of entities** $E = \{e_j\}$ representing the entities mentioned in the procedure or process. Each entity e_j is denoted by the set of its mentions in the paragraph, e.g., {`leaf, leaves`}
- A **set of properties** $P = \{p_k\}$ of entities to be tracked (e.g., location, existence)

predict:

- The **state** of each entity e_j after each sentence s_k, where an entity's state is the values of all its properties $\{p_k\}$. For example, in Figure 2, the state of the water after step 2 is {location(water) = turbine; exists(water) = true}.

This task definition covers the tasks used in earlier procedural text comprehension datasets. In bAbI tasks 1-3, a single propert (location) was tracked for a single entity throughout a paragraph (Weston et al., 2015). In the state tracking task of Bosselut et al. (2018), six properties (temperature, shape, etc.) were tracked for each ingredient in the recipe.

3.2 Data

In our work, we use the ProPara dataset (Dalvi et al., 2018) for both illustration and evalution. ProPara contains 488 paragraphs (3100 sentences) of a particular genre of procedural text, namely science processes (e.g., how hydroelectricity is generated). The dataset tracks two entity properties, existence and location, for all entities involved in each process, resulting in 81,000 annotations in the dataset. Figure 2 gives a (simplified) example of the data, visualized as an (entity x sentence) grid, where each column tracks a different entity (time progressing vertically downwards), and each row denotes the entities' state (existence and location) after each sentence. To evaluate the predictions, a set of templated questions whose answers can be computed from the predictions is posed (e.g., "What was destroyed, when and where?").

4 Model

We now describe our model, called PROSTRUCT.

4.1 Overview

We approach the task by predicting the state *changes* that occur at each step of the text, using a vocabulary (size K) of the possible state change types that can occur given the domain and properties being modeled. For example, for the ProPara dataset, we model $K = 4$ types of state change: ***`move`*****,** ***`create`*****,** ***`destroy`*****,** and ***`none`***. ***`move`*** changes an entity's location from one place to another, `create` from non-existence to a location, and *`destroy`* from a location to non-existence. State changes can be parameterized by text spans in the paragraph, e.g., ***`move`*** takes a before and after location parameter. If a parameterized state change is predicted, then the model also must predict its parameter values from the paragraph.

Previous models for process comprehension make a sequence of local predictions about the entities' states, one sentence at a time, maintaining a (typically neural) state at each sentence. However, none have the ability to reverse earlier predictions should an inconsistency arise later in the sequence. PROSTRUCT overcomes this limitation by reformulating the task as structured prediction. To do this, it uses a neural encoder-decoder from the semantic parsing literature (Krishnamurthy et al., 2017; Yin and Neubig, 2017) combined with a search procedure that integrates soft and hard constraints for finding the best candidate structure.

For each sentence and entity, the encoder first uses a bidirectional LSTM to encode the sentence and indicator variables identifying which entity is currently being considered (Figure 3). It then produces a (distributed) representation of the action that the sentence describes as being applied to that entity. During decoding, the model decodes each action embedding into a distribution over possible state changes that might result, then performs

---

[1] We use a broad definition of action to mean any event that changes the state of the world (including non-volitional events such as roots absorbing water).

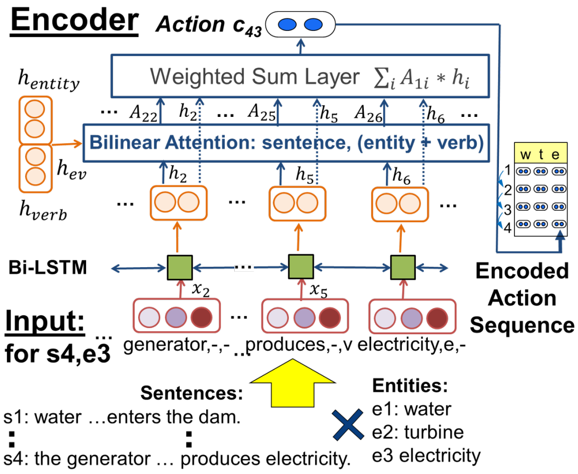


Figure 3: The encoder, illustrated for the ProPara domain with the paragraph from Figure 1. During encoding, ProStruct creates an action embedding c_{tj} representing the action at step t on entity e_k, for all entities at all steps. The overall action sequence (right-hand box) is the collection of these embeddings, for each entity (listed horizontally) and each step (listed vertically downwards).

a search over the space of possible state change sequences. Each node in the space is a partial sequence of state changes, and each edge is a prediction of the next state changes to add to the sequence (Figure 4).

During training, the model only follows the path along the gold sequence, and optimizes a loss function that drives up the likelihood of predictions along that path (thus driving down the probabilities for alternative, incorrect paths). At test time, the model does not have access to the gold path, and instead performs a beam search of the space to find the best candidate sequence.

Most importantly, by mapping the state change prediction problem to structured prediction, we can perform a search over the set of candidate paths that allows us to introduce hard and soft constraints that capture commonsense knowledge. Hard constraints are used to prune the search space (Equation 4 later), and soft constraints bias the search away from unlikely state changes via an additional term in the scoring function (Equations 5 and 6).

4.2 Encoder

The encoder operates over every $(s_t, e_j) \in S \times E$ pair to create an encoded representation c_{tj} of the action described by sentence s_t, as applied to entity e_j. In other words, we can consider the overall action to be represented by $|E|$ embeddings, one for each of the entities in E, encoding the action's effects on each. This novel feature allows us to model different effects on different entities by the same action. For example, a conversion action may simultaneously destroy one entity and create another. Figure 3 shows the encoder operating on s_4: "The generator spins, and produces electricity" and e_3: `electricity` from Figure 1.

Without loss of generality, we define an arbitrary sentence in S as $s_t = \{w_0, ..., w_I\}$. Each word w_i in the input sentence is encoded as a vector $x_i = [v_w : v_e : v_v]$, which is the concatenation of a pre-trained word embedding v_w for w_i, an indicator variable v_e for whether w_i is a reference to the specified entity e_j, and an indicator variable v_v for whether w_i is a verb. We use GloVe vectors as pre-trained embeddings (Pennington et al., 2014) and a POS tagger to extract verbs (Spacy, 2018).

Then, a BiLSTM is used to encode the word representations extracted above, yielding a contextualized vector h_i for each embedded word x_i that is the concatenated output of the backward and forward hidden states produced by the BiLSTM for word w_i. An attention over the contextualized embeddings h_i is performed to predict a distribution of weights over the sentence:

$$a_i = h_i * B * h_{ev} + b \tag{1}$$

$$c_{tj} = \sum_{i=1}^{I} a_i * h_i \tag{2}$$

where a_i is the attention weight for each contextualized embedding, c_{tj} is the vector encoding the action for the sentence-entity pair (s_t, e_j), B and b are learned parameters, and h_{ev} is the concatenation of the contextual embeddings of the hidden states where the entity h_e and verb h_v are mentioned:

$$h_{ev} = [\mu(\{h_i : x_i[v_e] = 1\}); \mu(\{h_i : x_i[v_v] = 1\}] \tag{3}$$

where μ is an average function, and $x_i[v_e]$ and $x_i[v_v]$ correspond to the entity indicator and verb indicator variables defined above for any word w_i, respectively. The output vector c_{tj} encodes the action at step s_t on entity e_j. This vector is computed for all steps and entities, populating a grid of the actions on each entity at each step (Figure 3).

4.3 Decoder

To decode the action vectors c_{tj} into their resulting state changes they imply, each is passed through a feedforward layer to generate $logit(\pi_t^j)$, a set of logistic activations over the K possible state changes π_t^j for entity e_j in sentence s_t. (For ProPara, there are $K = 4$ possible state changes: `move`, `create`, `destroy`, `none`). These logits denote how likely each state change π_t^j is for entity e_j at sentence s_t. The decoder then explores the search space of possible state change sequences for the **whole** paragraph (Figure 4), using these likelihoods to score each visited sequence (Equation 6).

Let π_t be the set of state changes for *all* entities at time t, i.e., $\pi_t = \{\pi_t^j\}_{j=1..|E|}$, and let Π_t be the sequence of state changes from time 1 to t, i.e., $\Pi_t = [\pi_1, ..., \pi_t]$. Each node in the search space is a Π_t, and each edge adds a π_{t+1} to it so that it becomes Π_{t+1}:

$$\Pi_t \xrightarrow{\pi_{t+1}} \Pi_{t+1}$$

Given there are K possible values for π_t^j, the number of possible configurations for π_t at time t (i.e., the branching factor during search) is exponential: $K^{|E|}$, where $|E|$ is the number of entities in the paragraph.

To explore this exponential number of paths, after every sentence s_t, we prune branches $\Pi_t \rightarrow \Pi_{t+1}$ where Π_{t+1} is impossible according to background knowledge (described in Section 5.1). We define the boolean function over state change sequences:

$$\begin{aligned} \text{allowable}(\Pi) &= 1 \text{ if hard constraints satisfied} \\ &= 0 \text{ otherwise} \end{aligned} \tag{4}$$

and prune paths Π_{t+1} where $allowable(\Pi_{t+1}) = 0$. For example for ProPara, a state transition such as *`DESTROY`* → *`MOVE`* is not allowed because a hard constraint prohibits non-existent entities from being moved (Section 5.1).

While hard constraints remove impossible state change predictions, there may also be other state changes that are implausible with respect to background knowledge. For example, commonsense dictates that it is unlikely (but not impossible) for plants to be destroyed during photosynthesis. Accordingly, our inference procedure should discourage (but not prohibit) predicting plant destruction when reading about photosynthesis. To discourage unlikely state changes, we make use of soft constraints that estimate the likelihood of a particular state change associated with an entity, denoted as:

$$P(\pi^j | e_j, topic) \tag{5}$$

In Section 5.2, we describe how these likelihoods can be estimated from large-scale corpora. We add this bias as an additional term (the second term below) when scoring the addition of π_{t+1} to the sequence so far Π_t:

$$\phi'(\pi_{t+1}) = \sum_{j=1}^{|E|} \Big(\lambda \; logit(\pi_{t+1}^j) + (1 - \lambda) \; \log P(\pi_{t+1}^j | e_j, topic) \Big) \tag{6}$$

where λ is a learned parameter controlling the degree of bias.

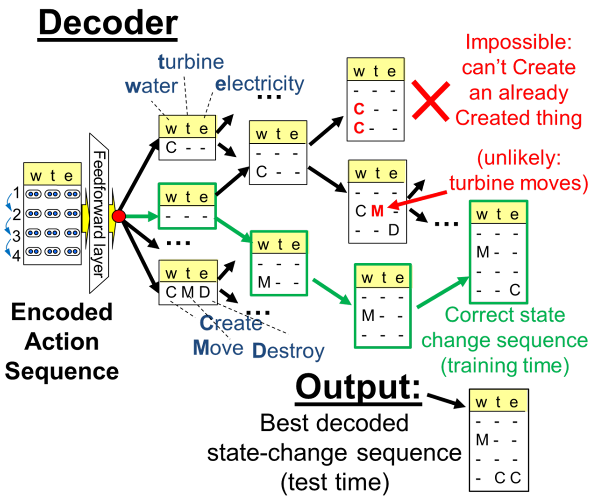

Figure 4: The decoder, illustrated for the ProPara domain. Each action embedding c_{tj} is first passed through a feedforward layer to generate a distribution over the (here $K = 4$) possible state changes that could result, for each entity (listed horizontally) at each step (listed vertically downwards). The decoder then explores the space of state-change sequences, using these distributions to guide the search. During end-to-end training, ProStruct follows the correct (green) path, and backpropagates to drive up probabilities along this path. During testing, the system performs a beam search to find the most globally plausible sequence.

During search, when making a transition along a path from Π_t to a valid Π_{t+1}, Π_{t+1} is scored by accumulating normalized scores along the path:

$$\phi(\Pi_{t+1}) = \phi(\Pi_t) + \frac{\phi'(\pi_{t+1})}{\sum_{\pi'_{t+1} \in \Pi_{t+1}} \phi'(\pi'_{t+1})} \tag{7}$$

Continuing state transitions in this manner, when we reach the finished state (i.e., last sentence), our objective is to maximize the score of the state changes produced when reading each sentence. During training, we only materialize a valid node when $\Pi_t \in \Pi_t^*$ where Π_t^* is the set of nodes along the gold path.

We use this constrained decoding to predict the state change sequence. For state changes that take additional parameters, e.g., in the ProPara model a *`move`* is parameterized by the before and after locations, we also predict those parameter values during decoding. This is done using standard span prediction layers (inspired by BiDAF, Seo et al. (2017a)) on top of the encoded input.

The model is trained to minimize the joint loss of predicting the correct state changes and correct state change parameters for every sentence in the paragraph:

$$\mathcal{L} = -\sum_{t=1}^{T}\Big(\log P(\pi_t) + \sum_{j=1}^{|E|}\sum_{p\in\text{param}(\pi_t^j)} \log P(v_{pjt}|\pi_t^j)\Big) \tag{8}$$

where $\text{param}(\pi_t^j)$ are the parameters of state change π_t^j, and v_{pjt} are the values of those parameters. For example, `move` is parameterized by before/after locations, and the 2nd loss term refers to the predicted values of those locations.

At test time, instead of following the gold state change path, we use beam search. After reading any sentence, we explore the top-k states sorted by the score $\phi'(\pi_t)$ that satisfy hard constraints. This way, we predict a sequence of state changes that have maximum score while being sensible w.r.t. hard constraints.

5 Incorporating Commonsense Knowledge

By formulating procedural text comprehension as a structured prediction task, we can introduce commonsense knowledge as hard and soft constraints into the model, allowing nonsensical and unlikely predictions to be avoided, and allowing the system to recover from early mistakes.

5.1 Hard Constraints

Hard constraints are introduced by defining the (boolean) function over a candidate sequence of state changes:

$$\text{allowable}(\Pi)$$

used in Equation 4.

While this function can be defined in any way, for the ProPara application we use six constraints. The first three below are based on basic "laws of physics" or commonsense (CS) and are universally applicable:

CS-1: An entity must **exist** before it can be **moved** or **destroyed**
CS-2: An entity cannot be **created** if it already **exists**
CS-3: An entity cannot change until it is mentioned in the paragraph

The next three constraints are observed in the training data:

D-1: Maximum number of toggles for an entity between Exists and not Exist $\leq f_{max\_toggles}$
D-2: Max fraction of entities that are changed per sentence $\leq f_{entities\_per\_sentence}$
D-3: Max fraction of sentences in which an entity changes $\leq f_{sentences\_per\_entity}$

The thresholds used in D-1, D-2 and D-3 are hyperparameters that can be tuned on the dev set.

5.2 Soft Constraints

Soft constraints are introduced by defining the prior probabilities used in Equation 6:

$$P(\pi^j|e_j, topic)$$

that entity e_j undergoes state change π^j in a sentence of text about *topic*. These probabilities are used to re-rank the candidate event sequences during decoding (see Equation 6).

While any method can be used to estimate these probabilities, we describe our corpus-based approach here. Although it was designed for ProPara, it generalizes easily to other domains, and is itself a contribution of this work. For a given state change π^j, entity e_j, and topic, we first gather a corpus of Web sentences mentioning that topic (using Bing search APIs), then count the number of times x that the entity is described as undergoing that state change (e.g., that `water` is said to `MOVE`). To determine this frequency, we first convert the sentences into a set of SRL frames (verb + role-argument pairs) using an off-the-shelf SRL labeler. We then use an existing rulebase, derived from VerbNet, that contains rules that map SRL frames to state changes, e.g., `e1/ARG0 "absorbs"/VERB e2/ARG1` $\Longrightarrow$ `e2 MOVES` (Clark et al., 2018). Although the rules and SRL labels are incomplete and noisy, redundancy in the corpus provides some robustness when estimating the frequency x. Finally, the observed frequency x is converted to a likelihood using a logistic transformation:

$$P(\pi^j|e_j, topic) = \frac{1}{1 + exp^{-(x-x_0)}} \tag{9}$$

where, x_0 is a hyperparameter tuned on the dev set.

5.3 Commonsense Constraints for New Domains

The commonsense constraints we have used for ProPara are general, covering the large variety of topics contain in ProPara (e.g., electricity, photosynthesis, earthquakes). However, if one wants to apply ProStruct to other genres of procedural text (e.g., fictional text, newswire articles), or broaden the state change vocabulary, different commonsense constraints may be needed. Note that our model architecture itself is agnostic to the source and quantity of hard and soft constraints. For example, one might leverage commonsense rules from existing ontologies such as SUMO (Niles and Pease, 2001) or Cyc (Lenat et al., 1985) to identify new hard constraints; and our corpus-based method could be extended to cover new state change types should the state change vocabulary be extended.

6 Evaluation

We evaluate our model using the ProPara dataset, and compare against several strong baselines published with the original dataset (Dalvi et al., 2018).

6.1 Evaluation setup

Given a paragraph and set of entities as input, the task is to answer four templated questions, whose answers are deterministically computed from the state change sequence:

Q1. What are the inputs to the process?
Q2. What are the outputs of the process?
Q3. What conversions occur, when and where?
Q4. What movements occur, when and where?

Inputs are defined as entities that existed at the start of the process, but not at the end. Outputs are entities that did not exist at the start, but did at the end. A conversion is when some entities are destroyed and others created. Finally, a movement is an event where an entity changes location.

For each process, as every question can have multiple answers, we compute a separate F1 score for each question by comparing the gold and predicted answers. For Q1 and Q2, this is straightforward as answers are atomic (i.e., individual names of entities). For Q3, as each answer is a 4-tuple (*convert-from, convert-to, location, sentence-id*), some answers may only be partially correct. To score partial correctness, we pair gold and predicted answers by requiring the *sentence-id* in each to be the same, and then score each pair by the Hamming distance of their tuples. For Q4, each answer is also a 4-tuple (*entity, from-location, to-location, sentence-id*), and the same procedure is applied. The four F1 scores are then macro-averaged. The total number of items to predict in the train/dev/test partitions is 7043/913/1095.

6.2 Baselines

We compare results using the following process comprehension models:

Recurrent Entity Networks (EntNet) (Henaff et al., 2017) are a state-of-the-art model for the bAbI tasks (Weston et al., 2015). The model uses a dynamic memory to maintain a representation of the world state as sentences are read, with a gated update at each step. These states are decoded to answer questions after each sentence is read.

Query Reduction Networks (QRN) (Seo et al., 2017b) perform a gated propagation of their hidden state across each time-step. Given a question, the hidden state is used to modify the query to keep pointing to the answer at each step.

ProLocal (Dalvi et al., 2018) predicts the state changes described in individual sentences, and then uses commonsense rules of inertia to propagate state values forwards and backwards in time.

ProGlobal (Dalvi et al., 2018) predicts states of an entity across all time steps. It considers the entire paragraph while predicting states for an entity, and learns to predict location spans at time-step $t + 1$ based on location span predictions at t.

7 Results

7.1 Comparison with Baselines

We compare our model (which make use of world knowledge) with the four baseline systems on the ProPara dataset. All models were trained on the training partition, and the best model picked based on prediction accuracy on the dev partition. Table 1 shows the precision, recall, and F1 for all models on the the test partition. PROSTRUCT significantly outperforms the baselines, suggesting that world knowledge helps PROSTRUCT avoid spurious predictions. This hypothesis is supported by the fact that the ProGlobal model has the highest recall and worst precision, indicating that it is over-generating state change predictions. Conversely, the ProLocal model has the highest precision, but its recall is much lower, likely because it makes predictions for individual sentences, and thus has no access to information in surrounding sentences that may suggest a state change is occurring.

We also examined the role of the constraint rules (both hard and soft) on efficiency. With all rules disabled, the training does not complete even one epoch in more than three hours. Because the number of valid states is exponential in the number of

	Precision	Recall	F1
ProLocal	77.4	22.9	35.3
QRN	55.5	31.3	40.0
EntNet	50.2	33.5	40.2
ProGlobal	46.7	52.4	49.4
ProStruct	74.2	42.1	**53.7**

Table 1: Results on the prediction task (test set).

	Precision	Recall	F1
ProStruct	70.4	47.8	56.9
- Soft constraints	61.9	47.4	53.7
- Hard constraints†	69.6	47.0	56.1

† Partial ablation, ablated at test only (training without these is computationally infeasible).

Table 2: Ablating world knowledge on the dev set.

entities, the training is particularly slow on paragraphs with many entities. In contrast, with all rules enabled, training takes less than 10 minutes per epoch. This illustrates that the constraints are not only contributing to the model scores, but also helping make the search efficient.

7.2 Ablations and Analysis

To explore the impact of world knowledge, we also performed two ablations on the dev set: Removing soft constraints (at both training and test time), and a partial ablation of removing hard constraints at test time only - note that hard constraints cannot be removed during training because model training time becomes prohibitively large without them, thus qualifying this second ablation. Table 4 shows that F1 drops when each type of knowledge is removed, illustrating that they are helping. The smaller drop for hard constraints suggests that they have primarily been incorporated into the network during training due to this ablation being partial.

Qualitatively, we compared dev set examples where the predicted event sequence changed, comparing predictions made without world knowledge to those made with world knowledge. For readability, we only show the event type predictions (M,C,D, and N (shown as "-")) and not their from-location/to-location arguments. If a prediction changes from X (without knowledge) to Y (with knowledge), we write this "$X \rightarrow Y$". For cases where the prediction changed, we show incorrect predictions in red, and correct predictions in green.

We first compare predictions made with and without the **BK** (corpus-based background knowledge, the soft constraints). Table 3 shows a paragraph about the process of nuclear-powered electricity generation, in the problematic prediction of the generator moving (M) was predicted in the second to last sentence. However, the background knowledge contains no examples of generators being moved. As a result, it drives the probability mass away from the move (M) prediction, resulting in a no state change (N) prediction instead.

Table 4 shows a second example where, without knowledge, no event was predicted for the spark entity. However, BK contains many examples of sparks being created (reflecting text about this topic), shifting the probability mass towards this prediction, resulting in the correct C (create).

Finally, Table 5 shows an example of a hard constraint preventing a nonsensical prediction (namely, electricity is created after it already exists).

7.3 Error Analysis

There are also many cases where incorrect predictions are made. The main causes are summarized below, and offer opportunities for future work.

Implicit reference is a challenge for ProStruct, where an entity affected by an event is not mentioned until a later sentence in the paragraph. For example, in the following ProPara paragraph snippet about combustion engines:

> "...(3) A spark ignites fuel...(4) The pressure pushes the piston down...."

both `spark` and `pressure` are created in sentence 3, even though `pressure` is not mentioned until the subsequent sentence. Recognizing this type of implicit mention is very hard. It is possible that BK could help in such situations, particularly if `ignite` were often associated with creating pressure in the context of a combustion engines, but we did not see such examples in practice.

A second challenge is **coreference**, in particular when different entities have similar names. For example, again for combustion, a snippet looks:

> ...(2) the fuel is injected... (6) the spent

	Without vs. with BK				
	Fuel	Heat	Turbine	Generator	Elec.
Fuel produces heat.	D	C	-	-	-
... Steam spins turbine.	-	-	-	-	-
Generator is turned.	-	-	-	M → N	-
Makes electricity.	-	-	-	-	C

Table 3: BK improves precision. In a nuclear powered electricity generation scenario, BK drives the probability mass away from the generator movement, as a generator does not generally change location.

	Without vs. with BK		
	Fuel	Air	Spark
Fuels burns in the chamber.	D	-	-
The burning fuel creates energy.	-	-	-
The upward motion cause air ...	-	M	-
The piston compresses the air.	-	-	-
A spark ignites the fuel and air ...	-	-	N → C
...	...	...	...

Table 4: BK improves coverage. BK has a strong signal that a spark is usually created in combustion engines, shifting the probability mass towards spark-creation.

	Without and with constraints		
	Electricity	Signals	...
Electricity enters supply unit.	M	-	-
The supply gives electricity to transistors.	C → D	-	
...	...	...	...
The energy is used to complete ...	-	-	

Table 5: Hard constraints avoid nonsensical predictions. In this example without ***CS*-2**, the electricity is predicted to be created after it already exists (impossible). This mistake is avoided using the constraints.

> fuel is ejected. (7) new fuel is injected....

Here `fuel` and `spent fuel` are the same entity, while `new fuel` is a different entity. Correctly tracking these references is challenging (in this case, ProStruct misidentifies (7) as describing an event on the original `fuel/spent fuel`).

A third, related problem is **pronoun resolution**. For example, in:

> The sound continues to bounce off of things and produce echoes until it is totally absorbed or dissipated.

the word `it` confuses ProStruct, and it predicts that the `echo` (rather than the `sound`) is destroyed. We observe several such failure cases.

Finally, we observed **BK retrieval failures** when there was appropriate background knowledge that was expressed in a lexically different way. Consider the example in Table 6 about oil formation. Without BK, the model correctly predicts that `sediment` is destroyed (D). However, BK has few examples of `sediment` being destroyed, and so biases the prediction away from this (correct) choice to an incorrect choice. Further examination of BK shows that it does in fact have knowledge about this destruction, but that is expressed using the word `deposit` instead (e.g., "deposits break down"). A soft (neural) means of accessing BK would help alleviate this problem.

	Without BK vs. with BK		
	Algae	Plankton	Sediment
Algae and plankton die.	D	D	-
The dead algae and plankton ...	-	-	-
The sediment breaks down.	-	-	D → M

Table 6: BK lookup limitation: though BK knows that `deposits` can be destroyed (broken down), it does not equate this with (synonymous) `sediments` being destroyed, hence biases model away from correct answer.

8 Conclusions

Answering questions about procedural text remains challenging, requiring models of actions and the state changes they produce. Predictions made locally throughout the text may together be globally inconsistent or improbable. We have shown how the predicted effects of actions can be improved by treating the task as a structured prediction problem, allowing commonsense knowledge to be injected to avoid an overall inconsistent or improbable set of predictions. In particular, we have shown how two kinds of knowledge can be exploited: hard constraints to exclude impossible and nonsensical state changes, and soft constraints to encourage likely state changes. The resulting system significantly outperforms previous state-of-the-art systems on a challenging dataset, and our ablations and analysis suggest that the knowledge is playing an important role. Our code is available at `https://github.com/allenai/propara`.

Abstract

We present a large scale collection of diverse natural language inference (NLI) datasets that help provide insight into how well a sentence representation captures distinct types of reasoning. The collection results from recasting 13 existing datasets from 7 semantic phenomena into a common NLI structure, resulting in over half a million labeled context-hypothesis pairs in total. We refer to our collection as the DNC: ***D**iverse **N**atural Language Inference **C**ollection*. The DNC is available online at `http://www.decomp.net`, and will grow over time as additional resources are recast and added from novel sources.

1 Introduction

A plethora of new natural language inference (NLI)[1] datasets has been created in recent years (Bowman et al., 2015; Williams et al., 2017; Lai et al., 2017; Khot et al., 2018). However, these datasets do not provide clear insight into what type of reasoning or inference a model may be performing. For example, these datasets cannot be used to evaluate whether competitive NLI models can determine if an event occurred, correctly differentiate between figurative and literal language, or accurately identify and categorize named entities. Consequently, these datasets cannot answer how well sentence representation learning models capture distinct semantic phenomena necessary for general natural language understanding (NLU).

To answer these questions, we introduce the **D**iverse **N**LI **C**ollection (DNC), a large-scale NLI dataset that tests a model's ability to perform diverse types of reasoning. DNC is a collection of NLI problems, each requiring a model to perform a unique type of reasoning. Each NLI dataset contains labeled context-hypothesis pairs that we recast from semantic annotations for specific structured prediction tasks. We extend various prior works on challenge NLI datasets (Zhang et al., 2017), and define recasting as leveraging existing datasets to create NLI examples (Glickman, 2006; White et al., 2017). We recast annotations from a total of 13 datasets across 7 NLP tasks into labeled NLI examples. The tasks include event factuality, named entity recognition, gendered anaphora resolution, sentiment analysis, relationship extraction, pun detection, and lexicosyntactic inference. Currently, the DNC contains over half a million labeled examples. Table 1 includes NLI pairs that test specific types of reasoning.

Event Factuality	► Find him before he finds the dog food The finding did not happen	✓
	► I'll need to ponder The pondering happened	✗
Relation Extraction	► Ward joined Tom in their native Perth Ward was born in Perth	✓
	► Stefan had visited his son in Bulgaria Stefan was born in Bulgaria	✗
Puns	► Kim heard masks have no face value Kim heard a pun	✓
	► Tod heard that thrift is better than annuity Tod heard a pun	✗

Table 1: Example sentence pairs for different semantic phenomena. ► indicates the line is a context and the following line is its corresponding hypothesis. ✓ and ✗ respectively indicate that the context entails, or does not entail the hypothesis. Appendix A includes more recast examples.

Using a *hypothesis-only* NLI model, with access to just hypothesis sentences, as a strong baseline (Tsuchiya, 2018; Gururangan et al., 2018; Poliak et al., 2018b), our experiments demonstrate how DNC can be used to probe a model's ability to capture different types of semantic reasoning

---

[1] The task of determining if a hypothesis would likely be inferred from a context, or premise; also known as Recognizing Textual Entailment (RTE) (Dagan et al., 2006, 2013).

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 67–81
Brussels, Belgium, October 31 - November 4, 2018.

necessary for general NLU. In short, this work answers a recent plea to the community to test "more kinds of inference" than in previous challenge sets (Chatzikyriakidis et al., 2017).

2 Motivation & Background

Compared to eliciting NLI datasets directly, i.e. asking humans to author contexts and/or hypothesis sentences, recasting can 1) help determine whether an NLU model performs distinct types of reasoning; 2) limit types of biases observed in previous NLI data; and 3) generate examples cheaply, potentially at large scales.

NLU Insights Popular NLI datasets, e.g. Stanford Natural Language Inference (SNLI) (Bowman et al., 2015) and its successor Multi-NLI (Williams et al., 2017), were created by eliciting hypotheses from humans. Crowd-source workers were tasked with writing one sentence each that is entailed, neutral, and contradicted by a caption extracted from the Flickr30k corpus (Young et al., 2014). Although these datasets are widely used to train and evaluate sentence representations, a high accuracy is not indicative of what types of reasoning NLI models perform. Workers were free to create any type of hypothesis for each context and label. Such datasets cannot be used to determine how well an NLI model captures many desired capabilities of language understanding systems, e.g. paraphrastic inference, complex anaphora resolution (White et al., 2017), or compositionality (Pavlick and Callison-Burch, 2016; Dasgupta et al., 2018). By converting prior annotation of a specific phenomenon into NLI examples, recasting allows us to create a diverse NLI benchmark that tests a model's ability to perform distinct types of reasoning.

Limit Biases Studies indicate that many NLI datasets contain significant biases. Examples in the early Pascal RTE datasets could be correctly predicted based on syntax alone (Vanderwende and Dolan, 2006; Vanderwende et al., 2006). Statistical irregularities, and annotation artifacts, within class labels allow a hypothesis-only model to significantly outperform the majority baseline on at least six recent NLI datasets (Poliak et al., 2018b). Class label biases may be attributed to the human-elicited protocol. Moreover, examples in such NLI datasets may contain racial and gendered stereotypes (Rudinger et al., 2017).

We limit some biases by not relying on humans to generate hypotheses. Recast NLI datasets may still contain some biases, e.g. non-uniform distributions over NLI labels caused by the distribution of labels in the original dataset that we recast.[2] Experimental results using Poliak et al. (2018b)'s hypothesis-only model indicate to what degree the recast datasets retain some biases that may be present in the original semantic datasets.

NLI Examples at Large-scale Generating NLI datasets from scratch is costly. Humans must be paid to generate or label natural language text. This linearly scales costs as the amount of generated NLI-pairs increases. Existing annotations for a wide array of semantic NLP tasks are freely available. By leveraging existing semantic annotations already invested in by the community we can generate and label NLI pairs at little cost and create large NLI datasets to train data hungry models.

Why These Semantic Phenomena? A long term goal is to develop NLU systems that can achieve human levels of understanding and reasoning. Investigating how different architectures and training corpora can help a system perform human-level general NLU is an important step in this direction. DNC contains recast NLI pairs that are easily understandable by humans and can be used to evaluate different sentence encoders and NLU systems. These semantic phenomena cover distinct types of reasoning that an NLU system may often encounter in the wild. While higher performance on these benchmarks might not be conclusive proof of a system achieving human-level reasoning, a system that does poorly should not be viewed as performing human-level NLU. We argue that these semantic phenomena play integral roles in NLU. There exist more semantic phenomena integral to NLU (Allen, 1995) and we plan to include them in future versions of the DNC.

Previous Recast NLI Example sentences in RTE1 (Dagan et al., 2006) were extracted from MT, IE, and QA datasets, with the process referred to as 'recasting' in the thesis by Glickman (2006). NLU problems were reframed under the NLI framework and candidate sentence pairs were extracted from existing NLP datasets and then labeled under NLI (Dagan et al., 2006). Years later, this term was independently used by White et al.

---

[2] In a corpus with part-of-speech tags, the distribution of labels for the word "the" will likely peak at the `Det` tag.

(2017), who proposed to "leverage existing large-scale semantic annotation collections as a source of targeted textual inference examples." The term 'recasting' was limited to automatically converting existing semantic annotations into labeled NLI examples without manual intervention. We adopt the broader definition of 'recasting' since our NLI examples were automatically or manually generated from prior NLU datasets.

Applied Framework versus Inference Probing Traditionally, NLI has not been viewed as a downstream, applied NLP task.[3] Instead, the community has often used it as "a generic evaluation framework" to compare models for distinct downstream tasks (Dagan et al., 2006) or to determine whether a model performs distinct types of reasoning (Cooper et al., 1996). These two different evaluation goals may affect which datasets are recast. We target both goals as we recast applied tasks and linguistically focused phenomena.

3 Recasting Semantic Phenomena

We describe efforts to recast 7 semantic phenomena from a total of 13 datasets into labeled NLI examples. Many of the recasting methods rely on simple templates that do not include nuances and variances typical of natural language. This allows us to specifically test how sentence representations capture distinct types of reasoning. When recasting, we preserve each dataset's train/dev/test split. If a dataset does not contain such a split, we create a random split with roughly a 80:10:10 ratio. Table 2 reports statistics about each recast dataset.

Event Factuality (EF) Event factuality prediction is the task of determining whether an event described in text occurred. Determining whether an event occurred enables accurate inferences, e.g. monotonic inferences, based on the event (Rudinger et al., 2018b).[4] Incorporating factuality has been shown to improve NLI (Sauri and Pustejovsky, 2007).

We recast event factuality annotations from UW (Lee et al., 2015), MEANTIME (Minard et al., 2016), and Decomp (Rudinger et al., 2018b). We use sentences from original datasets as contexts and templates (1a) and (1b) as hypotheses.[5]

(1) a. The *Event* happened
  b. The *Event* did not happen

If the predicate denoting the *Event* was annotated as having happened in the factuality dataset, the context paired with (1a) is labeled as ENTAILED and the same context paired with (1b) is labeled as NOT-ENTAILED. Otherwise, we swap the labels.

Named Entity Recognition (NER) Distinct types of entities have different properties and relational objects (Prince, 1978) that can help infer facts from a given context. For example, if a system can detect that an entity is a name of a nation, then that entity likely has a leader, a language, and a culture (Prince, 1978; Van Durme, 2010). When classifying NLI pairs, a model can determine if an object mentioned in the hypothesis can be a relational object typically associated with the type of entity described in the context. NER tags can also be directly used to determine if a hypothesis is likely to not be entailed by a context, such as when entities in contexts and hypotheses do not share NER tags (Castillo and Alemany, 2008; Sammons et al., 2009; Pakray et al., 2010).

Given a sentence annotated with NER tags, we recast the annotations by preserving the original sentences as contexts and creating hypotheses using the template "*NP* is a *Label*."[6] For ENTAILED hypotheses we replace *Label* with the correct NER label of the *NP*; for NOT-ENTAILED hypotheses, we choose an incorrect label from the prior distribution of NER tags for the given phrase. This prevents us from adding additional biases besides any class-label statistical irregularities present in the original data. We apply this procedure on the Gronigen Meaning Bank (Bos et al., 2017) and the ConLL-2003 Shared Task (Tjong Kim Sang and De Meulder, 2003).

Gendered Anaphora Resolution (GAR) The ability to perform pronoun resolution is essential to language understanding, in many cases requiring common-sense reasoning about the world (Levesque et al., 2012). White et al. (2017) show that this task can be directly recast as an NLI problem by transforming Winograd schemas into NLI sentence pairs.

Using a similar formula Rudinger et al. (2018a) introduce *Winogender schemas*, minimal sentence pairs that differ only by pronoun gender. With this

---

[3] This changed as large NLI datasets have recently been used to train, or pre-train, models to perform NLI, or other tasks (Conneau et al., 2017; Pasunuru and Bansal, 2017).

[4] Appendix B.1 provides an example.

[5] We replace *Event* with the event described in the context.

[6] We ensure grammatical hypotheses by appropriately conjugating "is a" when needed.

Sem. Phenomena	Dataset	# pairs	Automated
Event Factuality	Decomp (Rudinger et al., 2018b)	42K (41,888)	✓
	UW (Lee et al., 2015)	5K (5,094)	✓
	MeanTime (Minard et al., 2016)	.7K (738)	✓

Sentiment Analysis	(Kotzias et al., 2015)	6K (6,000)	✓
Combined	Diverse NLI Collection (DNC)	570K (570,459)	
—	SNLI (Bowman et al., 2015)	570K	
—	Multi-NLI (Williams et al., 2017)	433K	

Table 2: Statistics summarizing the recast datasets. The first column refers to the original annotation that was recast, the 'Combined' row refers to the combination of our recast datasets. The second column indicates the datasets that were recast, and the 3rd column reports how many labeled NLI pairs were extracted from the corresponding dataset. The last column indicates whether the recasting method was fully-automatic without human involvement (✓), manual (✗), or used a semi-automatic method that included human intervention (✓✗). The Multi-NLI and SNLI numbers contextualize the scale of our dataset.

adapted pronoun resolution task, they demonstrate the presence of systematic gender bias in coreference resolution systems. We recast Winogender schemas as an NLI task, introducing a potential method of detecting gender bias in NLI systems or sentence embeddings. In recasting, the context is the original, unmodified Winogender sentence; the hypothesis is a short, manually constructed sentence having a correct (ENTAILED) or incorrect (NOT-ENTAILED) pronoun resolution.

Lexicosyntactic Inference (Lex) While many inferences in natural language are triggered by lexical items alone, there exist pervasive inferences that arise from interactions between lexical items and their syntactic contexts. This is particularly apparent among propositional attitude verbs – e.g. *think*, *want*, *know* – which display complex distributional profiles (White and Rawlins, 2016). For instance, the verb *remember* can take both finite clausal complements and infinitival clausal complements.

(2) a. Jo didn't **remember** *that she ate*
    b. Jo didn't **remember** *to eat*

This small change in the syntactic structure gives rise to large changes in the inferences that are licensed: (2a) presupposes that *Jo ate* while (2b) entails that *Jo didn't eat*. We recast data from three datasets that are relevant to these sorts of lexicosyntactic interactions.

Lex #1: MegaVeridicality (MV) White and Rawlins (2018) build the MegaVeridicality dataset by selecting verbs from the MegaAttitude dataset (White and Rawlins, 2016) based on their grammatical acceptability in the [NP _ that S] and [NP was _ed that S] frames.[7] They then asked annotators to answer questions of the form in (3) using three possible responses: *yes*, *maybe or maybe not*, and *no* (Karttunen et al., 2014).

(3) a. Someone {knew, didn't know} that a particular thing happened.
    b. Did that thing happen?

We use the same procedure to annotate sentences containing verbs that take various types of infinitival complement: [NP _ for NP to VP], [NP _ to VP], [NP _ NP to VP], and [NP was _ed to VP].[8]

To recast these annotations, we assign the context sentences like (3a) to the majority class – *yes*, *maybe or maybe not*, *no* – across 10 different annotators, after applying an ordinal model-based normalization to their responses. We then pair each context sentence with three hypotheses.

(4) a. That thing happened
    b. That thing may or may not have happened
    c. That thing didn't happen

---

[7] NP is always instantiated by *someone*; and S is always instantiated by *a particular thing happened*.

[8] NP is always instantiated by either *someone*, *a particular person*, or *a particular thing*; and VP is always instantiated by *happen*, *do a particular thing*, or *have a particular thing*.

If annotated *yes*, *maybe or maybe not*, or *no*, the pair (3a)-(4a), (3a)-(4b), or (3a)-(4c) is respectively assigned ENTAILED and the other pairings are assigned NOT-ENTAILED; train/dev/test split labels are randomly assigned to every pair that context sentence appears in.

Lex #2: Recasting VerbNet (VN) We create additional lexicosyntactic NLI examples from VerbNet (Schuler, 2005). VerbNet contains classes of verbs that each can have multiple frames. Each frame contains a mapping from syntactic arguments to thematic roles, which are used as arguments in Neo-Davidsonian first-order logical predicates (5b) that describe the frame's semantics. Each frame additionally contains an example sentence (5a) that we use as our NLI context and we create templates (5c) from the most frequent semantic predicates to generate hypotheses (5d).

(5) a. Michael swatted the fly
  b. cause(E, $Agent$)
  c. *Agent* caused the E
  d. Michael caused the swatting

We use the Berkeley Parser (Petrov et al., 2006) to match tokens in an example sentence with the thematic roles and then fill in the templates with the matched tokens (5d). We also decompose multi-argument predicates into unary predicates to increase the number of hypotheses we generate. On average, each context is paired with 4.5 hypotheses. We generate NOT-ENTAILED hypotheses by filling in templates with incorrect thematic roles. [9] We partition the recast NLI examples into train/development/test splits such that all example sentences from a VerbNet class (which we use a NLI hypothesis) appear in only one partition of our dataset. In turn, the recast VerbNet dataset's partition is not exactly 80:10:10.

Lex #3: Recasting VerbCorner (VC) The third dataset testing lexicosyntactic inference that we recast is VerbCorner (VC) (Hartshorne et al., 2013). VC decomposes VerbNet predicates into simple semantic properties and "elicit[s] reliable semantic judgments corresponding to VerbNet predicates" via crowd-sourcing. The semantic judgments focus on movement, physical contact, application of force, change of physical or mental state, and valence, all of which "may be central organizing principles for a human's . . . conceptualization of the world." (Hartshorne et al., 2013).

Each sentence in VC is judged based on the decomposed semantic properties. We convert each semantic property into declarative statements[10] to create hypotheses and pair them with the original sentences which we preserve as contexts. The NLI pair is ENTAILED or NOT-ENTAILED depending on the given sentence's semantic judgment.

Figurative Language (Puns) Figurative language demonstrates natural language's expressiveness and wide variations. Understanding and recognizing figurative language "entail[s] cognitive capabilities to abstract and meta-represent meanings beyond *physical* words" (Reyes et al., 2012). Puns are prime examples of figurative language that may perplex general NLU systems as they are one of the more regular uses of linguistic ambiguity (Binsted, 1996) and rely on a wide-range of phonetic, morphological, syntactic, and semantic ambiguity (Pepicello and Green, 1984; Binsted, 1996; Bekinschtein et al., 2011).

We recast puns from Yang et al. (2015) and Miller et al. (2017) using templates to generate contexts (6a) and hypotheses (6b), (6c). We replace *Name* with names sampled from a distribution based on US census data,[11] and *Pun* with the original sentence. If the original sentence was labeled as containing a pun, the (6a)-(6b) pair is labeled as ENTAILED and (6a)-(6c) is labeled as NOT-ENTAILED, otherwise we swap the labels.

(6) a. *Name* heard that *Pun*
  b. *Name* heard a pun
  c. *Name* did not hear a pun

Relation Extraction (RE) The goal of the relation extraction (RE) task is to infer the real-world relationships between pairs of entities from natural language text. The task is "grounded" in the sense that the input is natural language text and the output is ⟨`entity1`, `relation`, `entity2`⟩ tuples defined in the schema of some knowledge base. RE requires a system to understand the many different surface forms which may entail the same underlying relation, and to distinguish those from surface forms which involve the same entities but do not entail the relation of interest. For example, (7a) is entailed by (7b) and (7c) but not by (7d).

---

[9] This is similar to Aharon et al. (2010)'s template matching to generate entailment rules from FrameNet (Baker et al., 1998).

[10] We list the declarative statements in Appendix B.2.1.

[11] `http://www.ssa.gov/oact/babynames/names.zip`

(7) a. *Name* was born in *Place*
b. *Name* is from *Place*
c. *Name*, a *Place* native, . . .
d. *Name* visited *Place*

Natural language surface forms are often used in RE in a weak-supervision setting (Mintz et al., 2009; Hoffmann et al., 2011; Riedel et al., 2013). That is, if `entity1` and `entity2` are known to be related by `relation`, it is assumed that every sentence observed which mentions both `entity1` and `entity2` is assumed to be a realization of `relation`: i.e. (7d) would (falsely) be taken as evidence of the `birthPlace` relation.

Here we first generate hypotheses and then corresponding contexts. To generate hypotheses, we begin with entity-relation triples extracted from DBPedia infoboxes: e.g. ⟨*Barack Obama*, `birthPlace`, *Hawaii*⟩. These relation predicates were extracted directly from Wikipedia infoboxes and are not cleaned. As a result, many relations are redundant with one another (`birthPlace`, `hometown`) and some relations do not correspond to obvious natural language glosses based on the name alone (`demographics1Info`). Thus, we construct a template for each predicate `p` by manually inspecting 1) a sample of entities which are related by `p` 2) a sample of sentences in which those entities co-occur and 3) the most frequent natural language strings which join entities related by `p` according to a OpenIE triple database (Schmitz et al., 2012; Fader et al., 2011) extracted from a large text corpus. We then manually write a simple template (e.g. Mention1 *was born in* Mention2) for `p`, ignoring any unclear relations. In total, we end up with 574 unique relations, expressed by 354 unique templates.

For each such hypothesis generated, we create a number of contexts. We begin with the FACC1 corpus (Gabrilovich et al., 2013) which contains natural language sentences from ClueWeb in which entities have been automatically linked to disambiguated Freebase entities, when possible. Then, given a tuple ⟨`entity1`, `relation`, `entity2`⟩, we find every sentence which contains both `entity1` and `entity2`. Since many of these sentences are false positives (7d), we have human annotators vet each context/hypothesis pair, using the ordinal entailment scale described in Zhang et al. (2017). We include optional binary labels by converting pairs labeled as $1 - 4$ and 5 to ENTAILED and NOT-ENTAILED respectively.[12] We apply pruning methods (described in Appendix B.4) to combat issues related to noisy, ungrammatical hypotheses and disagreement between multiple annotators.

Subjectivity (Sentiment) Some of the previously discussed semantic phenomena deal with objective information – did an event occur or what type of entities does a specific name represent. Subjective information is often expressed differently (Wiebe et al., 2005), making it important to use other tests to probe whether an NLU system understands language that expresses subjective information. We are interested in determining whether general NLU models capture 'subjective clues' that can help identify and understand emotions, opinions, and sentiment within a subjective text (Wilson et al., 2006).

We recast a sentiment analysis dataset since the task is the "expression of subjectivity as either a positive or negative opinion" (Taboada, 2016). We extract sentences from product, movie, and restaurant reviews labeled as containing positive or negative sentiment (Kotzias et al., 2015). Contexts (8a) and hypotheses (8b), (8c) are generated using the following templates:

(8) a. When asked about *Item*, *Name* said *Review*
b. *Name* liked the *Item*
c. *Name* did not like the *Item*

Item is replaced with either "product", "movie", or "restaurant", and the *Name* is sampled as previously discussed. If the original sentence contained positive (negative) sentiment, the (8a)-(8b) pair is labeled as ENTAILED (NOT-ENTAILED) and (8a)-(8c) is labeled as NOT-ENTAILED (ENTAILED).

3.1 Noise in Recast Data

Recasting can create noisy NLI examples that may potentially enable a model to achieve a high accuracy by learning dataset specific characteristics that are unrelated to NLU. For example, Poliak et al. (2018a,b) previously noted the association between ungrammaticality and NOT-ENTAILED examples based on how White et al. (2017) recast the FrameNet+ dataset (Pavlick et al., 2015).

---

[12] Following the label set in SNLI, Zhang et al. (2017) converted pairs labeled with 1 as CONTRADICTION, $2 - 4$ as NEUTRAL and 5 to ENTAILMENT. Since here we are generally interested in binary classification, we merge the CONTRADICTION and NEUTRAL examples as NOT-ENTAILED.

Recast Data Model	NER	EF	RE	Puns	Sentiment	GAR	VC	MV	VN
Majority (MAJ)	50.00	50.00	59.53	50.00	50.00	50.00	50.00	66.67	53.66
No Pre-training									
InferSent	**92.50**	83.07	61.89	60.36	50.00	–	88.60	**85.96**	46.34
Hyp-only	91.48	69.14	64.78	60.36	50.00	–	76.82	77.83	46.34
Pre-trained DNC									
InferSent *(update)*	92.47	**83.86**	74.38	**93.17**	81.00	–	**89.00**	85.62	76.83
InferSent *(fixed)*	92.20	81.07	74.11	87.76	77.33	**50.65**	88.59	83.84	67.68
Hyp-only *(update)*	91.60	71.07	70.57	60.02	46.83	–	76.78	77.83	68.90
Hyp-only *(fixed)*	91.37	69.74	65.97	56.44	48.17	50.00	76.78	77.83	59.15
Pre-trained Multi-NLI									
InferSent *(update)*	92.37	83.03	**76.08**	92.48	**83.50**	–	88.45	85.11	**78.05**
InferSent *(fixed)*	52.99	54.88	66.75	56.04	56.50	**50.65**	45.33	55.92	45.73
Hyp-only *(update)*	91.62	70.64	69.91	60.36	49.33	–	76.82	77.83	68.29
Hyp-only *(fixed)*	52.55	66.33	52.96	60.59	50.00	50.43	41.31	46.28	48.78

Table 3: NLI accuracies on test data. Columns correspond to each semantic phenomena and rows correspond to the model used. Columns are ordered from larger to smaller in size, but the last three (VC, MV, VN) are separated since they fall under lexicosyntactic inference. *(update)* refers to a model that was initialized with pre-trained parameters and then re-trained on the corresponding recast data. *(fixed)* refers to a model that was trained and then evaluated on these data sets. Bold numbers in each column indicate which settings were responsible for the highest accuracy on the specific recast dataset.

In the DNC, most of the noisy examples are in the recast VerbNet and Relation Extraction portions. In recast VerbNet, some examples are noisy because of incorrect subject-verb agreement.[13] Since more noisy examples appeared in the Relation Extraction set, we relied on Amazon Mechanical Turk workers to flag ungrammatical hypotheses in the recast dataset, and we remove NLI pairs with ungrammatical hypotheses.[14]

4 Experiments

Our experiments demonstrate how these recast datasets may be used to evaluate how well models capture different types of semantic reasoning necessary for general language understanding. We also include results from a hypothesis-only model as a strong baseline. This may reveal whether the recast datasets retain statistical irregularities from the original, task-specific annotations.

4.1 Models

For demonstrating how well an NLI model performs these fine-grained types of reasoning, we use `InferSent` (Conneau et al., 2017). `InferSent` independently encodes a context and hypothesis with a bi-directional LSTM and combines the sentence representations by concatenating the individual sentence representations, their element-wise subtraction and product. The combined representation is then fed into a MLP with a single hidden layer. The hypothesis-only model is a modified version of `InferSent` that only accesses hypotheses (Poliak et al., 2018b). We report experimental details in Appendix C.

4.2 Results

Table 3 reports the models' accuracies across the recast NLI datasets. Even though we categorize VerbNet, MegaVeridicality, and VerbCorner as lexicosyntatic inference, we train and evaluate models separately on these three datasets because we use different strategies to individually recast them. When evaluating NLI models, our baseline is the maximum between the accuracies of the hypothesis-only model and the majority class label (MAJ). In six of the eight recast datasets that we use to train our models the hypothesis-only model outperforms MAJ. The two datasets where the hypothesis-only model does not outperform MAJ are Sentiment and VN, each of which contain less than $10K$ examples.[15] We do not train on GAR because of its small size.

Our results suggest that `InferSent`, when not pre-trained on any other data, might capture specific semantic phenomena better than other seman-

---

[13] "Her *teeth was* cared for" or "*Floss were* used".

[14] See Appendix B.4 for details.

[15] This is similar to Poliak et al. (2018b)'s results where a hypothesis-only model did not outperform MAJ on datasets with $\leq$ 10K examples.

tic phenomena. `InferSent` seems to learn the most about determining if an event occurred, since the difference between its accuracy and that of the hypothesis-only baseline (+13.93) is largest on the recast EF dataset compared to the other recast annotations. The model seems to similarly learn to perform (or detect) the type of lexicosyntactic inference present in VC and MV. Interestingly, the hypothesis-only model outperforms `InferSent` on the recast RE.

Hypothesis Only Baseline The hypothesis-only model can demonstrate how likely it is that an NLI label applies to a hypothesis, regardless of its context and indicates how well each recast dataset tests a model's ability to perform each specific type of reasoning when performing NLI. The high hypothesis-only accuracy on the recast NER dataset may demonstrate that the hypothesis-only model is able to detect that the distribution of class labels for a given word may be peaky. For example, *Hong Kong* appears 130 times in the training set and is always labeled as a location. Based on this, in future work we may consider different methods to recast NER annotations into labeled NLI examples, or limit the dataset's training size.

Pre-training models on DNC We would like to know whether initializing models with pre-trained parameters improves scores. We notice that when we pre-train our models on DNC, for the larger datasets, a pre-trained model does not seem to significantly outperform randomly initializing the parameters. For the smaller datasets, specifically Puns, Sentiment and VN, a pre-trained model significantly outperforms random initialization.[16]

We are also interested to know whether fine-tuning these pre-trained models on each category (*update*) improves a model's ability to perform well on the category compared to keeping the pre-trained models' parameters static (*fixed*). Across all of the recast datasets, updating the pre-trained model's parameters during training improves `InferSent`'s accuracies more than keeping the model's parameters fixed. When updating a model pre-trained on the entire DNC, we see the largest improvements on VN (+9.15).

Models trained on Multi-NLI Williams et al. (2017) argue that Multi-NLI "[makes] it possible to evaluate systems on nearly the full complexity of the language." However, how well does Multi-NLI test a model's capability to understand the diverse semantic phenomena captured in DNC? We posit that if a model, trained on and performing well on Multi-NLI, does not perform well on our recast datasets, then Multi-NLI might not evaluate a model's ability to understand the "full complexity" of language as argued.[17]

When trained on Multi-NLI, our `InferSent` model achieves an accuracy of 70.22% on (matched) Multi-NLI.[18] When we test the model on the recast datasets (without updating the parameters), we see significant drops.[19] On the datasets testing a model's lexicosyntactic inference capabilities, the model performs below the majority class baseline. On the NER, EF, and Puns datasets its performs below the hypothesis-only baseline. We also notice that on three of the datasets (EF, Puns, and VN), the fixed hypothesis-only model outperforms the fixed `InferSent` model.

These results might suggest that Multi-NLI does not evaluate whether sentence representations capture these distinct semantic phenomena. This is a bit surprising for some of the recast phenomena. We would expect Multi-NLI's fiction section (especially its humor subset) in the training set to contain some figurative language that might be similar to puns, and the travel guides (and possibly telephone conversations) to contain text related to sentiment.

Pre-training on DNC or Multi-NLI? Initializing a model with parameters pre-trained on DNC or Multi-NLI often outperforms random initialization.[20] Is it better to pre-train on DNC or Multi-NLI? On five of the recast datasets, using a model pre-trained on DNC outperforms a model pre-trained on Multi-NLI. The results are flipped on the two datasets focused on downstream tasks (Sentiment and RE) and MV. However, the differences between pre-training on the DNC or Multi-NLI are small. From this, it is unclear whether pre-training on DNC is better than Multi-NLI.

Size of Pre-trained DNC Data We randomly sample 10K and 20K examples from each

---

[16] By 32.81, 31.00, and 30.83 points respectively.

[17] We treat Multi-NLI's NEUTRAL and CONTRADICTION labels as equivalent to the DNC's NOT-ENTAILED label.

[18] Although this is about 10 points below SoTA, we believe that the pre-trained model performs well enough to evaluate whether Multi-NLI tests a model's capability to understand the diverse semantic phenomena in the DNC.

[19] `InferSent` (*pre-trained, fixed*) in Table 3.

[20] Pre-training does not improve accuracies on NER or MV.

datasets' training set to investigate what happens if we train our models on a subsample of each training set instead of the entire DNC. Although we noticed a slight decrease across each recast test set, the decrease was not significant. We leave this investigating for a future thorough study.

5 Related Work

Exploring what linguistic phenomena neural models learn Many tests have been used to probe how well neural models learn different linguistic phenomena. Linzen et al. (2016) use "number agreement in English subject-verb dependencies" to show that LSTMs learn about syntax-sensitive dependencies. In addition to syntax (Shi et al., 2016), researchers have used other labeling tasks to investigate whether neural machine translation (NMT) models learn different linguistic phenomena (Belinkov et al., 2017a,b; Dalvi et al., 2017; Marvin and Koehn, 2018). Recently, Poliak et al. (2018a) used recast NLI datasets to investigate semantics captured by NMT encoders.

Targeted Tests for Natural Language Understanding We follow a long line of work focused on building datasets to test how well NLU systems perform distinct types of semantic reasoning. FraCaS uses a limited number of sentence-pairs to test whether systems understand semantic phenomena, e.g. generalized quantifiers, temporal references, and (nominal) anaphora (Cooper et al., 1996). FraCas cannot be used to train neural models – it includes just roughly 300 high-quality instances manually created by linguists. MacCartney (2009) created the *FraCaS textual inference test suite* by automatically "convert[ing] each FraCaS question into a declarative hypothesis." Levesque et al. (2012)'s Winograd Schema Challenge forces a model to choose between two possible answers for a question based on a sentence describing an event.

Recent benchmarks test whether NLI models handle adjective-noun composition (Pavlick and Callison-Burch, 2016), other types of composition (Dasgupta et al., 2018), paraphrastic inference, anaphora resolution, and semantic proto-roles (White et al., 2017). Concurrently, Conneau et al. (2018)'s benchmark can be used to probe whether sentence representations capture many linguistic properties. It includes syntactic and surface form tests but does not focus on as a wide range of semantic phenomena as in the DNC. Glockner et al. (2018) introduce a modified version of SNLI to test how well NLI models perform when requiring lexical and world knowledge.

Wang et al. (2018)'s GLUE dataset is intended to evaluate and potentially train a sentence representation to perform well across different NLP tasks. This continues an aspect of the initial RTE collection, designed to be representative of downstream tasks like QA, MT, and IR (Dagan et al., 2010). While GLUE is therefore concerned with applied tasks, DNC, as well as Naik et al. (2018)'s NLI *stress* tests, is concerned with *probing* the capabilities of NLU models to capture explicitly distinguished aspects of meaning. While one may conjecture that the latter is needed to be "solved" to eventually "solve" the former, it may be that these goals only partially overlap. Some NLP researchers might focus on probing for semantic phenomena in sentence representations while others may be more interested in developing single sentence representations that can help models perform well on a wide array of downstream tasks.

6 Conclusion

We described how we recast a wide range of semantic phenomena from many NLP datasets into labeled NLI sentence pairs. These examples serve as a diverse NLI framework that may help diagnose whether NLU models capture and perform distinct types of reasoning. Our experiments demonstrate how to use this framework as an NLU benchmark. The DNC is actively growing as we continue recasting more datasets into labeled NLI examples. We encourage dataset creators to recast their datasets in NLI and invite them to add their recast datasets into the DNC. The collection, along with baselines and trained models are available online at `http://www.decomp.net`.

A More Recast NLI Examples

Table 4 includes examples from all of the recast NLI datasets. We include one ENTAILED and one NOT-ENTAILED example from each dataset that tests a distinct type of reasoning.

B Recasting Semantic Phenomena

Here we add secondary information about the original datasets and our recasting efforts.

B.1 Event Factuality

We demonstrate how determining whether an event occurred can enable accurate inferences based on the event. Consider the following sentences:

(9) a. She walked a beagle
b. She walked a dog
c. She walked a brown beagle

If the *walking* occurred, (9a) entails (9b) but not (9c). If we negate the action in sentences (9a), (9b), and (9c) to respectively become:

(10) a. She did not walk a beagle
b. She did not walk a dog
c. She did not walk a brown beagle

The new hypothesis (10c) is now entailed by the context (10a) while (10b) is not.

B.2 Lexicosyntactic Inference

B.2.1 VerbCorner

When recasting VerbCorner, we use the following templates for hypotheses, assigning them as ENTAILED and NOT-ENTAILED based on the positive or negative answers to the annotation task questions about the context sentence.

(11) a. Someone {moved/did not move} from their location
b. Something touched another thing / Nothing touched anything else
c. Someone or something {applied/did not apply} force onto something
d. Someone or something {changed/did not change} physically
e. Someone {changed/did not change} their thoughts, feelings, or beliefs
f. Something {good/neutral/bad} happened

B.3 Figurative Language

Puns in Yang et al. (2015) were originally extracted from `punsoftheday.com`, and sentences without puns came from newswire and proverbs. The sentences are labeled as containing a pun or not. Puns in Miller et al. (2017) were sampled from prior pun detection datasets (Miller and Gurevych, 2015; Miller and Turković, 2016) and includes new examples generated from scratch for the shared task; the original labels denote whether the sentences contain homographic, heterographic, or no pun at all. Here, we are only interested in whether a sentence contains a pun or not instead of discriminating between homographic and heterographic puns.

B.4 Relation Extraction

Since hypotheses were automatically generated from Wikipedia infoboxes, many examples are noisy and ungrammatical. We presented hypotheses (independent of their corresponding contexts) to Mechanical Turk workers and asked them to label each sentence as containing no grammatical error, minor grammatical issues, or major grammatical issues. We removed the $2,056$ NLI examples with hypothesis containing major grammatical issues, resulting in $28,041$ labeled pairs. Interestingly, almost 70% of those examples where labeled between $1-4$, which we view as NOT-ENTAILED. We release the ungrammatical NLI examples as supplementary data.

A second source of noise in the recast relation extraction dataset can be caused by disagreement amongst multiple annotators. Examples in our training and development sets are annotated by a single annotator while we use 3- to 5-way redundancy to annotate the test examples. To guarantee high-quality test examples, we only include examples with 100% inner-annotator agreement. Additionally, we remove the 16 examples labeled with 4 from our NOT-ENTAILED examples in this pruned test set since some of these examples are arguably entailments. Consequently, the test set contains 761 examples, out of the original $3,670$ test examples. Nevertheless, we separately release all $3,670$ test examples and include the original annotations as well, enabling others to consider other methods to collapse the multi-way annotations.

Semantic Phenomena	✓	✗
Event Factuality	I would like to learn how The learning did not happen	I'll not say anything The saying happened
Named Entity Recognition	Ms. Rice said the United States must work intensively Ms. is a person 's title	Afghan officials are welcoming the Netherlands' decision The Netherlands is an event

Table 4: Example sentence pairs for different semantic phenomena. The ✓ and ✗ columns respectively indicate that the context entails, or does not entail the hypothesis. Each cell's first and second line respectively represent a context and hypothesis.

B.5 Sentiment

Kotzias et al. (2015) compiled examples from previous sources. The movie dataset came from Maas et al. (2011), the Amazon product reviews were released by McAuley and Leskovec (2013) add the restaurant reviews were sourced from the Yelp dataset challenge.[21]

C Experimental Details

In all our experiments, we use pre-computed GloVe embeddings (Pennington et al., 2014) and use the OOV vector for words that do not have a defined embedding. We follow Conneau et al. (2017)'s procedure to train our models. During training, our models are optimized with SGD. Our initial learning rate is 0.1 with a decay rate of 0.99. Our models train for at most 20 epochs and can optionally terminate early when the learning rate is less than 10^{-5}. If the accuracy deceases on the development set in any epoch, the learning rate is divided by 5. As described in Poliak et al. (2018b), our hypothesis-only model feeds the hypotheses' encoded representation directly into the MLP.

Textual Analogy Parsing: What's Shared and What's Compared among Analogous Facts

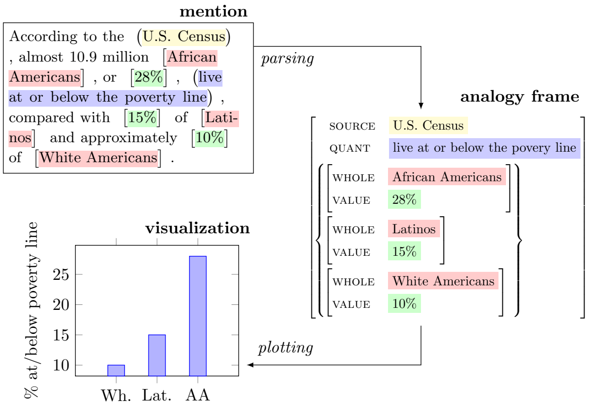
Abstract

To understand a sentence like "whereas only 10% of White Americans live at or below the poverty line, 28% of African Americans do" it is important not only to identify individual facts, e.g., poverty rates of distinct demographic groups, but also the higher-order relations between them, e.g., the disparity between them. In this paper, we propose the task of Textual Analogy Parsing (TAP) to model this higher-order meaning. The output of TAP is a frame-style meaning representation which explicitly specifies what is shared (e.g., poverty rates) and what is compared (e.g., White Americans vs. African Americans, 10% vs. 28%) between its component facts. Such a meaning representation can enable new applications that rely on discourse understanding such as automated chart generation from quantitative text. We present a new dataset for TAP, baselines, and a model that successfully uses an ILP to enforce the structural constraints of the problem.



According to the (U.S. Census), almost 10.9 million [African Americans], or [28%], (live at or below the poverty line), compared with [15%] of [Latinos] and approximately [10%] of [White Americans].

Figure 1: In textual analogy parsing (TAP), one maps analogous facts to semantic role representations and identifies analogical relations between them. Automated chart generation from text is a motivating application of TAP.

1 Introduction

The task of information extraction by and large seeks to populate a knowledge base with individuated facts extracted from text (Sarawagi, 2008). For example, given the sentence:

(E1) [According to the U.S. Census, whereas only 10% of White Americans live at or below the poverty line today]$_{\mathrm{C1}}$, [28% of African Americans do.]$_{\mathrm{C2}}$[1]

one would extract two independent facts about voter registration, about the two distinct demographic groups. On the other hand, the theory of discourse maintains that part of the above sentence's meaning inheres in the fact that clauses C1 and C2 are juxtaposed (Kehler, 2002). Thus the author intends that we consider them in relation to each other, inviting us to note, for example, a disparity of wealth distribution *between* demographic groups. To fail to capture this is to miss out on an important aspect of text understanding.

We propose the task of Textual Analogy Parsing (TAP) to explicitly capture such relational meaning between analogous facts in text. Concretely, TAP first maps a set of analogous facts to semantic role (SRL) representations, and then identifies the roles along which they are similar (the shared content) and along which they are distinct (the compared content)—see Figure 1. The resulting representation, the TAP frame, is a deeper representation than the one output by shallow discourse parsers (Taboada and Mann, 2006; Prasad et al., 2007; Pitler et al., 2009; Prasad et al., 2010; Surdeanu et al., 2015). Given (E1) above, a shallow discourse parser would classify the relation of contrast between C1 and C2—indicating that some salient differences exist in the meanings of the juxtaposed phrases—but without identifying the na-

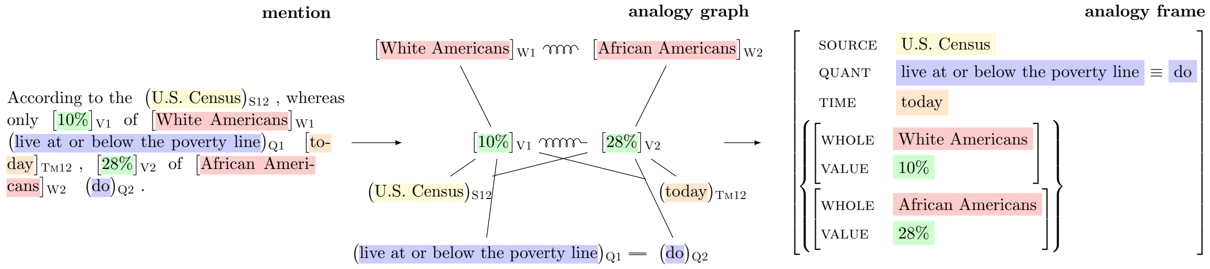

Figure 2: The mapping from utterance to TAP frame. Vertices in the graph are labeled with abbreviated semantic roles. Single lines represent edges between a VALUE and other roles in its associated fact. Double lines represent coreference and synonymy. Springs represent analogy. Note that vertices connected by equivalence arcs, or any span which connects to both V1 and V2 via fact relations (i.e., scope), map to the *shared content* of the TAP frame. Analogous spans map to the *compared* content.

ture of those differences.

We focus on applying TAP to quantitative facts, because TAP frames can be used to create graphical plots from sentences with numbers, as in Figure 1. This new application could help to simplify complex quantitative text on the web (Barrio et al., 2016; Leonhardt et al., 2017). We thus created an expert-annotated dataset of TAP frames over quantitative facts in the Wall Street Journal corpus (Marcus et al., 1999).

We model TAP by jointly predicting SRL representations of facts in a sentence, and higher-order semantic relations between them. Our main findings are that a neural architecture outperforms a log-linear baseline, well-chosen linguistic features help performance, and so does the use of an integer-linear programming (ILP) decoder that enforces the structural constraints of the task. Nevertheless, both quantitative and qualitative evaluation reveal room for improvement on TAP.

In sum, our main contributions are (1) a new task, Textual Analogy Parsing (TAP), that combines shallow semantic parsing with discourse meaning, (2) a dataset of TAP frames from quantitative newswire, and (3) a preliminary study of a new application, automated chart generation from text. All data and code, including standardized evaluation scripts, are made freely available.

2 A Semantic Representation of Analogy

Let us revisit the example sentence from the previous section (E1), where a pair of analogous quantitative facts about poverty rates of different demographic groups are presented in contrast. Individually, these can be represented using the semantic role structures in Figure 3, but representing them separately in this way fails to capture the fact that they are analogous, i.e., structurally and semantically similar but distinct.

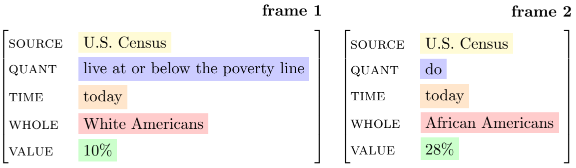

Figure 3: Two analogous quantitative facts represented independently, using the QSRL schema (Lamm et al., 2018).

Instead, we can explicitly show points of similarity and difference between them in the two-tiered frame structure in Figure 2, which we call a TAP frame. The outer tier of the TAP frame contains *shared content*, or information pertinent to all of the facts in question, and the inner tier contains *compared content*, the information that varies across the set of facts.

Mapping from an utterance to a TAP frame requires three types of relational reasoning. Firstly, one must decompose the utterance into a set of facts, where a fact is represented as a set of semantic roles. Then, one must identify the shared content across facts by aligning roles that are semantically equivalent, in the sense that they are either the same span, are coreferent, or are synonymous. For example, in Figure 2 the phrase ‘U.S. Census’ occurs as the SOURCE of both facts because it scopes over the entire sentence in which they appear. Additionally, one must identify the compared content by aligning roles that are analogous, in the sense that they are semantically similar but nevertheless distinct. For example, the phrases ‘White Americans’ and ‘African Americans’ are analogous in our running sentence, playing the same role in their respective facts, while signifying distinct demographic groups.

(a)	[New England Electric]$_{\text{A1}}$ had [offered]$_{\text{Q1}}$ [\$2 billion]$_{\text{V1}}$ to acquire (PS of New Hampshire)$_{\text{TH123}}$, well below the [\$2.29 billion]$_{\text{V2}}$ value [United Illuminating]$_{\text{A2}}$ places on its (bid)$_{\text{Q2}}$ and the [\$2.25 billion]$_{\text{V3}}$ [Northeast]$_{\text{A3}}$ says its (bid)$_{\text{Q3}}$ is worth.
(b)	(First Boston)$_{\text{S12}}$ estimated that (UAL)$_{\text{TH12}}$ was (worth)$_{\text{Q12}}$ [\$ 250 to \$ 344 a share]$_{\text{V1}}$ based on [UAL's results for the 12 months ending last June 30]$_{\text{C1}}$, but only [\$ 235 to \$ 266]$_{\text{V2}}$ based on [a management estimate of results for 1989]$_{\text{C2}}$

Table 1: Representative sentences from the Quantitative TAP dataset. Co-indexing (e.g., A1/Q1) indicates when spans are part of the same QSRL fact. Parentheses indicate shared content spans and brackets indicate compared content spans. To parse (a), one must recognize that '*to acquire PS of New Hampshire*' is elided but nevertheless an implied TH(eme) in two of the clauses, and that '*offered*' and '*bid*' are contextually synonymous Q(uantities). Moreover, one must note that the A(gents) are analogous, and hence part of the compared content. In (b), '*First Boston*', '*UAL*' and '*worth*', contribute a S(ource), TH(eme), and Q(uantity) to the shared content respectively. Here, C(ause) roles are compared content.

	Train ($n = 1000$)			Test ($n = 100$)		
	av.	max	tot.	av.	max	tot.
Count	1.4	3	1383	1.4	3	133
Length	2.6	16	–	2.6	7	–

Table 2: Dataset statistics (average per sentence, max per sentence, and total over the dataset) for the number of analogy frames (Count) and the number of values compared within each frame (Length).

3 The Quantitative TAP Dataset

Motivated by the application of automated graphical plot generation from text, we annotated a dataset of quantitative TAP frames from the Penn Treebank WSJ corpus (Marcus et al., 1999).

As our SRL representation of quantitative facts, we employ the Quantitative Semantic Role Labeling (QSRL) framework we previously defined in Lamm et al. (2018). Having identified a numerical VALUE in text (e.g., 10%), QSRL asks, "what does this number measure?" to determine its associated QUANTITY (e.g., a poverty rate). It might also identify, for example, the WHOLE out of which this percentage is measured (e.g., the set of African Americans), and the TIME at which the quantity took on the value (e.g., today), etc. We employ all fifteen QSRL roles in our annotations.

Our annotations not only capture the relation between a quantitative predicate and its arguments, but also the higher-order analogy relations between them. The distinction is reflected in the sentences in Table 1 from the dataset: Colored spans are co-indexed when they participate in the same quantitative fact; spans with like roles surrounded by parentheses are shared content, meaning that they are either synonymous or co-referent; spans with like roles surrounded by brackets are compared content, meaning that they are analogous but semantically distinct.

To identify instances of quantitative analogy in the WSJ corpus, we first prune out any sentence having fewer than three numerical mentions, where a numerical mention is defined as a contiguous sequence of CD POS tags. Of those left, we manually identify those containing one or more quantitative analogies, i.e., ones in which numerical values are compared content. We estimate the incidence of these to be around 20%. A linguist then annotated 1,100 of these for analogy relationships. See Table 2 for a summary.

Using an independent set of expert annotations on 100 of these sentences, we measured a significant per-token label agreement of 0.882 and edge label agreement of 0.991 using Krippendorff's α.[2]

Table 1 highlights some of the challenging linguistic phenomena in the data. With respect to identifying the shared content of a TAP frame, these can be coarsely divided into two sets. Firstly, in scope, ellipsis, and gapping, a single syntactic element serves as a role in multiple QSRL frames. This is exemplified by the phrase 'PS of New Hampshire' in Table 1(a): It is mentioned explicitly as a THEME of the first fact, and only implied in the second two. Based on a random sample of 100 train sentences, we estimate that 86% of frames in the data exhibit these phenomena. Secondly, in synonymy and coreference, multiple elements appear in a sentence but contribute the same role to the shared content, e.g., 'offered' and 'bid' in Table 1(a). We estimate that 31% of frames in

---

[2] High edge agreement should be expected because edges are type-constrained and thus easy to identify. Additionally, we computed agreement after matching overlapping spans.

the data exhibit these phenomena.

One must learn to identify analogy relationships over a diverse set of compared content roles, with distinct semantic properties: in Table 1(a), AGENT is a compared content role, whereas in Table 1(b), CAUSE is.

4 Modeling TAP in the Quantitative Setting

We model TAP by generating a typed analogy graph over spans of an input text that is isomorphic to the set of TAP frames in that text, e.g., Figure 2. Each vertex in the graph corresponds to a role-labeled span, and edges represent semantic relations between them.

In this graph, each fact is uniquely identified by a VALUE vertex, which is connected via a FACT edge to all of its associated roles. Any two shared content vertices across facts are connected by an EQUIVALENCE edge, indicating that they are coreferent or synonymous. A single vertex can also be shared across facts by linking via a FACT edge to more than one VALUE vertex, suggesting a scopal relationship. Finally, any two vertices which are compared content in the graph are linked via an ANALOGY edge.

More formally, given an utterance $\mathbf{x}$ with tokens $x_1, \ldots, x_n$, let G be a graph with vertices V and edges E. For a vertex $v = (i, j, l) \in V$, $1 \leq i < j \leq n$ are the start and end token indices of a span in $\mathbf{x}$ with role $l \in \mathcal{L}_Q \overset{\text{def}}{=} \{\text{VALUE}, \ldots, \text{QUANT}\}$, the set of QSRL roles. For an edge $e = (v, v', l) \in E$, $v, v' \in V$ and $l \in \mathcal{L}_\mathcal{R} \overset{\text{def}}{=} \{\text{FACT}, \text{EQUIVALENCE}, \text{ANALOGY}\}$.

For G so defined to encode a set of valid TAP frames, it must satisfy certain constraints:

1. **Well-formedness constraints.** For any two vertices $v, v' \in V$, their associated spans must not overlap. Furthermore, every vertex must participate in at least one FACT edge, i.e., no disconnected vertices.
2. **Typing constraints.** FACT relations are always drawn from a VALUE vertex to a non-VALUE vertex. ANALOGY and EQUIVALENCE are only ever drawn between two vertices of the same role.
3. **Unique facts.** If a VALUE vertex v is connected to two distinct vertices v' and v'' of the same role via a FACT edge, then $\text{EQUIVALENCE}(v', v'')$ exists.
4. **Transitivity constraints.** ANALOGY and EQUIVALENCE edges are transitive: if $\text{EQUIVALENCE}(v, v') \in E$ and $\text{EQUIVALENCE}(v', v'') \in E$ then $\text{EQUIVALENCE}(v, v'') \in E$ also. This also holds for ANALOGY edges, but only when v, v' and v'' are VALUE vertices.
5. **Analogy.** There must be at least one pair of analogous VALUE vertices, and for each such pair, there must be a pair of analogous facts connected to them: if v, v' are two VALUE vertices with $\text{ANALOGY}(v, v') \in E$, then there must also exist w, w' as two non-VALUE vertices with $\text{FACT}(v, w) \in E$, $\text{FACT}(v', w') \in E$, $\text{ANALOGY}(w, w') \in E$.

Note that while these constraints rely on the choice of VALUE as the role that grounds quantitative facts, they reflect the general idea that analogy is a structured mapping between meaning representations.

5 A Neural and ILP Model for TAP

We now present a neural and ILP model that predicts analogy graphs as defined in Section 4. Given a sentence, the neural model predicts a distribution over role-labeled spans with edges denoting semantic relations between them. Then, we use an ILP to decode while enforcing the TAP constraints defined in Section 4. Figure 4 presents an overview of the architecture.

Context-sensitive word embeddings. We first encode the words in a sentence by embedding each token using fixed word embeddings. We also concatenate a few linguistic features to the word embeddings, such as named entity tags and dependency relations. These features are generated using CoreNLP (Manning et al., 2014) and represented by randomly-initialized, learned embeddings for symbols together with the fixed word embedding of each token's dependency head and the dependency path length between adjacent tokens. The token embeddings are then passed through several stacked convolutional layers (Kim, 2014). While the first convolutional layer can only capture local information, subsequent layers allow for longer-distance reasoning.

Span prediction. Next, we feed the outputs of a single fully-connected hidden layer to a conditional random field (CRF) (Lafferty et al., 2001),

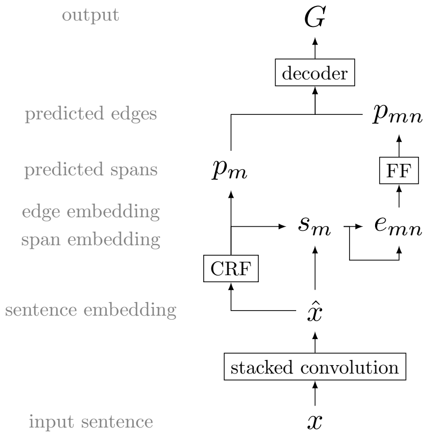

Figure 4: An overview of the proposed neural model: The sentence embedding represents features across the entire sentence using multiple convolutional layers. We then use a conditional random field (CRF) layer to predict labeled spans p_m and to generate span and edge embeddings. We use a feedforward (FF) layer on the edge embeddings to predict edge labels p_{mn}. Together, p_m and p_{mn} form a distribution over edges and labels that we decode into TAP frames.

which defines a joint distribution over per-token role labels. We thus obtain spans from this distribution corresponding to vertices of the graph described in Section 4 by merging contiguous role-labels in the maximum likelihood label sequence predicted by the CRF.

Edge prediction with PATHMAX features. For edge prediction, we use the spans identified above to construct span and edge embeddings: for every span (i, j) that was predicted, we construct a span vector $s_m = \sum_{k=i}^{j} \hat{x}_k$. We also construct a role-label score vector for the span, p_m by summing the role-label probability vectors of its constituent tokens. Then, for every vertex pair (m, n), we construct an edge representation e_{mn}. The basis of this representation is simply the concatenation of the span representations, the sum of the span representations, their respective role-label score vectors p_m and p_n, and relative token distances.

To capture long-distance phenomena like scope, we also incorporate features into e_{mn} from the dependency paths between the two spans by max-pooling the (learned) dependency relation embeddings along the path between the tokens.[3] When computing the representation between two spans, we take the average of the path embedding between each pair of tokens within them. We call this extension PATHMAX.

The resulting edge representation e_{mn} is passed through a single fully-connected hidden layer and an output layer to predict a distribution over edge labels p_{mn}, for each pair of spans.

Training. The supervised data described in Section 3 provides gold spans and edges between them. Thus we define a loss function with two terms: one for the log-likelihood of the span labels output by the CRF model, and one for the cross-entropy loss on the edge labels. We train the span and edge components of the model jointly.

Decoding. We consider two methods for decoding the span-level and edge-level label distributions p_m and $p_{m,n}$ into a labeled graph respecting the constraints described in Section 4.

As a simple greedy method to enforce these constraints, we begin by picking the most likely role for each span and edge and then discarding any edges and spans that violate the well-formedness (1) and typing constraints (2). We then enforce transitivity constraints (4) by incrementally building a cluster of analogous and equivalent spans. We then resolve the unique facts constraint (3) by keeping only the span with highest FACT edge score. Finally, for every cluster of analogous VALUE spans, we check that the analogy constraint (5) holds and if not, discard the cluster.

We also implement an optimal decoder that encodes the TAP constraints as an ILP (Roth and Yih, 2004; Do et al., 2012). The ILP tries to find an optimal decoding according to the model, subject to hard constraints imposed on the solution space. For example, we require that solutions satisfy the 'connected spans' constraint:

$$\forall s \exists s' : e(s, s', \text{FACT})$$

In plain English, this says that every span s in a solution must be connected via a FACT edge to some other span s'. See the supplementary material for the full list of constraints we employ. We solve the ILPs with Gurobi (Gurobi Optimization, Inc., 2018).

6 Experiments

We now describe the experimental setup of our neural model (Section 5) on the dataset of TAP frames we created (Section 3). Results and discussion are reported in Section 7.

---

[3] The dependency paths are directed but unlexicalized.

Evaluation metrics. The primary metric we use to measure the accuracy of a system on frame prediction is the precision, recall and F_1 between the labeled vertex-edge-vertex triples predicted by the model and those in the gold parse. If there are multiple predicted spans that overlap with a single gold span or vice versa, we find a matching of predicted and gold spans that maximizes overlap.

In addition to the primary metric, we also report precision, recall and F_1 when predicting labeled (non-VALUE) spans and predicting labeled edges before performing any decoding.[4] We also use the matching process described above for both these sets of metrics. Standardized evaluation code is provided with the dataset.

Experimental setup. We compare the neural models presented in Section 5 in addition to a log-linear baseline. The log-linear baseline uses the same fixed word embeddings as the neural model in addition to the named entity and dependency parse features described in Section 5. The key difference is that instead of learning a sentence embedding or hidden layers, the log-linear model simply uses a CRF to predict span labels directly from fixed input features, and then uses a single sigmoid layer to predict edge labels from deterministic edge embeddings, e_{mn}.

For the neural models, we used three convolutional layers for sentence embedding with a filter size of 3. Every layer other than the input layer used a hidden dimension of 50 with ReLU nonlinearities. We introduced a single dropout layer ($p = 0.5$) between every two layers in the network (including at the input). We used 50-dimensional GloVe embeddings (Pennington et al., 2014) learned from Wikipedia 2014 and Gigaword 5 as pre-trained word embeddings, and initialized the embeddings for the features randomly. We chose relatively low input- and hidden-vector dimension because of the size of our data. The network was trained for 15 epochs using ADADELTA (Zeiler, 2012) with a learning rate of 1.0. All models were implemented in `PyTorch` (Paszke et al., 2017).

7 Results and Discussion

			Frame prediction		
Model	Feats.	Dec.	P	R	F_1

w/o NER	41.6	79.1	54.5
w/o dep.	41.2	77.5	53.8
w/o CRF	36.1	73.1	48.3

Table 4: Performance of models on labeled (non-VALUE) span prediction during cross-validation prior to decoding. We found using a CRF to be the most important aspect: simply using fixed word vectors with a CRF (i.e., the log-linear model) was sufficient to predict spans.

Frame prediction results on the test set are summarized in Table 3. Our three main findings are that (i) the neural network model far outperforms the log-linear model on our frame metric, (ii) including linguistic features further increases performance, and (iii) so does using an optimal decoder over a greedy method.

Quantitative error analysis. To better understand which aspects of our model contribute to the task, we perform an ablation study on the span and edge predictions of our model *prior to decoding*.

With respect to span prediction (Table 4), we found that the fixed word vectors, along with a CRF, were able to capture the information needed to identify QSRL role-spans. Indeed, the log-linear baseline, which directly uses these word vectors as features for a CRF, did the best at span prediction. We believe that the drop in performance from introducing hidden layers with the neural models is a result of the model updating its span representations to do better edge prediction.[5]

---

[4] We exclude VALUE spans from span scores because they are easy to predict and thus inflate model performance.

[5] In a separate experiment, the neural model outperformed the log-linear model when they were trained only to do span prediction.

Model	Edge prediction P	Edge prediction R	Edge prediction F_1
Log-linear (all feats.)	33.6	15.7	18.9
Neural (no feats.)	73.7	65.8	68.7
Neural (all feats.)	74.4	**75.6**	**74.7**
w/o NER	74.8	72.2	73.1
w/o dep.	73.4	65.0	68.2
w/o PATHMAX.	72.8	64.0	67.2

Table 5: Performance of models on labeled edge prediction during cross-validation prior to decoding. We found that both dependency label (dep.) and path features (PATHMAX) help significantly.

While the log-linear model did well at predicting spans, it did a poor job predicting edges, indicating that learning to extract higher-order features from learned span embeddings is necessary for identifying semantic relations between them (Table 5). We also found that linguistic features were important: in particular, we found that syntactic features – the dependency path features (PATHMAX) and dependency labels – played a big role in edge prediction, followed by type information from NER tags.

Qualitative error analysis. Our model is tasked with jointly identifying QSRL parses of analogous facts in a sentence, and ANALOGY and EQUIVALENCE relations among them. As described in Section 4, these pieces interact in mutually constraining ways, and thus it is possible for local errors to have global effects on predicted frames.

In Figure 5, for example, the model correctly identifies the gold TIME spans as part of a TAP frame, but mistakenly predicts that they are linked by EQUIVALENCE, and thus modify the same VALUE span. In the gold parse, they are linked by ANALOGY, and modify distinct VALUE spans. As a result of this misclassification, the model leaves out an entire QSRL fact from the resulting parse.

In many cases, the model successfully identifies compared content roles between QSRL facts. In Figure 6, we show an example where it does not manage to do so. Here, unable to identify the ANALOGY relation between the phrases '*Those with a bullish view*' and '*the dollar bears*', the model instead chooses two identical sequences 'the dollar' as the non-VALUE compared content. Inspecting edge probability scores from the model *before decoding* reveals that the neural model thinks that the first instance of 'the dollar' in the sentence is semantically analogous to the second; it can be confused by surface similarity into classifying ANALOGY relations.

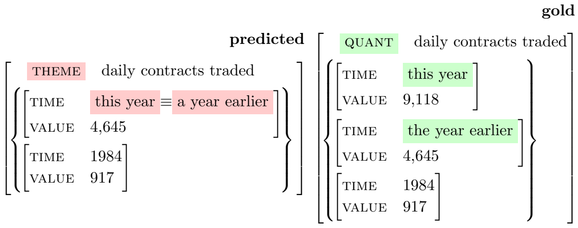

Figure 5: TAP frames for the sentence, '*This year ... daily contracts traded totaled 9,118, up from 4,645 a year earlier and from 917 in 1984.*' The model not only misclassifies the QSRL role of '*daily contracts traded*', but also mistakenly identifies an EQUIVALENCE between '*this year*' and '*the year earlier*'. As a result, the VALUE 9,118 is left without a compared content role, and is dropped.

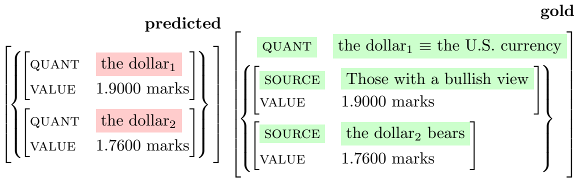

Figure 6: TAP frames for the sentence '*Those with a bullish view see [the dollar]$_1$ trading up near 1.900 marks... while [the dollar]$_2$ bears see the U.S. currency trading around 1.7600 marks*'. Among other errors, the model failed to identify analogous SOURCE spans and instead predicts that the two instances of the phrase '*the dollar*' (indicated with indexing) in the sentence contribute non-VALUE compared content.

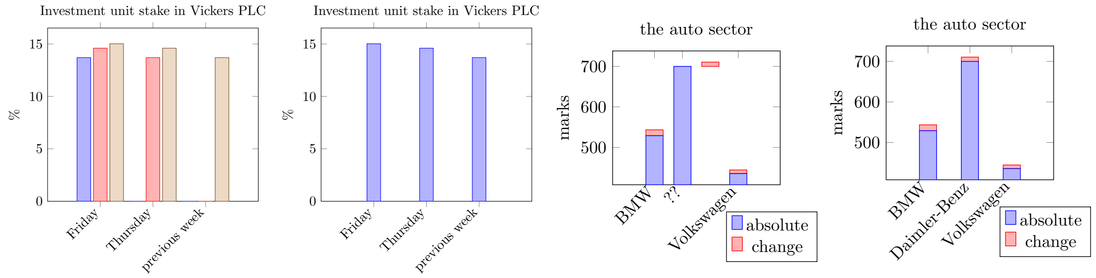
Application to plot generation. As we have seen, textual analogy is frequently used to compare quantities along some axis of differentiation. For example, one might compare the stock prices of different companies, or describe the change in some quantity's value over time. Such analogy relationships can alternately be expressed in the form of a plot.

Indeed, there is a natural correspondence between charts and TAP frames over quantitative facts: VALUES of a quantitative TAP frame are plotted against other compared content roles, and elements of the shared content correspond with scopal chart elements, such as titles. This mapping is well-defined provided analogous values share units. We present some initial results exploring this direction.

In Figure 7, we deterministically plot TAP



(a) Before constraints (b) After constraints (c) Before constraints (d) After constraints

Figure 7: Charts generated from TAP frames. Charts (a) and (b) are generated from the sentence '*Vicker's PLC ... raised its stake in the company Friday to 15.02% from about 14.6% Thursday and from 13.6% the previous week.*' Before imposing constraints, the neural model assigns multiple values to the TIME arguments '*Thursday*' and '*Friday*', over-extending their scope. Imposing structural constraints ensures the correct assignment of TIMES to VALUES. Charts (c) and (d) are generated from the sentence '*In the auto sector, Bayerische Motoren Werke plunged 14.5 marks to 529 marks, Daimler-Benz dropped 10.5 to 700, and Volkswagen slumped 9 to 435.5.*' Here, the model fails to associate an absolute (blue) and relative (red) VALUE pair with a THEME role. The imposition of global constraints corrects this, linking them to the THEME 'Diamler-Benz'.

frames generated by our system both before and after the imposition of global analogy constraints, for two sentences in the data. In the first sentence, VALUE spans are plotted against the TIME spans the model associates with their respective facts. In the second sentence, two analogy frames are plotted together, one reflecting the absolute values of the stock prices mentioned (blue) and the other reflecting the changes in prices mentioned (red). Units are extracted from VALUE spans using simple pattern matching. Chart titles are only illustrative and were generated by stitching together shared content identified by our system.

Note that with the imposition of global constraints reflecting the structure of analogy, the system yields well-formed charts. Without these constraints, generated charts either have multiple y-axis values assigned to the same x-axis value, or have floating y-axis values with no grounding on the x-axis.

8 Related Work

Analogy. In the cognitive science literature, analogy is a general form of relational reasoning unique to human cognition (Tversky and Gati, 1978; Holyoak and Thagard, 1996; Goldstone and Son, 2005; Penn et al., 2008; Holyoak, 2012). Our model of textual analogy is particularly influenced by Structure Mapping Theory (Falkenhainer et al., 1989; Gentner and Markman, 1997), an influential cognitive model of analogy as a structure-preserving map between concepts.

Within the NLP community, there has been much work focused on inferring lexical analogies between generic concepts, e.g., *tennis:racket::baseball:bat* (Mikolov et al., 2013; Turney, 2013), from global distributional statistics. Such analogies are generic, type-level patterns whose structure exists in the nature of the language; here, we are interested in specific analogies whose structure is conveyed by a particular sentence.

Discourse and Information Extraction. TAP is an information extraction task that synthesizes ideas from semantic role labeling on the one hand and discourse parsing on the other. The former produces predicate-argument representations of individual facts in a text (Baker et al., 1998; Gildea and Jurafsky, 2002; Palmer et al., 2005); the latter identifies discourse relations between syntactic clauses (Taboada and Mann, 2006; Prasad et al., 2007; Pitler et al., 2009; Prasad et al., 2010; Surdeanu et al., 2015).

TAP first maps from syntax to a set of SRL-style representations, and then identifies structurally-constrained, higher-order relations among them. It is in this sense reminiscent of, but distinct from, work on causal processes by Berant et al. (2014).

Numbers in NLP. There has been some work on understanding numbers in text. This includes quantitative reasoning (Kushman et al., 2014; Roy et al., 2015), numerical information extraction (Madaan et al., 2016), and techniques for making numbers more easily interpretable in text (Chaganty and Liang, 2016; Kim et al., 2016).

If pursued further, the application of plotting quantitative text that we discuss in this paper could help to clarify quantitative text on the web (Larkin and Simon, 1987; Barrio et al., 2016).

Neural modeling. Recent work has shown the promise of sophisticated neural models on semantic role labeling (He et al., 2017). Similar to other such sequence prediction models, e.g., those for named entity recognition (Lample et al., 2016) or semantic role labeling (Zhou and Xu, 2015), our span prediction utilizes a neural CRF. Our model also has an edge-prediction component, which benefits from a simplified version of the PathLSTM model of Roth and Lapata (2016). Our edge-prediction model also uses an embedding concatenation component, which was inspired by recent work on neural coreference resolution (Lee et al., 2017). He et al. (2017) also impose semantic constraints during prediction, but use A* search instead of an ILP.

9 Conclusion

In this paper we have presented a new task, textual analogy parsing, or TAP. Given a sentence about a set of analogous facts, TAP outputs a frame representation that expresses the points of similarity and difference in their meanings.

We note that in the particular case of quantitative text, TAP frames correspond with charts. We develop a new dataset of TAP frames from quantitative newswire, and compare a variety models for TAP. Our best model employs a globally optimal decoder to enforce the structural constraints of analogy; its outputs can be mapped to well-formed charts of quantitative information extracted from text.

We view this work to be an exciting step in the direction of deeper discourse modeling. Future work might further extend the recovery of analogy as part of information extraction. This might include TAP outside of the quantitative domain, or TAP at the paragraph level.

Abstract

Given a partial description like "she opened the hood of the car," humans can reason about the situation and anticipate what might come next ("then, she examined the engine"). In this paper, we introduce the task of grounded commonsense inference, unifying natural language inference and commonsense reasoning.

We present SWAG, a new dataset with 113k multiple choice questions about a rich spectrum of grounded situations. To address the recurring challenges of the annotation artifacts and human biases found in many existing datasets, we propose *Adversarial Filtering* (AF), a novel procedure that constructs a de-biased dataset by iteratively training an ensemble of stylistic classifiers, and using them to filter the data. To account for the aggressive adversarial filtering, we use state-of-the-art language models to massively oversample a diverse set of potential counterfactuals. Empirical results demonstrate that while humans can solve the resulting inference problems with high accuracy (88%), various competitive models struggle on our task. We provide comprehensive analysis that indicates significant opportunities for future research.

On stage, a woman takes a seat at the piano. She
a) sits on a bench as her sister plays with the doll.
b) smiles with someone as the music plays.
c) is in the crowd, watching the dancers.
d) nervously sets her fingers on the keys.

A girl is going across a set of monkey bars. She
a) jumps up across the monkey bars.
b) struggles onto the monkey bars to grab her head.
c) gets to the end and stands on a wooden plank.
d) jumps up and does a back flip.

The woman is now blow drying the dog. The dog
a) is placed in the kennel next to a woman's feet.
b) washes her face with the shampoo.
c) walks into frame and walks towards the dog.
d) tried to cut her face, so she is trying to do something very close to her face.

Table 1: Examples from SWAG; the correct answer is **bolded**. Adversarial Filtering ensures that stylistic models find all options equally appealing.

1 Introduction

When we read a story, we bring to it a large body of implicit knowledge about the physical world. For instance, given the context "on stage, a woman takes a seat at the piano," shown in Table 1, we can easily infer what the situation might *look* like: a woman is giving a piano performance, with a crowd watching her. We can furthermore infer her likely *next* action: she will most likely set her fingers on the piano keys and start playing.

This type of natural language inference requires commonsense reasoning, substantially broadening the scope of prior work that focused primarily on linguistic entailment (Chierchia and McConnell-Ginet, 2000). Whereas the dominant entailment paradigm asks if two natural language sentences (the 'premise' and the 'hypothesis') describe the same set of possible worlds (Dagan et al., 2006; Bowman et al., 2015), here we focus on whether a (multiple-choice) ending describes a possible (*future*) world that can be anticipated from the situation described in the premise, even when it is not strictly entailed. Making such inference necessitates a rich understanding about everyday physical situations, including object affordances (Gibson, 1979) and frame semantics (Baker et al., 1998).

A first step toward grounded commonsense inference with today's deep learning machinery is to create a large-scale dataset. However, recent work has shown that human-written datasets are susceptible to *annotation artifacts*: unintended stylistic patterns that give out clues for the gold labels (Gururangan et al., 2018; Poliak et al., 2018). As a result, models trained on such datasets with hu-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 93–104
Brussels, Belgium, October 31 - November 4, 2018.

man biases run the risk of over-estimating the actual performance on the underlying task, and are vulnerable to adversarial or out-of-domain examples (Wang et al., 2018; Glockner et al., 2018).

In this paper, we introduce Adversarial Filtering (AF), a new method to automatically detect and reduce stylistic artifacts. We use this method to construct **SWAG**: an adversarial dataset with 113k multiple-choice questions. We start with pairs of temporally adjacent video captions, each with a context and a follow-up event that we *know* is physically possible. We then use a state-of-the-art language model fine-tuned on this data to massively oversample a diverse set of possible negative sentence endings (or *counterfactuals*). Next, we filter these candidate endings aggressively and adversarially using a committee of trained models to obtain a population of de-biased endings with similar stylistic features to the real ones. Finally, these filtered counterfactuals are validated by crowd workers to further ensure data quality.

Extensive empirical results demonstrate unique contributions of our dataset, complementing existing datasets for natural langauge inference (NLI) (Bowman et al., 2015; Williams et al., 2018) and commonsense reasoning (Roemmele et al., 2011; Mostafazadeh et al., 2016; Zhang et al., 2017). **First**, our dataset poses a new challenge of grounded commonsense inference that is easy for humans (88%) while hard for current state-of-the-art NLI models (<60%). **Second**, our proposed adversarial filtering methodology allows for cost-effective construction of a large-scale dataset while substantially reducing known annotation artifacts. The generality of adversarial filtering allows it to be applied to build future datasets, ensuring that they serve as reliable benchmarks.

2 SWAG: Our new dataset

We introduce a new dataset for studying physically grounded commonsense inference, called **SWAG**.[1] Our task is to predict which event is most likely to occur next in a video. More formally, a model is given a context $\boldsymbol{c} = (\boldsymbol{s}, \boldsymbol{n})$: a complete sentence $\boldsymbol{s}$ and a noun phrase $\boldsymbol{n}$ that begins a second sentence, as well as a list of possible verb phrase sentence endings $\boldsymbol{V} = \{\boldsymbol{v}_1, \ldots, \boldsymbol{v}_4\}$. See Figure 1 for an example triple $(\boldsymbol{s}, \boldsymbol{n}, \boldsymbol{v}_i)$. The model must then select the most appropriate verb phrase $\boldsymbol{v}_{\hat{i}} \in \boldsymbol{V}$.

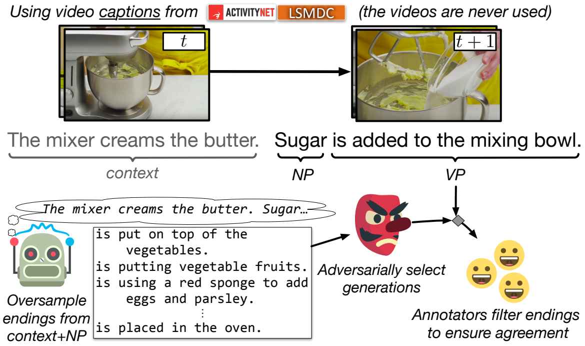

Figure 1: Overview of the data collection process. For a pair of sequential video captions, the second caption is split into noun and verb phrases. A language model generates many negative endings, of which a difficult subset are human-annotated.

Overview Our corpus consists of 113k multiple choice questions (73k training, 20k validation, 20k test) and is derived from pairs of consecutive video captions from ActivityNet Captions (Krishna et al., 2017; Heilbron et al., 2015) and the Large Scale Movie Description Challenge (LSMDC; Rohrbach et al., 2017). The two datasets are slightly different in nature and allow us to achieve broader coverage: ActivityNet contains 20k YouTube clips containing one of 203 activity types (such as doing gymnastics or playing guitar); LSMDC consists of 128k movie captions (audio descriptions and scripts). For each pair of captions, we use a constituency parser (Stern et al., 2017) to split the second sentence into noun and verb phrases (Figure 1).[2] Each question has a human-verified gold ending and 3 distractors.

3 A solution to annotation artifacts

In this section, we outline the construction of **SWAG**. We seek dataset diversity while minimizing *annotation artifacts*, conditional stylistic patterns such as length and word-preference biases. For many NLI datasets, these biases have been shown to allow shallow models (e.g. bag-of-words) obtain artificially high performance.

To avoid introducing easily "gamed" patterns, we present Adversarial Filtering (AF), a generally-applicable treatment involving the iterative refinement of a set of assignments to increase the entropy under a chosen model family. We then discuss how we generate counterfactual endings, and

---

[1] Short for **S**ituations **W**ith **A**dversarial **G**enerations.

[2] We filter out sentences with rare tokens ($\leq$3 occurrences), that are short ($l \leq 5$), or that lack a verb phrase.

Algorithm 1 Adversarial filtering (AF) of negative samples. During our experiments, we set $N^{easy} = 2$ for refining a population of $N^{-} = 1023$ negative examples to $k = 9$, and used a 80%/20% train/test split.

```
while convergence not reached do
    • Split the dataset $\mathcal{D}$ randomly up into training and testing portions $\mathcal{D}^{tr}$ and $\mathcal{D}^{te}$.
    • Optimize a model $f_\theta$ on $\mathcal{D}^{tr}$.
    for index $i$ in $\mathcal{D}^{te}$ do
        • Identify easy indices:
        $\mathcal{A}_i^{easy} = \{j \in \mathcal{A}_i : f_\theta(x_i^+) > f_\theta(x_{i,j}^-)\}$
        • Replace $N^{easy}$ easy indices $j \in \mathcal{A}_i^{easy}$ with adversarial indices $k \notin \mathcal{A}_i$ satisfying $f_\theta(x_{i,k}^-) > f_\theta(x_{i,j}^-)$.
    end for
end while
```

finally, the models used for filtering.

3.1 Formal definition

In this section, we formalize what it means for a dataset to be *adversarial*. Intuitively, we say that an adversarial dataset for a model f is one on which f will not generalize, even if evaluated on test data from the same distribution. More formally, let our input space be $\mathcal{X}$ and the label space be $\mathcal{Y}$. Our trainable classifier f, taking parameters θ is defined as $f_\theta : \mathcal{X} \rightarrow \mathbb{R}^{|\mathcal{Y}|}$. Let our dataset of size N be defined as $\mathcal{D} = \{(x_i, y_i)\}_{1 \le i \le N}$, and let the loss function over the dataset be $L(f_\theta, \mathcal{D})$. We say that a dataset is *adversarial* with respect to f if we expect high empirical error I over all leave-one-out train/test splits (Vapnik, 2000):

$$I(\mathcal{D}, f) = \frac{1}{N} \sum_{i=1}^{N} L(f_{\theta_i^\star}, \{(x_i, y_i)\}), \qquad (1)$$

$$\text{where } \theta_i^\star = \operatorname*{argmin}_{\theta} L(f_\theta, \mathcal{D} \setminus \{(x_i, y_i)\}), \qquad (2)$$

with regularization terms omitted for simplicity.

3.2 Adversarial filtering (AF) algorithm

In this section, we outline an approach for generating an adversarial dataset $\mathcal{D}$, effectively maximizing empirical error I with respect to a family of trainable classifiers f. Without loss of generality, we consider the situation where we have N *contexts*, each associated with a single positive example $(x_i^+, 1) \in \mathcal{X} \times \mathcal{Y}$, and a large population of context-specific negative examples $(x_{i,j}^-, 0) \in \mathcal{X} \times \mathcal{Y}$, where $1 \le j \le N^-$ for each i. For instance, the negative examples could be incorrect relations in knowledge-base completion (Socher et al., 2013), or all words in a dictionary for a single-word cloze task (Zweig and Burges, 2011).

Our goal will be to filter the population of negative examples for each instance i to a size of $k \ll N^-$. This will be captured by returning a set of *assignments* $\mathcal{A}$, where for each instance the assignment will be a k-subset $\mathcal{A}_i = [1 \ldots N^-]^k$. The filtered dataset will then be:

$$\mathcal{D}^{AF} = \{(x_i, 1), \{(x_{i,j}^-, 0)\}_{j \in \mathcal{A}_i}\}_{1 \le i \le N} \qquad (3)$$

Unfortunately, optimizing $I(\mathcal{D}^{AF}, f)$ is difficult as $\mathcal{A}$ is global and non-differentiable. To address this, we present Algorithm 1. On each iteration, we split the data into dummy 'train' and 'test' splits. We train a model f on the training portion and obtain parameters θ, then use the remaining test portion to reassign the indices of $\mathcal{A}$. For each context, we replace some number of 'easy' negatives in $\mathcal{A}$ that f_θ classifies correctly with 'adversarial' negatives outside of $\mathcal{A}$ that f_θ misclassifies.

This process can be thought of as increasing the overall entropy of the dataset: given a strong model f_θ that is compatible with a random subset of the data, we aim to ensure it cannot generalize to the held-out set. We repeat this for several iterations to reduce the generalization ability of the model family f over arbitrary train/test splits.

3.3 Generating candidate endings

To generate counterfactuals for **SWAG**, we use an LSTM (Hochreiter and Schmidhuber, 1997) language model (LM), conditioned on contexts from video captions. We first pretrain on BookCorpus (Zhu et al., 2015), then finetune on the video caption datasets. The architecture uses standard best practices and was validated on held-out perplexity of the video caption datasets; details are in the appendix. We use the LM to sample N^-=1023 unique endings for a partial caption.[3]

Importantly, we *greedily* sample the endings, since beam search decoding biases the generated endings to be of lower perplexity (and thus easily distinguishable from found endings). We find this process gives good counterfactuals: the generated endings tend to use *topical* words, but often make little sense physically, making them perfect for our task. Further, the generated endings are marked as "gibberish" by humans only 9.1% of the time (Sec 3.5); in that case the ending is filtered out.

---

[3] To ensure that the LM generates unique endings, we split the data into five validation folds and train five separate LMs, one for each set of training folds. This means that each LM never sees the found endings during training.

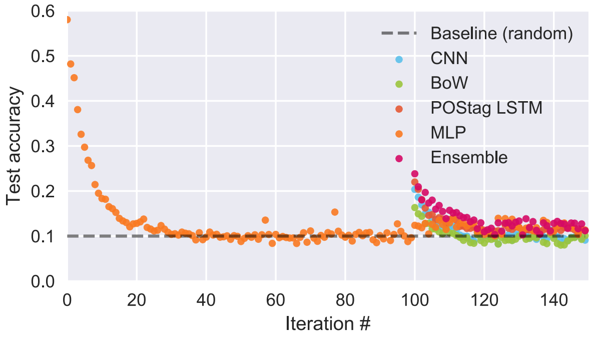

Figure 2: Test accuracy by AF iteration, under the negatives given by $\mathcal{A}$. The accuracy drops from around 60% to close to random chance. For efficiency, the first 100 iterations only use the MLP.

3.4 Stylistic models for adversarial filtering

In creating SWAG, we designed the model family f to pick up on low-level *stylistic features* that we posit should not be predictive of whether an event happens next in a video. These stylistic features are an obvious case of annotation artifacts (Cai et al., 2017; Schwartz et al., 2017).[4] Our final classifier is an ensemble of four stylistic models:

1. A multilayer perceptron (MLP) given LM perplexity features and context/ending lengths.
2. A bag-of-words model that averages the word embeddings of the second sentence as features.
3. A one-layer CNN, with filter sizes ranging from 2-5, over the second sentence.
4. A bidirectional LSTM over the 100 most common words in the second sentence; uncommon words are replaced by their POS tags.

We ensemble the models by concatenating their final representations and passing it through an MLP. On every adversarial iteration, the ensemble is trained jointly to minimize cross-entropy.

The accuracies of these models (at each iteration, evaluated on a 20% split of the test dataset before indices of $\mathcal{A}$ get remapped) are shown in Figure 2. Performance decreases from 60% to close to random chance; moreover, confusing the perplexity-based MLP is not sufficient to lower performance of the ensemble. Only once the other stylistic models are added does the ensemble accuracy drop substantially, suggesting that our approach is effective at reducing stylistic artifacts.

Imagine that you are watching a video clip. The clip has a caption, but it is missing the final phrase. Please choose the best 2 caption endings, and classify each as:

- **likely**, if it completes the caption in a reasonable way;
- **unlikely**, if it sounds ridiculous or impossible;
- **gibberish** if it has such serious errors that it doesn't feel like a valid English sentence.

Example: Someone is shown sitting on a fence and talking to the camera while pointing out horses. Someone

- stands in front of a podium. (**likely**, **second best**)
- rides a horse using a hose. (**unlikely**)
- is shown riding a horse. (**likely**, **best**)
- , the horse in a plaza field. (**gibberish**)

Figure 3: Mechanical Turk instructions (abridged).

3.5 Human verification

The final data-collection step is to have humans verify the data. Workers on Amazon Mechanical Turk were given the caption context, as well as six candidate endings: one found ending and five adversarially-sampled endings. The task was twofold: Turkers ranked the endings independently as likely, unlikely, or gibberish, and selected the best and second best endings (Fig 3).

We obtained the correct answers to each context in two ways. If a Turker ranks the found ending as either best or second best (73.7% of the time), we add the found ending as a gold example, with negatives from the generations not labelled best or gibberish. Further, if a Turker ranks a generated ending as best, and the found ending as second best, then we have reason to believe that the generation is good. This lets us add an additional training example, consisting of the generated best ending as the gold, and remaining generations as negatives.[5] Examples with $\leq$3 non-gibberish endings were filtered out.[6]

We found after 1000 examples that the annotators tended to have high agreement, also generally choosing found endings over generations (see Table 2). Thus, we collected the remaining 112k examples with one annotator each, periodically verifying that annotators preferred the found endings.

4 Experiments

In this section, we evaluate the performance of various NLI models on SWAG. Recall that models

---

[4] A broad definition of annotation artifacts might include aspects besides lexical/stylistic features: for instance, certain events are less likely semantically regardless of the context (e.g. riding a horse using a hose). For this work, we erred more conservatively and only filtered based on style.

[5] These two examples share contexts. To prevent biasing the test and validation sets, we didn't perform this procedure on answers from the evaluation sets' context.

[6] To be data-efficient, we reannotated filtered-out examples by replacing gibberish endings, as well as generations that outranked the found ending, with candidates from $\mathcal{A}$.

	Label distribution by ending type		Inter-annotator agreement	
Labels	Found end	Gen. end	α	ppa
Best	53.5%	9.3%	0.43	72%
Second Best	20.2%	15.9%		
Neither	26.3%	74.8%		
Likely	80.3%	33.3%	0.39	64%
Unlikely	19.0%	57.5%		
Gibberish	0.7%	9.1%		

Table 2: Annotators tend to label the found ending as likely and within the top 2 (column 2), in other cases the example is filtered out. Both label groups have high inter-annotator agreement, in terms of Krippendorff's α and pairwise percent agreement.

for our dataset take the following form: given a sentence and a noun phrase as context $\boldsymbol{c} = (\boldsymbol{s}, \boldsymbol{n})$, as well as a list of possible verb phrase endings $\boldsymbol{V} = \{\boldsymbol{v}_1, \dots, \boldsymbol{v}_4\}$, a model f_θ must select a verb $\hat{\imath}$ that hopefully matches i_{gold}:

$$\hat{\imath} = \operatorname*{argmax}_i f_\theta(\boldsymbol{s}, \boldsymbol{n}, \boldsymbol{v}_i) \tag{4}$$

To study the amount of bias in our dataset, we also consider models that take as input just the ending verb phrase $\boldsymbol{v}_i$, or the entire second sentence $(\boldsymbol{n}, \boldsymbol{v}_i)$. For our learned models, we train f by minimizing multi-class cross-entropy. We consider three different types of word representations: 300d GloVe vectors from Common Crawl (Pennington et al., 2014), 300d Numberbatch vectors retrofitted using ConceptNet relations (Speer et al., 2017), and 1024d ELMo contextual representations that show improvement on a variety of NLP tasks, including standard NLI (Peters et al., 2018). We follow the final dataset split (see Section 2) using two training approaches: training on the found data, and the found and highly-ranked generated data. See the appendix for more details.

4.1 Unary models

The following models predict labels from *a single span* of text as input; this could be the ending only, the second sentence only, or the full passage.

a. fastText (Joulin et al., 2017): This library models a single span of text as a bag of n-grams, and tries to predict the probability of an ending being correct or incorrect independently.[7]

b. Pretrained sentence encoders We consider two types of pretrained RNN sentence encoders, SkipThoughts (Kiros et al., 2015) and InferSent (Conneau et al., 2017). SkipThoughts was trained by predicting adjacent sentences in book data, whereas InferSent was trained on supervised NLI data. For each second sentence (or just the ending), we feed the encoding into an MLP.

c. LSTM sentence encoder Given an arbitrary span of text, we run a two-layer BiLSTM over it. The final hidden states are then max-pooled to obtain a fixed-size representation, which is then used to predict the potential for that ending.

4.2 Binary models

The following models predict labels from *two spans* of text. We consider two possibilties for these models: using just the second sentence, where the two text spans are $\boldsymbol{n}, \boldsymbol{v}_i$, or using the context and the second sentence, in which case the spans are $\boldsymbol{s}, (\boldsymbol{n}, \boldsymbol{v}_i)$. The latter case includes many models developed for the NLI task.

d. Dual Bag-of-Words For this baseline, we treat each sentence as a bag-of-embeddings $(\mathbf{c}, \mathbf{v}_i)$. We model the probability of picking an ending i using a bilinear model: $\text{softmax}_i(\mathbf{c}\mathbf{W}\mathbf{v}_i^T)$.[8]

e. Dual pretrained sentence encoders Here, we obtain representations from SkipThoughts or InferSent for each span, and compute their pairwise compatibility using either 1) a bilinear model or 2) an MLP from their concatenated representations.

f. SNLI inference Here, we consider two models that do well on SNLI (Bowman et al., 2015): Decomposable Attention (Parikh et al., 2016) and ESIM (Chen et al., 2017). We use pretrained versions of these models (with ELMo embeddings) on SNLI to obtain 3-way entailment, neutral, and contradiction probabilities for each example. We then train a log-linear model using these 3-way probabilities as features.

g. SNLI models (retrained) Here, we train ESIM and Decomposable Attention on our dataset: we simply change the output layer size to 1 (the potential of an ending $\boldsymbol{v}_i$) with a softmax over i.

4.3 Other models

We also considered the following models:

h. Length: Although length was used by the adversarial classifier, we want to verify that human validation didn't reintroduce a length bias. For this baseline, we always choose the shortest ending.

i. ConceptNet As our task requires world knowledge, we tried a rule-based system on top of the

---

[7] The fastText model is trained using binary cross-entropy; at test time we extract the prediction by selecting the ending with the highest positive likelihood under the model.

[8] We also tried using an MLP, but got worse results.

Table 3: Performance of all models in accuracy (%). All models substantially underperform humans, although performance increases as more context is provided (left to right). We optionally train on found endings only, or found and human-validated generated endings (found+gen).

ConceptNet knowledge base (Speer et al., 2017). For an ending sentence, we use the spaCy dependency parser to extract the head verb and its dependent object. The ending score is given by the number of ConceptNet causal relations[9] between synonyms of the verb and synonyms of the object.

j. Human performance To benchmark human performance, five Mechanical Turk workers were asked to answer 100 dataset questions, as did an 'expert' annotator (the first author of this paper). Predictions were combined using a majority vote.

4.4 Results

We present our results in Table 3. The best model that only uses the ending is the LSTM sequence model with ELMo embeddings, which obtains 43.6%. This model, as with most models studied, greatly improves with more context: by 3.1% when given the initial noun phrase, and by an additional 4% when also given the first sentence.

Further improvement is gained from models that compute pairwise representations of the inputs. While the simplest such model, DualBoW, obtains only 35.1% accuracy, combining InferSent sentence representations gives 40.5% accuracy (InferSent-Bilinear). The best results come from pairwise NLI models: when fully trained on SWAG, ESIM+ELMo obtains 59.2% accuracy.

When comparing machine results to human results, we see there exists a lot of headroom. Though there likely is some noise in the task, our results suggest that humans (even untrained) converge to a consensus. Our in-house "expert" annotator is outperformed by an ensemble of 5 Turk workers (with 88% accuracy); thus, the effective upper bound on our dataset is likely even higher.

5 Analysis

5.1 SWAG versus existing NLI datasets

The past few years have yielded great advances in NLI and representation learning, due to the availability of large datasets like SNLI and MultiNLI

---

[9] We used the relations 'Causes', 'CapableOf', 'ReceivesAction', 'UsedFor', and 'HasSubevent'. Though their coverage is low (30.4% of questions have an answer with ≥1 causal relation), the more frequent relations in ConceptNet, such as 'IsA', at best only indirectly relate to our task.

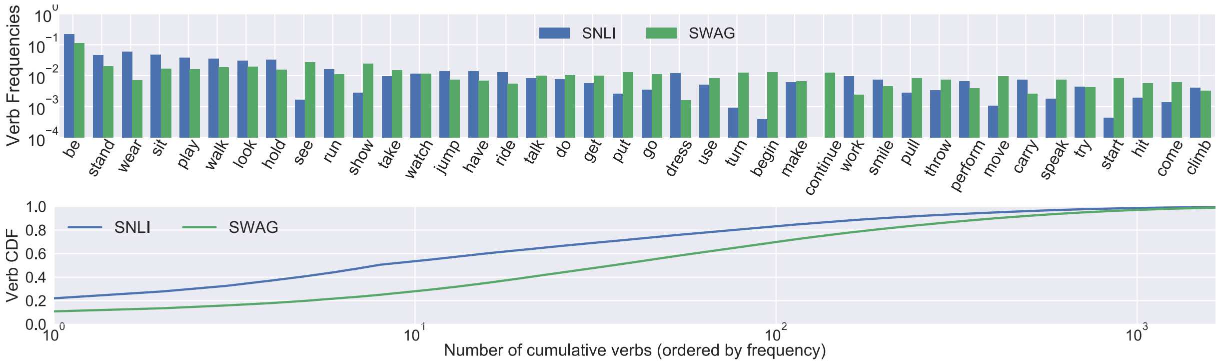

Figure 4: Top: Distribution of the 40 top verbs in the union of SNLI and **SWAG**. Our dataset shows a greater variety of dynamic verbs, such as "move", as well as temporal verbs such as "start" and "come." "Continue" is cut off for SNLI (it has frequency $6 \cdot 10^{-5}$). Bottom: CDF for verbs in SNLI and **SWAG**.

(Bowman et al., 2015; Williams et al., 2018). With the release of **SWAG**, we hope to continue this trend, particularly as our dataset largely has the same input/output format as other NLI datasets. We observe three key differences between our dataset and others in this space:

First, as noted in Section 1, **SWAG** requires a unique type of temporal reasoning. A state-of-the-art NLI model such as ESIM, when bottlenecked through the SNLI notion of entailment (SNLI-ESIM), only obtains 36.1% accuracy.[10] This implies that these datasets necessitate different (and complementary) forms of reasoning.

Second, our use of videos results in wide coverage of dynamic and temporal situations Compared with SNLI, with contexts from Flickr30K (Plummer et al., 2017) image captions, **SWAG** has more active verbs like 'pull' and 'hit,' and fewer static verbs like 'sit' and 'wear' (Figure 4).[11]

Third, our dataset suffers from few lexical biases. Whereas fastText, a bag of n-gram model, obtains 67.0% accuracy on SNLI versus a 34.3% baseline (Gururangan et al., 2018), fastText obtains only 29.0% accuracy on **SWAG**.[12]

5.2 Error analysis

We sought to quantify how human judgments differ from the best studied model, ESIM+ELMo. We randomly sampled 100 validation questions that ESIM+ELMo answered incorrectly, for each extracting both the gold ending and the model's preferred ending. We asked 5 Amazon Mechanical Turk workers to pick the better ending (of which they preferred the gold endings 94% of the time) and to select one (or more) multiple choice reasons explaining why the chosen answer was better.

Reason	Explanation	Freq.
Situational	The good ending is better *in context*.	53.7%
Plausibility	The bad ending is implausible *regardless of context*.	14.4%
Novelty	The bad ending seems redundant; it is entailed by the context.	1.8%
Weirdness	The bad ending is semantically or grammatically malformed, e.g. 'the man is getting out of the horse.'	18.1%
Ambiguous	Both endings seem equally likely.	12.0%

Table 4: Justifications for ranking the gold answer over a wrong answer chosen by ESIM+ELMo.

The options, and the frequencies, are outlined in Table 4. The most common reason for the turkers preferring the correct answer is situational (52.3% of the time), followed by weirdness (17.5%) and plausibility (14.4%). This suggests that ESIM+ELMo already does a good job at filtering out weird and implausible answers, with the main bottleneck being grounded physical understanding. The ambiguous percentage is also relatively low (12.0%), implying significant headroom.

5.3 Qualitative examples

Last, we show several qualitative examples in Table 5. Though models can do decently well by identifying complex alignment patterns between the two sentences (e.g. being "up a tree" implies that "tree" is the end phrase), the incorrect model predictions suggest this strategy is insuffi-

---

[10] The weights of SNLI-ESIM pick up primarily on entailment probability (0.59), as with neutral (0.46), while contradiction is negatively correlated (-.42).

[11] Video data has other language differences; notably, character names in LSMDC were replaced by 'someone'

[12] The most predictive individual words on SWAG are infrequent in number: 'dotted' with $P(+|\text{dotted}) = 77\%$ with 10.3 counts, and $P(-|\text{similar}) = 81\%$ with 16.3 counts. (Counts from negative endings were discounted 3x, as there are 3 times as many negative endings as positive endings).

A waiter brings a fork. The waiter **a) starts to step away. (74.76%)** b) adds spaghetti to the table. (21.57%) c) brings a bunch of pie to the food (2.67%) d) drinks from the mug in the bowl. (0.98%)	He is up a tree. Someone **a) stands underneath the tree. (97.44%)** b) is at a pool table holding a cup. (1.14%) c) grabs a flower from a paper. (0.96%) d) is eating some cereal. (0.45%)
An old man rides a small bumper car. Several people a) get in the parking lot. (76.58%) b) wait in the car. (15.28%) **c) get stuck with other bumper cars. (6.75%)** d) are running down the road. (1.39%)	He pours the raw egg batter into the pan. He a) drops the tiny pan onto a plate. (93.48%) **b) lifts the pan and moves it around to shuffle the eggs. (4.94%)** c) stirs the dough into a kite. (1.53%) d) swirls the stir under the adhesive. (0.05%)

Table 5: Example questions answered by the best model, ESIM+Elmo, sorted by model probability. Correct model predictions are in **blue**, incorrect model predictions are red. The right answers are **bolded**.

cient. For instance, answering "An old man rides a small bumper car" requires knowledge about *bumper cars* and how they differ from regular cars: bumper cars are tiny, don't drive on roads, and don't work in parking lots, eliminating the alternatives. However, this knowledge is difficult to extract from existing corpora: for instance, the ConceptNet entry for Bumper Car has only a single relation: bumper cars are a type of vehicle. Other questions require intuitive physical reasoning: e.g, for "he pours the raw egg batter into the pan," about what happens next in making an omelet.

5.4 Where to go next?

Our results suggest that SWAG is a challenging testbed for NLI models. However, the adversarial models used to filter the dataset are purely stylistic and focus on the second sentence; thus, subtle artifacts still likely remain in our dataset. These patterns are ostensibly picked up by the NLI models (particularly when using ELMo features), but the large gap between machine and human performance suggests that more is required to solve the dataset. As models are developed for commonsense inference, and more broadly as the field of NLP advances, we note that AF can be used again to create a more adversarial version of SWAG using better language models and AF models.

6 Related Work

Entailment NLI There has been a long history of NLI benchmarks focusing on linguistic entailment (Cooper et al., 1996; Dagan et al., 2006; Marelli et al., 2014; Bowman et al., 2015; Lai et al., 2017; Williams et al., 2018). Recent NLI datasets in particular have supported learning broadly-applicable sentence representations (Conneau et al., 2017); moreover, models trained on these datasets were used as components for performing better video captioning (Pasunuru and Bansal, 2017), summarization (Pasunuru and Bansal, 2018), and generation (Holtzman et al., 2018), confirming the importance of NLI research. The NLI task requires a variety of commonsense knowledge (LoBue and Yates, 2011), which our work complements. However, previous datasets for NLI have been challenged by unwanted annotation artifacts, (Gururangan et al., 2018; Poliak et al., 2018) or scale issues. Our work addresses these challenges by constructing a new NLI benchmark focused on grounded commonsense reasoning, and by introducing an adversarial filtering mechanism that substantially reduces known and easily detectable annotation artifacts.

Commonsense NLI Several datasets have been introduced to study NLI beyond linguistic entailment: for inferring likely causes and endings given a sentence (COPA; Roemmele et al., 2011), for choosing the most sensible ending to a short story (RocStories; Mostafazadeh et al., 2016; Sharma et al., 2018), and for predicting likelihood of a hypothesis by regressing to an ordinal label (JOCI; (Zhang et al., 2017)). These datasets are relatively small: 1k examples for COPA and 10k cloze examples for RocStories.[13] JOCI increases the scale by generating the hypotheses using a knowledge graph or a neural model. In contrast to JOCI where the task was formulated as a regression task on the degree of plausibility of the hypothesis, we frame commonsense inference as a multiple choice question to reduce the potential ambiguity in the labels and to allow for direct comparison between machines and humans. In addition, SWAG's use of adversarial filtering increases diversity of situations and counterfactual generation quality.

---

[13] For RocStories, this was by design to encourage learning from the larger corpus of 98k sensible stories.

Last, another related task formulation is sentence completion or cloze, where the task is to predict a single word that is removed from a given context (Zweig and Burges, 2011; Paperno et al., 2016).[14] Our work in contrast requires longer textual descriptions to reason about.

Vision datasets Several resources have been introduced to study temporal inference in vision. The Visual Madlibs dataset has 20k image captions about hypothetical next/previous events (Yu et al., 2015); similar to our work, the test portion is multiple-choice, with counterfactual answers retrieved from similar images and verified by humans. The question of 'what will happen next?' has also been studied in photo albums (Huang et al., 2016), videos of team sports, (Felsen et al., 2017) and egocentric dog videos (Ehsani et al., 2018). Last, annotation artifacts are also a recurring problem for vision datasets such as Visual Genome (Zellers et al., 2018) and Visual QA (Jabri et al., 2016); recent work was done to create a more challenging VQA dataset by annotating complementary image pairs (Goyal et al., 2016).

Reducing gender/racial bias Prior work has sought to reduce demographic biases in word embeddings (Zhang et al., 2018) as well as in image recognition models (Zhao et al., 2017). Our work has focused on producing a dataset with minimal annotation artifacts, which in turn helps to avoid some gender and racial biases that stem from elicitation (Rudinger et al., 2017). However, it is not perfect in this regard, particularly due to biases in movies (Schofield and Mehr, 2016; Sap et al., 2017). Our methodology could potentially be extended to construct datasets free of (possibly intersectional) gender or racial bias.

Physical knowledge Prior work has studied learning grounded knowledge about objects and verbs: from knowledge bases (Li et al., 2016), syntax parses (Forbes and Choi, 2017), word embeddings (Lucy and Gauthier, 2017), and images and dictionary definitions (Zellers and Choi, 2017). An alternate thread of work has been to learn scripts: high-level representations of event chains (Schank and Abelson, 1975; Chambers and Jurafsky, 2009). SWAG evaluates both of these strands.

7 Conclusion

We propose a new challenge of physically situated commonsense inference that broadens the scope of natural language inference (NLI) with commonsense reasoning. To support research toward commonsense NLI, we create a large-scale dataset SWAG with 113k multiple-choice questions. Our dataset is constructed using Adversarial Filtering (AF), a new paradigm for robust and cost-effective dataset construction that allows datasets to be constructed at scale while automatically reducing annotation artifacts that can be easily detected by a committee of strong baseline models. Our adversarial filtering paradigm is general, allowing potential applications to other datasets that require human composition of question answer pairs.

TwoWingOS: A Two-Wing Optimization Strategy for Evidential Claim Verification

Wenpeng Yin, Dan Roth
University of Pennsylvania
{wenpeng,danroth}@seas.upenn.edu

Abstract

Determining whether a given claim is supported by evidence is a fundamental NLP problem that is best modeled as Textual Entailment. However, given a large collection of text, finding evidence that could support or refute a given claim is a challenge in itself, amplified by the fact that different evidence might be needed to support or refute a claim. Nevertheless, most prior work decouples evidence identification from determining the truth value of the claim given the evidence.

We propose to consider these two aspects jointly. We develop TwoWingOS (**two-wing** **o**ptimization **s**trategy), a system that, while identifying appropriate evidence for a claim, also determines whether or not the claim is supported by the evidence. Given the claim, TwoWingOS attempts to identify a subset of the evidence candidates; given the predicted evidence, it then attempts to determine the truth value of the corresponding claim. We treat this challenge as coupled optimization problems, training a joint model for it. TwoWingOS offers two advantages: (i) Unlike pipeline systems, it facilitates flexible-size evidence set, and (ii) Joint training improves both the claim verification and the evidence identification. Experiments on a benchmark dataset show state-of-the-art performance.[1]

1 Introduction

A claim, e.g., "Marilyn Monroe worked with Warner Brothers", is an assertive sentence that may be true or false. While the task of claim verification *will not* tell us the absolute truth of this claim, it is expected to determine whether the claim is supported by evidence in a given text collection. Specifically, given a claim and a text corpus, *evidential claim verification*, demonstrated in Figure 1, aims at identifying text snippets in the corpus that act as evidence that supports or refutes the claim.

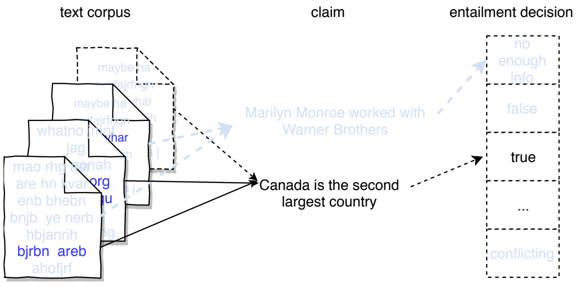

Figure 1: Illustration of evidential claim verification task. For a claim, we determine its truth value by evidence identified from a text corpus.

This problem has broad applications. For example, knowledge bases (KB), such as Freebase (Bollacker et al., 2008), YAGO (Suchanek et al., 2007), can be augmented with a new relational statement such as "(Afghanistan, is_source_of, Kushan Dynasty)". This needs to be first verified by a claim verification process and supported by evidence (Roth et al., 2009; Chaganty et al., 2017). More broadly, claim verification is a key component in any technical solution addressing recent concerns about the trustworthiness of online content (Vydiswaran et al., 2011; Pasternack and Roth, 2013; Hovy et al., 2013). In both scenarios, we care about whether or not a claim holds, and seek reliable evidence in support of this decision.

Evidential claim verification requires that we address three challenges. First, to locate text snippets in the given corpus that can potentially be used to determine the truth value of the given claim. This differs from the conventional textual entailment (TE) problem (Dagan et al., 2013) as here we first look for the premises given a hypothesis. Clearly, the evidence one seeks depends on the claim, as well as on the eventual entailment

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 105–114
Brussels, Belgium, October 31 - November 4, 2018.

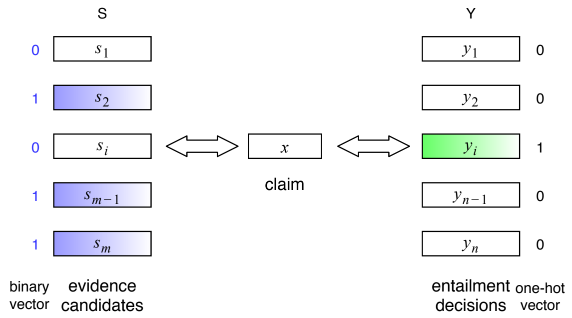

Figure 2: TwoWingOS, a generic two-wing optimization framework. A subset of the evidence candidates $S_e = \{s_1, \ldots, s_{m-1}, s_m\}$ is chosen via a binary vector (left), and an n-valued entailment decision $y_i \in Y$ is chosen (right), with respect to the claim x.

decision – the same claim would require different supporting than refuting evidence. This motivates us to develop an approach that can transfer knowledge from claim verification to evidence identification. Second, the evidence for a claim might require aggregating information from multiple sentences and even multiple documents (rf. #3 in Table 4). Therefore, a *set*, rather than a collection of independent text snippets, should be chosen to act as evidence. And, finally, in difference from TE, given a set of evidence sentences as a premise, the truth value of the claim should depend on *all of the evidence*, rather than on a single sentence there.

The discussion above suggests that claim verification and evidence identification are tightly coupled. Claim should influence the identification of appropriate evidence, and "trusted evidence boosts the claim's veracity" (Vydiswaran et al., 2011). Consequently, we propose TwoWingOS, a two-wing optimization strategy[2], to support this process. As shown in Figure 2, we consider a set of sentences S as the candidate evidence space, a claim x, and a decision space Y for the claim verification. In the optimal condition, a one-hot vector over Y indicates which decision to make towards the claim, and a binary vector over S indicates a subset of sentences S_e (in blue in Figure 2) to act as evidence.

Prior work mostly approached this problem as a pipeline procedure – first, given a claim x, determine S_e by some similarity matching; then, conduct textual entailment over (S_e, x) pairs. Our framework, TwoWingOS, optimizes the two subtasks jointly, so that both claim verification and evidence identification can enhance each other. TwoWingOS is a generic framework making use of a shared representation of the claim to co-train evidence identification and claim verification.

TwoWingOS is tested on the FEVER benchmark (Thorne et al., 2018), showing ≈30% F_1 improvement for evidence identification, and ≈23% accuracy increase in claim verification. Our analysis shows that (i) entity mentions in claims provide a strong clue for retrieving relevant passages; (ii) composition of evidence clues across sentences helps claim verification; and that (iii) the joint training scheme provides significant benefits of a pipeline architecture.

2 Related Work

Most work focuses on the dataset construction while lacking advanced models to handle the problem. Vlachos and Riedel (2014) propose and define the "fact checking" problem, without a concrete solution. Ferreira and Vlachos (2016) release the dataset "Emergent" for rumor debunking. Each claim is accompanied by an article headline as evidence. Then a three-way logistic regression model is used over some rule-based features. No need to search for evidence. Wang (2017) release a larger dataset for fake news detection, and propose a hybrid neural network to integrate the statement and the speaker's meta data to do classification. However, the presentation of evidences is ignored. Kobayashi et al. (2017) release a similar dataset to (Thorne et al., 2018), but they do not consider the evaluation of evidence reasoning.

Some work mainly pays attention to determining whether the claim is true or false, assuming evidence facts are provided or neglecting presenting evidence totally, e.g., (Angeli and Manning, 2014) – given a database of true facts as premises, predicting whether an unseen fact is true and should belong to the database by natural logic inference. Open-domain question answering (QA) against a text corpus (Yin et al., 2016; Chen et al., 2017; Wang et al., 2018) can also be treated as claim verification problem, if we treat (question, correct answer) as a claim. However, little work has studied how well a QA system can identify all the answer evidence.

Only a few works considered improving the evidence presentation in claim verification problems.

---

[2] By "two-wing optimization", we mean that the same object, i.e., the claim, is mapped into two target spaces in a joint optimization scheme.

Roth et al. (2009) introduce the task of Entailed Relation Recognition – given a set of short paragraphs and a relational fact in the triple form of (argument$_1$, relation, argument$_2$), finding the paragraphs that can entail this fact. They first use Expanded Lexical Retrieval to rank and keep the top-k paragraphs as candidates, then build a TE classifier over each (candidate, statement) pair. The work directly related to us is by Thorne et al. (2018). Given claims and a set of Wikipages, Thorne et al. (2018) use a retrieval model based on TF-IDF to locate top-5 sentences in top-5 pages as evidence, then utilize a neural entailment model to classify (evidence, claim) pairs.

In contrast, our work tries to optimize the claim verification as well as the evidence identification in a joint training scheme, which is more than just supporting or refuting the claims.

3 The TWOWINGOS Model

Figure 2 illustrates the two-wing optimization problem addressed in this work: given a collection of evidence candidates S=$\{s_1, s_2, \cdots, s_i, \cdots, s_m\}$, a claim x and a decision set $Y = \{y_1 \cdots, y_n\}$, the model TWOWINGOS predicts a binary vector p over S and a one-hot vector o over Y against the ground truth, a binary vector q and a one-hot vector z, respectively. A binary vector over S means a subset of sentences (S_e) act as evidence, and the one-hot vector indicates a single decision (y_i) to be made towards the claim x given the evidence S_e. Next, we use two separate subsections to elaborate the process of evidence identification (i.e., optimize p to q) and the claim verification (i.e., optimize o to z).

3.1 Evidence identification

A simple approach to identifying evidence is to detect the top-k sentences that are lexically similar to the claim, as some pipeline systems (Roth et al., 2009; Thorne et al., 2018) do. However, a claim-unaware fixed k is less optimal, adding noise or missing key supporting factors, consequently limiting the performance.

In this work, we approach the evidence by modeling sentences S=$\{s_1, \cdots, s_i, \cdots, s_m\}$ with the claim x as context in a supervised learning scheme. For each s_i, the problem turns out to be learning a probability: how likely s_i can entail the claim conditioned on other candidates as context, as shown by the blue items in Figure 2.

To start, a piece of text t ($t \in S \cup \{x\}$) is represented as a sequence of l hidden states, forming a feature map $\mathbf{T} \in \mathbb{R}^{d \times l}$, where d is the dimensionality of hidden states. We first stack a vanilla CNN (convolution & max-pooling) (LeCun et al., 1998) over $\mathbf{T}$ to get a representation for t. As a result, each evidence candidate s_i has a representation $\mathbf{s}_i$, and the claim x has a representation $\mathbf{x}$. To get a probability for each s_i, we need first to build its *claim-aware representation* $\mathbf{r}_i$.

Coarse-grained representation. We directly concatenate the representation of s_i and x, generated by the vanilla CNN, as:

$$\mathbf{r}_i = [\mathbf{s}_i, \mathbf{x}, \mathbf{s}_i \cdot \mathbf{x}^T] \tag{1}$$

This coarse-grained approach makes use of merely the sentence-level representations while neglecting more fine-grained interactions between the sentences and the claim.

Fine-grained representation. Instead of directly employing the sentence-level representations, here we explore claim-aware representations for each word in sentence s_i, then compose them as the sentence representation $\mathbf{r}_i$, inspired by the Attentive Convolution (Yin and Schütze, 2017).

For each word s_i^j in s_i, we first calculate its matching score towards each word x^z in x, by dot product over their hidden states. Then the representation of the claim, as the context for the word s_i^j, is formed as:

$$\mathbf{c}_i^j = \sum_z \mathrm{softmax}(\mathbf{s}_i^j \cdot (\mathbf{x}^z)^T) \cdot \mathbf{x}^z \tag{2}$$

Now, word s_i^j has left context $\mathbf{s}_i^{j-1}$, right context $\mathbf{s}_i^{j+1}$ in s_i, and the claim-aware context $\mathbf{c}_i^j$ from x. A convolution encoder generates its claim-aware representation $\mathbf{i}_i^j$:

$$\mathbf{i}_i^j = \tanh(\mathbf{W} \cdot [\mathbf{s}_i^{j-1}, \mathbf{s}_i^j, \mathbf{s}_i^{j+1}, \mathbf{c}_i^j] + \mathbf{b}) \tag{3}$$

where parameters $\mathbf{W} \in \mathbb{R}^{d \times 4d}$, $\mathbf{b} \in \mathbb{R}^d$.

To compose those claim-aware word representations as the representation for sentence s_i, we use a max-pooling over $\{\mathbf{i}_i^j\}$ along with j, generating $\mathbf{i}_i$.

We use term $f_{\mathrm{int}}(s_i, x)$ to denote this whole process, so that:

$$\mathbf{i}_i = f_{\mathrm{int}}(s_i, x) \tag{4}$$

At this point, the fine-grained representation for evidence candidate s_i is:

$$\mathbf{r}_i = [\mathbf{s}_i, \mathbf{x}, \mathbf{s}_i \cdot \mathbf{x}^T, \mathbf{i}_i] \tag{5}$$

Loss function. With a claim-aware representation $\mathbf{r}_i$, the sentence s_i subsequently gets a probability, acting as the evidence, $\alpha_i \in (0,1)$ via a non-linear sigmoid function:

$$\alpha_i = \mathrm{sigmoid}(\mathbf{v} \cdot \mathbf{r}_i^{\mathrm{T}}) \tag{6}$$

where parameter vector $\mathbf{v}$ has the same dimensionality as $\mathbf{r}_i$.

In the end, all evidence candidates in S have a ground-truth binary vector q and the predicted probability vector α; then loss l_{ev} ("ev": **ev**idence) is implemented as a binary cross-entropy:

$$l_{ev} = \sum_{i=1}^{m} -(q_i \log(\alpha_i) + (1-q_i)\log(1-\alpha_i)) \tag{7}$$

As the output of this evidence identification module, we binarize the probability vector α by $p_i = [\alpha_i > 0.5]$ ("$[x]$" is 1 if x is true or 0 otherwise). p_i indicates s_i is evidence or not. All $\{s_i\}$ with $p_i = 1$ act as evidence set S_e.

3.2 Claim verification

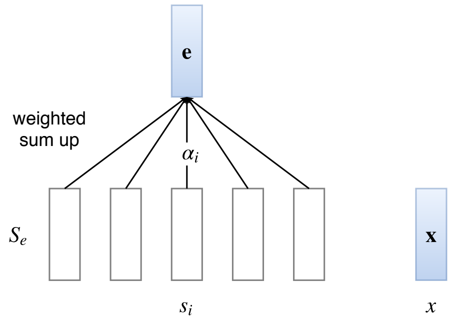
As shown in Figure 2, to figure out an entailment decision y_i for the claim x, the evidence S_e possibly consists of more than one sentence. Furthermore, those evidence sentences are not necessarily in textual order nor from the same passage. So, we need a mechanism that enables each evidence or even each word inside to be aware of the content from other evidence sentences. Similar to the aforementioned approach to evidence identification, we come up with three methods, with different representation granularity, to learn a representation for (S_e, x), i.e., the input for claim verification, shown in Figure 3.

Coarse-grained representation. In this case, we treat S_e as a whole, constructing its representation $\mathbf{e}$ by summing up the representations of all sentences in S_e in a weighted way:

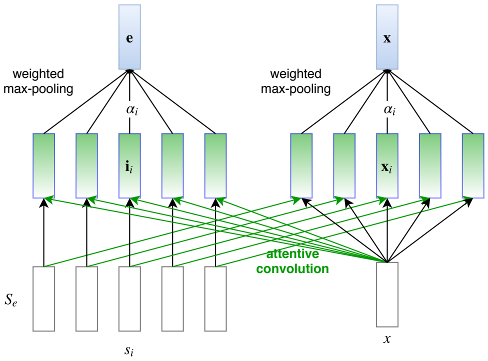
$$\mathbf{e} = \sum_{i=1}^{m} \alpha_i \cdot p_i \cdot \mathbf{s}_i \tag{8}$$

where α_i, from Equation 6, is the probability of s_i being the evidence.

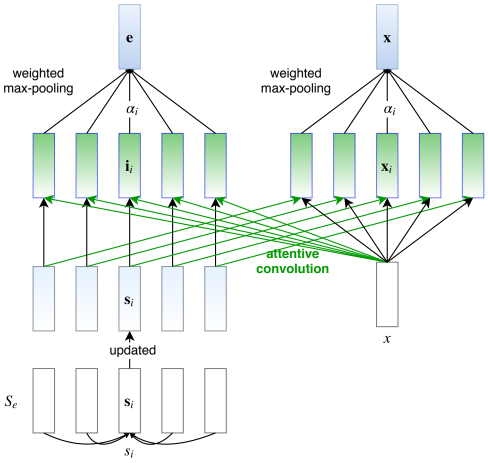
Then the (S_e, x) pair gets a coarse-grained concatenated representation: $[\mathbf{e}, \mathbf{x}]$. It does not model the interactions within the evidence nor the interactions between the evidence and the claim. Based on our experience in evidence identification module, the representation of a sentence is better learned by composing context-aware word-level representations. Next, we introduce how to learn fine-grained representation for the (S_e, x) pair.



(a) Coarse-grained representations



(b) Single-channel fine-grained representations



(c) Two-channel fine-grained representations

Figure 3: Three representation learning methods in claim verification. Green arrows act as context in attentive convolution.

Single-channel fine-grained representation. By "single-channel," we mean each sentence s_i is aware of the claim x as its single context.

For a single pair (s_i, x), we utilize the function $f_{\text{int}}()$ in Equation 4 to build the fine-grained representations for both s_i and x, obtaining $\mathbf{i}_i =$

$f_{\text{int}}(s_i, x)$ for s_i and $\mathbf{x}_i = f_{\text{int}}(x, s_i)$ for x.

For (S_e, x), we compose all the $\{\mathbf{i}_i\}$ and all the $\{\mathbf{x}_i\}$ along with i, via a weighted max-pooling:

$$\mathbf{e} = \text{maxpool}_i(\alpha_i \cdot p_i \cdot \mathbf{i}_i) \tag{9}$$

$$\mathbf{x} = \text{maxpool}_i(\alpha_i \cdot p_i \cdot \mathbf{x}_i) \tag{10}$$

This weighted max-pooling ensures that the sentences with higher probabilities of being evidence have a higher chance to present their features. As a result, (S_e, x) gets a concatenated representation: [**e**, **x**]

Two-channel fine-grained representation. By "two-channel," we mean that each evidence s_i is aware of two kinds of context, one from the claim x, the other from the remaining evidences.

Our first step is to accumulate evidence clues within S_e. To start, we concatenate all sentences in S_e as a fake long sentence $\hat{S}$ consisting of hidden states $\{\hat{\mathbf{s}}\}$. Similar to Equation 2, for each word s_i^j in sentence s_i, we *accumulate all of its related clues* ($\mathbf{c}_i^j$) from $\hat{S}$ as follows:

$$\mathbf{c}_i^j = \sum_z \text{softmax}(\mathbf{s}_i^j \cdot (\hat{\mathbf{s}}^z)^T) \cdot \hat{\mathbf{s}}^z \tag{11}$$

Then we update $\mathbf{s}_i^j$, the representation of word s_i^j, by element-wise addition:

$$\mathbf{s}_i^j = \mathbf{s}_i^j \oplus \mathbf{c}_i^j \tag{12}$$

This step enables the word s_i^j to "see" all related clues from S_e. The reason we add $\mathbf{s}_i^j$ and $\mathbf{c}_i^j$ is motivated by a simple experience: Assume the claim "Lily lives in the biggest city in Canada", and one sentence contains a clue "$\cdots$ Lily lives in Toronto $\cdots$" and another sentence contains a clue "$\cdots$ Toronto is Canada's largest city$\cdots$". The most simple yet effective approach to aggregating the two clues is to sum up their representation vectors (Blacoe and Lapata, 2012) (we do not concatenate them, as those clues have no consistent textual order across different $\mathbf{s}_i^j$).

After updating the representation of each word in s_i, we perform the aforementioned "single-channel fine-grained representation" between the updated s_i and the claim x, generating [**e**, **x**].

Loss function. For the claim verification input (S_e, x), we forward its representation [**e**, **x**] to a logistic regression layer in order to infer a probability distribution o over the label space Y:

	#SUPPORTED	#REFUTED	#NEI
train	80,035	29,775	35,639
dev	3,333	3,333	3,333
test	3,333	3,333	3,333

Table 1: Statistics of claims in FEVER dataset

$$\mathbf{o} = \text{softmax}(\mathbf{W} \cdot [\mathbf{e}, \mathbf{x}] + \mathbf{b}) \tag{13}$$

where $\mathbf{W} \in \mathbb{R}^{n \times 2d}$, $\mathbf{b} \in \mathbb{R}^n$

The loss l_{cv} ("cv": claim verification) is implemented as negative log-likelihood:

$$l_{\text{cv}} = -\log(\mathbf{o} \cdot \mathbf{z}^T) \tag{14}$$

where **z** is the ground truth one-hot label vector for the claim x on the space Y.

3.3 Joint optimization

Given the loss l_{ev} in evidence identification and the loss l_{cv} in claim verification, the overall training loss is represented by:

$$l = l_{\text{ev}} + l_{\text{cv}} \tag{15}$$

To ensure that we jointly train the two coupled subtasks with intensive knowledge communication instead of simply putting two pipeline neural networks together, our TWOWINGOS has following configurations:

- Both subsystems share the same set of word embeddings as parameters; the vanilla CNNs for learning sentence and claim representations share parameters as well.
- The output binary vector p by the evidence identification module is forwarded to the module of claim verification, as shown in Equations 8-10.
- Though the representation of a claim's decision y_i is not put explicitly into the module of evidence identification, the claim's representation **x** will be fine-tuned by the y_i, so that the evidence candidates can get adjustment from the decision y_i, since the claims are shared by two modules.

4 Experiments

4.1 Setup

Dataset. In this work, we use FEVER (Thorne et al., 2018). The claims in FEVER were generated from the introductory parts of about 50K

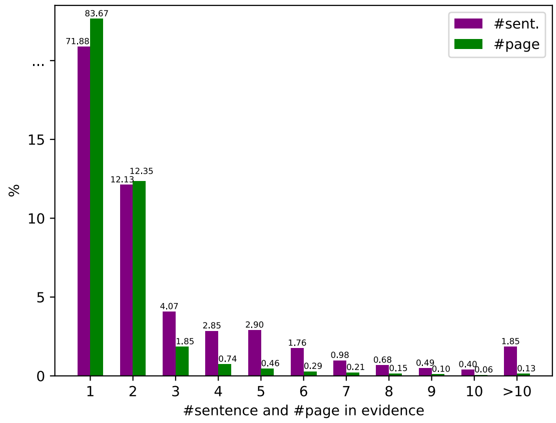


Figure 4: Distribution of #sentence and #pages in FEVER evidence

Wikipedia pages of a June 2017 dump. Annotators construct claims about a single fact of the title entity with arbitrarily complex expressions and entity forms. To increase the claim complexity so that claims would not be trivially verified, annotators adopt two routes: (i) Providing additional knowledge: Annotators can explore a dictionary of terms that were (hyper-)linked, along with their pages; (ii) Mutate claims in six ways: negation, paraphrasing, substitution of a relation/entity with a similar/dissimilar one, and making the claims more general/specific. All resulting claims have 9.4 tokens in average. Apart from claims, FEVER also provides a Wikipedia corpus in size of about 5.4 million.

Each claim is labeled as SUPPORTED, REFUTED or NOTENOUGHINFO (NEI). In addition, evidence sentences, from any wiki page, are required to be provided for SUPPORTED and REFUTED. Table 1 lists the data statistics. Figure 4 shows the distributions of sentence sizes and page sizes in FEVER's evidence set. We can see that roughly 28% of the evidence covers more than one sentence, and approximately 16.3% of the evidence covers more than one wiki page.

This task has three evaluations: (i) NOSCOREEV – accuracy of claim verification, neglecting the validity of evidence; (ii) SCOREEV – accuracy of claim verification with a requirement that the predicted evidence fully covers the gold evidence for SUPPORTED and REFUTED; (iii) F_1 – between the predicted evidence sentences and the ones chosen by annotators. We use the officially released evaluation scorer [3].

Wiki page retrieval[4]**.** For each claim, we search in the given dictionary of wiki pages in the form of {title: sentence_list}, and keep the top-5 ranked pages for fair comparison with Thorne et al. (2018). Algorithm 1 briefly shows the steps of wiki page retrieval. To speed up, we first build an inverted index from words to titles, then for each claim, we only search in the titles that cover at least one claim word.

```
Input: A claim, wiki={title: page_vocab}
Output: A ranked top-$k$ wiki titles
Generate entity_mentions from the claim;
while each title do
    if claim.vocab∩title.vocab is empty then
        discard this title
    else
        title_score = the max recall value of title.vocab
          in claim and in entity_mentions of the claim;
        if title_score = 1.0 then
            title.score = title_score
        else
            page_score = recall of claim in
              page_vocab;
            title.score = title_score + page_score
        end
    end
end
Sort titles by title.score in descending order
```

Algorithm 1: Algorithm description of wiki page retrieval for FEVER claims.

All sentences of the top-5 retrieved wiki pages are kept as evidence candidates for claims in train, dev and test. It is worth mentioning that this page retrieval step is a reasonable preprocessing which controls the complexity of evidence searching in real-world, such as the big space – 5.4 million – in this work.

Training setup. All words are initialized by 300D Word2Vec (Mikolov et al., 2013) embeddings, and are fine-tuned during training. The whole system is trained by AdaGrad (Duchi et al., 2011). Other hyperparameter values include: learning rate 0.02, hidden size 300, mini-batch size 50, filter width 3.

Baselines. In this work, we first consider the two systems reported by Thorne et al. (2018): (i) MLP: A multi-layer perceptron with one hidden layer, based on TF-IDF cosine similarity between the claim and the evidence (all evidence sentences are concatenated as a longer text piece) (Riedel et al., 2017); (ii) Decomp-Att (Parikh et al., 2016): A decomposable attention model that develops atten-

[4] Our retrieval results are released as well.

k	(Thorne et al., 2018)		ours	
	rate	acc_ceiling	rate	acc_ceiling
1	25.31	50.21	76.58	84.38
5	55.30	70.20	89.63	93.08
10	65.86	77.24	91.19	94.12
25	75.92	83.95	92.81	95.20
50	82.49	90.13	93.36	95.57
100	86.59	91.06	94.19	96.12

Table 2: Wikipage retrieval evaluation on dev. "rate": claim proportion, e.g., $x\%$, if its gold passages are fully retrieved (for "SUPPORT" and "REFUTE" only); "acc_ceiling": $\frac{x\%\cdot(\#\mathrm{S}+\#\mathrm{R})+\#\mathrm{N}}{\#\mathrm{S}+\#\mathrm{R}+\#\mathrm{N}}$, the upper bound of accuracy for three classes if the coverage $x\%$ satisfies.

tion mechanisms to decompose the problem into subproblems to solve in parallel. Note that both systems first employed an IR system to keep top-5 relevant sentences from the retrieved top-5 wiki pages as *static evidence* for claims.

We further consider the following variants of our own system TwoWingOS:

- *Coarse-coarse*: Both evidence identification and claim verification adopt coarse-grained representations.

To further study our system, we test this "coarse-coarse" in three setups: (i) "pipeline" – train the two modules independently. Forward the predicted evidence to do entailment for claims; (ii) "diff-CNN" – joint training with separate CNN parameters to learn sentence/claim representations; (iii) "share-CNN" – joint training with shared CNN parameters.

The following variants are in joint training.

- *Fine&sentence-wise*: Given the evidence with multiple sentences, a natural baseline is to do entailment reasoning for each (sentence, claim), then compose. We do entailment reasoning between each predicted evidence sentence and the claim, generating a probability distribution over the label space Y. Then we sum up all the distribution vectors element-wise, as an ensemble system, to predict the label;

- Four combinations of different grained representation learning: "*coarse&fine(single)*", "*coarse&fine(two)*", "*fine&coarse*" and "*fine&fine(two)*". "Single" and "two" refer to the single/two-channel cases respectively.

4.2 Results

Performance of passage retrieval. Table 2 compares our wikipage retriever with the one in (Thorne et al., 2018), which used a document retriever[5] from DrQA (Chen et al., 2017).

Our document retrieval module surpasses the competitor by a big margin in terms of the coverage of gold passages: 89.63% vs. 55.30% ($k = 5$ in all experiments). Its powerfulness should be attributed to: (i) Entity mention detection in the claims. (ii) As wiki titles are entities, we have a bi-channel way to match the claim with the wiki page: one with the title, the other with the page body, as shown in Algorithm 1.

Performance on FEVER Table 3 lists the performances of baselines and the TwoWingOS variants on FEVER (dev&test). From the *dev* block, we observe that:

- TwoWingOS (from "share-CNN") surpasses prior systems in big margins. Overall, fine-grained schemes in each subtask contribute more than the coarse-grained counterparts;

- In the three setups – "pipeline", "diff-CNN" and "share-CNN" – of *coarse-coarse*, "pipeline" gets better scores than (Thorne et al., 2018) in terms of evidence identification. "Share-CNN" has comparable F_1 as "diff-CNN" while gaining a lot on NoScoreEv (72.32 vs. 39.22) and ScoreEv (50.12 vs. 21.04). This clearly shows that the claim verification gains much knowledge transferred from the evidence identification module. Both "diff-CNN" and "share-CNN" perform better than "pipeline" (except for the slight inferiority at ScoreEv: 21.04 vs. 22.26).

- Two-channel fine-grained representations show more effective than the single-channel counterpart in claim verification (NoScoreEv: 78.77 vs. 75.65, ScoreEv: 53.64 vs. 52.65). As we expected, evidence sentences should *collaborate* in inferring the truth value of the claims. Two-channel setup enables an evidence candidate aware of other candidates as well as the claim.

- In the last three rows of *dev*, there is no clear difference among their evidence identification scores. Recall that "sent-wise" is essentially an ensemble system over each (sentence, claim) entailment result. "Coarse-grained", instead, first sums up all sentence representation, then performs ($\sum(\mathit{sentence})$, claim) reasoning. We can also treat this "sum up" as an ensemble. Their comparison shows that *these two kinds of tricks do not*

[5] It compares passages and claims as TF-IDF weighted bag-of-bigrams.

		system	claim verification		evidence identification		
			NoScoreEv	ScoreEv	recall	precision	F_1
dev		MLP	41.86	19.04	44.22	10.44	16.89
		Decomp-Att	52.09	32.57	44.22	10.44	16.89
	TwoWingOS	coarse&coarse					
		pipeline	35.72	22.26	53.75	29.42	33.80
		diff-CNN	39.22	21.04	46.88	43.01	44.86
		share-CNN	72.32	50.12	45.55	40.77	43.03
		coarse&fine(single)	75.65	52.65	45.81	42.53	44.11
		coarse&fine(two)	78.77	53.64	45.78	39.23	42.25
		fine&sent-wise	71.02	53.43	52.70	**48.31**	50.40
		fine&coarse	71.48	53.17	52.75	47.30	49.87
		fine&fine(two)	**78.90**	**56.16**	**53.81**	47.73	**50.59**
test		(Thorne et al., 2018)	50.91	31.87	45.89	10.79	17.47
		TwoWingOS	**75.99**	**54.33**	**49.91**	**44.68**	**47.15**

Table 3: Performance on *dev* and *test* of FEVER. TwoWingOS outperforms prior systems if vanilla CNN parameters are shared by evidence identification and claim verification subsystems. It gains more if fine-grained representations are adopted in both subtasks.

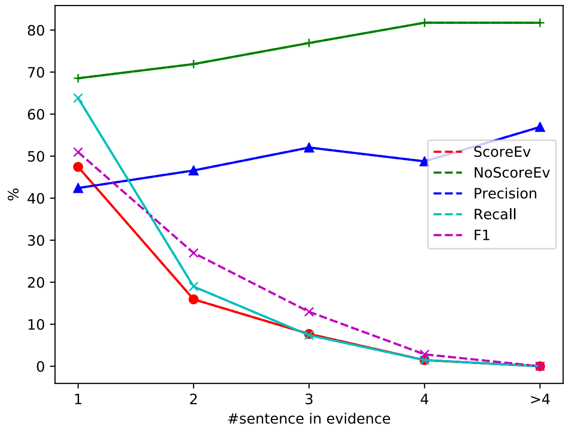

Figure 5: Performance vs. #sentence in evidence. Our system has robust precisions. The overall performance NoScoreEv is not influenced by the decreasing recall; this verifies the fact that the truth value of most claims can be determined by a single identified evidence sentence.

make much difference.

If we adopt "two-channel fine-grained representation" in claim verification, big improvements are observed in both NoScoreEv (+7.42%) and ScoreEv (+3%).

In the *test* block, our system (fine&fine(two)) beats the prior top system across all measurements by big margins – F_1: 47.15 vs. 17.47; ScoreEv: 54.33 vs. 31.87; NoScoreEv: 75.99 vs. 50.91.

In both *dev* and *test* blocks, we can observe that our evidence identification module consistently obtains balanced recall and precision. In contrast, the pipeline system by Thorne et al. (2018) has much higher recall than precision (45.89 vs. 10.79). It is worth mentioning that the ScoreEv metric is highly influenced by the recall value, since ScoreEv is computed on the claim instances whose evidences are fully retrieved, regardless of the precision. So, ideally, a system can set all sentences as evidence, so that ScoreEv can be promoted to be equal to NoScoreEv. Our system is more reliable in this perspective.

Performance vs. #sent. in evidence. Figure 5 shows the results of the five evaluation measures against different sizes of gold evidence sentences in test set. We observe that: (i) Our system has robust precisions across #sentence; however, the recall decreases. This is not that surprising, since the more ground-truth sentences in evidence, the harder it is to retrieve all of them; (ii) Due to the decrease in recall, the ScoreEv also gets influenced for bigger #sentence. Interestingly, high precision and worse recall in evidence with more sentences still make consistently strong overall performance, i.e., NoScoreEv. This should be due to the fact that the majority (83.18% (Thorne et al., 2018)) of claims can be correctly entailed by a single ground truth sentence, even if any remaining ground truth sentences are unavailable.

Error analysis. The case #1 in Table 4 shows that our system identifies two pieces of evidence

#	G/P	claim	gold evidence	predicted evidence
1	0/1	Telemundo is an English-language television network.	(Telemundo, 0) (Telemundo, 1) (Telemundo, 4) (Telemundo, 5) (Hispanic_and_Latino_Americans, 0)	(Telemundo, 0) (Telemundo, 4) (Fourth_television_network, 0) (Fourth_television_network, 4)
2	1/2	Home for the Holidays stars a famous American actor.	(Anne_Bancroft, 0) (Charles_Durning, 0) (Holly_Hunter, 0) (Home_for_the_Holidays_(1995_film), 5)	$\emptyset$
3	0/2	Both hosts of Weekly Idol were born in 1983.	(Weekly_Idol, 0) (Weekly_Idol, 1) (Defconn, 0)	(Weekly_Idol, 1)

Table 4: Error cases of TWOWINGOS in FEVER. "G/P": gold/predicted label ("0": refute; "1": support; "2": not enough information). To save space, we use "(title, i)" to denote the i^{th} sentence in the corresponding wiki page.

(i.e., (Telemundo, 0) and (Telemundo, 4)) correctly; however, it falsely predicts the claim label. (Telemundo, 0): *Telemundo is an American Spanish-language terrestrial television* $\cdots$. We can easily find that the keyword "Spanish-language" should refute the claim. However, both "Spanish-language" in this evidence and the "English-language" in the claim are unknown tokens with randomly initialized embeddings. This hints that a more careful data preprocessing may be helpful. In addition, to refute the claim, another clue comes from the combination of (Telemundo, 4) and (Hispanic_and_Latino_Americans, 0). (Telemundo, 4): "*The channel* $\cdots$ *aimed at Hispanic and Latino American audiences*"; (Hispanic_and_Latino_Americans, 0): "*Hispanic Americans and Latino Americans* $\cdots$ *are descendants of people from countries of Latin America and Spain.*". Our system only retrieved (Telemundo, 4). And this clue is hard to grasp as it requires some background knowledge – people from Latin America and Spain usually are not treated as English-speaking.

In the case #2, our system fails to identify any evidence. This is due to the failure of our passage retrieval module: it detects entity mentions "Home", "Holidays" and "American", and the top-5 retrieved passages are "Home", "Home_for_the_Holidays", "American_Home", "American" and "Home_for_the_Holidays_(song)", which unfortunately cover none of the four ground truth passages. Interestingly, (i) given the falsely retrieved passages, our system predicts "no sentence is valid evidence" (denoted as $\emptyset$ in Table 4); (ii) given the empty evidence, our system predicts "NoEnoughInfo" for this claim. Both make sense.

In the case #3, a successful classification of the claim requires information aggregation over the three gold evidence sentences: (Weekly_Idol, 0): "*Weekly Idol is a South Korean variety show* $\cdots$"; (Weekly_Idol, 1): "*The show is hosted by comedian Jeong Hyeong-don and rapper Defconn.*"; (Defconn, 0): "*Defconn (born Yoo Dae-joon; January 6 , 1977) is a* $\cdots$". To successfully retrieve the three sentences as a whole set of evidence is challenging in evidence identification. Additionally, this example relies on the recognition and matching of digital numbers (1983 vs. 1977), which is beyond the expressivity of word embeddings, and is expected to be handled by rules more easily.

5 Summary

In this work, we build TWOWINGOS, a two-wing optimization framework to address the claim verification problem by presenting precise evidence. Differing from a pipeline system, TWOWINGOS ensures the evidence identification module and the claim verification module are trained jointly, in an end-to-end scheme. Experiments show the superiority of TWOWINGOS in the FEVER benchmark.

Abstract

In this paper we address the problem of learning multimodal word representations by integrating textual, visual and auditory inputs. Inspired by the re-constructive and associative nature of human memory, we propose a novel *associative multichannel autoencoder* (AMA). Our model first learns the associations between textual and perceptual modalities, so as to predict the missing perceptual information of concepts. Then the textual and predicted perceptual representations are fused through reconstructing their original and associated embeddings. Using a gating mechanism our model assigns different weights to each modality according to the different concepts. Results on six benchmark concept similarity tests show that the proposed method significantly outperforms strong unimodal baselines and state-of-the-art multimodal models.

1 Introduction

Representing the meaning of a word is a prerequisite to solve many linguistic and non-linguistic problems, such as retrieving words with the same meaning, finding the most relevant images or sounds of a word and so on. In recent years we have seen a surge of interest in building computational models that represent word meanings from patterns of word co-occurrence in corpora (Turney and Pantel, 2010; Mikolov et al., 2013; Pennington et al., 2014; Clark, 2015; Wang et al., 2018b). However, word meaning is also tied to the physical world. Many behavioral studies suggest that human semantic representation is grounded in the external environment and sensorimotor experience (Landau et al., 1998; Barsalou, 2008). This has led to the development of multimodal representation models that utilize both textual and perceptual information (e.g., images, sounds).

As evidenced by a range of evaluations (Andrews et al., 2009; Bruni et al., 2014; Silberer et al., 2016), multimodal models can learn better semantic word representations (a.k.a. embeddings) than text-based models. However, most existing models still have a number of drawbacks. First, they ignore the associations between modalities, and thus lack the ability of information transferring between modalities. Consequently they cannot handle words without perceptual information. Second, they integrate textual and perceptual representations with simple concatenation, which is insufficient to effectively fuse information from various modalities. Third, they typically treat the representations from different modalities equally. This is inconsistent with many psychological findings that information from different modalities contributes differently to the meaning of words (Paivio, 1990; Anderson et al., 2017).

In this work, we introduce the associative multichannel autoencoder (AMA), a novel multimodal word representation model that addresses all the above issues. Our model is built upon the stacked autoencoder (Bengio et al., 2007) to learn semantic representations by integrating textual and perceptual inputs. Inspired by the re-constructive and associative nature of human memory, we propose two associative memory modules as extensions. One is to learn associations between modalities (e.g., associations between textual and visual features), so as to reconstruct corresponding perceptual information of concepts. The other is to learn associations between related concepts, by reconstructing embeddings of both target words and their associated words. Furthermore, we propose a gating mechanism to learn the importance weights of different modalities to each word.

To summarize, our main contributions in this work are two-fold:

- We present a novel associative multichannel autoencoder for multimodal word representation, which is capable of utilizing associations between different modalities and related

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 115–124
Brussels, Belgium, October 31 - November 4, 2018.

concepts, and assigning different importance weights to each modality according to different words. Results on six standard benchmarks demonstrate that our methods outperform strong unimodal baselines and state-of-the-art multimodal models.

- Our model successfully integrates cognitive insights of the re-constructive and associative nature of semantic memory in humans, suggesting that rich information contained in human cognitive processing can be used to enhance NLP models. Furthermore, our results shed light on the fundamental questions of how to learn semantic representations, such as the plausibility of reconstructing perceptual information, associating related concepts and grounding word symbols to external environment.

2 Background and Related Work

2.1 Cognitive Grounding

A large body of research evidences that human semantic memory is inherently re-constructive and associative (Collins and Loftus, 1975; Anderson and Bower, 2014). That is, memories are not exact static copies of reality, but are rather reconstructed from their stimuli and associated concepts each time they are retrieved. For example, when we see a *dog*, not only the concept itself, but also the corresponding perceptual information and associated words will be jointly activated and reconstructed. Moreover, various theories state that the different sources of information contribute differently to the semantic representation of a concept (Wang et al., 2010; Ralph et al., 2017). For instance, Dual Coding Theory (Hiscock, 1974) posits that concrete words are represented in the brain in terms of a perceptual and linguistic code, whereas abstract words are encoded only in the linguistic modality.

In these respects, our method employs a retrieval and representation process analogous to that of humans, in which the retrieval of perceptual information and associated words is triggered and mediated by a linguistic input. The learned cross-modality mapping and reconstruction of associated words are inspired by the human mental model of associations between different modalities and related concepts. Moreover, word meaning is tied to both linguistic and physical environment, and relies differently on each modality inputs (Wang et al., 2018a). These are also captured by our multimodal representation model.

2.2 Multimodal Models

The existing multimodal representation models can be generally classified into two groups: 1) *Jointly training models* build multimodal representations with raw inputs of textual and perceptual resources. 2) *Separate training models* independently learn textual and perceptual representations and integrate them afterwards.

2.2.1 Jointly training models

A class of models extends Latent Dirichlet Allocation (Blei et al., 2003) to jointly learn topic distributions from words and perceptual units (Andrews et al., 2009; Silberer and Lapata, 2012; Roller and Schulte im Walde, 2013). Recently introduced work is an extension of the Skip-gram model (Mikolov et al., 2013). For instance, Hill and Korhonen (2014) propose a corpus fusion method that inserts the perceptual features of concepts in the training corpus, which is then used to train the Skip-gram model. Lazaridou et al. (2015) propose MMSkip model, which injects visual information in the process of learning textual representations by adding a max-margin objective to minimize the distance between textual and visual vectors. Kiela and Clark (2015) adopt the MMSkip to learn multimodal vectors with auditory perceptual inputs.

These methods can implicitly propagate perceptual information to word representations and at the same time learn multimodal representations. However, they utilize raw text corpus in which words having perceptual information account for a small portion. This weakens the effect of introducing perceptual information and consequently leads to the slight improvement of textual vectors.

2.2.2 Separate training models

The simplest approach is concatenation which fuses textual and visual vectors by concatenating them. It has been proven to be effective in learning multimodal representations (Bruni et al., 2014; Hill et al., 2014; Collell et al., 2017). Variations of this method employ transformation and dimension reduction on the concatenation result, including application of singular value decomposition (SVD) (Bruni et al., 2014) or canonical correlation analysis (CCA) (Hill et al., 2014). There is also work using deep learning methods to project different modality inputs into a common space, including restricted Boltzman machines (Ngiam et al., 2011; Srivastava and Salakhutdinov, 2012), autoencoders (Silberer and Lapata, 2014; Silberer et al., 2016), and recursive neural networks (Socher et al., 2013). However, the above methods can only generate multimodal vectors of those words that have perceptual information, thus reducing multimodal vocabulary drastically.

An empirically superior model addresses this problem by predicting missing perceptual information firstly. This includes Hill et al. (2014) who utilize the ridge regression method to learn a mapping matrix from textual modality to visual modality, and Collell et al. (2017) who employ a feed-forward neural network to learn the mapping relation between textual vectors and visual vectors. Applying the mapping function on textual representations, they obtain the predicted visual vectors for all words in textual vocabulary. Then they calculate multimodal representations by concatenating textual and predicted visual vectors. However, the above methods learn separate mapping functions and fusion models, which are somewhat inelegant. In this paper we employ a neural-network mapping function to integrate these two processes into a unified multimodal models.

According to this classification, our method falls into the second group. However, existing models ignore either the associative relations among modalities, associative relations among relative words, or the different contributions of each modality. This paper aims to integrate more perceptual information and the human-like associative memory into a unified multimodal model to learn better word representations.

3 Associative Multichannel Autoencoder

We first provide a brief description of the basic multichannel autoencoder for learning multimodal word representations (Figure 1). Then we extend the model with two associative memory modules and a gating mechanism (Figure 2) in the next sections.

3.1 Basic Mutichannel Autoencoder

An autoencoder is an unsupervised neural network which is trained to reconstruct a given input from its latent representation (Bengio, 2009). In this work, we propose a variant of autoencoder called multichannel autoencoder, which maps multimodal inputs into a common space.

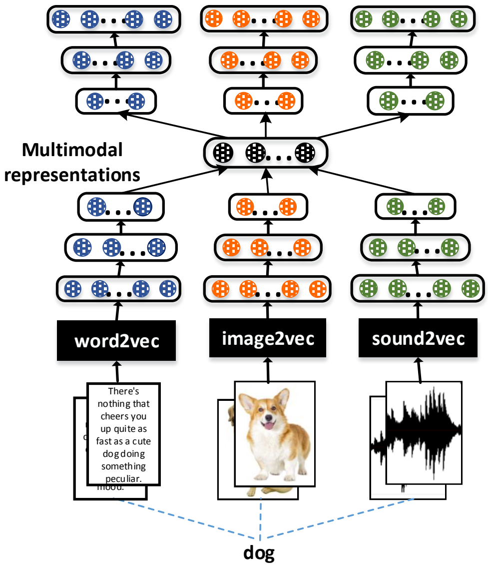

Figure 1: Architecture of the multichannel autoencoder with inputs of textual, visual and auditory sources.

Our model extends the unimodal and bimodal autoencoder (Ngiam et al., 2011; Silberer and Lapata, 2014) to induce semantic representations integrating textual, visual and auditory information. As shown in Figure 1, our model first transforms input textual vector x_t, visual vector x_v and auditory vector x_a to hidden representations:

$$\begin{aligned} h_t &= g(W_t x_t + b_t) \\ h_v &= g(W_v x_v + b_v) \\ h_a &= g(W_a x_a + b_a). \end{aligned} \tag{1}$$

Then the hidden representations are concatenated together and mapped to a common space:

$$h_m = g(W_m[h_t; h_v; h_a] + b_m). \tag{2}$$

The model is trained to reconstruct the hidden representations of the three modalities from the multimodal representation h_m:

$$[\hat{h}_t; \hat{h}_v; \hat{h}_a] = g(W'_m h_m + b_{\hat{m}}), \tag{3}$$

and finally to reconstruct the original embeddings of textual, visual and auditory inputs:

$$\begin{aligned} \hat{x}_t &= g(W'_t \hat{h}_t + b_{\hat{t}}) \\ \hat{x}_v &= g(W'_v \hat{h}_v + b_{\hat{v}}) \\ \hat{x}_a &= g(W'_a \hat{h}_a + b_{\hat{a}}), \end{aligned} \tag{4}$$

where $\hat{x}_t$, $\hat{x}_v$, $\hat{x}_a$ are the reconstruction of input vectors x_t, x_v, x_a, and $\hat{h}_t$, $\hat{h}_v$, $\hat{h}_a$

are the reconstruction of hidden representations h_t, h_v, h_a. The learning parameters $\{W_t, W_v, W_a, W_t', W_v', W_a', W_m, W_m'\}$ are weight matrices, $\{b_t, b_v, b_a, b_{\hat{t}}, b_{\hat{v}}, b_{\hat{a}}, b_m, b_{\hat{m}}\}$ are bias vectors. Here $[\cdot\,;\,\cdot]$ denotes the vector concatenation, and g denotes the non-linear function which we use $tanh(\cdot)$.

Training a single-layer autoencoder corresponds to optimizing the learning parameters to minimize the overall loss between inputs and their reconstructions. Following (Vincent et al., 2010), we use squared loss:

$$\min_{\theta_1} \sum_{i=1}^{n} (||x_t^i - \hat{x}_t^i||^2 + ||x_v^i - \hat{x}_v^i||^2 + ||x_a^i - \hat{x}_a^i||^2), \tag{5}$$

where i denotes the i^{th} word, and the model parameters are $\theta_1 = \{W_t, W_v, W_a, W_m, W_t', W_v', W_a', W_m', b_t, b_v, b_a, b_m, b_{\hat{t}}, b_{\hat{v}}, b_{\hat{a}}, b_{\hat{m}}\}$.

Autoencoders can be stacked to create deep networks. To enhance the quality of semantic representations, we employ a stacked multichannel autoencoder, which is composed of multiple hidden layers that are stacked together.

3.2 Integrating Modality Associations

In reality, the words that have corresponding images or sounds are only a small subset of the textual vocabulary. To obtain the perceptual vectors for each word, we need associations between modalities (i.e., text-to-vision and text-to-audition mapping functions), that transform the textual vectors into visual and auditory ones. Previous methods learn separate mapping functions and fusion models, which are somewhat inelegant. Here we employ a neural-network mapping function to incorporate this modality association module into multimodal models.

Take text-to-vision mapping as an example. Suppose that $T \in \mathbb{R}^{m_t \times n_t}$ is the textual representation containing m_t words, $V \in \mathbb{R}^{m_v \times n_v}$ is the visual representation containing m_v ($\ll m_t$) words, where n_t and n_v are dimensions of the textual and visual representations respectively. The textual and visual representations of the i^{th} concept are denoted as T_i and V_i respectively. Our goal is to learn a mapping function $f : g(W_p T + b_p)$ from textual to visual space such that the prediction $f(T_i)$ is similar to the actual visual vector V_i. The set of visual representations along with their corresponding textual representations are used to learn the mapping function. To train the model, we employ a square loss:

$$\min_{\theta_2} \sum_{i=1}^{m_v} ||f(T_i) - V_i||^2, \tag{6}$$

where the training parameters are $\theta_2 = \{W_p, b_p\}$. We adopt the same method to learn the text-to-audition mapping function.

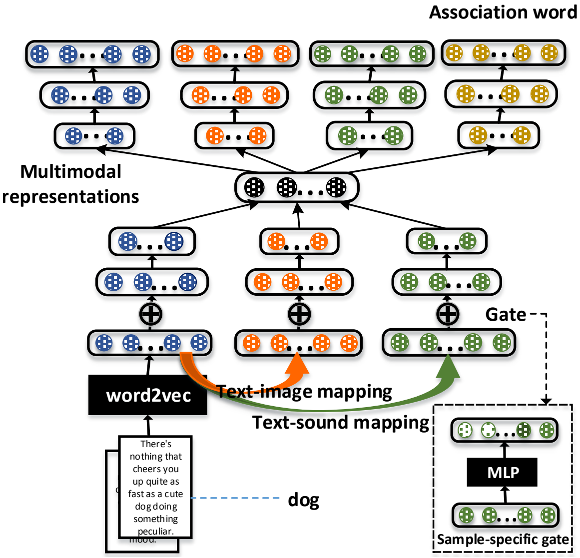

Figure 2: Architecture of the proposed associative multichannel autoencoder.

3.3 Integrating Word Associations

Word associations are a proxy for an aspect of human semantic memory that is not sufficiently captured by the usual training objectives of multimodal models. Therefore we assume that incorporating the objective of word associations helps to learn better semantic representations. To achieve this, we propose to reconstruct the vector of associated word from the corresponding multimodal semantic representation. Specifically, in the decoding process we change the equation (3) to:

$$[\hat{h}_t, \hat{h}_v, \hat{h}_a, \hat{h}_{asc}] = g(W_m' h_m + b_{\hat{m}}), \tag{7}$$

and equation (4) to:

$$\begin{aligned} \hat{x}_t &= g(W_t' \hat{h}_t + b_{\hat{t}}) \\ \hat{x}_v &= g(W_v' \hat{h}_v + b_{\hat{v}}) \\ \hat{x}_a &= g(W_a' \hat{h}_a + b_{\hat{a}}) \\ \hat{x}_{asc} &= g(W_{asc} \hat{h}_{asc} + b_{asc}). \end{aligned} \tag{8}$$

To train the model, we add an additional objective function, which is the mean square error between the embeddings of the associated word y and their re-constructive embeddings $\hat{x}_{asc}$:

$$\min_{\theta_3} \sum_{i=1}^{n} ||y^i - \hat{x}^i_{asc}||^2, \tag{9}$$

where y^i and x^i are the embeddings of a pair of associated words. Here, y is the concatenation of three unimodal vectors $[y_t; y_v; y_a]$. The parameters of word association module are $\theta_3 = \{W_t, W_v, W_a, W_m, \hat{W}_m, W_{asc}, b_t, b_v, b_a, b_m, b_{\hat{m}}, b_{asc}\}$. This additional criterion drives the learning towards a semantic representation capable of reconstructing its associated representation.

3.4 Integrating a Gating Mechanism

Considering that the meaning of each word has different dependencies on textual and perceptual information, we propose the sample-specific gate to assign different weights to each modality according to different words. The weight parameters are calculated by the following feed-forward neural networks:

$$\begin{aligned} g_t &= g(W_{gt}x_t + b_{gt}) \\ g_v &= g(W_{gv}x_v + b_{gv}) \\ g_a &= g(W_{ga}x_a + b_{ga}), \end{aligned} \tag{10}$$

where g_t, g_v and g_a are value or vector gate of textual, visual and auditory representations respectively. For the value gate, W_{gt}, W_{gv} and W_{ga} are vectors, and b_{gt}, b_{gv} and b_{ga} are value parameters. For the vector gate, the parameters W_{gt}, W_{gv} and W_{ga} are matrices, b_{gt}, b_{gv} and b_{ga} are vectors. The value gate controls the importance weights of different input representations as a whole, whereas the vector gate can adjust the importance weights of each dimension of input representations.

Finally, we compute element-wise multiplication of the textual, visual and auditory representations with their corresponding gates:

$$\begin{aligned} x_{gt} &= x_t \odot g_t \\ x_{gv} &= x_v \odot g_v \\ x_{ga} &= x_a \odot g_a. \end{aligned} \tag{11}$$

The x_{gt}, x_{gv} and x_{ga} can be seen as the weighted textual, visual and auditory representations. The parameters of our gating mechanism is trained together with that of the proposed model.

3.5 Model Training

To train the AMA model, we use overall objective function of equation $(5) + (6) + (9)$. In the training phase, model inputs are textual vectors, the corresponding visual vectors, auditory vectors, and association words (Figure 2). In the testing phase, we only need textual inputs to generate multimodal word representations.

4 Experimental Setup

4.1 Datasets

Textual vectors. We use 300-dimensional GloVe vectors[1] which are trained on the Common Crawl corpus consisting of 840B tokens and a vocabulary of 2.2M words[2].

Visual vectors. Our source of visual vectors are collected from ImageNet (Russakovsky et al., 2015) which covers a total of 21,841 WordNet synsets (Fellbaum, 1998) that have 14,197,122 images. For our experiments, we delete words with fewer than 50 images or words not in the Glove vectors, and sample at most 100 images for each word. To generate a visual vector for each word, we use the forward pass of a pre-trained VGG-net model[3] and extract the hidden representation of the last layer as the feature vector. Then we use averaged feature vectors of the multiple images corresponding to the same word. Finally, we get 8,048 visual vectors of 128 dimensions.

Auditory vectors. For auditory data, we gather audio files from Freesound[4], in which we select words with more than 10 audio files and sample at most 50 sounds for one word. To extract auditory features, we use the VGG-net model which is pre-trained on Audioset[5]. The final auditory vectors are averaged feature vectors of multiple audios of the same word, which contains 9,988 words of 128 dimensions[6].

Word associations. We use the word association data collected by (De Deyne et al., 2016), in which each word pair is generated by at least

[5] `https://research.google.com/audioset`

[6] We build auditory vectors with the released code at: `https://github.com/tensorflow/models/tree/master/research/audioset`

one subject[7]. This dataset includes mostly words with similar meaning (e.g., occasionally & sometimes, adored & loved, supervisor & boss) and related words (e.g., eruption & volcano, cortex & brain, umbrella & rain). We calculate the association score for each word pair (cue word + target word) as: *the number of person who generated the word pair divided by the total number of people who were presented with the cue word.* For training, we select pairs of associated words above a threshold of 0.15 and delete those that are not in the Glove vocabulary, which results in 7,674 word association data sets[8]. For the development set, we randomly sample 5,000 word association collections together with their association scores.

4.2 Model Settings

Our models are implemented with PyTorch (Paszke et al., 2017), optimized with Adam (Kingma and Ba, 2014). We set the initial learning rate to 0.05, and batch size to 64. We tune the number of layers over 1, 2, 3, the size of multimodal vectors over 100, 200, 300, and the size of each layer in textual channel over 300, 250, 200, 150, 100 and in visual/auditory channel over 128, 120, 90, 60. We train the model for 500 epochs and select the best parameters on the development set. All models are trained for 3 times and the average results are reported in Table 1.

To test the effect of each module, we separately train the following models: multichannel autoencoder with modality association (AMA-M), with modality and word associations (AMA-MW), with modality and word associations plus value/vector gate (AMA-MW-Gval/vec).

For AMA-M model, we initialize the text-to-vision and text-to-audition mapping functions with pre-trained mapping matrices, which are parameters of one-layer feed-forward neural networks. The network uses input of the textual vectors, output of visual or auditory vectors, and is trained with SGD for 100 epochs. We initialize the network biases as zeros and network weights with He-initialisation (He et al., 2015). The best parameters of AMA-M model are 2 hidden layers, with textual channel size of 300, 250 and 150, visual/auditory channel size of 128, 90, 60. For AMA-MW model, we use the best AMA-M model parameters as initialization, and train the model with word association data. The optimal parameter of association channel size is 300, 350, 556 (or 428 for bimodal inputs). For AMA-MW-Gval and AMA-MW-Gvec, we adopt the same training strategy as AMA-MW model. The code for training and evaluation can be found at: `https://github.com/wangshaonan/Associative-multichannel-autoencoder`.

5 Experiments

5.1 Evaluation Tasks

We test the baseline and proposed models on six standard evaluation benchmarks, covering two different tasks: (i) Semantic relatedness: Men-3000 (Bruni et al., 2014) and Wordrel-252 (Agirre et al., 2009); (ii) Semantic similarity: Simlex-999 (Hill et al., 2016), Semsim-7576 (Silberer and Lapata, 2014), Wordsim-203 and Simverb-3500 (Gerz et al., 2016). All test sets contain a list of word pairs along with their subject ratings.

We employ Spearman's correlation method to evaluate the performance of our models. This method calculates the correlation coefficients between model predictions and subject ratings, in which the model prediction is the cosine similarity between semantic representations of two words.

5.2 Baseline Multimodal Models

Most of existing multimodal models only utilize textual and visual modalities. For fair comparison, we re-implement several representative systems with our own textual and visual vectors. The **Concatenation (CONC) model** (Kiela and Bottou, 2014) is simple concatenation of normalized textual and visual vectors. The **Mapping** (Collell et al., 2017) and **Ridge** (Hill et al., 2014) models first learn a mapping matrix from textual to visual modality using feed-forward neural network and ridge regression respectively. After applying the mapping function on the textual vectors, they obtain the predicted visual vectors for all words in textual vocabulary. Then they concatenate the normalized textual and predicted visual vectors to get multimodal word representations. The **SVD** (Bruni et al., 2014) and **CCA** (Hill et al., 2014) models first concatenate normalized textual and visual vectors, and then conduct SVD or CCA transformations on the concatenated vectors.

For multimodal models with textual, visual and

---

[7] The dataset can be found at: `https://simondedeyne.me/data`.

[8] We have done experiments with Synonyms (which are extracted from WordNet and PPDB corpora), and the results are not as good as using word associations.

Table 1: Spearman's correlations between model predictions and human ratings on six evaluation datasets. Here T, V, A denote textual, visual and auditory. TV denotes bimodal inputs of textual and visual. TVA denotes trimodal inputs of textual, visual and auditory. The bold scores are the best results per column in bimodal models and trimodal models respectively. For each test, ALL corresponds to the whole testing set, V/A to those word pairs for which we have textual&visual vectors in bimodal models or textual&visual&auditory in trimodal models, and ZS (zero-shot) denotes word pairs for which we have only textual vectors. The #inst. denotes the number of word pairs.

auditory inputs, we implement **CONC** and **Ridge** as baseline models. The trimodal CONC model simply concatenates normalized textual, visual and auditory vectors. The trimodal Ridge model first learns text-to-vision and text-to-audition mapping matrices with ridge regression method. Then it applies the mapping functions on the textual vectors to get the predicted visual and auditory vectors. Finally, the normalized textual, predicted-visual and predicted-auditory vectors are concatenated to get the multimodal representations.

All above baseline models are implemented with Sklearn[9]. Same as the proposed AMA model, the hyper-parameters of baseline models are tuned on the development set using Spearman's correlation method. In Ridge model, the optimal regularization parameter is 0.6. The Mapping model is trained with SGD for maximum 100 epochs with early stopping, and the optimal learning rate is 0.001. The output dimension of SVD and CCA models are 300.

5.3 Results and Discussion

As shown in Table 1, we divide all models into six groups: (1) existing multimodal models (with textual and visual inputs) in which results are reprinted from Collell et al. (2017). (2) Unimodal models with textual, (predicted) visual or (pre-

---

[9] `http://scikit-learn.org/`

dicted) auditory inputs. (3) Our re-implementation of baseline bimodal models with textual and visual inputs (TV). (4) Our AMA models with textual and visual inputs. (5) Our implementation of trimodal baseline models with textual, visual and auditory inputs (TVA). (6) Our AMA model with textual, visual and auditory inputs.

Overall performance Our AMA models (in group 4 and 6) clearly outperform their baseline unimodal and multimodal models (in group 2, 3 and 5). We use Wilcoxon signed-rank test to check if significant difference exists between two models. Results show that our multimodal models perform significantly better ($p < 0.05$) than all baseline models.

As shown clearly, our bimodal and trimodal AMA models achieve better performance than baselines in both V/A (visual or auditory, the testing data that have associated visual or auditory vectors) and ZS (zero-shot, the testing data that do not have associated visual or auditory vectors) region. In other words, our models outperform baseline models on words with or without perceptual information. The good results in ZS region also indicate that our models have good generalization capacity.

Unimodal baselines As shown in group 2, the Glove vectors are much better than CNN-visual and CNN-auditory vectors, in which CNN-auditory has the worst performance on capturing concept similarities. Comparing with visual and auditory vectors, the predicted visual and auditory vectors achieve much better performance. This indicates that the predicted vectors contain richer information than purely perceptual representations and are more useful for building semantic representations.

Multimodal baselines For bimodal models (group 3), the CONC model that combines Glove and visual vectors performs worse than Glove on four out of six datasets, suggesting that simple concatenation might be suboptimal. The Mapping and Ridge models, which combine Glove and predicted visual vectors, improve over Glove on five out of six datasets in ALL regions. This reinforces the conclusion that the predicted visual vectors are more useful in building multimodal models. The SVD model gets similar results as Ridge model. The CCA model maps different modality inputs into a common space, achieving better results on some datasets and worse results on the others. The improvement on three benchmark tests shows the potential of mapping multimodal inputs into a common space.

The above results can also be observed in the trimodal CONC and Ridge models (group 5). Overall, the trimodal models, which utilize additional auditory inputs, get slightly worse performance than bimodal models. This is partly caused by the fusion method of concatenation. Note that our proposed AMA models are more effective with trimodal inputs as shown in group 6.

Our multimodal models With either bimodal or trimodal inputs, the proposed AMA-M model outperforms all baseline models by a large margin. Specifically our AMA-M model achieves an relative improvement of 4.1% on average (4.5% with trimodal inputs) over the state-of-the-art Ridge model. This illustrates that our AMA models can productively combine textual and perceptual representations. Moreover, our AMA-MW model, which employs word associations, achieves an average improvement of 1.5% (2.7% with trimodal inputs) over the AMA-M model. That is to say, the representation ability of multimodal models can be clearly improved by learning associative relations between words. Furthermore, the AMA-MW-Gval model improves the AMA-MW model by 1.3% (0.3% with trimodal inputs) on average, illustrating that the gating mechanism (especially the value gate) helps to learn better semantic representations.

In addition, we explore the effect of word association data size. We find that the decrease of association data has no discernible effect on model performance: when using 100%, 80%, 60%, 40%, 20% of the data, the average results are 0.6479, 0.6409, 0.6361, 0.6430, 0.6458 in bimodal model. The same trend is observed in trimodal models.

6 Conclusions and Future Work

We have proposed a cognitively-inspired multimodal model — associative multichannel autoencoder — which utilizes the associations between modalities and related words to learn multimodal word representations. Performance improvement on six benchmark tests shows that our models can efficiently fuse different modality inputs and build better semantic representations.

Ultimately, the present paper sheds light on the fundamental questions of how to learn word meanings, such as the plausibility of reconstructing perceptual information, associating related concepts and grounding word symbols to external environment. We believe that one of the promising future directions is to learn from how humans learn and store semantic word representations to build a more effective computational model.

Game-Based Video-Context Dialogue

Ramakanth Pasunuru and **Mohit Bansal**
UNC Chapel Hill
{ram, mbansal}@cs.unc.edu

Abstract

Current dialogue systems focus more on textual and speech context knowledge and are usually based on two speakers. Some recent work has investigated static image-based dialogue. However, several real-world human interactions also involve dynamic visual context (similar to videos) as well as dialogue exchanges among multiple speakers. To move closer towards such multimodal conversational skills and visually-situated applications, we introduce a new video-context, many-speaker dialogue dataset based on live-broadcast soccer game videos and chats from Twitch.tv. This challenging testbed allows us to develop visually-grounded dialogue models that should generate relevant temporal and spatial event language from the live video, while also being relevant to the chat history. For strong baselines, we also present several discriminative and generative models, e.g., based on tridirectional attention flow (TriDAF). We evaluate these models via retrieval ranking-recall, automatic phrase-matching metrics, as well as human evaluation studies. We also present dataset analyses, model ablations, and visualizations to understand the contribution of different modalities and model components.

1 Introduction

Dialogue systems or conversational agents which are able to hold natural, relevant, and coherent interactions with humans have been a long-standing goal of artificial intelligence and machine learning. There has been a lot of important previous work in this field for decades (Weizenbaum, 1966; Isbell et al., 2000; Rambow et al., 2001; Rieser et al., 2005; Georgila et al., 2006; Rieser and Lemon, 2008; Ritter et al., 2011), including recent work on introduction of large textual-dialogue datasets (e.g., Lowe et al. (2015); Serban et al. (2016)) and end-to-end neural network based models (Sordoni et al., 2015; Vinyals and Le, 2015; Su et al., 2016; Luan et al., 2016; Li et al., 2016; Serban et al., 2017a,b).

Figure 1: Sample example from our many-speaker, video-context dialogue dataset, based on live soccer game chat. The task is to predict the response (bottom-right) using the video context (left) and the chat context (top-right).

Current dialogue tasks are usually focused on the textual or verbal context (conversation history). In terms of multimodal dialogue, speech-based spoken dialogue systems have been widely explored (Eckert et al., 1997; Singh et al., 2000; Young, 2000; Janin et al., 2003; Celikyilmaz et al., 2017; Wen et al., 2015; Su et al., 2016; Mrkšić et al., 2016), as well as work on gesture and haptics based dialogue (Johnston et al., 2002; Cassell, 1999; Foster et al., 2008). In order to address the additional advantage of using visually-grounded context knowledge in dialogue, recent work introduced the visual dialogue task (Das et al., 2017; de Vries et al., 2017; Mostafazadeh et al., 2017). However, the visual context in these tasks is lim-

Brussels, Belgium, October 31 - November 4, 2018.

ited to one static image. Moreover, the interactions are between two speakers with fixed roles (one asks questions and the other answers).

Several situations of real-world dialogue among humans involve more 'dynamic' visual context, i.e., video-style information of the world moving around us (both spatially and temporally). Further, several human conversations involve more than two speakers, with changing roles. In order to develop such dynamically-visual multimodal dialogue models, we introduce a new 'many-speaker, video-context chat' testbed, along with a new dataset and models for the same. Our dataset is based on live-broadcast soccer (FIFA-18) game videos from the 'Twitch.tv' live video streaming platform, along with the spontaneous, many-speaker live chats about the game. This challenging testbed allows us to develop dialogue models where the generated response is required to be relevant to the temporal and spatial events in the live video, as well as be relevant to the chat history (with potential impact towards video-grounded applications such as personal assistants, intelligent tutors, and human-robot collaboration).

We also present several strong discriminative and generative baselines that learn to retrieve and generate bimodal-relevant responses. We first present a triple-encoder discriminative model to encode the video, chat history, and response, and then classify the relevance label of the response. We then improve over this model via tridirectional attention flow (TriDAF). For the generative models, we model bidirectional attention flow between the video and textual chat context encoders, which then decodes the response. We evaluate these models via retrieval ranking-recall, phrase-matching metrics, as well as human evaluation studies. We also present dataset analysis as well as model ablations and attention visualizations to understand the contribution of the video vs. chat modalities and the model components.

2 Related Work

Early dialogue systems had components of natural language (NL) understanding unit, dialogue manager, and NL generation unit (Bates, 1995). Statistical learning methods were used for automatic feature extraction (Dowding et al., 1993; Mikolov et al., 2013), dialogue managers incorporated reward-driven reinforcement learning (Young et al., 2013; Shah et al., 2016), and the generation units have been extended with seq2seq neural network models (Vinyals and Le, 2015; Serban et al., 2016; Luan et al., 2016).

In addition to the focus on textual dialogue context, using multimodal context brings more potential for having real-world grounded conversations. For example, spoken dialogue systems have been widely explored (Singh et al., 2000; Gurevych and Strube, 2004; Georgila et al., 2006; Eckert et al., 1997; Young, 2000; Janin et al., 2003; De Mori, 2007; Wen et al., 2015; Su et al., 2016; Mrkšić et al., 2016; Hori et al., 2016; Celikyilmaz et al., 2015, 2017), as well as gesture and haptics based dialogue (Johnston et al., 2002; Cassell, 1999; Foster et al., 2008). Additionally, dialogue systems for digital personal assistants are also well explored (Myers et al., 2007; Sarikaya et al., 2016; Damacharla et al., 2018). In the visual modality direction, some important recent attempts have been made to use static image based context in dialogue systems (Das et al., 2017; de Vries et al., 2017; Mostafazadeh et al., 2017), who proposed the 'visual dialog' task, where the human can ask questions on a static image, and an agent interacts by answering these questions based on the previous chat context and the image's visual features. Also, Celikyilmaz et al. (2014) used visual display information for on-screen item resolution in utterances for improving personal digital assistants.

In contrast, we propose to employ dynamic video-based information as visual context knowledge in dialogue models, so as to move towards video-grounded intelligent assistant applications. In the video+language direction, previous work has looked at video captioning (Venugopalan et al., 2015) as well as Q&A and fill-in-the-blank tasks on videos (Tapaswi et al., 2016; Jang et al., 2017; Maharaj et al., 2017) and interactive 3D environments (Das et al., 2018; Yan et al., 2018; Gordon et al., 2017; Anderson et al., 2017). There has also been early related work on generating sportscast commentaries from simulation (RoboCup) soccer videos represented as non-visual state information (Chen and Mooney, 2008). Also, Liu et al. (2016a) presented some initial ideas on robots learning grounded task representations by watching and interacting with humans performing the task (i.e., by converting human demonstration videos to Causal And-Or graphs). On the other hand, we propose a new video-chat dataset where the

Figure 2: Sample page of live broadcast of FIFA-18 game on twitch.tv with concurrent user chat.

dialogue models need to generate the next response in the sequence of chats, conditioned both on the raw video features as well as the previous textual chat history. Moreover, our new dataset presents a many-speaker conversation setting, similar to previous work on meeting understanding and Computer Supported Cooperative Work (CSCW) (Janin et al., 2003; Waibel et al., 2001; Schmidt and Bannon, 1992). In the live video stream direction, Fu et al. (2017) and Ping and Chen (2017) used real-time comments to predict the frame highlights in a video, and Barbieri et al. (2017) presented emotes and troll prediction.

3 Twitch-FIFA Dataset

3.1 Dataset Collection and Processing

For our new video-context dialogue task, we used the publicly accessible Twitch.tv live broadcast platform, and collected videos of soccer (FIFA-18) games along with the users' live chat conversations about the game. This dataset has videos involving various realistic human actions and events in a complex sports environment and hence serves as a good testbed and first step towards multimodal video-based dialogue data. An example is shown in Fig. 1 (and an original screenshot example in Fig. 2), where the users perform a complex 'many-speaker', 'multimodal' dialogue. Overall, we collected 49 FIFA-18 game videos along with their users' chat, and divided them into 33 videos for training, 8 videos for validation, and 8 videos for testing. Each such video is several hours long, providing a good amount of data (Table 2).

To extract triples (instances) of video context, chat context, and response from this data, we divide these videos based on the fixed time frames instead of fixed number of utterances in order to maintain conversation topic clusters (because of the sparse nature of chat utterances count over the time). First, we use 20-sec context windows to extract the video clips and users utterances in this time frame, and use it as our video and chat contexts, resp. Next, the chat utterances in the immediately-following 10-sec window (response window) that do not overlap with the next instance's context window are considered as potential responses.[1] Hence, there are only two instances (triples) in a 60-sec long video, i.e., 20-sec video+chat context window and 10-sec response window, and there is no overlap between the instances. Now, out of these potential responses, to only allow the response that has at least some good coherence and relevance with the chat context's topic, we choose the first (earliest) response that has high similarity with some other utterance in this response window (using 0.5 BLEU-4 threshold, based on manual inspection).[2]

	Relevance to Video+Chat
filtered response wins	34%
1st response wins	3%
Non-distinguishable	63% (56 both-good, 7 both-bad)

Table 1: Human evaluation of our dataset, comparing our filtered responses versus the first response in the window (for relevance w.r.t. video and chat contexts).

Human Quality Evaluation of Data Filtering Process: To evaluate the quality of the responses that result from our filtering process described above, we performed an anonymous (randomly shuffled w/o identity) human comparison between the response selected by our filtering process vs. the first response from the response window without any filtering, based on relevance w.r.t. video and chat context. Table 1 presents the results on 100 sample size, showing that humans in a blind-test found 90% (34+56) of our filtered responses as valid responses, verifying that our response selection procedure is reasonable. Furthermore, out of these 90% valid responses, we found that 55% are chat-only relevant, 11% are video-only relevant, and 24% are both video+chat relevant.

In order to make the above procedure safe and to make the dataset more challenging, we also discourage frequent responses (top-20 most-frequent

---

[1] We use non-overlapping windows because: (1) the utterances are non-uniformly distributed in time and hence if we have a shifting window, sometimes a particular data instance/chunk becomes very sparse and contains almost zero utterances; (2) we do not want overlap between response of one window with the context of the next window, so as to avoid the encoder already having seen the response (as part of context) that the decoder needs to generate for the other window.

[2] Based on intuition that if multiple speakers are saying the same response in that 10-second window, then this response should be more meaningful/relevant w.r.t. chat context.

Statistics	Train	Val	Test
#Videos	33	8	8
Total Hours	58.4	11.9	15.4
Final Filtered #Instances	10,150	2,153	2,780
Avg. Chat Context Length	69.0	63.5	71.2
Avg. Response Length	6.5	6.5	6.1

Table 2: Twitch-FIFA dataset's chat statistics (lengths are defined in terms of number of words).

generic utterances) unless no other response satisfies the similarity condition, hence suppressing the frequent responses.[3] If we couldn't find any utterance based on the multi-response matching procedure described above, then we just consider the first utterance in the 10-second window as the response.[4] We also make sure that the chat context window has at least 4 utterances, otherwise we exclude that context window and also the corresponding response window from the dataset. After all this processing, our final resulting dataset contains $10,510$ samples in training, $2,153$ samples in validation, and $2,780$ samples in test.[5]

3.2 Dataset Analysis

Dataset Statistics Table 2 presents the full statistics on train, validation, and test sets of our Twitch-FIFA dataset, after the filtering process described in Sec. 3.1. As shown, the average chat context length in the dataset is around 68 words, and the average response length is 6.3 words.

Chat Context Size Fig. 3 presents the study of number of utterances in the chat context vs. the number of such training samples. As we limit the minimum number of utterances to 4, chat context with less than 4 utterances is not present in the dataset. From the Fig. 3, it is clear that as the number of utterances in the chat context increases, the number of such training samples decrease.

Frequent Words Fig. 4 presents the top-20 frequent words (excluding stop words) and their corresponding frequency in our Twitch-FIFA dataset. Most of these frequent words are related to soccer vocabulary. Also, some of these frequent words are twitch emotes (e.g. 'kappa', 'inceptionlove').

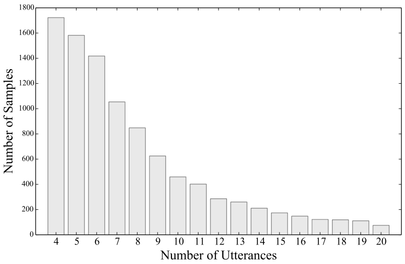

Figure 3: Distribution of #utterances in chat context (w.r.t. the #training examples for each case).

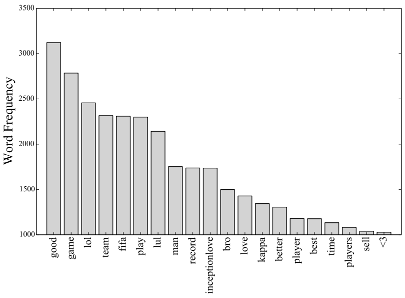

Figure 4: Frequent words in our Twitch-FIFA dataset.

4 Models

Let $v = \{v_1, v_2, .., v_m\}$ be the video context frames, $u = \{u_1, u_2, .., u_n\}$ be the textual chat (utterance) context tokens, and $r = \{r_1, r_2, .., r_k\}$ be response tokens generated (or retrieved).

4.1 Baselines

Our simple non-trained baselines are Most-Frequent-Response (re-rank the candidate responses based on their frequency in the training set), Chat-Response-Cosine (re-rank the candidate responses based on their similarity score w.r.t. the chat context), and Nearest-Neighbor (find the K-best similar chat contexts in the training set, take their corresponding responses, and then re-rank the candidate responses based on mean similarity score w.r.t. this K-best response set). For trained baselines, we use logistic regression and Naive Bayes methods. We use the final state of a Twitch-trained RNN Language Model to represent the chat context and response. Please see supplementary for full details.

4.2 Discriminative Models

4.2.1 Triple Encoder

For our simpler discriminative model, we use a 'triple encoder' to encode the video context, chat context, and response (see Fig. 5), as an extension of the dual encoder model in Lowe et al. (2015). The task here is to predict the given train-

---

[3] Note that this filtering suppresses the performance of simple frequent-response baseline described in Sec. 4.1.

[4] Other preprocessing steps include: omit the utterances in the response window which refer to a speaker name out of the current chat context; remove non-representative utterances, e.g., those with hyperlinks; replace (anonymize) all the user identities mentioned in the utterances with a common tag (i.e., anonymizing due to similar intuitions from the Q&A community (Hermann et al., 2015)).

[5] Note that this is substantially larger than or comparable to most current video captioning datasets. We plan to further extend our dataset based on diverse games and video types.

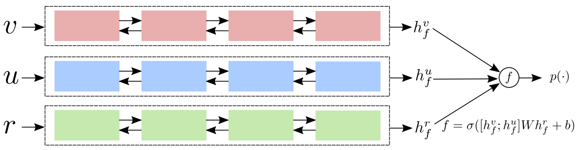

Figure 5: Overview of our 'triple encoder' discriminative model, with bidirectional-LSTM-RNN encoders for video, chat context, and response.

ing triple (v, u, r) as positive or negative. Let h_f^v, h_f^u, and h_f^r be the final state information of the video, chat, and response LSTM-RNN (bidirectional) encoders respectively; then the probability of a positive training triple is defined as follows:

$$p(v, u, r; \theta) = \sigma([h_f^v; h_f^u]^T W h_f^r + b) \qquad (1)$$

where W and b are trainable parameters. Here, W can be viewed as a similarity matrix which will bring the context $[h_f^v; h_f^u]$ into the same space as the response h_f^r, and get a suitable similarity score.

For optimizing our discriminative model, we use max-margin loss function similar to Mao et al. (2016) and Yu et al. (2017). Given a positive training triple (v, u, r), let the corresponding negative training triples be (v', u, r), (v, u', r), and (v, u, r'), i.e., one modality is wrong at a time in each of these three (see Sec. 5 for the negative example selection). The max-margin loss is:

$$\begin{aligned} L(\theta) = \sum [&\max(0, M + \log p(v', u, r) - \log p(v, u, r)) \\ &+ \max(0, M + \log p(v, u', r) - \log p(v, u, r)) \\ &+ \max(0, M + \log p(v, u, r') - \log p(v, u, r))] \end{aligned} \qquad (2)$$

where the summation is over all the training triples in the dataset. M is a tunable margin hyperparameter between positive and negative training triples.

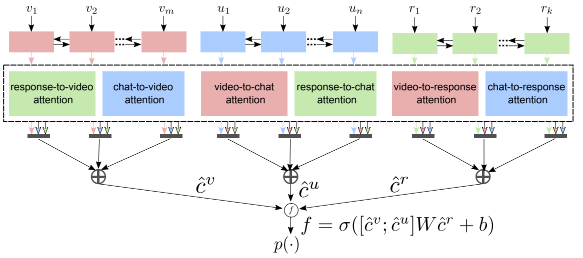

Figure 6: Overview of our tridirectional attention flow (TriDAF) model with all pairwise modality attention modules, as well as self-attention on video context, chat context, and response as inputs.

4.2.2 Tridirectional Attention Flow (TriDAF)

Our tridirectional attention flow model learns stronger joint spaces between the three modalities in a mutual-information way. We use bidirectional attention flow mechanisms (Seo et al., 2017) between the video and chat contexts, between the video context and the response, as well as between the chat context and the response, hence enabling attention flow across all three modalities, as shown in Fig. 6. We name this model Tridirectional Attention Flow or TriDAF. We will next discuss the bidirectional attention flow mechanism between video and chat contexts, but the same formulation holds true for bidirectional attention between video context and response, and between chat context and response. Given the video context hidden state h_i^v and chat context hidden state h_j^u at time steps i and j respectively, the bidirectional attention mechanism is based on the similarity score:

$$S_{i,j}^{(v,u)} = w_{S^{(v,u)}}^T [h_i^v; h_j^u; h_i^v \odot h_j^u] \qquad (3)$$

where $S_{i,j}^{(v,u)}$ is a scalar, $w_{S^{(v,u)}}$ is a trainable parameter, and $\odot$ denote element-wise multiplication. The attention distribution from chat context to video context is defined as $\alpha_{i:} = softmax(S_{i:})$, hence the chat-to-video context vector $c_i^{v \leftarrow u} = \sum_j \alpha_{i,j} h_j^u$. Similarly, the attention distribution from video context to chat context is defined as $\beta_{j:} = softmax(S_{:j})$, hence the video-to-chat context vector $c_j^{u \leftarrow v} = \sum_i \beta_{j,i} h_i^v$.

We then compute similar bidirectional attention flow mechanisms between the video context and response, and between the chat context and response. Then, we concatenate each hidden state and its corresponding context vector from other two modalities, e.g., $\hat{h}_i^v = [h_i^v; c_i^{v \leftarrow u}; c_i^{v \leftarrow r}]$ for the i^{th} timestep of the video context. Finally, we add self-attention mechanism (Lin et al., 2017) across the concatenated hidden states of each of the three modules.[6] If $\hat{h}_i^v$ is the final concatenated vector of the video context at time step i, then the self-attention weights α^s for this video context are the softmax of e^s:

$$e_i^s = V_a^v \tanh(W_a^v \hat{h}_i^v + b_a^v) \qquad (4)$$

where V_a^v, W_a^v, and b_a^v are trainable self-attention parameters. The final representation vector of the full video context after self-attention is $\hat{c}^v = \sum_i \alpha_i^s \hat{h}_i^v$. Similarly, the final representation vectors of the chat context and the response are $\hat{c}^u$ and $\hat{c}^r$, respectively. Finally, the probability that

---

[6] In our preliminary experiments, we found that adding self-attention is 0.92% better in recall@1 and faster than passing the hidden states through another layer of RNN, as done in Seo et al. (2017).

the given training triple (v, u, r) is positive is:

$$p(v, u, r; \theta) = \sigma([\hat{c}^v; \hat{c}^u]^T W \hat{c}^r + b) \quad (5)$$

Again, here also we use max-margin loss (Eqn. 2).

4.3 Generative Models

4.3.1 Seq2seq with Attention

Our simpler generative model is a sequence-to-sequence model with bilinear attention mechanism (similar to Luong et al. (2015)). We have two encoders, one for encoding the video context and another for encoding the chat context, as shown in Fig. 7. We combine the final state information from both encoders and give it as initial state to the response generation decoder. The two encoders and the decoder are all two-layer LSTM-RNNs. Let h_i^v and h_j^u be the hidden states of video and chat encoders at time step i and j respectively. At each time step t of the decoder with hidden state h_t^r, the decoder attends to parts of video and chat encoders and uses the combined information to generate the next token. Let α_t and β_t be the attention weight distributions for video and chat encoders respectively with video context vector $c_t^v = \sum_i \alpha_{t,i} h_i^v$ and chat context vector $c_t^u = \sum_j \beta_{t,j} h_j^u$. The attention distribution for video encoder is defined as (and the same holds for chat encoder):

$$e_{t,i} = h_t^{rT} W_a^v h_i^v; \quad \alpha_t = \text{softmax}(e_t) \quad (6)$$

where W_a^v is a trainable parameter. Next, we concatenate the attention-based context information (c_t^v and c_t^u) and decoder hidden state (h_t^r), and do a non-linear transformation to get the final hidden state $\hat{h}_t^r$ as follows:

$$\hat{h}_t^r = \tanh(W_c[c_t^v; c_t^u; h_t^r]) \quad (7)$$

where W_c is again a trainable parameter. Finally, we project the final hidden state information to vocabulary size and give it as input to a *softmax* layer to get the vocabulary distribution $p(r_t|r_{1:t-1}, v, u; \theta)$. During training, we minimize the cross-entropy loss defined as follows:

$$L_{\text{XE}}(\theta) = -\sum \sum_t \log p(r_t|r_{1:t-1}, v, u; \theta) \quad (8)$$

where the final summation is over all the training triples in the dataset.

Further, to train a stronger generative model with negative training examples (which teaches the model to give higher generative decoder probability to the positive response as compared to all the negative ones), we use a max-margin loss (similar to Eqn. 2 in Sec. 4.2.1):

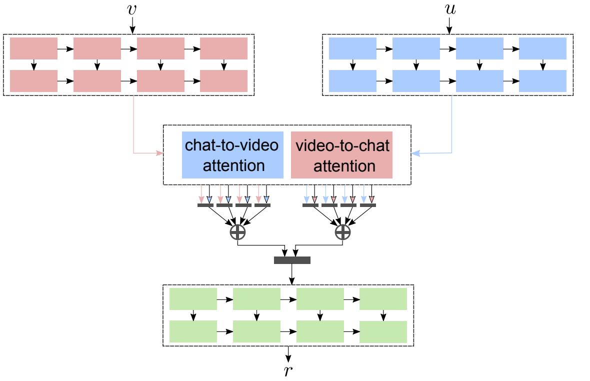

Figure 7: Overview of our generative model with bidirectional attention flow between video context and chat context during response generation.

$$\begin{aligned} L_{\text{MM}}(\theta) = \sum [&\max(0, M + \log p(r|v', u) - \log p(r|v, u)) \\ &+ \max(0, M + \log p(r|v, u') - \log p(r|v, u)) \\ &+ \max(0, M + \log p(r'|v, u) - \log p(r|v, u))] \end{aligned} \quad (9)$$

where the summation is over all the training triples in the dataset. Overall, the final joint loss function is a weighted combination of cross-entropy loss and max-margin loss: $L(\theta) = L_{\text{XE}}(\theta) + \lambda L_{\text{MM}}(\theta)$, where λ is a tunable hyperparameter.

4.3.2 Bidirectional Attention Flow (BiDAF)

The stronger version of our generative model extends the two-encoder-attention-decoder model above to add bidirectional attention flow (BiDAF) mechanism (Seo et al., 2017) between video and chat encoders, as shown in Fig. 7. Given the hidden states h_i^v and h_j^u of video and chat encoders at time step i and j, the final hidden states after the BiDAF are $\hat{h}_i^v = [h_i^v; c_i^{v \leftarrow u}]$ and $\hat{h}_j^u = [h_i^u; c_j^{u \leftarrow v}]$ (similar to as described in Sec. 4.2.2), respectively. Now, the decoder attends over these final hidden states, and the rest of the decoder process is similar to Sec 4.3.1 above, including the weighted joint cross-entropy and max-margin loss.

5 Experimental Setup

Evaluation We first evaluate both our discriminative and generative models using retrieval-based recall@k scores, which is a concrete metric for such dialogue generation tasks (Lowe et al., 2015). For our discriminative models, we simply rerank the given responses (in a candidate list of size 10, based on 9 negative examples; more details below)

Models	r@1	r@2	r@5
BASELINES			
Most-Frequent-Response	10.0	16.0	20.9
Naive Bayes	9.6	20.9	51.5
Logistic Regression	10.8	21.8	52.5
Nearest Neighbor	11.4	22.6	53.2
Chat-Response-Cosine	11.4	22.0	53.2
DISCRIMINATIVE MODEL			
Dual Encoder (C)	17.1	30.3	61.9
Dual Encoder (V)	16.3	30.5	61.1
Triple Encoder (C+V)	18.1	33.6	68.5
TriDAF+Self Attn (C+V)	20.7	35.3	69.4
GENERATIVE MODEL			
Seq2seq +Attn (C)	14.8	27.3	56.6
Seq2seq +Attn (V)	14.8	27.2	56.7
Seq2seq + Attn (C+V)	15.7	28.0	57.0
Seq2seq + Attn + BiDAF (C+V)	16.5	28.5	57.7

Table 3: Performance of our baselines, discriminative models, and generative models for recall@k metrics on our Twitch-FIFA test set. C and V represent chat and video context, respectively.

in the order of the probability score each response gets from the model. If the positive response is within the top-k list, then the recall@k score is 1, otherwise 0, following previous Ubuntu-dialogue work (Lowe et al., 2015). For the generative models, we follow a similar approach, but the reranking score for a candidate response is based on the log probability score given by the generative models' decoder for that response, following the setup of previous visual-dialog work (Das et al., 2017). In our experiments, we use recall@1, recall@2, and recall@5 scores. For completeness, we also report the phrase-matching metric scores: METEOR (Denkowski and Lavie, 2014) and ROUGE (Lin, 2004) for our generative models. We also present human evaluation.

Training Details For negative samples, during training, for every positive triple (video, chat, response) in the training set, we sample 3 random negative triples. For validation/test, we sample 9 random negative responses elsewhere from the validation/test set. Also, the negative samples don't come from the video corresponding to the positive response. More details of negative samples and other training details (e.g., dimension/vocab sizes, visual feature details, validation-based hyperparamater tuning and model selection), are discussed in the supplementary.

6 Results and Analysis

6.1 Human Evaluation of Dataset

First, the overall human quality evaluation of our dataset (shown in Table 1) demonstrates that it contains 90% responses relevant to video and/or chat context. Next, we also do a blind human study on the recall-based setup (on a set of 100 samples from the validation set), where we anonymize the positive response by randomly mixing it with 9 tricky negative responses in the retrieval list, and ask the user to select the most relevant response for the given video and/or chat context. We found that human performance on this task is around 55% recall@1, demonstrating that this 10-way-discriminative recall-based task setup is reasonably challenging for humans,[7] but also that there is a lot of scope for future model improvements because the chance baseline is only 10% and the best-performing model so far (see Sec. 6.3) achieves only 22% recall@1 (on dev set), and hence there is a large 33% gap.

6.2 Baseline Results

Table 3 displays all our primary results. We first discuss results of our simple non-trained and trained baselines (see Sec. 4.1). The 'Most-Frequent-Response' baseline, which just ranks the 10-sized response retrieval list based on their frequency in the training data, gets only around 10% recall@1.[8] Our other non-trained baselines: 'Chat-Response-Cosine' and 'Nearest Neighbor', which ranks the candidate responses based on (Twitch-trained RNN encoder's vector) cosine similarity with chat-context and K-best training contexts' response vectors, respectively, achieves slightly better scores. We also show that our simple trained baselines (logistic regression and nearest neighbor) also achieve relatively low scores, indicating that a simple, shallow model will not work on this challenging dataset.

6.3 Discriminative Model Results

Next, we present the recall@k retrieval performance of our various discriminative models in Ta-

---

[7] This relatively low human recall@1 performance is because this is a challenging, 10-way-discriminative evaluation, i.e., the choice comes w.r.t. 9 tricky negative examples along with just 1 positive example (hence chance-baseline is only 10%). Note that these negative examples are an artifact of specifically recall-based evaluation only, and will not affect the more important real-world task of response generation (for which our dataset's response quality is 90%, as shown in Table 1). Moreover, our dataset filtering (see Sec. 3.1) also 'suppresses' simple baselines and makes the task even harder.

[8] Note that the performance of this baseline is worse than the random choice baseline (recall@1:10%, recall@2:20%, recall@5:50%) because our dataset filtering process already suppresses frequent responses (see Sec. 3.1), in order to provide a challenging dataset for the community.

Models	METEOR	ROUGE-L
Multiple References		
Seq2seq + Atten. (C)	2.59	8.44
Seq2seq + Atten. (V)	2.66	8.34
Seq2seq + Atten. (C+V) $\otimes$	3.03	8.84
$\otimes$ + BiDAF (C+V)	3.70	9.82

Table 4: Performance of our generative models on phrase matching metrics.

Models	Relevance
Seq2seq + Atten. (C+V) wins	41.0 %
BiDAF wins	34.0 %
Non-distinguishable	25.0 %

Table 5: Human evaluation comparing the baseline and BiDAF generative models.

Models	recall@1	recall@2	recall@5
1 neg.	18.21	32.19	64.05
3 neg.	22.20	35.90	68.09

Table 6: Ablation (dev) of one vs. three negative examples for TriDAF self-attention discriminative model.

ble 3: dual encoder (chat context only), dual encoder (video context only), triple encoder, and TriDAF model with self-attention. Our dual encoder models are significantly better than random choice and all our simple baselines above, and further show that they have complementary information because using both of them together (in 'Triple Encoder') improves the overall performance of the model. Finally, we show that our novel TriDAF model with self-attention performs significantly better than the triple encoder model.[9]

6.4 Generative Model Results

Next, we evaluate the performance of our generative models with both retrieval-based recall@k scores and phrase matching-based metrics as discussed in Sec. 5 (as well as human evaluation). We first discuss the retrieval-based recall@k results in Table 3. Starting with a simple sequence-to-sequence attention model with video only, chat only, and both video and chat encoders, the recall@k scores are better than all the simple baselines. Moreover, using both video+chat context is again better than using only one context modality. Finally, we show that the addition of the bidirectional attention flow mechanism improves the performance in all recall@k scores.[10] Note that generative model scores are lower than the discriminative models on retrieval recall@k metric, which is expected (see discussion in previous visual dialogue work (Das et al., 2017)), because discriminative models can tune to the biases in the response candidate options, but generative models are more useful for real-world tasks such as generation of novel responses word-by-word from scratch in Siri/Alexa/Cortana style applications (whereas discriminative models can only rank the pre-given list of responses).

We also evaluate our generative models with phrase-level matching metrics: METEOR and ROUGE-L, as shown in Table 4. Again, our BiDAF model is stat. significantly better than non-BiDAF model on both METEOR ($p < 0.01$) and ROUGE-L ($p < 0.02$) metrics. Since dialogue systems can have several diverse, non-overlapping valid responses, we consider a multi-reference setup where all the utterances in the 10-sec response window are treated as valid responses.[11]

6.5 Human Evaluation of Models

Finally, we also perform human evaluation to compare our top two generative models, i.e., the video+chat seq2seq with attention and its extension with BiDAF (Sec. 4.3), based on a 100-sized sample. We take the generated response from both these models, and randomly shuffle these pairs to anonymize model identity. We then ask two annotators (for 50 task instances each) to score the responses of these two models based on relevance. Note that the human evaluators were familiar with Twitch FIFA-18 video games and also the Twitch's unique set of chat mannerisms and emotes. As shown in Table 5, our BiDAF based generative model performs better than the non-BiDAF one, which is already quite a strong video+chat encoder model with attention.

7 Ablations and Analysis

7.1 Negative Training Pairs

We also compare the effect of different negative training triples that we discussed in Sec. 5. Table 6 shows the comparison between one negative

---

[9] Statistical significance of $p < 0.01$ for recall@1, based on the bootstrap test (Noreen, 1989; Efron and Tibshirani, 1994) with 100K samples.

[10] Stat. signif. $p < 0.05$ for recall@1 w.r.t. Seq2seq+Atten (video+chat); $p < 0.01$ w.r.t. chat- and video-only models.

[11] Liu et al. (2016b) discussed that BLEU and most phrase matching metrics are not good for evaluating dialogue systems. Also, generative models have very low phrase-matching metric scores because the generated response can be valid but still very different from the ground truth reference (Lowe et al., 2015; Liu et al., 2016b; Li et al., 2016). We present results for the relatively better metrics like paraphrase-enabled METEOR for completeness, but still focus on retrieval recall@k and human evaluation.

training triple (with just a negative response) vs. three negative training triples (one with negative video context, one with negative chat context, and another with negative response), showing that using the 3-negative examples setup is substantially better.

7.2 Discriminative Loss Functions

Table 7 shows the performance comparison between the classification loss and max-margin loss on our TriDAF with self-attention discriminative model (Sec. 4.2.2). We observe that max-margin loss performs better than the classification loss, which is intuitive because max-margin loss tries to differentiate between positive and negative training example triples.

Models	recall@1	recall@2	recall@5
Classification loss	19.32	33.72	66.60
Max-margin loss	22.20	35.90	68.09

Table 7: Ablation of classification vs. max-margin loss on our TriDAF discriminative model (on dev set).

7.3 Generative Loss Functions

For our best generative model (BiDAF), Table 8 shows that using a joint loss of cross-entropy and max-margin is better than just using only cross-entropy loss optimization (Sec. 4.3.1). Max-margin loss provides knowledge about the negative samples for the generative model, hence improves the retrieval-based recall@k scores.

7.4 Attention Visualization and Examples

Finally, we show some interesting output examples from both our discriminative and generative models as shown in Fig. 8. Additionally, Fig. 9 visualizes that our models can learn some correct attention alignments from the generated output response word to the appropriate (goal-related) video frames as well as chat context words.

Models	recall@1	recall@2	recall@5
Cross-entropy (XE)	13.12	23.45	54.78
XE+Max-margin	15.61	27.39	57.02

Table 8: Ablation of cross-entropy loss vs. cross-entropy+maxmargin loss for our BiDAF-based generative model (on dev set).

8 Conclusion

We presented a new game-chat based video-context, many-speaker dialogue task and dataset. We also presented several baselines and state-of-the-art discriminative and generative models on this task. We hope that this testbed will be a good starting point to encourage future work on the challenging video-context dialogue paradigm. In future work, we plan to investigate the effects of multiple users, i.e., the multi-party aspect of this dataset. We also plan to explore advanced video features such as activity recognition, person identification, etc.

Abstract

The encode-decoder framework has shown recent success in image captioning. Visual attention, which is good at detailedness, and semantic attention, which is good at comprehensiveness, have been separately proposed to ground the caption on the image. In this paper, we propose the *S*tepwise *I*mage-Topic *M*erging *N*etwork (*simNet*) that makes use of the two kinds of attention at the same time. At each time step when generating the caption, the decoder adaptively merges the attentive information in the extracted topics and the image according to the generated context, so that the visual information and the semantic information can be effectively combined. The proposed approach is evaluated on two benchmark datasets and reaches the state-of-the-art performances.[1]

1 Introduction

Image captioning attracts considerable attention in both natural language processing and computer vision. The task aims to generate a description in natural language grounded on the input image. It is a very challenging yet interesting task. On the one hand, it has to identify the objects in the image, associate the objects, and express them in a fluent sentence, each of which is a difficult subtask. On the other hand, it combines two important fields in artificial intelligence, namely, natural language processing and computer vision. More importantly, it has a wide range of applications, including text-based image retrieval, helping visually impaired people see (Wu et al., 2017), human-robot interaction (Das et al., 2017), etc.

Soft-Attention: a open laptop computer sitting on top of a table
ATT-FCN: a dog sitting on a desk with a laptop computer and mouse
simNet: a open laptop computer and mouse sitting on a table with a dog nearby

Figure 1: Examples of using different attention mechanisms. Soft-Attention (Xu et al., 2015) is based on visual attention. The generated caption is **detailed** in that it knows the visual attributes well (e.g. *open*). However, it omits many objects (e.g. *mouse* and *dog*). ATT-FCN (You et al., 2016) is based on semantic attention. The generated caption is more **comprehensive** in that it includes more objects. However, it is bad at associating details with the objects (e.g. missing *open* and mislocating *dog*). simNet is our proposal that effectively merges the two kinds of attention and generates a detailed and comprehensive caption.

Models based on the encoder-decoder framework have shown success in image captioning. According to the pivot representation, they can be roughly categorized into models based on visual information (Vinyals et al., 2015; Chen and Zitnick, 2015; Mao et al., 2014; Karpathy and Li, 2015, 2017), and models based on conceptual information (Fang et al., 2015; You et al., 2016; Wu et al., 2016). The later explicitly provides the visual words (e.g. *dog*, *sit*, *red*) to the decoder instead of the image features, and is more effective in image captioning according to the evaluation on benchmark datasets. However, the models based on conceptual information have a major drawback that it is hard for the model to associate the details with the specific objects in the image, because the visual words are inherently unordered in semantics. Figure 1 shows an example. For semantic attention, although *open* is provided as a visual word, due to the insufficient use of visual information, the model gets confused about what objects *open* should be associated with and thus discards *open* in the caption. The model may even associate the details incorrectly, which is the case

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 137–149
Brussels, Belgium, October 31 - November 4, 2018.

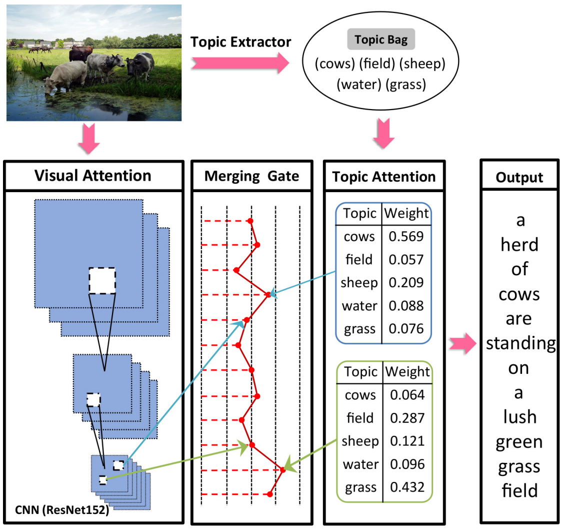

Figure 2: Illustration of the main idea. The visual information captured by CNN and the conceptual information in the extracted topics are first condensed by attention mechanisms respectively. The merging gate then adaptively adjusts the weight between the visual information and the conceptual information for generating the caption.

for the position of the dog. In contrast, models based on the visual information often are accurate in details but have difficulty in describing the image comprehensively and tend to only describe a subregion.

In this work, we get the best of both worlds and integrate visual attention and semantic attention for generating captions that are both detailed and comprehensive. We propose a **Stepwise Image-Topic Merging Network** as the decoder to guide the information flow between the image and the extracted topics. At each time step, the decoder first extracts focal information from the image. Then, it decides which topics are most probable for the time step. Finally, it attends differently to the visual information and the conceptual information to generate the output word. Hence, the model can efficiently merge the two kinds of information, leading to outstanding results in image captioning.

Overall, the main contributions of this work are:

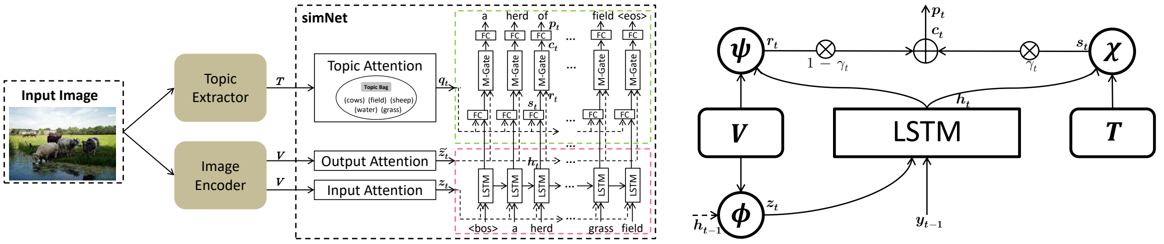
- We propose a novel approach that can effectively merge the information in the image and the topics to generate cohesive captions that are both detailed and comprehensive. We refine and combine two previous competing attention mechanisms, namely visual attention and semantic attention, with an importance-based merging gate that effectively combines and balances the two kinds of information.
- The proposed approach outperforms the state-of-the-art methods substantially on two benchmark datasets, Flickr30k and COCO, in terms of SPICE, which correlates the best with human judgments. Systematic analysis shows that the merging gate contributes the most to the overall improvement.

2 Related Work

A large number of systems have been proposed for image captioning. Neural models based on the encoder-decoder framework have been attracting increased attention in the last few years in several multi-discipline tasks, such as neural image/video captioning (NIC) and visual question answering (VQA) (Vinyals et al., 2015; Karpathy and Li, 2015; Venugopalan et al., 2015; Zhao et al., 2016; Zhang et al., 2017). State-of-the-art neural approaches (Anderson et al., 2018; Liu et al., 2018; Lu et al., 2018) incorporate the attention mechanism in machine translation (Bahdanau et al., 2014) to generate grounded image captions. Based on what they attend to, the models can be categorized into visual attention models and semantic attention models.

Visual attention models pay attention to the image features generated by CNNs. CNNs are typically pre-trained on the image recognition task to extract general visual signals (Xu et al., 2015; Chen et al., 2017; Lu et al., 2017). The visual attention is expected to find the most relevant image regions in generating the caption. Most recently, image features based on predicted bounding boxes are used (Anderson et al., 2018; Lu et al., 2018). The advantages are that the attention no longer needs to find the relevant generic regions by itself but instead find relevant bounding boxes that are object orientated and can serve as semantic guides. However, the drawback is that predicting bounding boxes is difficult, which requires large datasets (Krishna et al., 2017) and complex models (Ren et al., 2015, 2017a).

Semantic attention models pay attention to a predicted set of semantic concepts (Fang et al., 2015; You et al., 2016; Wu et al., 2016). The semantic concepts are the most frequent words in the captions, and the extractor can be trained using various methods but typically is only trained on the given image captioning dataset. This kind



(a) The overall framework.

(b) The data flow in the proposed simNet.

Figure 3: Illustration of the proposed approach. In the right plot, we use ϕ, ψ, χ to denote input attention, output attention, and topic attention, respectively.

of approach can be seen as the extension of the earlier template-based slotting-filling approaches (Farhadi et al., 2010; Kulkarni et al., 2013).

However, few work studies how to combine the two kinds of attention models to take advantage of both of them. On the one hand, due to the limited number of visual features, it is hard to provide comprehensive information to the decoder. On the other hand, the extracted semantic concepts are unordered, making it hard for the decoder to portray the details of the objects correctly.

This work focuses on combining the visual attention and the semantic attention efficiently to address their drawbacks and make use of their merits. The visual attention is designed to focus on the attributes and the relationships of the objects, while the semantic attention only includes words that are objects so that the extracted topics could be more accurate. The combination is controlled by the importance-based merging mechanism that decides at each time step which kind of information should be relied on. The goal is to generate image captions that are both detailed and comprehensive.

3 Approach

Our proposed model consists of an image encoder, a topic extractor, and a stepwise merging decoder. Figure 3 shows a sketch. We first briefly introduce the image encoder and the topic extractor. Then, we introduce the proposed stepwise image-topic merging decoder in detail.

3.1 Image Encoder

For an input image, the image encoder expresses the image as a series of visual feature vectors $\boldsymbol{V} = \{\boldsymbol{v}_1, \boldsymbol{v}_2, \ldots, \boldsymbol{v}_k\}, \boldsymbol{v}_i \in \mathbb{R}^g$. Each feature corresponds to a different perspective of the image. The visual features serve as descriptive guides of the objects in the image for the decoder. We use a ResNet152 (He et al., 2016), which is commonly used in image captioning, to generate the visual features. The output of the last convolutional layer is used as the visual information:

$$\boldsymbol{V} = \boldsymbol{W}^{V,I}\mathrm{CNN}(\boldsymbol{I}) \qquad (1)$$

where $\boldsymbol{I}$ is the input image, and $\boldsymbol{W}^{V,I}$ shrinks the last dimension of the output.[2]

3.2 Topic Extractor

Typically, identifying an object requires a combination of visual features, and considering the limited capacity of the visual features, it is hard for the conventional decoder to describe the objects in the image comprehensively. An advance in image captioning is to provide the decoder with the semantic concepts in the image directly so that the decoder is equipped with an overall perspective of the image. The semantic concepts can be objects (e.g. *person*, *car*), attributes (e.g. *off*, *electric*), and relationships (e.g. *using*, *sitting*). We only use the words that are objects in this work, the reason of which is explained later. We call such words **topics**. The topic extractor concludes a list of candidate topic embeddings $\boldsymbol{T} = \{\boldsymbol{w}_1, \boldsymbol{w}_2, \ldots, \boldsymbol{w}_m\}, \boldsymbol{w}_i \in \mathbb{R}^e$ from the image, where e is the dimension of the topic word embeddings. Following common practice (Fang et al., 2015; You et al., 2016), we adopt the weakly-supervised approach of Multiple Instance Learning (Zhang et al., 2006) to build a topic extractor. Due to limited space, please refer to Fang et al. (2015) for detailed explanation.

Different from existing work that uses all the most frequent words in the captions as valid semantic concepts or visual words, we only include the object words (nouns) in the topic word list. Existing work relies on attribute words and rela-

---

[2] For conciseness, all the bias terms of linear transformations in this paper are omitted.

tionship words to provide visual information to the decoder. However, it not only complicates the extracting procedure but also contributes little to the generation. For an image containing many objects, the decoder is likely to combine the attributes with the objects arbitrarily, as such words are specific to certain objects but are provided to the decoder unordered. In contrast, our model has visual information as additional input and we expect that the decoder should refer to the image for such kind of information instead of the extracted concepts.

3.3 Stepwise Image-Topic Merging Decoder

The essential component of the decoder is the proposed stepwise image-topic merging network. The decoder is based on an LSTM (Hochreiter and Schmidhuber, 1997). At each time step, it combines the textual caption, the attentive visual information, and the attentive conceptual information as the context for generating an output word. The goal is achieved by three modules, the visual attention, the topic attention, and the merging gate.

Visual Attention as Output The visual attention attends to attracting parts of the image based on the state of the LSTM decoder. In existing work (Xu et al., 2015), only the previous hidden state $\boldsymbol{h}_{t-1} \in \mathbb{R}^d$ of the LSTM is used in computation of the visual attention:

$$\boldsymbol{Z}_t = \tanh(\boldsymbol{W}^{Z,V}\boldsymbol{V} \oplus \boldsymbol{W}^{Z,h}\boldsymbol{h}_{t-1}) \tag{2}$$

$$\boldsymbol{\alpha}_t = \text{softmax}(\boldsymbol{Z}_t\boldsymbol{w}^{\alpha,Z}) \tag{3}$$

where $\boldsymbol{W}^{Z,V} \in \mathbb{R}^{k\times g}, \boldsymbol{W}^{Z,h} \in \mathbb{R}^{k\times d}, \boldsymbol{w}^{\alpha,Z} \in \mathbb{R}^k$ are the learnable parameters. We denote the matrix-vector addition as $\oplus$, which is calculated by adding the vector to each column of the matrix. $\boldsymbol{\alpha}_t \in \mathbb{R}^k$ is the attentive weights of $\boldsymbol{V}$ and the attentive visual input $\boldsymbol{z}_t \in \mathbb{R}^g$ is calculated as

$$\boldsymbol{z}_t = \boldsymbol{V}\boldsymbol{\alpha}_t \tag{4}$$

The visual input $\boldsymbol{z}_t$ and the embedding of the previous output word $\boldsymbol{y}_{t-1}$ are the input of the LSTM.

$$\boldsymbol{h}_t = \text{LSTM}(\begin{bmatrix}\boldsymbol{z}_t\\ \boldsymbol{y}_{t-1}\end{bmatrix}, \boldsymbol{h}_{t-1}) \tag{5}$$

However, there is a noticeable drawback that the previous output word y_{t-1}, which is a much stronger indicator than the previous hidden state $\boldsymbol{h}_{t-1}$, is not used in the attention. As $\boldsymbol{z}_t$ is used as the input, we call it **input attention**. To overcome that drawback, we add another attention that incorporates the current hidden state $\boldsymbol{h}_t$, which is based on the last generated word y_{t-1}:

$$\widetilde{\boldsymbol{Z}}_t = \tanh(\widetilde{\boldsymbol{W}}^{Z,V}\boldsymbol{V} \oplus \widetilde{\boldsymbol{W}}^{Z,h}\boldsymbol{h}_t) \tag{6}$$

$$\widetilde{\boldsymbol{\alpha}}_t = \text{softmax}(\widetilde{\boldsymbol{Z}}_t\widetilde{\boldsymbol{w}}^{\alpha,Z}) \tag{7}$$

$$\widetilde{\boldsymbol{z}}_t = \boldsymbol{V}\widetilde{\boldsymbol{\alpha}}_t \tag{8}$$

The procedure resembles the input attention, and we call it **output attention**. It is worth mentioning that the output attention is essentially the same with the spatial visual attention proposed by Lu et al. (2017). However, they did not see it from the input-output point of view nor combine it with the input attention.

The attentive visual output is further transformed to $\boldsymbol{r}_t = \tanh(\boldsymbol{W}^{s,z}\widetilde{\boldsymbol{z}}_t), \boldsymbol{W}^{s,z} \in \mathbb{R}^{e\times g}$, which is of the same dimension as the topic word embedding to simplify the following procedure.

Topic Attention In an image caption, different parts concern different topics. In the existing work (You et al., 2016), the conceptual information is attended based on the previous output word:

$$\boldsymbol{\beta}_t = \text{softmax}(\boldsymbol{T}^\mathsf{T}\boldsymbol{U}\boldsymbol{y}_{t-1}) \tag{9}$$

where $\boldsymbol{U} \in \mathbb{R}^{e\times e}, \boldsymbol{\beta}_t \in \mathbb{R}^m$. The profound issue is that this approach neglects the visual information. It should be beneficial to provide the attentive visual information when selecting topics. The hidden state of the LSTM contains both the information of previous words and the attentive input visual information. Therefore, the model attends to the topics based on the hidden state of the LSTM:

$$\boldsymbol{Q}_t = \tanh(\boldsymbol{W}^{Q,T}\boldsymbol{T} \oplus \boldsymbol{W}^{Q,h}\boldsymbol{h}_t) \tag{10}$$

$$\boldsymbol{\beta}_t = \text{softmax}(\boldsymbol{Q}_t\boldsymbol{w}^{\beta,Q}) \tag{11}$$

where $\boldsymbol{W}^{Q,T} \in \mathbb{R}^{m\times e}, \boldsymbol{W}^{Q,h} \in \mathbb{R}^{m\times d}, \boldsymbol{w}^{\beta,Q} \in \mathbb{R}^m$ are the parameters to be learned. $\boldsymbol{\beta}_t \in \mathbb{R}^m$ is the weight of the topics, from which the attentive conceptual output $\boldsymbol{q}_t \in \mathbb{R}^e$ is calculated:

$$\boldsymbol{q}_t = \boldsymbol{T}\boldsymbol{\beta}_t \tag{12}$$

The topic attention $\boldsymbol{q}_t$ and the hidden state $\boldsymbol{h}_t$ are combined as the contextual information $\boldsymbol{s}_t$:

$$\boldsymbol{s}_t = \tanh(\boldsymbol{W}^{s,q}\boldsymbol{q}_t + \boldsymbol{W}^{s,h}\boldsymbol{h}_t) \tag{13}$$

where $\boldsymbol{W}^{s,q} \in \mathbb{R}^{e\times e}, \boldsymbol{W}^{s,h} \in \mathbb{R}^{e\times d}$ are learnable parameters.

Merging Gate We have prepared both the visual information $\boldsymbol{r}_t$ and the contextual information $\boldsymbol{s}_t$. It is not reasonable to treat the two kinds of information equally when the decoder generates different types of words. For example, when generating descriptive words (e.g., *behind*, *red*), $\boldsymbol{r}_t$ should matter more than $\boldsymbol{s}_t$. However, when generating object words (e.g., *people*, *table*), $\boldsymbol{s}_t$ is more important. We introduce a novel score-based merging mechanism to make the model adaptively learn to adjust the balance:

$$\gamma_t = \sigma(S(\boldsymbol{s}_t) - S(\boldsymbol{r}_t)) \tag{14}$$

$$\boldsymbol{c}_t = \gamma_t \boldsymbol{s}_t + (1 - \gamma_t)\boldsymbol{r}_t \tag{15}$$

where σ is the sigmoid function, $\gamma_t \in [0, 1]$ indicates how important the topic attention is compared to the visual attention, and S is the scoring function. The scoring function needs to evaluate the importance of the topic attention. Noticing that Eq. (10) and Eq. (11) have a similar purpose, we define S similarly:

$$S(\boldsymbol{s}_t) = \tanh(\boldsymbol{W}^{S,h}\boldsymbol{h}_t + \boldsymbol{W}^{S,s}\boldsymbol{s}_t) \cdot \boldsymbol{w}^S \tag{16}$$

$$S(\boldsymbol{r}_t) = \tanh(\boldsymbol{W}^{S,h}\boldsymbol{h}_t + \boldsymbol{W}^{S,r}\boldsymbol{r}_t) \cdot \boldsymbol{w}^S \tag{17}$$

where $\cdot$ denotes dot product of vectors, $\boldsymbol{W}^{S,s} \in \mathbb{R}^{m \times e}, \boldsymbol{W}^{S,r} \in \mathbb{R}^{m \times e}$ are the parameters to be learned, and $\boldsymbol{W}^{S,h}, \boldsymbol{w}^s$ share the weights of $\boldsymbol{W}^{Q,h}, \boldsymbol{w}^{\beta,Q}$ from Eq. (10) and Eq. (11), respectively.

Finally, the output word is generated by:

$$y_t \sim \boldsymbol{p}_t = \text{softmax}(\boldsymbol{W}^{p,c}\boldsymbol{c}_t) \tag{18}$$

where each value of $\boldsymbol{p}_t \in \mathbb{R}^{|D|}$ is a probability indicating how likely the corresponding word in vocabulary D is the current output word. The whole model is trained using maximum log likelihood and the loss function is the cross entropy loss.

In all, our proposed approach encourages the model to take advantage of all the available information. The adaptive merging mechanism makes the model weigh the information elaborately.

4 Experiment

We describe the datasets and the metrics used for evaluation, followed by the training details and the evaluation of the proposed approach.

4.1 Datasets and Metrics

There are several datasets containing images and their captions. We report results on the popular Microsoft COCO (Chen et al., 2015) dataset and the Flickr30k (Young et al., 2014) dataset. They contain 123,287 images and 31,000 images, respectively, and each image is annotated with 5 sentences. We report results using the widely-used publicly-available splits in the work of Karpathy and Li (2015). There are 5,000 images each in the validation set and the test set for COCO, 1,000 images for Flickr30k.

We report results using the COCO captioning evaluation toolkit (Chen et al., 2015) that reports the widely-used automatic evaluation metrics SPICE, CIDEr, BLEU, METEOR, and ROUGE. SPICE (Anderson et al., 2016), which is based on scene graph matching, and CIDEr (Vedantam et al., 2015), which is based on n-gram matching, are specifically proposed for evaluating image captioning systems. They both incorporate the consensus of a set of references for an example. BLEU (Papineni et al., 2002) and METOR (Banerjee and Lavie, 2005) are originally proposed for machine translation evaluation. ROUGE (Lin and Hovy, 2003; Lin, 2004) is designed for automatic evaluation of extractive text summarization. In the related studies, it is concluded that SPICE correlates the best with human judgments with a remarkable margin over the other metrics, and is expert in judging detailedness, where the other metrics show negative correlations, surprisingly; CIDEr and METEOR follows with no particular precedence, followed by ROUGE-L, and BLEU-4, in that order (Anderson et al., 2016; Vedantam et al., 2015).

4.2 Settings

Following common practice, the CNN used is the ResNet152 model (He et al., 2016) pre-trained on ImageNet.[3] There are 2048 7 × 7 feature maps, and we project them into 512 feature maps, i.e. g is 512. The word embedding size e is 256 and the hidden size d of the LSTM is 512. We only keep caption words that occur at least 5 times in the training set, resulting in 10,132 words for COCO and 7,544 for Flickr30k. We use the topic extractor pre-trained by Fang et al. (2015) for 1,000 concepts on COCO. We only use 568 manually-annotated object words as topics. For an image, only the top 5 topics are selected, which means m is 5. The same topic extractor is used for Flickr30k, as COCO provides adequate generality. The caption words and the topic words share the same embeddings. In training, we first train the model without visual attention (freezing the CNN parameters) for 20 epochs with the batch size of 80. The learning rate for the LSTM is 0.0004. Then, we switch to jointly train the full model with a learning rate of 0.00001, which exponentially decays with the number of epochs so that it is halved every 50 epochs. We also use momen-

Table 2: Performance on the COCO Karpathy test split. Symbols, * and †, are defined similarly. Our model outperforms the current state-of-the-art Up-Down substantially in terms of SPICE.

tum of 0.8 and weight decay of 0.999. We use Adam (Kingma and Ba, 2014) for parameter optimization. For fair comparison, we adopt early stop based on CIDEr within maximum 50 epochs.

4.3 Results

We compare our approach with various representative systems on Flickr30k and COCO, including the recently proposed NBT that is the state-of-the-art on the two datasets in comparable settings. Table 1 shows the result on Flickr30k. As we can see, our model outperforms the comparable systems in terms of all of the metrics except BLEU-4. Moreover, our model overpasses the state-of-the-art with a comfortable margin in terms of SPICE, which is shown to correlate the best with human judgments (Anderson et al., 2016).

Table 2 shows the results on COCO. Among the directly comparable models, our model is arguably the best and outperforms the existing models except in terms of BLEU-4. Most encouragingly, our model is also competitive with Up-Down (Anderson et al., 2018), which uses much larger dataset, Visual Genome (Krishna et al., 2017), with dense annotations to train the object detector, and directly optimizes CIDEr. Especially, our model outperforms the state-of-the-art substantially in SPICE and METEOR. Breakdown of SPICE F-scores over various subcategories (see Table 3) shows that our model is in dominant lead in almost all subcategories. It proves the effectiveness of our approach and indicates that our model is quite data efficient.

For the methods that directly optimize CIDEr, it is intuitive that CIDEr can improve significantly. The similar improvement of BLEU-4 is evidence that optimizing CIDEr leads to more n-gram matching. However, it comes to our notice that the improvements of SPICE, METEOR, and ROUGE-L are far less significant, which suggests there may be a gaming situation where the n-gram matching is wrongfully exploited by the model in reinforcement learning. As shown by Liu et al. (2017), it is most reasonable to jointly optimize

Methods	SPICE							CIDEr	METEOR	ROUGE-L	BLEU-4

Table 5: Effect of using different visual words.

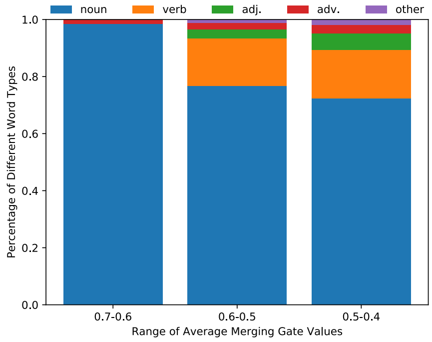

Figure 4: Average merging gate values according to word types. As we can see, object words (noun) dominate the high value range, while attribute and relation words are assigned lower values, indicating the merging gate learns to efficiently combine the information.

all the metrics at the same time.

We also evaluate the proposed model on the COCO evaluation server, the results of which are shown in Appendix A.1, due to limited space.

5 Analysis

In this section, we analyze the contribution of each component in the proposed approach, and give examples to show the strength and the potential improvements of the model. The analysis is conducted on the test set of COCO.

Topic Extraction The motivation of using objects as topics is that they are easier to identify so that the generation suffers less from erroneous predictions. This can be proved by the F-score of the identified topics in the test set, which is shown in Table 4. Using top-5 object words is at least as good as using top-10 all words. However, using top-10 all words introduces more erroneous visual words to the generation. As shown in Table 5, when extracting all words, providing more words to the model indeed increases the captioning performance. However, even when top-20 all words are used, the performance is still far behind using only top-5 object words and seems to reach the performance ceiling. It proves that for semantic attention, it is also important to limit the absolute number of incorrect visual words instead of merely the precision or the recall. It is also interesting to check whether using other kind of words can reach the same effect. Unfortunately, in our experiments, only using verbs or adjectives as semantic concepts works poorly.

To examine the contributions of the sub-modules in our model, we conduct a series of experiments. The results are summarized in Table 3. To help with the understanding of the differences, we also report the breakdown of SPICE F-scores.

Visual Attention Our input attention achieves similar results to previous work (Xu et al., 2015),

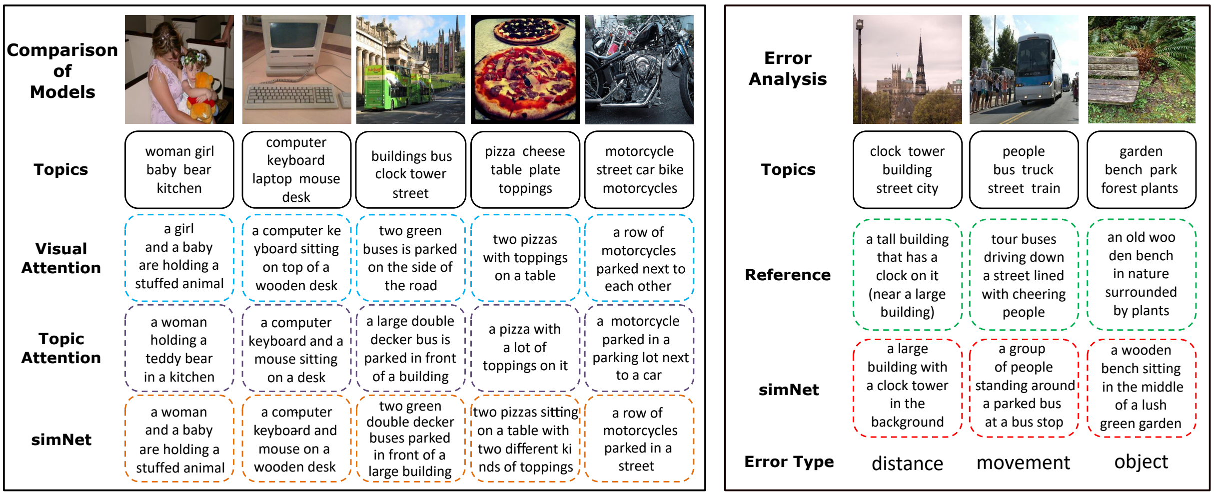

Figure 5: Examples of the generated captions. The left plot compares simNet with visual attention and topic attention. Visual attention is good at portraying the relations but is less specific in objects. Topic attention includes more objects but lacks details, such as material, color, and number. The proposed model achieves a very good balance. The right plot shows the error analysis of the proposed simNet.

if not better. Using only the output attention is much more effective than using only the input attention, with substantial improvements in all metrics, showing the impact of information gap caused by delayed input in attention. Combining the input attention and the output attention can further improve the results, especially in color and size descriptions.

Topic Attention As expected, compared with visual attention, the topic attention is better at identifying objects but worse at identifying attributes. We also apply the merging gate to the topic attention, but it now merges $\boldsymbol{q}_t$ and $\boldsymbol{h}_t$ instead of $\boldsymbol{s}_t$ and $\boldsymbol{r}_t$. With the merging gate, the model can balance the information in caption text and extracted topics, resulting in better overall scores. While it overpasses the conventional visual attention, it lags behind the output attention.

Merging Gate Combing the visual attention and the topic attention directly indeed results in a huge boost in performance, which confirms our motivation. However, directly combining them also causes lower scores in attributes, color, count, and size, showing that the advantages are not fully made use of. The most dramatic improvements come from applying the merging gate to the combined attention, showing that the proposed balance mechanism can adaptively combine the two kinds of information and is essential to the overall performance. The average merging gate value summarized in Figure 4 suggests the same.

We give some examples in the left plot of Figure 5 to illustrate the differences between the models more intuitively. From the examples, it is clear that the proposed simNet generates the best captions in that more objects are described and many informative and detailed attributes are included, such as the quantity and the color.

Visualization Figure 6 shows the visualization of the topic attention and the visual attention with running examples. As we can see, the topic attention is active when generating a phrase containing the related topic. For example, *bathroom* is always most attended when generating *a bathroom*. The merging gate learns to direct the information flow efficiently. When generating words such as *on* and *a*, it gives lower weight to the topic attention and prefers the visual attention. As to the visual attention, the output attention is much more focused than the input attention. As we hypothesized, the conventional input attention lacks the information of the last generated word and does not know what to look for exactly. For example, when generating *bathroom*, the input attention does not know the previous generated word is *a*, and it loses its focus, while the output attention is relatively more concentrated. Moreover, the merging gate learns to overcome the erroneous topics, as shown in the second example. When generating *chair*, the topic attention is focused on a wrong object *bed*, while the visual attention attends correctly to the chair, and especially the output attention attends to the armrest. The merging gate effectively remedies

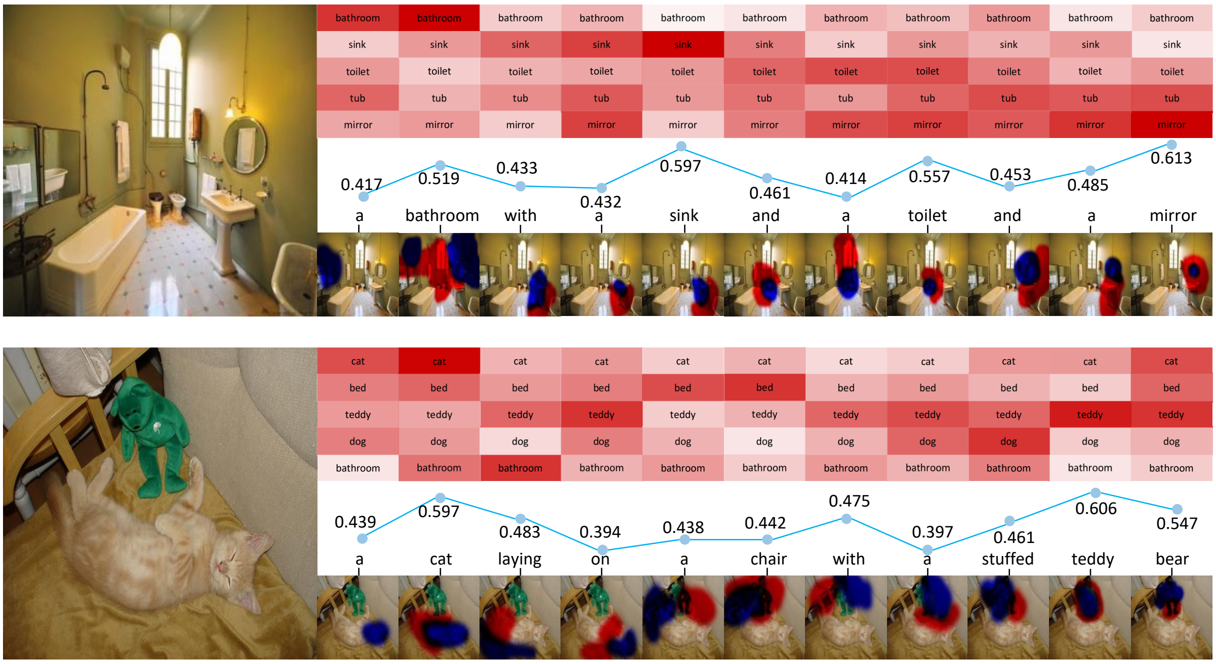

Figure 6: Visualization. Please view in color. Here, we give two running examples. The upper part of each example shows the attention weights of each of 5 extracted topics. Deeper color means larger in value. The middle part shows the value of the merging gate that determines the importance of the topic attention. The lower part shows the visualization of visual attention. The attended region is covered with color. The blue shade indicates the output attention. The red shade indicates the input attention.

the misleading information from the topic attention and outputs a lower weight, resulting in the model correctly generating the word *chair*.

Error Analysis We conduct error analysis using the proposed (full) model on the test set to provide insights on how the model may be improved. We find 123 out of 1000 generated captions that are not satisfactory. There are mainly three types of errors, i.e. distance (32, 26%), movement (22, 18%), and object (60, 49%), with 9 (7%) other errors. Distance error takes place when there is a lot of objects and the model cannot grasp the foreground and the background relationship. Movement error means that the model fails to describe whether the objects are moving. Those two kinds of errors are hard to eliminate, as they are fundamental problems of computer vision waiting to be resolved. Object error happens when there are incorrect extracted topics, and the merging gate regards the topic as grounded in the image. In the given example, the incorrect topic is *garden*. The tricky part is that the topic is seemingly correct according to the image features or otherwise the proposed model will choose other topics. A more powerful topic extractor may help with the problem but it is unlikely to be completely avoided.

6 Conclusions

We propose the stepwise image-topic merging network to sequentially and adaptively merge the visual and the conceptual information for improved image captioning. To our knowledge, we are the first to combine the visual and the semantic attention to achieve substantial improvements. We introduce the stepwise merging mechanism to efficiently guide the two kinds of information when generating the caption. The experimental results demonstrate the effectiveness of the proposed approach, which substantially outperforms the state-of-the-art image captioning methods in terms of SPICE on COCO and Flickr30k datasets. Quantitative and qualitative analysis show that the generated captions are both detailed and comprehensive in comparison with the existing methods.

Table 6: Performance on the online COCO evaluation server. The SPICE metric is unavailable for our model, thus not reported. c5 means evaluating against 5 references, and c40 means evaluating against 40 references. The symbol * denotes directly optimizing CIDEr. The symbol † denotes model ensemble. The symbol ‡ denotes using extra data for training, thus not directly comparable. Our submission does not use the three aforementioned techniques. Nonetheless, our model is second only to Up-Down and surpasses almost all the other models in published work, especially when 40 references are considered.

A Supplementary Material

A.1 Results on COCO Evaluation Server

Table 6 shows the performance on the online COCO evaluation server[4]. We put it in the appendix because the results are incomplete and the SPICE metric is not available for our submission, which correlates the best with human evaluation. The SPICE metrics are only available at the leaderboard on the COCO dataset website[5], which, unfortunately, has not been updated for more than a year. Our submission does not directly optimize CIDEr, use model ensemble, or use extra training data. The three techniques typically result in orthogonal improvements (Lu et al., 2017; Rennie et al., 2017; Anderson et al., 2018). Moreover, the SPICE results are missing, in which the proposed model has the most advantage. Nonetheless, our model is second only to Up-Down (Anderson et al., 2018) and surpasses almost all the other models in published work, especially when 40 references are considered.

Abstract

Computational modeling of human multimodal language is an emerging research area in natural language processing spanning the language, visual and acoustic modalities. Comprehending multimodal language requires modeling not only the interactions within each modality (intra-modal interactions) but more importantly the interactions between modalities (cross-modal interactions). In this paper, we propose the Recurrent Multistage Fusion Network (RMFN) which decomposes the fusion problem into multiple stages, each of them focused on a subset of multimodal signals for specialized, effective fusion. Cross-modal interactions are modeled using this multistage fusion approach which builds upon intermediate representations of previous stages. Temporal and intra-modal interactions are modeled by integrating our proposed fusion approach with a system of recurrent neural networks. The RMFN displays state-of-the-art performance in modeling human multimodal language across three public datasets relating to multimodal sentiment analysis, emotion recognition, and speaker traits recognition. We provide visualizations to show that each stage of fusion focuses on a different subset of multimodal signals, learning increasingly discriminative multimodal representations.

1 Introduction

Computational modeling of human multimodal language is an upcoming research area in natural language processing. This research area focuses on modeling tasks such as multimodal sentiment analysis (Morency et al., 2011), emotion recognition (Busso et al., 2008), and personality traits recognition (Park et al., 2014). The multimodal temporal signals include the language (spoken words), visual (facial expressions, gestures) and acoustic modalities (prosody, vocal expressions). At its core, these multimodal signals are highly structured with two prime forms of interactions: intra-modal and cross-modal interactions (Rajagopalan et al., 2016). Intra-modal interactions refer to information within a specific modality, independent of other modalities. For example, the arrangement of words in a sentence according

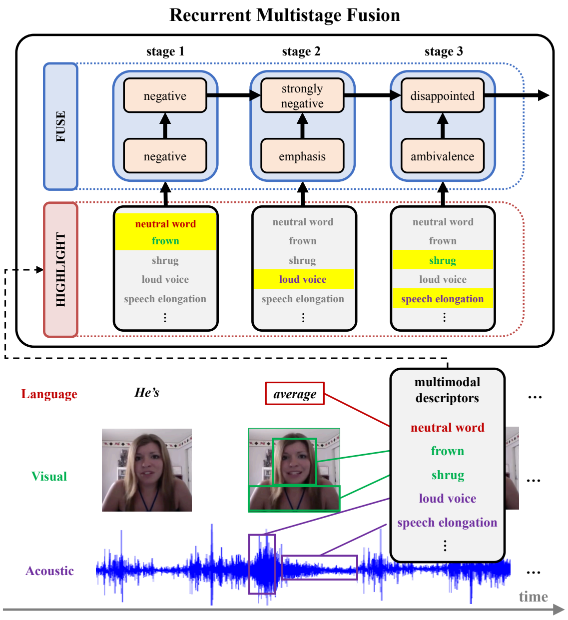

Figure 1: An illustrative example for Recurrent Multistage Fusion. At each recursive stage, a subset of multimodal signals is highlighted and then fused with previous fusion representations. The first fusion stage selects the neutral word and frowning behaviors which create an intermediate representation reflecting negative emotion when fused together. The second stage selects the loud voice behavior which is locally interpreted as emphasis before being fused with previous stages into a strongly negative representation. Finally, the third stage selects the shrugging and speech elongation behaviors that reflect ambivalence and when fused with previous stages is interpreted as a representation for the disappointed emotion.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 150–161
Brussels, Belgium, October 31 - November 4, 2018.

to the generative grammar of a language (Chomsky, 1957) or the sequence of facial muscle activations for the presentation of a frown. Cross-modal interactions refer to interactions between modalities. For example, the simultaneous co-occurrence of a smile with a positive sentence or the delayed occurrence of a laughter after the end of a sentence. Modeling these interactions lie at the heart of human multimodal language analysis and has recently become a centric research direction in multimodal natural language processing (Liu et al., 2018; Pham et al., 2018; Chen et al., 2017), multimodal speech recognition (Sun et al., 2016; Gupta et al., 2017; Harwath and Glass, 2017; Kamper et al., 2017), as well as multimodal machine learning (Tsai et al., 2018; Srivastava and Salakhutdinov, 2012; Ngiam et al., 2011).

Recent advances in cognitive neuroscience have demonstrated the existence of multistage aggregation across human cortical networks and functions (Taylor et al., 2015), particularly during the integration of multisensory information (Parisi et al., 2017). At later stages of cognitive processing, higher level semantic meaning is extracted from phrases, facial expressions, and tone of voice, eventually leading to the formation of higher level cross-modal concepts (Parisi et al., 2017; Taylor et al., 2015). Inspired by these discoveries, we hypothesize that the computational modeling of cross-modal interactions also requires a *multistage fusion* process. In this process, cross-modal representations can build upon the representations learned during earlier stages. This decreases the burden on each stage of multimodal fusion and allows each stage of fusion to be performed in a more specialized and effective manner.

In this paper, we propose the Recurrent Multistage Fusion Network (RMFN) which automatically decomposes the multimodal fusion problem into multiple recursive stages. At each stage, a subset of multimodal signals is highlighted and fused with previous fusion representations (see Figure 1). This divide-and-conquer approach decreases the burden on each fusion stage, allowing each stage to be performed in a more specialized and effective way. This is in contrast with conventional fusion approaches which usually model interactions over multimodal signals altogether in one iteration (e.g., early fusion (Baltrušaitis et al., 2017)). In RMFN, temporal and intra-modal interactions are modeled by integrating our new multistage fusion process with a system of recurrent neural networks. Overall, RMFN jointly models intra-modal and cross-modal interactions for multimodal language analysis and is differentiable end-to-end.

We evaluate RMFN on three different tasks related to human multimodal language: sentiment analysis, emotion recognition, and speaker traits recognition across three public multimodal datasets. RMFN achieves state-of-the-art performance in all three tasks. Through a comprehensive set of ablation experiments and visualizations, we demonstrate the advantages of explicitly defining multiple recursive stages for multimodal fusion.

2 Related Work

Previous approaches in human multimodal language modeling can be categorized as follows:

Non-temporal Models: These models simplify the problem by using feature-summarizing temporal observations (Poria et al., 2017). Each modality is represented by averaging temporal information through time, as shown for language-based sentiment analysis (Iyyer et al., 2015; Chen et al., 2016) and multimodal sentiment analysis (Abburi et al., 2016; Nojavanasghari et al., 2016; Zadeh et al., 2016; Morency et al., 2011). Conventional supervised learning methods are utilized to discover intra-modal and cross-modal interactions without specific model design (Wang et al., 2016; Poria et al., 2016). These approaches have trouble modeling long sequences since the average statistics do not properly capture the temporal intra-modal and cross-modal dynamics (Xu et al., 2013).

Multimodal Temporal Graphical Models: The application of graphical models in sequence modeling has been an important research problem. Hidden Markov Models (HMMs) (Baum and Petrie, 1966), Conditional Random Fields (CRFs) (Lafferty et al., 2001), and Hidden Conditional Random Fields (HCRFs) (Quattoni et al., 2007) were shown to work well on modeling sequential data from the language (Misawa et al., 2017; Ma and Hovy, 2016; Huang et al., 2015) and acoustic (Yuan and Liberman, 2008) modalities. These temporal graphical models have also been extended for modeling multimodal data. Several methods have been proposed including multi-view HCRFs where the potentials of the HCRF are designed to model data from multiple views (Song et al., 2012), multi-layered CRFs with latent variables to learn hidden spatio-temporal dynamics from multi-view data (Song et al., 2012), and multi-view Hierarchical Sequence Summarization models that recursively build up hierarchical representations (Song et al., 2013).

Multimodal Temporal Neural Networks: More recently, with the advent of deep learning, Recurrent Neural Networks (Elman, 1990; Jain and Medsker, 1999) have been used extensively for language and speech based sequence modeling (Zilly et al., 2016; Soltau et al., 2016), sentiment analysis (Socher et al., 2013; dos Santos and Gatti, 2014; Glorot et al., 2011; Cambria, 2016), and emotion recognition (Han et al., 2014; Bertero et al., 2016; Lakomkin et al., 2018). Long-short Term Memory (LSTM) networks (Hochreiter and Schmidhuber, 1997a) have also been extended for multimodal settings (Rajagopalan et al., 2016) and by learning binary gating mechanisms to remove noisy modalities (Chen et al., 2017). Recently, more advanced models were proposed to model both intra-modal and cross-modal interactions. These use Bayesian ranking algorithms (Herbrich et al., 2007) to model both person-independent and person-dependent features (Liang et al., 2018), generative-discriminative objectives to learn either joint (Pham et al., 2018) or factorized multimodal representations (Tsai et al., 2018), external memory mechanisms to synchronize multimodal data (Zadeh et al., 2018a), or low-rank tensors to approximate expensive tensor products (Liu et al., 2018). All these methods assume that cross-modal interactions should be discovered all at once rather than across multiple stages, where each stage solves a simpler fusion problem. Our empirical evaluations show the advantages of the multistage fusion approach.

3 Recurrent Multistage Fusion Network

In this section we describe the Recurrent Multistage Fusion Network (RMFN) for multimodal language analysis (Figure 2). Given a set of modalities $\{l(anguage), v(isual), a(coustic)\}$, the signal from each modality $m \in \{l, v, a\}$ is represented as a temporal sequence $\mathbf{X}^m = \{\mathbf{x}_1^m, \mathbf{x}_2^m, \mathbf{x}_3^m, \cdots, \mathbf{x}_T^m\}$, where $\mathbf{x}_t^m$ is the input at time t. Each sequence $\mathbf{X}^m$ is modeled with an intra-modal recurrent neural network (see subsection 3.3 for details). At time t, each intra-modal recurrent network will output a unimodal representation $\mathbf{h}_t^m$. The Multistage Fusion Process uses a recursive approach to fuse all unimodal representations $\mathbf{h}_t^m$ into a cross-modal representation $\mathbf{z}_t$ which is then fed back into each intra-modal recurrent network.

3.1 Multistage Fusion Process

The Multistage Fusion Process (MFP) is a modular neural approach that performs multistage fusion to model cross-modal interactions. Multistage fusion is a divide-and-conquer approach which decreases the burden on each stage of multimodal fusion, allowing each stage to be performed in a more specialized and effective way. The MFP has three main modules: `HIGHLIGHT`, `FUSE` and `SUMMARIZE`.

Two modules are repeated at each stage: `HIGHLIGHT` and `FUSE`. The `HIGHLIGHT` module identifies a subset of multimodal signals from $[\mathbf{h}_t^l, \mathbf{h}_t^v, \mathbf{h}_t^a]$ that will be used for that stage of fusion. The `FUSE` module then performs two subtasks simultaneously: a local fusion of the highlighted features and integration with representations from previous stages. Both `HIGHLIGHT` and `FUSE` modules are realized using memory-based neural networks which enable coherence between stages and storage of previously modeled cross-modal interactions. As a final step, the `SUMMARIZE` module takes the multimodal representation of the final stage and translates it into a cross-modal representation $\mathbf{z}_t$.

Figure 1 shows an illustrative example for multistage fusion. The `HIGHLIGHT` module selects "neutral words" and "frowning" expression for the first stage. The local and integrated fusion at this stage creates a representation reflecting negative emotion. For stage 2, the `HIGHLIGHT` module identifies the acoustic feature "loud voice". The local fusion at this stage interprets it as an expression of emphasis and is fused with the previous fusion results to represent a strong negative emotion. Finally, the highlighted features of "shrug" and "speech elongation" are selected and are locally interpreted as "ambivalence". The integration with previous stages then gives a representation closer to "disappointed".

3.2 Module Descriptions

In this section, we present the details of the three multistage fusion modules: `HIGHLIGHT`, `FUSE` and `SUMMARIZE`. Multistage fusion begins with the concatenation of intra-modal network outputs $\mathbf{h}_t = \bigoplus_{m \in M} \mathbf{h}_t^m$. We use superscript $^{[k]}$ to denote the indices of each stage $k = 1, \cdots, K$ during K total stages of multistage fusion. Let Θ denote the neural network parameters across all modules.

`HIGHLIGHT`: At each stage k, a subset of the multimodal signals represented in $\mathbf{h}_t$ will be au-

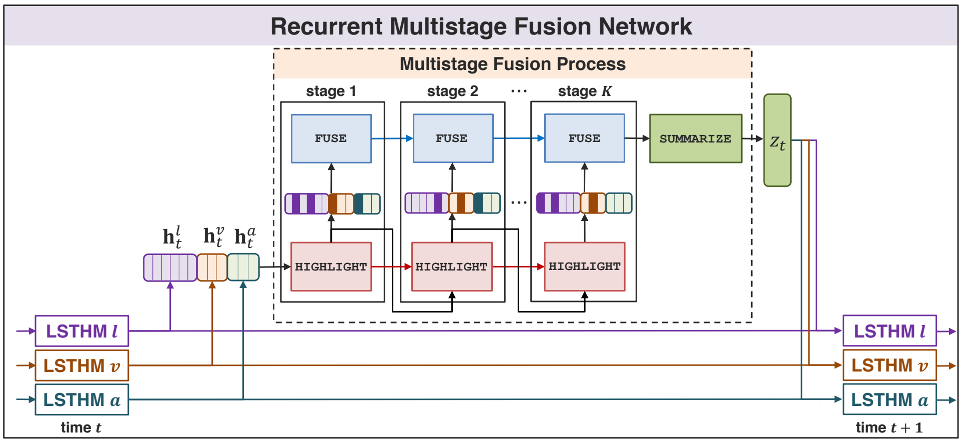

Figure 2: The Recurrent Multistage Fusion Network for multimodal language analysis. The Multistage Fusion Process has three modules: `HIGHLIGHT`, `FUSE` and `SUMMARIZE`. Multistage fusion begins with the concatenated intra-modal network outputs $\mathbf{h}_t^l, \mathbf{h}_t^v, \mathbf{h}_t^a$. At each stage, the `HIGHLIGHT` module identifies a subset of multimodal signals and the `FUSE` module performs local fusion before integration with previous fusion representations. The `SUMMARIZE` module translates the representation at the final stage into a cross-modal representation $\mathbf{z}_t$ to be fed back into the intra-modal recurrent networks.

tomatically highlighted for fusion. Formally, this module is defined by the process function f_H:

$$\mathbf{a}_t^{[k]} = f_H(\mathbf{h}_t \,;\, \mathbf{a}_t^{[1:k-1]}, \Theta) \tag{1}$$

where at stage k, $\mathbf{a}_t^{[k]}$ is a set of attention weights which are inferred based on the previously assigned attention weights $\mathbf{a}_t^{[1:k-1]}$. As a result, the highlights at a specific stage k will be dependent on previous highlights. To fully encapsulate these dependencies, the attention assignment process is performed in a recurrent manner using a LSTM which we call the `HIGHLIGHT` LSTM. The initial `HIGHLIGHT` LSTM memory at stage 0, $\mathbf{c}_t^{\texttt{HIGHLIGHT}[0]}$, is initialized using a network $\mathcal{M}$ that maps $\mathbf{h}_t$ into LSTM memory space:

$$\mathbf{c}_t^{\texttt{HIGHLIGHT}[0]} = \mathcal{M}(\mathbf{h}_t \,;\, \Theta) \tag{2}$$

This allows the memory mechanism of the `HIGHLIGHT` LSTM to dynamically adjust to the intra-modal representations $\mathbf{h}_t$. The output of the `HIGHLIGHT` LSTM $\mathbf{h}_t^{\texttt{HIGHLIGHT}[k]}$ is softmax activated to produce attention weights $\mathbf{a}_t^{[k]}$ at every stage k of the multistage fusion process:

$$\mathbf{a}_t^{[k]}{}_j = \frac{\exp\left(\mathbf{h}_t^{\texttt{HIGHLIGHT}[k]}{}_j\right)}{\sum_{d=1}^{|\mathbf{h}_t^{\texttt{HIGHLIGHT}[k]}|} \exp\left(\mathbf{h}_t^{\texttt{HIGHLIGHT}[k]}{}_d\right)} \tag{3}$$

and $\mathbf{a}_t^{[k]}$ is fed as input into the `HIGHLIGHT` LSTM at stage $k+1$. Therefore, the `HIGHLIGHT` LSTM functions as a decoder LSTM (Sutskever et al., 2014; Cho et al., 2014) in order to capture the dependencies on previous attention assignments. Highlighting is performed by element-wise multiplying the attention weights $\mathbf{a}_t^{[k]}$ with the concatenated intra-modal representations $\mathbf{h}_t$:

$$\tilde{\mathbf{h}}_t^{[k]} = \mathbf{h}_t \odot \mathbf{a}_t^{[k]} \tag{4}$$

where $\odot$ denotes the Hadamard product and $\tilde{\mathbf{h}}_t^{[k]}$ are the attended multimodal signals that will be used for the fusion at stage k.

`FUSE`: The highlighted multimodal signals are simultaneously fused in a local fusion and then integrated with fusion representations from previous stages. Formally, this module is defined by the process function f_F:

$$\mathbf{s}_t^{[k]} = f_F(\tilde{\mathbf{h}}_t^{[k]} \,;\, \mathbf{s}_t^{[1:k-1]}, \Theta) \tag{5}$$

where $\mathbf{s}_t^{[k]}$ denotes the integrated fusion representations at stage k. We employ a `FUSE` LSTM to simultaneously perform the local fusion and the integration with previous fusion representations. The `FUSE` LSTM input gate enables a local fusion while the `FUSE` LSTM forget and output gates enable integration with previous fusion results. The initial `FUSE` LSTM memory at stage 0, $\mathbf{c}_t^{\texttt{FUSE}[0]}$, is initialized using random orthogonal matrices (Arjovsky et al., 2015; Le et al., 2015).

`SUMMARIZE`: After completing K recursive stages of `HIGHLIGHT` and `FUSE`, the `SUMMARIZE` operation generates a cross-modal representation using all final fusion representations $\mathbf{s}_t^{[1:K]}$. Formally, this operation is defined as:

$$\mathbf{z}_t = \mathcal{S}(\mathbf{s}_t^{[1:K]}\ ;\ \Theta) \tag{6}$$

where $\mathbf{z}_t$ is the final output of the multistage fusion process and represents all cross-modal interactions discovered at time t. The summarized cross-modal representation is then fed into the intra-modal recurrent networks as described in the subsection 3.3.

3.3 System of Long Short-term Hybrid Memories

To integrate the cross-modal representations $\mathbf{z}_t$ with the temporal intra-modal representations, we employ a system of Long Short-term Hybrid Memories (LSTHMs) (Zadeh et al., 2018b). The LSTHM extends the LSTM formulation to include the cross-modal representation $\mathbf{z}_t$ in a hybrid memory component:

$$\mathbf{i}_{t+1}^m = \sigma(\mathbf{W}_i^m\ \mathbf{x}_{t+1}^m + \mathbf{U}_i^m\ \mathbf{h}_t^m + \mathbf{V}_i^m\ \mathbf{z}_t + \mathbf{b}_i^m) \tag{7}$$
$$\mathbf{f}_{t+1}^m = \sigma(\mathbf{W}_f^m\ \mathbf{x}_{t+1}^m + \mathbf{U}_f^m\ \mathbf{h}_t^m + \mathbf{V}_f^m\ \mathbf{z}_t + \mathbf{b}_f^m) \tag{8}$$
$$\mathbf{o}_{t+1}^m = \sigma(\mathbf{W}_o^m\ \mathbf{x}_{t+1}^m + \mathbf{U}_o^m\ \mathbf{h}_t^m + \mathbf{V}_o^m\ \mathbf{z}_t + \mathbf{b}_o^m) \tag{9}$$
$$\bar{\mathbf{c}}_{t+1}^m = \mathbf{W}_{\bar{c}}^m\ \mathbf{x}_{t+1}^m + \mathbf{U}_{\bar{c}}^m\ \mathbf{h}_t^m + \mathbf{V}_{\bar{c}}^m\ \mathbf{z}_t + \mathbf{b}_{\bar{c}}^m \tag{10}$$
$$\mathbf{c}_{t+1}^m = \mathbf{f}_t^m \odot \mathbf{c}_t^m + \mathbf{i}_t^m \odot tanh(\bar{\mathbf{c}}_{t+1}^m) \tag{11}$$
$$\mathbf{h}_{t+1}^m = \mathbf{o}_{t+1}^m \odot tanh(\mathbf{c}_{t+1}^m) \tag{12}$$

where σ is the (hard-)sigmoid activation function, $tanh$ is the tangent hyperbolic activation function, $\odot$ denotes the Hadamard product. $\mathbf{i}, \mathbf{f}$ and $\mathbf{o}$ are the input, forget and output gates respectively. $\bar{\mathbf{c}}_{t+1}^m$ is the proposed update to the hybrid memory $\mathbf{c}_t^m$ at time $t+1$ and $\mathbf{h}_t^m$ is the time distributed output of each modality. The cross-modal representation $\mathbf{z}_t$ is modeled by the Multistage Fusion Process as discussed in subsection 3.2. The hybrid memory $\mathbf{c}_t^m$ contains both intra-modal interactions from individual modalities $\mathbf{x}_t^m$ as well as the cross-modal interactions captured in $\mathbf{z}_t$.

3.4 Optimization

The multimodal prediction task is performed using a final representation $\mathcal{E}$ which integrate (1) the last outputs from the LSTHMs and (2) the last cross-modal representation $\mathbf{z}_T$. Formally, $\mathcal{E}$ is defined as:

$$\mathcal{E} = (\bigoplus_{m \in M} \mathbf{h}_T^m) \bigoplus \mathbf{z}_T \tag{13}$$

where $\oplus$ denotes vector concatenation. $\mathcal{E}$ can then be used as a multimodal representation for supervised or unsupervised analysis of multimodal language. It summarizes all modeled intra-modal and cross-modal representations from the multimodal sequences. RMFN is differentiable end-to-end which allows the network parameters Θ to be learned using gradient descent approaches.

4 Experimental Setup

To evaluate the performance and generalization of RMFN, three domains of human multimodal language were selected: multimodal sentiment analysis, emotion recognition, and speaker traits recognition.

4.1 Datasets

All datasets consist of monologue videos. The speaker's intentions are conveyed through three modalities: language, visual and acoustic.

Multimodal Sentiment Analysis involves analyzing speaker sentiment based on video content. Multimodal sentiment analysis extends conventional language-based sentiment analysis to a multimodal setup where both verbal and non-verbal signals contribute to the expression of sentiment. We use **CMU-MOSI** (Zadeh et al., 2016) which consists of 2199 opinion segments from online videos each annotated with sentiment in the range [-3,3].

Multimodal Emotion Recognition involves identifying speaker emotions based on both verbal and nonverbal behaviors. We perform experiments on the **IEMOCAP** dataset (Busso et al., 2008) which consists of 7318 segments of recorded dyadic dialogues annotated for the presence of human emotions happiness, sadness, anger and neutral.

Multimodal Speaker Traits Recognition involves recognizing speaker traits based on multimodal communicative behaviors. **POM** (Park et al., 2014) contains 903 movie review videos each annotated for 12 speaker traits: confident (con), passionate (pas), voice pleasant (voi), credible (cre), vivid (viv), expertise (exp), reserved (res), trusting (tru), relaxed (rel), thorough (tho), nervous (ner), persuasive (per) and humorous (hum).

4.2 Multimodal Features and Alignment

GloVe word embeddings (Pennington et al., 2014), Facet (iMotions, 2017) and COVAREP (Degottex et al., 2014) are extracted for the language, visual and acoustic modalities respectively [1]. Forced alignment is performed using P2FA (Yuan and Liberman, 2008) to obtain the exact utterance times

Table 2: Emotion recognition results on IEMOCAP. Best results are highlighted in bold and Δ_{SOTA} shows improvement over previous SOTA. Symbols denote baseline model which achieves the reported performance: MFN: $\star$, MARN: §, BC-LSTM: $\bullet$, TFN: †, MV-LSTM: $\#$, EF-LSTM: $\flat$, SVM: $\times$. The RMFN outperforms the current SOTA across evaluation metrics except Δ_{SOTA} entries in gray. Improvements are highlighted in green.

of each word. We obtain the aligned video and audio features by computing the expectation of their modality feature values over each word utterance time interval (Tsai et al., 2018).

4.3 Baseline Models

We compare to the following models for multimodal machine learning: **MFN** (Zadeh et al., 2018a) synchronizes multimodal sequences using a multi-view gated memory. It is the current state of the art on CMU-MOSI and POM. **MARN** (Zadeh et al., 2018b) models intra-modal and cross-modal interactions using multiple attention coefficients and hybrid LSTM memory components. **GME-LSTM(A)** (Chen et al., 2017) learns binary gating mechanisms to remove noisy modalities that are contradictory or redundant for prediction. **TFN** (Zadeh et al., 2017) models unimodal, bimodal and trimodal interactions using tensor products. **BC-LSTM** (Poria et al., 2017) performs context-dependent sentiment analysis and emotion recognition, currently state of the art on IEMOCAP. **EF-LSTM** concatenates the multimodal inputs and uses that as input to a single LSTM (Hochreiter and Schmidhuber, 1997b). We also implement the Stacked, (**EF-SLSTM**) (Graves et al., 2013) Bidirectional (**EF-BLSTM**) (Schuster and Paliwal, 1997) and Stacked Bidirectional (**EF-SBLSTM**) LSTMs. For descriptions of the remaining baselines, we refer the reader to **EF-HCRF** (Quattoni et al., 2007), **EF/MV-LDHCRF** (Morency et al., 2007), **MV-HCRF** (Song et al., 2012), **EF/MV-HSSHCRF** (Song et al., 2013), **MV-LSTM** (Rajagopalan et al., 2016), **DF** (Nojavanasghari et al., 2016), **SAL-CNN** (Wang et al., 2016), **C-MKL** (Poria et al., 2015), **THMM** (Morency et al., 2011), **SVM** (Cortes and Vapnik, 1995; Park et al., 2014) and **RF** (Breiman, 2001).

4.4 Evaluation Metrics

For classification, we report accuracy Ac where c denotes the number of classes and F1 score. For regression, we report Mean Absolute Error MAE and Pearson's correlation r. For MAE lower values indicate stronger performance. For all remaining metrics, higher values indicate stronger performance.

5 Results and Discussion

5.1 Performance on Multimodal Language

Results on CMU-MOSI, IEMOCAP and POM are presented in Tables 1, 2 and 3 respectively[2]. We achieve state-of-the-art or competitive results for all domains, highlighting RMFN's capability in human multimodal language analysis. We observe that RMFN does not improve results on IEMOCAP neutral emotion and the model outperforming RMFN is a memory-based fusion baseline (Zadeh et al., 2018a). We believe that this is because neutral expressions are quite idiosyncratic. Some people may always look angry given their facial configuration (e.g., natural eyebrow raises of actor Jack Nicholson). In these situations, it becomes useful to compare the current image with a memorized or aggregated representation of the speaker's face. Our proposed multistage fusion approach can easily be extended to memory-based fusion methods.

---

[2] Results for all individual baseline models are in supplementary. State-of-the-art (SOTA)1/2/3 represent the three best performing baseline models on each dataset.

Table 5: Comparison studies of RMFN on CMU-MOSI. Modeling cross-modal interactions using multistage fusion and attention weights are crucial in multimodal language analysis.

5.2 Analysis of Multistage Fusion

To achieve a deeper understanding of the multistage fusion process, we study five research questions. (Q1): whether modeling cross-modal interactions across multiple stages is beneficial. (Q2): the effect of the number of stages K during multistage fusion on performance. (Q3): the comparison between multistage and independent modeling of cross-modal interactions. (Q4): whether modeling cross-modal interactions are helpful. (Q5): whether attention weights from the `HIGHLIGHT` module are required for modeling cross-modal interactions.

Q1: To study the effectiveness of the multistage fusion process, we test the baseline RMFN-R1 which performs fusion in only one stage instead of across multiple stages. This model makes the strong assumption that all cross-modal interactions can be modeled during only one stage. From Table 4, RMFN-R1 underperforms as compared to RMFN which performs multistage fusion.

Q2: We test baselines RMFN-RK which perform K stages of fusion. From Table 4, we observe that increasing the number of stages K increases the model's capability to model cross-modal interactions up to a certain point ($K = 3$) in our experiments. Further increases led to decreases in performance and we hypothesize this is due to overfitting on the dataset.

Q3: To compare multistage against independent modeling of cross-modal interactions, we pay close attention to the performance comparison with respect to MARN which models multiple cross-modal interactions all at once (see Table 5). RMFN shows improved performance, indicating that multistage fusion is both effective and efficient for human multimodal language modeling.

Q4: RMFN (no MFP) represents a system of LSTHMs without the integration of $\mathbf{z}_t$ from the MFP to model cross-modal interactions. From Table 5, RMFN (no MFP) is outperformed by RMFN, confirming that modeling cross-modal interactions is crucial in analyzing human multimodal language.

Q5: RMFN (no `HIGHLIGHT`) removes the `HIGHLIGHT` module from MFP during multistage fusion. From Table 5, RMFN (no `HIGHLIGHT`) underperforms, indicating that highlighting multimodal representations using attention weights are important for modeling cross-modal interactions.

5.3 Visualizations

Using an attention assignment mechanism during the `HIGHLIGHT` process gives more interpretability to the model since it allows us to visualize the attended multimodal signals at each stage and

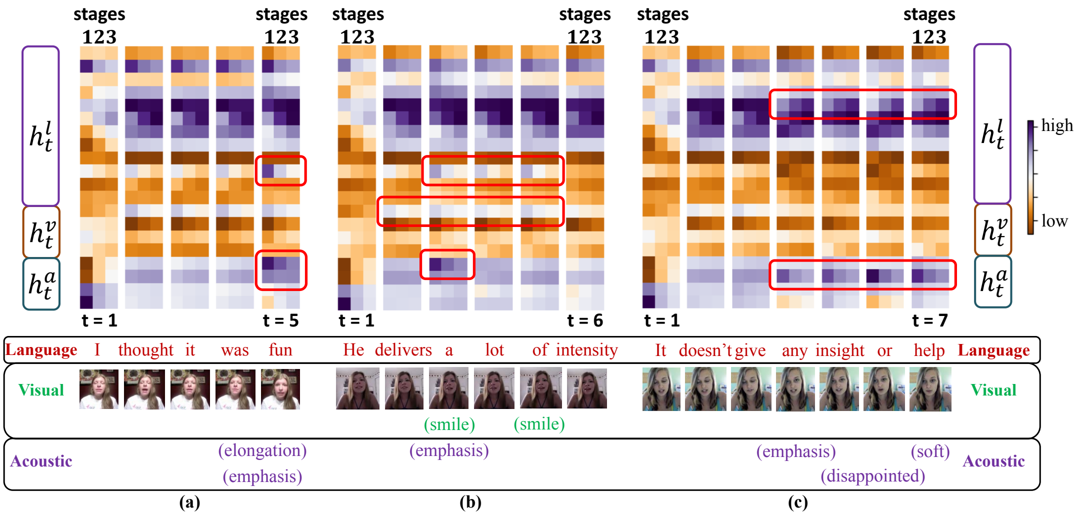

Figure 3: Visualization of learned attention weights across stages 1,2 and 3 of the multistage fusion process and across time of the multimodal sequence. We observe that the attention weights are diverse and evolve across stages and time. In these three examples, the red boxes emphasize specific moments of interest. (a) Synchronized interactions: the positive word "fun" and the acoustic behaviors of emphasis and elongation ($t = 5$) are synchronized in both attention weights for language and acoustic features. (b) Asynchronous trimodal interactions: the asynchronous presence of a smile ($t = 2 : 5$) and emphasis ($t = 3$) help to disambiguate the language modality. (c) Bimodal interactions: the interactions between the language and acoustic modalities are highlighted by alternating stages of fusion ($t = 4 : 7$).

time step (see Figure 3). Using RMFN trained on the CMU-MOSI dataset, we plot the attention weights across the multistage fusion process for three videos in CMU-MOSI. Based on these visualizations we first draw the following general observations on multistage fusion:

Across stages: Attention weights change their behaviors across the multiple stages of fusion. Some features are highlighted by earlier stages while other features are used in later stages. This supports our hypothesis that RMFN learns to specialize in different stages of the fusion process.

Across time: Attention weights vary over time and adapt to the multimodal inputs. We observe that the attention weights are similar if the input contains no new information. As soon as new multimodal information comes in, the highlighting mechanism in RMFN adapts to these new inputs.

Priors: Based on the distribution of attention weights, we observe that the language and acoustic modalities seem the most commonly highlighted. This represents a prior over the expression of sentiment in human multimodal language and is closely related to the strong connections between language and speech in human communication (Kuhl, 2000).

Inactivity: Some attention coefficients are not active (always orange) throughout time. We hypothesize that these corresponding dimensions carry only intra-modal dynamics and are not involved in the formation of cross-modal interactions.

5.4 Qualitative Analysis

In addition to the general observations above, Figure 3 shows three examples where multistage fusion learns cross-modal representations across three different scenarios.

Synchronized Interactions: In Figure 3(a), the language features are highlighted corresponding to the utterance of the word "fun" that is highly indicative of sentiment ($t = 5$). This sudden change is also accompanied by a synchronized highlighting of the acoustic features. We also notice that the highlighting of the acoustic features lasts longer across the 3 stages since it may take multiple stages to interpret all the new acoustic behaviors (elongated tone of voice and phonological emphasis).

Asynchronous Trimodal Interactions: In Figure 3(b), the language modality displays ambiguous sentiment: "delivers a lot of intensity" can be inferred as both positive or negative. We observe that the circled attention units in the visual and acoustic features correspond to the asynchronous presence of a smile ($t = 2 : 5$) and phonological emphasis ($t = 3$) respectively. These nonverbal behaviors resolve ambiguity in language and result in an overall display of positive sentiment. We further note the coupling of attention weights that highlight the language, visual and acoustic features across stages ($t = 3 : 5$), further emphasizing the coordination of all three modalities during multistage fusion despite their asynchronous occurrences.

Bimodal Interactions: In Figure 3(c), the language modality is better interpreted in the context of acoustic behaviors. The disappointed tone and soft voice provide the nonverbal information useful for sentiment inference. This example highlights the bimodal interactions ($t = 4 : 7$) in alternating stages: the acoustic features are highlighted more in earlier stages while the language features are highlighted increasingly in later stages.

6 Conclusion

This paper proposed the Recurrent Multistage Fusion Network (RMFN) which decomposes the multimodal fusion problem into multiple stages, each focused on a subset of multimodal signals. Extensive experiments across three publicly-available datasets reveal that RMFN is highly effective in modeling human multimodal language. In addition to achieving state-of-the-art performance on all datasets, our comparisons and visualizations reveal that the multiple stages coordinate to capture both synchronous and asynchronous multimodal interactions. In future work, we are interested in merging our model with memory-based fusion methods since they have complementary strengths as discussed in subsection 5.1.

Abstract

We introduce an effective and efficient method that grounds (*i.e.*, localizes) natural sentences in long, untrimmed video sequences. Specifically, a novel Temporal GroundNet (TGN)[1] is proposed to temporally capture the evolving fine-grained frame-by-word interactions between video and sentence. TGN sequentially scores a set of temporal candidates ended at each frame based on the exploited frame-by-word interactions, and finally grounds the segment corresponding to the sentence. Unlike traditional methods treating the overlapping segments separately in a sliding window fashion, TGN aggregates the historical information and generates the final grounding result in one single pass. We extensively evaluate our proposed TGN on three public datasets with significant improvements over the state-of-the-arts. We further show the consistent effectiveness and efficiency of TGN through an ablation study and a runtime test.

1 Introduction

We examine the task of Natural Sentence Grounding in Video (NSGV). Given an untrimmed video and a natural sentence, the goal is to determine the start and end timestamps of the segment in the video which corresponds to the given sentence, as shown in Figure 1 (a). Comparing with the other video researches, such as bidirectional video-sentence retrieval (Xu et al., 2015b), video attractiveness prediction (Chen et al., 2018, 2016), and video captioning (Pasunuru and Bansal, 2017; Wang et al., 2018a,b), NSGV needs to model not only the characteristics of sentence and video but also the fine-grained interactions between the two modalities, which is even more challenging.

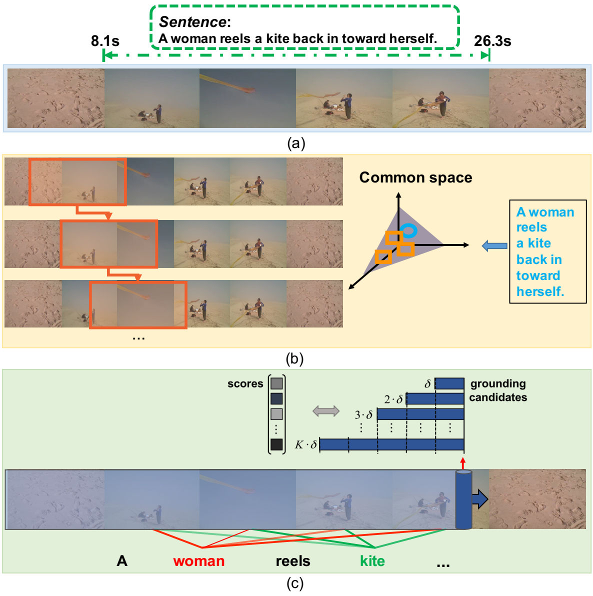

Figure 1: (a) The Natural Sentence Grounding in Video (NSGV) task. (b) A common space based matching method performs in a sliding window fashion. (c) Our proposed Temporal GroundNet (TGN) localizes the candidate video segments at multiple scales in a single processing pass. The frames in the video and the words in the sentence interact attentively to perform fine-grained frame-by-word matchings for grounding sentence in video.

Recently, several related works (Gao et al., 2017; Hendricks et al., 2017) leverage one temporal sliding window approach over video sequences to generate video segment candidates, which are then independently combined (Gao et al., 2017) or compared (Hendricks et al., 2017) with the given sentence to make the grounding prediction. Although the existing works have achieved promising performances, they are still suffering from inferior effectiveness and efficiency. First, existing methods project the video segment and sentence into one common space, as shown in Figure 1 (b),

Brussels, Belgium, October 31 - November 4, 2018. ©2018 Association for Computational Linguistics

where the two generated embedding vectors are used to perform the matching between video segment and sentence. Such a matching is only performed in the global segment and sentence level and thus not expressive enough, which ignores the fine-grained matching relations between video frames and the words in sentences. Second, in order to handle the diverse temporal scales and locations of the candidate segments, exhaustive matching between the large amount of overlapping segments and the sentence is required. As such, the sliding window methods are very computationally expensive.

In order to tackle the above two limitations, we introduce a novel Temporal GroundNet (TGN) model, the first dynamic single-stream deep architecture for the NSGV task that takes full advantage of fine-grained interactions between video frames and words in a sentence, as shown in Figure 1 (c). TGN sequentially processes video frames, where at each time step we rely on a novel multimodal interactor to exploit the evolving fine-grained frame-by-word interactions. Then, TGN works on the yielded interaction status to simultaneously score a set of temporal candidates of multiple scales and finally localize the video segment that corresponds to the sentence. More importantly, our proposed TGN is able to analyze an untrimmed video frame by frame without resorting to handling overlapping temporal video segments.

2 Related Work

2.1 Grounding Natural Language in Image

Grounding natural language in image is also known as natural language object retrieval. The task is to localize an image region described by natural language, which involves comprehending and modeling different spatial contexts, such as spatial configurations (Hu et al., 2016), attributes (Yu et al., 2018), and relationships between objects (Hu et al., 2017). Specifically, the task is usually formulated as a ranking problem over a set of candidate regions in a given image, where candidate spatial locations come from region proposal methods (Uijlings et al., 2013; Jie et al., 2016b,a; Ren et al., 2017) such as EdgeBox (Zitnick and Dollár, 2014). Earlier studies (Mao et al., 2016; Rohrbach et al., 2016) score the generated candidate regions according to their appearances and spatial features along with features of the entire image. However, these methods fail to incorporate the interactions between objects, because the scoring process of each region proposal is isolated. More recent studies (Hu et al., 2017; Nagaraja et al., 2016) improve the performance with the aid of modeling relationships between objects.

2.2 Grounding Natural Language in Video

Analogous to spatial grounding in image, this work studies a similar problem—temporal natural language grounding in video. Earlier works (Yu and Siskind, 2013; Lin et al., 2014) learn the semantics of sentences, which are then matched to visual concepts via exploiting object appearance, motion and spatial relationships. However, they are limited to a small set of objects. Recently, larger datasets (Gao et al., 2017; Hendricks et al., 2017) are constructed to support more flexible groundings. The methods proposed in (Gao et al., 2017; Hendricks et al., 2017) learn a common embedding space shared by video segment features and sentence representations, in which their similarities are measured. Specifically, moment context network (MCN) (Hendricks et al., 2017) learns a shared embedding for video clip-level features and language features. The video features integrate local video features, global features, and temporal endpoint features. Cross-modal temporal regression localizer (CTRL) (Gao et al., 2017) contains four modules, specifically a visual encoder extracting clip-level features with context, a sentence encoder yielding its embedding through LSTM, a multimodal processing network generating the fused representations via element-wise operations, and a temporal regression network producing the alignment scores and location offsets. One limitation of those common space matching methods is that the video segment generation process is computationally expensive, as they carry out overlapping sliding window matching (Gao et al., 2017) or exhaustive search (Hendricks et al., 2017). Another weakness is that they exploit the relationships between textual and visual modalities by conducting a simple concatenation (Gao et al., 2017) or measuring a squared distance loss (Hendricks et al., 2017), which ignores the evolving fine-grained video-sentence interactions. In this paper, a novel model TGN is proposed to deal with the aforementioned limitations for the task of natural sentence grounding in video.

3 Approach

Given a long and untrimmed video sequence V and a natural sentence S, the NSGV task is to localize a video segment $V_s = \{f_t\}_{t=t_b}^{t_e}$ from V, beginning at t_b and ending at t_e, which corresponds to and expresses the same semantic meaning as the given sentence S. In order to perform the grounding, each video is represented as $V = \{f_t\}_{t=1}^{T}$, where T is the total number of frames and f_t denotes the feature representation of the t-th video frame. Similarly, each sentence is represented as $S = \{w_n\}_{n=1}^{N}$, where w_n is the embedding vector of the n-th word in the sentence and N denotes the total number of words.

We propose a novel model, namely Temporal GroundNet (TGN), to tackle the NSGV problem. As illustrated in Figure 2, TGN consists of three modules. 1) Encoder: visual and textual encoders are used to compose the video frame representations and word embeddings, respectively. 2) Interactor: a multimodal interactor learns the frame-by-word interactions between the video and sentence. 3) Grounder: a grounder generates the temporal localization in one single pass. Please note that these three modules are fully coupled together, which can thus be trained in an end-to-end fashion.

3.1 Encoder

With the obtained video frame features $V = \{f_t\}_{t=1}^{T}$ and word embeddings of the sentence $S = \{w_n\}_{n=1}^{N}$, we employ two long short-term memory networks (LSTMs) (Hochreiter and Schmidhuber, 1997) to sequentially process the two different modalities, *i.e.*, video and sentence, independently. Specifically, one LSTM sequentially models the video V, yielding the hidden states $\{\mathbf{h}_t^v\}_{t=1}^{T}$, while the other LSTM processes the sequential words in the sentence S, resulting in its corresponding hidden states $\{\mathbf{h}_n^s\}_{n=1}^{N}$. Owing to natural behaviors and characteristics of LSTMs, both $\{\mathbf{h}_t^v\}_{t=1}^{T}$ and $\{\mathbf{h}_n^s\}_{n=1}^{N}$ can encode and aggregate the contextual evidences (Wang and Jiang, 2016b) from the sequential video frame representations and word embeddings of the sentence, respectively, meanwhile casting aside the irrelevant information.

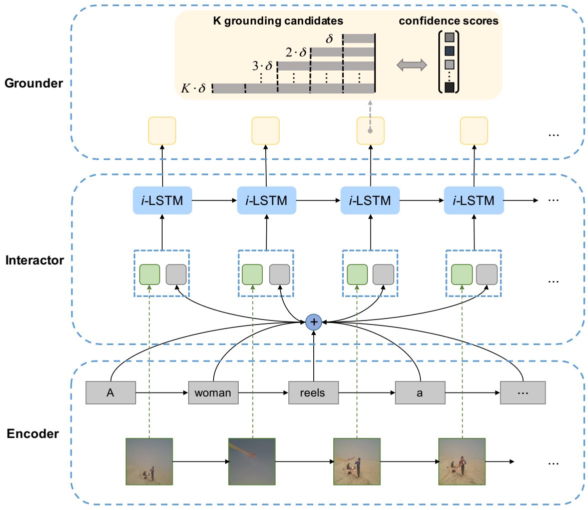

Figure 2: The architecture of our proposed TGN model. TGN consists of three modules. The visual and textural encoders aggregate the contextual evidences from the sequential video frame representations and word embeddings of the sentence, respectively. The multimodal interactor learns the fine-grained frame-by-word interactions between the video and sentence. The grounder yields the temporal grounding of the sentence in the video sequence via one single pass.

3.2 Interactor

Based on the hidden states of the video and sentence yielded from the leveraged encoders, we design a multimodal interactor to perform the frame-by-word interactions between the video and sentence. First, the frame-specific sentence feature is generated through summarizing the sentence hidden states by considering their relationships with the specific video frame at each time step. Afterwards, an interaction LSTM, dubbed i-LSTM, is performed to aggregate frame-by-word interactions.

3.2.1 Frame-Specific Sentence Feature

Directly operating on the clip-level and sentence-level features generated by the encoders cannot well exploit the frame-by-word relationships between video and sentence that evolve over time. Inspired by (Wang and Jiang, 2016a; Feng et al., 2018), we introduce one novel frame-specific sentence feature, which adaptively summarizes the hidden states of the sentence $\{\mathbf{h}_n^s\}_{n=1}^{N}$ with respect to the t-th video frame:

$$\mathbf{H}_t^s = \sum_{n=1}^{N} \alpha_t^n \mathbf{h}_n^s, \tag{1}$$

where $\mathbf{H}_t^s$ denotes the summarized sentence representation specified by the t-th video frame. At each time step t, we utilize the hidden state $\mathbf{h}_t^v$ to selectively attend the words and summarize them accordingly. The attention weight α_t^n encodes the degree to which the n-th word in the sentence is aligned with the t-th video frame. As the processing of video frames proceeds, the attention weights dynamically change regarding to the current video frame. As such, the generated frame-specific sentence features $\{\mathbf{H}_t^s\}_{t=1}^T$ consider the frame-by-word relationships between all the video frames and all the words in the sentence.

As the generation of frame-specific sentence feature is deeply coupled with the following interaction LSTM, we will explain the calculation of the attention weight α_t^n later.

3.2.2 Interaction LSTM (i-LSTM)

In order to accurately ground the sentence in a video, the multimodal interation behaviors between the video and sentence need to be comprehensively modeled. Previous approaches on multimodal interactions were limited to concatenation (Zhu et al., 2016), element-wise product or sum (Gao et al., 2017), and bilinear pooling (Fukui et al., 2016). These methods are not expressive enough since they ignore the evolving fine-grained interactions across video and sentence, particularly the frame-by-word interactions. In this paper, we propose a novel multimodal interaction model, which is realized by LSTM. We term it interaction LSTM (i-LSTM), which sequentially processes the video sequence frame by frame, holding deep interactions with the words in the sentence.

In order to well capture the complicated temporal interactions between the video and sentence, at each time step t, the input of the i-LSTM is formed by concatenating the t-th video hidden state $\mathbf{h}_t^v$ and the t-th frame-specific sentence feature $\mathbf{H}_t^s$ as: $\mathbf{r}_t = \mathbf{h}_t^v \parallel \mathbf{H}_t^s$. $\mathbf{r}_t$ is then fed into the i-LSTM unit to yield the t-th intermediate interaction status between the video and sentence:

$$\mathbf{h}_t^r = i\text{-LSTM}(\mathbf{r}_t, \mathbf{h}_{t-1}^r), \tag{2}$$

where $\mathbf{h}_t^r$ is the yielded hidden state, encoding the fine-grained interactions between the word and video frame. $\mathbf{h}_t^r$ will be further used to perform the grounding process. Due to the inherent properties and characteristics of LSTMs, important cues regarding to grounding up to the current stage will be "remembered", while non-essential ones will be "forgotten".

Now we go back to the generation of attention weight α_t^n in Eq. (1), based on the obtained visual hidden states h_t^v and textual hidden state h_n^s as well as the yielded interaction status h_{t-1}^r in the previous step. The widely used soft-attention mechanism (Xu et al., 2015a; Chen et al., 2017) is used to generate the attention weights in a frame-by-word manner. As aforementioned, the i-LSTM models the evolving frame-by-word interactions between the sentence and video. Therefore, the attention weight between the n-th word $\mathbf{h}_n^s$ and the t-th video frame $\mathbf{h}_t^v$ is determined by not only the content of the video and sentence but also their interaction status. Thus, we design one network to compute the relevance score of one video frame with respect to each word:

$$\beta_t^n = \mathbf{w}^\intercal \tanh(\mathbf{W}^S\mathbf{h}_n^s + \mathbf{W}^V\mathbf{h}_t^v + \mathbf{W}^R\mathbf{h}_{t-1}^r + \mathbf{b}) + c, \tag{3}$$

where vector $\mathbf{w}$, matrices $\mathbf{W}^*$, bias vector $\mathbf{b}$, and bias c are the network parameters to be learned. $\mathbf{h}_{t-1}^r$ is the hidden state of the i-LSTM at $t-1$ time step. The final word-level attention weights are obtained by:

$$\alpha_t^n = \frac{\exp(\beta_t^n)}{\sum_{j=1}^N \exp(\beta_t^j)}. \tag{4}$$

The obtained attention weight α_t^n is thereafter to generate the frame-specific sentence feature as in Eq. (1).

3.3 Grounder

In this section, we introduce the grounder, which works on the yielded interaction status $\mathbf{h}_t^r$ from i-LSTM, to localize the video segment that corresponds to the sentence. Our proposed grounder works in one single pass without introducing overlapping sliding windows, which thus results in a fast runtime. As shown in Figure 2, at each time step t, the grounder efficiently scores a set of K grounding candidates by considering multiple time scales (Buch et al., 2017) that end at time step t. Specifically, we use different K for different datasets, which is determined by the distribution of the lengths of all ground-truth groundings in a certain dataset. To simplify the following discussions, the lengths of K time scales are assumed to be an arithmetic sequence with the common difference δ and all the temporal candidates are sorted by increasing lengths. In other words, the length of the k-th candidate is $k\delta$. Note that all grounding candidates considered at time t have a fixed ending boundary.

Specifically, at each time step t, the grounder will classify each temporal candidate in consideration as a positive grounding or a negative one with respect to the given sentence. Considering multiple time scales, the grounder will generate the confidence scores $\mathbf{C}_t = (c_t^1, c_t^2, ..., c_t^K)$ that correspond to the set of K visual grounding candidates, all ending at time step t. The hidden state $\mathbf{h}_t^r$ generated by i-LSTM at time t, representing the interaction status between the sentence and video sequence up to the current position, is naturally suited to yield the confidence scores for the different time scales ending at time step t. In this paper, the confidence scores, indicating the sentence grounding, are generated by a fully-connected layer with sigmoid nonlinearity:

$$\mathbf{C}_t = \sigma(\mathbf{W}^K \mathbf{h}_t^r + \mathbf{b}_t^r), \tag{5}$$

where $\mathbf{W}^K$ and $\mathbf{b}_t^r$ are the corresponding parameters, and σ denotes the nonlinear sigmoid function.

3.4 Training

The training samples collected in $\mathcal{X}$ for NSGV are video-sentence pairs. Specifically, each video V is temporally associated with a set of sentence annotations: $A = \{(S_i, t_i^b, t_i^e)\}_{i=1}^M$, where M is the number of annotated sentences of the video, and S_i is a sentence description of a video clip, with t_i^b and t_i^e indicating the beginning and ending time in the video. Each training sample corresponds to a ground-truth matrix $\mathbf{y} \in \mathbb{R}^{T \times K}$ with binary entries. We use y_t^k to denote the (t, k)-th entry of the ground-truth matrix. y_t^k is interpreted as whether the k-th grounding candidate at time step t corresponds to the given natural sentence. Concretely, the entry y_t^k is set as 1, indicating that the corresponding video segment (ends at time step t with length $k\delta$) has a temporal Intersection-over-Union (IoU) with (t^b, t^e) larger than a threshold θ. Otherwise y_t^k is set as 0.

For a training pair $(V, S) \in \mathcal{X}$, the objective at time step t is given by a weighted binary cross entropy loss $\mathcal{L}(t, V, S)$:

$$-\sum_{k=1}^{K} w_0^k y_t^k \log c_t^k + w_1^k (1 - y_t^k) \log(1 - c_t^k), \tag{6}$$

where the weights w_0^k and w_1^k are calculated according to the frequencies of positive and negative samples in the training set with length $k\delta$. y_t^k is the ground-truth value and c_t^k denotes the prediction results by our proposed model.

Our TGN backpropagates at every time step t to learn all the parameters of the fully-coupled three modules: encoder, interactor, and grounder. The objective of all training video-sentence pairs $\mathcal{X}$ is defined as:

$$\mathcal{L}_{\mathcal{X}} = \sum_{(V,S)\in\mathcal{X}} \sum_{t=1}^{T} \mathcal{L}(t, V, S). \tag{7}$$

3.5 Inference

During the inference stage, given a testing video V and a sentence S, the textual and visual encoders first generate hidden states for each word and video frame, respectively. Then, the interactor sequentially goes through the video frame by frame to yield the frame-by-word interaction status. At each position t, a K-dimensional score vector $\mathbf{C}_t$ is generated by the grounder. Therefore, after processing the last frame in the video, a $T \times K$ score matrix is obtained for the whole video, with the (t, k)-th entry in the matrix indicating the probability that the video segment ended at position t with length $k\delta$ in video V corresponds to sentence S. Eventually, the evaluation is reduced to a ranking problem over all the grounding candidates based on the generated scores.

4 Experiments

In this section, we evaluate the effectiveness of our proposed TGN on the NSGV task. We begin by describing the datasets used for evaluation, followed by the introduction of the experimental settings including the baselines, configurations, as well as the evaluation metrics. Afterwards, we demonstrate the effectiveness of TGN by comparing with the state-of-the-art approaches and efficiency through a runtime test.

4.1 Datasets

We experiment on three publicly accessible datasets: DiDeMo (Hendricks et al., 2017), TACoS (Regneri et al., 2013), and ActivityNet Captions (Fabian Caba Heilbron and Niebles, 2015). These datasets consist of videos as well as their associated temporally annotated sentences.

DiDeMo[2] consists of 10464 25-50 second long videos. The same split provided by (Hendricks et al., 2017) is used for a fair comparison, with 33008, 4180, and 4022 video-sentence pairs for training, validation, and testing, respectively.

---

[2] `https://goo.gl/JpbAhg`.

TACoS[3] consists of 127 videos selected from the MPII Cooking Composite Activities video corpus (Rohrbach et al., 2012). The same split as in (Gao et al., 2017) is used, consisting of 10146, 4589, and 4083 video-sentence pairs for training, validation, and testing, respectively.

ActivityNet Captions[4] consists of $19,209$ videos amounting to 849 hours. The public split is used for our experiments, which has 37421, 17505, and 17031 video-sentence pairs for training, validation, and testing, respectively.

4.2 Experimental Settings

4.2.1 Baselines

We compare our proposed TGN against the following two state-of-the-art models, specifically, the MCN (Hendricks et al., 2017), CTRL (Gao et al., 2017), visual-semantic alignment with LSTM (VSA-RNN) (Karpathy and Li, 2015), and visual-semantic alignment with skip thought vector (VSA-STV) (Kiros et al., 2015). For fair comparisons, we compare the results of MCN on DiDeMo and the results of CTRL, VSA-RNN, VSA-STV on TACoS reported in their papers.

4.2.2 Evaluation Metrics

A grounding of one natural sentence in a video is considered as "correct" if its temporal IoU with the ground-truth boundary is above a threshold θ. To be consistent with the baselines, we adopt R@N, IoU=θ, and mean IoU (mIoU) as our evaluation metrics. R@N, IoU=θ represents the percentage of testing samples which have at least one of the top-N results with IoU larger than θ. mIoU means the average IoU over all testing samples.

4.2.3 Configurations

Generally, the video frame features are usually extracted with a time resolution. For the videos in DiDeMo and TACoS, we sample every 5 second as done by (Hendricks et al., 2017). As the videos in DiDeMo are 25-30 second long, the video feature length is reduced to 6. For videos in ActivityNet Captions, we sample every second. To extract visual features, we consider both appearance and optical flow features. Specifically, we study four widely-used visual features: VGG16 (Simonyan and Zisserman, 2014), C3D (Tran et al., 2015), Inception-V4 (Szegedy et al., 2017), and optical flow (Wang et al., 2016). Please note that when comparing with specific baseline methods, we use the same features as baseline methods, specifically, VGG16 and optical flow for MCN and C3D for CTRL, VSA-RNN, and VSA-STV.

Table 1: Performance comparisons of different methods on DiDeMo. The best performance for each metric entry is highlighted in boldface.

Method	R@1 IoU=1	R@5 IoU=1	mIoU
MFP	19.40	66.38	26.65
MCN-VGG16	13.10	44.82	25.13
MCN-Flow	18.35	56.25	31.46
MCN-Fusion	19.88	62.39	33.51
MCN-Fusion+TEF	28.10	78.21	41.08
TGN-VGG16	24.28	71.43	38.62
TGN-Flow	27.52	76.94	42.84
TGN-Fusion	**28.23**	**79.26**	**42.97**

For sentences, we tokenize each sentence by Stanford CoreNLP (Manning et al., 2014) and use the 300-D word embeddings from GloVe (Pennington et al., 2014) to initialize the models. The words not found in GloVe are initialized as zero vectors. The hidden state dimensions of all LSTMs (including the video, sentence, and interaction LSTMs) are set as 512. We use the Adam (Kingma and Ba, 2014) optimizer with β_1 = 0.5 and β_2 = 0.999. The initial learning rate is set to 0.001. We train the network for 200 iterations, and the learning rate is gradually decayed over time. The mini-batch size is set to 64.

4.3 Experimental Results and Analysis

4.3.1 Comparisons with State-of-the-Arts

Experiments on DiDeMo. Table 1 illustrates the performance comparisons on the DiDeMo dataset. In addition to MCN, we also compare with the baseline Moment Frequency Prior (MFP) in (Hendricks et al., 2017), which selects segments corresponding to the positions of videos in the training dataset with most annotations. First, TGN with different features can significantly outperforms the "prior baseline" MFP, which retrieves segments corresponding to the most common start and end points in the dataset. Second, it can be observed that with the same visual features, specifically VGG16 and optical flow, TGN significantly outperforms MCN. And the performance of TGN with optical flow is better than that with VGG16. One possible reason is that the videos in DiDeMo are relatively short, which only contain a single event. In such a case, the action information plays

[4] `https://goo.gl/N355bG`.

Table 2: Performance comparisons of different methods on TACoS. The best performance for each metric entry is highlighted in boldface.

Method	R@1 IoU=0.5	R@1 IoU=0.3	R@1 IoU=0.1	R@5 IoU=0.5	R@5 IoU=0.3	R@5 IoU=0.1
VSA-RNN	4.78	6.91	8.84	9.10	13.90	19.05
VSA-STV	7.56	10.77	15.01	15.5	23.92	32.82
CTRL-C3D	13.30	18.32	24.32	25.42	36.39	48.73
TGN-C3D	**18.90**	**21.77**	**41.87**	**31.02**	**39.06**	**53.40**

a more critical role. This finding is also consistent with (Hendricks et al., 2017). By fusing the results obtained by VGG16 and optical flow together, the performance can be further boosted, as demonstrated by TGN-Fusion and MCN-Fusion. Third, MCN introduces the temporal endpoint feature (TEF) as prior knowledge, which indicates when a segment occurs in a video. With TEF, the performance of MCN can be significantly improved. However, it is still inferior to our proposed TGN.

MCN is designed as an enumeration-based approach. Each video in the DiDeMo dataset is split into six five-second chunks which are considered as the time unit for localization. Therefore, in total there are only $\mathrm{C}_7^2 = 7 \times 6/2 = 21$ different ways of localization for DiDeMo videos. Therefore, although MCN can be effectively applied to videos with several chunks due to the small search space, it is not practical for untrimmed long videos. In the Section 4.3.3, we will evaluate and compare the efficiencies of MCN, CTRL, and our proposed TGN.

Experiments on TACoS. Table 2 illustrates the experimental results on TACoS. First, it can be observed that CTRL performs much better than VSA-RNN and VSA-STV. The reasons lie in twofold (Gao et al., 2017). On one hand, CTRL utilizes a multilayer alignment network to learn better alignment. On the other hand, VSA-RNN and VSA-STV do not encode temporal context information of video. Second, with the same visual feature, specifically C3D, TGN-C3D significantly outperforms CTRL-C3D. This is due to the fact that TGN exploits not only the contextual information but also the fine-grained interaction behaviors. More concretely, TGN considers the frame-by-word correlations by introducing an attentive combinations of the words in the sentence, where each weight encodes the degree to which the word is aligned with each specific frame. This mechanism is beneficial to capturing the informative semantics in the sentences for alignment.

Table 3: Performance comparisons of different visual features on ActivityNet Captions. The best performance for each metric entry is highlighted in boldface.

Feature	R@1 IoU=0.5	R@1 IoU=0.3	R@1 IoU=0.1	R@5 IoU=0.5	R@5 IoU=0.3	R@5 IoU=0.1
C3D	27.93	43.81	69.59	**44.20**	54.56	78.66
VGG16	23.90	42.24	65.76	40.17	51.82	76.21
Inception-V4	**28.47**	**45.51**	**70.06**	43.33	**57.32**	**79.10**

Table 4: Ablation studies on TACoS. The best performance for each metric entry is highlighted in boldface.

Feature	R@1 IoU=0.5	R@1 IoU=0.3	R@1 IoU=0.1	R@5 IoU=0.5	R@5 IoU=0.3	R@5 IoU=0.1
NA	5.53	7.67	24.23	15.20	18.94	41.25
NM	13.89	18.60	41.41	26.60	31.74	47.70
TGN	**18.90**	**21.77**	**41.87**	**31.02**	**39.06**	**53.40**

Experiments on ActivityNet Captions. Besides the two benchmarks, we also evaluate our model on the ActivityNet Captions dataset. Different CNNs are used to encode video visual information. Specifically, we consider VGG16, C3D, and Inception-V4. The results are included in Table 3. First, our proposed TGN can perform effectively on long untrimmed videos. Second, Inception-V4 performs generally better than VGG16 and C3D, which is consistent with the finding in (Canziani et al., 2016). Therefore, more powerful visual representations of video features will undoubtedly improve the the performance of our proposed TGN on the NSGV task.

Some qualitative results of our proposed TGN on ActiveityNet Captions dataset is illustrated in Figure 3. It can be observed that with different visual features, different grounding results are obtained. For the first and second examples, TGN with VGG16 and Inception-V4 generates more accurate groundings than that with C3D, while TGN with C3D yields more accurate grounding results for the third example. More specifically, our proposed TGN with VGG16 and Inception-V4 can well identify the visual information related with the sentence, i.e. "`A man in a red shirt claps his hands`".

4.3.2 Effect of Frame-by-Word Attention

We examine the effect of the frame-by-word attention in interactor. We ablate TGN into two other methods. 1) NA: There is no attention layer in this model. After obtaining the sequential hidden states of the sentence, mean pooling is used to generate the representation for the whole sentence.

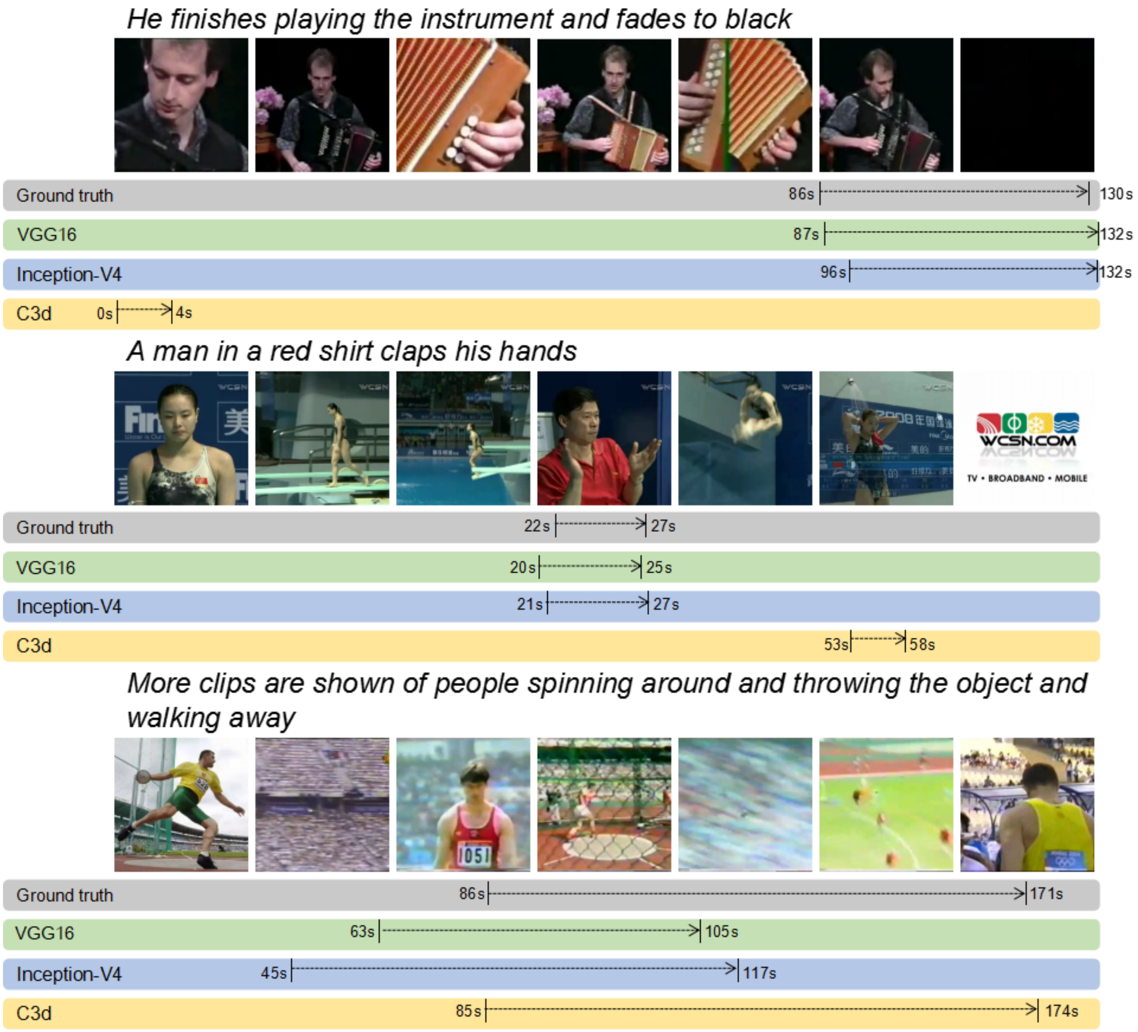

Figure 3: The qualitative grounding results of our TGN model on the ActiveityNet Captions dataset with different visual features.

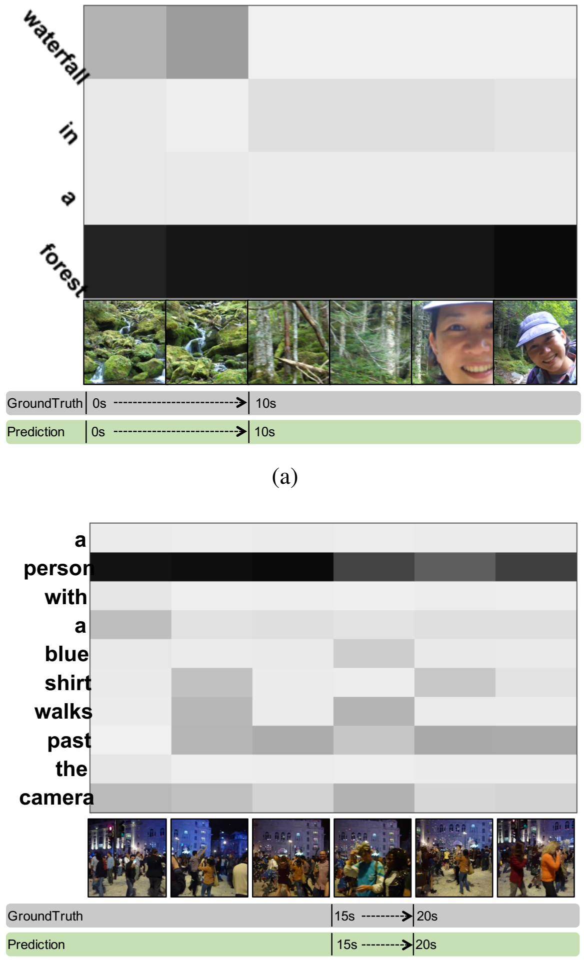
Then the generated representation is concatenated with video representation, based on which the scores for multiple grounding candidates are predicted. 2) NM: The idea of generating frame-specific sentence feature is still reserved in the NM model. The difference between NM and TGN is that there is no interaction LSTM in NM. Specifically, when calculating the attention weight for each word as in Eq. (3), the hidden state $\mathbf{h}^r_{t-1}$ indicating the interaction status is not incorporated.

The quantitative results are displayed in Table 4. First, when the attention mechanism is applied (NM), the performance is improved as compared with utilizing mean pooling (NA) for sentence features. The better performance demonstrates that our assumption about the evolving frame-by-word correlations between two modalities is reasonable. This also indicates that it is necessary to discriminate the contribution of each word in a sentence to perform the NSGV task. Second, utilizing the interaction LSTM module (TGN) achieves better performance than simply concatenating the video representation and the attentive sentence representation (NM). This result indicates that the interaction LSTM yields better interaction status between these two modalities, which can thereby benefit the final grounding.

We provide some qualitative examples in Figure 4 for a better understanding of the frame-by-word attention. Meanwhile, the grounding results yielded by TGN-Fusion (considering both VGG16 and optical flow) are also illustrated. This experiment is designed to verify whether the frame-by-word attention mechanism in interactor is useful to highlight the representative concepts in the sentence. The attention weights α for two testing samples in DiDeMo are illustrated in Figure 4, where the darker the color is, the larger



(a)

(b)

Figure 4: Visualization results on frame-by-word attention. The darker the color is, the larger its represented attention value is.

Table 5: Efficiency comparison in terms of frame per second.

	CTRL	MCN	TGN
FPS	562	286	1,363

the attention weight is. It can be observed that some words well match the frames. For example, in Figure 4 (a), the concept “`forest`” appears across all the video frames presenting an evenly distributed attention weights, while the other concept “`waterfall`” only presents in the first two frames. In addition to nouns, the adjective “`blue`” in Figure 4 (b) also receives relatively higher attention weights in relevant frames. Lastly, for stop words like “`a`”, “`the`” and “`in`”, their attention weights, which are very small, also present an even distribution.

4.3.3 Efficiency

We evaluate the efficiency of our proposed TGN, by comparing its runtime with MCN and CTRL on a Tesla M40 GPU. The efficiency is measured by frames per second (FPS) as shown in Table 5. Please not that the feature extraction time is excluded. It can be observed that our TGN model achieves much faster processing speeds, with 1,363 fps vs. 562 and 286 for CTRL and MCN, respectively. The reason mainly attributes to that the proposed TGN only process each video in one single pass without processing overlapped sliding windows.

5 Conclusion

In this paper, we focused on the task of natural sentence grounding in video that is believed to offer a comprehensive understanding of bridging computer vision and natural language processing. Towards this task, we proposed an end-to-end Temporal GroundNet (TGN) by incorporating the evolving fine-grained frame-by-word interactions across video-sentence modalities to generate a visual grounding tailored to each given natural sentence. Moreover, TGN performs efficiently, which only needs to process the video sequence in one single pass. Extensive experiments on three real-world datasets clearly demonstrate the effectiveness and efficiency of the proposed TGN.

Abstract

We introduce PreCo, a large-scale English dataset for coreference resolution. The dataset is designed to embody the core challenges in coreference, such as entity representation, by alleviating the challenge of low overlap between training and test sets and enabling separated analysis of mention detection and mention clustering. To strengthen the training-test overlap, we collect a large corpus of 38K documents and 12.5M words which are mostly from the vocabulary of English-speaking preschoolers. Experiments show that with higher training-test overlap, error analysis on PreCo is more efficient than the one on OntoNotes, a popular existing dataset. Furthermore, we annotate singleton mentions making it possible for the first time to quantify the influence that a mention detector makes on coreference resolution performance. The dataset is freely available at `https://preschool-lab.github.io/PreCo/`.

1 Introduction

Coreference resolution, identifying mentions that refer to the same entities, is an important NLP problem. Resolving coreference is critical for many downstream applications, such as reading comprehension, translation, and text summarization. Identifying a mention depends not only on its lexicons but also its contexts, and requires representations of all the entities before the mention. This is still a challenging task for the approaches based on the cutting-edge word2vec-like lexical representation. For example, it is hard to identify the mention "he" between two entities "Tom" and "Jerry" because they have almost the same word embeddings.

A number of datasets have been proposed to study the coreference resolution problem, such as MUC (Hirschman and Chinchor, 1997), ACE (Doddington et al., 2004), and OntoNotes (Pradhan et al., 2012). The most popular one is OntoNotes, and recent work on coreference resolution (Clark and Manning, 2016a,b; Lee et al., 2017; Peters et al., 2018) evaluated their models on it. Other datasets were rarely studied after OntoNotes was published.

Previous work (Sadat Moosavi and Strube, 2017) suggests that the overlap between training and test sets makes significant impact on the performance of current coreference resolvers. In OntoNotes, which has relatively low training-test overlap, this impact is mixed together with the core challenges of coreference resolution. For example, consider the failure of referencing "them" to "the wounded" in "..., the wounded were carried off so fast and it was difficult to count them". It is hard to tell whether the algorithm can succeed if the currently low-frequency phrase "the wounded" has not been seen enough times in the training set. From a machine learning perspective, high overlap is needed to ensure that the training and test datasets have similar statistics.

Another limitation of OntoNotes is that it only has annotations for non-singleton mentions, while singleton mentions are not annotated. Most of the algorithms for coreference resolution have two steps: mention detection and mention clustering (Wiseman et al., 2016; Clark and Manning, 2016a,b). The lack of singleton mention annotations makes training and evaluation of mention detectors more difficult.

To address both limitations of OntoNotes, we build a new dataset, PreCo. To alleviate the negative impact of low training-test overlap, we restrict the data domain and collect a sufficient amount of data to achieve a relatively high training-test overlap. Restricting the data domain is a common way to enable better studies of unsolved NLP tasks, such as language modeling (Hill et al., 2015) and

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 172–181
Brussels, Belgium, October 31 - November 4, 2018.

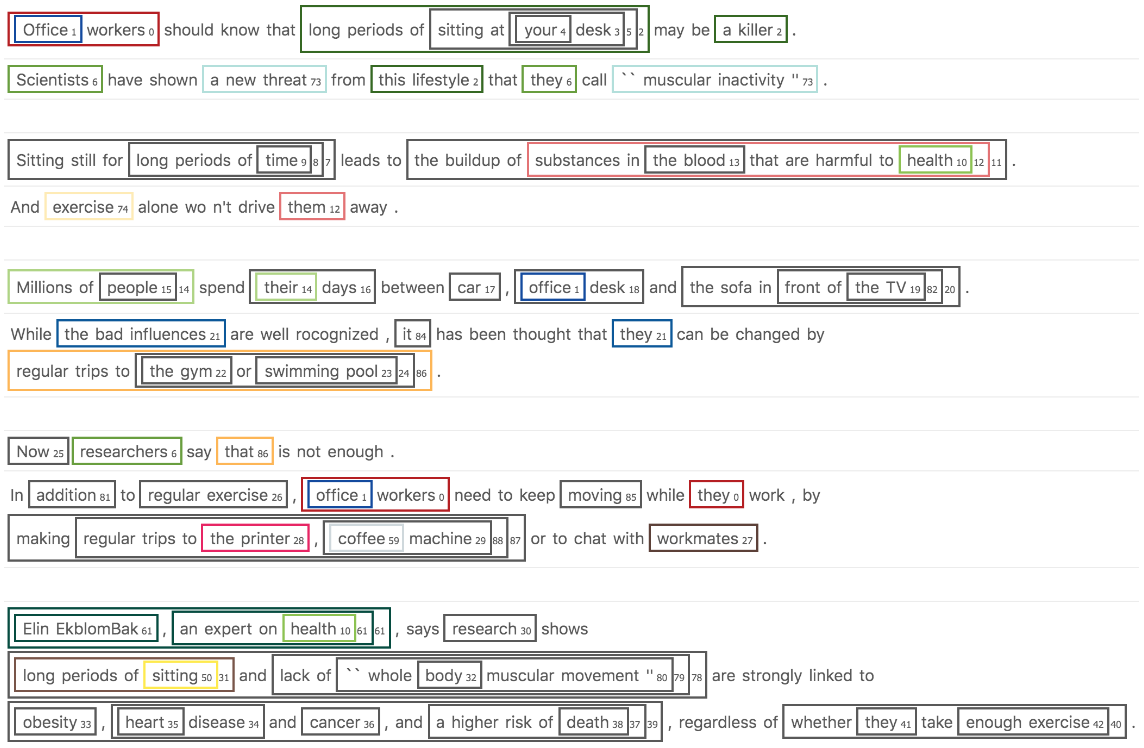

Figure 1: An Example from PreCo. In the example, mentions are indicated by boxes, and mention clustering is indicated by the subscripted numbers. If two mentions have the same number, they refer to the same entity.

visual question answering (Johnson et al., 2017).

We select our data from English reading comprehension tests for middle and high school Chinese students, which has several advantages. On one hand, the vocabulary size is appropriate. The English vocabulary of a typical Chinese high school student contains about 3000 commonly used words. This is similar to the vocabulary of a preschool English-speaking child (Wikipedia, 2018). Most words from the English tests are in this limited vocabulary. On the other hand, it is practical to collect enough data of this type from the Internet. With 12.5M words, PreCo is about 10 times larger than OntoNotes. Large scale datasets, e.g. ImageNet (Deng et al., 2009), SQuAD (Rajpurkar et al., 2016), have played an important role for driving computer vision and NLP forward.

We use the rate of out-of-vocabulary (OOV) words between training and test sets to measure their overlap. PreCo shows much higher training-test overlap than OntoNotes by having an OOV rate of 0.8%, which is about 1/3 of OntoNotes's 2.1%. At the same time, PreCo presents a good challenge for coreference resolution research since its documents are in the open domain and have various writing styles. We test a state-of-the-art system (Peters et al., 2018) on PreCo and get an F1 score of 81.5. However, a modest human performance (87.9, which will be described in 4.1) is much higher, verifying there remain challenges.

To help training and evaluation of mention detection, we annotate singleton mentions in PreCo. Besides singleton mentions, we follow most other annotation rules of OntoNotes to label the new dataset. We show that in a state-of-the-art coreference resolution system (Peters et al., 2018), we can improve the model performance from 77.3 to 81.6 F1 on a training set of 2.5K PreCo documents by using an oracle mention detector, and the remaining gap of 18.4 F1 to the perfect 100 F1 can only be reduced by improving mention clustering. This indicates that future work should concern more about mention clustering than mention detection.

The advantages of our proposed dataset over existing ones in coreference resolution can be summarized as follows:

- Its OOV rate is about 1/3 of OntoNotes.
- It has about 10 times larger corpus size than OntoNotes.
- It has annotated singleton mentions.

2 Related Work

Existing Datasets. The first two resources for coreference resolution study were MUC-6 and MUC-7 (Hirschman and Chinchor, 1997). The MUC datasets are too small for training and testing, containing a total of 127 documents with 65K words. The next standard dataset was ACE (Doddington et al., 2004) which has a much larger corpus of 1M words. But its annotations are restricted to a small subset of entities and are less consistent. OntoNotes (Pradhan et al., 2012) was presented to overcome those limitations. Machine learning based approaches, especially deep learning based, benefitted from this well annotated and large-scale (1.3M words) dataset. Continuous research on OntoNotes over the past 6 years improved performance by 10 F1 score (Durrett and Klein, 2013; Peters et al., 2018). Datasets after OntoNotes, such as WikiCoref (Ghaddar and Langlais, 2016), are seldom studied. Therefore, we mainly compare PreCo with OntoNotes in this paper. With a much larger scale, PreCo builds on the advantages of OntoNotes. Some of these existing datasets also have corpus in other languages, but we just focus on coreference resolution in English.

Out-of-domain Evaluation. (Sadat Moosavi and Strube, 2017) show that if coreference resolvers mainly rely on lexical representation, as it is the case in state-of-the-art ones, they are weak at generalizing to unseen domains. Even in the seen domains, the low degree of overlap for non-pronominal mentions between the training and test sets cause serious deterioration of coreference resolution performance. As a conclusion, (Sadat Moosavi and Strube, 2017) suggested that out-of-domain evaluation is a must in the literature. But we think the problem can be relieved by expanding the training data for the target domains to increase overlap, so that the field can pay more attention to the other challenges of coreference resolution.

Data Simplification. Many simplified datasets were built to enable better study on unsolved tasks. Such simplifications can guide researchers to the core problems and make data collection easier. For example, (Hill et al., 2015) introduced the Children's Book Test to distinguish the task of predicting syntactic function words from that of predicting low-frequency words for language model. The dataset helped them to develop a generalizable model with explicit memory representations. The reading comprehension dataset SQuAD (Rajpurkar et al., 2016) imposes the constraint that every answer is always a segment of the input text. This constraint benefits both labeling and evaluation of the dataset, which has significant influences in terms of benchmarks. Similarly, the reinforcement learning literature develops algorithms by studying games instead of the real world environment (Mnih et al., 2013). We hope that, with high training-test overlap, PreCo can serve as a valuable resource for research on coreference resolution.

3 Dataset Creation

We discuss the data collection and annotation in this section. The overview of the process is shown in Figure 2.

3.1 Corpus Collection

We crawl English tests from several web sites. The web pages often contain the full English tests in a lot of formats. We build an annotation website and hire annotators to manually extract the relevant contents. We have a total of 80 part-time Chinese annotators, most of whom are university students. They are required to have a minimum score in standard English tests. During annotation training, the annotators read the annotation rules, and take several practice tasks, in which they annotate sample articles, and their results are compared with ground truth side by side for them to study. Before formal annotation, the annotators will need to pass an assessment.

Some data cleaning is done during annotation, such as unifying paragraph separators, etc. The questions with answers in these tests are also extracted for future research. Finally, we use NLTK's sentence and word tokenizer (Bird et al., 2009) to tokenize the crawled text.

In addition to having annotators manually clean the data, we also use heuristic rules to further clean the data. For example, in some cases the whitespaces between two words are missing. We use a spell checker to identify and correct most of these cases. We also use heuristic rules to fix some sentence partition boundaries, e.g., to make sure opening quotes are placed at the beginning of a sentence, instead of being wrongly placed at the end of a previous sentence (closing quotes are handled similarly).

In addition to the crawled data, we include the

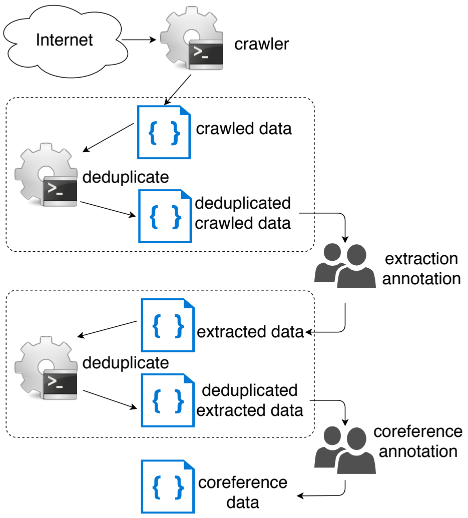

Figure 2: Overview of dataset creation.

documents from the RACE dataset (Lai et al., 2017). RACE is a reading comprehension dataset from English tests for middle and high school Chinese students, which has similar types of data sources as PreCo. About 2/3 of PreCo documents are from the RACE dataset.

Since documents are from several data sources, we want to remove duplicated documents, and documents that are not exactly the same but have a high rate of repetitions. The similarity of two documents D_1 and D_2 is estimated using the bag-of-words model. Assume S_1 and S_2 are bag-of-words multisets to represent the two documents. The similarity between D_1 and D_2 is defined as $\max(\frac{|S_1 \cap S_2|}{|S_1|}, \frac{|S_1 \cap S_2|}{|S_2|})$. If the similarity between two documents are larger than 0.9, we remove the shorter one. This process is referred as *deduplicate* in Figure 2.

3.2 Data Partition

The dataset has a total of 38K documents. We use 500 documents for the development set, 500 documents for the test set, and the rest 37K documents for the training set. The development and test documents were randomly selected from RACE's development and test sets.

3.3 Coreference Annotation and Refinement

We manually annotate coreferences on these documents. The annotation rules are slightly different from OntoNotes (Pradhan et al., 2012). We modify some of the rules to make the definition of coreference more consistent and easier to be understood by the annotators. The major differences are listed in Table 1. Figure 1 shows an example document in PreCo with annotations.

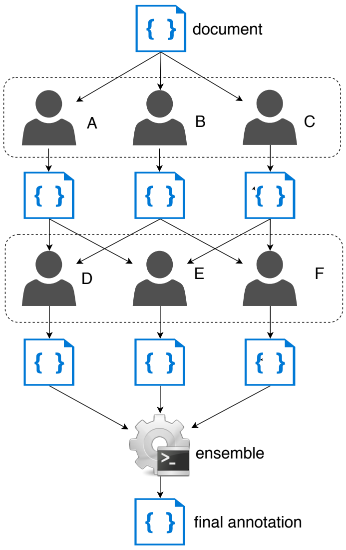

Figure 3: Process of annotation refinement. A document is firstly annotated by 3 annotators A, B, and C, independently. Then another annotator D merges annotations from A and B. Similarly, annotator E merges annotations from A and C, and annotator F merges annotations from B and C. Finally, annotations from D, E and F are merged using an ensemble algorithm.

Good quality control of annotation is essential, since the rules are complicated and coreference resolution depends on meticulous reading of the whole document over and over. We found that annotators get low recall and insufficient precision mainly because of negligence, as opposed to the lack of annotation rules or other ambiguities. For example, two co-referred mentions could be far apart and require careful searches, and an annotator may miss it. Therefore we further refine annotations as shown in Figure 3. Annotators can think about the complicated inconsistent cases when merging annotations, and the voting process will fix some errors while preserving the mentions and coreferences that are found only once by individual annotators.

The quality of different annotation processes is shown in Table 2. OntoNotes took 2 individual annotations for each document and got an adjudicated version based on them. Taking the adjudicated version as ground truth, the average MUC score (Vilain et al., 1995) [1] of individual annota-

---

[1] MUC score is one of the metrics to evaluate the quality of coreference resolution.

Type	Example	OntoNotes	PreCo
verbs	Sales [grew] 10%. [The growth] is exciting.	Verbs can be coreferred.	Usually, verbs cannot be coreferred. Certain gerunds can.
generic mentions	[Parents] are usually busy. [Parents] should get involved.	Generic mentions can only be coreferred by pronouns.	Generic mentions can be coreferred directly.
non-proper modifiers	[Wheat] is important. [Wheat] fields are everywhere.	Non-proper modifiers cannot be coreferred.	Non-proper modifiers can be coreferred as generic mentions.
copular structures	[John] is [a good teacher].	The referent and the attribute cannot be coreferred.	The referent and the attribute can be coreferred.
appositives	[[John]$_a$, [a linguist I know]$_b$]$_c$, ...	Sub-spans are not coreferred with the whole-span. a and b are not coreferent with c.	Sub-spans are coreferred with the whole-span. a and b are coreferred with c.
misc.	The [U.S.] policy ... [Secretary of State] [Colin Powell] ...	Nationality acronyms and job titles in appositives cannot be coreferred.	Nationality acronyms and all job titles can be coreferred.

Table 1: Major differences of annotation rules between PreCo and OntoNotes. The annotation rules of OntoNotes are described in (OntoNotes Guidelines)

tions is 89.6, and the inter-annotator MUC score is 83.0. The corresponding numbers for PreCo are 85.3 and 77.5. The actual gap of individual annotation quality between OntoNotes and PreCo is not as large as it looks like. Note that, OntoNotes's two individual coreference annotations of each document are based on the same syntactic annotations of the document, so they could be more consistent than PreCo's which are annotated on raw text. Therefore, if we want to fairly compare PreCo with OntoNotes, we should take into account OntoNotes's inter-annotator consistency of syntactic parsing annotations. As it has a rough upper bound of 98.5 F1 score according to the reannotation of English Treebank on OntoNotes by the principal annotator a year after the original annotation (Weischedel et al., 2011), we could infer that the individual annotation quality of PreCo is quite close to OntoNotes.

Labeling the whole dataset is costly because each annotation from scratch or comparison takes an average of about 10 minutes. Prompts from an algorithm do not help since they do not speed up the annotation much but instead introduce biases. We observed some biases when using an algorithm to help annotation. We have two models, M_1 and M_2, and we have a test set T which is annotated manually, and a test set T' which uses prompts from model M_1 to help annotation. While M_1 and M_2 have similar performance on T, M_1's performance is much higher than M_2's on T', which shows the biases.

Because of limited annotation resources, we have only finished the refinements on the development and test sets with the process shown in Figure 3. We refine the training set annotations as follows: for each document, two annotators annotate it separately, and a third annotator compares and merges the two annotations. We use a training set of 2.5K documents to quantify the impact of this annotation refinement to model performance. Table 3 shows the model performances of the training set that is annotated once, and the training set of the merged annotation. The performance difference is quite significant. Furthermore, the difference is consistent with Table 2: the "AB-merge" model has a similar precision as the "Once" model, but it has a much higher recall. It indicates that a further refinement of the training set such as DEF-voting could be essential. A more interesting question is: how to make the definition of coreference more consistent and executable? We leave it as future work.

Process	Avg. Prec	Avg. Rec	Avg. F1
Once	87.3	71.7	78.7
ABC-voting	93.5	76.1	83.9
AB-merge	87.5	88.3	87.9
DEF-voting	100.0	100.0	100.0

Table 2: Annotation quality. DEF-voting is taken as the ground truth to evaluate other annotation processes. The annotation "AB-merge" is merged by annotator G, who is different from D, E and F.

Annotation	Avg. Prec	Avg. Rec	Avg. F1
Once	79.3	69.1	73.9
AB-merge	78.1	76.5	77.3

Table 3: The annotation quality's impact on model performance. Each row shows the development set performance of the EE2E-Coref model (training details in Section 4.1) trained by data of different annotation quality. Each training set contains 2.5K documents. In the training set "Once", each document is annotated by one annotator. In the training set "AB-merge", each document is annotated by two annotators independently, and the annotations are compared and merged by a third annotator.

3.4 Dataset Properties

Table 4 shows some properties of OntoNotes and PreCo. As intended, PreCo has a lower OOV rate than OntoNotes. For a training set with vocabulary $\mathcal{V}$ and a test set with n tokens $[t_1, t_2, ..., t_n]$, ignoring the tokens with non-alphabetic characters, the OOV rate is defined by:

$$\frac{\sum_i o(t_i)}{n}, \text{where } o(t_i) = \begin{cases} 0 & \text{if } t_i \in \mathcal{V} \\ 1 & \text{if } t_i \notin \mathcal{V} \end{cases}$$

The OOV rate can be extended to the rate of low-frequency words which also indicates the training-test overlap, by simply replacing $\mathcal{V}$ in the definition above with the non-low-frequency vocabulary of the training set. We find that the OOV rate is consistent to the rates of low-frequency words in different levels. So we use the OOV rate for convenience.

In PreCo, about 50.8% of the mentions are singleton mentions. Figure 4 shows the distribution of cluster sizes within non-singleton clusters. The distribution is similar between OntoNotes and PreCo.

4 Analysis

To verify our assumption that PreCo embodies the core challenges of coreference, we evaluate a strong baseline coreference resolver on it. Specifically, we (i) estimate the room for improvement of the baseline system to show that the dataset is challenging, (ii) study the impact of training-test overlap to model performance and error analysis to show the advantages of PreCo, and (iii) quantitatively evaluate the mention detector to understand the bottlenecks of the coreference resolution system.

Property	OntoNotes	PreCo
Training documents	2.8K	37K
Training tokens	1.3M	12.2M
Dev-test documents	0.7K	1K
Dev-test tokens	0.3M	0.3M
Tokens per document	467	330
OOV rate	2.1%	0.8%
Non-singleton mentions		
Mention length	2.29	2.02
Mention density	0.12	0.16
Cluster size	4.40	4.49
Cluster density	0.027	0.035
Singleton mentions		
Mention length	N/A	3.32
Mention density	N/A	0.16
Singleton mention rate	N/A	50.8%

Table 4: Properties of OntoNotes and PreCo. The mention (cluster) density is defined by: number of mentions (clusters) / number of tokens.

4.1 Baseline Performance

We use the end-to-end neural coreference resolver, E2E-Coref (Lee et al., 2017), enhanced by the deep contextualized word representations (Peters et al., 2018) as the baseline system, and we refer to this system as EE2E-Coref. This is the state-of-the-art model on OntoNotes, achieving a test average F1 score of 70.4, which is the main evaluation metric for coreference resolution. The metric is computed by averaging the F1 of MUC, B^3, and $CEAF_{\phi 4}$, which are three metrics of coreference resolution that have different focuses.

Our implementation EE2E-Coref[2] gets 81.5 Avg. F1 score on PreCo. We follow the setting of most hyperparameters on OntoNotes and do grid-search for the decay parameter of the learning rate and the size of the hidden layers on the development set, since these two hyperparameters are relatively sensitive to the scale of the training data. The F1 score increment from OntoNotes to PreCo is probably due to the higher overlap between the training and test sets in PreCo.

---

[2] It gets an F1 score of 70.0±0.3 on OntoNotes, slightly lower than the F1 score reported in the original paper.

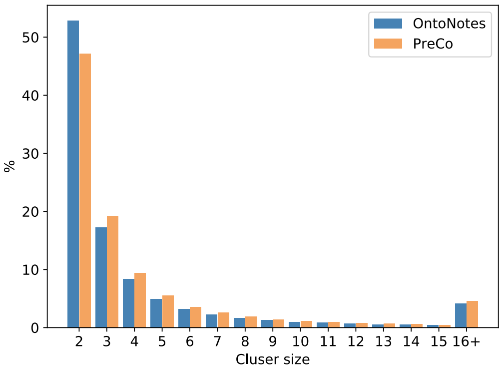

Figure 4: Distribution of cluster sizes within non-singleton clusters. We ignore singleton clusters in this figure so that it is easier to compare between OntoNotes and PreCo.

[<His father> and he] get off the car. [They] find the old man lying near the taxi. The banana skin is near him. The old man looks at [them] and says, "Teach [**your**] child to throw the banana skin to the right place!"
He gave his last few coins to [a beggar], but then he saw <another one>, and forgot that he did not have any money. He asked <the man> if <he> would like to have lunch with him, and [**the beggar**] accepted, so they went into a small restaurant and had a good meal.
[Holmes] and <Dr. Watson> went on a camping trip. After a good meal and a bottle of wine, they lay down in a tent for the night and went to sleep. Some hours later, Holmes woke up and pushed [**his friend**].

Table 5: Error cases of EE2E-Coref on PreCo. Each bold mention is incorrectly referred to the entity in []s. The mentions of its gold entity are in <>s.

We demonstrate three typical error cases made by EE2E-Coref on PreCo in Table 5. Coreference resolution in these cases requires good understanding of multiple sentences, which is an open problem in NLP. A capable entity representation for "them", "another one" or "Dr. Watson" may help to resolve these error cases. We also compare the performance of EE2E-Coref with human performance to estimate the room for improvement on PreCo. As described in Section 3.4, human annotators get low recall mostly due to negligence. So we use the AB-merge annotation to estimate human's ability on coreference resolution. The gap of performance between model and human is 6.4 F1 score, from 81.5 to 87.9. The actual gap is larger, since AB-merge still has some missed coreference annotations due to negligence. This shows that the dataset is challenging and encourages future research. The error cases show the challenges as well.

Note that PreCo is not a general purpose dataset. Our motivation of designing PreCo is to make it easier to improve coreference resolution algorithms, e.g., to make error analysis easier. It is not a goal of PreCo to generalize well on corpus from other domains. Furthermore, we find that there are a certain amount of annotation errors in the development and test sets. We suggest that researchers working on PreCo should be careful about these errors, especially after a model gets F1 score beyond 90.0.

4.2 Impact of Training-test Overlap

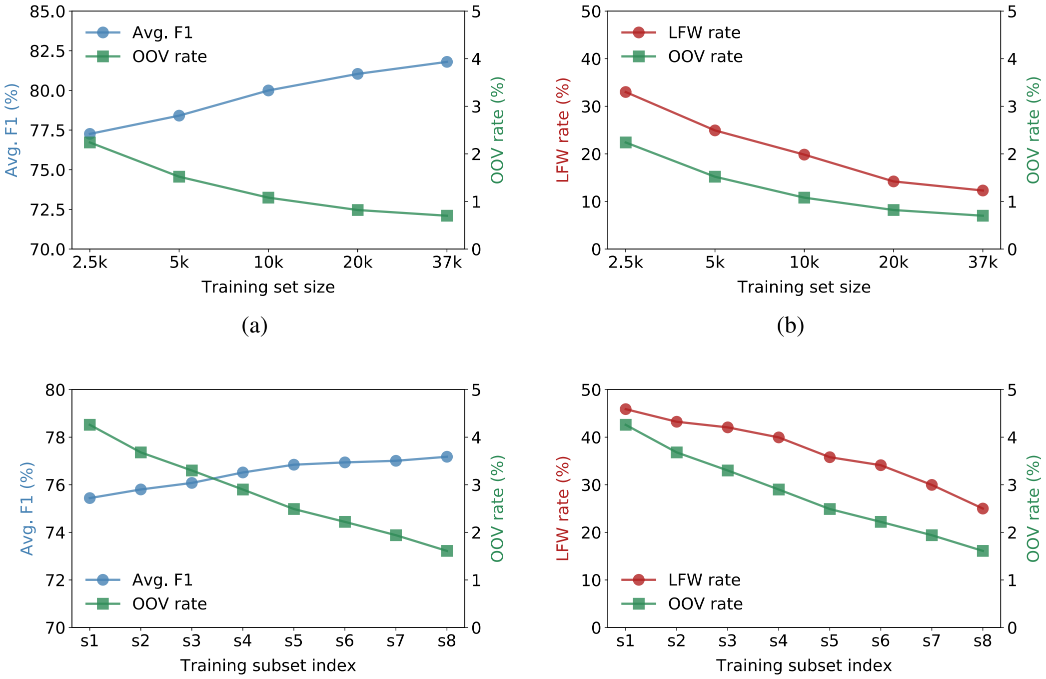
Training-test overlap makes significant impact on error analysis. Consider an error case of coreference resolution, if there are low-frequency words in the related mentions, then it will be hard to tell whether the algorithm can succeed if the words has not been seen enough times in the training set. We call an error case LFW if there are low-frequency words[3] in its related mentions[4]. Therefore, the lower LFW rate a training set contains, the more precisely it may expose the drawbacks of the algorithm.

To study the impact of training-test overlap, actually, the training-dev overlap, we pick different subsets from the training data and evaluate the models trained on them. At first, we control overlap by picking different sizes of the training data randomly. Figure 5(a) shows that, as the training data size grows, the OOV rate, which is the overlap indicator, decreases and the F1 score of EE2E-Coref increases significantly. Figure 5(b) shows that when training set size increases, the OOV rate and the LFW rate drop together. Then, to remove the impact of data size, we pick training sets which have a fixed size but different overlaps with the development set vocabulary. The OOV rates and F1 scores of these subsets are shown in Figure 5(c). This experiment verifies the positive cor-

---

[3] In our experiments, a word is defined as low-frequency if it appears in the training set less than 10 times.

[4] There are 3 kinds of error cases of coreference resolution: false-new, false-link and wrong-link. In our experiments, the related mentions include: the current mention in all 3 kinds of cases, the nearest gold antecedent in false-new and wrong-link and the false referred antecedent in false-link and wrong-link.



(a) (b)

(c) (d)

Figure 5: Impact of training-dev overlap. (a) and (b) show the impact of training set sizes. (c) and (d) show the impact of the training-dev OOV rate, when the training sets have the same size of 2.5K documents. The 8 subsets, s1-s8, consist of documents ranked by their overlaps with the development set vocabulary.

relation between training-dev overlap and coreference resolution performance suggested by (Sadat Moosavi and Strube, 2017). Figure 5(d) shows that for training sets with the same size, the OOV rate and the LFW rate also drop together.

We observe that the training set of 2.5K documents in Figure 5(a) has a higher model performance than all the training sets in Figure 5(c). This is not expected. One hypothesis is that the lower performance in Figure 5(c) is due to the smaller diversity of these training sets, which are selected to have certain training-dev OOV rates.

The training-dev LFW rate of OntoNotes is 34.8%. As a comparison, the number for PreCo is 12.3%. A subset of PreCo with a similar token number to OntoNotes has a LFW rate of 33.0%. This indicates that research of coreference algorithms on PreCo will be much more efficient than on OntoNotes. Even if we can ignore the LFW error cases, there are others related to low-frequency word senses, phrases and sentence structures, which are hard to filter out. They will also obscure the error analysis. It is reasonable to believe that training-dev overlap impacts the rate of these error cases in a similar way to impact LFW rate.

4.3 Mention Detection

Since most coreference systems consist of a mention detection module and a mention clustering module, an important question is: with a perfect mention detection module, what is the model performance on coreference resolution? The answer would help us understand the bottlenecks of the entire system, by quantifying the impact of the mention detection module on the final F1 score. (Lee et al., 2017) gave an answer by taking ground truth non-singleton mentions as the input of the coreference resolver for both training and evaluation, assuming that the perfect mention detector can also make perfect anaphoricity decisions, e.g., to decide whether a mention should be linked to an antecedent. But this assumption can be violated since mention detectors usually take local information but anaphoricity decisions usually need more context, nearly as much as entity identification. The anaphoricity decisions should be made in the mention clustering module.

Mention	OntoNotes	PreCo
detected	66.7	77.3
*all	N/A	81.6
*non-singleton	85.2	89.2

Table 6: Coreference resolution performances on development set under different mention detection qualities. A prefixed * denotes ground truth. The model trained on OntoNotes is E2E-Coref (Lee et al., 2017) while the one trained on PreCo is EE2E-Coref. The PreCo training set contains the same 2.5K documents as in Table 3.

We argue that a better way to answer the question is to take all ground truth mentions (including singletons) for coreference. This operation is not feasible in OntoNotes since it does not have annotations for singleton mentions. We do this on PreCo and the results are shown in Table 6. There is an obvious difference between the F1 scores achieved with all gold mentions and non-singleton gold mentions. Therefore, the room for improvement by better mention detection is not as enormous as suggested in (Lee et al., 2017). The major challenge remained in coreference resolution is mention clustering.

5 Conclusion

In this paper, we propose a large-scale coreference resolution dataset to overcome the limitations of existing ones. Our dataset, PreCo, features higher training-test overlap, about 10 times larger scale than previous datasets, and singleton mention annotations. By evaluating a state-of-the-art coreference resolver, we show that there is a wide gap between the model and human performance, which demonstrated challenges of the dataset. We verified the expectation that PreCo's higher training-test overlap helps research on coreference resolution. For the first time, we quantified the impact of mention detector to the entire system, thanks to our singleton mention annotations. We make the dataset public, and hope it will stimulate further research on coreference resolution.

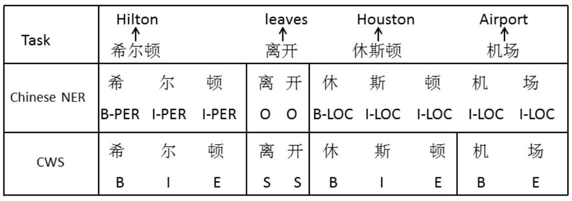
Abstract

Named entity recognition (NER) is an important task in natural language processing area, which needs to determine entities boundaries and classify them into pre-defined categories. For Chinese NER task, there is only a very small amount of annotated data available. Chinese NER task and Chinese word segmentation (CWS) task have many similar word boundaries. There are also specificities in each task. However, existing methods for Chinese NER either do not exploit word boundary information from CWS or cannot filter the specific information of CWS. In this paper, we propose a novel adversarial transfer learning framework to make full use of task-shared boundaries information and prevent the task-specific features of CWS. Besides, since arbitrary character can provide important cues when predicting entity type, we exploit self-attention to explicitly capture long range dependencies between two tokens. Experimental results on two different widely used datasets show that our proposed model significantly and consistently outperforms other state-of-the-art methods.

1 Introduction

The task of named entity recognition (NER) is to recognize the named entities in given text. NER is a preliminary and important task in natural language processing (NLP) area and can be used in many downstream NLP tasks, such as relation extraction (Bunescu and Mooney, 2005), event extraction (Chen et al., 2015) and question answering (Yao and Van Durme, 2014). In recent years, numerous methods have been carefully studied for NER task, including Hidden Markov Models (HMMs) (Bikel et al., 1997), Support Vector Machines (SVMs) (Isozaki and Kazawa, 2002) and Conditional Random Fields (CRFs) (Lafferty et al., 2001). Currently, with the development of deep learning, neural networks (Lample et al., 2016; Peng and Dredze, 2016; Luo and Yang, 2016) have been introduced to NER task. All these methods need to **determine entities boundaries** and **classify them into pre-defined categories**.



Task	Hilton ↑ 希尔顿			leaves ↑ 离开		Houston ↑ 休斯顿			Airport ↑ 机场	
Chinese NER	希	尔	顿	离	开	休	斯	顿	机	场
	B-PER	I-PER	I-PER	O	O	B-LOC	I-LOC	I-LOC	I-LOC	I-LOC
CWS	希	尔	顿	离	开	休	斯	顿	机	场
	B	I	E	S	S	B	I	E	B	E

Figure 1: An example of illustrating the similarities and specificities between Chinese NER and CWS.

Although great improvements have been achieved by these methods on Chinese NER task, some issues still have not been well addressed. One significant drawback is that there is only a very small amount of annotated data available. Weibo NER dataset (Peng and Dredze, 2015; He and Sun, 2017a) and Sighan2006 NER dataset (Levow, 2006) are two widely used datasets for Chinese NER task, containing 1.3k and 45k training examples, respectively. On the two datasets, the highest F1 scores are 48.41% and 89.21%, respectively. As a basic task in NLP area, the performance is not satisfactory. Fortunately, Chinese word segmentation (CWS) task is to recognize word boundaries and the amount of supervised training data for CWS is abundant compared with NER. There are many similarities between Chinese NER task and CWS task, which we call task-shared information. As shown in Figure 1, given a sentence “希尔顿离开休斯顿机场 (Hilton leaves Houston Airport)”, the two tasks have the same boundaries for some words such as “希尔顿 (Hilton)” and “离开 (leaves)”, while Chinese NER has more coarse-grained boundaries

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 182–192
Brussels, Belgium, October 31 - November 4, 2018.

than CWS task for certain word such as “休斯顿机场 (Houston Airport)” in the example of Figure 1, which we call task-specific information. In order to incorporate word boundary information from CWS task into NER task, Peng and Dredze (2016) propose a joint model that performs Chinese NER with CWS task. However, their proposed model only focuses on task-shared information between Chinese NER and CWS, and ignores filtering the specificities of each task, which will bring noise for both of the tasks. For example, the CWS task splits “休斯顿机场 (Houston Airport)” into “休斯顿 (Houston)” and “机场 (Airport)”, while the NER task takes “休斯顿机场 (Houston Airport)” as a whole entity. Thus, how to exploit task-shared information and prevent the noise brought by CWS task to Chinese NER task is a challenging problem.

Another issue is that most proposed models cannot explicitly model long range dependencies when predicting entity type. Though bidirectional long short term memory (BiLSTM) can learn long-distance dependencies, it cannot conduct direct connections between arbitrary two characters. As shown in Figure 1, if the model only focuses on the word “希尔顿 (Hilton)”, it can be a person or organization. However, when the model explicitly captures the dependencies between “希尔顿 (Hilton)” and “离开 (leaves)”, it is easy to classify “希尔顿 (Hilton)” into “person” category. Context information is very crucial for determining the entity type. While in the sentence “我将住在希尔顿 (I will be staying at the Hilton)”, the entity type of “希尔顿 (Hilton)” is “organization”. Thus, how to better capture the global dependencies of the whole sentence is another challenging problem.

To address the above problems, we propose an adversarial transfer learning framework to integrate the task-shared word boundary information into Chinese NER task in this paper. The adversarial transfer learning is incorporating adversarial training into transfer learning. To better capture long range dependencies and synthesize the information of the sentence, we extend self-attention mechanism into the framework. Specifically, we try to improve Chinese NER task performance by incorporating shared boundary information from CWS task. To prevent the specific information of CWS task from lowering the performance of the Chinese NER task, we introduce adversarial training to ensure that the Chinese NER task only exploits task-shared word boundary information. Then, for tackling the long range dependency problems, we utilize self-attention to synthesize the hidden representation of BiLSTM. Finally, we evaluate our model on two different widely used Chinese NER datasets. Experimental results show that our proposed model achieves better performance than other state-of-the-art methods and gains new benchmarks.

In summary, the contributions of this paper are as follows:

- We propose an adversarial transfer learning framework to incorporate task-shared word boundary information from CWS task into Chinese NER task. To our best knowledge, it is the first work to apply adversarial transfer learning method into NER task.

- We introduce self-attention mechanism into our model, which aims to capture the global dependencies of the whole sentence and learn inner structure features of sentence.

- We conduct our experiment on two different widely used Chinese NER datasets, and the experimental results demonstrate that our proposed model significantly and consistently outperforms previous state-of-the-art methods. We release the source code publicly for further research[1].

2 Related Work

NER Many methods have been proposed for NER task. Early studies on NER often exploit SVMs (Isozaki and Kazawa, 2002), HMMs (Bikel et al., 1997) and CRFs (Lafferty et al., 2001), heavily relying on feature engineering. Zhou et al. (2013) formulate Chinese NER as a joint identification and categorization task. In recent years, neural network models have been introduced to NER task (Collobert et al., 2011; Huang et al., 2015; Peng and Dredze, 2016). Huang et al. (2015) exploit BiLSTM to extract features and feed them into CRF decoder. After that, the BiLSTM-CRF model is usually exploited as the baseline. Lample et al. (2016) use a character LSTM to represent spelling characteristics. In addition, Wang et al. (2017) propose a gated convolutional neural network (GCNN) model for Chinese NER. Peng and Dredze (2016) propose a joint model for Chinese

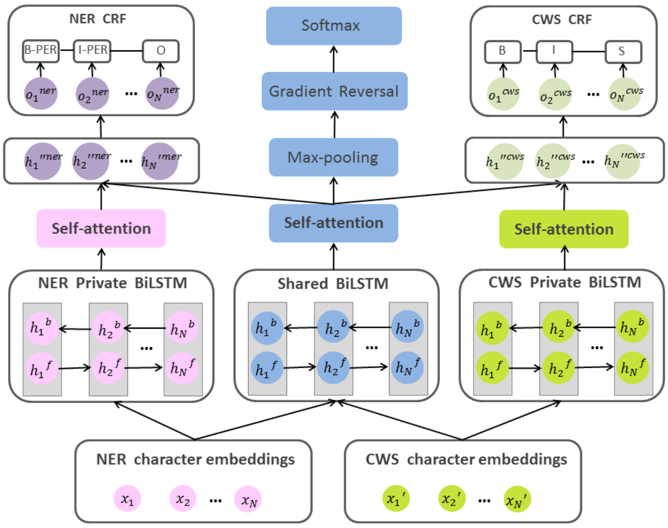

Figure 2: The general architecture of our proposed model. The left and right part are Chinese NER space and CWS private space, respectively, including embedding layer, feature extractor (Private BiLSTM), self-attention and CRF layer. The middle part is shared space consisting of feature extractor (Shared BiLSTM), self-attention and task discriminator.

NER, which are jointly trained with CWS task. However, the specific features brought by CWS task can lower the performance of the Chinese NER task.

Adversarial Training Adversarial networks have achieved great success in computer vision (Goodfellow et al., 2014; Denton et al., 2015). In NLP area, adversarial training has been introduced for domain adaptation (Ganin and Lempitsky, 2014; Zhang et al., 2017; Gui et al., 2017), cross-lingual transfer learning (Chen et al., 2016; Kim et al., 2017), multi-task learning (Chen et al., 2017; Liu et al., 2017) and crowdsourcing learning (Yang et al., 2018). Bousmalis et al. (2016) propose shared-private model in domain separation network. Different from these works, we exploit adversarial network to jointly train Chinese NER task and CWS task, aiming to extract task-shared word boundary information from CWS task. To our knowledge, it is the first work to apply adversarial transfer learning framework to Chinese NER task.

Self-Attention Self-attention has been introduced to machine translation by Vaswani et al. (2017) for capturing global dependencies between input and output and achieves state-of-the-art performance. For language understanding task, Shen et al. (2017) exploit self-attention to learn long range dependencies. Tan et al. (2017) apply self-attention to semantic role labelling task and achieve state-of-the-art results. We are the first to introduce self-attention mechanism to Chinese NER task.

3 Method

In this paper, we propose a novel adversarial transfer learning framework that will learn task-shared word boundary information from CWS task, filter specific information of CWS and explicitly capture the long range dependencies between arbitrary two characters in sentence. The architecture of our proposed model is illustrated in Figure 2. The model mainly consists of five components: embedding layer, shared-private feature extractor, self-attention, task-specific CRF and task discriminator. In the following sections, we will describe each part of our proposed model in detail.

3.1 Embedding Layer

Similar to other neural network models, the first step of our proposed model is to map discrete characters into the distributed representations. For a given Chinese sentence $\mathbf{x} = \{c_1, c_2, \ldots, c_N\}$ from Chinese NER dataset or CWS dataset, we lookup embedding vector from pre-trained embedding matrix for each character c_i as $\mathbf{x}_i \in \mathbb{R}^{d_e}$.

3.2 Shared-Private Feature Extractor

Long short term memory (LSTM) (Hochreiter and Schmidhuber, 1997) is a variant of recurrent neural network (RNN) (Elman, 1990), which enables to address the gradient vanishing and exploding problems in RNN via introducing gate mechanism and memory cell. The unidirectional LSTM only leverages information from the past, ignoring the future information. In order to incorporate information from both sides of sequence, we adopt BiLSTM to extract features. Specially, the hidden state of BiLSTM could be expressed as follows:

$$\overrightarrow{\mathbf{h}_i} = \overrightarrow{\mathrm{LSTM}}(\overrightarrow{\mathbf{h}}_{i-1}, \mathbf{x}_i) \quad (1)$$

$$\overleftarrow{\mathbf{h}_i} = \overleftarrow{\mathrm{LSTM}}(\overleftarrow{\mathbf{h}}_{i+1}, \mathbf{x}_i) \quad (2)$$

$$\mathbf{h}_i = \overrightarrow{\mathbf{h}_i} \oplus \overleftarrow{\mathbf{h}_i} \quad (3)$$

where $\overrightarrow{\mathbf{h}_i} \in \mathbb{R}^{d_h}$ and $\overleftarrow{\mathbf{h}_i} \in \mathbb{R}^{d_h}$ are the hidden states of the forward and backward LSTM at position i, respectively. $\oplus$ denotes concatenation operation.

As shown in Figure 2, we propose a shared-private feature extractor, which assigns a private BiLSTM layer and shared BiLSTM layer for task $k \in \{NER, CWS\}$. The private BiLSTM layer is used to extract task-specific features, and the shared BiLSTM layer is used to learn task-shared word boundaries. Formally, for any sentence in dataset of task k, the hidden states of shared and private BiLSTM layer can be computed as follows:

$$\mathbf{s}_i^k = \mathrm{BiLSTM}(\mathbf{x}_i^k, \mathbf{s}_{i-1}^k; \theta_s) \quad (4)$$

$$\mathbf{h}_i^k = \mathrm{BiLSTM}(\mathbf{x}_i^k, \mathbf{h}_{i-1}^k; \theta_k) \quad (5)$$

where θ_s and θ_k are the shared BiLSTM parameters and private BiLSTM parameters of task k, respectively.

3.3 Self-Attention

Inspired by the self-attention applied to machine translation (Vaswani et al., 2017) and semantic role labelling (Tan et al., 2017), we exploit self-attention to explicitly learn the dependencies between any two characters in sentence and capture the inner structure information of sentence. In this paper, we adopt the multi-head self-attention mechanism. $\mathbf{H} = \{\mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_N\}$ denotes the output of private BiLSTM. Correspondingly, $\mathbf{S} = \{\mathbf{s}_1, \mathbf{s}_2, \ldots, \mathbf{s}_N\}$ is the output of shared BiLSTM. We will take the self-attention in private space as example to illustrate how it works. The scaled dot-product attention can be precisely described as follows:

$$\mathrm{Attention}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \mathrm{softmax}(\frac{\mathbf{Q}\mathbf{K}^T}{\sqrt{\mathbf{d}}})\mathbf{V} \quad (6)$$

where $\mathbf{Q} \in \mathbb{R}^{N\times 2d_h}$, $\mathbf{K} \in \mathbb{R}^{N\times 2d_h}$ and $\mathbf{V} \in \mathbb{R}^{N\times 2d_h}$ are query matrix, keys matrix and value matrix, respectively. In our setting, $\mathbf{Q} = \mathbf{K} = \mathbf{V} = \mathbf{H}$. $\mathbf{d}$ is the dimension of hidden units of BiLSTM, which equals to $2d_h$.

Multi-head attention first linearly projects the queries, keys and values h times by using different linear projections. Then h projections perform the scaled dot-product attention in parallel. Finally, these results of attention are concatenated and once again projected to get the new representation. Formally, the multi-head attention can be expressed as follows:

$$head_i = \mathrm{Attention}(\mathbf{Q}\mathbf{W}_i^Q, \mathbf{K}\mathbf{W}_i^K, \mathbf{V}\mathbf{W}_i^V) \quad (7)$$

$$\mathbf{H}' = (head_i \oplus \ldots \oplus head_h)\mathbf{W}_o \quad (8)$$

where $\mathbf{W}_i^Q \in \mathbb{R}^{2d_h\times d_k}$, $\mathbf{W}_i^K \in \mathbb{R}^{2d_h\times d_k}$ and $\mathbf{W}_i^V \in \mathbb{R}^{2d_h\times d_k}$ are trainable projection parameters and $d_k = 2d_h/h$. $\mathbf{W}_o \in \mathbb{R}^{2d_h\times 2d_h}$ is also trainable parameter.

3.4 Task-Specific CRF

For a sentence in dataset of task k, we compute the final representation via concatenating the representations from private space and shared space after self-attention layer:

$$\mathbf{H}''^k = \mathbf{H}'^k \oplus \mathbf{S}'^k \quad (9)$$

where $\mathbf{H}'^k$ and $\mathbf{S}'^k$ are the outputs of private self-attention and shared self-attention of task k, respectively.

Considering the dependencies between successive labels, we exploit CRF (Lafferty et al., 2001) to inference tags instead of making tagging decisions using $\mathbf{h}_i''$ independently. Due to the difference of labels, we introduce a specific CRF layer for each task. Given a sentence $\mathbf{x} = \{c_1, c_2, \ldots, c_N\}$ with a predicted tag sequence $\mathbf{y} = \{y_1, y_2, \ldots, y_N\}$, the CRF tagging process can be formalized as follows:

$$\mathbf{o}_i = \mathbf{W}_s\mathbf{h}_i'' + \mathbf{b}_s \quad (10)$$

$$s(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^{N}(\mathbf{o}_{i,y_i} + \mathbf{T}_{y_{i-1},y_i}) \quad (11)$$

$$\bar{\mathbf{y}} = \arg\max_{\mathbf{y}\in\mathbf{Y}_x} s(\mathbf{x}, \mathbf{y}) \quad (12)$$

where $\mathbf{W}_s \in \mathbb{R}^{|T|\times 4d_h}$ and $\mathbf{b}_s \in \mathbb{R}^{|T|}$ are trainable parameters. $|T|$ denotes the number of output labels. $\mathbf{o}_{i,y_i}$ represents the score of the y_i-th tag of the character c_i. $\mathbf{T}$ is a transition score matrix which defines the scores of two successive labels. $\mathbf{Y}_x$ represents all candidate tag sequences for given sentence $\mathbf{x}$. In decoding, we use Viterbi algorithm to get the predicted tag sequence $\bar{\mathbf{y}}$.

For training, we exploit negative log-likelihood objective as the loss function. The probability of the ground-truth label sequence is computed by:

$$p(\hat{\mathbf{y}}|\mathbf{x}) = \frac{e^{s(\mathbf{x},\hat{\mathbf{y}})}}{\sum_{\widetilde{\mathbf{y}}\in\mathbf{Y}_x} e^{s(\mathbf{x},\widetilde{\mathbf{y}})}} \tag{13}$$

where $\hat{\mathbf{y}}$ denotes the ground-truth label sequence. Given T training examples $(\mathbf{x}^{(i)};\hat{\mathbf{y}}^{(i)})$, the loss function L_{Task} can be defined as follows:

$$L_{Task} = -\sum_{i=1}^{T} \log p(\hat{\mathbf{y}}^{(i)}|\mathbf{x}^{(i)}) \tag{14}$$

We use gradient back-propagation method to minimize the loss function.

3.5 Task Discriminator

Inspired by adversarial networks (Goodfellow et al., 2014), we incorporate adversarial training into shared space to guarantee that specific features of tasks do not exist in shared space. We propose a task discriminator to estimate which task the sentence comes from. Formally, the task discriminator can be expressed as follows:

$$\mathbf{s}'^{k} = \text{Maxpooling}(\mathbf{S}'^{k}) \tag{15}$$

$$D(\mathbf{s}'^{k};\theta_d) = \text{softmax}(\mathbf{W}_d\mathbf{s}'^{k} + \mathbf{b}_d) \tag{16}$$

where θ_d indicates the parameters of task discriminator. $\mathbf{W}_d \in \mathbb{R}^{K\times 2d_h}$ and $\mathbf{b}_d \in \mathbb{R}^{K}$ are trainable parameters. K is the number of tasks.

Besides the task loss L_{Task}, we introduce an adversarial loss L_{Adv} to prevent specific features of CWS task from creeping into shared space. The adversarial loss trains the shared model to produce shared features such that the task discriminator cannot reliably recognize which task the sentence comes from. The adversarial loss can be computed as follows:

$$L_{Adv} = \min_{\theta_s}(\max_{\theta_d}\sum_{k=1}^{K}\sum_{i=1}^{T_k}\log D(E_s(\mathbf{x}_k^{(i)}))) \tag{17}$$

where θ_s denotes the trainable parameters of shared BiLSTM. E_s denotes the shared feature extractor. T_k is the number of training examples of task k. $\mathbf{x}_k^{(i)}$ is the i-th example of task k. There is a minimax optimization that the shared BiLSTM generates a representation to mislead the task discriminator and the discriminator tries its best to correctly determine the type of task.

We add a gradient reversal layer (Ganin and Lempitsky, 2014) below the softmax layer to address the minimax optimization problem. In the training phrase, we minimize the task discriminator errors, and through gradient reversal layer the gradients will become opposed sign to adversarially encourage the shared feature extractor to learn task-shared word boundary information. After training phrase, the shared feature extractor and task discriminator reach a point where the discriminator cannot differentiate the tasks according to the representations learned from shared feature extractor.

3.6 Training

The final loss function of our proposed model can be written as follows:

$$L = L_{NER}\cdot I(\mathbf{x}) + L_{CWS}\cdot(1 - I(\mathbf{x})) + \lambda L_{Adv} \tag{18}$$

where λ is a hyper-parameter. L_{NER} and L_{CWS} can be computed via Eq.14. $I(\mathbf{x})$ is a switching function to identify which task the input comes from. It is defined as follows:

$$I(\mathbf{x}) = \begin{cases} 1, & if \quad \mathbf{x}\in\mathcal{D}_{NER} \\ 0, & if \quad \mathbf{x}\in\mathcal{D}_{CWS} \end{cases} \tag{19}$$

where $\mathcal{D}_{NER}$ and $\mathcal{D}_{CWS}$ are Chinese NER training corpora and CWS training corpora, respectively.

In the training phrase, at each iteration, we first select a task from $\{NER, CWS\}$ in turn. Then, we sample a batch of training instances from the given task to update the parameters. We use Adam (Kingma and Ba, 2014) algorithm to optimize the final loss function. Since Chinese NER task and CWS task may have different convergence rate, we repeat the above iterations until early stopping according to the Chinese NER task performance.

4 Experiments

4.1 Datasets

To evaluate our proposed model on Chinese NER, we experiment on two different widely used datasets, including Weibo NER dataset (WeiboNER) (Peng and Dredze, 2015; He and Sun,

Dataset	Task	# Train sent	# Dev sent	# Test sent
WeiboNER	Chinese NER	1350	270	270
SighanNER	Chinese NER	41728	4636	4365
MSR	CWS	86924	—	3985

Table 1: Statistics of the datasets.

Models	P(%)	R(%)	F1(%)
CRF (Peng and Dredze, 2015)	56.98	25.26	35.00
CRF+word (Peng and Dredze, 2015)	64.94	25.77	36.90
CRF+character (Peng and Dredze, 2015)	57.89	34.02	42.86
CRF+character+position (Peng and Dredze, 2015)	57.26	34.53	43.09
Joint(cp) (main) (Peng and Dredze, 2015)	57.98	35.57	44.09
Pipeline Seg.Repr.+NER (Peng and Dredze, 2016)	64.22	36.08	46.20
Jointly Train Char.Emb (Peng and Dredze, 2016)	63.16	37.11	46.75
Jointly Train LSTM Hidden (Peng and Dredze, 2016)	63.03	38.66	47.92
Jointly Train LSTM+Emb (main) (Peng and Dredze, 2016)	63.33	39.18	48.41
BiLSTM+CRF+adversarial+self-attention	55.72	**50.68**	**53.08**

Table 2: NER results for named entities on the original WeiboNER dataset (Peng and Dredze, 2015). There are three blocks. The first two blocks contain the main and simplified models proposed by Peng and Dredze (2015) and Peng and Dredze (2016), respectively. The last block lists the performance of our proposed model.

2017a) and SIGHAN2006 NER dataset (SighanNER) (Levow, 2006). We use the MSR dataset (from SIGHAN2005) for CWS task.

The WeiboNER is annotated with four entity types (person, location, organization and geo-political entities), including named entities and nominal mentions. The SighanNER is simplified Chinese, which contains three entity types (person, location and organization). For WeiboNER, we use the same training, development and testing splits as Peng and Dredze (2015). Since the SighanNER does not have development set, we sample 10% data of training set as development set. We use MSR dataset to improve the performance of the Chinese NER task. Table 1 gives the details of the three datasets.

4.2 Settings

For evaluation, we use the Precision (P), Recall (R) and F1 score as metrics in our experiment.

For hyper-parameter configurations, we adjust them according to the performance on development set of Chinese NER task. We set the character embedding size d_e to 100. The dimensionality of LSTM hidden states d_h is 120. The initial learning rate is set to 0.001. The loss weight coefficient λ is set to 0.06. We set the dropout rate to 0.3. The number of projections h is 8. We set the batch size of SighanNER and WeiboNER as 64 and 20, respectively.

For trainable parameters initialization, we use xavier initializer (Glorot and Bengio, 2010) to initialize parameters. The character embeddings used in our experiment are pre-trained on Baidu Encyclopedia corpus and Weibo corpus by using word2vec toolkit (Mikolov et al., 2013).

4.3 Compared with State-of-the-art Methods

In this section, we will give the experimental results of our proposed model and previous state-of-the-art methods on WeiboNER dataset and SighanNER dataset, respectively.

4.3.1 Evaluation on WeiboNER

We compare our proposed model with the latest models on WeiboNER dataset. Table 2 shows the experimental results for named entities on the original WeiboNER dataset.

In the first block of Table 2, we give the performance of the main model and baselines proposed by Peng and Dredze (2015). They propose a CRF-based model to jointly train the embeddings with NER task, which achieves better results than pipeline models. In addition, they consider the po-

Models	Named Entity			Nominal Mention			Overall
	P(%)	R(%)	F1(%)	P(%)	R(%)	F1(%)	F1(%)
Peng and Dredze (2015)	74.78	39.81	51.96	71.92	53.03	61.05	56.05
Peng and Dredze (2016)	66.67	47.22	55.28	74.48	54.55	62.97	58.99
He and Sun (2017a)	66.93	40.67	50.60	66.46	53.57	59.32	54.82
He and Sun (2017b)	61.68	48.82	54.50	74.13	53.54	62.17	58.23
BiLSTM+CRF+adv+self-attention	59.51	**50.00**	54.34	71.43	47.90	57.35	58.70

Table 3: Experimental results on the updated WeiboNER dataset (He and Sun, 2017a). There are two blocks. The first block is the performance of latest models. The second block reports the performance of our proposed model. With the limited length of the page, we use "adv" to denote "adversarial".

Models	P(%)	R(%)	F1(%)
Chen et al. (2006)	91.22	81.71	86.20
Zhou et al. (2006)	88.94	84.20	86.51
Luo and Yang (2016)	91.30	87.22	89.21
BiLSTM+CRF+adversarial+self-attention	**91.73**	**89.58**	**90.64**

Table 4: Results on SighanNER dataset. There are two blocks. The first block reports the result of previous methods. The second block gives the performance of our proposed model.

sition of each character in a word to train character and position embeddings.

In the second block of Table 2, we report the performance of the main model and baselines proposed by Peng and Dredze (2016). Aiming to incorporate word boundary information into the NER task, they propose an integrated model that can joint training CWS task, improving the F1 score from 46.20% to 48.41% as compared with pipeline model (Pipeline Seg.Repr.+NER).

In the last block of Table 2, we give the experimental result of our proposed model (BiLSTM+CRF+adversarial+self-attention). We can observe that our proposed model significantly outperforms other models. Compared with the model proposed by Peng and Dredze (2016), our method gains 4.67% improvement in F1 score. Interestingly, WeiboNER dataset and MSR dataset are different domains. The WeiboNER dataset is social media domain, while the MSR dataset can be regard as news domain. The improvement of performance indicates that our proposed adversarial transfer learning framework may not only learn task-shared word boundary information from CWS task but also tackle the domain adaptation problem.

We also conduct an experiment on the updated WeiboNER dataset. Table 3 lists the performance of the latest models and our proposed model on the updated dataset. In the first block of Table 3, we report the performance of the latest models. The model proposed by Peng and Dredze (2015) achieves F1 score of 56.05% on overall performance. He and Sun (2017b) propose an unified model for Chinese NER task to exploit the data from out-of-domain corpus and in-domain unlabelled texts. The unified model improves the F1 score from 54.82% to 58.23% compared with the model proposed by He and Sun (2017a).

In the second block of Table 3, we give the result of our proposed model. It can be observed that our proposed model achieves a very competitive performance. Compared with the latest model proposed by He and Sun (2017b), our model improves the F1 score from 58.23% to 58.70% on overall performance. The improvement demonstrates the effectiveness of our proposed model.

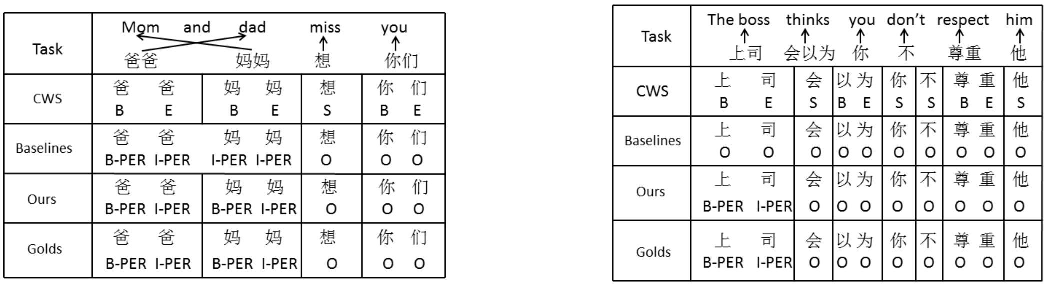
4.3.2 Evaluation on SighanNER

Table 4 lists the comparisons on SighanNER dataset. We observe that our proposed model achieves new state-of-the-art performance.

In the first block, we give the performance of previous methods for Chinese NER task on SighanNER dataset. Chen et al. (2006) propose a character-based CRF model for Chinese NER task. Zhou et al. (2006) introduce a pipeline model, which first segments the text with character-level CRF model and then applies word-level CRF to tag. Luo and Yang (2016) first train a word segmenter and then use word segmentation as addi-

Models	SighanNER			WeiboNER		
	P(%)	R(%)	F1(%)	P(%)	R(%)	F1(%)
BiLSTM+CRF	89.84	88.42	89.13	58.99	44.93	51.01
BiLSTM+CRF+transfer	90.60	89.19	89.89	60.00	46.03	52.09
BiLSTM+CRF+adversarial	90.52	89.56	90.04	61.94	45.48	52.45
BiLSTM+CRF+self-attention	90.62	88.81	89.71	57.81	47.67	52.25
BiLSTM+CRF+adversarial+self-attention	**91.73**	**89.58**	**90.64**	55.72	**50.68**	**53.08**

Table 5: Comparison between our proposed model and simplified models on SighanNER dataset and original WeiboNER dataset.



(a) Example for the effectiveness of boundary information.

(b) Example for the effectiveness of self-attention.

Figure 3: The analysis of Chinese NER cases from WeiboNER dataset.

tional features for sequence tagging. Although the model achieves competitive performance, giving the F1 score of 89.21%, it suffers from the error propagation problem.

In the second block, we report the result of our proposed model. Compared with the state-of-the-art model proposed by Luo and Yang (2016), our method improves the F1 score from 89.21% to 90.64% without any additional features, which demonstrates the effectiveness of our proposed model.

4.4 Effectiveness of Adversarial Transfer Learning and Self-Attention

Table 5 provides the experimental results of our proposed model and baseline as well as its simplified models on SighanNER dataset and WeiboNER dataset. The simplified models are described as follows:

- BiLSTM+CRF: The model is used as strong baseline in our work, which is trained using Chinese NER training data.
- BiLSTM+CRF+transfer: We apply transfer learning to BiLSTM+CRF model without adversarial loss and self-attention mechanism.
- BiLSTM+CRF+adversarial: Compared with BiLSTM+CRF+transfer model, the BiLSTM+CRF+adversarial model incorporates adversarial training.
- BiLSTM+CRF+self-attention: The model integrates the self-attention mechanism based on BiLSTM+CRF model.

From the experimental results of Table 5, we have following observations:

- **Effectiveness of transfer learning.** BiLSTM+CRF+transfer improves F1 score from 89.13% to 89.89% as compared with BiLSTM+CRF on SighanNER dataset and achieves 1.08% improvement on WeiboNER dataset, which indicates the word boundary information from CWS is very effective for Chinese NER task.
- **Effectiveness of adversarial training.** By introducing adversarial training, BiLSTM+CRF+adversarial boosts the performance as compared with BiLSTM+CRF+transfer model, showing 0.15% and 0.36% improvement on SighanNER dataset and WeiboNER dataset, respectively. It proves that adversarial training can prevent specific features of CWS task from creeping into shared space.
- **Effectiveness of self-attention mechanism.** When compared with BiLSTM+CRF, the

BiLSTM+CRF+self-attention significantly improves the performance on the two different datasets with the help of information learned from self-attention, which verifies that the self-attention mechanism is effective for Chinese NER task.

We observe that our proposed adversarial transfer learning framework and self-attention lead to noticeable improvements over the baseline, improving F1 score from 51.01% to 53.08% on WeiboNER dataset and giving 1.51% improvement on SighanNER dataset.

4.5 Detailed Analysis

4.5.1 Case Study

Word boundary information from CWS task is very important for Chinese NER task, especially when different entities appear together, . We take a sentence in WeiboNER test set as example for illustrating the effectiveness of our proposed model. As shown in Figure 4(a), when two "person" entities appearing together, our proposed method exploits word segmentation information to determine the boundary between them and then make correct taggings. In Figure 4(b), when labelling the word "上司 (the boss)", the self-attention explicitly learns the dependencies with "尊重 (respect)", therefore, our model enables to correctly classify the word into "person" category. It verifies that the self-attention is very effective for Chinese NER task.

4.5.2 Error Analysis

According to the results of Table 2 and Table 4, our proposed model achieves 4.67% and 1.43% improvement as compared with previous state-of-the-art methods on WeiboNER dataset and SighanNER dataset, respectively. However, the overall performance on WeiboNER dataset is relatively low. Two reasons can be explained for this issue. One reason is that the number of training examples in WeiboNER dataset is very limited as compared with SighanNER dataset. There are only 1.3k examples in WeiboNER training corpora, which is not enough to train deep neural networks. Another reason is that the expression is informal in social media, lowering the performance on WeiboNER dataset. While the greater improvement on WeiboNER dataset proves that our method is helpful to solve the problem.

5 Conclusions

In this paper, we propose a novel adversarial transfer learning framework for Chinese NER task, which can exploit task-shared word boundaries features and prevent the specific information of CWS task. Besides, we introduce self-attention mechanism to capture the dependencies of arbitrary two characters and learn the inner structure information of sentence. Experiments on two different widely used datasets demonstrate that our method significantly and consistently outperforms previous state-of-the-art models.

Using Linguistic Features to Improve the Generalization Capability of Neural Coreference Resolvers

Nafise Sadat Moosavi[1,2*] and **Michael Strube**[1]
[1]Heidelberg Institute for Theoretical Studies gGmbH
[2]Research Training Group AIPHES
moosavi@ukp.informatik.tu-darmstadt.de, michael.strube@h-its.org

Abstract

Coreference resolution is an intermediate step for text understanding. It is used in tasks and domains for which we do not necessarily have coreference annotated corpora. Therefore, generalization is of special importance for coreference resolution. However, while recent coreference resolvers have notable improvements on the CoNLL dataset, they struggle to generalize properly to new domains or datasets. In this paper, we investigate the role of linguistic features in building more generalizable coreference resolvers. We show that generalization improves only slightly by merely using a set of additional linguistic features. However, employing features and subsets of their values that are informative for coreference resolution, considerably improves generalization. Thanks to better generalization, our system achieves state-of-the-art results in out-of-domain evaluations, e.g., on WikiCoref, our system, which is trained on CoNLL, achieves on-par performance with a system designed for this dataset.

1 Introduction

Coreference resolution is the task of recognizing different expressions that refer to the same entity. The referring expressions are called mentions. For instance, the sentence "[Susan]$_1$ sent [her]$_1$ daughter to a boarding school" contains two coreferring mentions. "her" is an anaphor which refers to the antecedent "Susan".

The availability of coreference information benefits various Natural Language Processing (NLP) tasks including automatic summarization, question answering, machine translation and information extraction. Current coreference developments are almost only targeted at improving scores on the CoNLL official test set. However, the superiority of a coreference resolver on the CoNLL evaluation sets does not necessarily indicate that it also performs better on new datasets. For instance, the ranking model of Clark and Manning (2016a), the reinforcement learning model of Clark and Manning (2016b) and the end-to-end model of Lee et al. (2017) are three recent coreference resolvers, among which the model of Lee et al. (2017) performs the best and that of Clark and Manning (2016b) performs the second best on the CoNLL development and test sets. However, if we evaluate these systems on the WikiCoref dataset (Ghaddar and Langlais, 2016a), which is consistent with CoNLL with regard to coreference definition and annotation scheme, the performance ranking would be in a reverse order[1].

In Moosavi and Strube (2017a), we investigate the generalization problem in coreference resolution and show that there is a large overlap between the coreferring mentions in the CoNLL training and evaluation sets. Therefore, higher scores on the CoNLL evaluation sets do not necessarily indicate a better coreference model. They may be due to better memorization of the training data. As a result, despite the remarkable improvements in coreference resolution, the use of coreference resolution in other applications is mainly limited to the use of simple rule-based systems, e.g. Lapata and Barzilay (2005),Yu and Ji (2016), and Elsner and Charniak (2008).

In this paper, we explore the role of linguistic features for improving generalization. The incorporation of linguistic features is considered as a potential solution for building more generalizable NLP systems[2]. While linguistic features[3]

[3] We refer to features that are based on linguistic intu-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 193–203
Brussels, Belgium, October 31 - November 4, 2018.

were shown to be important for coreference resolution, e.g. Uryupina (2007) and Bengtson and Roth (2008), state-of-the-art systems no longer use them and mainly rely on word embeddings and deep neural networks. Since all recent systems are using neural networks, we focus on the effect of linguistic features on a neural coreference resolver.

The contributions of this paper are as follows:

- We show that linguistic features are more beneficial for a neural coreference resolver if we incorporate features and subsets of their values that are informative for discriminating coreference relations. Otherwise, employing linguistic features with all their values only slightly affects the performance and generalization.
- We propose an efficient discriminative pattern mining algorithm, called EPM, for determining (feature, value) pairs that are informative for the given task. We show that while the informativeness of EPM mined patterns is on-par with those of its counterparts, it scales best to large datasets.[4]
- By improving generalization, we achieve state-of-the-art performance on all examined out-of-domain evaluations. Our out-of-domain performance on WikiCoref is on-par with that of Ghaddar and Langlais (2016b)'s coreference resolver, which is a system specifically designed for WikiCoref and uses its domain knowledge.

2 Importance of Features in Coreference

Uryupina (2007)'s thesis is one of the most thorough analyses of linguistically motivated features for coreference resolution. She examines a large set of linguistic features, i.e. string match, syntactic knowledge, semantic compatibility, discourse structure and salience, and investigates their interaction with coreference relations. She shows that even imperfect linguistic features, which are extracted using error-prone preprocessing modules, boost the performance and argues that coreference resolvers could and should benefit from linguistic theories. Her claims are based on analyses on the MUC dataset. Ng and Cardie (2002), Yang et al. (2004), Ponzetto and Strube (2006), Bengtson and Roth (2008), and Recasens and Hovy (2009) also study the importance of features in coreference resolution.

Apart from the mentioned studies, which are mainly about the importance of individual features, studies like Björkelund and Farkas (2012), Fernandes et al. (2012), and Uryupina and Moschitti (2015) generate new features by combining basic features. Björkelund and Farkas (2012) do not use a systematic approach for combining features. Fernandes et al. (2012) use the Entropy guided Feature Induction (EFI) approach (Fernandes and Milidiú, 2012) to automatically generate discriminative feature combinations. The first step is to train a decision tree on a dataset in which each sample consists of features describing a mention pair. The EFI approach traverses the tree from the root in a depth-first order and recursively builds feature combinations. Each pattern that is generated by EFI starts from the root node. As a result, EFI tends to generate long patterns. A decision tree does not represent all patterns of data. Therefore, it is not possible to explore all feature combinations from a decision tree.

Uryupina and Moschitti (2015) propose an alternative approach to EFI. They formulate the problem of generating feature combinations as a pattern mining approach. They use the Jaccard Item Mining (JIM) algorithm[5] (Segond and Borgelt, 2011). They show that the classifier that uses the JIM features significantly outperforms the one that employs the EFI features.

3 Baseline Coreference Resolver

deep-coref (Clark and Manning, 2016a) and e2e-coref (Lee et al., 2017) are among the best performing coreference resolvers from which e2e-coref performs better on the CoNLL test set. deep-coref is a pipelined system, i.e. a mention detection first determines the list of candidate mentions with their corresponding features. It contains various coreference models including the mention-pair, mention-ranking, and entity-based models. The mention-ranking model of deep-coref has three variations: (1) "ranking" uses the slack-rescaled max-margin training objective of Wiseman et al. (2015), (2) "reinforce" is a variation of the "ranking" model in which the hyper-parameters are set in a reinforcement learning framework (Sutton and Barto, 1998), and (3) "top-

---

itions, e.g. string match, or are acquired from linguistic preprocessing modules, e.g. POS tags, as linguistic features.

[4] The EPM code is available at `https://github.com/ns-moosavi/epm`

[5] `http://www.borgelt.net/jim.html`

pairs" is a simple variation of the "ranking" model that uses a probabilistic objective function and is used for pretraining the "ranking" model.

e2e-coref is an end-to-end system that jointly models mention detection and coreference resolution. It considers all possible (start, end) word spans of each sentence as candidate mentions. Apart from a single model, e2e-coref includes an ensemble of five models.

We use deep-coref as the baseline in our experiments. The reason is that some of the examined features require the head of each mention to be known, e.g. head match, while e2e-coref mentions do not have specific heads and heads are automatically determined using an attention mechanism. We also observe that if we limit e2e-coref candidate spans to those that correspond to deep-coref's detected mentions, the performance of e2e-coref drops to a level on-par with deep-coref[6].

4 Examined Features

The examined linguistic features include string match, syntactic, shallow semantic and discourse features. **Mention-based** features include:

- Mention type: proper, nominal or pronominal
- Fine mention type: proper, definite or indefinite nominal, or the citation form of pronouns
- Gender: female, male, neutral, unknown
- Number: singular, plural, unknown
- Animacy: animate, inanimate, unknown
- Named entity type: person, location, organization, date, time, number, etc.
- Dependency relation: enhanced dependency relation (Schuster and Manning, 2016) of the head word to its parent
- POS tags of the first, last, head, two words preceding and following of each mention

Pairwise features include:

- Head match: both mentions have the same head, e.g. "red hat" and "the hat"
- String of one mention is contained in the other, e.g. "Mary's hat" and "Mary"
- Head of one mention is contained in the other, e.g. "Mary's hat" and "hat"
- Acronym, e.g. "Heidelberg Institute for Theoretical Studies" and "HITS"
- Compatible pre-modifiers: the set of pre-modifiers of one mention is contained in that of the other, e.g. "the red hat that she is wearing" and "the red hat"
- Compatible[7] gender, e.g. "Mary" and "women"
- Compatible number, e.g. "Mary" and "John"
- Compatible animacy, e.g. "those hats" and "it"
- Compatible attributes: compatible gender, number and animacy, e.g. "Mary" and "she"
- Closest antecedent that has the same head and compatible premodifiers, e.g. "this new book" and "This book" in "Take a look at this new book. This book is one of the best sellers."
- Closest antecedent that has compatible attributes, e.g. the antecedent "Mary" and the anaphor "she" in the sentence "John saw Mary, and she was in a hurry"
- Closest antecedent that has compatible attributes and is a subject, e.g. the antecedent "Mary" and the anaphor "she" in the sentence "Mary saw John, but she was in a hurry"
- Closest antecedent that has compatible attributes and is an object, e.g. "Mary" and "she" in "John saw Mary, and she was in a hurry"

The last three features are similar to the discourse-level features discussed by Uryupina (2007), which are created by combining *proximity*, *agreement* and *salience* properties. She shows that such features are useful for resolving pronouns. we estimate proximity by considering the distance of two mentions. The salience is also incorporated by discriminating subject or object antecedents. We do not use any gold information. All features are extracted using Stanford CoreNLP (Manning et al., 2014).

5 Impact of Linguistic Features

In this section, we examine the effect of employing all linguistic features described in Section 4 in a neural coreference resolver, i.e. deep-coref. We use *MUC* (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), $CEAF_e$ (Luo, 2005), *LEA* (Moosavi and Strube, 2016), and the *CoNLL* score (Pradhan et al., 2014), i.e. the average F_1 value of *MUC*, B^3, and $CEAF_e$, for evaluations.

The results of employing those features in deep-coref's "ranking" and "top-pairs" models on the

---

[6] The CoNLL score of the e2e-coref single model on the CoNLL development set drops from 67.36 to 65.81, while that of the deep-coref "ranking" model is 66.09.

[7] One value is unknown, or both values are identical.

CoNLL development set are reported in Table 1.

	MUC	B^3	CEAF$_e$	CoNLL	LEA
ranking	74.31	64.23	59.73	66.09	60.47
+linguistic	74.35	63.96	60.19	66.17	60.20
top-pairs	73.95	63.98	59.52	65.82	60.07
+linguistic	74.32	64.45	60.19	66.32	60.62

Table 1: Impact of linguistic features on deep-coref models on the CoNLL development set.

The rows "ranking" and "top-pairs" show the base results of deep-coref's "ranking" and "top-pairs" models, respectively. "+linguistic" rows represents the results for each of the mention-ranking models in which the feature set of Section 4 is employed. The gender, number, animacy and mention type features, which have less than five values, are converted to binary features. Named entity and POS tags, and dependency relations are represented as learned embeddings.

We observe that incorporating all the linguistic features bridges the gap between the performance of "top-pairs" and "ranking". However, it does not improve significantly over "ranking". Henceforth, we use the "top-pairs" model of deep-coref as the baseline model to incorporate linguistic features.

To assess the impact on generalization, we evaluate "top-pairs" and "+linguistic"[8] models that are trained on CoNLL, on WikiCoref (see Table 2). We observe that the impact on generalization is also not notable, i.e. the CoNLL score improves only by 0.5pp over "ranking".

	MUC	B^3	CEAF$_e$	CoNLL	LEA
ranking	63.10	48.43	47.18	52.90	44.40
top-pairs	63.09	48.42	46.05	52.52	44.21
+linguistic	63.99	49.63	46.60	53.40	45.66

Table 2: Out-of-domain evaluation of deep-coref models on the WikiCoref dataset.

Based on an ablation study, while our feature set contains numerous features, the resulting improvements of "linguistic" over "top-pairs" mainly comes from the last four pairwise features in Section 4, which are carefully designed features.

6 Better Exploiting Linguistic Features

As discussed by Moosavi and Strube (2017a), there is a large lexical overlap between the coreferring mentions of the CoNLL training and evaluation sets. As a result, lexical features provide a very strong signal for resolving coreference relations.

For linguistic features to be more effective in current coreference resolvers, which rely heavily on lexical features, they should also provide a strong signal for coreference resolution.

Additional linguistic features are not necessarily all informative for coreference resolution, especially if they are extracted automatically and are noisy. Besides, for features with multiple values, e.g. mention-based features, only a small subset of values may be informative.

To better exploit linguistic features, we only employ (feature, value) pairs[9] that are informative for coreference resolution. Coreference resolution is a complex task in which features have complex interactions (Recasens and Hovy, 2009). As a result, we cannot determine the informativeness of feature-values in isolation.

We use a discriminative pattern mining approach (Cheng et al., 2007, 2008; Batal and Hauskrecht, 2010) that examines all combinations of feature-values, up to a certain length, and determines which feature-values are informative when they are considered in combination.

Due to the large data size (all mention-pairs of the CoNLL training data) and the high dimensionality of feature-values, compared to common evaluation sets of pattern mining methods, the existing discriminative pattern mining approaches were not applicable to our data. In this section, we propose an efficient discriminative pattern mining approach, called Efficient Pattern Miner (EPM), that is scalable to large NLP datasets. The most important properties of EPM are (1) it examines all frequent feature-values combinations, up to the desired length, (2) it is scalable to large datasets, and (3) it is only data dependent and independent of the coreference resolver.

6.1 Notation

We use the following notations and definitions throughout this section:

- $D = \{X_i, c(X_i)\}_{i=1}^{n}$: set of n training samples. X_i is the set of feature-values that describes the ith sample. $c(X_i) \in C$ is the label of X_i, e.g. coreferent and non-coreferent.
- $A = \{a_1, \ldots, a_l\}$: set of all feature-values present in D. Each $a_i \in A$ is called an item, e.g. $a_i =$"anaphor type=proper".

---

[8] i.e. "top-pairs+linguistic"

[9] Henceforth, we refer to them as feature-values.

- p: pattern $p = \{a_{i_1}, \dots, a_{i_k}\}$ is a set of one or more items, e.g. p ={“anaphor type=proper”, “antecedent type=proper”}.
- $support(p, c_i)$: the number of samples that contain pattern p and are labeled with c_i.

6.2 Data Structure

For representing the input samples, we use the Frequent Pattern Tree (FP-Tree) structure that is the data structure of the FP-Growth algorithm (Han et al., 2004), i.e. one of the most common algorithms for frequent pattern mining. FP-Tree provides a structure for representing all existing patterns of data in a compressed form. Using the FP-Tree structure allows an efficient enumeration of all frequent patterns. In the FP-Tree structure, items are arranged in descending order of frequency. Frequency of an item corresponds to $\sum_{c_i \in C} support(a_i, c_i)$. Except for the root, which is a null node, each node n contains an item $a_i \in A$. It also contains the support values of a_i in the subpath of the tree that starts from the root and ends with n, i.e. $support_n(a_i, c_j)$.

The FP-Tree construction method (Han et al., 2004) is as follows: (a) scan D to collect the set of all items, i.e. A. Compute $support(a_i, c_j)$ for each item $a_i \in A$ and label $c_j \in C$. Sort A’s members in descending order according to their frequencies, i.e. $\sum_{c_i \in C} support(a_i, c_i)$. (b) create a null-labeled node as the root, and (c) scan D again. For each $(X_i, c(X_i)) \in D$:

1. Order all items $a_j \in X_i$ according to the order in A.
2. Set the current node (T) to the root.
3. Consider $X_i = [a_k|\bar{X}_i]$, where a_k is the first (ordered) item of x_i, and $\bar{X}_i = X_i - a_k$. If T has a child n that contains a_k then increment $support_n(a_k, c(X_i))$ by one. Otherwise, create a new node n that contains a_k with $support_n(a_k, c(X_i)) = 1$. Add n to the tree as a child of T.
4. If $\bar{X}_i$ is non-empty, set T to n. Assign $X_i = \bar{X}_i$ and go to step 3.

As an example, assume D contains the following two samples:

X_1={ana-type=NAM, ant-type=NAM, head-match=F}, $C(X_1) = 0$

X_2={ana-type=NAM, ant-type=NAM, head-match=T}, $C(X_2) = 1$

Based on these samples A={ana-type=NAM, ant-type=NAM, head-match=F, head-match=T}, $support(a_i, 0)_{a_i \in A}$= {1,1,1,0}, and $support(a_i, 1)_{a_i \in A}$={1,1,0,1}. If we sort A based on a_i’s frequencies ($support(a_i, 0) + support(a_i, 1)$), the ordering of A’s items will remain the same.

The FP-Tree construction steps for the above samples are demonstrated in Figure 1. ana-type, ant-type, and head-match features are abbreviated as ana, ant, and head, respectively.

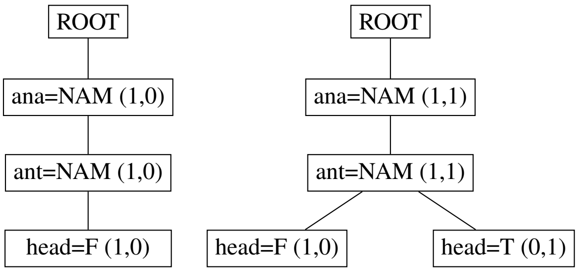

Figure 1: Left to right: (partially) constructed FP-Tree for the example in Section 6.2.

From an initial FP-Tree (T) that represents all existing patterns, one can easily obtain a new FP-Tree in which all patterns include a given pattern p. This can be done by only including sub-paths of T that contain pattern p. The new tree is called conditional FP-Tree of p, T_p. An example of conditional FP-Tree is included in the supplementary materials.

6.3 Informativeness Measures

We use a *discriminative power* and an *information novelty* measure for determining informativeness. We also use a *frequency* measure which determines the required minimum frequency of a pattern in training samples. It helps to avoid overfitting to the properties of the training data.

Discriminative power: We use the G^2 likelihood ratio test (Agresti, 2007) in order to choose patterns whose association with the class variable is statistically significant.[10] The G^2 test is successfully used for text analysis (Dunning, 1993).

Information Novelty: A large number of redundant patterns can be generated by adding irrelevant items to a base pattern that is discriminative itself.

---

[10] A pattern is considered discriminative if the corresponding p-value is less than a fixed threshold (0.01).

We consider the pattern p as novel if (1) p predicts the target class label c significantly better than all of its containing items, and (2) p predicts c significantly better than all of its sub-patterns that satisfy the frequency, discriminative power, and the first information novelty conditions. Similar to Batal and Hauskrecht (2010), we employ a binomial distribution to determine information novelty.

6.4 Mining Algorithm

The EPM algorithm is summarized in Algorithm 1. It takes FP-Tree T, pattern p on which T is conditioned, and set of items ($A_j \subset A$) whose combinations with p will be examined. Initially, p is empty and the FP-Tree is constructed based on all frequent items of data and $A_j = A$. Resulting patterns are collected in P.

For each $a_i \in A_j$, the algorithm builds new pattern q by combining a_i with p. $frequent(q)$ checks whether q meets the frequency condition. If q is frequent, the algorithm continues the search process. Otherwise, it is not possible to build any frequent pattern out of a non-frequent one. *Discriminative power* and the first condition of *information novelty* are then checked for pattern q.

```
Algorithm $EPM$ ($T$, $p$, $A_j$)
    foreach $a_i \in A_j$ do
        $q = p \cup \{a_i\}$
        if $Frequent(q)$ then
            if $Discriminative(q)$ then
                if $Novel(q)$ then
                    $P = P \cup q$
                end
            end
            if $|q| >= \Theta_l$ then
                continue
            end
            construct $T_q$ = $q$'s conditional tree
            $EPM(T_q, q, ancestors(a_i))$
        end
    end
```

Algorithm 1: The EPM algorithm.

We use a threshold (Θ_l) for the maximum length of mined patterns. Θ_l can be set to large values if more complex and specific patterns are desirable.

If $|q|$ is smaller than Θ_l, the conditional FP-Tree T_q is built that represents patterns of T that include the pattern q. The mining algorithm then continues to recursively search for more specific patterns by combining q with the items included in $ancestors(a_i)$, which keeps the list of all ancestors of a_i in the original FP-Tree. EPM examines all frequent patterns of up to length Θ_l.

If we use a statistical test multiple times, the risk of making false discoveries increases (Webb, 2006). To tackle this, we apply the Bonferroni correction for multiple tests in a post-pruning function after the mining process. This function also applies the second information novelty condition on the resulting patterns.

7 Why Use EPM?

In this section, we explain why EPM is a better alternative compared to its counterparts for large NLP datasets. We compare EPM with two efficient discriminative pattern mining algorithms, i.e. Minimal Predictive Patterns (MPP) (Batal and Hauskrecht, 2010) and Direct Discriminative Pattern Mining (DDPMine) (Cheng et al., 2008), on standard machine learning datasets.

MPP selects patterns that are significantly more predictive than all their sub-patterns. It measures significance by the binomial distribution. For each pattern of length l, MPP checks $2^l - 1$ sub-patterns. DDPMine is an iterative approach that selects the most discriminative pattern at each iteration and reduces the search space of the next iteration by removing all samples that include the selected pattern. DDPMine uses the FP-Tree structure.

We show that EPM scales best and compares favorably based on the informativeness of resulting patterns. Due to its efficiency, EPM can handle large datasets similar to ones that are commonly used in various NLP tasks.

7.1 Experimental Setup

We use the same FP-Tree implementation for DDPMine and EPM. In all algorithms, we consider a pattern as frequent if it occurs in 10% of the samples of one of the classes. We use $\Theta_l = 3$ for both MPP and EPM.

We perform 5-times repeated 5-fold cross validation and the results are averaged. In each validation, all experiments are performed on the same split. We use a linear SVM, i.e. LIBLINEAR 2.11 (Fan et al., 2008), as the baseline classifier.

We use several datasets from the UCI machine learning repository (Lichman, 2013) whose characteristics are presented in the first three columns of Table 3, i.e. the number of (1)

	Data characteristics			# Patterns			Micro-F				Macro-F

Table 3: Evaluating the informativeness of DDPMine, MPP and EPM patterns on standard datasets.

(real/integer/nominal) features (#Features), (2) frequent items (#FI), and (3) samples (n). We use one[the minority class]-vs-all technique for datasets with more than two classes.

7.2 How Informative are EPM Patterns?

To evaluate the informativeness of mined patterns, the common practice is to add them as new features to the feature set of the baseline classifier; the more informative the patterns, the greater impact they would have on the overall performance. All patterns are added as binary features, i.e. the feature is true for samples that contain all items of the corresponding pattern.

The effect of the patterns of DDPMine, MPP and EPM on the overall accuracy is presented in Table 3. The columns #Patterns show the number of patterns mined by each of the algorithms. The *Orig* columns show the results of the SVM using the original feature sets. The *DDP*, *MPP*, and *EPM* columns show the results of the SVM on the datasets for which the feature set is extended by the features mined by DDPMine, MPP, and EPM, respectively. The results of the 5-repeated 5-fold cross validation are reported if each single validation takes less than 10 hours.

Based on the results of Table 3 (1) EPM efficiently scales to larger datasets, (2) MPP and EPM patterns considerably improves the performance, and (3) EPM has on-par results with MPP while it mines considerably fewer patterns.

7.3 How Does it Scale?

Figure 2 compares EPM mining time (in seconds) with those of DDPMine and MPP. The parameter in the parentheses is the pattern size threshold, e.g. $\Theta_l = 4$ for EPM(4). The experiments that take more than two days are terminated and are not included. EPM is notably faster in comparison to the other two approaches. It is notable that the examined datasets are considerably smaller than the coreference data, which includes more than 33 million samples and 200 frequent feature-values.

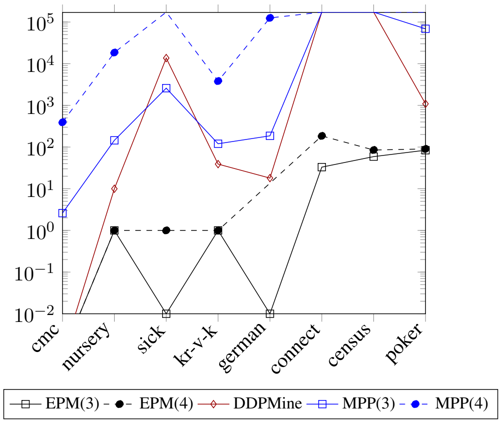

Figure 2: Comparison of mining times (seconds).

8 Impact of Informative Feature-values

8.1 Experimental Setup

For determining informative feature-values, we extract all features for all mention-pairs[11] of the CoNLL training data and then apply EPM on this data. In order to prevent learning annotation errors and specific properties of the training data, we consider a pattern as frequent if it occurs in coreference relations of at least m different coreferring anaphors ($m = 20$). Since the majority of mention-pairs are non-coreferent and we are not interested in patterns for non-coreferring relations, we also consider the coreference probability of each pattern p, i.e. $\frac{|\{X_i|p\in X_i \wedge c(X_i)=coreferent\}|}{|\{X_i|p\in X_i\}|}$, in the post-pruning function. The coreference probability should be higher than a threshold (60% in our experiments), so we only mine patterns that are informative for coreferring mentions.

For the coreference resolution experiments, instead of incorporating informative patterns, we incorporate feature-values that are included in the

---

[11] Each mention is paired with all the preceding mentions.

Table 4: Comparisons on the CoNLL test set. The F_1 gains that are statistically significant: (1) "+EPM" compared to "top-pairs", "ranking" and "JIM", (2) "+EPM" compared to "reinforce" based on MUC, B^3 and LEA, (3) "single" compared to "+EPM" based on MUC and B^3, and (4) "ensemble" compared to other systems. Significance is measured based on the approximate randomization test ($p < 0.05$) (Noreen, 1989).

informative patterns mined by EPM. The reason is that deep-coref, or any other recent coreference resolver, uses a deep neural network, which has a fully automated feature generation process. We add these feature-values as binary features.

By setting Θ_l to five,[12] EPM results in 13 pairwise feature-values, 112 POS tags, i.e. 53 POS for anaphors and 59 for antecedents, 25 dependency relations, 26 mention types (mention types or fine mention types), and finally, 14 named entity tags.[13]

Based on the observation in Section 5, we use the top-pairs model of deep-coref as the baseline to employ additional features, i.e. "+EPM" is the top-pairs model in which EPM feature-values are incorporated.

8.2 Impact on In-domain Performance

The performance of the "+EPM" model compared to recent state-of-the-art coreference models on the CoNLL test set is presented in Table 4. The "single" and "ensemble" rows represent the results of the single and ensemble models of e2e-coref.

We also compare EPM with the pattern mining approach used by Uryupina and Moschitti (2015), i.e. Jaccard Item Mining (JIM). For a fair comparison, while Uryupina and Moschitti (2015) used mined patterns for extracting feature templates, we use them for selecting feature-values. We run the JIM algorithm on the same data and with the same setup as that of EPM.[14] This results in nine pairwise features, 260 POS tags, 38 dependency relations, 32 mention types, and 18 named entity tags. The "+JIM" row shows the results of deep-coref top-pairs model in which these feature-values are incorporated. As we see, EPM feature-values result in significantly better performance than those of JIM while the number of EPM feature-values is considerably less than JIM.

	MUC	B^3	CEAF$_e$	CoNLL	LEA

-NER	74.61	65.05	60.93	66.86	61.27
-POS	74.74	65.04	60.88	66.89	61.30
+pairwise	74.25	64.33	60.02	66.20	60.57

Table 5: Impact of different EPM feature groups on the CoNLL development set.

Feature Ablation Table 5 shows the effect of each group of EPM feature-values, i.e. pairwise features, mention types, dependency relations, named entity tags and POS tags, on the performance of "+EPM". The performance of "+EPM" from which each of the above feature groups is removed, one feature group at a time, is represented as "-pairwise", "-types", "-dep", "-NER", and "-POS", respectively. The POS and named entity tags have the least and the pairwise features have the most significant effect. Since pairwise features have the most significant effect, we also perform an experiment in which only pairwise features are incorporated in the "top-pairs" model, i.e. "+pairwise". The results of "-pairwise" compared to "+pairwise" show that pairwise feature-values have a significant impact, but only when they are considered in combination with other EPM

---

[12] We observe that using larger Θ_l values will result in many over-specified patterns.

[13] Following the previous studies that show different features are of different importance for various types of mentions, e.g. Denis and Baldridge (2008) and Moosavi and Strube (2017b), we mine a separate set of patterns for each type of anaphor. These resulting feature-values are the union of informative feature-values for all types of anaphora.

[14] We set the minimum frequency, maximum pattern length and $score^+$ threshold parameters of JIM to 20, 5 and 0.6.

8.3 Impact on Generalization

We use the same setup as that of Moosavi and Strube (2017a) for evaluating generalization including (1) training on the CoNLL data and testing on WikiCoref[15] and (2) excluding a genre of the CoNLL data from training and development sets and testing on the excluded genre. Similar to Moosavi and Strube (2017a), we use the *pt* and *wb* genres for the latter evaluation setup.

The results of the first evaluation setup are shown in Table 6. The best performance on WikiCoref is achieved by Ghaddar and Langlais (2016a) ("G&L" in Table 6) who introduced WikiCoref and design a domain-specific coreference resolver that makes use of the Wikipedia markups of a document as well as links to Freebase, which are annotated in WikiCoref.

Incorporating EPM feature-values improves the performance by about three points. While "+EPM" does not use the WikiCoref data during training, and unlike "G&L", it does not employ any domain-specific features, it achieves on-par performance with that of "G&L". This indeed shows the effectiveness of informative feature-values in improving generalization.

The second set of generalization experiments is reported in Table 7. "in-domain" columns show the results when the evaluation genres were included in training and development sets while the "out-of-domain" columns show the results when the evaluation genres were excluded. As we can see, "+EPM" generalizes best, and in out-of-domain evaluations, it considerably outperforms the ensemble model of e2e-coref, which has the best performance on the CoNLL test set.

9 Conclusions

In this paper, we show that employing linguistic features in a neural coreference resolver significantly improves generalization. However, the incorporated features should be informative enough to be taken into account in the presence of lexical features, which are very strong features in the CoNLL dataset. We propose an efficient algorithm to determine informative feature-values in large datasets. As a result of a better generalization, we achieve state-of-the-art results in all examined out-of-domain evaluations.

Neural Segmental Hypergraphs for Overlapping Mention Recognition

Abstract

In this work, we propose a novel *segmental hypergraph* representation to model overlapping entity mentions that are prevalent in many practical datasets. We show that our model built on top of such a new representation is able to capture features and interactions that cannot be captured by previous models while maintaining a low time complexity for inference. We also present a theoretical analysis to formally assess how our representation is better than alternative representations reported in the literature in terms of representational power. Coupled with neural networks for feature learning, our model achieves the state-of-the-art performance in three benchmark datasets annotated with overlapping mentions.[1]

1 Introduction

One of the most crucial steps towards building a natural language understanding system is the identification of basic semantic chunks in text. Such a task is typically characterized by the named entity recognition task (Grishman, 1997; Tjong Kim Sang and De Meulder, 2003), or the more general mention recognition task, where mentions are defined as references to entities that could be named, nominal or pronominal (Florian et al., 2004). The extracted mentions can be used in various downstream tasks for performing further semantic related tasks, including question answering (Abney et al., 2000), relation extraction (Mintz et al., 2009; Liu et al., 2017), event extraction (Riedel and McCallum, 2011; Li et al., 2013), and coreference resolution (Soon et al., 2001; Ng and Cardie, 2002; Chang et al., 2013).

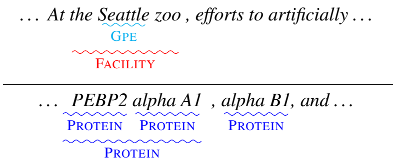

Figure 1: Examples of overlapping mentions.

One popular approach to the task of mention extraction is to regard it as a sequence labeling problem, with the underlying primary assumption being that the mentions are non-overlapping spans in the text. However, as highlighted in several prior research efforts (Alex et al., 2007; Finkel and Manning, 2009; Lu and Roth, 2015), mentions may overlap with one another in practice. Thus, models based on such a simplified assumption may result in sub-optimal performance for a down-stream task when they are deployed in practice. For example, consider a phrase "*At the Seattle zoo, . . .*" shown in Figure 1, the relation LOCATEDIN between the mentions "*the Seattle zoo*" (of type FACILITY) and "*Seattle*" (of type GPE: Geo-political entities) will not be extracted unless both of these two overlapping mentions could be extracted. Similarly, there are 4 mentions of the same type (PROTEIN) in the text span "*. . . PEBP2 alpha A1, alpha B1 . . .*" taken from the biomedical domain. A downstream question answering system may fail to return the correct answer as desired, if the mention extraction system it relies on is unable to extract all these valid mentions.

Various approaches to extracting overlapping mentions have been proposed in the past decade. The cascaded approach (Alex et al., 2007) builds a pipeline of sequence labeling models using conditional random fields (CRF) (Lafferty et al., 2001). However, the model is unable to handle overlapping mentions of the same type. Finkel and Manning (2009) presented a parsing based approach to nested mention extraction. Due to the chart-based parsing algorithm involved, the model has a cubic time complexity in the number of words in the sen-

tence. A recent approach by Lu and Roth (2015) introduced a hypergraph representation for capturing overlapping mentions, which was shown fast and effective. The work was improved by Muis and Lu (2017), who proposed a sequence labeling approach that assigns tags to gaps between words. However, both approaches suffer from the *structural ambiguity* issue during inference, as we will further discuss in this paper.

We summarize our contributions as:

1. We propose a novel *segmental hypergraph* representation that is capable of modeling arbitrary combinations of (potentially overlapping) mentions in a given sentence. The model has a $\mathcal{O}(cmn)$ time complexity (m is the number of mention types, n is the number of words in a sentence, and c is the maximal number of words for each mention), and is able to capture features that cannot be captured by existing approaches.
2. Theoretically, we show that our approach based on such a new representation does not have the limitations associated with some recently proposed state-of-the-art approaches for overlapping mention extraction.
3. We show through extensive experiments on standard data that by exploiting both word-level and span-level features learned from neural networks, our model is able to achieve the state-of-the-art performance for recognizing overlapping mentions.

Our model is also general and robust. Further experiments show that our model yields competitive results when evaluated on data that does not have overlapping mentions annotated when comparing against other recently proposed state-of-the-art neural models that are capable of extracting non-overlapping mentions only.

2 Related Work

Overlapping Mention Recognition

One of the earliest research efforts on handling overlapping mentions is a rule-based approach (Zhang et al., 2004; Zhou et al., 2004; Zhou, 2006) that is evaluated on the GENIA dataset (Kim et al., 2003). The authors first detected the innermost mentions and then relied on rule-based post-processing methods to identify overlapping mentions. McDonald et al. (2005) presented a multilabel classification algorithm to model overlapping segments in a sentence systematically.

Alex et al. (2007) proposed several ways to combine multiple conditional random fields (CRF) (Lafferty et al., 2001) for such tasks. Their best results were obtained by cascading several CRF models in a specific order while each model is responsible for detecting mentions of a particular type. Outputs of one model can also serve as features to the next model. However, such an approach cannot model overlapping mentions of the same type, which frequently appear in practice.

Finkel and Manning (2009) approached this task from a parsing perspective by constructing a constituency tree, mapping each mention to a node in the tree. This approach assumes one mention is *contained by* the other when they overlap. While such an assumption largely holds in practice, it comes with a cost – the chart-based parser suffers from its cubic time complexity, making it not scalable to large datasets involving long sentences. Based on the same idea, Wang et al. (2018) proposed a scalable transition-based approach to construct a constituency forest (a collection of constituency trees).

Instead of relying on structured models, Xu et al. (2017) proposed a local classifier for each possible span. However, this local approach is unable to capture the interactions between spans. Similar to (Alex et al., 2007), Ju et al. (2018) dynamically stacked multiple flat layers which recognize mentions sequentially from innermost mentions to outermost mentions.

Our work is inspired by the model of Lu and Roth (2015), who introduced a *mention hypergraph* representation for capturing overlapping mentions. Their model was shown fast and effective, and was improved by the mention separator model (Muis and Lu, 2017). However, we note that (as also highlighted in their papers) both models suffer from the *structural ambiguity* issue during inference, which we will discuss later. Our new representation does not have this limitation.[2] Recently, Katiyar and Cardie (2018) also proposed a hypergraph-based representation based on the BILOU tagging scheme. Their model is trained greedily using neural networks by viewing the hypergraph construction procedure as a multi-label assignment process.

Neural Models for Mention Recognition

Recently, neural network based approaches to entity or mention recognition have received signifi-

---

[2] A model comparison can be found later in Table 1.

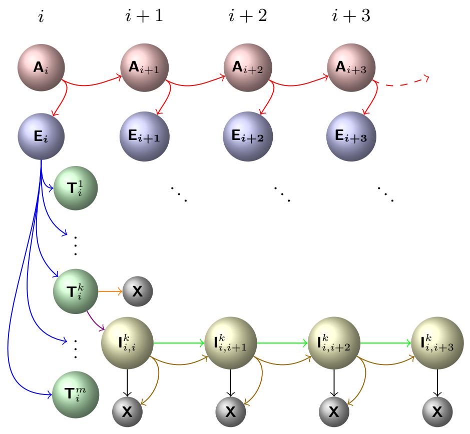

Figure 2: An example of partial segmental hypergraph (hyperedges of different types in different colors).

cant attention. They have been proven effective, even in the absence of handcrafted features. Collobert et al. (2011) used convolutional neural networks (CNN) over word sequences, paired with a CRF output layer. Huang et al. (2015) replaced the CNN with a bidirectional long short-term memory network (LSTM) (Hochreiter and Schmidhuber, 1997). Strubell et al. (2017) proposed an iterated dilated CNN to improve computational efficiency. Beyond word-level compositions, several methods incorporated character-level compositions with character embeddings, either through CNN (Chiu and Nichols, 2016; Ma and Hovy, 2016) or LSTM (Lample et al., 2016).

3 Segmental Hypergraph

A segmental hypergraph is a representation that aims at representing all possible combinations of (potentially overlapping) mentions in a given sentence. It belongs to a class of directed hypergraphs (Gallo et al., 1993), where each hyperedge e consists of a single designated parent node (*head* of e) and an ordered list of child nodes (*tail* of e). Specifically, our segmental hypergraph consists of the following 5 types of nodes:

- $\mathbf{A}_i$ encodes all such mentions that start with the i-th or a later word
- $\mathbf{E}_i$ encodes all mentions that start exactly with the i-th word
- $\mathbf{T}_i^k$ represents all mentions of type k starting with the i-th word
- $\mathbf{I}_{i,j}^k$ represents all mentions of type k that contain the j-th word and start with the i-th word
- $\mathbf{X}$ marks the end of a mention.

Hyperedges connecting these nodes are designed to indicate how the semantics of a parent node can be re-expressed in terms of its child nodes. Figure 2 gives a partial segmental hypergraph representing all combinations of mentions within the span $[i, i+3]$ consisting of 4 words. There are 4 types of hyperedges:

1. A hyperedge $\{\mathbf{A}_i \rightarrow (\mathbf{A}_{i+1}, \mathbf{E}_i)\}$ from $\mathbf{A}_i$ to its children implies the fact that $\mathbf{A}_i$ consists of those mentions that either "start exactly with the i-th word" ($\mathbf{E}_i$), or "start with a word that appears strictly after the i-th word" ($\mathbf{A}_{i+1}$).
2. A hyperedge $\{\mathbf{E}_i \rightarrow (\mathbf{T}_i^1, \ldots, \mathbf{T}_i^m)\}$ from $\mathbf{E}_i$ to its children implies that we should consider all possible types for the mentions (possibly of length 0) that start with the i-th word.
3. Two hyperedges $\{\mathbf{T}_i^k \rightarrow \mathbf{I}_{i,i}^k\}$ and $\{\mathbf{T}_i^k \rightarrow \mathbf{X}\}$ from $\mathbf{T}_i^k$ indicate that either there exists at least one mention starting with the i-th word (the former hyperedge), or there does not exist any such mention (the latter hyperedge).
4. Three hyperedges $\{\mathbf{I}_{i,j}^k \rightarrow \mathbf{I}_{i,j+1}^k\}$, $\{\mathbf{I}_{i,j}^k \rightarrow \mathbf{X}\}$, and $\{\mathbf{I}_{i,j}^k \rightarrow (\mathbf{I}_{i,j+1}^k, \mathbf{X})\}$ from $\mathbf{I}_{i,j}^k$ indicate the following three cases respectively: 1) both the j-th and $(j+1)$-th words belong to at least one mention that starts with the i-th word, 2) there exists one mention that starts with the i-th word and ends with the j-th word, and 3) both cases are valid.

Essentially, the complete hypergraph compactly encodes the whole search space of all possible mentions that can ever appear within a sentence, where such mentions may or may not overlap with one another. When we traverse the complete segmental hypergraph by following the directions as specified by the hyperedges, selecting only one outgoing hyperedge at a time at each node, we arrive at a *hyperpath*[3] – a rooted, directed substructure contained by the original hypergraph.

Figure 3 shows an example. Here, "*Israeli UN Ambassador*" of type PERSON is captured by the following sequence of nodes (along a hyperpath): "$\mathbf{A}_1$, $\mathbf{E}_1$, $\mathbf{T}_1^2$, $\mathbf{I}_{1,1}^2$, $\mathbf{I}_{1,2}^2$, $\mathbf{I}_{1,3}^2$, $\mathbf{X}$", while "*Israeli UN Ambassador Danny*" of type PERSON corresponds to the following node sequence: "$\mathbf{A}_1$, $\mathbf{E}_1$, $\mathbf{T}_1^2$, $\mathbf{I}_{1,1}^2$, $\mathbf{I}_{1,2}^2$, $\mathbf{I}_{1,3}^2$, $\mathbf{I}_{1,4}^2$, $\mathbf{X}$". Similarly, the following sequence "$\mathbf{A}_1$, $\mathbf{A}_2$, $\mathbf{E}_2$, $\mathbf{T}_2^1$, $\mathbf{I}_{2,2}^1$, $\mathbf{X}$" represents the mention "*UN*" of type ORGANIZATION. As we can see, such node sequences together form a single hyperpath that encodes this specific combination of mentions that overlap with one another.

---

[3] Each hyperpath is a *hypertree* (Brandstädt et al., 1998).

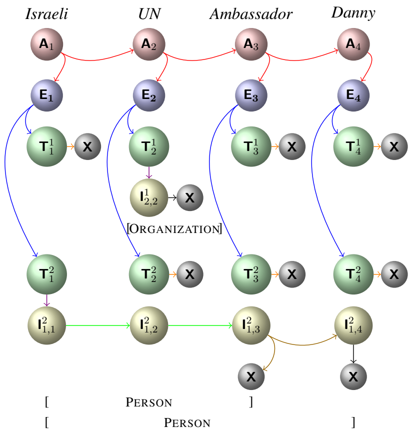

Figure 3: A specific hyperpath for encoding three mentions. For brevity, we only show two types.

More details on segmental hypergraph and hyperpaths are in the supplementary material.

Theoretical Analysis

Our proposed segmental hypergraph representation has the following theoretical property:

Theorem 3.1. (Structural Ambiguity Free) *For any sentence and its segmental hypergraph* $\mathcal{G} = (\mathcal{V}, \mathcal{E})$*, let* $\mathcal{S}$ *be the set of all possible mention combinations for the given sentence, and* $\mathcal{P}$ *be the set of all hyperpaths contained by* $\mathcal{G}$*, there is a one-to-one correspondence between elements in* $\mathcal{P}$ *and* $\mathcal{S}$*.*

Due to space, we provide a proof sketch and include more details in the supplementary material. **Proof Sketch** We note that each hyperpath is uniquely characterized by its collection of hyperedges that involve **X** nodes. These hyperedges uniquely determine the collection of mentions. Conversely, a collection of mentions can be uniquely characterized by a collection of such hyperedges, which yields a unique hyperpath. ☐

Note that such a theorem states that our novel representation has no *structural ambiguity*, a nice property that both mention hypergraph model of (Lu and Roth, 2015) and mention separator model of (Muis and Lu, 2017) do not hold. As the authors have mentioned in their papers, for a given sub-structure in their model, there exist multiple ways of interpreting the combination of mentions. Specifically, in both representations, the decisions on where the *beginning* and the *end* of a mention are made *locally*. Such a design will lead to the structural ambiguity as there will be multiple interpretations to the mentions given a particular collection of positions marked as beginning and end of mentions. To illustrate, consider a phrase with 4 words "*A B C D*" where there are only two overlapping mentions "*B C*" and "*A B C D*". In both of the previous approaches, their models would make local predictions and assign both "*A*" and "*B*" as left boundaries, and both "*C*" and "*D*" as right boundaries. However, based on such local predictions one could also interpret "*A B C*" as a mention – this is where the ambiguity arises. In contrast, our model enjoys the structural ambiguity free property as it uses our newly defined **I** nodes (together with **X** nodes) to jointly capture the complete boundary information of mentions. Table 1 shows a full comparison. [4]

4 Learning

We adopt a log-linear approach to model the conditional probability of each hyperpath as follows:

$$p(\boldsymbol{y}|\boldsymbol{x}) = \frac{\exp f(\boldsymbol{x}, \boldsymbol{y})}{\sum_{\boldsymbol{y}'} \exp f(\boldsymbol{x}, \boldsymbol{y}')} \tag{1}$$

where $f(\boldsymbol{x}, \boldsymbol{y})$ is the score function for any pair of input sentence $\boldsymbol{x}$ and output mention combination $\boldsymbol{y}$, which corresponds to a unique hyperpath $\mathcal{G}_{\boldsymbol{y}}$. Our objective is to minimize the negative log-likelihood of all instances in the training set $\mathcal{D}$:

$$-\sum_{(\boldsymbol{x}, \boldsymbol{y}^*) \in \mathcal{D}} \log p(\boldsymbol{y}^*|\boldsymbol{x}) \tag{2}$$

We define features over each hyperedge within the hyperpath $\mathcal{G}_{\boldsymbol{y}}$. The score function can be decomposed into the following form:

$$f(\boldsymbol{x}, \boldsymbol{y}) = \sum_{e \in \mathcal{G}_{\boldsymbol{y}}} \psi(e, \boldsymbol{x}) \tag{3}$$

where $e \in \mathcal{G}_{\boldsymbol{y}}$ denotes a hyperedge that appears within the hyperpath $\mathcal{G}_{\boldsymbol{y}}$, and $\psi(e, \boldsymbol{x})$ is a score defined over e when the input sentence is $\boldsymbol{x}$.

Apart from *word-level* features, the segmental hypergraph also allows *span-level* features to be defined. The node $\mathbf{I}^k_{i,j}$ corresponds to a particular span $[i, j]$ over which we can extract our local features. The hyperedge between **I** nodes can capture the interactions between partial mentions and hyperedge between $\mathbf{I}^k_{i,j}$ and **X** precisely represents the mention $[i, j]$ with type k. We note that such features and interactions cannot be captured by the models of (Lu and Roth, 2015) and (Muis and Lu, 2017). Such a unique property makes our segmental hypergraph model more expressive than theirs.

---

[4] The mention hypergraph (Lu and Roth, 2015) also suffers from the *spurious structures* issue, while we do not. We refer the readers to (Muis and Lu, 2017) for details.

	Spurious Structures	Structural Ambiguity	Only Nested Mentions	Pipeline Approach	Different Types Only	Time Complexity
Alex et al. (2007)	NO	NO	NO	YES	YES	$\mathcal{O}(mn)$

This work	**NO**	**NO**	**NO**	**NO**	**NO**	$\mathcal{O}(cmn)$

Table 1: Model comparison. $|G|$ is the number of rules in grammar G.

4.1 Softmax-Margin Training

Inspired by (Mohit et al., 2012), we consider the softmax-margin (Gimpel and Smith, 2010) in our model. The function $\psi(e, \boldsymbol{x})$ is defined as follows:

$$\psi(e, \boldsymbol{x}) = \phi(e, \boldsymbol{x}) + \Delta(e, \mathcal{G}_{\boldsymbol{y}^*}) \tag{4}$$

where $\phi(e, \boldsymbol{x})$ is a feature function, and $\Delta(e, \mathcal{G}_{\boldsymbol{y}^*})$ is the cost function that defines the margin:

$$\Delta(e, \mathcal{G}_{\boldsymbol{y}^*}) = \begin{cases} \beta & \mathrm{TX}[e] \wedge e \notin \mathcal{G}_{\boldsymbol{y}^*} \\ 1 & \mathrm{TI}[e] \wedge e \notin \mathcal{G}_{\boldsymbol{y}^*} \\ 0 & \text{otherwise} \end{cases} \tag{5}$$

Here, $\boldsymbol{y}^*$ is the gold mention combination, and $\mathrm{TX}[e]$ and $\mathrm{TI}[e]$ are indicator functions that return true if e is between T and X and between T and I respectively, and false otherwise. We set $\beta \geq 1$ such that the cost function will assign more penalty to false negatives than to false positives.

4.2 Feature Representation

We use two bidirectional LSTMs to learn word-level and span-level feature representations that can be used in our approach, resulting in our *neural segmental hypergraph* model. We first map the i-th word in a sentence to its pre-trained word embedding $\mathbf{e}_i$, and its POS tag to its embedding $\mathbf{p}_i$ if it exists. The final representation for i-th word is the concatenation of them: $\mathbf{v}_i = [\mathbf{e}_i, \mathbf{p}_i]$. Next, we use the a bidirectional LSTM to capture context-specific information for each word, resulting in the word-level features:

$$\mathbf{h}^w_i = [\mathrm{biLSTM}_1(\mathbf{v}_0, ..., \mathbf{v}_n)]_i \tag{6}$$

Such representations are then used as inputs to a second LSTM to generate span-level features: Inspired by (Kong et al., 2016), we compute all possible span embeddings efficiently with time complexity $\mathcal{O}(cn)$ using dynamic programming, with n being the number of words in the input $\boldsymbol{x}$ and c being the maximal length of a mention.

$$\mathbf{h}^s_{i:j} = \mathrm{biLSTM}_2(\mathbf{h}^w_i, ..., \mathbf{h}^w_j) \tag{7}$$

Recall that there are 4 types of hyperedges in our hypergraph, over which we can define the score functions. Since every valid mention hyperpath contains the first and second kind of hyperedges, defining scores over such hyperedges are unnecessary as their scores would serve as a constant factor that can be eliminated in the overall loss function of the log-linear model. Thus we only need to define the score functions on the latter two types of hyperedges. For hyperedges that only involve two nodes, we use a linear layer to compute their scores:

$$\phi(\{\mathsf{T}^k_i \rightarrow \mathsf{X}\}, \boldsymbol{x}) = \mathbf{W}^{(k)}_{\mathrm{TX}} \cdot \mathbf{h}^w_i \tag{8}$$

$$\phi(\{\mathsf{T}^k_i \rightarrow \mathsf{I}^k_{i,j}\}, \boldsymbol{x}) = \mathbf{W}^{(k)}_{\mathrm{TI}} \cdot \mathbf{h}^w_i \tag{9}$$

$$\phi(\{\mathsf{I}^k_{i,j} \rightarrow \mathsf{I}^k_{i,j+1}\}, \boldsymbol{x}) = \mathbf{W}^{(k)}_{\mathrm{II}} \cdot [\mathbf{h}^s_{i:j}, \mathbf{h}^s_{i:j+1}] \tag{10}$$

$$\phi(\{\mathsf{I}^k_{i,j} \rightarrow \mathsf{X}\}, \boldsymbol{x}) = \mathbf{W}^{(k)}_{\mathrm{IX}} \cdot \mathbf{h}^s_{i:j} \tag{11}$$

where matrices $\mathbf{W}_{\mathrm{TX}}, \mathbf{W}_{\mathrm{TI}} \in \mathbb{R}^{d_1 \times m}$, $\mathbf{W}_{\mathrm{II}} \in \mathbb{R}^{2d_2 \times m}$, $\mathbf{W}_{\mathrm{IX}} \in \mathbb{R}^{d_2 \times m}$, with superscript (k) referring to the k-th column of the matrix, d_1 is the dimension of $\mathbf{h}^w$, d_2 is the dimension of $\mathbf{h}^s$, and m is the number of mention types.

For the hyperedges that involve more than two nodes, the score is computed as follows:

$$\begin{aligned} &\phi(\{\mathsf{I}^k_{i,j} \rightarrow (\mathsf{X}, \mathsf{I}^k_{i,j+1})\}, \boldsymbol{x}) \\ &= \mathbf{W}'^{(k)}_{\mathrm{II}} \cdot [\mathbf{h}^s_{i:j}, \mathbf{h}^s_{i:j+1}] + \mathbf{W}'^{(k)}_{\mathrm{IX}} \cdot \mathbf{h}^s_{i:j} \end{aligned} \tag{12}$$

where $\mathbf{W}'_{\mathrm{II}} \in \mathbb{R}^{2d_2 \times m}$, $\mathbf{W}'_{\mathrm{IX}} \in \mathbb{R}^{d_2 \times m}$. Note that in this work, we set $\mathbf{W}'_{\mathrm{II}} = \mathbf{W}_{\mathrm{II}}$ and $\mathbf{W}'_{\mathrm{IX}} = \mathbf{W}_{\mathrm{IX}}$ to reduce the number of free parameters.

Learning uses stochastic gradient descent with the update rule of Adam (Kingma and Ba, 2014) and a gradient clipping of 3.0. Dropout (Srivastava et al., 2014) for input vectors $\mathbf{v}$ and ℓ_2 regularization are used to reduce overfitting; both are tuned during the development process.

4.3 Character-level Representation

To make fair comparisons with recent models (Ju et al., 2018; Wang et al., 2018) that additionally incorporate character-level components in capturing orthographic and morphological features of words, we follow Lample et al. (2016) to use a bidirectional LSTM that takes the character embeddings as input. Specifically, the character-level representation $\mathbf{ch}_i$ for each word is obtained by concatenating the last hidden vectors of the forward and backward LSTMs. When this component is activated, the representation of each word is changed to: $\mathbf{v}_i = [\mathbf{e}_i, \mathbf{p}_i, \mathbf{ch}_i]$.

5 Inference

Inference can be done efficiently using a generalized inside-outside style message-passing algorithm (Baker, 1979). The partition function of (1) can be computed using the inside algorithm applied to the complete hypergraph $\mathcal{G}$, where we traverse from leaf nodes $\mathsf{\mathbf{X}}$ to the root node $\mathsf{\mathbf{A}}_1$, passing messages to a parent node $\mathsf{\mathbf{p}}$ from its child nodes:

$$\mu[\mathsf{\mathbf{p}}] \leftarrow \log\Big(\sum_{e:h(e)\equiv\mathsf{\mathbf{p}}} \exp\big(\psi(e,\boldsymbol{x}) + \sum_{\mathsf{\mathbf{c}}\in\mathcal{T}(e)} \mu[\mathsf{\mathbf{c}}]\big)\Big) \tag{13}$$

where $h(e)$ is the head of the hyperedge e, and $\mathcal{T}(e)$ is the collection of nodes that form the tail of e – they are the child nodes of $h(e)$ given e. The message passing step for the outside algorithm can be defined analogously. It can be verified that such a message passing algorithm, that is analogous to the sum-product belief propagation algorithm (Kschischang et al., 2001) used in standard graphical models, will converge after one forward and one backward pass.

For decoding, we perform the standard MAP inference on top of the complete hypergraph to find the most probable hyperpath. The resulting procedure is similar to the max-product message passing algorithm, where we consider only the feature function ϕ for constructing the messages:

$$\mu[\mathsf{\mathbf{p}}] \leftarrow \max_{e:h(e)\equiv\mathsf{\mathbf{p}}} \Big(\phi(e,\boldsymbol{x}) + \sum_{\mathsf{\mathbf{c}}\in\mathcal{T}(e)} \mu[\mathsf{\mathbf{c}}]\Big) \tag{14}$$

During inference, each node corresponds to a sum/max computation. Since one node is incident to 3 hyperedges maximally, the time complexity of inference algorithm can be implied by the number of nodes in the graph, which is $\mathcal{O}(cmn)$, where c is the maximal length for any mention. This complexity is the same as that of a zero-th order semi-Markov CRF model (Sarawagi and Cohen, 2005). Please refer to the supplementary material for a detailed explanation of the inference algorithm.

6 Experiments

6.1 Datasets

We mainly evaluate our models on the standard ACE-2004, ACE-2005 (Doddington et al., 2004), and GENIA (Kim et al., 2003) datasets with the same splits used by previous works (Lu and Roth, 2015; Muis and Lu, 2017). Sample data statistics of these datasets are listed in Table 2. [5] We can see that overlapping mentions frequently appear in such datasets. For ACE2004, over 46% of the mentions overlap with one another. GENIA focuses on biomedical entity recognition[6] and overlapping mentions are also common in it. Most mentions (over 93%) are not longer than 6 tokens which we select as maximal length (c) for the restricted models.

6.2 Baseline Approaches

We consider the following baseline models:

- CRF (LINEAR): a linear-chain CRF model. Since the linear-chain CRF cannot handle overlapping structures, we only use the outer-most mentions for learning. Specifically, every outer-most mention is labeled based on the BILOU tagging scheme, which was empirically shown to be better than the BIO scheme (Ratinov and Roth, 2009).
- CRF (CASCADED): the cascaded CRF based approach following (Alex et al., 2007). Note that this approach cannot model the overlapping mentions of the same type.
- Semi-CRF: the semi-Markov CRF model (Sarawagi and Cohen, 2005). The semi-CRF model is also only trained on the outer-most mentions. It can also capture span-level fea-

---

[5] See supplementary material for complete data statistics.

[6] Following previous works, we used version 3.02p which comes with annotated POS tags (Tateisi, 2004) . Following (Finkel and Manning, 2009), we collapse *DNA*, *RNA* and *protein* subtypes into *DNA*, *RNA* and *protein* respectively, keep cell line and cell type and remove mentions of other types.

Table 3: Main results. SH: segmental hypergraphs (our approach).

tures defined over a complete segment. Similar to our model, semi-CRF typically comes with a length restriction (c) which indicates the maximal length of a mention.

- Finkel and Manning (2009): a parsing-based approach for recognizing nested mentions that reported results on the GENIA dataset.
- Lu and Roth (2015): the model that makes use of mention hypergraphs for recognizing overlapping mentions.
- Muis and Lu (2017): the model that makes use of mention separators to tag gaps between words for recognizing overlapping mentions.
- FOFE (Xu et al., 2017): a local classifier based on neural networks that runs on every possible span to detect mentions. The maximal mention length (c) can also be used here.
- Katiyar and Cardie (2018): a hypergraph-based model that uses LSTM for learning feature representations.
- Ju et al. (2018): a cascaded model that makes use of multiple LSTM-CRF layers to recognize mentions in an inside-out manner.
- Wang et al. (2018): a neural transition-based model that construct nested mentions through a sequence of actions.
- SH (-NN): a non-neural version of our segmental hypergraph model that excludes the LSTMs but employs handcrafted features. [8]

Table 4: Results of various ablations. D: dropout, SM: softmax-margin, P: pre-trained embeddings.

As discussed earlier, we also evaluate the variants of our model that takes character-level representations (+*char*).

6.3 Training

Pre-trained embeddings GloVe (Pennington et al., 2014) of dimension 100 are used to initialize the trainable word vectors for experiments in ACE and GENIA datasets.[9] The embeddings for POS tags are initialized randomly with dimension 32. Early stopping is used based on the performance of development set. The value β used in softmax-margin is chosen from [1, 3] with step size 0.5.

6.4 Experimental Results

Main results can be found in Table 3. Using the same set of handcrafted features, our unrestricted non-neural model SH (-NN, c=n) achieves the best performance compared with other non-neural models, revealing the effectiveness of our newly proposed segmental hypergraph representation. It achieves around 1-2% gain in terms of F_1 compared with mention hypergraph of Lu and Roth (2015) and mention separator of Muis and Lu (2017), showing the necessity of eliminating structural ambiguity. CRF (LINEAR) and Semi-CRF do not perform well due to incapability of handling

---

[7] Note that in ACE2005, Ju et al. (2018) did their experiments with a different split than Lu and Roth (2015) which we follow as our split.

[8] To make a proper comparison, we use the same handcrafted features used by (Lu and Roth, 2015), which were proven effective in previous approaches.

[9] We also additionally tried using embeddings trained on PubMed for GENIA but the performance was comparable.

overlapping mentions. In contrast, the pipeline approach CRF (CASCADED) performs better.

Our unrestricted neural segmental hypergraph model SH (c=n) already achieves the best results among all previous models in ACE datasets, showing the effectiveness of our neural segmental hypergraph. The improvement mainly comes from its ability to recall more mentions. In GENIA, even without using external features like Brown clustering features as all non-neural models do, our neural models still get significant improvements. Compared with the non-neural SH (-NN) which has around 4.2M parameters, our neural model SH only has 1.9M parameters yet it still performs better. We empirically see that the representations learned by LSTM can better capture complex contextual dependencies in sentences. The character-level representations (+ *char*) make both restricted and unrestricted SH perform even better. Particularly, SH (c=n) + *char* achieves the best results in all datasets compared with other recent neural models (Katiyar and Cardie, 2018; Ju et al., 2018; Wang et al., 2018).

One hypothesis we may have is that, without length restriction, a model will enjoy the benefit of recalling more long mentions, but also will be exposed to more false positives. This poses a challenge for a model – whether it is capable of balancing these two factors. Empirically, we find that the length restriction (c=6) improves the precision of semi-CRF and SH at the expense of the recall, providing some evidence to support the hypothesis. However, in terms of F_1, the unrestricted semi-CRF performs worse while unrestricted SH performs better compared to their restricted counterparts. The reason is that the span-level handcrafted features that the semi-CRF relies on can be very sparse when mentions are overly long. We empirically found this issue is alleviated in the model SH (-NN), possibly due to its ability in capturing interactions between neighboring spans. Even with length restriction, SH still yields competitive results, making it attractive in processing large-scale datasets considering its linear time complexity. Furthermore, we find that as c increases, SH performs better consistently in terms of F_1. The choice of c then becomes a tradeoff between time complexity and performance. Please refer to the supplementary material for details.

Compared with the local approach FOFE, our global approach gives a much better performance, showing its effectiveness in capturing interactions between spans. Moreover, FOFE's performance suffers significantly in the absence of the length restriction. The reason is that it will generate much more negative training instances under this setting, which makes its learning more challenging.

	Overlapping			Non-Overlapping			*w/s*
	P	R	F_1	P	R	F_1	
Lu and Roth (2015)	68.1	52.6	59.4	64.1	65.1	64.6	503
Muis and Lu (2017)	70.4	55.0	61.8	67.2	63.4	65.2	253
Wang et al. (2018)	77.4	70.5	73.8	76.1	69.6	72.7	1445

6.5 Additional Analyses

To understand our model better, we conduct some further experiments in this section.

Ablation study

We first conduct an ablation study by removing dropout, softmax-margin and pre-trained embeddings from our model respectively. The results are shown in Table 4. The dropout and pre-trained embeddings can improve the performance of our model significantly and this behavior is consistent with previous neural models for NER (Chiu and Nichols, 2016; Lample et al., 2016). Meanwhile, our new cost function based on softmax margin training also contributes significantly to the good performance of our model across these datasets.

How well does it handle overlapping mentions?

To further understand how well our model can handle overlapping mentions, we split the test data into two portions: sentences with and without overlapping mentions. We compare our model with the two state-of-the-art models and report results on ACE-05 in Table 5.[10] In both portions, SH achieves significant improvements, especially in the portion with overlapping mentions. This observation indicates that our model can better capture the structure of overlapping mentions than these two previous models. It also helps explain why the margin of improvement is larger in ACE than in GENIA since the former has more overlapping mentions than the latter, as shown in Table 2. Compared with the model with length restriction c, the unrestricted model mainly benefits from its ability to recall more overlapping mentions.

Table 6: Additional results on CoNLL-2003.

Running time

Since other compared models also feature linear time complexity (see Table 1), we examine the decoding speed in terms of the number of words processed per second. We re-implement the models of Lu and Roth (2015) and Muis and Lu (2017) using the same platform as ours (PyTorch) and run them on the same machine (CPU: Intel i5 2.7 GHz). The model of (Wang et al., 2018) is also tested with the same environment. Results on ACE-05 are listed in Table 5. The length bound (c=6) makes our model much faster, resulting in a speed comparable to the model of Muis and Lu (2017). The transition-based model by (Wang et al., 2018) has the best scalability partially because of its greedy strategy for decoding.

What if the data has no overlapping mentions?

To assess the robustness of our model and understand whether it could serve as a general mention extraction model, we additionally evaluate our model on CoNLL 2003 dataset which is annotated with non-overlapping mentions only. We compared our model with recent state-of-the-art neural network based models. For a fair comparison, we used the Collobert et al. (2011) embeddings widely used by previous models, and ignored POS tag features even though they are available. Results are in Table 6. Only neural models without using external features are included. [11] By only relying on word (and character) embeddings, our model achieves competitive results compared with other state-of-the-art neural models that also do not exploit external features, yet these models are mostly designed to handle only non-overlapping mentions. The only exception is the FOFE approach by (Xu et al., 2017) as we discussed earlier.

Notes on mention interactions

The dependencies between overlapping mentions can be very beneficial. SH can capture a specific kind of interaction between neighboring spans. Such interactions happen between mentions that share the same type and the same left boundary. As we can see from the sentence in Figure 3, one mention could also serve as a pre-modifier for another mention and both could share the same type. As shown in Table 2, there are over 8% such mentions in ACE and over 4% in GENIA. Specifically, SH relies on the hyperedges between **I** nodes to capture such interactions explicitly. To verify the effectiveness of this connection, we zero the weights between **I** nodes. The ablated model only achieves around 70.0% in ACEs and 71.4% in GENIA, implying the impact of this dependency connection. On the other hand, it also reveals the potential direction of improving SH by explicitly modeling more dependencies between mentions, such as the dependencies between mentions with different types. LSTM that serves as feature representation may capture such interactions implicitly, but building the connections could still be an important aspect for improvement.

7 Conclusion and Future Work

In this work, we propose a novel neural segmental hypergraph model that is able to capture overlapping mentions. We show that our model has some theoretical advantages over previous state-of-the-art approaches for recognizing overlapping mentions. Through extensive experiments, we show that our model is general and robust in handling both overlapping and non-overlapping mentions. The model achieves the state-of-the-art results in three standard datasets for recognizing overlapping mentions. We anticipate this model could be leveraged in other similar sequence modeling tasks that involve predicting overlapping structures such as recognizing overlapping and discontinuous entities (Muis and Lu, 2016) which frequently exist in the biomedical domain.

Abstract

We introduce a family of multitask variational methods for semi-supervised sequence labeling. Our model family consists of a latent-variable generative model and a discriminative labeler. The generative models use latent variables to define the conditional probability of a word given its context, drawing inspiration from word prediction objectives commonly used in learning word embeddings. The labeler helps inject discriminative information into the latent space. We explore several latent variable configurations, including ones with hierarchical structure, which enables the model to account for both label-specific and word-specific information. Our models consistently outperform standard sequential baselines on 8 sequence labeling datasets, and improve further with unlabeled data.

1 Introduction

Sequence labeling tasks in natural language processing (NLP) often have limited annotated data available for model training. In such cases regularization can be important, and it can be helpful to use additional unlabeled data. One approach for both regularization and semi-supervised training is to design latent-variable generative models and then develop neural variational methods for learning and inference (Kingma and Welling, 2014; Rezende and Mohamed, 2015).

Neural variational methods have been quite successful for both generative modeling and representation learning, and have recently been applied to a variety of NLP tasks (Mnih and Gregor, 2014; Bowman et al., 2016; Miao et al., 2016; Serban et al., 2017; Zhou and Neubig, 2017; Hu et al., 2017). They are also very popular for semi-supervised training; when used in such scenarios, they typically have an additional task-specific prediction loss (Kingma et al., 2014; Maale et al., 2016; Zhou and Neubig, 2017; Yang et al., 2017b). However, it is still unclear how to use such methods in the context of sequence labeling.

In this paper, we apply neural variational methods to sequence labeling by combining a latent-variable generative model and a discriminatively-trained labeler. We refer to this family of procedures as variational sequential labelers (VSLs). Learning maximizes the conditional probability of each word given its context and minimizes the classification loss given the latent space. We explore several models within this family that use different kinds of conditional independence structure among the latent variables within each time step. Intuitively, the multiple latent variables can disentangle information pertaining to label-oriented and word-specific properties.

We study VSLs in the context of named entity recognition (NER) and several part-of-speech (POS) tagging tasks, both on English Twitter data and on data from six additional languages. Without unlabeled data, our models consistently show 0.5-0.8% accuracy improvements across tagging datasets and 0.8 F_1 improvement for NER. Adding unlabeled data further improves the model performance by 0.1-0.3% accuracy or 0.2 F_1 score. We obtain the best results with a hierarchical structure using two latent variables at each time step.

Our models, like generative latent variable models in general, have the ability to naturally combine labeled and unlabeled data. We obtain small but consistent performance improvements by adding unlabeled data. In the absence of unlabeled data, the variational loss acts as regularizer on the learned representation of the supervised sequence prediction model. Our results demonstrate that this regularization improves performance even when only labeled data is used. We also compare different ways of applying the classification loss when using a latent variable hierar-

Brussels, Belgium, October 31 - November 4, 2018.

chy, and find that the most effective structure also provides the cleanest separation of information in the latent space.

2 Related Work

There is a growing amount of work applying neural variational methods to NLP tasks, including document modeling (Mnih and Gregor, 2014; Miao et al., 2016; Serban et al., 2017), machine translation (Zhang et al., 2016), text generation (Bowman et al., 2016; Serban et al., 2017; Hu et al., 2017), language modeling (Bowman et al., 2016; Yang et al., 2017b), and sequence transduction (Zhou and Neubig, 2017), but we are not aware of any such work for sequence labeling. Before the advent of neural variational methods, there were several efforts in latent variable modeling for sequence labeling (Quattoni et al., 2007; Sun and Tsujii, 2009).

There has been a great deal of work on using variational autoencoders in semi-supervised settings (Kingma et al., 2014; Maale et al., 2016; Zhou and Neubig, 2017; Yang et al., 2017b). Semi-supervised sequence labeling has a rich history (Altun et al., 2006; Jiao et al., 2006; Mann and McCallum, 2008; Subramanya et al., 2010; Søgaard, 2011). The simplest methods, which are also popular currently, use representations learned from large amounts of unlabeled data (Miller et al., 2004; Owoputi et al., 2013; Peters et al., 2017). Recently, Zhang et al. (2017) proposed a structured neural autoencoder that can be jointly trained on both labeled and unlabeled data.

Our work involves multi-task losses and is therefore also related to the rich literature on multi-task learning for sequence labeling (Plank et al., 2016; Augenstein and Søgaard, 2017; Bingel and Søgaard, 2017; Rei, 2017, *inter alia*).

Another related thread of work is learning interpretable latent representations. Zhou and Neubig (2017) factorize an inflected word into lemma and morphology labels, using continuous and categorical latent variables. Hu et al. (2017) interpret a sentence as a combination of an unstructured latent code and a structured latent code, which can represent attributes of the sentence.

There have been several efforts in combining variational autoencoders and recurrent networks (Gregor et al., 2015; Chung et al., 2015; Fraccaro et al., 2016). While the details vary, these models typically contain latent variables at each time step in a sequence. This prior work mainly focused on ways of parameterizing the time dependence between the latent variables, which gives them more power in modeling distributions over observation sequences. In this paper, we similarly use latent variables at each time step, but we adopt stronger independence assumptions which leads to simpler models and inference procedures. Also, the models cited above were developed for modeling data distributions, rather than for supervised or semi-supervised learning, which is our focus here.

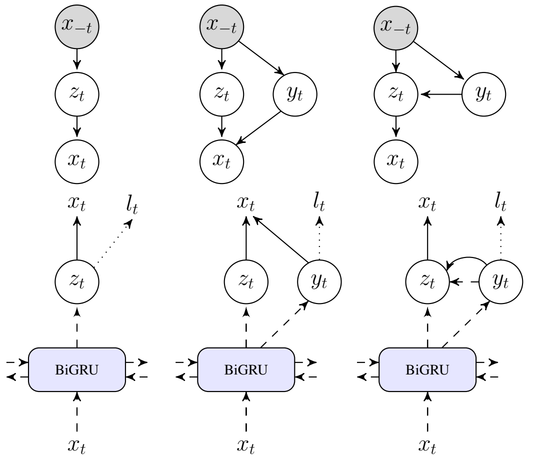
The key novelties in our work compared to the prior work mentioned above are the proposed sequential variational labelers and the investigation of latent variable hierarchies within these models. The empirical effectiveness of latent hierarchical structure in variational modeling is a key contribution of this paper and may be applicable to the other applications discussed above. Recent work, contemporaneous with this submission, similarly showed the advantages of combining hierarchical latent variables and variational learning for conversational modeling, in the context of a non-sequential model (Park et al., 2018).

3 Proposed Methods

We begin by describing variational autoencoders and the notation we will use in the following sections. We denote the input word sequence by $x_{1:T}$, the corresponding label sequence by $l_{1:T}$, the input words other than the word at position t by x_{-t}, the generative model by $p_\theta(\cdot)$, and the posterior inference model by $q_\phi(\cdot)$.

3.1 Background: Variational Autoencoders

We review variational autoencoders (VAEs) by describing a VAE for an input sequence $x_{1:T}$. When using a VAE, we assume a generative model that generates an input using a latent variable z, typically assumed to follow a multivariate Gaussian distribution. We seek to maximize the marginal likelihood of inputs $x_{1:T}$ when marginalizing out the latent variable z. Since this is typically intractable, especially when using continuous latent variables, we instead maximize a lower bound on the marginal log-likelihood (Kingma and Welling,



(a) VSL-G (b) VSL-GG-Flat (c) VSL-GG-Hier

Figure 1: Variational sequential labelers. The first row shows the original graphical models of each variant where shaded circles are observed variables. The second row shows how we perform inference and learning, showing inference models (in dashed lines), generative models (in solid lines), and classifier (in dotted lines). All models are trained to maximize $p_\theta(x_t|x_{-t})$ and predict the label l_t.

2014):

$$\log\ p_\theta(x_{1:T}) \geq \mathop{\mathbb{E}}_{z\sim q_\phi(\cdot|x_{1:T})}\left[\log p_\theta(x_{1:T}|z) - \log\frac{q_\phi(z|\ x_{1:T})}{p_\theta(z)}\right] = \underbrace{\mathop{\mathbb{E}}_{z\sim q_\phi(\cdot|x_{1:T})}[\log p_\theta(x_{1:T}|z)]}_{\text{Reconstruction Loss}} - \underbrace{KL(q_\phi(z|x_{1:T})\|p_\theta(z))}_{\text{KL divergence}} \tag{1}$$

where we have introduced the variational posterior q parametrized by new parameters ϕ. q is referred to as an "inference model" as it encodes an input into the latent space. We also have the generative model probabilities p parametrized by θ. The parameters are trained in a way that reflects a classical autoencoder framework: encode the input into a latent space, decode the latent space to reconstruct the input. These models are therefore referred to as "variational autoencoders".

The lower bound consists of two terms: reconstruction loss and KL divergence. The KL divergence term provides a regularizing effect during learning by ensuring that the learned posterior remains close to the prior over the latent variables.

3.2 Variational Sequential Labelers

We now introduce variational sequential labelers (VSLs) and propose several variants for sequence labeling tasks. Although the latent structure varies, a VSL maximizes the conditional probability of $p_\theta(x_t|x_{-t})$ and minimizes a classification loss using the latent variables as the input to the classifier. Unlike VAEs, VSLs do not autoencode the input, so they are more similar to recent conditional variational formulations (Sohn et al., 2015; Miao et al., 2016; Zhou and Neubig, 2017). Intuitively, the VSL variational objective is to find the information that is useful for predicting the word x_t from its surrounding context, which has similarities to objectives for learning word embeddings (Collobert et al., 2011; Mikolov et al., 2013). This objective serves as regularization for the labeled data and as an unsupervised objective for the unlabeled data.

All of our models use latent variables for each position in the sequence. These characteristics are shown in the visual depictions of our models in Figure 1. We consider variants with multiple latent variables per time step and attach the classifier to only particular variables. This causes the different latent variables to capture different characteristics.

In the following sections, we will describe various latent variable configurations that we will evaluate empirically in subsequent sections.

3.3 Single Latent Variable

We begin by defining a basic VSL and corresponding parametrization, which will also be used in other variants. This first model (which we call VSL-G and show in Figure 1a) has a Gaussian latent variable at each time step. VSL-G uses two training objectives; the first is similar to the lower bound on log-likelihood used by VAEs:

$$\log\ p_\theta(x_t|x_{-t}) \geq \mathop{\mathbb{E}}_{z_t\sim q_\phi(\cdot|\ x_{1:T},t)}[\log p_\theta(x_t|\ z_t) - \log\frac{q_\phi(z_t|\ x_{1:T},t)}{p_\theta(z_t|\ x_{-t})}] = \mathop{\mathbb{E}}_{z_t\sim q_\phi(\cdot|\ x_{1:T},t)}[\log p_\theta(x_t|\ z_t)] - KL(q_\phi(z_t|\ x_{1:T},t)\|\ p_\theta(z_t|\ x_{-t})) = U_0(x_{1:T},t) \tag{2}$$

VSL-G additionally uses a classifier f on the latent variable z_t which is trained with the following objective:

$$C_0(x_{1:T},l_t) = \mathop{\mathbb{E}}_{z_t\sim q_\phi(\cdot|x_{1:T},t)}[-\log f(l_t|z_t)] \tag{3}$$

The final loss is

$$L(x_{1:T},l_{1:T}) = \sum_{t=1}^{T}[C_0(x_{1:T},l_t) - \alpha U_0(x_{1:T},t)]$$

where α is a trade-off hyperparameter. α is set to zero during supervised training but it is tuned based on development set performance during semi-supervised training. The same procedure is adopted for the other VSL models below.

For the generative model, we parametrize $p_\theta(x_t|z_t)$ as a feedforward neural network with two hidden layers and ReLU (Nair and Hinton, 2010) as activation function. As reconstruction loss, we use cross-entropy over the words in the vocabulary. We defer the descriptions of the parametrization of $p_\theta(z_t|\ x_{-t})$ to Section 3.6.

We now discuss how we parametrize the inference model $q_\phi(z_t|x_{1:T}, t)$. We use a bidirectional gated recurrent unit (BiGRU; Chung et al., 2014) network to produce a hidden vector h_t at position t. The BiGRU is run over the input $x_{1:T}$, where each x_t is the concatenation of a word embedding and the concatenated final hidden states from a character-level BiGRU. The inference model $q_\phi(z_t|x_{1:T}, t)$ is then a single layer feedforward neural network that uses h_t as input. When parametrizing the posterior over latent variables in the following models below, we use this same procedure to produce hidden vectors with a BiGRU and then use them as input to feedforward networks. The structure of our inference model is similar to those used in previous state-of-the-art models for sequence labeling (Lample et al., 2016; Yang et al., 2017a).

In order to focus more on the effect of our variational objective, the classifier we use is always the same as our baseline model (see Section 4.3), which is a one layer feedforward neural network without a hidden layer, and it is also used in test-time prediction.

3.4 Flat Latent Variables

We next consider ways of factorizing the functionality of the latent variable into label-specific and other word-specific information. We introduce VSL-GG-Flat (shown in Figure 1b), which has two conditionally independent Gaussian latent variables at each time step, denote z_t and y_t for time step t. The variational lower bound is derived as follows:

$$\begin{aligned}
&\log\ p_\theta(x_t|x_{-t}) \geq \\
&\quad \mathop{\mathbb{E}}_{z_t, y_t \sim q_\phi(\cdot|x_{1:T}, t)} [\log p_\theta(x_t|\ z_t, y_t) \\
&\quad - \log \frac{q_\phi(z_t|x_{1:T}, t)}{p_\theta(z_t|x_{-t})} - \log \frac{q_\phi(y_t|x_{1:T}, t)}{p_\theta(y_t|x_{-t})}] \\
&\quad = \mathop{\mathbb{E}}_{z_t, y_t \sim q_\phi(\cdot|x_{1:T}, t)} [\log p_\theta(x_t|z_t, y_t)] \\
&\quad - KL(q_\phi(z_t|x_{1:T}, t) \| p_\theta(z_t|x_{-t})) \\
&\quad - KL(q_\phi(y_t|x_{1:T}, t) \| p_\theta(y_t|x_{-t})) \\
&\quad = U_1(x_{1:T}, t)
\end{aligned} \tag{4}$$

The classifier f is on the latent variable y_t and its loss is

$$C_1(x_{1:T}, l_t) = \mathop{\mathbb{E}}_{y_t \sim q_\phi(\cdot|x_{1:T}, t)} [-\log f(l_t|y_t)] \tag{5}$$

The final loss for the model is

$$L(x_{1:T}, l_{1:T}) = \sum_{t=1}^{T} [C_1(x_{1:T}, l_t) - \alpha U_1(x_{1:T}, t)] \tag{6}$$

Where α is a trade-off hyperparameter.

Similarly to the VSL-G model, $q_\phi(z_t|x_{1:T}, t)$ and $q_\phi(y_t|x_{1:T}, t)$ are parametrized by single layer feedforward neural networks using the hidden state h_t as input.

3.5 Hierarchical Latent Variables

We also explore hierarchical relationships among the latent variables. In particular, we introduce the VSL-GG-Hier model which has two Gaussian latent variables with the hierarchical structure shown in Figure 1c. This model encodes the intuition that the word-specific latent information z_t may differ depending on the class-specific information of y_t.

For this model, the derivations are similar to Equations (4) and (5). The first is:

$$\begin{aligned}
&\log\ p_\theta(x_t|x_{-t}) \geq \\
&\quad \mathop{\mathbb{E}}_{z_t, y_t \sim q_\phi(\cdot|x_{1:T}, t)} [\log p_\theta(x_t|z_t) \\
&\quad - \log \frac{q_\phi(z_t|y_t, x_{1:T}, t)}{p_\theta(z_t|y_t, x_{-t})} - \log \frac{q_\phi(y_t|x_{1:T}, t)}{p_\theta(y_t|x_{-t})}] \\
&\quad = \mathop{\mathbb{E}}_{z_t, y_t \sim q_\phi(\cdot|x_{1:T}, t)} [\log p_\theta(x_t|z_t)] \\
&\quad - KL(q_\phi(z_t|y_t, x_{1:T}, t) \| p_\theta(z_t|y_t, x_{-t})) \\
&\quad - KL(q_\phi(y_t|x_{1:T}, t) \| p_\theta(y_t|x_{-t})) \\
&\quad = U_2(x_{1:T}, t)
\end{aligned} \tag{7}$$

The classifier f uses y_t as input and is trained with the following loss:

$$C_2(x_{1:T}, l_t) = \underset{y_t \sim q_\phi(\cdot|x_{1:T}, t)}{\mathbb{E}} [-\log f(l_t|y_t)] \quad (8)$$

Note that C_1 and C_2 have the same form. The final loss is

$$L(x_{1:T}, l_{1:T}) = \sum_{t=1}^{T} [C_2(x_{1:T}, l_t) - \alpha\, U_2(x_{1:T}, t)] \quad (9)$$

Where α is a trade-off hyperparameter.

The hierarchical posterior $q_\phi(z_t|y_t, x_{1:T}, t)$ is parametrized by concatenating the hidden vector h_t and the random variable y_t and then using them as input to a single layer feedforward network.

3.6 Parametrization of Priors

Traditional variational models assume extremely simple priors (e.g., multivariate standard Gaussian distributions). Recently there have been efforts to learn the prior and posterior jointly during training (Fraccaro et al., 2016; Serban et al., 2017; Tomczak and Welling, 2018). In this paper, we follow this same idea but we do not explicitly parametrize the prior $p_\theta(z_t|x_{-t})$. This is partially due to the lack of computationally-efficient parametrization options for $p_\theta(z_t|x_{-t})$. In addition, since we are not seeking to do generation with our learned models, we can let part of the generative model be parametrized implicitly.

More specifically, the approach we use is to learn the priors by updating them iteratively. During training, we first initialize the priors of all examples as multivariate standard Gaussian distributions. As training proceeds, we use the last optimized posterior as our current prior based on a particular "update frequency" (see supplementary material for more details).

Our learned priors are implicitly modeled as

$$p_\theta^k(z_t|x_{-t}) \approx \sum_x q_\phi^{k-1}(z_t|X_t = x, x_{-t}, t) p_{\text{data}}(X_t = x|x_{-t}) \quad (10)$$

where p_{data} is the empirical data distribution, X_t is a random variable corresponding to the observation at position t, and k is the prior update time step. The intuition here is that the prior is obtained by marginalizing over values for the missing observation represented by the random variable X_t. The posterior q_ϕ^{k-1} is as defined in our latent variable models. We assume $p_{\text{data}}(X_t = x|x_{-t}) = 0$ for $x_{1:T} \notin$ training set. For context x_{-t} that can pair with multiple values of X_t, its prior is the data-dependent weighted average posterior. For simplicity of implementation and efficient computation, however, if context x_{-t} can pair with multiple values in our training data, we ignore this fact and simply use instance-dependent posteriors. Another way to view this is as conditioning on the index of the training examples while parametrizing the above. That is

$$p_\theta^{k,i}(z_t|x_{-t}) \leftarrow q_\phi^{k-1,i}(z_t|x_{1:T}, t) \quad (11)$$

where i is the index of the instance.

3.7 Training

In this subsection, we introduce techniques we have used to address difficulties during training.

Reparametrization Trick. It is challenging to use gradient descent for a random variable as it involves a non-differentiable sampling procedure. Kingma and Welling (2014) introduced a reparametrization trick to tackle this problem. They parametrize a Gaussian random variable z as $u_\varphi(x) + g_\psi(x) \circ \epsilon$ where $\epsilon \sim \mathcal{N}(0, \mathbf{I})$ and $u_\varphi(x)$, $g_\psi(x)$ are deterministic and differentiable functions, so the gradient can go through $u_\varphi(\cdot)$ and $g_\psi(\cdot)$. In our experiments, we use one sample for each time step during training. For evaluation at test time, we use the mean value $u_\varphi(x)$.

KL Divergence Weight Annealing. Although the use of prior updating lets us avoid tuning the weight of the KL divergence, the simple priors can still hinder learning during the initial stages of training. To address this, we follow the method described by Bowman et al. (2016) to add weights to all KL divergence terms and anneal the weights from a small value to 1.

4 Experiments

We describe key details of our experimental setup in the subsections below but defer details about hyperparameter tuning to the supplementary material. Our implementation is available at `https://github.com/mingdachen/vsl`

4.1 Datasets

We evaluate our model on the CoNLL 2003 English NER dataset (Tjong Kim Sang and De Meulder, 2003) and 7 POS tagging datasets: the

Twitter tagging dataset of Gimpel et al. (2011) and Owoputi et al. (2013), and 6 languages from the Universal Dependencies (UD) 1.4 dataset (McDonald et al., 2013).

Twitter POS Dataset. The Twitter dataset has 25 tags. We use OCT27TRAIN and OCT27DEV as the training set, OCT27TEST as the development set, and DAILY547 as the test set. We randomly sample {1k, 2k, 3k, 4k, 5k, 10k, 20k, 30k, 60k} tweets from 56 million English tweets as our unlabeled data and tune the amount of unlabeled data based on development set accuracy.

UD POS Datasets. The UD datasets have 17 tags. We use French, German, Spanish, Russian, Indonesian and Croatian. We follow the same setup as Zhang et al. (2017), randomly sampling 20% of the original training set as our labeled data and 50% as unlabeled data. There is no overlap between the labeled and unlabeled data. See Zhang et al. (2017) for more details about the setup.

NER Dataset. We use the BIOES labeling scheme and report micro-averaged F_1. We preprocessed the text by replacing all digits with 0. We randomly sample 10% of the original training set as our labeled data and 50% as unlabeled data. We also ensure there is no overlap between the labeled and unlabeled data.

4.2 Pretrained Word Embeddings

For all experiments, we use pretrained 100-dimensional word embeddings. For Twitter, we trained skip-gram embeddings (Mikolov et al., 2013) on a dataset of 56 million English tweets. For the UD datasets, we trained skip-gram embeddings on Wikipedia for each of the six languages. For NER, we use 100-dimensional pretrained GloVe (Pennington et al., 2014) embeddings. Our models perform better with word embeddings kept fixed during training while for the baselines the word embeddings are fine tuned as this improves the baseline performance.

4.3 Baselines

Our primary baseline is a BiGRU tagger where the input consists of the concatenation of a word embedding and the concatenation of the final hidden states of a character-level BiGRU. This BiGRU architecture is identical to that used in the inference networks in our VSL models. Predictions are made based on a linear transformation given the current hidden state. The output dimensionality of the transformation is task-dependent (e.g., 25 for Twitter tagging). We use the standard per-position cross entropy loss for training.

	dev.		test	
	acc.	ULΔ	acc.	ULΔ
BiGRU baseline	90.8	-	90.6	-
VSL-G	91.1	+0.1	-	-

VSL-GG-Hier	***88.4***	***+0.2***	***84.7***	*+0.0*

(b) NER F_1 score (%)

Table 1: For dev and test, we show results when only using labeled data and the change in performances ("ULΔ") when adding unlabeled data. Bold is highest in each column. Italic is the best model including unlabeled data. We only show test results for the baseline and our best-performing model, which achieves 91.9% accuracy on the Twitter test set and 84.7% F_1 on the NER test set when using unlabeled data.

We also report results from the best systems from Zhang et al. (2017), namely the NCRF and NCRF-AE models. Both use feedforward networks as encoders and conditional random field layers for capturing sequential information. The NCRF-AE model additionally can benefit from unlabeled data.

5 Results

Table 1a shows results on the Twitter development and test sets. All of our VSL models outperform the baseline and our best VSL models outperform the BiGRU baseline by 0.8–1% absolute. When comparing different latent variable configurations, we find that a hierarchical structure performs best. Without unlabeled data, our models already outperform the BiGRU baseline. Adding unlabeled data enlarges the gap between the baseline and our models by up to 0.1–0.3% absolute.

Table 1b shows results on the CoNLL 2003 NER development and test sets. We observe similar trends as in the Twitter data, except that the model does not show improvement on the test set when adding unlabeled data.

	French		German		Indonesian		Spanish		Russian		Croatian

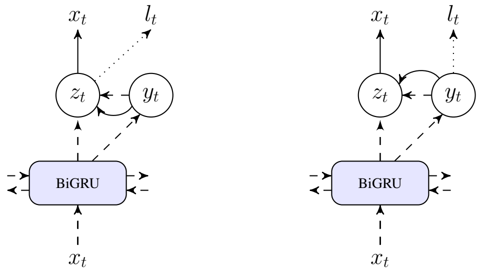
VSL-GG-Hier	***96.4***	***+0.1***	***93.3***	***+0.1***	***92.8***	***+0.1***	***95.3***	***+0.2***	***95.9***	***+0.1***	***96.3***	***+0.2***

Table 2: Tagging accuracies (%) on UD test sets. For each language, we show test accuracy ("acc.") when only using labeled data and the change in test accuracy ("ULΔ") when adding unlabeled data. Results for NCRF and NCRF-AE are from Zhang et al. (2017), though results are not strictly comparable because we used pretrained word embeddings for all languages on Wikipedia. Bold is highest in each column, excluding the NCRF variants. Italic is the best accuracy including the unlabeled data.



(a) VSL-GG-Hier with classification loss on z

(b) VSL-GG-Hier

Figure 2: Comparison of attaching classification loss to different latent variables in VSL-GG-Hier.

Table 2 shows our results on the UD datasets. The trends are broadly consistent with those of Table 1a and 1b. The best performing models use hierarchical structure in the latent variables. There are some differences across languages. For French, German, Indonesian and Russian, VSL-G does not show improvement when using unlabeled data. This may be resolved with better tuning, since the model actually shows improvement on the dev set.

Note that results reported by Zhang et al. (2017) and ours are not strictly comparable as their word embeddings were only pretrained on the UD training sets while ours were pretrained on Wikipedia. Nonetheless, they also mentioned that using embeddings pretrained on larger unlabeled data did not help. We include these results to show that our baselines are indeed strong compared to prior results reported in the literature.

	Twitter		NER		UD average	
	acc.	ULΔ	F_1	ULΔ	acc.	ULΔ
classifier on y	91.6	+0.3	88.4	+0.2	95.0	+0.1
classifier on z	91.1	+0.2	87.8	+0.1	94.4	+0.0

Table 3: Twitter and NER dev results (%), UD averaged test accuracies (%) for two choices of attaching the classification loss to latent variables in the VSL-GG-Hier model. All previous results for VSL-GG-Hier used the classification loss on y.

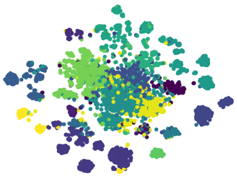
6 Discussion

6.1 Effect of Position of Classification Loss

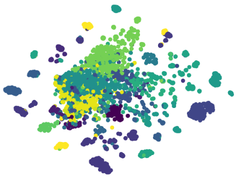
We investigate the effect of attaching the classifier to different latent variables. In particular, for the VSL-GG-Hier model, we compare the attachment of the classifier between z and y. See Figure 2. The results in Table 3 suggest that attaching the reconstruction and classification losses to the same latent variable (z) harms accuracy although attaching the classifier to z effectively gives the classifier an extra layer. We can observe why this occurs by looking at the latent variable visualizations in Figure 3d. Compared with Figure 3e, where the two variables are more clearly disentangled, the latent variables in Figure 3d appear to be capturing highly similar information.

6.2 Effect of Latent Hierarchy

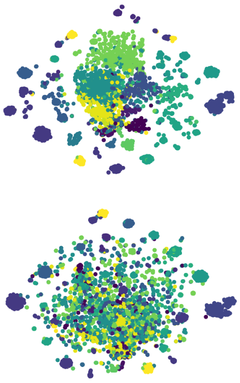
To verify our assumption of the latent structure, we visualize the latent space for Gaussian models using t-SNE (Maaten and Hinton, 2008) in Figure 3. The BiGRU baseline (Figure 3a) and the VSL-G (Figure 3b) do not show significant differences. However, when using multiple latent variables, the different latent variables capture different characteristics. In the VSL-GG-Flat model (Figure 3c), the y variable (the upper plot) reflects



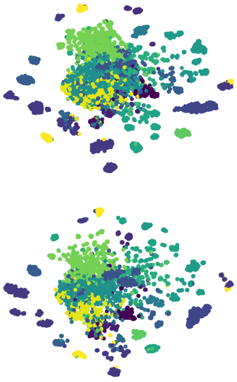
(a) BiGRU Baseline



(b) VSL-G



(c) VSL-GG-Flat



(d) VSL-GG-Hier, classification loss on z

(e) VSL-GG-Hier

Figure 3: t-SNE visualization of Gaussian latent variables and baseline hidden states for Twitter development set. In plot 3c, 3d, and 3e, the upper subplot is latent variable y and the lower is z. Each point in the plot is a token and the color represents the true tag of the token.

the clustering of the tagging space much more closely than the z variable (the lower plot). Since both variables are used to reconstruct the word, but only the y variable is trained to predict the tag, it appears that z is capturing other information useful for reconstructing the word. However, since they are both used for reconstruction, the two spaces show signs of alignment; that is, the "tag" latent variable y does not show as clean a separation into tag clusters as the y variable in the VSL-GG-Hier model in Figure 3e.

In Figure 3e (VSL-GG-Hier), the clustering of words with respect to the tag is clearest. This may account for the consistently better performance of this model relative to the others. The z variable reflects a space that is conditioned on y but that diverges from it, presumably in order to better reconstruct the word. The closer the latent variable is to the decoder output, the weaker the tagging information becomes while other word-specific information becomes more salient.

	Twitter		NER	
	acc.	no VR	F_1	no VR
BiGRU baseline	90.8	-	87.6	-
VSL-G	91.1	90.9	87.8	87.7
VSL-GG-Flat	91.4	90.9	88.0	87.8
VSL-GG-Hier	91.6	91.0	88.4	87.9

Table 4: Results on Twitter and NER dev sets. For each model, we show supervised results for the models with variational regularization ("acc." or F_1) and results when replacing variational components with their deterministic counterparts ("no VR").

Figure 3d shows that VSL-GG-Hier with classification loss on z, which consistently underperforms both the VSL-GG-Flat and VSL-GG-Hier models in our experiments, appears to be capturing the same latent space in both variables. Since the z variable is used to both predict the tag and reconstruct the word, it must capture both the tag and word reconstruction spaces, and may be limited by capacity in doing so. The y variable does not seem to be contributing much modeling power, as its space is closely aligned to that of z.

6.3 Effect of Variational Regularization

We investigate the beneficial effects of variational frameworks ("variational regularization") by replacing our variational components in VSLs with their deterministic counterparts, which do not have randomness in the latent space and do not use the KL divergence term during optimization. Note that these BiGRU encoders share the same architectures as their variational posterior counterparts and still use both the classification and reconstruction losses. While other subsets of losses could be considered in this comparison, our motivation is to compare two settings that correspond to well-known frameworks. The "no VR" setting corresponds roughly to the combination of a classifier and a traditional autoencoder. We note that these experiments do not use any unlabeled data.

The results in Table 4 demonstrate that compared to the baseline BiGRU, adding the reconstruction loss ("VSL-G, no VR") yields only 0.1 improvement for both Twitter and NER. Although adding hierarchical structure further improves performance, the improvements are small (+0.1 and +0.2 for Twitter and NER respectively). For VSL-

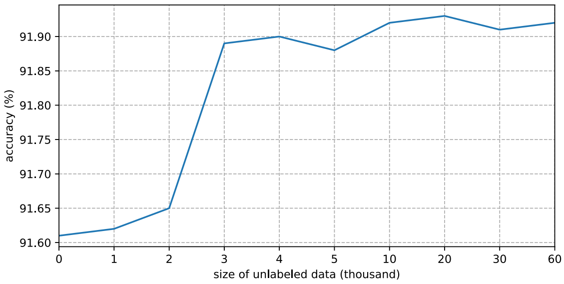


Figure 4: Twitter dev accuracies (%) when varying the amount of unlabeled data.

GG-Hier, variational regularization accounts for relatively large differences of 0.6 for Twitter and 0.5 for NER. These results show that the improvements do not come solely from adding a reconstruction objective to the learning procedure. In limited preliminary experiments, we did not find a benefit from adding unlabeled data under the "no VR" setting.

6.4 Effect of Unlabeled Data

In order to examine the effect of unlabeled data, we report our Twitter dev accuracies when varying the unlabeled data size. We choose VSL-GG-Hier as the model for this experiment since it benefits the most from unlabeled data. As Figure 4 shows, gradually adding unlabeled data helps a little at the beginning. Further adding unlabeled data boosts the accuracy of the model. The improvements that come from unlabeled data quickly plateau after the amount of unlabeled data goes beyond 10,000. This suggests that with little unlabeled data, the model is incapable of fully utilizing the information in the unlabeled data. However if the amount of unlabeled data is too large, the supervised training signal becomes too weak to extract something useful from the unlabeled data.

We also notice that when there is a large amount of unlabeled data, it is always better to pretrain the prior first using a small α (e.g., 0.1) and then use it as a warm start to train a new model using a larger α (e.g., 1.0). Tuning the weight of the KL divergence could achieve a similar effect, but it may require tuning the weight for labeled data and unlabeled data separately. We prefer to pretrain the prior as it is simpler and involves less hyperparameter tuning.

7 Conclusion

We introduced variational sequential labelers for semi-supervised sequence labeling. They consist of latent-variable generative models with flexible parametrizations for the variational posterior (using RNNs over the entire input sequence) and a classifier at each time step. Our best models use multiple latent variables arranged in a hierarchical structure. We demonstrate systematic improvements in NER and POS tagging accuracy across 8 datasets over a strong baseline. We also find small, but consistent, improvements by using unlabeled data.

Acknowledgments

We would like to thank NVIDIA for donating GPUs used in this research, the anonymous reviewers for their comments that improved this paper, and Google for a faculty research award to K. Gimpel that partially supported this research. This research was funded by NSF grant 1433485.

Abstract

Joint representation learning of words and entities benefits many NLP tasks, but has not been well explored in cross-lingual settings. In this paper, we propose a novel method for joint representation learning of cross-lingual words and entities. It captures mutually complementary knowledge, and enables cross-lingual inferences among knowledge bases and texts. Our method does not require parallel corpora, and automatically generates comparable data via distant supervision using multi-lingual knowledge bases. We utilize two types of regularizers to align cross-lingual words and entities, and design knowledge attention and cross-lingual attention to further reduce noises. We conducted a series of experiments on three tasks: word translation, entity relatedness, and cross-lingual entity linking. The results, both qualitatively and quantitatively, demonstrate the significance of our method.

1 Introduction

Multi-lingual knowledge bases (KB) store millions of entities and facts in various languages, and provide rich background structural knowledge for understanding texts. On the other hand, text corpus contains huge amount of statistical information complementary to KBs. Many researchers leverage both types of resources to improve various natural language processing (NLP) tasks, such as machine reading (Yang and Mitchell, 2017), question answering (He et al., 2017; Hao et al., 2017).

Most existing work jointly models KB and text corpus to enhance each other by learning word and entity representations in a unified vector space. For example, Wang et al. (2014); Yamada et al. (2016); Cao et al. (2017) utilize the co-occurrence information to align similar words and entities with similar embedding vectors. Toutanova et al. (2015); Wu et al. (2016); Han et al. (2016); Weston et al. (2013a); Wang and Li (2016) represent entities based on their textual descriptions together with the structured relations. These methods focused on mono-lingual settings. However, for cross-lingual tasks (e.g., cross-lingual entity linking), these approaches need to introduce additional tools to do translation, which suffers from extra costs and inevitable errors (Ji et al., 2015, 2016).

In this paper, we carry out cross-lingual joint representation learning, which has not been fully researched in the literature. We aim at creating a unified space for words and entities in various languages, and easing cross-lingual semantic comparison, which will benefit from the complementary information in different languages. For instance, two different meanings of word *center* in English are expressed by two different words in Chinese: *center* as *the activity-specific building* is expressed by 中心, *center* as *the basketball player role* is 中锋.

Our main challenge is the limited availability of parallel corpus, which is usually either expensive to obtain, or only available for certain narrow domains (Gouws et al., 2015). Many work has been done to alleviate the problem. One school of methods uses adversarial technique or domain adaption to match linguistic distribution (Zhang et al., 2017b; Barone, 2016; Cao et al., 2016). These methods do not require parallel corpora. The weakness is that the training process is unstable and that the high complexity restricts the methods only to small-scale data. Another line of work uses pre-existing multi-lingual resources to automatically generate "pseudo bilingual documents" (Vulic and Moens, 2015, 2016). However, negative results have been observed due to the occasional poor quality of training data (Vulic and Moens, 2016). All above methods only focus on words. We consider both words and entities, which

Brussels, Belgium, October 31 - November 4, 2018.

makes the parallel data issue more challenging.

In this paper, we propose a novel method for joint representation learning of cross-lingual words and entities. The basic idea is to capture mutually complementary knowledge in a shared semantic space, which enables joint inference among cross-lingual knowledge base and texts without additional translations. We achieve it by (1) utilizing an existing multi-lingual knowledge base to automatically generate cross-lingual supervision data, (2) learning mono-lingual word and entity representations, (3) applying cross-lingual sentence regularizer and cross-lingual entity regularizer to align similar words and entities with similar embeddings. The entire framework is trained using a unified objective function, which is efficient and applicable to arbitrary language pairs that exist in multi-lingual KBs.

Particularly, we build a bilingual entity network from inter-language links [1] in KBs for regularizing cross-lingual entities through a variant of skip-gram model (Mikolov et al., 2013c). Thus, mono-lingual structured knowledge of entities are not only extended to cross-lingual settings, but also augmented from other languages. On the other hand, we utilize **distant supervision** to generate comparable sentences for cross-lingual sentence regularizer to model co-occurrence information across languages. Compared with “pseudo bilingual documents”, comparable sentences achieve higher quality, because they rely not only on the shared semantics at document level, but also on cross-lingual information at sentence level. We further introduce two attention mechanisms, knowledge attention and cross-lingual attention, to select informative data in comparable sentences.

Our contributions can be concluded as follows:

- We proposed a novel method that jointly learns representations of not only cross-lingual words but also cross-lingual entities in a unified vector space, aiming to enhance the embedding quality from each other via complementary semantics.
- Our proposed model introduces distant supervision coupled with attention mechanisms to generate comparable data as cross-lingual supervision, which can benefit many cross-lingual analysis.
- We did qualitative analysis to have an intuitive impression of our embeddings, and quantitative analysis in three tasks: word translation, entity relatedness, and cross-lingual entity linking. Experiment results show that our method demonstrates significant improvements in all three tasks.

2 Related Work

Jointly representation learning of words and entities attracts much attention in the fields of Entity Linking (Zhang et al., 2017a; Cao et al., 2018), Relation Extraction (Weston et al., 2013b) and so on, yet little work focuses on cross-lingual settings. Inspiringly, we investigate the task of cross-lingual word embedding models (Ruder et al., 2017), and classify them into three groups according to parallel corpora used as supervisions: (i) methods requiring **parallel corpus with aligned words** as constraint for bilingual word embedding learning (Klementiev et al., 2012; Zou et al., 2013; Wu et al., 2014; Luong et al., 2015; Ammar et al., 2016; Soricut and Ding, 2016). (ii) methods using **parallel sentences** (i.e. translated sentence pairs) as the semantic composition of multi-lingual words (Gouws et al., 2015; Kociský et al., 2014; Hermann and Blunsom, 2014; Chandar et al., 2014; Shi et al., 2015; Mogadala and Rettinger, 2016). (iii) methods requiring **bilingual lexicon** to map words from one language into the other (Mikolov et al., 2013b; Faruqui and Dyer, 2014; Xiao and Guo, 2014).

The major weakness of these methods is the limited availability of parallel corpora. One remedy is to use existing multi-lingual resources (i.e. multi-lingual KB). Camacho-Collados et al. (2015) combines several KBs (Wikipedia, WordNet and BabelNet) and leverages multi-lingual synsets to learn word embeddings at sense level through an extra post-processing step. Artetxe et al. (2017) starts from a small bilingual lexicon and using a self-learning approach to induce the structural similarity of embedding spaces. Vulic and Moens (2015, 2016) collect comparable documents on same themes from multi-lingual Wikipedia, shuffle and merge them to build “pseudo bilingual documents” as training corpora. However, the quality of “pseudo bilingual documents” are difficult to control, resulting in poor performance in several cross-lingual tasks (Vulic and Moens, 2016).

Another remedy matches linguistic distribu-

Red texts with brackets are anchors, dashed lines denote entity relations, and solid lines are cross-lingual links.

tion via adversarial training (Barone, 2016; Zhang et al., 2017b; Lample et al., 2018), domain adaption (Cao et al., 2016). However, these methods suffer from the instability of training process and the high complexity. This either limits the scalability of vocabulary size or relies on a strong distribution assumption.

Inspired by Vulic and Moens (2016), we generate highly qualified **comparable sentences** via distant supervision, which is one of the most promising approaches to addressing the issue of sparse training data, and performs well in relation extraction (Lin et al., 2017a; Mintz et al., 2009; Zeng et al., 2015; Hoffmann et al., 2011; Surdeanu et al., 2012). Our comparable sentences may further benefit many other cross-lingual analysis, such as information retrieval (Dong et al., 2014).

3 Preliminaries and Framework

3.1 Preliminaries

Given a multi-lingual KB, we take (i) text corpus, (ii) entity and their relations, (iii) a set of anchors as inputs, and learn embeddings for each word and each entity in various languages. For clarity, we use English and Chinese as sample languages in the rest of the paper, and use superscript $y \in \{en, zh\}$ to denote language-specific parameters[2].

We use multi-lingual Wikipedia as KB including a set of entities $\mathcal{E}^y = \{e_i^y\}$ and their articles. We concatenate these articles together, and form text corpus $\mathcal{D}^y = \langle w_1^y, \dots, w_i^y, \dots, w_{|\mathcal{D}|}^y \rangle$. Hyper links in articles are denoted by Anchors $\mathcal{A}^y = \{\langle w_i^y, e_j^y \rangle\}$, which indicates that word w_i^y refers to entity e_j^y. $\mathcal{G}^y = (\mathcal{E}^y, \mathcal{R}^y)$ is the mono-lingual Entity Network (EN), where $\mathcal{R}^y = \{\langle e_i^y, e_j^y \rangle\}$ if there is a link between e_i^y, e_j^y. We use interlanguage links in Wikipedia as cross-lingual links $\mathcal{R}^{en-zh} = \{\langle e_i^{en}, e_{i'}^{zh} \rangle\}$, indicating e_i^{en}, $e_{i'}^{zh}$ refer to the same thing in English and Chinese. **Cross-lingual word and entity representation learning** is to map words and entities in different languages into a unified semantic space. Each word and entity obtain their embedding vectors[3] $\mathbf{w}_i^y$ and $\mathbf{e}_j^y$.

3.2 Framework

To alleviate the heavy burden of limited parallel corpora and additional translation efforts, we utilize existing multi-lingual resources to distantly supervise cross-lingual word and entity representation learning, so that the shared embedding space supports joint inference among KB and texts across languages. As shown in Figure 1, our framework has two steps: (1) **Cross-lingual Su-**

---

[2] We choose English and Chinese as example languages because they are top-ranked according to total number of speakers, the full list can be found in `https://en.wikipedia.org/wiki/Lists_of_languages_by_number_of_speakers`.

[3] For the cross-lingual linked entities sharing the same strings (e.g., *NBA* and *NBA (zh)*), which is an infrequent situation between languages, we use separated representations to keep training objective consistent and avoid confusion.

pervision Data Generation builds a bilingual entity network and generates comparable sentences based on cross-lingual links; (2) **Joint Representation Learning** learns cross-lingual word and entity embeddings using a unified objective function. Our assumption throughout the entire framework is as follows: *The more words/entities two contexts share, the more similar they are.*

As shown in Figure 1, we build a bilingual EN $\mathcal{G}^{en-zh}$ by using $\mathcal{G}^{en}, \mathcal{G}^{zh}$ and cross-lingual links $\mathcal{R}^{en-zh}$. Thus, entities in different languages shall be connected in a unified network to facilitate cross-lingual entity alignments. Meanwhile, from KB articles, we extract comparable sentences $\mathcal{S}^{en-zh} = \{\langle s_k^{en}, s_k^{zh} \rangle\}$ as high qualified parallel data to align similar words in different languages.

Based on generated cross-lingual data $\mathcal{G}^{en-zh}, \mathcal{S}^{en-zh}$ and mono-lingual data $\mathcal{D}^y$, $\mathcal{A}^y$, where $y \in \{en, zh\}$, we jointly learn cross-lingual word and entity embeddings through three components: (1) **Mono-lingual Representation Learning**, which learns mono-lingual word and entity embeddings for each language by modeling co-occurrence information through a variant of skip-gram model (Mikolov et al., 2013c). (2) **Cross-lingual Entity Regularizer**, which aligns entities that refer to the same thing in different languages by extending the mono-lingual model to bilingual EN. For example, entity *Foust* in English and entity 福斯特 *(Foust)* in Chinese are closely embedded in the semantic space because they share common neighbors in two languages, *All-star* and *NBA* 选秀 *(draft)*, etc.. (3) **Cross-lingual Sentence Regularizer**, which models cross-lingual co-occurrence at sentence level in order to learn translated words to have most similar embeddings. For example, English word *basketball* and the translated Chinese word 篮球 frequently co-occur in a pair of comparable sentences, therefore, their vector representations shall be close in the semantic space. The above components are trained jointly under a unified objective function.

4 Cross-lingual Supervision Data Generation

This section introduces how to build a bilingual entity network $\mathcal{G}^{en-zh}$ and comparable sentences $\mathcal{S}^{en-zh}$ from a multi-lingual KB.

4.1 Bilingual Entity Network Construction

Entities with cross-lingual links refer to the same thing, which implies they are equivalent across languages. Conventional knowledge representation methods only add edges between e_i^{en} and $e_{i'}^{zh}$ indicating a special "equivalent" relation (Zhu et al., 2017). Instead, we build $\mathcal{G}^{en-zh} = (\mathcal{E}^{en} \cup \mathcal{E}^{zh}, \mathcal{R}^{en} \cup \mathcal{R}^{zh} \cup \tilde{\mathcal{R}}^{en-zh})$ by enriching the neighbors of cross-lingual linked entities. That is, we add edges $\tilde{\mathcal{R}}^{en-zh}$ between two mono-lingual ENs by letting all neighbors of e_i^{en} be neighbors of $e_{i'}^{zh}$, and vice versa, if $\langle e_i^{en}, e_{i'}^{zh} \rangle \in \mathcal{R}^{en-zh}$.

$\mathcal{G}^{en-zh}$ extends $\mathcal{G}^{en}$ and $\mathcal{G}^{zh}$ to bilingual settings in a natural way. It not only keeps a consistent objective in mono-lingual ENs—entities, no matter in which language, will be embedded closely if share common neighbors—but also enhances each other with more neighbors in the foreign language.

Following the method in Zhu et al. (2017), there will be no edge between Chinese entity 福斯特 *(Foust)* and English entity *Pistons*, which implies a wrong fact that 福斯特 *(Foust)* does not belong to *Pistons*. Our method enriches the missing relation between entities 福斯特 *(Foust)* and 活塞队 *(Pistons)* in incomplete Chinese KB through corresponding English common neighbors, *Allstar*, *NBA*, etc., as illustrated in Figure 1.

4.2 Comparable Sentences Generation

To supervise the cross-lingual representation learning of words, we automatically generate comparable sentences as cross-lingual training data. Comparable sentences are not translated paired sentences, but sentences with the same topic in different languages. As shown in the middle layer (Figure 1), the pair of sentences are comparable sentences: (1) "*Lawrence Michael Foust was an American basketball player who spent 12 seasons in NBA*", (2) "拉里·福斯特 *(Lawrence Foust)* 是 *(was)* 美国 *(American) NBA* 联盟 *(association)* 的 *(of)* 前 *(former)* 职业 *(professional)* 篮球 *(basketball)* 运动员 *(player)*".

Inspired by the distant supervision technique in relation extraction, we assume that sentence s_k^{en} in Wikipedia articles of entity e_i^{en} explicitly or implicitly describes e_i^{en} (Yamada et al., 2017), and that s_k^{en} shall express a relation between e_i^{en} and e_j^{en} if another entity e_j^{en} is in s_k^{en}. Meanwhile, we find a comparable sentence $s_{k'}^{zh}$ in another language which satisfies $s_{k'}^{zh}$ containing $e_{j'}^{zh}$

in Wikipedia articles of Chinese entity $e_{i'}^{zh}$, where $\langle e_i^{en}, e_{i'}^{zh}\rangle, \langle e_j^{en}, e_{j'}^{zh}\rangle \in \mathcal{R}^{en-zh}$. As shown in Figure 1, the sentences in the second level are comparable due to the similar theme of the relation between entity *Foust* and *NBA*. To find this type of sentences, we search the anchors in the English aritcle and Chinese article of cross-lingual entity *Foust*, respectively, and extract the sentences including another crosslingual entity *NBA*. Comparable sentences can be regarded as cross-lingual contexts.

Unfortunately, comparable sentences suffer from two issues caused by distant supervision:

Wrong labelling. Take English as sample, there may be several sentences $s_{k,l}^{en}|_{l=1}^{L}$ containing the same entity e_j^{en} in the article of e_i^{en}. A straightforward solution is to concatenate them into a longer sentence s_k^{en}, but this increases the chance to include unrelated sentences.

Unbalanced information. Sometimes the pair of sentences convey unbalanced information, e.g., the English sentence in the middle layer (Figure 1) contains *Foust spent 12 seasons in NBA* while the comparable Chinese sentence not.

To address the issues, we propose knowledge attention and cross-lingual attention to filter out unrelated information at sentence level, and at word level respectively.

5 Joint Representation Learning

As shown in Figure 2, there are three components in learning cross-lingual word and entity representations, which are trained jointly. In this section, we will describe them in detail.

5.1 Mono-lingual Representation Learning

Following Yamada et al. (2016); Cao et al. (2017), we learn mono-lingual word/entity embeddings based on corpus $\mathcal{D}^y$, anchors $\mathcal{A}^y$ and entity network $\mathcal{G}^y$. Capturing the cooccurrence information among words and entities, these embeddings serve as the foundation and will be further extended to bilingual settings using the proposed cross-lingual regularizers, which will be detailed in the next section. Monolingually, we utilize a variant of Skip-gram model (Mikolov et al., 2013c) to predict the contexts given current word/entity:

$$\mathcal{L}_m = \sum_{y\in\{en,zh\}} \sum_{x_i^y \in \{\mathcal{D}^y,\mathcal{A}^y,\mathcal{G}^y\}} \log P(\mathcal{C}(x_i^y)|x_i^y)$$

where x_i^y is either a word or an entity, and $\mathcal{C}(x_i^y)$ denotes: (i) contextual words in a pre-defined window of x_i^y if $x_i^y \in \mathcal{D}^y$, (ii) neighbor entities that linked to x_i^y if $x_i^y \in \mathcal{G}^y$, (iii) contextual words of w_j^y if x_i^y is entity e_i^y in an anchor $\langle w_j^y, e_i^y\rangle \in \mathcal{A}^y$.

5.2 Cross-lingual Entity Regularizer

The bilingual EN $\mathcal{G}^{en-zh}$ merges entities in different languages into a unified network, resulting in the possibility of using the same objective as in mono-lingual ENs. Thus, we naturally extend mono-lingual function to cross-lingual settings:

$$\mathcal{L}_e = \sum_{e_i^y \in \{\mathcal{G}^{en-zh}\}} \log P(\mathcal{C}'(e_i^y)|e_i^y)$$

where $\mathcal{C}'(e_i^y)$ denotes cross-lingual contexts—neighbor entities in different languages that linked to e_i^y. Thus, by jointly learning mono-lingual representation with cross-lingual entity regularizer, words and entities share more common contexts, and will have similar embeddings. As shown in Figure 1, English entity *NBA* co-occurs with words *basketball* and *player* in texts, so they are embedded closely in the semantic space. Meanwhile, cross-lingual linked entities *NBA* and *NBA (zh)* have similar representations due to the most common neighbor entities, e.g., *Foust*.

5.3 Cross-lingual Sentence Regularizer

Comparable sentences provide cross-lingual co-occurrence of words, thus, we can use them to learn similar embeddings for the words that frequently co-occur by minimizing the Euclidean distance as follows:

$$\mathcal{L}_s = \sum_{\langle s_k^{en}, s_{k'}^{zh}\rangle \in S^{en-zh}} ||\mathbf{s}_k^{en} - \mathbf{s}_{k'}^{zh}||^2$$

where $\mathbf{s}_k^{en}, \mathbf{s}_{k'}^{zh}$ are sentence embeddings. Take English as sample language, we define it as the average sum of word vectors weighted by the combination of two types of attentions:

$$\mathbf{s}_k^{en} = \sum_{l=1}^{L} \psi(e_m^{en}, s_{k,l}^{en}) \sum_{w_i^{en} \in s_{k,l}^{en}} \psi'(w_i^{en}, w_j^{zh}) \mathbf{w}_i^{en}$$

where $s_{k,l}^{en}|_{l=1}^{L}$ are sentences containing the same entity (as mentioned in Section 4.2), and $\psi(e_m^{en}, s_{k,l}^{en})$ is knowledge attention that aims

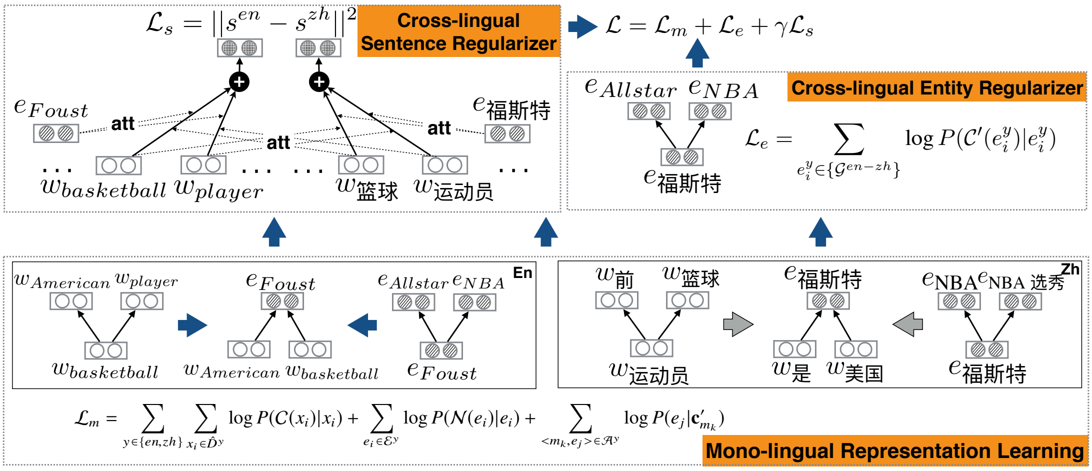

Figure 2: The nerual model for jointly representation learning.

at filtering out wrong labelling sentences, and $\psi'(w_i^{en}, w_j^{zh})$ is cross-lingual attention to deal with the unbalanced information through possible aligned words.

Next, we will introduce the two types of attentions in detail.

Knowledge Attention

Suppose that sentences $s_{k,l}^{en}|_{l=1}^{L}$ contain the same entities in articles of entity e_m^{en}, the wrong labelling errors increase, because some $s_{k,l}^{en}$ is almost irrelevant to e_m^{en}. Knowledge attention assigns smaller weights to wrong labelled sentences, and higher weights to related sentences. Thus, we define it proportional to the similarity between $s_{k,l}^{en}$ and e_m^{en}:

$$\psi(e_m^{en}, s_{k,l}^{en}) \propto sim(\mathbf{e}_m^{en}, \sum_{w_i^{en} \in s_{k,l}^{en}} \mathbf{w}_i^{en})$$

where sim is similarity measurement. We use cosine similarity in the presented work. Knowledge attention is normalized to satisfy $\sum_l^L \psi(e_m^{en}, s_{k,l}^{en}) = 1$.

Cross-lingual Attention

Inspired by self-attention mechanism (Lin et al., 2017b), we motivate cross-lingual attention focusing on potential information from comparable sentences themselves. The intuition is to find possible aligned words between languages, and filter out the words without alignments. We define it according to the maximum similarity computed by our cross-lingual word embeddings:

$$\psi'(w_i^{en}, w_j^{zh}) \propto \max_{w_i^{en} \in s_k^{en}, w_j^{zh} \in s_{k'}^{zh}} sim(\mathbf{w}_i^{en}, \mathbf{w}_j^{zh})$$

We set a threshold for discarding non-aligned words if $\psi'(w_i^{en}, w_j^{zh}) < \theta$, and make a normalization for selected words. We set $\theta = 0$ in experiments. Thus, unbalanced information is trimmed to the common meanings between s_k^{en} and $s_{k'}^{zh}$. For example (Figure 1), words *American*, *basketball*, *player* are selected due to their aligned Chinese words 美国, 篮球, 运动员, while *12 seasons* in s_k^{en} or 前 *(former)* in $s_{k'}^{zh}$ are discarded due to low attentions.

The reason of using such regularizer lies in two points: (1) the embeddings of cross-lingual aligned words become closer within the pair of comparable sentences, and meanwhile (2) the distance between their contexts is also minimized, which keeps the same way as used in mono-lingual word embeddings training—the words sharing more contexts have similar embeddings. In this way, our regularizer follows a similar assumption with (Gouws et al., 2015): *The more frequently two words occur in parallel/comparable sentence pairs, the closer their representation will be.*

5.4 Training

All above components are jointly trained using the overall objective function as follows:

$$\mathcal{L} = \mathcal{L}_m + \mathcal{L}_e + \gamma\mathcal{L}_s$$

where γ is a hyper-parameter to tune the effect of cross-lingual sentence regularizer, and set to 1 in experiments. We use Softmax as probability function, and negative sampling and SGD for efficient optimization (Mikolov et al., 2013a).

6 Experiments

In this section, we describe some qualitative analysis with nearest neighbors and quantitative experiments with the tasks of word translation, entity relatedness and cross-lingual entity linking to verify the quality of cross-lingual word embeddings, entity embeddings and the joint inference among them, respectively. The codes of our proposed model can be found in `https://github.com/TaoMiner/MultiLingualEmbedding`.

Table 1: Multi-lingual KB Statistics.

We choose Wikipedia, the April 2017 dump, as multi-lingual KB and six popular languages for evaluation. The preprocessing consists of following steps: converting texts into lower cases, filtering out symbols and low frequency words and entities (less than 5), and tokenizing Chinese corpus using Jieba[4] and Japanese corpus using mecab[5]. The statistics is listed in Table 1. For brevity, we adopt two-letter abbreviations: 'En', 'Zh', 'Es', 'Ja', 'It' and 'Tr' for English, Chinese, Spanish, Japanese, Italian and Turkish, respectively. The token sub-column denotes the total number of word/entity in the entire training corpus, and we use 'm' to denote million and 'b' for billion.

For cross-lingual settings, we choose five language pairs to compare with state-of-the-art methods, whose statistics is listed in Table 2.

We trained our method using the suggested parameters in Skip-gram model (Mikolov et al., 2013c) and evaluate the embeddings shared by all tasks for fairly comparison. We set training epoch as 2 to ensure convergence, which costs nearly 20 hours on the server with 64 core CPU and 188GB memory. The embedding dimension is set to 200 and context window size is 5. For each positive example, we sample 5 negative examples.

	Cross-lingual Links (m)	Comparable Sentences(m)	Bilingual EN	
			$\mathcal{E}$(m)	$\mathcal{R}$(b)
Es-En	0.82	4.66	4.64	0.58
Zh-En	0.51	2.02	4.52	0.57
Ja-Zh	0.26	1.04	1.46	0.19
It-En	0.74	3.83	5.03	0.68
Tr-En	0.15	0.75	4.16	0.44

Table 2: Cross-lingual Data Statistics.

6.2 Qualitative Analysis

Translation words (Chinese)
篮球 (+), 篮球队 (basketball team), 湖人 (lakers), 男子篮球 (men's basketball), 湖人队 (the lakers), 国王队 (the Kings), 美式足球 (American football), 中锋 (center)
Nearest entities (Chinese)
NBA, 篮球 (Basketball) , 控球后卫 (Point guard), NBA 选秀 (draft), 香港男子甲一组男子篮球联赛 (Hong Kong men's top basketball league), 橄榄球 (American football), 东方篮球队 (Eastern basketball team)
Nearest words
nba, wnba, player, twyman, professional, pick, 76ers
Nearest entities
Professional sports, Varsity letter, Sports agent, All-America, Final four, All-star, College basketball

Table 3: Cross-lingual nearest words and entities of English word *basketball*.

We manually checked nearest neighbors to have a straightforward impression of the quality of our embeddings. The nearest neighbors of English word *basketball* is listed in Table 3.

As Table 3 shows, we find the correct translation ranked at top 1 (marked by +), and the listed words as well as English nearest words are all basketball related, indicating a higher quality of our cross-lingual word embeddings. Interestingly, we found that although all nearest entities are sports related, e.g., *NBA* or *Professional sports*, there is an obvious culture divergence between Chinese entities and English entities, such as *Hong Kong basketball league* v.s. *All-America*.

6.3 Word Translation

Following (Zhang et al., 2017b), we test our cross-lingual word embeddings on benchmark dataset including over 2,000 bilingual word pairs on average. The ground truth is obtained from Open

IA	-	60.41	-	46.52	-	36.35	-	17.11	7.08	32.29
Bilbowa	53	65.96	-	-	-	-	-	-	-	-
BWESG	48.88	66.38	36.84	51.29	30.93	37.80	21.36	35.59	20.57	29.17
Adversarial	-	71.97	-	58.60	-	43.02	-	17.18	7.92	43.31
Ours-noatt	68.34	77.1	62.22	65.90	37.00	42.30	**57.47**	**60.51**	**35.90**	42.80
Ours	**70.41**	**78.50**	**63.07**	**67.85**	**41.30**	**46.70**	54.40	59.31	35.66	**44.67**

Table 4: Word Translation.

Multilingual WordNet[6] or Google translation. We compare all methods using the same vocabulary, and analyze the vocabulary size's impact by setting a nearly 5k small scale and 50k large scale.

We choose several state-of-the-art methods as baseline, using different level of parallel data: (1) TM (Mikolov et al., 2013b), IA (Zhang et al., 2016) are pioneers and popular transformation based methods using **bilingual lexicon**. (2) Bilbowa (Gouws et al., 2015) is typical work using **parallel sentences** and performs quite well. (3) BWESG (Vulic and Moens, 2016) is similar to our method and achieves best performance in the literature of using **comparable data**. (4) Adversarial model (Zhang et al., 2017b) is the state-of-the-arts **without parallel data**. Besides, we remove attention from our method to investigate the impacts from attention mechanisms, marked with *Ours-noatt*.

For fair comparison, we report the results in original paper (Zhang et al., 2017b) except Bilbowa and BWESG, which didn't report their results on the same benchmark datasets. So, we carefully implement them using released codes on the same training corpus as ours with suggested parameters. Nevertheless, we do not have performance reports of Zh-En, It-En, Tr-En and Ja-Zh with Bilbowa due to the lack of parallel data used in the original paper. As shown in Table 4, we can see:

- Our proposed method significantly outperforms all the baseline methods with average gains of 21% and 9.1% on large and small vocabulary. This proves the high quality of our generated cross-lingual data and the effectiveness of our joint framework.
- The pair of languages have similar culture achieves better performance (Es-En, It-En, Tr-En, Ja-Zh) than that have different cultural origins, e.g., Zh-En.
- Languages with richer corpus have better translations because adequate training data helps to capture more accurate cross-lingual semantics (Es-En, It-En, Tr-En v.s. Ja-Zh).
- Our method has less performance reduction between small and large vocabulary than methods based on parallel word pairs, because we adopt a consistent objective function which aligns cross-lingual semantics, and simultaneously keeps their own monolingual semantics.
- Attention mechanisms further improve the performance, mainly because they help to select the most informative words and sentences, filtering out unrelated data.

6.4 Entity Relatedness

With respect to our entity embeddings, we have conducted experiments to evaluate English entity relatedness following (Ganea and Hofmann, 2017; Hoffart et al., 2011), in which the dataset contains 3,314 entities, and each entity has 91 candidate entities labeled with 1 or 0, indicating whether they are semantically related. Given an entity, we rank candidate entities according to their similarity based on our embeddings, and evaluate the ranking quality through two standard metrics: normalized discounted cumulative gain (NDCG) (Järvelin and Kekäläinen, 2002) and mean average precision (MAP) (Manning et al., 2008).

To give a comprehensive fair comparison, we choose several widely used and state-of-the-art methods as our baselines, and compare with the results in the original papers: (1) WLM (Milne and Witten, 2008), the popular semantic similarity measurement based on Wikipedia anchor links. (2) ALIGN (Yamada et al., 2016) and MPME (Cao et al., 2017), state-of-the-arts that jointly learn word and entity embeddings using mono-lingual EN. (3) Deep Joint (DJ) model (Ganea and Hofmann, 2017), deep neural model that achieves the

---

[6] `http://compling.hss.ntu.edu.sg/omw`

best performance of entity relatedness.

	NDCG			MAP
	@1	@5	@10	
WLM	.54	.52	.55	.48
ALIGN (d=500)	.59	.56	.59	.52
MPME	.61	.61	.65	.58
DJ (d=300)	.63	.61	.64	.58
Ours (Zh-En)	.62	.62	.66	.59
Ours (Es-En)	.61	.61	.65	.59
Ours (Tr-En)	.62	.62	.65	.59
Ours (It-En)	.61	.61	.65	.58
Ours-e (Es-En)	.62	.62	.67	.61
Ours-e (Es-En,epoch=5)	**.64**	**.64**	**.68**	**.62**

Table 5: Entity Relatedness.

Table 5 shows the results of baseline methods as well as our methods based on different languages. We also test the cases of our method without training cross-lingual words, marked as Ours-e. We can see our method outperforms all baseline methods by introducing cross-lingual information, and all bilingual ENs lead to similar results. Strangely, ALIGN and DJ with more embedding dimensions seemly fails to capture overall relatedness (performance reduction from top@1 to top@5). The best performance of Ours-e implies that training cross-lingual word slightly harms the performance of entity embeddings. We can introduce additional sense embeddings in future (Cao et al., 2017).

Although favorable improvements has been achieved by using our English entity embeddings, it shall be fewer than that of other languages, because resources of English are already quite rich, and even richer than many other languages, thus contributions from other languages will be less significant than vice versa. Due to the limitation of the publication, we neglect to report experiment results on the vice versa direction.

6.5 Cross-lingual Entity Linking

Entity linking, the task of identifing the language-specific reference entity for mentions in texts, raises the key challenges of comparing the relevance between entities and contextual words around the mentions (Cao et al., 2015; Nguyen et al., 2016). Recently, the surge of cross-lingual analysis pushes the entity linking task on cross-lingual settings (Ji et al., 2015). Therefore, we comprehensively measure our joint inference ability among words and entities using the tri-lingual EL benchmark dataset KBP2015, which consists of 944 documents and 38,831 mentions, and divides them into 444 and 500 documents for training and evaluation. Note that the main purpose of it is not to beat other EL models but to evaluate the quality of our embeddings, so we adopt a simple classifier GBRT (Gradient Boost Regression Tree) based method as in (Cao et al., 2017; Yamada et al., 2016), replace with our cross-lingual embeddings, and filter out mentions that are out of our vocabulary.

	English	Spanish	Chinese
Top system	73.7	80.4	83.1
Second system	66.2	71.5	78.1
Ours	73.9	79.1	81.3

Table 6: Tri-lingual Entity Linking.

Table 6 shows the top 1 linking accuracy (%). We can see our method performs much better than the second ranked system, and is competitive with the top ranked system. Considering that the systems utilize additional translation tools (Ji et al., 2015), we conclude that our embeddings are high qualified for joint inference among entities and words in different languages.

7 Conclusions

In this paper, we propose a novel method to jointly learn cross-lingual word and entity representations that enables effective inference among cross-lingual knowledge bases and texts. Instead of parallel data, we use distant supervision over multi-lingual KB to generate high quality comparable data as cross-lingual supervision signals for two types of regularizer. We introduce attention mechanism to further improve the training quality. A series of experiments on several tasks verify the effectiveness of our methods as well as the quality of cross-lingual word and entity embeddings.

In the future, we will enrich semantics of low-resourced languages by cross-lingual linking to rich-resourced languages, and extend more cross-lingual words and entities to multi-lingual settings.

Deep Pivot-Based Modeling for Cross-language Cross-domain Transfer with Minimal Guidance

Yftah Ziser and **Roi Reichart**
Faculty of Industrial Engineering and Management, Technion, IIT
syftah@campus.technion.ac.il, roiri@technion.ac.il

Abstract

While cross-domain and cross-language transfer have long been prominent topics in NLP research, their combination has hardly been explored. In this work we consider this problem, and propose a framework that builds on pivot-based learning, structure-aware Deep Neural Networks (particularly LSTMs and CNNs) and bilingual word embeddings, with the goal of training a model on labeled data from one (language, domain) pair so that it can be effectively applied to another (language, domain) pair. We consider two setups, differing with respect to the unlabeled data available for model training. In the *full* setup the model has access to unlabeled data from both pairs, while in the *lazy* setup, which is more realistic for truly resource-poor languages, unlabeled data is available for both domains but only for the source language. We design our model for the lazy setup so that for a given target domain, it can train once on the source language and then be applied to any target language without re-training. In experiments with nine English-German and nine English-French domain pairs our best model substantially outperforms previous models even when it is trained in the lazy setup and previous models are trained in the full setup.[1]

1 Introduction

The field of Natural Language Processing (NLP) has made impressive progress in the last two decades and text processing applications are now performed in a quality that was beyond imagination only a few years ago. With this success, it is only natural that researchers seek ways to apply NLP algorithms in as many languages and textual domains as possible. However, the success of NLP algorithms most often relies on the availability of non-trivial supervision such as corpora annotated with linguistic classes or structures, and for multilingual applications often also on parallel corpora. This resource bottleneck seriously challenges the world-wide accessibility of NLP technology.

To address this problem substantial efforts have been put into the development of cross-domain (*CD*, (Daumé III, 2007; Ben-David et al., 2010)) and cross-language (CL) transfer methods. For both areas, while a variety of methods have been developed for many tasks throughout the years (§ 2), with the prominence of deep neural networks (DNNs) the focus of modern methods is shifting towards learning data representations that can serve as a bridge across domains and languages.

For CD, this includes: (a) pre-DNN work ((Blitzer et al., 2006, 2007), known as *structural correspondence learning (SCL)*), that models the connections between *pivot features* – features that are frequent in the source and the target domains and are highly correlated with the task label in the source domain – and the other, non-pivot, features; (b) DNN work (Glorot et al., 2011; Chen et al., 2012) which employs compress-based noise reduction to learn cross-domain features; and recently also (c) works that combine the two approaches (Ziser and Reichart, 2017, 2018) (henceforth ZR17 and ZR18). For CL, the picture is similar: multilingual representations (usually word embeddings) are prominent in the transfer of NLP algorithms from one language to another (e.g. (Upadhyay et al., 2016)).

In this paper we aim to take CL and CD transfer a significant step forward and design methods that can adapt NLP algorithms simultaneously across languages and domains. We consider this research problem fundamental to our field as manually annotated resources are often scarce in many domains, even for languages that are consid-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 238–249
Brussels, Belgium, October 31 - November 4, 2018.

ered resource-rich. With effective cross-language cross-domain (CLCD) methods it is sufficient to have training resources in a single domain of one language in order to solve the task in any other (language, domain) pair.

As a first step, our focus in this work is on the task of sentiment classification that has been extensively researched in the CD literature. Surprisingly, even for this task we are aware of only one previous work that aims to perform CLCD learning (Fernández et al., 2016). However, this work does not employ modern DNN techniques and is substantially outperformed by our methods.

Our approach to CLCD learning is rooted in the family of methods that combine the power of both DNNs and pivot-based ideas, and is based on two principles. First, we build on the recent progress in learning multilingual word embeddings (Ruder et al., 2017). Such embeddings help close the lexical gap between languages as they map their different vocabularies to a shared vector space. Second, we follow (Prettenhofer and Stein, 2010, 2011; Fernández et al., 2016) and redefine the concept of pivot features for CLCD setups (§ 5). While these authors already employed this idea in order to design pivot-based methods in CL (Prettenhofer and Stein, 2010, 2011) and CLCD (Fernández et al., 2016) for text classification and sentiment analysis, their algorithms do not employ DNNs and multilingual embeddings. In this paper we show that it is the combination of bilingual word embeddings *(BEs)* and structure aware DNNs with the re-defined pivots that leads to high quality CLCD models.

Aiming to facilitate transfer to resource poor languages and domains, our methods rely on as little supervision as possible. Particularly, we explore two scenarios. In the first, *full CLCD* setup, models have access to manually annotated reviews from the source (language, domain) pair, and unannotated reviews from both the source and the target (language, domain) pairs. In the second, *lazy CLCD* setup, models have access only to source language reviews - annotated reviews from the source domain, and unannotated reviews from both the source and the target domains.

We consider the lazy setup to be the desired standard setup of CLCD learning for two reasons. First, in true resource-poor languages we expect it to be hard to find a sufficient number of reviews from many domains, even if they are unannotated (imagine for example trying to obtain 50K unlabeled spinner reviews in Swahili). Second, it allows a *train once, adapt everywhere* mode: instead of training a separate model for each target language, in this setup for each target domain only a single model is trained on the source language, and the target language is considered only at test time through BEs (§ 5). Notice that in order to allow the lazy setup, the BEs should be trained such that the source language embeddings have no knowledge about any particular target language. In § 5 we discuss the BEs we employ (Smith et al., 2017), which have this property.

We create CLCD variants of DNN- and pivot-based methods originally designed to learn effective representations for CD learning. To the best of our knowledge, there are three such methods, which employ two types of DNNs (§ 4): (a) AE-SCL and AE-SCL-SR (Ziser and Reichart, 2017) that integrate pivot-based ideas (SCL) with autoencoder-based (AE) noise reduction; and (b) pivot-based language modeling (PBLM, (Ziser and Reichart, 2018)) that combines pivot-based ideas with LSTMs for representation learning, and integrates this architecture with an LSTM or a CNN for task classification. In § 5 we discuss how to employ these methods for CLCD transfer where the lexical gap between languages is bridged by pivot translation and BEs, and show that PBLM allows for more effective transfer.

We address the task of binary sentiment classification and experiment with nine English-German and nine English-French domain pairs (§ 6, 7). Our PBLM-based models substantially outperform all previous models, even when the PBLM model is trained in the lazy setup and the previous models are trained in the full setup.

2 Previous Work

We briefly survey work on CL and CD learning and on multilingual word embeddings. We focus on aspects that are relevant to our work rather than on a comprehensive survey of the extensive previous work on these problems.

Cross-language transfer CL has been explored extensively in NLP. Example applications include POS tagging (Täckström et al., 2013), syntactic parsing (Guo et al., 2015; Ammar et al., 2016), text classification (Shi et al., 2010; Prettenhofer and Stein, 2010) and sentiment analysis (Wan, 2009; Zhou et al., 2016) among others.

Our work is mostly related to two works: (a) Cross-lingual SCL (CL-SCL, (Prettenhofer and Stein, 2010, 2011)); and (b) Distributional Correspondence Indexing (DCI, (Fernández et al., 2016)) – in both cases pivot features were redefined to support CL (in (a)) and CLCD (in (b)) with non-DNN models, in order to perform sentiment analysis. Below we show how we combine this idea with modern DNNs and BEs to substantially improve CLCD learning.

Cross-domain transfer In NLP, CD transfer (a.k.a domain adaptation) has been addressed for many tasks, including sentiment classification (Bollegala et al., 2011b), POS tagging (Schnabel and Schütze, 2013), syntactic parsing (Reichart and Rappoport, 2007; McClosky et al., 2010; Rush et al., 2012) and relation extraction (Jiang and Zhai, 2007; Bollegala et al., 2011a), if to name a handful of examples.

Several approaches to CD transfer have been proposed in the ML literature, including instance reweighting (Huang et al., 2007; Mansour et al., 2009), sub-sampling from both domains (Chen et al., 2011) and learning joint target and source feature representations. Representation learning, the latter, has become prominent in the DNN era, and is the approach we take here. As noted in § 1 we adopt CD models that integrate pivot-based learning with DNNs to perform CLCD.

Multilingual word embeddings Multilingual word embeddings learning is an active field of research. For example, Ruder et al. (2017) compare 49 papers that have addressed the problem since 2011. Such embeddings are of importance as they provide means of bridging the lexical gap between languages, which supports CL transfer.

Surveying this extensive literature is well beyond our scope. Since our focus is on performing CLCD with minimal supervision, we quote Ruder et al. (2017) that categorize multilingual embedding methods with respect to two criteria on the data they require for their training: (a) type of alignment (word, sentence or document); and (b) comparability (parallel data: exact translation, vs. comparable data: data that is only similar). The BEs we use in our work are those of Smith et al. (2017) that require several thousands translated words as a supervision signal. That is, except from BEs induced using comparable word alignment signals – words aligned through indirect signals such as related images or through comparability of their features (e.g. POS tags) – the BEs we employ belong to the class of the most minimal supervision. In addition, as noted in § 1, in order to allow the lazy CLCD setup, we would like BEs where the source language embeddings are induced with no knowledge of the target language, and we indeed choose such BEs (§ 5).

3 Task Definition

The task we address is cross-language cross-domain (CLCD) learning. Formally, we are given a set of labeled examples from language L_s and domain D_s (denoted as the pair (L_s, D_s)). Our goal is to train an algorithm that will be able to correctly label examples from language L_t and domain D_t (L_t, D_t). The same label set, T, is used across the participating source and target domains and languages.

The setup we consider is similar in spirit to the setup known as unsupervised domain adaptation (e.g. (Blitzer et al., 2007; Ziser and Reichart, 2017, 2018)). When taking the representation learning approach to CLCD learning, the training pipeline usually consists of two steps. In the first step, the representation learning model is trained on unlabeled data from the source and target languages and domains, with the goal of generating a joint representation for the source and the target. Below we describe the unlabeled data in the full and the lazy CLCD setups. In the second step, a classifier for the supervised task is trained on the (L_s, D_s) labeled data. To facilitate language and domain transfer, every example that is fed to the task classifier in this second step is first represented by the representation model that was trained with unlabeled data at the first step. This is true both when the task classifier is trained and at test time when it is applied to data from (L_t, D_t).

We consider two setups which differ with respect to the unlabeled examples available for the representation learning model. In the full CLCD setup, the training algorithm has access to unlabeled examples from both (L_s, D_s) and (L_t, D_t). Since for truly resource poor languages it may be challenging to find a sufficient number of unlabeled examples from (L_t, D_t), we also consider the lazy setup where the training algorithm has access to unlabeled examples from (L_s, D_s) and (L_s, D_t) – that is, target domain unlabeled examples are available only in the source language.

4 Preliminaries

In this paper we aim to adapt CD models that integrate the power of DNNs and of pivot-based learning so that they can be applied to CLCD learning. In this section we hence briefly describe the works in this line. We start with the concept of domain adaptation using pivot-based methods, continue with works that are based on autoencoders and end with works that are based on sequence modeling with LSTMs.

Pivot based domain adaptation This approach was proposed by Blitzer et al. (2006, 2007), through their SCL method. Its main idea is to divide the shared feature space of the source and the target domains to a set of pivot features that are: (a) frequent in both domains; and (b) have a strong correlation with the task label in the source domain labeled data. The features which do not comply with at least one of these criteria form a complementary set of non-pivot features.

In SCL, after the original feature set is divided into the pivot and non-pivot subsets, this division is utilized in order to map the original feature space of both domains into a shared, low-dimensional, real-valued feature space. To do so, a binary classifier is defined for each of the pivot features. This classifier takes the non-pivot features of an input example as its representation, and is trained on the unlabeled data from both the source and the target domains, to predict whether its associated pivot feature appears in the example or not. Note that no human annotation is required for the training of these classifiers, the supervision signal is in the unlabeled data. The matrix whose columns are the weight vectors of the classifiers is post-processed with singular value decomposition (SVD) and the derived matrix maps feature vectors from the original space to the new.

Since the presentation of SCL, pivot-based cross-domain learning has been researched extensively (e.g. (Pan et al., 2010; Gouws et al., 2012; Bollegala et al., 2015; Yu and Jiang, 2016; Yang et al., 2017)).

4.1 Autoencoder Based Methods

An autoencoder (AE) is comprised of an encoder function e and a decoder function d, and its output is a reconstruction of its input x: $r(x) = d(e(x))$. The model is trained to minimize a loss between x and $r(x)$. Over the last decade AEs have become prominent in CD learning with methods such as Stacked Denoising Autoencoders (SDA, (Vincent et al., 2008; Glorot et al., 2011) and marginalized SDA (MSDA, (Chen et al., 2012)) outperforming earlier state-of-the-art methods that were based on the concept of pivots but did not employ DNNs (Blitzer et al., 2006, 2007). A survey of AE-based models in CD learning can be found in ZR17.

ZR17 combined AEs and pivot-based modeling for CD learning. Their basic model (AE-SCL) is a feed-forward NN where the non-pivot features of the input example are encoded into a hidden representation that is then decoded into the pivot features of the example. Their advanced model (AE-SCL-SR) is identical in structure but its reconstruction matrix is fixed and consists of pre-trained embeddings of the pivot features, so that input examples with similar pivots are biased to have similar hidden representations. Since no CL learning was attempted in that work, the pre-trained embeddings used in AE-SCL-SR are monolingual. Both models are illustrated in Figure 1.

After one of the above representation models is trained with unlabeled data from the source and target domains, it is employed when training the task (sentiment analysis) classifier and when applying this classifier to test data. ZR17 learned a standard linear classifier (logistic regression), and fed it with the hidden representation of AE-SCL or AE-SCL-SR. They demonstrated the superiority of their models (especially, AE-SCL-SR) over non-DNN pivot-based methods and a variety of AE-based methods that do not consider pivots.

4.2 LSTM Based Methods

ZR18 observed that AE-based representation learning models do not exploit the structure of their input examples. Obviously, this can negatively impact text classification tasks, such as sentiment analysis. They hence proposed a structure-aware representation learning model, named Pivot Based Language Modeling (PBLM, Figure 2a).

PBLM is an LSTM fed with the embeddings of the input example words. As is standard in the LSTM literature, it is possible to feed the model with 1-hot word vectors and multiply them by a (randomly initialized) embeddings matrix (as done by ZR18) or to feed the model with pre-trained embeddings. In this paper we consider both options, taking advantage of the second in order to feed the model with BEs.

In contrast to standard LSTM-based language

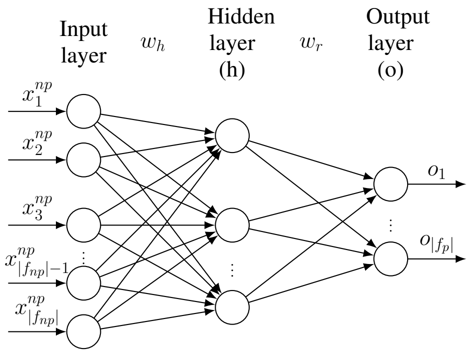

Figure 1: The AE-SCL and AE-SCL-SR models (figure imported from ZR17). x^{np} is a binary vector indicating whether each of the non-pivot features appears in the input example. x^{p} is a similar vector defined with respect to pivot features. o, the output vector of the model, provides the probability that each of the pivot features appears in the example. The loss function of both models is the cross-entropy loss between o and x^{p}. While in AE-SCL both the encoding matrix w^{h} and the reconstruction matrix w^{r} are optimized, in AE-SCL-SR w^{r} consists of pre-trained word embeddings.

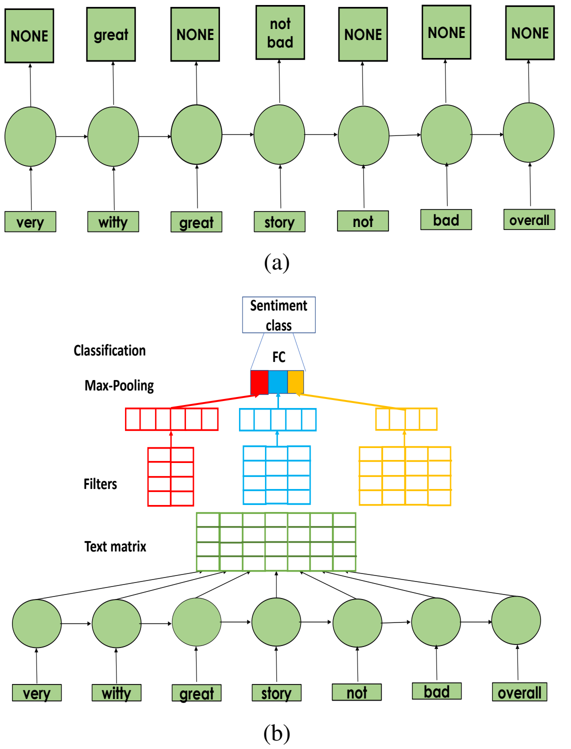
models that predict at each point the most likely next input word, PBLM predicts the next input unigram or bigram if one of these is a pivot (if both are, it predicts the bigram) and NONE otherwise. Similarly to AE-SCL and AE-SCL-SR, PBLM is trained with unlabeled data from both the source and target domains.

consider the example in Figure 2a, provided in ZR18 for adaptation of a sentiment classifier between English book reviews and English reviews of kitchen appliances. PBLM learns the connection between witty - an adjective that is often used to describe books, but not kitchen appliances - and great - a common positive adjective in both domains, and hence a pivot feature. Another example in ZR18 for the same domain pair (see Figure 1 in their paper) is: ”I was at first very excited with my new Zyliss salad spinner - it is easy to spin and looks great”, from this sentence PBLM learns the connection between easy - an adjective that is often used to describe kitchen appliances, but not books - and great. That is, PBLM is able to learn the connection between witty and easy to facilitate adaptation between the domains.

PBLM can naturally feed a structure-aware task classifier. Particularly, in the PBLM-CNN architecture that we consider here (Figure 2b),[2] the PBLM's softmax layer (that computes the probabilities of each pivot to be the next unigram/bigram) is cut and a matrix whose columns are the PBLM's h_t vectors is fed to the CNN.



(a)

(b)

Figure 2: The PBLM model (figure imported form ZR18). (a) The PBLM representation learning model. (b) Adapting a classifier with PBLM: the PBLM-CNN model where PBLM representations are fed into a CNN task classifier.

ZR18 demonstrated the superiority of PBLM-CNN over AE-SCL, AE-SCL-SR and a variety of other previous models, emphasizing the importance of structure-awareness in CD transfer. We next discuss the adaptation of these models so that they can perform CLCD learning.

5 Cross-language Cross-domain Transfer

The models described in the previous section employ pivot-based learning (all models) and allow a convenient integration of BEs (AE-SCL-SR and PBLM). Below we discuss how we adapt these models so that they can perform CLCD learning.

---

[2] ZR18 also considered a PBLM-LSTM architecture where the PBLM representations feed an LSTM classifier. We focus on PBLM-CNN which demonstrated superior performance in 13 of 20 of their experimental setups.

Pivot translation We follow (Prettenhofer and Stein, 2010, 2011; Fernández et al., 2016) and redefine pivot features to be features that: (a) are frequent in (L_s, D_s) and that *their translation* is frequent in (L_t, D_t) ; and (b) are highly correlated with the task label in (L_s, D_s) . Note, that except for the translation requirement in (a) this is the classical definition of pivot features (§ 1).

Translated pivots are integrated into the models in a way that creates a shared cross-lingual output space. For both PBLM and the AE-based models a source language pivot feature and its translation are considered to be the same predicted class of the model. Consider, for example, a setup where we learn representations in order to adapt a classifier from (English, books) to (French, music). The pivot feature magnificent(English)/magnifique(French) will be considered the same PBLM prediction when trained on the unlabeled data from both (L_s, D_s) and (L_t, D_t). Similarly, in AE-SCL and AE-SCL-SR magnificent and magnifique will be assigned the same coordinate in the x^p (gold standard pivot indicators) and o (model output) vectors. In the lazy setup, where training is done with unlabeled data from (English, books) and (English, music) pivot translation is irrelevant as the representation learning model is trained only in the source language.

Note that when only pivot translation is used to make the CD methods address CLCD learning, the input space is not shared across languages. Instead, 1-hot vectors are used to encode the vocabularies of both languages, whose overlap is limited. This mismatch is somewhat reduced when training on unlabeled data from both (L_s, D_s) and (L_t, D_t). That is, we rely on the trained parameters of the models to align the input spaces when trained on unlabeled data from both (L_s, D_s) and (L_t, D_t).

In § 7 we show that this technique alone leads to improved CLCD results compared to existing methods. The lazy setup, however, is not supported by this technique, as training is not performed on unlabeled data from the target language. We next describe how to integrate BEs into our models, which provides a shared input layer that is crucial for both full and lazy CLCD.

Multilingual word embeddings Translated pivot features provide the models with a shared output layer. But can we use the same mechanism in order to map the input layers of the models into a shared cross-lingual space ?

Unfortunately, word-level translation does not seem like the right solution to this problem, due to two reasons. First, word-level translation is inherently ambiguous – it is very frequent that the set of senses associated with a given word in one language, is not identical to the set of senses associated with any other word in another given language. Moreover, large scale word-level translation may impose prohibitively high costs – either financial or in human time. Hence word-level translation is feasible mostly when dealing with a relatively small number of pivot features. The input layers of the models, consisting of words from the entire vocabulary (PBLM) or of non-pivot unigrams and bigrams (AE-SCL and AE-SCL-SR), require a cheaper and more stable mapping.

Our solution is hence based on BEs which embed words from the source and the target language in a shared vector space. As discussed in § 2 the BEs we use are those of Smith et al. (2017) that require several thousands of translated word pairs as a supervision signal, which reflects a low supervision level (Ruder et al., 2017). While bilingual word embedding models do not provide accurate word-level translation (to the level that such translation is possible), they do embed words from the two languages that have similar meaning with similar vectors, in terms of euclidean distance.

The BEs of Smith et al. (2017) also have the property required for our lazy setup: they are induced such that the source language embeddings have no knowledge of any particular target language. The embedding algorithm achieves that by learning two sets of monolingual embeddings and then aligning them with an SVD-based method.

Once we obtain the BEs, it is straightforward to integrate them into the PBLM model. We start by considering the full CLCD setup. When PBLM is applied to text from (L_s, D_s) – both when it is trained with unlabeled data (Figure 2a) and when it is used as part of the task classifier, when this classifier is trained with labeled data (Figure 2b) – the BEs of the source language words are fed into the model. Likewise, when PBLM is applied to text from (L_t, D_t) – both when it is trained with unlabeled data and when it is used as part of the task classifier when this classifier is applied to test data – it is fed with the bilingual representations of the target language words. In the lazy setup, the details are very similar except that PBLM is not trained with unlabeled data from (L_t, D_t), only with unlabeled data from (L_s, D_s) and (L_s, D_t).

Unfortunately, BEs do not provide a sufficient solution for the AE-based models. In AE-SCL the input layer consists of a non-pivots indicator vector, x^{np}, that cannot be replaced by embedding vectors in a straight forward manner. In AE-SCL-SR the input layer is identical to that of AE-SCL, but this model replaces the reconstruction matrix w^r with a matrix whose rows consist of pre-trained word embeddings of the pivot features. Hence, similarly to PBLM we can construct a w^r matrix with the source language BEs when this model is applied to source language data, and with target language BEs when this model is applied to target language data. This construction of w^r provides an additional shared cross-lingual layer, added to the translated pivot features of the output layer.

Consequently, an inherent limitation of the AE-based models when it comes to CLCD transfer, is that they cannot be employed in the lazy setup. The intersection of their input spaces when applied to the source and the target languages is limited to the vectors representing the shared vocabulary items (see above in this section). Hence, these models have to be trained with unlabeled data from both languages in order to align the input layers of the two languages with each other.

6 Experiments

Task and data [3] As in our most related previous work (Prettenhofer and Stein, 2010, 2011; Fernández et al., 2016) we experiment with the Websis-CLS-10 dataset (Prettenhofer and Stein, 2010) consisting of Amazon product reviews written in 4 languages (English, German, French and Japanese), from 3 product domains (Books (B), DVDs (D) and Music (M)). Due to our extensive experimental setup we leave Japanese for future.[4]

For each (language, domain) pair the dataset includes 2000 train and 2000 test documents, labeled as positive or negative, and between 9,358 to 50,000 unlabeled documents. As in the aforementioned related works, we consider English as the source language, as it is likely to have labeled documents from the largest number of domains.

Following ZR18 we also consider a more challenging setup where the English source domain consists of user airline (A) reviews (Nguyen, 2015). We use the dataset of ZR18, consisting of 1000 positive and 1000 negative reviews in the labeled set, and 39396 reviews as the unlabeled set.

We employ a 5-fold cross-validation protocol. In all folds 1600 (English, D_s) train-set examples are randomly selected for training and 400 for development. The German and French test sets are used in all folds. All sets contain the same number of positive and negative reviews. For each model we report averaged performance across the folds.

The BEs were downloaded from the author's github. More details are in the appendix.

Models and baselines Our main model is PBLM+BE that is trained in the full setup and employs both translated pivots for CL output alignment and BEs for CL input alignment (§ 5). We also experiment with PBLM+BE+Lazy: the same model employed in the lazy setup, and with PBLM: a model similar to PBLM+BE except that BEs are not employed.

We further experiment with AE-SCL that employs translated pivots for CL output alignment and AE-SCL-SR that does the same and also integrates BEs into its fixed reconstruction matrix. Following ZR17 and ZR18 the linear classifier we use is logistic regression. To compare to previous work, we implemented the CL-SCL and the DCI models, for which we use the cosine kernel that performs best in (Fernández et al., 2016).

To consider the power of BEs, we experiment with a classifier fed with the BEs of the input document's words. We consider both a CNN classifier (where the BEs are fed into the columns of the CNN input matrix) and logistic regression (where the embeddings of the document's words are averaged) and report results with CNN as they are superior. We denote this model with BE+CNN.

For reference, we also compare to a setup where $L_s = L_t$, and to a setup where $L_s = L_t$ and $D_s = D_t$. For these setups we report results with a linear classifier with unigram and bigram features, as it outperforms both a linear classifier and a CNN with BE features. The models are denoted with Linear-IL and Linear-ILID, respectively (IL stands for in-language and ID for in-domain).

Pivot features For all models we consider unigrams and bigrams as features. To divide these

---

[3] The URLs of the code (previous models and standard packages) and data we used, are in the appendix.

[4] We add an English domain to our experiments. Moreover, training the models we consider here is substantially more time consuming as we employ DNNs, as opposed to previous methods that use linear classifiers.

features into pivots and non-pivots we follow (Blitzer et al., 2007; Ziser and Reichart, 2017, 2018). Pivots are translated with Google translate. Pivot features are frequent in the unlabeled data of both the source and the target (language, domain) pairs: we require them to appear at least 10 times in each. Among those frequent features we select the ones with the highest mutual information with the task (sentiment) label in the source (language, domain) labeled data. For non-pivot features we consider unigrams and bigrams that appear at least 10 times in one of the (language, domain) pairs.

Hyper-parameter tuning For all models we follow the tuning process described in the original papers. Details are in the appendix.

7 Results

Our results (Table 1) support the integration of structure-aware DNNs, translated pivots and BEs as advocated in this paper. Indeed, PBLM+BE which integrates all these factors and trained in the full setup is the best performing model in all 12 product setups (top table) and in 2 of 6 airline-product setups (middle table). PBLM+BE+lazy, the same model when trained in the lazy setup in which no target language unlabeled data is available for training, is the second best model in 9 of 12 product-product setups (in the other three setups only PBLM+BE and PBLM perform better) and is the best performing model in 4 of 6 airline-product setup and on average across these setups.

To better understand this last surprising result of the airline-product setups, we consider the pivot selection process (§ 6): (a) sort the source features by their mutual information with the source domain sentiment label; and (b) iterate over the pivots and exclude the ones whose translation frequency is not high enough in the target domain.

Let's examine the number of feature candidates that should be considered (in step (b)) from the list of criterion (a) in order to get 100 pivots. In product to product domain pairs: 182; In airline to product domain pairs: 304 (numbers are averaged across setups). In the lazy setup (where no pivot translation is performed) the corresponding numbers are: product to product domain pairs: 148; airline to product domain pairs: 173.

Hence, for domain pairs that involve airline and product, in the full setup many good pivots are *lost in translation* which affects the representation learning quality of PBLM+BE. While PBLM+BE+lazy does not get access to target language data, many more of its pivot features are preserved. We hypothesize that this can be one reason to the surprising superior performance of PBLM+BE+lazy when adapting from airline to product domains.

The success of PBLM+BE+lazy provides a particularly strong support to the validity of our approach, as this model lacks a major source of supervision available to the other CLCD models. As noted in § 1, we believe that the lazy setup is crucial for the future of CLCD learning.

Excluding BEs (PBLM) or changing the model to not generate a shared cross-lingual input layer (AE-SCL-SR that is also unaware of the review structure) results in substantial performance degradation. PBLM is better on average for all four CLCD setups, which emphasizes the importance of structure-awareness. Excluding both BEs and structure-awareness (AE) yields further degradation in most cases and on average. Yet, this degradation is minor (0.5% - 1.7% in the averages of the different setups), suggesting that the way AE-SCL-SR employs BEs, which is useful for CD transfer (ZR17), is less effective for CLCD.

CL-SCL and DCI, that employ pivot translation but neither DNNs nor BEs, lag behind the PBLM-based models and often also the AE-based models, although they outperform the latter in some cases. Likewise, BE+CNN, where BEs are employed but without any other CLCD learning technique, is also substantially outperformed by the PBLM-based models, but it does better than the AE-based models with the airline source domain.

Finally, comparison to the within-language models of the bottom table allows us to quantify the gap between current CLCD models and standard models that do not perform CD and/or CL transfer. The averaged differences between our best product-product model, PBLM-BE, and Linear-ILID are 3.5% (English-German) and 6.5% (English-French). When adapting from the airline domain the gap is much larger: averaged gaps of 17% and 16.2% from the best performing PBLM+BE-lazy, for English-German and English-French, respectively. This is not a surprise as ZR18 already demonstrated the challenging nature of within-language airline-product transfer. We consider our results to be encouraging, especially given the improvement over previous work, and the smaller gaps in the product-product setups.

8 Conclusions

We addressed the problem of CLCD transfer in sentiment analysis and proposed methods based on pivot-based learning, structure-aware DNNs and BEs. We considered full and lazy training, and designed a lazy model that, for a given target domain, can be trained with unlabeled data from the source language only and then be applied to any target language without re-training. Our models outperform previous models across 18 CLCD setups, even when ours are trained in the lazy setup and previous models are trained in the full setup.

In future work we wish to improve our results for large domain gaps and for more dissimilar languages, particularly in the important lazy setup. As our airline-product results indicate, increasing the domain gap harms our results, and we expect the same with more diverse language pairs.

A Hyper-parameter Tuning

As promised in Section 6 of the main paper we detail here our hyper-parameter tuning process.

For all models, we tune the number of pivot features among $[100, 200, 300, 400, 500]$. For PBLM, the input embedding size (when no word embeddings are used) is tuned among $[128, 256]$, and the hidden representation dimension is selected from $[128, 256, 512]$. The size of the hidden layer of AE-SCL and AE-SCL-SR is set to 300.

The dimension of our bilingual embeddings is 300, as decided by (Smith et al., 2017). For all CNN models we use 256 filters of size $3 \times |embedding|$ and perform max pooling for each of the 256 vectors to generate a single 1×256 vector that is fed into the classification layer. In the SVD step of CL-SCL we tune the output dimension among $[50, 75, 100, 125, 150]$.

For AE-SCL and AE-SCL-SR, we follow ZR17 and represent each example fed into the sentiment classifier with its $w^h x^{np}$ vector. Unlike ZR17 we do not concatenate this representation with a bag of unigrams and bigrams representation of the example – due to the cross-lingual nature of our task. As in the original papers, the input features of AE-SCL, AE-SCL-SR, CL-SCL and DCI are word unigrams and bigrams.

All the algorithms in the paper that involve a CNN or a LSTM are trained with the ADAM algorithm (Kingma and Ba, 2015). For this algorithm we follow ZR18 and use the parameters described in the original ADAM article:

- Learning rate: $lr = 0.001$.
- Exponential decay rate for the 1st moment estimates: $\beta_1 = 0.9$.
- Exponential decay rate for the 2nd moment estimates: $\beta_2 = 0.999$.
- Fuzz factor: $\epsilon = 1e-08$.
- Learning rate decay over each update: $decay = 0.0$.

B Code and Data

Here we provide the URLs of the code and data we used in this paper:

Abstract

We construct a multilingual common semantic space based on distributional semantics, where words from multiple languages are projected into a shared space via which all available resources and knowledge can be shared across multiple languages. Beyond word alignment, we introduce multiple cluster-level alignments and enforce the word clusters to be consistently distributed across multiple languages. We exploit three signals for clustering: (1) neighbor words in the monolingual word embedding space; (2) character-level information; and (3) linguistic properties (e.g., apposition, locative suffix) derived from linguistic structure knowledge bases available for thousands of languages. We introduce a new cluster-consistent correlational neural network to construct the common semantic space by aligning words as well as clusters. Intrinsic evaluation on monolingual and multilingual QVEC tasks shows our approach achieves significantly higher correlation with linguistic features which are extracted from manually crafted lexical resources than state-of-the-art multi-lingual embedding learning methods do. Using low-resource language name tagging as a case study for extrinsic evaluation, our approach achieves up to 14.6% absolute F-score gain over the state of the art on cross-lingual direct transfer. Our approach is also shown to be robust even when the size of bilingual dictionary is small.[1]

1 Introduction

More than 3,000 languages have electronic record, e.g., at least a portion of the Christian Bible had been translated into 2,508 different languages. However, the training data for mainstream natural language processing (NLP) tasks such as Information Extraction (IE) and Machine Translation (MT) is only available for dozens of dominant languages. In this paper we aim to construct a multilingual common semantic space where words in multiple languages are mapped into a distributed, language-agnostic semantic continuous space, so that resources and knowledge can be shared across languages.

Previous multilingual embedding methods align the semantic distributions of words from multiple languages within the common semantic space. Though several recent attempts (Artetxe et al., 2017, 2018; Conneau et al., 2017) have shown that it is possible to extract multilingual word embedding from a pair of potentially unaligned corpora in multiple languages, we claim that it is necessary to impose more constraints to preserve linguistic properties and facilitate downstream NLP tasks, such as cross-lingual IE, and MT. We find that words also can be clustered through explicit (e.g., sharing affixes of certain linguistic functions) or implicit clues (e.g., sharing neighbors from monolingual word embedding) and such clusters should also be consistent across multiple languages. To do so, we design a new algorithm, called cluster-consistent multilingual word embedding, that extracts multilingual word embedding vectors which preserve the natural clustering structures of words across multiple languages.

We propose to create clusters through three kinds of signals as follows, without any extra human annotation effort. Then we aggregate the embedding vectors of words in each cluster and ensure that the clusters (or the words therein) are consistent across multiple languages.

Neighbor based clustering and alignment. We build our common space based on correlational neural network (CorrNet) which is an extension of autoencoder framework by enabling cross-lingual reconstruction. In contrast to previous work (Chandar et al., 2016; Rajendran et al.,

---

[1] The resources and programs are available for research purpose: https://github.com/wilburOne/CommonSpace/

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 250–260
Brussels, Belgium, October 31 - November 4, 2018.

2015), we extend CorrNet to *neighbor-consistent correlation network* by using each word's neighbors (the nearest words within monolingual semantic space) to ensure that the cross-lingual mapping from and to the common semantic space is locally smooth. For instance, the neighboring words of *China* in English (*Japan*, *India* and *Taiwan*) should be close to the neighboring words of *Cina* in Italian (*Beijing*, *Korea*, *Japan*) in the common semantic space. In other words, we encourage the consistency of neighborhoods across multiple languages.

Character based clustering and alignment. Many related languages share very similar character set, and many words that refer to the same concept share similar compositional characters or patterns, e.g., *China* (English), *Kina* (Danish), and *Cina* (Italian).

Linguistic property based clustering and alignment. Many languages also share linguistic properties, e.g., apposition, conjunction, and plural suffix (English (*-s* / *-es*), Turkish (*-lar* / *-ler*), Somali (*-o*)). Linguists have created a wide variety of linguistic property knowledge bases, which are readily available for thousands of languages. For example, the CLDR (Unicode Common Locale Data Repository)[2] includes closed word classes and affixes indicating various linguistic properties. We propose to take advantage of these language-universal resources to create clusters, where the words within one cluster share the same linguistic property, and build alignment between clusters for common semantic space construction.

We evaluate our approach on monolingual and multilingual QVEC (Tsvetkov et al., 2015) tasks, which measure the quality of word embeddings based on the alignment of the embeddings to linguistic feature vectors extracted from manually crafted linguistic resources, as well as an extrinsic evaluation on name tagging for low-resource languages. Experiments demonstrate that our framework is effective at capturing linguistic properties and significantly outperforms state-of-the-art multi-lingual embedding learning methods.

2 Related Work

Multilingual word embeddings have advanced many multilingual NLP tasks, such as machine translation (Zou et al., 2013; Mikolov et al., 2013b; Madhyastha and España-Bonet, 2017), dependency parsing (Guo et al., 2015; Ammar et al., 2016a), and name tagging (Zhang et al., 2017a; Tsai and Roth, 2016; Zhang et al., 2018; Cheung et al.; Zhang et al., 2017b; Feng et al., 2017). Using bilingual aligned words, previous methods project multiple monolingual embeddings into a shared semantic space using linear mappings (Mikolov et al., 2013b; Rothe et al., 2016; Zhang et al., 2016; Baroni et al., 2015; Xing et al., 2015; Smith et al., 2017) or canonical correlation analysis (CCA) (Ammar et al., 2016b; Faruqui and Dyer, 2014; Lu et al., 2015). Compared with CCA, which only optimizes the correlation for each individual pair of languages, linear mapping based methods can jointly optimize all the languages in the common semantic space. We focus on learning linear mappings to construct the common semantic space and adopt correlational neural networks (CorrNet) (Chandar et al., 2016; Rajendran et al., 2015) as the basic model. In contrast to previous work which only exploited monolingual word semantics, we introduce multiple cluster-level alignments and design a new cluster consistent CorrNet to align both words and clusters.

Another branch of approaches for multilingual word embeddings are based on parallel or comparable data, such as parallel sentences (AP Chandar et al., 2014; Gouws et al., 2015; Luong et al., 2015; Hermann and Blunsom, 2014; Schwenk et al., 2017), phrase translations (Duong et al., 2016) and comparable documents (Vulic and Moens, 2015). Moreover, to reduce the need of bilingual alignment, several approaches have been designed to learn cross-lingual embeddings based on a small seed dictionary (Vulic and Korhonen, 2016; Zhang et al., 2016; Artetxe et al., 2017), or even with no supervision (Cao et al., 2016; Zhang et al., 2017d,c; Conneau et al., 2017; Artetxe et al., 2018). However, such methods are still limited to bilingual word embedding learning and remaining to be explored for common semantic space construction.

3 Approach

3.1 Overview

Figure 1 shows the overview of our neural architecture. We project all monolingual word embeddings into a common semantic space based on word-level as well as cluster-level alignments and learn the transformation functions. First, on

---

[2] cldr.unicode.org

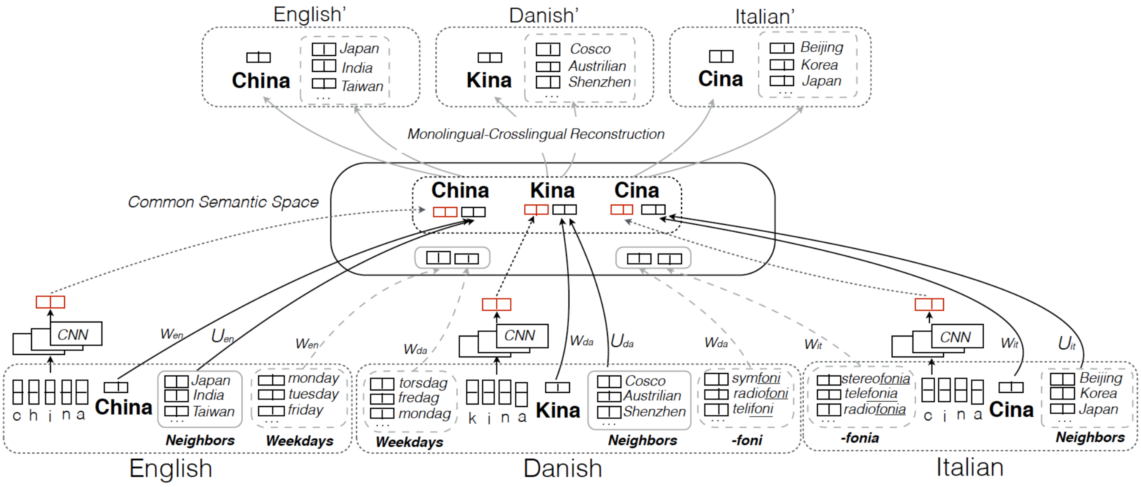

Figure 1: Architecture Overview. In each monolingual semantic space, the words within solid rectangle denote a neighbor based cluster and the words within dotted rectangle denote a linguistic property based cluster.

word-level, we build a neighborhood-consistent CorrNet to augment word representations with neighbor based clusters and align them in the common semantic space. In addition, we apply a language-independent convolutional neural networks to compose character-level word representation and concatenate it with word representation in the common semantic space. Finally, we construct clusters based on linguistic properties, including closed word classes and affixes, and align them in the common semantic space. We jointly optimize for all the alignments in the common semantic space for each pair of languages.

3.2 Basic Model

We briefly describe the basic model for learning the common semantic space: correlational neural networks (CorrNets) (Chandar et al., 2016; Rajendran et al., 2015). It combines the advantages of canonical correlation analysis (CCA) and autoencoder (AE).

Given the bilingual aligned word pairs between two languages l_1 and l_2, we first use their monolingual word embeddings to initialize each word with a vector and obtain $M_{l_1} \in \mathbb{R}^{|V_{l_1}|\times d_{l_1}}$ and $M_{l_2} \in \mathbb{R}^{|V_{l_2}|\times d_{l_2}}$, where V_{l_1} and V_{l_2} are the bilingual dictionary of l_1 and l_2. $V_{l_1}^i$ is the translation of $V_{l_2}^i$, and d_{l_1} and d_{l_2} are the vector dimensionalities. Then for each language we learn a linear projection function to project M_{l_1} and M_{l_2} into the common semantic space:

$$H_{l_1} = \sigma(M_{l_1} \cdot W_{l_1} + b_{l_1}) ,$$

$$H_{l_2} = \sigma(M_{l_2} \cdot W_{l_2} + b_{l_2}) ,$$

where $H_{l_1} \in \mathbb{R}^{|V_{l_1}|\times h}$ and $H_{l_2} \in \mathbb{R}^{|V_{l_2}|\times h}$ are the vector representations for V_{l_1} and V_{l_2} in the common semantic space respectively. h is the vector dimensionality in the shared semantic space. $W_{l_1} \in \mathbb{R}^{d_{l_1}\times h}$ and $W_{l_2} \in \mathbb{R}^{d_{l_2}\times h}$ are the transformation matrices, and b_{l_1} and b_{l_2} are the bias vectors. σ denotes Sigmoid function.

After we project the monolingual embeddings into the common semantic space, we further reconstruct M_{l_1} and M_{l_2} from H_{l_1} and H_{l_2} separately:

$$M'_{l_1} = \sigma(H_{l_1} \cdot W_{l_1}^{\top} + b'_{l_1}) ,$$

$$M^*_{l_1} = \sigma(H_{l_2} \cdot W_{l_1}^{\top} + b'_{l_1}) ,$$

$$M'_{l_2} = \sigma(H_{l_2} \cdot W_{l_2}^{\top} + b'_{l_2}) ,$$

$$M^*_{l_2} = \sigma(H_{l_1} \cdot W_{l_2}^{\top} + b'_{l_2}) ,$$

where b'_{l_1}, b'_{l_2} are the bias vectors. M'_{l_1} and M'_{l_2} are the monolingual reconstructions of M_{l_1} and M_{l_2} from the common space, and $M^*_{l_1}$ and $M^*_{l_2}$ are cross-lingual reconstructions. $W_{l_1}^{\top}$ and $W_{l_2}^{\top}$ are the transposes of W_{l_1} and W_{l_2} respectively.

To learn the common semantic representations, we minimize the distance between the aligned word vectors as well as the loss of monolingual and cross-lingual reconstruction:

$$O_W = \sum_{\{l_i,l_j\}\in A} L(M'_{l_i}, M_{l_i}) + L(M^*_{l_i}, M_{l_i})$$
$$+ L(M'_{l_j}, M_{l_j}) + L(M^*_{l_j}, M_{l_j}) + L(H_{l_i}, H_{l_j}) ,$$

where l denotes any language that we want to project into the common semantic space, A denotes all bilingual dictionaries, and L denotes a similarity metric. In our work, we use cosine similarity as the similarity metric.

3.3 Neighborhood-Consistent CorrNet

CorrNet can project multiple monolingual word embeddings into a common semantic space using bilingual word alignment. However, the same concepts may have different semantic bias in various languages. For example, the top five nearest words of the concept "*China*" are: (*Japan, India, Taiwan, Chinese, Asia*) in English, (*Cosco, Shenzhen, Australian, Shanghai, manufacturing*) in Danish, and (*Beijing, Korea, Japan, aluminum, copper*) in Italian respectively. In order to ensure the consistency of the neighborhoods within the common semantic space and make the cross-lingual mapping locally smooth, we propose to augment monolingual word representation with its top-N nearest neighboring words from the original monolingual semantic space.[3]

Given the monolingual embeddings of the bilingual aligned words for two languages l_1 and l_2, M_{l_1} and M_{l_2}, for each word, we extract the top-N nearest neighbors and construct the neighborhood clusters. Each cluster $t_l = \{w_1, w_2, ..., w_{|t_l|}\}$ in language l is represented by

$$c_{t_l} = \frac{1}{|t_l|} \sum_{w \in t_l} E_w \ ,$$

where E_w denotes the monolingual word embedding for w.

We obtain all the neighborhood cluster vector representations C_{l_1}, C_{l_2} for l_1 and l_2. We incorporate the neighborhood cluster information into the common semantic space when projecting monolingual embeddings:

$$\begin{aligned} H_{l_1} &= \sigma(M_{l_1} \cdot W_{l_1} + C_{l_1} \cdot U_{l_1} + b_{l_1}), \\ H_{l_2} &= \sigma(M_{l_2} \cdot W_{l_2} + C_{l_2} \cdot U_{l_2} + b_{l_2}), \end{aligned} \qquad (1)$$

Besides the monolingual and cross-lingual reconstructions for M_{l_1} and M_{l_2} in CorrNets, we also add monolingual and cross-lingual reconstructions for the neighborhood clusters:

$$C'_{l_1} = \sigma(H_{l_1} \cdot U_{l_1}^\top + b^*_{l_1}) \ ,$$

$$C^*_{l_1} = \sigma(H_{l_2} \cdot U_{l_1}^\top + b^*_{l_1}) \ ,$$

$$C'_{l_2} = \sigma(H_{l_2} \cdot U_{l_2}^\top + b^*_{l_2}) \ ,$$

$$C^*_{l_2} = \sigma(H_{l_1} \cdot U_{l_2}^\top + b^*_{l_2}) \ ,$$

In addition to optimizing the loss functions described in the Section 3.2, we further optimize the monolingual and cross-lingual reconstruction for neighborhood clusters:

$$\begin{aligned} O_N = \sum_{\{l_i, l_j\} \in A} & L(C'_{l_i}, C_{l_i}) + L(C^*_{l_i}, C_{l_i}) \\ & + L(C'_{l_j}, C_{l_j}) + L(C^*_{l_j}, C_{l_j}) \ , \end{aligned}$$

3.4 Character-Level Word Alignment

Bilingual word alignment is not always enough or available to induce a common semantic space, especially for low-resource languages. Although the words that refer to the same concept are not exactly the same in multiple languages, they often share a set of similar characters, especially in related languages written in the same script. For example, the same entity is spelled slightly differently in three languages: *Semsettin Gunaltay* in English, *Şemsettin Günaltay* in Turkish, and *Semsetin Ganoltey* in Somali. Beyond word-level alignment, we introduce character-level alignment by composing word representations from its compositional characters using convolutional neural networks (CNN). For each language, we adopt a language-independent CNN to generate character-level word representation.

Character Lookup Embeddings Let S_l be the character set for language l and $E_{S_l} \in \mathbb{R}^{|S_l| \times d}$ be the character lookup embeddings, where d is the dimensionality of each character embedding. Here, we use a simple yet effective method to induce character embeddings from word embeddings[4]. For each character c, we initialize its embedding by averaging the embeddings of all words which contain the character. The character embeddings will be further tuned by the model.

Character-Level CNN (Kim et al., 2016) The input layer is a sequence of characters of length k for each word. Each character is represented by a d-dimensional lookup embedding. Thus each input sequence is represented as a feature map of dimensionality $d \times k$.

We use the convolution layer to learn the representation for each sliding n-gram characters. We make p_i as the concatenated embeddings of n continuous columns from the input matrix, where n

---

[3] We set $N = 10$ in our experiments since it performed best on the intrinsic evaluation among {2, 5, 10, 20, 50}.

[4] This approach is proved to be better than random initialization of character embeddings.

is the filter width. We then apply the convolution weights $W \in \mathbb{R}^{d \times nd}$ to p_i with a biased vector $b \in \mathbb{R}^d$, i.e., $p_i^{'} = \tanh(W \cdot p_i + b)$. All n-gram representations $p_i^{'}$ are used to generate the word representation y by max-pooling.

In our experiments, we apply multiple filters with various widths to obtain the representation for word w_i^l. The final character-level word representation $\hat{w}_i^l$ is the concatenation of all word representations with varying filter widths.

Cross-lingual Mapping Given the bilingual aligned word pairs, we directly minimize the distance of the character-level word representations in the common semantic space by:

$$O_{char} = \sum_{\{l_i, l_j\} \in A} L(\hat{W}_{l_i}^{char}, \hat{W}_{l_j}^{char})$$

The final word representation of w_i^l in the common semantic space is the concatenation of character-level word presentation $\hat{w}_i^l$ and projected word representation h_i^l.

3.5 Linguistic Property Alignment

Linguists have made great efforts at building linguistic property knowledge bases for thousands of languages in the world. These knowledge bases include a large number of topological properties (phonological, lexical and grammatical) which we will use to build a high-level alignment between words across languages. We exploit the following resources:

- **CLDR** (Unicode Common Locale Data Repository)[5] which includes multilingual gazetteers for months, weekdays, cardinal and ordinal numbers;
- **Wiktionary**[6] which is a multilingual, web-based collaborative project to create an English content dictionary, includes word and prefix/suffix dictionaries for 1,247 languages;
- **Panlex**[7] database which contains 1.1 billion pairwise translations among 21 million expressions in about 10,000 language varieties.

We mainly exploit two types of linguistic properties to extract word clusters. The first type is language-independent closed word classes, such as colors, weekdays, and months. Table 1 shows some examples of the word clusters we automatically extracted from CLDR and Wiktionary for English. The second type of word clusters is generated based on morphological information, including affixes that indicate various linguistic properties. These properties tend to be consistent across many languages. For example, "-like" is a suffix denoting "similar to" in English, while in Danish "-agtig" performs the same function. Wiktionary and Panlex include the affix alignments between English and any other languages. We filtered out the many-to-many affix alignments and obtained hundreds of alignments between each language and English. For each affix, we derive a set of word pairs (*basic word*, *extended word with affix*) by first selecting all the word pairs where *basic word* $+$ *affix* $=$ *extended word*, then ranking all word pairs based on the cosine similarity of their monolingual word embedding. Finally we select the top ranked 20 word pairs to form the cluster for each affix.

Class Name	Words / Word Pairs
Colors	white, yellow, red, blue, green ...
Weekdays	monday, tuesday, friday, sunday ...
Months	january, february, march, april ...
numbers	one, two, three, four, five ...
pronouns	i, me, you, he, she, her, they ...
prepositions	of, in, on, for, from, about ...
conjunctions	but, and, so, or, when, while ...
clothes	hat, shirt, pants, skirt, socks ...
-like	(god, godlike), (bird, birdlike) ...
-able	(accept, acceptable), (adopt, adoptable) ...
micro-	(gram, microgram), (chip, microchip) ...
auto-	(maker, automaker), (gas, autogas) ...

Table 1: Examples of closed word classes and linguistic properties based clusters for English

We extract a set of word clusters from each language, and align the clusters based on their functions defined in CLDR, Wiktionary and Panlex. For each language l, each cluster $r_i^l \in R^l$ contains a set of words or word-pairs sharing the same function. We use the average operation to obtain an overall vector representation for each cluster M_l^R.[8] Then, we project the cluster-level vectors into the shared semantic space and minimize the distance between them:

$$H_{l_i}^R = \sigma(M_{l_i}^R \cdot W_{l_i} + b_{l_i}^R) \,,$$

$$H_{l_j}^R = \sigma(M_{l_j}^R \cdot W_{l_j} + b_{l_j}^R) \,,$$

---

[5] http://cldr.unicode.org/index/charts

[6] https://en.wiktionary.org

[7] http://panlex.org/

[8] For each word pair, we use the vector of the extend word minus the vector of the basic word as the vector representation of the word pair.

Parameter Name	Value
Monolingual Word Embedding Size	512
Multilingual Word Embedding Size	512
# of Filters in Convolution Layer	20
Filter Widths	1, 2, 3
Batch Size	500
Initial Learning Rate	0.5
Optimizer	Adadelta

Table 2: Hyper-parameters.

$$O_R = \sum_{\{l_i,l_j\}\in A} L(H^R_{l_i}, H^R_{l_j}) \,,$$

where W is the same as the W used in Section 3.3 for each language. We finally optimize the sum of the losses by finding the parameters $\theta = \{W_l, b_l, b_l^{'}, U_l, b_l^{*}, \text{CNN}_l, b_l^R\}$, where l denotes a specific language:

$$O_\theta = O_W + O_N + O_{char} + O_R$$

4 Experiments

4.1 Experiment Setup

Previous work (Ammar et al., 2016b; Duong et al., 2017) evaluated multilingual word embeddings on a series of intrinsic (e.g., monolingual and cross-lingual word similarity, word translation) and extrinsic (e.g., multilingual document classification, multilingual dependency parsing) evaluation tasks. In order to evaluate the quality of the multilingual embeddings, we use QVEC (Tsvetkov et al., 2015) tasks (details will be described in Section 4.2) as the intrinsic evaluation platform. In addition, to demonstrate the effectiveness of our common semantic space for knowledge transfer, especially for low-resource scenarios, we adopt the low-resource language name tagging task for extrinsic evaluation.

For fair comparison with state-of-the-art methods on building multi-lingual embeddings (Ammar et al., 2016b; Duong et al., 2017), we use the same monolingual data and bilingual dictionaries as in their work. We build multilingual word embeddings for 3 languages (*English, Italian, Danish*) and 12 languages (*Bulgarian, Czech, Danish, German, Greek, English, Spanish, Finnish, French, Hungarian, Italian, Swedish*) respectively. The monolingual data for each language is the combination of the Leipzig Corpora Collection[9] and Europarl.[10] The bilingual dictionaries are the same as those used in Ammar et al. (2016b).[11]

For each task, we evaluate the performance of our common semantic space in comparison with previously published multilingual word embeddings (MultiCluster, MultiCCA, MultiSkip, and MultiCross)[12]. MultiCluster (Ammar et al., 2016b) groups multilingual words into clusters based on bilingual dictionaries and forces all the words from various languages within one cluster share the same embedding. MultiCCA (Ammar et al., 2016b; Faruqui and Dyer, 2014) uses CCA to estimate linear projections for each pair of languages. MultiSkip is an extension of the multilingual skip-gram model (Luong et al., 2015), which requires parallel data. MultiCross is an approach to unify bilingual word embeddings into a shared semantic space using post hoc linear transformations (Duong et al., 2017).

Table 2 lists the hyper-parameters used in the experiments.

4.2 Intrinsic Evaluation: QVEC

In order to evaluate the quality of multilingual embeddings, we adopt QVEC (Tsvetkov et al., 2015) as the intrinsic evaluation measure. It evaluates the quality of word embeddings based on the alignment of distributional word vectors to linguistic feature vectors extracted from manually crafted lexical resources, e.g., SemCor (Miller et al., 1993). For each word, each dimension of its linguistic feature vector defines the probability of that word belongs to a supersense (e.g., NN.FOOD) which is summarized from WordNet (Fellbaum, 1998).

QVEC is computed as

$$\text{QVEC} = \max_{\sum_j a_{ij} \leq 1} \sum_{i=1}^{D} \sum_{j=1}^{P} r(x_i, s_j) \times a_{ij},$$

where $x \in \mathbb{R}^{D\times 1}$ denotes a distributional word vector and $s \in \mathbb{R}^{P\times 1}$ denotes a linguistic word vector. D and P denote the sizes of vectors respectively. $a_{ij} = 1$ iff x_i is aligned to s_j, otherwise $a_{ij} = 0$. $r(x_i, s_j)$ is the Pearson's correlation between x_i and s_j. QVEC-CCA (Ammar et al., 2016b) is extended from QVEC by using CCA to measure the correlation between the distributional matrix and the linguistic vector matrix, instead of cumulative dimension-wise correlation.

	W+N+L	**16.2**	66.1	**13.1**	44.8	16.1	64.7	13.8	44.9
	W+N+C+L	**16.2**	**67.3**	12.4	45.4	**16.3**	**66.7**	**14.1**	**45.2**

Table 3: QVEC and QVEC-CCA scores. W: word alignment. N: neighbor based clustering and alignment. C: character based clustering and alignment. L: linguistic property based clustering and alignment.

As shown in Table 3, our approaches outperform previous approaches in almost all cases[13]. Specifically, by augmenting word representation with neighboring words in the common semantic space as in Eq. (1), the performance for monolingual and multilingual QVEC and QVEC-CCA tasks is consistently improved. In addition, by aligning character-level compositional representations and linguistic property based clusters in the shared semantic space, the monolingual and multilingual representation quality is further improved.

4.3 Impact of Bilingual Dictionary Size

In order to show the impact of the size of bilingual lexicons, we use three languages as a case study, and gradually reduce the size of the lexicons for each pair of languages from 40,000 to 10,000 and further to 2,000, 1,000, 500 and 250. For following experiments, we use MultiCluster and MultiCCA as baselines [14]. Table 4 shows the results. We observe that both MultiCCA and CorrNet approaches are sensitive to the size of the bilingual lexicons. Our approach on the other hand can maintain high performance, even when the size of bilingual lexicons is reduced to 250. The performances of MultiCluster based on various sizes of bilingual dictionary are close because it jointly trains the embedding of multiple languages from scratch and by default takes advantage of identical strings among all the languages.

4.4 Low-Resource Name Tagging

We evaluate the quality of multilingual embeddings on a downstream task by using the embeddings as input features. Here, we use low-resource language name tagging as a target task, which aims to automatically identify and named entities from text and classify them into certain types, including Person (PER), Location (LOC), Organization (ORG), and Geo-Political Entities (GPE). We experiment with two sets of languages. The first set *Amh+Tig* consists of Amharic and Tigrinya. Both languages share the same Ge'ez script and descend from the proto-Semitic language family. The other set *Eng+Uig+Tur* consists of one high-resource language (English), one medium-resource language (Turkish) and one low-resource language (Uighur). It also consists of two distinct language scripts: English and Turkish use Latin script while Uighur uses Arabic script.

We use an LSTM-CRF architecture (Huang et al., 2015; Lample et al., 2016; Ma and Hovy, 2016) for name tagging. It takes only word embedding as input and predict a tag for each word. Table 5 shows the statistics of training, development, and test sets for each language released by Linguistic Data Consortium (LDC).[15] For each language pair, we combine the bilingual aligned words extracted from Wiktionary and monolingual dictionaries based on identical strings.[16] We evaluate the quality from several aspects:

---

[13] We conduct paired t-test between CorrNet W+N+Ch+L and all the other models on 10 randomly sampled subsets. The differences are all statistically significant while all p-values are less than 0.05

[14] MultiSkip requires parallel corpora to train cross-lingual embeddings while the original implementation of MultiCross is not public.

[15] The annotations are from: Amh (LDC2016E87), Tig (LDC2017E27), Uig (LDC2016E70), Tur (LDC2014E115), Eng (Tjong Kim Sang and De Meulder, 2003). We combined these corpora with Wikipedia dump to train word embeddings with Word2Vec toolkit (Mikolov et al., 2013a).

[16] We extracted 23,781 pairs of words for Amh and Tig, 16,868 pairs for Eng and Tur, 3,353 pairs for Eng and Uig, and 3,563 pairs for Tur and Uig.

Table 6: Comparison on Monolingual Embedding Quality: name tagging performance (F-score, %) using monolingual embedding and multilingual embeddings.

Monolingual embedding quality evaluation Table 6 shows the name tagging performance for each language using the original monolingual embeddings and multilingual embeddings. For all languages, the multilingual embeddings learned from our approach significantly outperform those learned from MultiCCA and MultiCluster, which shows the effectiveness of our approach. More importantly, the multilingual embeddings learned from our approach also outperform original monolingual embeddings, which demonstrates that by projecting multiple languages into one common space, the monolingual embedding quality can be further improved.

Cross-lingual direct transfer In this setting, we train a name tagger on one or two languages using multilingual embeddings and test it on a new language without any annotated data. Table 7 shows the performance. For most testing languages, our approach achieves better performance than MultiCCA and MultiCluster. The closer that the languages are, such as Amharic and Tigrinya, the better performance is achieved.

Cross-lingual mutual enhancement We finally show the improvement by adding more cross-lingual annotated data and also using multilingual embeddings in Table 8. The multilingual embeddings learned by our approach consistently outperforms MultiCCA and MultiCluster. Particularly, when there are not enough annotated examples, the performance could be improved by incorporating annotated examples from other languages. This is evident for Amharic, Tigrinya and Uighur. For Turkish, we notice that a larger extra anno-

Train	Test	Multi-CCA	Multi-Cluster	CorrNet W	CorrNet W+N+C+L

Eng+Tur+Uig	Uig	65.8	64.8	64.6	**68.5**
Eng+Tur	Tur	50.3	56.1	59.3	**65.5**
Uig+Tur	Tur	51.4	52.7	57.8	**62.7**
Eng+Uig+Tur	Tur	48.1	54.3	56.6	**61.5**

Table 8: Comparison on Cross-lingual Mutual Enhancement: name tagging performance (F-score, %) when the training set for the tagger was enhanced by annotated examples in other languages.

tated set from other languages (e.g., Uig+Tur or Eng+Uig+Tur) doesn't necessarily result in improvement. This is partially due to the use of Arabic script in Uighur, which differs from Turkish and English. Thus we suggest to project closely related languages using the same script into the common semantic space.

We take Turkish name tagging as a case study to show the benefit of the common semantic space with extra English annotations. The monolingual model failed to identify *Belgrad´da* as a geopolitical entity (GPE) because it doesn't occur in Turkish training data. However, by adding English annotations, the tagger successfully tags it as a GPE since it's semantically close to *Belgrade* in the common semantic space according to their character level compositional embeddings and *Belgrade* is frequently tagged as GPE in English annotations. In another example, using Turkish annotations only, *Kraliyet Donanması´na* is mistakenly tagged as a GPE since it's following *da* and all entity mentions following *da* in Turkish annotations are annotated as GPE. After adding English annotations into training, it is correctly tagged as an ORG because *da* is well aligned with *in* in the common semantic space according to the linguistic property alignment between Turkish and English, and many entity mentions following *in* are annotated as ORG in English annotations.

5 Conclusions and Future Work

We construct a common semantic space for multiple languages based on a cluster-consistent correlational neural network. It combines word-level alignment and multi-level cluster alignment, including neighbor based clusters, character-level compositional word representations, and linguistic property based clusters induced from the readily available language-universal linguistic knowledge bases. Our approach achieved significantly higher performance than state-of-the-art multilingual embedding learning methods through both intrinsic and extrinsic evaluations. In the future, we will further extend our approach to multi-lingual multimedia common semantic space construction.

Abstract

Multilingual Word Embeddings (MWEs) represent words from multiple languages in a single distributional vector space. Unsupervised MWE (UMWE) methods acquire multilingual embeddings without cross-lingual supervision, which is a significant advantage over traditional supervised approaches and opens many new possibilities for low-resource languages. Prior art for learning UMWEs, however, merely relies on a number of independently trained Unsupervised Bilingual Word Embeddings (UBWEs) to obtain multilingual embeddings. These methods fail to leverage the interdependencies that exist among many languages. To address this shortcoming, we propose a fully unsupervised framework for learning MWEs[1] that directly exploits the relations between all language pairs. Our model substantially outperforms previous approaches in the experiments on multilingual word translation and cross-lingual word similarity. In addition, our model even beats supervised approaches trained with cross-lingual resources.

1 Introduction

Continuous distributional word representations (Turian et al., 2010) have become a common technique across a wide variety of NLP tasks. Recent research, moreover, proposes cross-lingual word representations (Klementiev et al., 2012; Mikolov et al., 2013a) that create a shared embedding space for words across *two* (Bilingual Word Embeddings, BWE) or *more* languages (Multilingual Word Embeddings, MWE). Words from different languages with similar meanings will be close to one another in this cross-lingual embedding space. These embeddings have been found beneficial for a number of cross-lingual and even monolingual NLP tasks (Faruqui and Dyer, 2014; Ammar et al., 2016).

The most common form of cross-lingual word representations is the BWE, which connects the lexical semantics of two languages. Traditionally for training BWEs, cross-lingual supervision is required, either in the form of parallel corpora (Klementiev et al., 2012; Zou et al., 2013), or in the form of bilingual lexica (Mikolov et al., 2013a; Xing et al., 2015). This makes learning BWEs for low-resource language pairs much more difficult. Fortunately, there are attempts to reduce the dependence on bilingual supervision by requiring a very small parallel lexicon such as identical character strings (Smith et al., 2017), or numerals (Artetxe et al., 2017). Furthermore, recent work proposes approaches to obtain unsupervised BWEs without relying on *any* bilingual resources (Zhang et al., 2017; Lample et al., 2018b).

In contrast to BWEs that only focus on a pair of languages, MWEs instead strive to leverage the interdependencies among multiple languages to learn a multilingual embedding space. MWEs are desirable when dealing with multiple languages simultaneously and have also been shown to improve the performance on some bilingual tasks thanks to its ability to acquire knowledge from other languages (Ammar et al., 2016; Duong et al., 2017). Similar to training BWEs, cross-lingual supervision is typically needed for training MWEs, and the prior art for obtaining *fully unsupervised* MWEs simply maps all the languages independently to the embedding space of a chosen target language[2] (usually English) (Lample et al., 2018b). There are downsides, however, when using a single fixed target language with no interaction between any of the two source languages. For instance, French and Italian are very similar, and the fact that each of them is individually converted to a less similar language, English for example, in

---

[2] Henceforth, we refer to this method as BWE-Pivot as the target language serves as a pivot to connect other languages.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 261–270
Brussels, Belgium, October 31 - November 4, 2018.

order to produce a shared embedding space will inevitably degrade the quality of the MWEs.

For certain multilingual tasks such as translating between any pair of N given languages, another option for obtaining UMWEs exists. One can directly train UBWEs for each of such language pairs (referred to as BWE-Direct). This is seldom used in practice, since it requires training $O(N^2)$ BWE models as opposed to only $O(N)$ in BWE-Pivot, and is too expensive for most use cases. Moreover, this method still does not fully exploit the language interdependence. For example, when learning embeddings between French and Italian, BWE-Direct only utilizes information from the pair itself, but other Romance languages such as Spanish may also provide valuable information that could improve performance.

In this work, we propose a novel unsupervised algorithm to train MWEs using *only* monolingual corpora (or equivalently, monolingual word embeddings). Our method exploits the interdependencies between any two languages and maps all monolingual embeddings into a shared multilingual embedding space via a two-stage algorithm consisting of (i) Multilingual Adversarial Training (`MAT`) and (ii) Multilingual Pseudo-Supervised Refinement (`MPSR`). As shown by experimental results on multilingual word translation and cross-lingual word similarity, our model is as efficient as BWE-Pivot yet outperforms both BWE-Pivot and BWE-Direct despite the latter being much more expensive. In addition, our model achieves a higher overall performance than state-of-the-art *supervised* methods in these experiments.

2 Related Work

There is a plethora of literature on learning cross-lingual word representations, focusing either on a pair of languages, or multiple languages at the same time (Klementiev et al., 2012; Zou et al., 2013; Mikolov et al., 2013a; Gouws et al., 2015; Coulmance et al., 2015; Ammar et al., 2016; Duong et al., 2017, *inter alia*). One shortcoming of these methods is the dependence on cross-lingual supervision such as parallel corpora or bilingual lexica. Abundant research efforts have been made to alleviate such dependence (Vulić and Moens, 2015; Artetxe et al., 2017; Smith et al., 2017), but consider only the case of a single pair of languages (BWEs). Furthermore, fully unsupervised methods exist for learning BWEs (Zhang et al., 2017; Lample et al., 2018b; Artetxe et al., 2018a). For unsupervised MWEs, however, previous methods merely rely on a number of independent BWEs to separately map each language into the embedding space of a chosen target language (Smith et al., 2017; Lample et al., 2018b).

Adversarial Neural Networks have been successfully applied to various cross-lingual NLP tasks where annotated data is not available, such as cross-lingual text classification (Chen et al., 2016), unsupervised BWE induction (Zhang et al., 2017; Lample et al., 2018b) and unsupervised machine translation (Lample et al., 2018a; Artetxe et al., 2018b). These works, however, only consider the case of two languages, and our `MAT` method (§3.1) is a generalization to multiple languages.

Mikolov et al. (2013a) first propose to learn cross-lingual word representations by learning a linear mapping between the monolingual embedding spaces of a pair of languages. It has then been observed that enforcing the linear mapping to be orthogonal could significantly improve performance (Xing et al., 2015; Artetxe et al., 2016; Smith et al., 2017). These methods solve a linear equation called the orthogonal Procrustes problem for the optimal orthogonal linear mapping between two languages, given a set of word pairs as supervision. Artetxe et al. (2017) find that when using weak supervision (e.g. digits in both languages), applying this Procrustes process iteratively achieves higher performance. Lample et al. (2018b) adopt the iterative Procrustes method with pseudo-supervision in a fully unsupervised setting and also obtain good results. In the MWE task, however, the multilingual mappings no longer have a closed-form solution, and we hence propose the `MPSR` algorithm (§3.2) for learning multilingual embeddings using gradient-based optimization methods.

3 Model

In this work, our goal is to learn a single multilingual embedding space for N languages, without relying on *any* cross-lingual supervision. We assume that we have access to monolingual embeddings for each of the N languages, which can be obtained using unlabeled monolingual corpora (Mikolov et al., 2013b; Bojanowski et al., 2017). We now present our unsupervised MWE (UMWE) model that jointly maps the monolingual embeddings of all N languages into a single space by explicitly leveraging the interdependencies between arbitrary language pairs, but is computationally as efficient as learning $O(N)$ BWEs (instead of $O(N^2)$).

Denote the set of languages as $\mathscr{L}$ with $|\mathscr{L}| = N$. Suppose for each language $l \in \mathscr{L}$ with vocabulary $\mathcal{V}_l$, we have a set of d-dimensional monolingual word embeddings $\mathcal{E}_l$ of size $|\mathcal{V}_l| \times d$. Let $\mathcal{S}_l$ denote the monolingual embedding space for l, namely the distribution of the monolingual embeddings of l. If a set of embeddings $\mathcal{E}$ are in an embedding space $\mathcal{S}$, we write $\mathcal{E} \vdash \mathcal{S}$ (e.g. $\forall l : \mathcal{E}_l \vdash \mathcal{S}_l$). Our models learns a set of encoders $\mathcal{M}_l$, one for each language l, and the corresponding decoders $\mathcal{M}_l^{-1}$. The encoders map all $\mathcal{E}_l$ to a single target space $\mathcal{T}$: $\mathcal{M}_l(\mathcal{E}_l) \vdash \mathcal{T}$. On the other hand, a decoder $\mathcal{M}_l^{-1}$ maps an embedding in $\mathcal{T}$ back to $\mathcal{S}_l$.

Previous research (Mikolov et al., 2013a) shows that there is a strong linear correlation between the vector spaces of two languages, and that learning a complex non-linear neural mapping does not yield better results. Xing et al. (2015) further show that enforcing the linear mappings to be orthogonal matrices achieves higher performance. Therefore, we let our encoders $\mathcal{M}_l$ be orthogonal linear matrices, and the corresponding decoders can be obtained by simply taking the transpose: $\mathcal{M}_l^{-1} = \mathcal{M}_l^{\top}$. Thus, applying the encoder or decoder to an embedding vector is accomplished by multiplying the vector with the encoder/decoder matrix.

Another benefit of using linear encoders and decoders (also referred to as *mappings*) is that we can learn $N - 1$ mappings instead of N by choosing the target space $\mathcal{T}$ to be the embedding space of a specific language (denoted as the *target language*) without losing any expressiveness of the model. Given a MWE with an arbitrary $\mathcal{T}$, we can construct an equivalent one with only $N-1$ mappings by multiplying the encoders of each language $\mathcal{M}_l$ to the decoder of the chosen target language $\mathcal{M}_t^{\top}$:

$$\mathcal{M}_t' = \mathcal{M}_t^{\top}\mathcal{M}_t = I$$
$$\mathcal{M}_l'\mathcal{E}_l = (\mathcal{M}_t^{\top}\mathcal{M}_l)\mathcal{E}_l \vdash \mathcal{S}_t$$

where I is the identity matrix. The new MWE is isomorphic to the original one.

We now present the two major components of our approach, Multilingual Adversarial Training (§3.1) and Multilingual Pseudo-Supervised Refinement (§3.2).

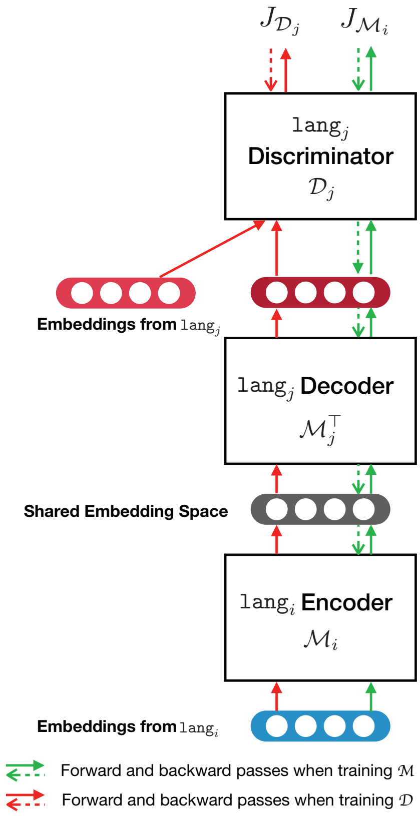

Figure 1: Multilingual Adversarial Training (Algorithm 1). `lang`$_i$ and `lang`$_j$ are two randomly selected languages at each training step. $J_{\mathcal{D}_j}$ and $J_{\mathcal{M}_i}$ are the objectives of $\mathcal{D}_j$ and $\mathcal{M}_i$, respectively (Eqn. 1 and 2).

3.1 Multilingual Adversarial Training

In this section, we introduce an adversarial training approach for learning multilingual embeddings without cross-lingual supervision. Adversarial Training is a powerful technique for minimizing the divergence between complex distributions that are otherwise difficult to directly model (Goodfellow et al., 2014). In the cross-lingual setting, it has been successfully applied to unsupervised cross-lingual text classification (Chen et al., 2016) and unsupervised bilingual word embedding learning (Zhang et al., 2017; Lample et al., 2018b). However, these methods only consider one pair of languages at a time, and do not fully exploit the cross-lingual relations in the multilingual setting.

Figure 1 shows our Multilingual Adversarial Training (`MAT`) model and the training procedure is described in Algorithm 1. Note that as explained in §3, the encoders and decoders adopted in practice are orthogonal linear mappings while the shared embedding space is chosen to be the same space as a selected target language.

22:         $\hat{y}_j = \mathcal{D}_j(\hat{x}_j)$
23:         loss += $L_d(1, \hat{y}_j)$
24:     Update all $\mathcal{M}$ parameters to minimize loss
25:     orthogonalize($\mathcal{M}$)                      ▷ see §3.3
26: until convergence
```

In order to learn a multilingual embedding space without supervision, we employ a series of *language discriminators* $\mathcal{D}_l$, one for each language $l \in \mathscr{L}$. Each $\mathcal{D}_l$ is a binary classifier with a sigmoid layer on top, and is trained to identify how likely a given vector is from $\mathcal{S}_l$, the embedding space of language l. On the other hand, to train the mappings, we convert a vector from a random language `lang`$_i$ to another random language `lang`$_j$ (via the target space $\mathcal{T}$ first). The objective of the mappings is to confuse $\mathcal{D}_j$, the language discriminator for `lang`$_j$, so the mappings are updated in a way that $\mathcal{D}_j$ cannot differentiate the converted vectors from the real vectors in $\mathcal{S}_j$. This multilingual objective enables us to explicitly exploit the relations between all language pairs during training, leading to improved performance.

Formally, for any language `lang`$_j$, the objective that $\mathcal{D}_j$ is minimizing is:

$$J_{\mathcal{D}_j} = \mathop{\mathbb{E}}_{i\sim\mathscr{L}} \mathop{\mathbb{E}}_{\substack{x_i\sim\mathcal{S}_i\\ x_j\sim\mathcal{S}_j}} \Big[\!\Big[L_d\left(1, \mathcal{D}_j(x_j)\right) + L_d\left(0, \mathcal{D}_j(\mathcal{M}_j^\top \mathcal{M}_i x_i)\right)\Big]\!\Big] \tag{1}$$

where $L_d(y, \hat{y})$ is the loss function of $\mathcal{D}$, which is chosen as the *cross entropy loss* in practice. y is the language label with $y = 1$ indicates a real embedding from that language.

Furthermore, the objective of $\mathcal{M}_i$ for `lang`$_i$ is:

$$J_{\mathcal{M}_i} = \mathop{\mathbb{E}}_{j\sim\mathscr{L}} \mathop{\mathbb{E}}_{\substack{x_i\sim\mathcal{S}_i\\ x_j\sim\mathcal{S}_j}} L_d\left(1, \mathcal{D}_j(\mathcal{M}_j^\top \mathcal{M}_i x_i)\right) \tag{2}$$

where $\mathcal{M}_i$ strives to make $\mathcal{D}_j$ believe that a converted vector to `lang`$_j$ is instead real. This adversarial relation between $\mathcal{M}$ and $\mathcal{D}$ stimulates $\mathcal{M}$ to learn a shared multilingual embedding space by making the converted vectors look as authentic as possible so that $\mathcal{D}$ cannot predict whether a vector is a genuine embedding from a certain language or converted from another language via $\mathcal{M}$.

In addition, we allow `lang`$_i$ and `lang`$_j$ to be the same language in (1) and (2). In this case, we are encoding a language to $\mathcal{T}$ and back to itself, essentially forming an adversarial autoencoder (Makhzani et al., 2015), which is reported to improve the model performance (Zhang et al., 2017). Finally, on Line 5 and 17 in Algorithm 1, a for loop is used instead of random sampling. This is to ensure that in each step, every discriminator (or mapping) is getting updated at least once, so that we do not need to increase the number of training iterations when adding more languages. Computationally, when compared to the BWE-Pivot and BWE-Direct baselines, one step of `MAT` training costs similarly to N BWE training steps, and in practice we train `MAT` for the same number of iterations as training the baselines. Therefore, `MAT` training scales linearly with the number of languages similar to BWE-Pivot (instead of quadratically as in BWE-Direct).

3.2 Multilingual Pseudo-Supervised Refinement

Using `MAT`, we are able to obtain UMWEs with reasonable quality, but they do not yet achieve state-of-the-art performance. Previous research on learning unsupervised BWEs (Lample et al., 2018b) observes that the embeddings obtained from adversarial training do a good job aligning the frequent words between two languages, but performance degrades when considering the full vocabulary. They hence propose to use an iterative refinement method (Artetxe et al., 2017) to repeatedly refine the embeddings obtained from the adversarial training. The idea is that we can anchor on the more accurately predicted relations between frequent words to improve the mappings learned by adversarial training.

Algorithm 2 Multilingual Pseudo-Supervised Refinement

```
Require: A set of (pseudo-)supervised lexica of word pairs
    between each pair of languages $\texttt{Lex}(\texttt{lang}_i, \texttt{lang}_j)$.
repeat
    $\texttt{loss} = 0$
    for all $\texttt{lang}_i \in \mathscr{L}$ do
        Select at random $\texttt{lang}_j \in \mathscr{L}$
        Sample $(x_i, x_j) \sim \texttt{Lex}(\texttt{lang}_i, \texttt{lang}_j)$
        $t_i = \mathcal{M}_i(x_i)$                          ▷ encode $x_i$
        $t_j = \mathcal{M}_j(x_j)$                          ▷ encode $x_j$
        $\texttt{loss} \mathrel{+}= L_r(t_i, t_j)$          ▷ refinement loss
    Update all $\mathcal{M}$ parameters to minimize $\texttt{loss}$
    $\texttt{orthogonalize}(\mathcal{M})$                   ▷ see §3.3
until convergence
```

When learning MWEs, however, it is desirable to go beyond aligning each language with the target space individually, and instead utilize the relations between all languages as we did in `MAT`. Therefore, we in this section propose a generalization of the existing refinement methods to incorporate a multilingual objective.

In particular, `MAT` can produce an approximately aligned embedding space. As mentioned earlier, however, the training signals from $\mathcal{D}$ for rare words are noisier and may lead to worse performance. Thus, the idea of Multilingual Pseudo-Supervised Refinement (`MPSR`) is to induce a dictionary of highly confident word pairs for every language pair, used as pseudo supervision to improve the embeddings learned by `MAT`. For a specific language pair $(\texttt{lang}_i, \texttt{lang}_j)$, the pseudo-supervised lexicon $\texttt{Lex}(\texttt{lang}_i, \texttt{lang}_j)$ is constructed from *mutual nearest neighbors* between $\mathcal{M}_i\mathcal{E}_i$ and $\mathcal{M}_j\mathcal{E}_j$, among the most frequent $15k$ words of both languages.

With the constructed lexica, the `MPSR` objective is:

$$J_r = \mathop{\mathbb{E}}_{(i,j)\sim\mathscr{L}^2} \; \mathop{\mathbb{E}}_{(x_i,x_j)\sim\texttt{Lex}(i,j)} L_r(\mathcal{M}_i x_i, \mathcal{M}_j x_j) \tag{3}$$

where $L_r(x, \hat{x})$ is the loss function for `MPSR`, for which we use the *mean square loss*. The `MPSR` training is depicted in Algorithm 2.

Cross-Lingual Similarity Scaling (CSLS) When constructing the pseudo-supervised lexica, a distance metric between embeddings is needed to compute nearest neighbors. Standard distance metrics such as the Euclidean distance or cosine similarity, however, can lead to the *hubness* problem in high-dimensional spaces when used to calculate nearest neighbors (Radovanović et al., 2010; Dinu and Baroni, 2015). Namely, some words are very likely to be the nearest neighbors of many others (hubs), while others are not the nearest neighbor of any word. This problem is addressed in the literature by designing alternative distance metrics, such as the inverted softmax (Smith et al., 2017) or the CSLS (Lample et al., 2018b). In this work, we adopt the CSLS similarity as a drop-in replacement for cosine similarity whenever a distance metric is needed. The CSLS similarity (whose negation is a distance metric) is calculated as follows:

$$\begin{aligned} \mathrm{CSLS}(x, y) = {} & 2\cos(x, y) \\ & - \frac{1}{n} \sum_{y' \in N_Y(x)} \cos(x, y') \\ & - \frac{1}{n} \sum_{x' \in N_X(y)} \cos(x', y) \end{aligned} \tag{4}$$

where $N_Y(x)$ is the set of n nearest neighbors of x in the vector space that y comes from: $Y = \{y_1, ..., y_{|Y|}\}$, and vice versa for $N_X(y)$. In practice, we use $n = 10$.

3.3 Orthogonalization

As mentioned in §3, orthogonal linear mappings are the preferred choice when learning transformations between the embedding spaces of different languages (Xing et al., 2015; Smith et al., 2017). Therefore, we perform an orthogonalization update (Cisse et al., 2017) after each training step to ensure that our mappings $\mathcal{M}$ are (approximately) orthogonal:

$$\forall l : \mathcal{M}_l = (1 + \beta)\mathcal{M}_l - \beta \mathcal{M}_l \mathcal{M}_l^\top \mathcal{M}_l$$

where β is set to 0.001.

3.4 Unsupervised Multilingual Validation

In order to do model selection in the unsupervised setting, where no validation set can be used, a surrogate validation criterion is required that does not depend on bilingual data. Previous work shows promising results using such surrogate criteria for model validation in the bilingual case (Lample et al., 2018b), and we in this work adopt a variant adapted to our multilingual setting:

$$\begin{aligned} V(\mathcal{M}, \mathcal{E}) &= \mathop{\mathbb{E}}_{(i,j)\sim P_{ij}} \texttt{mean\_csls}(\mathcal{M}_j^\top \mathcal{M}_i \mathcal{E}_i, \mathcal{E}_j) \\ &= \sum_{i \neq j} p_{ij} \cdot \texttt{mean\_csls}(\mathcal{M}_j^\top \mathcal{M}_i \mathcal{E}_i, \mathcal{E}_j) \end{aligned}$$

where p_{ij} forms a probability simplex. In this work, we let all $p_{ij} = \frac{1}{N(N-1)}$ so that $V(\mathcal{M}, \mathcal{E})$ reduces to the macro average over all language pairs. Using different p_{ij} values can place varying weights on different language pairs, which might be desirable in certain scenarios.

The `mean_csls` function is an unsupervised bilingual validation criterion proposed by Lample et al. (2018b), which is the mean CSLS similarities between the most frequent $10k$ words and their translations (nearest neighbors).

4 Experiments

In this section, we present experimental results to demonstrate the effectiveness of our unsupervised MWE method on two benchmark tasks, the multilingual word translation task, and the SemEval-2017 cross-lingual word similarity task. We compare our `MAT+MPSR` method with state-of-the-art unsupervised and supervised approaches, and show that ours outperforms previous methods, supervised or not, on both tasks.

Pre-trained $300d$ fastText (monolingual) embeddings (Bojanowski et al., 2017) trained on the Wikipedia corpus are used for all systems that require monolingual word embeddings for learning cross-lingual embeddings.

4.1 Multilingual Word Translation

In this section, we consider the task of word translation between arbitrary pairs of a set of N languages. To this end, we use the recently released multilingual word translation dataset on six languages: English, French, German, Italian, Portuguese and Spanish (Lample et al., 2018b). For any pair of the six languages, a ground-truth bilingual dictionary is provided with a train-test split of 5000 and 1500 unique source words, respectively. The $5k$ training pairs are used in training supervised baseline methods, while all unsupervised methods do not rely on any cross-lingual resources. All systems are tested on the 1500 test word pairs for each pair of languages.

For comparison, we adopted a state-of-the-art unsupervised BWE method (Lample et al., 2018b) and generalize it for the multilingual setting using the two aforementioned approaches, namely BWE-Pivot and BWE-Direct, to produce unsupervised baseline MWE systems. English is chosen as the pivot language in BWE-Pivot. We further incorporate the supervised BWE-Direct (Sup-BWE-Direct) method as a baseline, where each BWE is trained on the $5k$ gold-standard word pairs via the orthogonal Procrustes process (Artetxe et al., 2017; Lample et al., 2018b).

Table 1 presents the evaluation results, wherein the numbers represent *precision@1*, namely how many times one of the correct translations of a source word is retrieved as the top candidate. All systems retrieve word translations using the CSLS similarity in the learned embedding space. Table 1a shows the detailed results for all 30 language pairs, while Table 1b summarizes the results in a number of ways. We first observe the training cost of all systems summarized in Table 1b. #BWEs indicates the training cost of a certain method measured by how many BWE models it is equivalent to train. BWE-Pivot needs to train $2(N-1)$ BWEs since a separate BWE is trained for each direction in a language pair for increased performance. BWE-Direct on the other hand, trains an individual BWE for all (again, directed) pairs, resulting a total of $N(N-1)$ BWEs. The supervised Sup-BWE-Direct method trains the same number of BWEs as BWE-Direct but is much faster in practice, for it does not require the unsupervised adversarial training stage. Finally, while our `MAT+MPSR` method does not train independent BWEs, as argued in §3.1, the training cost is roughly equivalent to training $N-1$ BWEs, which is corroborated by the real training time shown in Table 1b.

We can see in Table 1a that our `MAT+MPSR` method achieves the highest performance on all but 3 language pairs, compared against both the unsupervised and supervised approaches. When looking at the overall performance across all language pairs, BWE-Direct achieves a $+0.6\%$ performance gain over BWE-Pivot at the cost of being much slower to train. When supervision is available, Sup-BWE-Direct further improves another 0.4% over BWE-Direct. Our `MAT+MPSR` method, however, attains an impressive 1.3% improvement against Sup-BWE-Direct, despite the lack of cross-lingual supervision.

To provide a more in-depth examination of the results, we first consider the Romance language pairs, such as fr-es, fr-it, fr-pt, es-it, it-pt and their reverse directions. BWE-Pivot performs notably worse than BWE-Direct on these pairs, which validates our hypothesis that going through a less similar language (English) when translating between

(b) Summarized Results

Table 1: Multilingual Word Translation Results for English, German, French, Spanish, Italian and Portuguese. The reported numbers are *precision@1* in percentage. All systems use the nearest neighbor under the CSLS distance for predicting the translation of a certain word.

similar languages will result in reduced accuracy. Our `MAT+MPSR` method, however, overcomes this disadvantage of BWE-Pivot and achieves the best performance on all these pairs through an explicit multilingual learning mechanism without increasing the computational cost.

Furthermore, our method also beats the BWE-Direct approach, which supports our second hypothesis that utilizing knowledge from languages beyond the pair itself could improve performance. For instance, there are a few pairs where BWE-Pivot outperforms BWE-Direct, such as de-it, it-de and pt-de, even though it goes through a third language (English) in BWE-Pivot. This might suggest that for some less similar language pairs, leveraging a third language as a bridge could in some cases work better than only relying on the language pair itself. German is involved in all these language pairs where BWE-Pivot outperforms than BWE-Direct, which is potentially due to the similarity between German and the pivot language English. We speculate that if choosing a different pivot language, there might be other pairs that could benefit. This observation serves as a possible explanation of the superior performance of our multilingual method over BWE-Direct, since our method utilizes knowledge from all languages during training.

4.2 Cross-Lingual Word Similarity

In this section, we evaluate the quality of our MWEs on the cross-lingual word similarity (CLWS) task, which assesses how well the similarity in the cross-lingual embedding space corresponds to a human-annotated semantic similarity score. The high-quality CLWS dataset from SemEval-2017 (Camacho-Collados et al., 2017) is

Table 2: Results for the SemEval-2017 Cross-Lingual Word Similarity task. Spearman's ρ is reported. Luminoso (Speer and Lowry-Duda, 2017) and NASARI (Camacho-Collados et al., 2016) are the two top-performing systems for SemEval-2017 that reported results on all language pairs.

used for evaluation. The dataset contains word pairs from any two of the five languages: English, German, Spanish, Italian, and Farsi (Persian), annotated with semantic similarity scores.

In addition to the BWE-Pivot and BWE-Direct baseline methods, we also include the two best-performing systems on SemEval-2017, Luminoso (Speer and Lowry-Duda, 2017) and NASARI (Camacho-Collados et al., 2016) for comparison. Note that these two methods are supervised, and have access to the Europarl[3] (for all languages but Farsi) and the OpenSubtitles2016[4] parallel corpora.

Table 2 shows the results, where the performance of each model is measured by the Spearman correlation. When compared to the BWE-Pivot and the BWE-Direct baselines, `MAT+MPSR` continues to perform the best on all language pairs. The qualitative findings stay the same as in the word translation task, except the margin is less significant. This might be because the CLWS task is much more lenient compared to the word translation task, where in the latter one needs to correctly identify the translation of a word out of hundreds of thousands of words in the vocabulary. In CLWS though, one can still achieve relatively high correlation in spite of minor inaccuracies.

On the other hand, an encouraging result is that when compared to the state-of-the-art supervised results, our `MAT+MPSR` method outperforms NASARI by a very large margin, and achieves top-notch overall performance similar to the competition winner, Luminoso, without using any bitexts. A closer examination reveals that our unsupervised method lags a few points behind Luminoso on the European languages wherein the supervised methods have access to the large-scale high-quality Europarl parallel corpora. It is the low-resource language, Farsi, that makes our unsupervised method stand out. All of the unsupervised methods outperform the supervised systems from SemEval-2017 on language pairs involving Farsi, which is not covered by the Europarl bitexts. This suggests the advantage of learning unsupervised embeddings for lower-resourced languages, where the supervision might be noisy or absent. Furthermore, within the unsupervised methods, `MAT+MPSR` again performs the best, and attains a higher margin over the baseline approaches on the low-resource language pairs, vindicating our claim of better multilingual performance.

5 Conclusion

In this work, we propose a fully unsupervised model for learning multilingual word embeddings (MWEs). Although methods exist for learning high-quality unsupervised BWEs (Lample et al., 2018b), little work has been done in the unsupervised multilingual setting. Previous work relies solely on a number of unsupervised BWE models to generate MWEs (e.g. BWE-Pivot and BWE-Direct), which does not fully leverage the interdependencies among all the languages. Therefore, we propose the `MAT+MPSR` method that explicitly exploits the relations between all language pairs without increasing the computational cost. In our experiments on multilingual word translation and cross-lingual word similarity (SemEval-2017), we show that `MAT+MPSR` outperforms existing unsupervised and even supervised models, achieving new state-of-the-art performance.

For future work, we plan to investigate how our

---

[4] `http://opus.nlpl.eu/OpenSubtitles2016.php`

method can be extended to work with other BWE frameworks, in order to overcome the instability issue of Lample et al. (2018b). As pointed out by recent work (Søgaard et al., 2018; Artetxe et al., 2018a), the method by Lample et al. (2018b) performs much worse on certain languages such as Finnish, etc. More reliable multilingual embeddings might be obtained on these languages if we adapt our multilingual training framework to work with the more robust methods proposed recently.

Abstract

This paper proposes a modularized sense induction and representation learning model that jointly learns bilingual sense embeddings that align well in the vector space, where the cross-lingual signal in the English-Chinese parallel corpus is exploited to capture the collocation and distributed characteristics in the language pair. The model is evaluated on the Stanford Contextual Word Similarity (SCWS) dataset to ensure the quality of monolingual sense embeddings. In addition, we introduce Bilingual Contextual Word Similarity (BCWS), a large and high-quality dataset for evaluating cross-lingual sense embeddings, which is the first attempt of measuring whether the learned embeddings are indeed aligned well in the vector space. The proposed approach shows the superior quality of sense embeddings evaluated in both monolingual and bilingual spaces.[1]

1 Introduction

Word embeddings have recently become the basic component in most NLP tasks for its ability to capture semantic and distributed relationships learned in an unsupervised manner. The higher similarity between word vectors can indicate similar meanings of words. Therefore, embeddings that encode semantics have been shown to serve as the good initialization and benefit several NLP tasks. However, word embeddings do not allow a word to have different meanings in different contexts, which is a phenomenon known as polysemy. For example, "*apple*" may have different meanings in *fruit* and *technology* contexts. Several attempts have been proposed to tackle this problem by inferring multi-sense word representations (Reisinger and Mooney, 2010; Neelakantan et al., 2014; Li and Jurafsky, 2015; Lee and Chen, 2017).

These approaches relied on the "one-sense per collocation" heuristic (Yarowsky, 1993), which assumes that presence of nearby words correlates with the sense of the word of interest. However, this heuristic provides only a weak signal for discriminating sense identities, and it requires a large amount of training data to achieve competitive performance.

Considering that different senses of a word may be translated into different words in a foreign language, Guo et al. (2014) and Šuster et al. (2016) proposed to learn multi-sense embeddings using this additional signal. For example, "*bank*" in English can be translated into *banc* or *banque* in French, depending on whether the sense is financial or geographical. Such information allows the model to identify which sense a word belongs to. However, the drawback of these models is that the trained foreign language embeddings are not aligned well with the original embeddings in the vector space.

This paper addresses these limitations by proposing a bilingual modularized sense induction and representation learning system. Our learning framework is the first pure sense representation learning approach that allows us to utilize two different languages to disambiguate words in English. To fully use the linguistic signals provided by bilingual language pairs, it is necessary to ensure that the embeddings of each foreign language are related to each other (i.e., they align well in the vector space). We solve this by proposing an algorithm that jointly learns sense representations between languages. The contributions of this paper are four-fold:

- We propose the first system that maintains purely sense-level cross-lingual representation learning with linear-time sense decoding.
- We are among the first to propose a single ob-

Brussels, Belgium, October 31 - November 4, 2018.

jective for modularized bilingual sense embedding learning.
- We are the first to introduce a high-quality dataset for directly evaluating bilingual sense embeddings.
- Our experimental results show the state-of-the-art performance for both monolingual and bilingual contextual word similarities.

2 Related Work

There are a lot of prior works focusing on representation learning, while this work mainly focuses on bridging the work about sense embeddings and cross-lingual embeddings and introducing a newly collected bilingual data for better evaluation.

Sense Embeddings Reisinger and Mooney (2010) first proposed multi-prototype embeddings to address the lexical ambiguity when using a single embedding to represent multiple meanings of a word. Huang et al. (2012); Neelakantan et al. (2014); Li and Jurafsky (2015); Bartunov et al. (2016) utilized neural networks as well as the Bayesian non-parametric method to learn sense embeddings. Lee and Chen (2017) first utilized a reinforcement learning approach and proposed a modularized framework that separates learning of senses from that of words. However, none of them leverages the bilingual signal, which may be helpful for disambiguating senses.

Cross-Lingual Word Embeddings Klementiev et al. (2012) first pointed out the importance of learning cross-lingual word embeddings in the same space and proposed the cross-lingual document classification (CLDC) dataset for extrinsic evaluation. Gouws et al. (2015) trained directly on monolingual data and extracted a bilingual signal from a smaller set of parallel data. Kočiskỳ et al. (2014) used a probabilistic model that simultaneously learns alignments and distributed representations for bilingual data by marginalizing over word alignments. Hermann and Blunsom (2014) learned word embeddings by minimizing the distances between compositional representations between parallel sentence pairs. Šuster et al. (2016) reconstructed the bag-of-words representation of semantic equivalent sentence pairs to learn word embeddings. Shi et al. (2015) proposed a training algorithm in the form of matrix decomposition, and induced cross-lingual constraints for simultaneously factorizing monolingual matrices. Luong et al. (2015) extended the skip-gram model to bilingual corpora where contexts of bilingual word pairs were jointly predicted. Wei and Deng (2017) proposed a variational autoencoding approach that explicitly models the underlying semantics of the parallel sentence pairs and guided the generation of the sentence pairs. Although the above approaches aimed to learn cross-lingual embeddings jointly, they fused different meanings of a word in one embedding, leading to lexical ambiguity in the vector space model.

Cross-Lingual Sense Embeddings Guo et al. (2014) adopted the heuristics where different meanings of a polysemous word usually can be represented by different words in another language and clustered bilingual word embeddings to induce senses. Šuster et al. (2016) proposed an encoder, which uses parallel corpora to choose a sense for a given word, and a decoder that predicts context words based on the chosen sense. Bansal et al. (2012) proposed an unsupervised method for clustering the translations of a word, such that the translations in each cluster share a common semantic sense. Upadhyay et al. (2017) leveraged cross-lingual signals in more than two languages. However, they either used pretrained embeddings or learned only for the English side, which is undesirable since cross-lingual embeddings shall be jointly learned such that they aligned well in the embedding space.

Evaluation Datasets Several datasets can be used to justify the performance of learned sense embeddings. Huang et al. (2012) presented SCWS, the first and only dataset that contains word pairs and their sentential contexts for measuring the quality of sense embeddings. However, it is a monolingual dataset constructed in English, so it cannot evaluate cross-lingual semantic word similarity. On the other hand, while Camacho-Collados et al. (2017) proposed a cross-lingual semantic similarity dataset, it ignored the contextual words but kept only word pairs, making it impossible to judge sense-level similarity. In this paper, we present an English-Chinese contextual word similarity dataset in order to benchmark the experiments about bilingual sense embeddings.

3 CLUSE: Cross-Lingual Unsupervised Sense Embeddings

Our proposed model borrows the idea about modularization from Lee and Chen (2017), which treats the sense induction and representation mod-

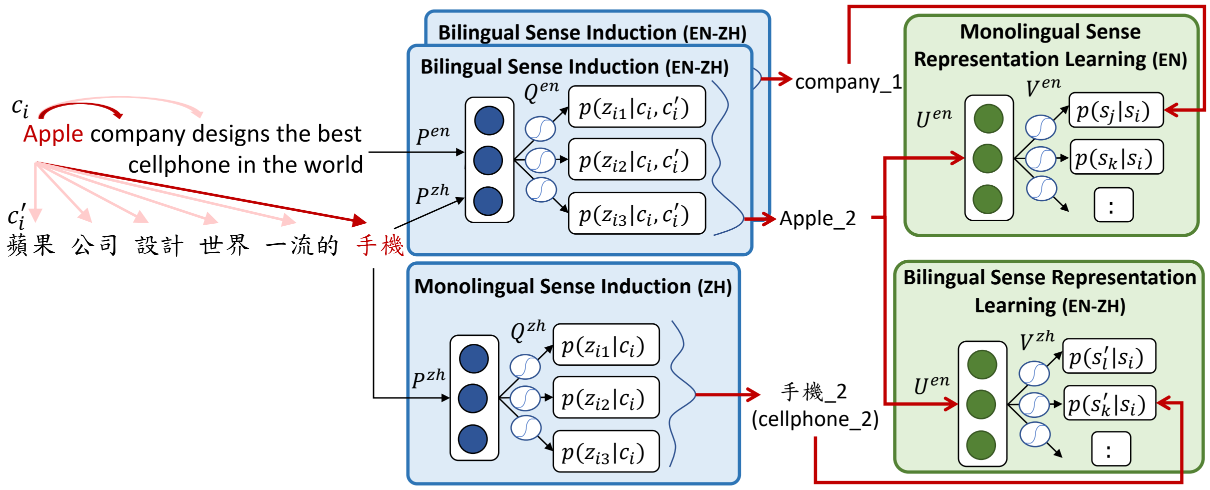

Figure 1: Sense induction modules decide the senses of words, and two sense representation learning modules optimize the sense collocated likelihood for learning sense embeddings within a language and between two languages. Two languages are treated equally and optimized iteratively.

ules separately to avoid mixing word-level and sense-level embeddings together.

Our model consists of four different modules illustrated in Figure 1, where sense induction modules decide the senses of words, and two sense representation learning modules optimize the sense collocated likelihood for learning sense embeddings within a language and between two languages in a joint manner. All modules are detailed below.

3.1 Notations

We denote our parallel corpus without word alignment C, where C^{en} is for the English part and C^{zh} is for the Chinese part. Our English vocabulary is W^{en} and Chinese vocabulary is W^{zh}. Moreover, C^{en}_t and C^{zh}_t are the t-th sentence-level parallel sentences in English and Chinese respectively. In the following sections, we treat English as the major language and Chinese as an additional bilingual signal, while their roles can be mutually exchanged. Specifically, English and Chinese iteratively become the major language during the training procedure.

3.2 Bilingual Sense Induction Module

The bilingual sense induction module takes a parallel sentence pair as input and determines which sense identity a target word belongs to given the bilingual contextual information. Formally, for the t-th English sentence C^{en}_t, we aim to decode the most probable sense $z_{ik} \in Z_i$ for the i-th word $w_i \in W^{en}$ in C^{en}_t, where Z_i is the set of sense candidates for w_i and $1 \le k \le |Z_i|$. We assume that the meaning of w_i can be determined by its surrounding words, or the so-called local context, $c_i = \{w_{i-m}, \cdots, w_{i+m}\}$, where m is the size of context window.

Aside from monolingual information, it is desirable to exploit the parallel sentences as additional bilingual contexts to enable cross-lingual embedding learning. Note that word alignment is not required in this work, so we consider the whole parallel bilingual sentence during training. Considering training efficiency, we sample M words in the parallel bilingual sentence with their original relative order or pad it to M for those shorter than M. Formally, given the t-th parallel bilingual sentence C^{zh}_t, the bilingual context of w_i is therefore $c'_i = \{w'_0, \cdots, w'_{M-1}\}$ and $w' \in W^{zh}$.

To ensure efficiency, continuous bag-of-words (CBOW) model is applied, where it takes word-level input tokens and outputs sense-level identities. Specifically, given an English *word* embedding matrix P^{en}, the local context can be modeled as the average of word embeddings from its context, $\frac{1}{|c_i|}\sum_{w_j \in c_i} P^{en}_j$. Similarly, we can model the bilingual contextual information given Chinese word embedding matrix P^{zh} using the CBOW formulation and obtain $\frac{1}{M}\sum_{w'_j \in c'_i} P^{zh}_j$. We linearly combine the contextual information from different languages as:

$$\bar{C} = \alpha \cdot \frac{1}{|c_i|} \sum_{w_j \in c_i} P^{en}_j + (1-\alpha) \cdot \frac{1}{M} \sum_{w'_j \in c'_i} P^{zh}_j. \tag{1}$$

The likelihood of selecting each sense identity z_{ik} for w_i can be formulated in the form of *Bernoulli* distribution with a sigmoid function $\sigma(\cdot)$:

$$p(z_{ik} \mid c_i, c'_i) = \sigma((Q^{en}_{ik})^T \bar{C}), \qquad (2)$$

where Q^{en} is a 3-dimensional tensor with each dimension denotes W^{en}, z_{ik} for a specific word i in W^{en}, and the corresponding latent variable, respectively. Therefore, Q^{en}_{ik} will retrieve the latent variable of k-th sense of i-th English word. Finally, we can induce the sense identity, z^*_{ik}, given the contexts of a word w_i from different languages, c_i and c'_i.

$$z^*_{ik} = \arg\max_{z_{ik}} p(z_{ik} \mid c_i, c'_i) \qquad (3)$$

In order to allow the module to explore other potential sense identities, we apply an ϵ-greedy algorithm (Mnih et al., 2013) for exploration in the training procedure.

3.3 Monolingual Sense Induction Module

This module is the degraded version of bilingual sense induction module when $\alpha = 1$, which occurs where *no* parallel bilingual signal exists. In other words, every bilingual sense induction module will experience the degradation during the training process presented in Algorithm 1. The only difference is that it cannot access the bilingual information. The purpose of this module is to maintain the stability of sense induction and to decode the sampled bilingual sense identity which will later be used in the bilingual sense representation learning module. As shown in Figure 1, given the monolingual context of a word, this module selects its sense identity using (2) and (3) with $\alpha = 1$.

3.4 Monolingual Sense Representation Learning Module

Given the decoded sense identities from the sense induction module, the skip-gram architecture (Mikolov et al., 2013) is applied considering that it only requires two decoded sense identities for stochastic training. We first create an input English sense representation matrix U^{en} and an English collocation estimation matrix V^{en} as the learning targets. Given a target word w_i and its collocated word w_j in the t-th English sentence C^{en}_t, we map them to their sense identities as $z^*_{ik} = s_i$ and $z^*_{jl} = s_j$ by the sense induction module and maximize the sense collocation likelihood. The skip-gram objective can be formulated as $p(s_j \mid s_i)$:

$$p(s_j \mid s_i) = \frac{\exp((U^{en}_{s_i})^T V^{en}_{s_j})}{\sum_{s_k} \exp((U^{en}_{s_i})^T V^{en}_{s_k})}, \qquad (4)$$

where s_k iterates over all possible English sense identities in the denominator. This formulation shares the same architecture as skip-gram but extends to rely on senses. Note that the Chinese sense representation learning module is built similarly.

3.5 Bilingual Sense Representation Learning Module

To ensure sense embeddings of two different languages align well, we hypothesize that the target sense identity s_i not only predicts the sense identity s_j of w_j in C^{en}_t but also one sampled sense identity s'_l of w'_l from the parallel sentence C^{zh}_t, where s'_l is decoded by the Chinese monolingual sense induction module. Specifically, the *bilingual* skip-gram objective can be formulated using the English sense embedding matrix U^{en} and the bilingual collocation estimation matrix V^{zh} as:

$$p(s'_l \mid s_i) = \frac{\exp((U^{en}_{s_i})^T V^{zh}_{s'_l})}{\sum_{s'_k} \exp((U^{en}_{s_i})^T V^{zh}_{s'_k})}, \qquad (5)$$

where s'_k iterates over all possible Chinese sense identities in the denominator.

3.6 Joint Learning

In this learning framework, the gradient cannot be back-propagated from the representation module to the induction module due to the usage of $\arg\max$ operator. It is therefore desirable to connect these two modules in a way such that they can improve each other by their own estimations. In one direction, forwarding the prediction of the sense induction module to the sense representation learning module is trivial, while in another direction, we treat the estimated collocation likelihood as the reward for the induction module.

First note that calculating the partition function in the denominator of (4) and (5) is intractable since it involves a computationally expensive summation over all sense identities. In practice, we adopt the negative sampling strategy technique (Mikolov et al., 2013) and rewrite (4) and (5) as:

$$\log p(s_j \mid s_i) = \log \sigma((U^{en}_{s_i})^T V^{en}_{s_j}) + \sum_{k=1}^{N} \mathbb{E}_{s_k \sim p_{\text{neg}}(s)}[\sigma(-(U^{en}_{s_i})^T V^{en}_{s_k})], \tag{6}$$

$$\log p(s'_l \mid s_i) = \log \sigma((U^{en}_{s_i})^T V^{zh}_{s'_l}) + \sum_{k=1}^{N} \mathbb{E}_{s'_k \sim p_{\text{neg}}(s')}[\sigma(-(U^{en}_{s_i})^T V^{zh}_{s'_k})], \tag{7}$$

where $p_{\text{neg}}(s)$ and $p_{\text{neg}}(s')$ is the distribution over all English senses and all Chinese senses for negative samples respectively, and N is the number of negative sample. The rewritten objective for optimizing two sense representation learning modules is the same as maximizing (6) and (7). Moreover, we can utilize the probability of correctly classifying the skip-gram sense pair as the reward signal. The intuition is that a correctly decoded sense identity is more likely to predict its neighboring sense identity compared to incorrectly decoded ones.

This learning framework can now be viewed as a reinforcement learning agent solving one-step Markov Decision Process (Sutton and Barto, 1998; Lee and Chen, 2017). For bilingual modules, the state, action, and reward correspond to bilingual context $\bar{C}$, sense z_{ik}, and $\sigma((U^{en}_{s_i})^T V^{zh}_{s'_l})$ respectively. As for the monolingual modules, the state, action, and reward correspond to monolingual context c_t, sense z_{ik}, and $\sigma((U^{en}_{s_i})^T V^{en}_{s_j})$. Finally, we can optimize both bilingual and monolingual sense induction modules (P and Q from (2) by minimizing the cross entropy loss between decoded sense probability and reward. We also include an entropy regularization term as suggested in (Šuster et al., 2016) to let the sense induction module converge faster and make more confident predictions. Formally,

$$\min H(\sigma((U^{en}_{s_i})^T V^{zh}_{s'_l}), p(z_{ik} \mid c_i, c'_i)) + \lambda E(p(z_{ik} \mid c_i, c'_i)) \tag{8}$$

$$\min H(\sigma((U^{en}_{s_i})^T V^{en}_{s_j}), p(z_{ik} \mid c_i)) + \lambda E(p(z_{ik} \mid c_i)) \tag{9}$$

E is the entropy of selection probability weighted by λ. Note that the major language is switched iteratively among two languages. Algorithm 1 presents the full learning procedure.

4 New Dataset—Bilingual Contextual Word Similarity (BCWS)

We propose a new dataset to measure the bilingual contextual word similarity. English and Chinese are chosen as our language pair for three reasons:

1. They are the top widely used languages in the world.
2. English and Chinese belong to completely different language families, making it interesting to explore syntactic and semantic difference among them.
3. Chinese is a language that requires segmentation, this dataset can also help researchers experiment on different segmentation levels and investigate how segmentation affects the

English Sentence	**Chinese Sentence**	**Score**
Judges must give both sides an equal opportunity to <**state**> their cases.	我非常喜歡這個故事，它<**告訴**>我們一些重要的啓示。 (I like this story a lot, which <**tells**> us some important inspiration.)	7.00
It was of negligible <**importance**> prior to 1990, with antiquated weapons and few members.	黃斑部病變的預防及早期治療是相當<**重要**>的。 (The prevention and early treatment of macular lesions is very <**important**>.)	6.94
Due to the San Andreas Fault bisecting the hill, one side has <**cold**> water, the other has hot.	水果攤老闆似乎很意外眞有人買這<**冷**>貨，露出「你眞内行」的眼神與我聊了幾句。 (The owner of the fruit stall seemed surprised that someone bought this <**unpopular**> product, talking me few words about “you are such a pro”.)	3.70

Table 1: Sentence pair examples and average annotated scores in BCWS.

sense similarity.

This dataset also provides a *direct* measure to determine whether the two language embeddings align well in the vector space. Note that we focus on word-level, and this is different from (Klementiev et al., 2012), which also measured the cross-lingual embedding similarity but rely on the ambiguous document-level classification.

Our dataset contains 2093 question pairs, where each pair consists of exactly one English and one Chinese sentence; note that they are **not** parallel but with their own sentential contexts shown in Table 1. Eleven raters[2] were recruited to annotate this dataset. Each rater gives a score ranging from 1.0 (different) to 10.0 (same) for each question to indicate the semantic similarity of bilingual word pairs based on sentential clues. The annotated dataset shows very high intra-rater consistency; we leave one rater out and calculate Spearman correlation between the rater and the average of the rest, and the average number is about 0.83, indicating the human-level performance (the average number in SCWS is 0.52).

We describe the construction of BCWS below.

Chinese Multi-Sense Word Extraction We utilize the Chinese Wikipedia dump to extract the most frequent 10000 Chinese words that are *nouns*, *adjective*, and *verb* based on Chinese Wordnet (Huang et al., 2010). In order to test the sense-level representations, we discard single-sense words to ensure that the selected words are polysemous. Also, the words with more than 20 senses are deleted, since those senses are too fine-grained and even hard for human to disambiguate. We denote the list of Chinese words l_c.

English Candidate Word Extraction We have to find an English counterpart for each Chinese word in l_c. We utilize *BabelNet* (Navigli and Ponzetto, 2010), a free and open-sourced knowledge resource, to serve as our bilingual dictionary. To be more concrete, we first query the selected Chinese word using the free API call provided by Babelnet to retrieve all *WordNet* senses[3]. For example, the Chinese word “制服” has two major meanings:

- *a type of clothing worn by members of an organization*
- *force to submit or subdue*.

Hence, we can obtain two candidate English words “*uniform*” and “*subjugate*”. Each word in l_c retrieves its associated English candidate words and obtain the dictionary D.

Enriching Semantic Relationship Note that D is merely a simple translation mapping between Chinese and English words. It is desirable that we have a more complicated and interesting relationship between bilingual word pairs. Hence, we traverse D and for each English word we find its *hyponyms*, *hypernyms*, *holonyms* and *attributes*, and add the additional words into D. In our example, we may obtain {制服:[uniform, subjugate, livery, clothing, repress, dominate, enslave, dragoon...]}. We sample 2 English words if the number of English candidate words is more than 5, 3 English words if more than 10, and 1 English word oth-

---

[2] They are all Chinese native speaker whose scores are at least 29 in the TOEFL reading section or 157 in the GRE verbal section.

[3] *BabelNet* contains sense definitions from various resources such as Wordnet, Wikitionary, Wikidata, etc

erwise to form the final bilingual pair. For example, a bilingual word pair (制服, enslave) can be formed accordingly. After this step, we obtain 2093 bilingual word pairs P.

Adding Contextual Information Given the bilingual word pairs P, appropriate contexts should be found in order to form the full sentences for human judgment. For each Chinese word, we randomly sample one example sentence in Chinese WordNet that matches the PoS tag we selected in section 4. For each English word, we traverse the whole English Wikipedia dump to find the sentences that contain the target English word. We then sample one sentence where the target word is tagged as the matched PoS tag[4].

5 Experiments

5.1 Experimental Setup

Two sets of parallel data are used in the experiments, one for English-Chinese (EN-ZH) and another for English-German (EN-DE). UM-corpus (Tian et al.) is used for EN-ZH training, while Europarl corpus (Koehn, 2005) is used for EN-DE training. UM-corpus contains 15,764,200 parallel sentences with 381,921,583 English words and 572,277,658 unsegmented Chinese words. Europarl contains 1,920,209 parallel sentences with 44,548,491 German words and 47,818,827 English words. We evaluate our proposed model on the benchmark monolingual dataset, SCWS, and on the bilingual dataset, our proposed BCWS, where the evaluation metrics are actually introduced in section 5.4.

5.2 Hyperparameter Settings

In our experiments, we use a mini-batch size of 512, context window size for major language is set to $m = 5$ and we sample $M = 20$ words for bilingual context. For the exploration of sense induction module, we set $\epsilon = 0.05$. The λ of entropy regularization is set to 1.[5] For negative sampling in (6) and (7), we pick $N = 25$. The fixed learning rate is set to 0.025. The embedding dimension is 300 and the sense number per word is set to 3 for both Chinese, German, and English ($|Z_i| = 3$). This setting is for a fair comparison with prior works.

5.3 Baseline

The baselines for comparison can be categorized into three:

- *Monolingual sense embeddings*: Lee and Chen (2017) is the current state-of-the-art model of monolingual sense embedding evaluated on SCWS. We re-train the sense embeddings using the same data but only in English for fair comparison.
- *Cross-lingual word embeddings*: Luong et al. (2015) treated words from different languages the same and trained cross-lingual embeddings in the same space. Conneau et al. (2017) utilized adversarial training to map pretrained word embeddings into another language space.
- *Cross-lingual sense embeddings*: Upadhyay et al. (2017) utilized more than two languages to learn multilingual embeddings. We report the number shown in the paper for comparison.

5.4 Evaluation Metric

Reisinger and Mooney (2010) introduced two contextual similarity estimations, AvgSimC and MaxSimC. AvgSimC is a *soft* measurement that addresses the contextual information with a probability estimation:

$$\text{AvgSimC}(w_i, \bar{C}_t, w_j, \bar{C}_{t'}) = \sum_{k=1}^{|Z_i|} \sum_{l=1}^{|Z_j|} \pi(z_{ik}|\bar{C}_t)\pi(z_{jl}|\bar{C}_{t'})d(z_{ik}, z_{jl}),$$

AvgSimC weights the similarity measurement of each sense pair z_{ik} and z_{jl} by their probability estimations. On the other hand, MaxSimC is a *hard* measurement that only considers the most probable senses:

$$\text{MaxSimC}(w_i, \bar{C}_t, w_j, \bar{C}_{t'}) = d(z_{ik}, z_{jl}),$$
$$z_{ik} = \arg\max_{z_{ik'}} \pi(z_{ik'}|\bar{C}_t),$$
$$z_{jl} = \arg\max_{z_{jl'}} \pi(z_{jl'}|\bar{C}_{t'}).$$

$d(z_{ik}, z_{jl})$ refers to the cosine similarity between $U^{maj}_{z_{ik}}$ and $U^{bi}_{z_{jl}}$ in the bilingual case (BCWS) and $U^{maj}_{z_{ik}}$ and $U^{maj}_{z_{jl}}$ in the monolingual case (SCWS).

5.5 Bilingual Embedding Evaluation

Cross-lingual sense embeddings are the main contribution of this paper. Table 2 shows that all results from the proposed model are significantly

---

[4] We use the NLTK PoS tagger to obtain the tags.

[5] We tried different values of $\lambda = 0.001, 0.5$, and the model converges approximately 12, 5 times slower compared to $\lambda = 1$.

Model	α	EN-ZH		EN-DE
		Bilingual/BCWS	Mono(EN)/SCWS	Mono(EN)/SCWS
1) Monolingual Sense Embeddings				
Lee and Chen (2017)			**66.8** / 65.5	**63.8** / 63.4
2) Cross-Lingual Word Embeddings				
Luong et al. (2015)		49.2	61.1	62.1
Conneau et al. (2017)		52.5	65.5	**64.0**
3) Cross-Lingual Sense Embeddings				
Upadhyay et al. (2017)		-	45.0*	-
Proposed	0.1	55.8 / 55.8	65.6 / 65.6	**63.8** / 63.9
	0.3	55.7 / 55.7	64.9 / 65.1	**63.8 / 64.0**
	0.5	56.3 / 56.3	65.8 / 66.0	63.6 / 63.9
	0.7	**56.7 / 56.7**	65.6 / 65.8	63.1 / 63.2
	0.9	56.0 / 56.0	66.0 / **66.2**	62.9 / 63.1

Table 2: Contextual similarity results evaluated on the SCWS/BCWS dataset, where the reported numbers indicate Spearman's rank correlation $\rho \times 100$ on AvgSimC / MaxSimC. * indicates that Upadhyay et al. (2017) trained the sense embeddings using a different parallel dataset.

better than the baselines that learn cross-lingual word embeddings. It indicates that the sense-level information is critical for precise vector representations. In addition, all results for AvgSimC and MaxSimC are the same in the proposed model, showing that the learned selection distribution is reliable for sense decoding.

5.6 Monolingual Embedding Evaluation

Because our model considers multiple languages and learns the embeddings jointly, the multilingual objective makes learning more difficult due to more noises. In order to ensure the quality of the monolingual sense embeddings, we also evaluate our learned English sense embeddings on the benchmark SCWS data. Comparing the results between training on EN-ZH and training on EN-DE, all results using EN-ZH are better than ones using EN-DE. The probable reason is that the language difference between English and Chinese is larger than English and German; parallel Chinese sentences therefore provide informative cues for learning better sense embeddings. Furthermore, our proposed model achieves comparable or superior performance than the current state-of-the-art monolingual sense embeddings proposed by Lee and Chen (2017) when trained on our monolingual data.

5.7 Sensitivity of Bilingual Contexts

To investigate how much the bilingual sense induction module relies on another language, the results with different α are shown in the table.

Model	EN2DE	DE2EN
1) Sentence-Level Training		
Hermann and Blunsom (2014)	83.7	71.4
AP et al. (2014)	**91.8**	72.8
Wei and Deng (2017)	91.0	**80.4**
2) Word-Level Training		
Klementiev et al. (2012)	77.7	71.1
Gouws et al. (2015)	86.5	75.0
Kočiský et al. (2014)	83.1	75.4
Shi et al. (2015)	91.3	**77.2**
Luong et al. (2015)	**86.4**	75.6
Conneau et al. (2017)	78.7	67.1
Proposed	81.8	76.0

Table 3: Accuracy on cross-lingual document classification (%).

To justify the usefulness of utilizing bilingual signal, we compare our model with Lee and Chen (2017), which used monolingual signal in a similar modular framework. Our method outperforms theirs in terms of MaxSimC on both EN-ZH and EN-DE. However, this trend is not observed on AvgSimC. The reason may be that bilingual signal is indicative but noisy, which largely affects AvgSimC due to its weighted sum operation. MaxSimC only picks the most probable senses, which makes it robust to noises.

In addition, our performance slightly degrades as α increases for EN-DE, and the best performance is obtained when α is small, indicating that

Target	kNN Senses (EN)	kNN Senses (ZH)
apple_0	fruit, cake, sweet	蘋果, 春天, 蛋糕, iphone, 雞蛋, 巧克力, 葡萄 (apple, spring, cake, iphone, egg, chocolate, purples)
apple_1	iphone, cake, google, stores	蘋果, iphone, 微軟, 競爭對手, 春天, 谷歌 (apple, iphone, microsoft, competitor, spring, google)
uniform_0	dressed, worn, tape, wearing, cloth	均匀,光滑,衣服,鞋子,穿著,服裝 (even, smooth, clothes, shoes, wearing, clothing)
uniform_1	particle, computed, varying, gradient	態,粉末,縱向,等離子體,剪切,剛度 (phase, powder, longitudinal, plasma, cut, stiffness)

Table 4: Words with similar senses obtained by kNN.

bilingual signal does help. However, this trend is not observed on EN-ZH, because English is very different from Chinese, such that it can benefit little from Chinese than from German.

5.8 Extrinsic Evaluation

We further evaluate our bilingual sense embeddings using a downstream task, cross-lingual document classification (CLDC), with a standard setup (Klementiev et al., 2012). To be more concrete, a set of labeled documents in language *A* is available to train a classifier, and we are interested in classifying documents in another language *B* at test time, which tests semantic transfer of information across different languages. We use the averaged sense embeddings as word embeddings for a fair comparison.

The result is shown in Table 3. We can see that our proposed model achieves comparable performance or even superior performance to most prior work on the DE2EN direction; however, the same conclusion does not hold for the EN2DE direction. The reason may be that we test the model that works best on BCWS and hence not able to tune hyperparameters on the development set of CLDC. In addition, we use the average of sense vectors as input word embeddings, which may induce some noises into the resulting vectors. In sum, the comparable performance of the downstream task shows the practical usage and the potential extension of the proposed model.

5.9 Qualitative Analysis

Some examples of our learned sense embeddings are shown in Table 4. It is obvious to see that the first sense of *Apple* is related to *fruit and things to eat*, while the second one means the *tech company Apple Inc*. Most English and Chinese nearest neighbors match the meanings of the induced senses, but there are still some noises that are underlined. For example, *cake* should be the neighbor of the first sense rather than the second one. The same observation applies to *iphone* and *spring*. In our second example for *uniform*, the first sense is related to *outfit and clothes*, while the second is related to *engineering terms*. However, *even* appears in the *outfit and clothes* sense, which is incorrect. The reason may be that the size of the parallel corpus is not large enough for the model to accurately distinguish all senses via unsupervised learning. Hence, utilizing external resources such as bilingual dictionaries or designing a new model that can use existing large monolingual corpora like Wikipedia can be our future work.

6 Conclusion

This paper is the first purely sense-level cross-lingual representation learning model with efficient sense induction, where several monolingual and bilingual modules are jointly optimized. The proposed model achieves superior performance on both bilingual and monolingual evluation datasets. A newly collected dataset for evaluating bilingual contextual word similarity is presented, which provides potential research directions for future work.

Abstract

Semantic *specialization* is a process of fine-tuning pre-trained distributional word vectors using external lexical knowledge (e.g., WordNet) to accentuate a particular semantic relation in the specialized vector space. While post-processing specialization methods are applicable to arbitrary distributional vectors, they are limited to updating only the vectors of words occurring in external lexicons (i.e., *seen words*), leaving the vectors of all other words unchanged. We propose a novel approach to specializing the full distributional vocabulary. Our *adversarial post-specialization* method propagates the external lexical knowledge to the full distributional space. We exploit words seen in the resources as training examples for learning a global specialization function. This function is learned by combining a standard L_2-distance loss with a adversarial loss: the adversarial component produces more realistic output vectors. We show the effectiveness and robustness of the proposed method across three languages and on three tasks: word similarity, dialog state tracking, and lexical simplification. We report consistent improvements over distributional word vectors and vectors specialized by other state-of-the-art specialization frameworks. Finally, we also propose a cross-lingual transfer method for *zero-shot specialization* which successfully specializes a full target distributional space without any lexical knowledge in the target language and without any bilingual data.

1 Introduction

Word representation learning is a mainstay of modern Natural Language Processing (NLP), and its usefulness has been proven across a wide spectrum of NLP applications (Collobert et al., 2011; Chen and Manning, 2014; Melamud et al., 2016b, *inter alia*). Standard *distributional* word vector models are grounded in the distributional hypothesis (Harris, 1954), that is, they leverage information about word co-occurrences in large text corpora (Mikolov et al., 2013; Pennington et al., 2014; Levy and Goldberg, 2014; Bojanowski et al., 2017). This dependence on contextual signal results in a well-known tendency to conflate semantic similarity with other types of semantic association (Hill et al., 2015; Schwartz et al., 2015; Vulić et al., 2017) in the induced word vector spaces.[1]

A common remedy is to move beyond purely unsupervised word representation learning, in a process referred to as *semantic specialization* or *retrofitting*. Specialization methods exploit lexical knowledge from external resources, such as WordNet (Fellbaum, 1998) or the Paraphrase Database (Ganitkevitch et al., 2013) to refine the semantic properties of pre-trained vectors and *specialize* the distributional spaces for a particular relation, e.g., synonymy (i.e., true similarity) (Faruqui et al., 2015; Mrkšić et al., 2017) or hypernymy (Nickel and Kiela, 2017; Nguyen et al., 2017; Vulić and Mrkšić, 2018).

The best-performing specialization models (cf. Mrkšić et al. 2017) are deployed as *post-processors of the vector space*: distributional vectors are *fine-tuned* to satisfy linguistic constraints extracted from external resources to offer improved support to downstream NLP applications (Faruqui, 2016). Such models are versatile as they can be applied to arbitrary distributional spaces, but they have a major drawback: they *locally* update only vectors of words present in linguistic constraints (i.e., *seen* words), whereas vectors of all other (i.e., *unseen*) words remain intact (see Figure 1).

---

[*] Both authors equally contributed to this work.

[1] For instance, it is difficult to discern synonyms from antonyms in distributional vector spaces: this has a negative impact on language understanding tasks such as statistical dialog modeling or text simplification (Glavaš and Štajner, 2015; Faruqui et al., 2015; Mrkšić et al., 2016; Kim et al., 2016)

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 282–293
Brussels, Belgium, October 31 - November 4, 2018.

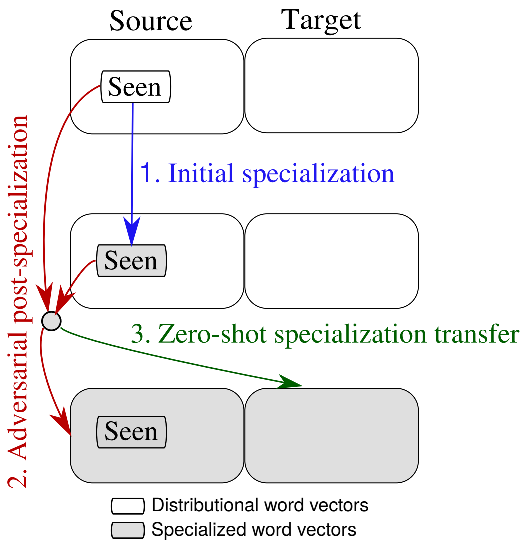

Figure 1: High-level illustration of the adversarial post-specialization process and cross-lingual zero-shot specialization, described in detail in §2.

Vulić et al. (2018) have recently proposed a model which, based on the updates of vectors of seen words, learns a global specialization function that can be applied to the large subspace of unseen words. Their global method, termed *post-specialization* and implemented as a deep feed-forward network, effectively specializes *all* distributional vectors.

In this paper, we propose a new approach to post-specialization which addresses the following two research questions: **a)** Is it possible to use a more sophisticated learning approach to yield more realistic specialized vectors for the full vocabulary? **b)** Given that specialization methods inherently require a large number of constraints, is it possible to specialize distributional word vectors where such resources are scarce or non-existent? Our novel model learns the global specialization function by casting the feed-forward specialization network as a generator component of an adversarial architecture, see Figure 2. The corresponding discriminator component learns to discern original specialized vectors (produced by any *local* specialization model) from vectors produced by transforming distributional vectors with the feed-forward post-specialization network (i.e., the generator).

We show that the proposed adversarial model yields state-of-the-art performance on standard word similarity benchmarks, outperforming the post-specialization model of Vulić et al. (2018). We further demonstrate the effectiveness of the proposed model in two downstream tasks: lexical text simplification and dialog state tracking. Finally, we demonstrate that, by coupling our adversarial specialization model with any unsupervised model for inducing bilingual vector spaces, such as the algorithm proposed by Conneau et al. (2018), we can successfully perform zero-shot language transfer of the specialization, that is, we can specialize distributional spaces of languages without any linguistic constraints in those languages, and without any bilingual data.

2 Methodology

The post-specialization procedure (Vulić et al., 2018) is a two-step process. First, a subspace of vectors for words observed in external resources is fine-tuned using any off-the-shelf specialization model, such as the original retrofitting model (Faruqui et al., 2015), counter-fitting (Mrkšić et al., 2016), dLCE (Nguyen et al., 2016), or state-of-the-art ATTRACT-REPEL (AR) specialization (Mrkšić et al., 2017; Vulić et al., 2017). We outline the initial specialization algorithms in §2.1. In the second step, the initial specialization is propagated to the entire vocabulary, including words not observed in the resources, relying on an adversarial architecture augmented with a distance loss. This adversarial post-specialization model, compatible with any specialization model, is described in §2.2.

Finally, in §2.3, we introduce a *cross-lingual zero-shot specialization model* which transfers the specialization to a target language without any lexical resources. An overview of the proposed methodology from this section is provided in Figure 1.

2.1 Initial Specialization

Linguistic Constraints. Adopting the nomenclature from Mrkšić et al. (2017), post-processing models are generally guided by two broad sets of constraints: **1)** ATTRACT constraints specify which words should be close to each other in the fine-tuned vector space (e.g. synonyms like *graceful* and *amiable*); **2)** REPEL constraints describe which words should be pulled away from each other (e.g. antonyms like *innocent* and *sinful*). Earlier post-processors (Faruqui et al., 2015; Jauhar et al., 2015; Wieting et al., 2015) operate only with ATTRACT constraints, and are thus not suited to model both aspects contributing to the specialization process.

We first outline the state-of-the-art ATTRACT-REPEL specialization model (Mrkšić et al., 2017) which leverages both sets of constraints. Here, we again stress two important aspects relevant to our post-specialization model: **a)** all initial specialization models fine-tune only representations for the subspace of words seen in the external constraints, while all other words remain unaffected by specialization; **b)** post-specialization is not tied to ATTRACT-REPEL in particular; it is applicable on top of any other post-processor.[2]

Specialization of Seen Words. The key idea is to inject the knowledge from linguistic constraints into pre-trained distributional word vectors. Given a set A of ATTRACT word pairs and a set R of REPEL word pairs, each word pair (v_l, v_r) from the vocabulary $\mathcal{V}_s$ of seen words present in these sets can be represented as a vector pair $(\mathbf{x}_l, \mathbf{x}_r)$.

The optimization is driven by mini-batches of ATTRACT pairs $\mathcal{B}_A$ (batch size k_A), and of REPEL pairs $\mathcal{B}_R$ (size k_R). For both of these, two sets of negative example pairs of equal size are drawn from the $2(k_A + k_R)$ vectors occurring in $\mathcal{B}_A$ and $\mathcal{B}_R$. This defines the mini-batches $T_A(B_A) = [(\mathbf{t}_l^1, \mathbf{t}_r^1) \dots (\mathbf{t}_l^{k_A}, \mathbf{t}_r^{k_A})]$ and $T_R(B_R) = [(\mathbf{t}_l^1, \mathbf{t}_r^1) \dots (\mathbf{t}_l^{k_R}, \mathbf{t}_r^{k_R})]$. Negative examples $\mathbf{t}_l$ and $\mathbf{t}_r$ for ATTRACT (or REPEL) pairs are the nearest (or farthest) neighbours by cosine similarity to $\mathbf{x}_l$ and $\mathbf{x}_r$, respectively. They ensure that the paired vectors for words in the constraints are closer to each other (or more distant for antonyms) than to their respective negative examples.

The overall objective function consists of three terms. The first term pulls ATTRACT pairs together:

$$
\begin{aligned}
Att(\mathcal{B}_A, \mathcal{T}_A) = \sum_{i=1}^{k_A} \Big[& \tau\big(\delta_A + \mathbf{x}_l^i \mathbf{t}_l^i - \mathbf{x}_l^i \mathbf{x}_r^i\big) + \\
& + \tau\big(\delta_A + \mathbf{x}_r^i \mathbf{t}_r^i - \mathbf{x}_l^i \mathbf{x}_r^i\big) \Big] \quad (1)
\end{aligned}
$$

$\tau(z) = \max(0, z)$ is the standard rectifier (Nair and Hinton, 2010). δ_A is the ATTRACT margin: it specifies the tolerance for the difference between the two distances (with the other pair member and with the negative example). The second term, $Rep(\mathcal{B}_R, \mathcal{T}_R)$, is similar but now pushes REPEL pairs away from each other, relying on the REPEL margin δ_R:

$$
\begin{aligned}
Rep(\mathcal{B}_R, \mathcal{T}_R) = \sum_{i=1}^{k_R} [& \tau\left(\delta_R - \mathbf{x}_l^i \mathbf{t}_l^i + \mathbf{x}_l^i \mathbf{x}_r^i\right) + \\
& + \tau\left(\delta_R - \mathbf{x}_r^i \mathbf{t}_r^i + \mathbf{x}_l^i \mathbf{x}_r^i\right)] \quad (2)
\end{aligned}
$$

The final term is tasked to *preserve* the quality of the original vectors through L_2-regularization:

$$
Pre(\mathcal{B}_A, \mathcal{B}_R) = \sum_{\mathbf{x}_i \in \mathcal{B}_A \cup \mathcal{B}_R} \lambda_P ||\mathbf{y}_i - \mathbf{x}_i||_2 \quad (3)
$$

$\mathbf{y}_i$ is the vector specialized from the original distributional vector $\mathbf{x}_i$, and λ_P is a regularization hyper-parameter. The optimizer finally minimizes the following objective: $\mathcal{L}_{AR} = Att(\mathcal{B}_A, \mathcal{T}_A) + Rep(\mathcal{B}_R, \mathcal{T}_R) + Pre(\mathcal{B}_A, \mathcal{B}_R)$.

2.2 Adversarial Post-Specialization

Motivation. The AR method affects only a subset of the full vocabulary $\mathcal{V}$, and consequently only a (small) subspace of the original space $\mathbf{X}$ (see Figure 1). In particular, it specializes the embeddings $\mathbf{X}_s$ corresponding to $\mathcal{V}_s$, the vocabulary of words observed in the constraints. It leaves the embeddings $\mathbf{X}_u$ corresponding to all other (unseen) words $\mathcal{V}_u$ identical.

Nevertheless, the perturbation underwent by the original observed embeddings can provide evidence about the general effects of specialization. In particular, it allows to learn a global mapping function $f : \mathbf{X} \in \mathbb{R}^d \rightarrow \mathbf{Y} \in \mathbb{R}^d$ for d-dimensional vectors. The parameters for this function can be trained in a supervised fashion from pairs of original and initially specialized word embeddings $(\mathbf{x}_i^{(s)}, \mathbf{y}_i^{(s)})$ from $\mathcal{V}_s$, as illustrated by Figure 2. Subsequently, the mapping can be applied to distributional word vectors $\mathbf{x}_u$ from the vocabulary of unseen words $\mathcal{V}_u$ to predict $\hat{\mathbf{y}}_u$, their specialized counterpart. This procedure, called post-specialization, effectively propagates the information stored in the external constraints to the entire word vector space.

However, this mapping should not just model the inherent transformation, but also ensure that the resulting vector is 'natural'. In particular, assuming that word representations lie on a manifold, the mapping should return one of its values. The intuition behind our formulation of the training objective is that: **a)** an L_2-distance loss can retrieve a faithful mapping whereas **b)** an adversarial loss can prevent unrealistic outputs, as already proven in the the visual domain (Pathak et al., 2016; Ledig et al., 2017; Odena et al., 2017).

---

[2] We have empirically validated the robustness of the proposed adversarial post-specialization by applying it also on top of other post-processing methods: retrofitting (Faruqui et al., 2015) and counter-fitting (Mrkšić et al., 2016). For brevity, we only report the (best) results with ATTRACT-REPEL, the best-performing initial/local specialization model.

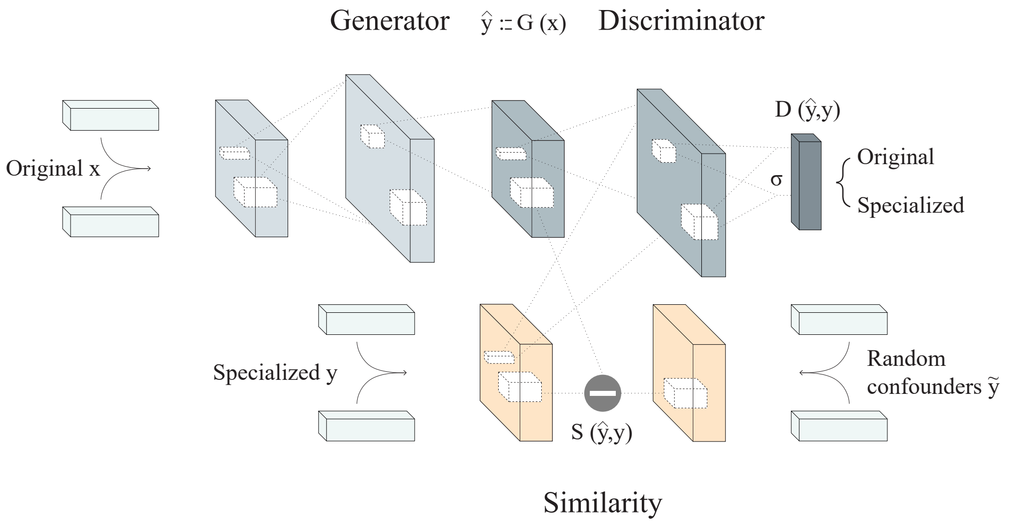

Figure 2: Architecture of the AuxGAN: an adversarial generator-discriminator loss (above) is combined with a max-margin L_2-distance loss with random confounders (below).

Objective Function. The pairs of original and specialized embeddings for seen words allow to train the global mapping function. In principle, this can be any differentiable parametrized function $G(\mathbf{x};\theta_G)$. Vulić et al. (2018) showed that non-linear functions ensure a better mapping than linear transformations which seem inadequate to mimic the complex perturbations of the specialization process, guided by possibly millions of pairwise constraints. Our preliminary experiments corroborate this intuition. Thus, in this work we also opt for implementing $G(\mathbf{x};\theta_G)$ as a deep neural network. Each of the l hidden layers of size h non-linearly transforms its input. The output layer is a linear transformation into the prediction $\hat{\mathbf{y}} \in \mathcal{R}^d$.

The parameters θ_G are learned by minimizing the L_2 distance between the training pairs. In particular, the loss is a contrastive margin-based ranking loss with negative sampling (MM) as proposed by Weston et al. (2011, *inter alia*). The gist of this loss is that the first component increases the cosine similarity *cos* of predicted and initially specialized vectors of the same word up to a margin δ_{MM}. On the other hand, the second component encourages the predicted vectors to distance themselves from k *random confounders*. These are negative examples sampled uniformly from the batch $\mathcal{B}$ excluding the current vector:

$$\mathcal{L}_{MM} = \sum_{i=1}^{||\mathcal{V}_s||} \sum_{j=1|j\neq i}^{k} \tau[\delta_{MM} - \cos(G(\mathbf{x}_i^{(s)};\theta_G), \mathbf{y}_i^{(s)}) + \\ + \cos(G(\mathbf{x}_i^{(s)};\theta_G), \mathbf{y}_j^{(s)})] \quad (4)$$

One of the original contributions of this work is combining the L_2 distance with an adversarial loss, resulting in an auxiliary-loss Generative Adversarial Network (AuxGAN) as shown in Figure 2. The role of the adversarial component, as mentioned above, is to 'soften' the mapping and guarantee realistic outputs from the target distribution.

The mapping can be considered a generator $G(\mathbf{x}|\theta_G)$. On top of this, a discriminator $D(\mathbf{x}|\theta_D)$, implemented also as a multi-layer neural net, tries to distinguish whether a vector is sampled from the predicted vectors or the AR-specialized vectors. Its output layer performs binary classification through *softmax*. The objective minimizes the loss $\mathcal{L}_D$:

$$\mathcal{L}_D = -\sum_{i=1}^{n} \log P(\text{specialized} = 0|G(\mathbf{x}_i;\theta_G);\theta_D) - \\ - \sum_{i=1}^{m} \log P(\text{specialized} = 1|\mathbf{y}_i;\theta_D) \quad (5)$$

In a two-player game (Goodfellow et al., 2014), the generator is trained to fool the discriminator by maximizing $\log(1 - P(0|G(\mathbf{x}_i;\theta_G);\theta_D))$. However, to avoid vanishing gradients of G early on, the loss $\mathcal{L}_G$ is reformulated by swapping the labels of Eq. (5) as follows:

$$\mathcal{L}_G = -\sum_{i=1}^{n} \log P(\text{specialized} = 1|G(\mathbf{x}_i;\theta_G);\theta_D) - \\ - \sum_{i=1}^{m} \log P(\text{specialized} = 0|\mathbf{y}_i;\theta_D) \quad (6)$$

During the optimization procedure through stochastic gradient descent, we alternate among s steps for

$\mathcal{L}_D$, one step for $\mathcal{L}_G$, and one step for $\mathcal{L}_{MM}$ to avoid the overfitting of D. The reason why $s \geq 1$ is that D can be kept close to a minimum of its loss function by updating G less frequently.

2.3 Zero-shot Transfer to Other Languages

Once the AuxGAN has learned a global mapping function $G(\mathbf{x}; \theta_G)$ in a resource-rich language, it can be directly applied to unseen words. In this work, we propose a method to additionally post-specialize the whole vocabulary $\mathcal{V}_t$ of a resource-poor target language. We assume a real-world scenario where no target language constraints are available to specialize it directly.

What is more, we assume that no bilingual data or dictionaries are available either. Hence, we rely on unsupervised cross-lingual word embedding induction, and in particular on Conneau et al. (2018)'s method. By virtue of these assumptions, there is no limitation to the range of potential target languages that can be specialized. Incidentally, please note that the proposed transfer method is equally applicable on top of other cross-lingual word embedding induction methods. These may require more bilingual supervision to learn the cross-lingual vector space.[3]

After learning the shared cross-lingual word embedding space in an unsupervised fashion (Conneau et al., 2018), the global post-specialization function learnt on the seen source language vectors is applied to the target language vectors, since they lie in the same shared space (see Figure 1 again). By virtue of the transfer, linguistic constraints in the source language can enhance the distributional vectors of target language vocabularies.

Conneau et al. (2018) learn a shared cross-lingual vector space as follows. They first learn a coarse initial mapping between two monolingual embedding spaces in two different languages through a GAN where the generator is a linear transformation with an orthogonal matrix $\hat{\mathbf{W}}$. Its loss is identical to Eq. (5) and Eq. (6), but unlike our AuxGAN model it discriminates between embeddings drawn from the source language and the target language distributions. Using the shared space, they extract for each source vector the closest target vector according to a distance metric designed to mitigate the hubness problem (Radovanović et al., 2010), the Cross-Domain Similarity Local Scaling (CSLS).

This creates a bilingual synthetic dictionary that allows to further refine the coarse initial mapping. In particular, the optimal parameters for the linear mapping minimizing the L_2-distance between source-target pairs are provided by the closed-form Procrustes solution (Schönemann, 1966) based on singular value decomposition (SVD):

$$\hat{\mathbf{W}} = \arg\min_W ||\mathbf{W}\,\mathbf{X}_t - \mathbf{X}_s||_F = \mathbf{U}\mathbf{V}^\top$$
$$\mathbf{U}\boldsymbol{\Sigma}\mathbf{V}^\top = \mathrm{SVD}(\mathbf{X}_t\mathbf{X}_s^\top) \quad (7)$$

where $||\cdot||_F$ is the Frobenius norm. After mapping the original target embeddings into the shared space with this method, we post-specialize them with the function outlined in §2.2, learnt on the source language. This yields the specialized target vectors $\hat{\mathbf{Y}}_t = G(\hat{\mathbf{W}}\,\mathbf{X}_t; \theta_G)$.

3 Experimental Setup

Distributional Vectors. We estimate the robustness of adversarial post-specialization by experimenting with three widely used collections of distributional English vectors. 1) SGNS-W2 vectors are trained on the cleaned and tokenized Polyglot Wikipedia (Al-Rfou et al., 2013) using Skip-Gram with Negative Sampling (SGNS) (Mikolov et al., 2013) by Levy and Goldberg (2014) with bag-of-words contexts (window size is 2). 2) GLOVE-CC are GloVe vectors trained on the Common Crawl (Pennington et al., 2014). 3) FASTTEXT are vectors trained on Wikipedia with a SGNS variant that builds word vectors by summing the vectors of their constituent character n-grams (Bojanowski et al., 2017). All vectors are 300-dimensional.[4]

Constraints and Initial Specialization. We experiment with the sets of linguistic constraints used in prior work (Zhang et al., 2014; Ono et al., 2015; Vulić et al., 2018). These constraints, extracted from WordNet (Fellbaum, 1998) and Roget's Thesaurus (Kipfer, 2009), comprise a total of 1,023,082 synonymy/ATTRACT word pairs and 380,873 antonymy/REPEL pairs.

Note that the sets of constraints cover only a fraction of the full distributional vocabulary, providing direct motivation for post-specialization methods

---

[3] See the recent survey papers on cross-lingual word embeddings and their typology (Upadhyay et al., 2016; Vulić and Korhonen, 2016; Ruder et al., 2017)

[4] Experiments with other standard word vectors, such as CONTEXT2VEC (Melamud et al., 2016a) and dependency-based embeddings (Bansal et al., 2014) show similar trends and lead to same conclusions.

which are able to specialize the full vocabulary. For instance, only 15.3% of the SGNS-W2 vocabulary words are seen words present in the constraints.[5]

The constraints are initially injected into the distributional vector space (see Figure 1 again) using ATTRACT-REPEL, a state-of-the-art specialization model, for which we adopt the original suggested model setup (Mrkšić et al., 2017).[6] Hyperparameter values are set to: $\delta_A = 0.6$, $\delta_R = 0.0$, $\lambda_P = 10^{-9}$. The models are trained for 5 epochs with Adagrad (Duchi et al., 2011), with batch sizes set to $k_A = k_R = 50$, again as in the original work.

AuxGAN Setup and Hyper-Parameters. Both the generator and the discriminator are feed-forward nets with $l = 2$ hidden layers, each of size $h = 2048$, and LeakyReLU as non-linear activation (Maas et al., 2013). The dropout for the input and hidden layers of the generator is 0.2 and for the input layer of the discriminator 0.1. In evaluation, the noise is blanketed out in order to ensure a deterministic mapping (Isola et al., 2017). Moreover, we smooth the golden labels for prediction by a factor of 0.1 to make the model less vulnerable to adversarial examples (Szegedy et al., 2016).

We train our model with SGD for 10 epochs of 1 million iterations each, feeding mini-batches of size 32. For each pair in a batch we generate 25 negative examples; $s = 5$ (see §2.2). As a way to normalize the mini-batches (Salimans et al., 2016), these are constructed to contain exclusively either original or specialized vectors. At each epoch, the initial learning rate of 0.1 is decayed by a factor of 0.98, or 0.5 if the score on the validation set (computed as the average cosine similarity between the predicted and AR-specialized embeddings)[7] has not increased. The hyper-parameters k and δ_{MM} are tuned via grid search on the validation set.

Zero-Shot Specialization Setup. The GAN discriminator for learning a shared cross-lingual vector space (see §2.3) has hyper-parameters identical to the AuxGAN. The generator instead is a linear layer initialized as an identity matrix and enforced to lie on the manifold of orthogonal matrices during training (Cisse et al., 2017). No dropout is used. The unsupervised validation metric for early stopping is the cosine distance between dictionary pairs extracted with the CSLS similarity metric.

4 Results and Discussion

4.1 Word Similarity

Evaluation Setup. We first evaluate adversarial post-specialization intrinsically, using two standard word similarity benchmarks for English: SimLex-999 (Hill et al., 2015) and SimVerb-3500 (Gerz et al., 2016), a dataset containing human similarity ratings for 3,500 verb pairs.[8] The evaluation measure is Spearman's ρ rank correlation between gold and predicted word pair similarity scores.

We evaluate word vectors in two settings, similar to Vulić et al. (2018). **a)** In the synthetic DISJOINT setting, we discard all linguistic constraints that contain any of the words found in SimLex or SimVerb. This means that all test words from SimLex and SimVerb are effectively unseen words, and through this setting we are able to *in vitro* evaluate the model's ability to generalize the specialization function to unseen words. **b)** In the FULL setting we leverage all constraints. This is a standard "real-life" scenario where some test words do occur in the constraints, while the mapping is learned for the remaining words. We use the FULL setting in all subsequent downstream applications (§4.2).

We compare our model to ATTRACT-REPEL (AR), which specializes only the vectors of words occurring in the constraints. We also provide comparisons to a post-specialization model of Vulić et al. (2018) which specializes the full vocabulary, but substitutes the AuxGAN architecture from §2.2 with a deep 5-layer feed-forward neural net also based on the max-margin loss (see Eq. (4)) to learn the mapping function (POST-DFFN).

Results and Analysis. The results are summarized in Table 1. The scores suggest that the proposed adversarial post-specialization model is universally useful and robust: we observe gains over input distributional word vectors for all three vector collections. The results in the DISJOINT setting illustrate the core limitation of the initial specialization/post-processing models and indicate the extent of improvement achieved when generalizing the specialization function to unseen words

---

[5] The respective coverage for the 200K most frequent GLOVE-CC and FASTTEXT words is only 13.3% and 14.6%.

[6] `https://github.com/nmrksic/attract-repel`

[7] The score is computed as the average cosine similarity between the original and specialized embeddings.

[8] Unlike WordSim-353 (Finkelstein et al., 2002) or MEN (Bruni et al., 2014), SimLex and SimVerb provide explicit guidelines to discern between true semantic similarity and (more broad) conceptual relatedness, so that related but non-similar words (e.g. *tiger* and *jungle*) have a low rating.

	Setting: DISJOINT						Setting: FULL

Table 1: Spearman's ρ correlation scores for three standard English distributional vectors spaces on English SimLex-999 (SL) and SimVerb-3500 (SV). POST-DFFN (Vulić et al., 2018) uses a deep non-linear feed-forward network to learn the mapping function f. AUXGAN is our adversarial model (see §2.2).

through adversarial post-specialization. Moreover, the scores suggest that the more sophisticated adversarial post-specialization method (AUXGAN) outperforms POST-DFFN across a large number of experimental runs, verifying its effectiveness.

We observe only modest and inconsistent gains over ATTRACT-REPEL and POST-DFFN in the FULL setting. However, the explanation of this finding is straightforward: 99.2% of SimLex words and 99.9% of SimVerb words are present in the external constraints, making this an unrealistic evaluation scenario. The usefulness of the initial ATTRACT-REPEL specialization is less pronounced in real-life downstream applications in which such high coverage cannot be guaranteed, as shown in §4.2.

4.2 Downstream Tasks

We next evaluate the embedding spaces specialized with the AuxGAN method in two tasks in which discerning semantic similarity from semantic relatedness is crucial: lexical text simplification (LS) and dialog state tracking (DST).

4.2.1 Lexical Text Simplification

The goal of lexical simplification is to replace complex words (typically words that are used less often in language and are therefore less familiar to readers) with their simpler synonyms, without infringing the grammaticality and changing the meaning of the text. Replacing complex words with related words instead of true synonyms affects the original meaning (e.g., *Ferrari pilot Vettel* vs *Ferrari airplane Vettel*) and often yields ungrammatical text (e.g., *they drink all pizzas*).

LS Using Word Vectors. We use Light-LS, a publicly available LS tool based on word embeddings (Glavaš and Štajner, 2015). Light-LS generates and then ranks substitution candidates based on similarity in the input word vector space. The quality of the space thus directly affects LS performance: by plugging any word vector space into Light-LS, we extrinsically evaluate that embedding space for LS. Furthermore, the better the embedding space captures true semantic similarity, the better the substitutions made by Light-LS.

	GLOVE-CC	FASTTEXT	SGNS-W2
Vector space	Acc	Acc	Acc
Distributional	.660	.578	.560
Specialized: AR	.676	.698	.644
Post-Specialized:			
POST-DFFN	**.723**	.723	.709
AUXGAN	.717	**.739**	**.721**

Table 2: Lexical simplification results for three (post-specialized) distributional spaces.

Evaluation Setup. We use the standard LS dataset of Horn et al. (2014). It contains 500 sentences with indicated complex words (one word per sentence) that have to be substituted with simpler synonyms. For each word, simplifications were crowdsourced from 50 human annotators. Following prior work (Horn et al., 2014; Glavaš and Štajner, 2015), we evaluate the performance of Light-LS using the metric that quantifies both the quality and the frequency of word replacements: *Accurracy (Acc)* metric is the number of correct simplifications made divided by the total number of complex words.

Results and Analysis. Scores for all three pretrained vector spaces are shown in Table 2. Similar to the word similarity task, embedding spaces produced with post-specialization models outperform the vectors produced with AR and original distributional vectors. The gains are now more pronounced in the real-life FULL setup, as only 59.6 % of all indicated complex words and substitution candidates from the LS dataset are covered in the external con-

GLOVE-CC word vectors	JGA
Distributional	.797
Specialized: ATTRACT-REPEL	.817
Post-Specialized: POST-DFFN	.829
Post-Specialized: AUXGAN	**.836**

Table 3: English DST performance (joint goal accuracy). GLOVE-CC word vectors.

straints. Adversarial post-specialization (AUXGAN) has a slight edge over the post-specialization with a simple feed-forward network (POST-DFFN) for FASTTEXT and SGNS-W2 embeddings, but not for GLOVE-CC vectors. In general, the fact that both post-specialization methods outperform ATTRACT-REPEL by a wide margin shows the importance of specializing the full word vector space for downstream NLP applications.

4.2.2 Dialog State Tracking

Finally, we evaluate the importance of full-vocabulary (adversarial) post-specialization in another language understanding task: dialog state tracking (DST) (Henderson et al., 2014; Williams et al., 2016), which is a standard task to measure the impact of specialization in prior work (Mrkšić et al., 2017). A DST model is typically the first component of a dialog system pipeline (Young, 2010), tasked with capturing user's goals and updating the dialog belief state at each dialog turn. Distinguishing similarity from relatedness is crucial for DST (e.g., a dialog system should not recommend an *"expensive restaurant in the west"* when asked for an *"affordable pub in the north"*).

Evaluation Setup. To evaluate the effects of specialized word vectors on DST, following prior work we utilize the Neural Belief Tracker (NBT), a statistical DST model that makes inferences purely based on pre-trained word vectors (Mrkšić et al., 2017).[9] Again, as in prior work the DST evaluation is based on the Wizard-of-Oz (WOZ) v2.0 dataset (Wen et al., 2017; Mrkšić et al., 2017), comprising 1,200 dialogues split into training (600 dialogues), development (200), and test data (400). We report the standard DST metric: *joint goal accuracy (JGA)*, the proportion of dialog turns where all the user's search goal constraints were correctly identified, computed as average over 5 NBT runs.

	Similarity (ρ)		LS (Acc)		DST (JGA)	
Vector space	IT	DE	IT	DE	IT	DE
Distrib.	.297	.417	.308	-	.681	.621
AUXGAN	**.431**	**.525**	**.392**	-	**.714**	**.651**

Table 4: Results of zero-shot specialization applied to IT and DE FASTTEXT distributional vectors.

Results and Analysis. We show English DST performance in the FULL setting in Table 3. Only NBT performance with GLOVE-CC vectors is reported for brevity, as similar performance gains are observed with the other two pre-trained vector collections. The results confirm our findings established in the other two tasks: **a)** initial AR specialization of distributional vectors is useful, but **b)** it is crucial to specialize the full vocabulary for improved performance (e.g., 57% of all WOZ words are present in the constraints), and **c)** the more sophisticated AUXGAN model yields additional gains.

4.3 Cross-Lingual Zero-Shot Specialization

Evaluation Setup. Large collections of linguistic constraints do not exist for many languages. Therefore, we test if the specialization knowledge from a resoure-rich language (i.e., English) can be transferred to resource-lean target languages (see §2.3). We simulate resource-lean scenarios using two target languages: Italian (IT) and German (DE).[10] We evaluate zero-specialized IT and DE FASTTEXT vectors, using English FASTTEXT vectors as the source, on the same three tasks as before. We report the same evaluation measures, using the following evaluation data: 1) IT and DE SimLex-999 datasets (Leviant and Reichart, 2015) for word similarity; 2) IT lexical simplification data (SIMPITIKI) (Tonelli et al., 2016); 3) IT and DE WOZ data (Mrkšić et al., 2017) for DST.

Results and Analysis. The results are summarized in Table 4. The gains over the original distributional vectors are substantial across all three tasks and for both languages. This finding indicates that the semantic content of distributional vectors can be enriched even for languages without any readily available lexical resources.

The gap between performances of language transfer and the monolingual setting is explained

---

[9] `https://github.com/nmrksic/neural-belief-tracker`; For full model details, we refer the reader to the original paper.

[10] Note that the two languages are not resource-poor, but we treat them as such in our experiments. This choice of languages was determined by the availability of high-quality evaluation data to measure the effects of zero-shot specialization.

by the noise introduced by the bilingual vector alignment and the different ways concepts are lexicalized across languages, as studied by semantic typology (Ponti et al., 2018). Nonetheless, in the long run, these transfer results hold promise to support the specialization of vector spaces even for resource-lean languages, and their applications.

5 Related Work

Vector Space Specialization. Specialization methods embed external information into vector spaces. Some of them integrate external linguistic constraints into distributional training and *jointly* optimize distributional and non-distributional objectives: they modify the prior or the regularization (Yu and Dredze, 2014; Xu et al., 2014; Bian et al., 2014; Kiela et al., 2015), or use a variant of the SGNS-style objective (Liu et al., 2015; Ono et al., 2015; Osborne et al., 2016).

Other models inject external knowledge from available lexical resources (e.g., WordNet, PPDB) into pre-trained word vectors as a *post-processing step* (Faruqui et al., 2015; Rothe and Schütze, 2015; Wieting et al., 2015; Nguyen et al., 2016; Mrkšić et al., 2016; Cotterell et al., 2016; Mrkšić et al., 2017). They offer a portable, flexible, and lightweight approach to incorporating external knowledge into *arbitrary* vector spaces, outperforming less versatile joint models and yielding state-of-the-art results on language understanding tasks (Mrkšić et al., 2016; Kim et al., 2016; Vulić et al., 2017). By design, these methods fine-tune only vectors of words seen in external resources.

Vulić et al. (2018) suggest that specializing the full vocabulary is beneficial for downstream applications. Comparing to their work, we show that a more sophisticated adversarial post-specialization can yield further gains across different tasks and boost full-vocabulary specialization in resource-lean settings through cross-lingual transfer.

Generative Adversarial Networks. GANs were originally devised to generate images from input noise variables (Goodfellow et al., 2014). The generation process is typically conditioned on discrete labels or data from other modalities, such as text (Mirza and Osindero, 2014). Otherwise, the condition can take the form of real data in input rather than (or in addition to) noise: in this case, the generator parameters are better conceived as a mapping function. For instance, it can bridge between pixel-to-pixel (Isola et al., 2017) or character-to-pixel (Reed et al., 2016) transformations.

The GAN objective can be mixed with more traditional loss functions: in these cases, apart from trying to fool the discriminator, the generator also minimizes the distance between input and target data (Pathak et al., 2016; Li and Wand, 2016; Ledig et al., 2017). The distance can be formulated as the mean squared error between the input and the target (Pathak et al., 2016), their feature maps (Li and Wand, 2016), both (Zhu et al., 2016), or a loss calculated on feature maps of a deep convolutional network (Ledig et al., 2017).

In the textual domain, adversarial models have been proven to support domain adaptation (Ganin et al., 2016) and language transfer (Chen et al., 2016) by learning domain/language-invariant latent features. Adversarial training also powers unsupervised mapping between monolingual vector spaces to learn cross-lingual word embeddings (Zhang et al., 2017; Conneau et al., 2018). In this work, we show how to apply adversarial techniques to the problem of vector specialization, which has a substantial impact on language understanding tasks.

6 Conclusion and Future Work

We have presented adversarial post-specialization, a novel model supported by adversarial training which specializes word vectors for the full vocabulary of the input distributional vector space, including words unseen in external lexical resources. We have also introduced a method for zero-shot specialization of word vectors in languages without any external resources. The benefits of adversarial post-specialization and its zero-shot transfer have been demonstrated across three tasks (word similarity, lexical text simplification, and dialog state tracking) and for three languages.

In future work, we will explore more sophisticated adversarial models such as Cycle-GAN (Zhu et al., 2017). Moreover, we will experiment with bootstrapping approaches to extract new lexical constraints from post-specialized embeddings. We also plan to extend the method to asymmetric relations (e.g., hypernymy) and to more target (resource-lean) languages. The code is available at `https://github.com/cambridgeltl/adversarial-postspec`.

Abstract

Cross-lingual word embeddings are becoming increasingly important in multilingual NLP. Recently, it has been shown that these embeddings can be effectively learned by aligning two disjoint monolingual vector spaces through linear transformations, using no more than a small bilingual dictionary as supervision. In this work, we propose to apply an additional transformation after the initial alignment step, which moves cross-lingual synonyms towards a middle point between them. By applying this transformation our aim is to obtain a better cross-lingual integration of the vector spaces. In addition, and perhaps surprisingly, the monolingual spaces also improve by this transformation. This is in contrast to the original alignment, which is typically learned such that the structure of the monolingual spaces is preserved. Our experiments confirm that the resulting cross-lingual embeddings outperform state-of-the-art models in both monolingual and cross-lingual evaluation tasks.

1 Introduction

Word embeddings are one of the most widely used resources in NLP, as they have proven to be of enormous importance for modeling linguistic phenomena in both supervised and unsupervised settings. In particular, the representation of words in cross-lingual vector spaces (henceforth, *cross-lingual word embeddings*) is quickly gaining in popularity. One of the main reasons is that they play a crucial role in transferring knowledge from one language to another, specifically in downstream tasks such as information retrieval (Vulić and Moens, 2015b), entity linking (Tsai and Roth, 2016) and text classification (Mogadala and Rettinger, 2016), while at the same time providing improvements in multilingual NLP problems such as machine translation (Zou et al., 2013).

There exist different approaches for obtaining these cross-lingual embeddings. One of the most successful methodological directions, which constitutes the main focus of this paper, attempts to learn bilingual embeddings via a two-step process: first, word embeddings are trained on monolingual corpora and then the resulting monolingual spaces are aligned by taking advantage of bilingual dictionaries (Mikolov et al., 2013b; Faruqui and Dyer, 2014; Xing et al., 2015).

These *alignments* are generally modeled as linear transformations, which are constrained such that the structure of the initial monolingual spaces is left unchanged. This can be achieved by imposing an orthogonality constraint on the linear transformation (Xing et al., 2015; Artetxe et al., 2016). Our hypothesis in this paper is that such approaches can be further improved, as they rely on the assumption that the internal structure of the two monolingual spaces is identical. In reality, however, this structure is influenced by language-specific phenomena, e.g., the fact that Spanish distinguishes between masculine and feminine nouns (Davis, 2015) as well as the specific biases of the different corpora from which the monolingual spaces were learned. Because of this, monolingual embedding spaces are not isomorphic (Søgaard et al., 2018; Kementchedjhieva et al., 2018). On the other hand, simply dropping the orthogonality constraints leads to overfitting, and is thus not effective in practice.

The solution we propose is to start with existing state-of-the-art alignment models (Artetxe et al., 2017; Conneau et al., 2018), and to apply a further transformation to the resulting initial alignment. For each word w with translation w', this additional transformation aims to map the vector representations of both w and w' onto their average, thereby creating a cross-lingual vector space which intuitively corresponds to the average of the

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 294–304
Brussels, Belgium, October 31 - November 4, 2018.

two aligned monolingual vector spaces. Similar to the initial alignment, this mapping is learned from a small bilingual lexicon.

Our experimental results show that the proposed additional transformation does not only benefit cross-lingual evaluation tasks, but, perhaps surprisingly, also monolingual ones. In particular, we perform an extensive set of experiments on standard benchmarks for bilingual dictionary induction and monolingual and cross-lingual word similarity, as well as on an extrinsic task: cross-lingual hypernym discovery.

Code and pre-trained embeddings to reproduce our experiments and to apply our model to any given cross-lingual embeddings are available at `https://github.com/yeraidm/meemi`.

2 Related Work

Bilingual word embeddings have been extensively studied in the literature in recent years. Their nature varies with respect to the supervision signals used for training (Upadhyay et al., 2016; Ruder et al., 2018). Some common signals to learn bilingual embeddings come from parallel (Hermann and Blunsom, 2014; Luong et al., 2015; Levy et al., 2017) or comparable corpora (Vulić and Moens, 2015a; Søgaard et al., 2015; Vulić and Moens, 2016), or lexical resources such as WordNet, ConceptNet or BabelNet (Speer et al., 2017; Mrksic et al., 2017; Goikoetxea et al., 2018). However, these sources of supervision may be scarce, limited to certain domains or may not be directly available for certain language pairs.

Another branch of research exploits pre-trained monolingual embeddings with weak signals such as bilingual lexicons for learning bilingual embeddings (Mikolov et al., 2013b; Faruqui and Dyer, 2014; Ammar et al., 2016; Artetxe et al., 2016). Mikolov et al. (2013b) was one of the first attempts into this line of research, applying a linear transformation in order to map the embeddings from one monolingual space into another. They also noted that more sophisticated approaches, such as using multilayer perceptrons, do not improve with respect to their linear counterparts. Xing et al. (2015) built upon this work by normalizing word embeddings during training and adding an orthogonality constraint. In a complementary direction, Faruqui and Dyer (2014) put forward a technique based on canonical correlation analysis to obtain linear mappings for both monolingual embedding spaces into a new shared space. Artetxe et al. (2016) proposed a similar linear mapping to Mikolov et al. (2013b), generalizing it and providing theoretical justifications which also served to reinterpret the methods of Faruqui and Dyer (2014) and Xing et al. (2015). Smith et al. (2017) further showed how orthogonality was required to improve the consistency of bilingual mappings, making them more robust to noise. Finally, a more complete generalization providing further insights on the linear transformations used in all these models can be found in Artetxe et al. (2018a).

These approaches generally require large bilingual lexicons to effectively learn multilingual embeddings (Artetxe et al., 2017). Recently, however, alternatives which only need very small dictionaries, or even none at all, have been proposed to learn high-quality embeddings via linear mappings (Artetxe et al., 2017; Conneau et al., 2018). More details on the specifics of these two approaches can be found in Section 3.1. These models have in turn paved the way for the development of machine translation systems which do not require any parallel corpora (Artetxe et al., 2018b; Lample et al., 2018). Moreover, the fact that such approaches only need monolingual embeddings, instead of parallel or comparable corpora, makes them easily adaptable to different domains (e.g., social media or web corpora).

In this paper we build upon these state-of-the-art approaches by applying an additional transformation, which aims to map each word and its translation onto the average of their vector representations. This strategy bears some resemblance with the idea of learning meta-embeddings (Yin and Schütze, 2016). Meta-embeddings are vector space representations which aggregate several pre-trained word embeddings from a given language (e.g., trained using different corpora and/or different word embedding models). Empirically it was found that such meta-embeddings can often outperform the individual word embeddings from which they were obtained. In particular, it was recently argued that word vector averaging can be a highly effective approach for learning such meta-embeddings (Coates and Bollegala, 2018). The main difference between such approaches and our work is that because we rely on a small dictionary, we cannot simply average word vectors, since for most words we do not know the corresponding translation. Instead, we train a regression model to predict this average word vector from the vector representation of the given word only, i.e., without using the vector representation of its translation.

3 Methodology

Our approach for improving cross-lingual embeddings consists of three main steps, where the first two steps are the same as in existing methods. In particular, given two monolingual corpora, a word vector space is first learned independently for each language. This can be achieved with common word embedding models, e.g., Word2vec (Mikolov et al., 2013a), GloVe (Pennington et al., 2014) or FastText (Bojanowski et al., 2017). Second, a linear alignment strategy is used to map the monolingual embeddings to a common bilingual vector space (Section 3.1). Third, a final transformation is applied on the aligned embeddings so the word vectors from both languages are refined and further integrated with each other (Section 3.2). This third step is the main contribution of our paper.

3.1 Aligning monolingual spaces

Once the monolingual word embeddings have been obtained, a linear transformation is applied in order to integrate them into the same vector space. This linear transformation is generally carried out using a supervision signal, typically in the form of a bilingual dictionary. In the following we explain two state-of-the-art models performing this linear transformation.

`VecMap` (Artetxe et al., 2017). `VecMap` uses an orthogonal transformation over normalized word embeddings. An iterative two-step procedure is also implemented in order to avoid the need of starting with a large seed dictionary (e.g., in the original paper it was tested with a very small bilingual dictionary of just 25 pairs). In this procedure, first, the linear mapping is estimated using a small bilingual dictionary, and then, this dictionary is augmented by applying the learned transformation to new words from the source language. Lastly, the process is repeated until some convergence criterion is met.

`MUSE` (Conneau et al., 2018). In this case, the transformation matrix is learned through an iterative Procrustes alignment (Schönemann, 1966).[1] The anchor points needed for this alignment can be obtained either through a supplied bilingual dictionary or through an unsupervised model. This unsupervised model is trained using adversarial learning to obtain an initial alignment of the two monolingual spaces, which is then refined by the Procrustes alignment using the most frequent words as anchor points. A new distance metric for the embedding space, referred to as cross-domain similarity local scaling, is also introduced. This metric, which takes into account the nearest neighbors of both source and target words, was shown to better handle high-density regions of the space, thus alleviating the hubness problem of word embedding models (Radovanović et al., 2010; Dinu et al., 2015), which arises when a few points (known as hubs) become the nearest neighbors of many other points in the embedding space.

3.2 Meeting in the middle

After the initial alignment of the monolingual word embeddings, our proposed method leverages an additional linear model to refine the resulting bilingual word embeddings. This is because the methods presented in the previous section apply constraints to ensure that the structure of the monolingual embeddings is largely preserved. As already mentioned in the introduction, conceptually this may not be optimal, as embeddings for different languages and trained from different corpora can be expected to be structured somewhat differently. Empirically, as we will see in the evaluation, after applying methods such as `VecMap` and `MUSE` there still tend to be significant gaps between the vector representations of words and their translations. Our method directly attempts to reduce these gaps by moving each word vector towards the middle point between its current representation and the representation of its translation. In this way, by bringing the two monolingual fragments of the space closer to each other, we can expect to see an improved performance on cross-lingual evaluation tasks such as bilingual dictionary induction. Importantly, the internal structure of the two monolingual fragments themselves is also affected by this step. By aver-

---

[1] Very recently, Kementchedjhieva et al. (2018) showed that projecting both monolingual embedding spaces onto a third space (instead of directly onto each other) using a generalized Procrustes analysis facilitates the learning of alignments.

aging between the representations obtained from different languages, we hypothesize that the impact of language-specific phenomena and corpus specific biases will be reduced, thereby ending up with more "neutral" monolingual embeddings.

In the following, we detail our methodological approach. First, we leverage the same bilingual dictionary that was used to obtain the initial alignment (Section 3.1). Specifically, let $D = \{(w, w')\}$ be the given bilingual dictionary, where $w \in V$ and $w' \in V'$, with V and V' representing the vocabulary of the first and second language, respectively. For pairs $(w, w') \in D$, we can simply compute the corresponding average vector $\vec{\mu}_{w,w'} = \frac{\vec{v}_w + \vec{v}_{w'}}{2}$. Then, using the pairs in D as training data, we learn a linear mapping X such that $X\vec{v}_w \approx \vec{\mu}_{w,w'}$ for all $(w, w') \in D$. This mapping X can then be used to predict the averages for words outside the given dictionary. To find the mapping X, we solve the following least squares linear regression problem:

$$E = \sum_{(w,w') \in D} \|X\vec{w} - \vec{\mu}_{w,w'}\|^2 \qquad (1)$$

Similarly, for the other language, we separately learn a mapping X' such that $X'\vec{v}_{w'} \approx \vec{\mu}_{w,w'}$.

It is worth pointing out that we experimented with several variants of this linear regression formulation. For example, we also tried using a multilayer perceptron to learn non-linear mappings, and we experimented with several regularization terms to penalize mappings that deviate too much from the identity mapping. None of these variants, however, were found to improve on the much simpler formulation in (1), which can be solved exactly and efficiently. Furthermore, one may wonder whether the initial alignment is actually needed, since e.g., Coates and Bollegala (2018) obtained high-quality meta-embeddings without such an alignment set. However, when applying our approach directly to the initial monolingual non-aligned embedding spaces, we obtained results which were competitive but slightly below the two considered alignment strategies.

4 Evaluation

We test our bilingual embedding refinement approach on both intrinsic and extrinsic tasks. In Section 4.1 we describe the common training setup for all experiments and language pairs. The languages we considered are English, Spanish, Italian, German and Finnish. Throughout all the experiments we use publicly available resources in order to make comparisons and reproducibility of our experiments easier.

4.1 Cross-lingual embeddings training

Corpora. In our experiments we make use of web-extracted corpora. For English we use the 3B-word UMBC WebBase Corpus (Han et al., 2013), while we chose the Spanish Billion Words Corpus (Cardellino, 2016) for Spanish. For Italian and German, we use the itWaC and sdeWaC corpora from the WaCky project (Baroni et al., 2009), containing 2 and 0.8 billion words, respectively.[2] Lastly, for Finnish, we use the Common Crawl monolingual corpus from the Machine Translation of News Shared Task 2016[3], composed of 2.8B words. All corpora are tokenized and lowercased.

Monolingual embeddings. The monolingual word embeddings are trained with the Skipgram model from FastText (Bojanowski et al., 2017) on the corpora described above. The dimensionality of the vectors was set to 300, with the default FastText hyperparameters.

Bilingual dictionaries. We use the bilingual dictionaries packaged together by Artetxe et al. (2017), each one conformed by 5000 word translations. They are used both for the initial bilingual mappings and then again for our linear transformation.

Initial mapping. Following previous works, for the purpose of obtaining the initial alignment, English is considered as source language and the remaining languages are used as target. We make use of the open-source implementations of **`VecMap`**[4] (Artetxe et al., 2017) and **`MUSE`**[5] (Conneau et al., 2018), which constitute strong baselines for our experiments (cf. Section 3.1). Both of them were used with the recommended parameters and in their supervised setting, using the aforementioned bilingual dictionaries.

Meeting in the Middle. Then, once the initial cross-lingual embeddings are trained, and as explained in Section 3.2, we obtain our linear transformation by using the exact solution to the least

---

[2] UMBC, Spanish Billion-Words and ItWaC are the official corpora of the hypernym discovery SemEval task (Section 4.2.3) for English, Spanish and Italian, respectively.

squares linear regression problem. To this end, we use the same bilingual dictionaries as in the previous step. Henceforth, we will refer to our transformed models as **VecMap**$_\mu$ and **MUSE**$_\mu$, depending on the initial mapping.

4.2 Experiments

We test our cross-lingual word embeddings in two intrinsic tasks, i.e., bilingual dictionary induction (Section 4.2.1) and word similarity (Section 4.2.2), and an extrinsic task, i.e., cross-lingual hypernym discovery (Section 4.2.3).

4.2.1 Bilingual dictionary induction

The dictionary induction task consists in automatically generating a bilingual dictionary from a source to a target language, using as input a list of words in the source language.

Experimental setting For this task, and following previous works, we use the English-Italian test set released by Dinu et al. (2015) and those released by Artetxe et al. (2017) for the remaining language pairs. These test sets have no overlap with respect to the training and development sets, and contain around 1900 entries each. Given an input word from the source language, word translations are retrieved through a nearest-neighbor search of words in the target language, using cosine distance. Note that this gives us a ranked list of candidates for each word from the source language. Accordingly, the performance of the embeddings is evaluated with the precision at k ($P@k$) metric, which evaluates for what percentage of test pairs, the correct answer is among the k highest ranked candidates.

Results As can be seen in Table 1, our refinement method consistently improves over the baselines (i.e., `VecMap` and `MUSE`) on all language pairs and metrics. The higher scores indicate that the two monolingual embedding spaces become more tightly integrated because of our additional transformation. It is worth highlighting here the case of English-Finnish, where the gains obtained in $P@5$ and $P@10$ are considerable. This might indicate that our approach is especially useful for morphologically richer languages such as Finnish, where the limitations of the previous bilingual mappings are most apparent.

Analysis When analyzing the source of errors in $P@1$, we came to similar conclusions as Artetxe et al. (2017).[6] Several source words are translated to words that are closely related to the one in the gold reference in the target language; e.g., for the English word *essentially* we obtain *básicamente* (*basically*) instead of *fundamentalmente* (*fundamentally*) in Spanish, both of them closely related, or the closest neighbor for *dirt* being *mugre* (*dirt*) instead of *suciedad* (*dirt*), which in fact was among the five closest neighbors. We can also find multiple examples of the higher performance of our models compared to the baselines. For instance, in the English-Spanish cross-lingual models, after the initial alignment, we can find that *seconds* has *minutos* (*minutes*) as nearest neighbour, but after applying our additional transformation, *seconds* becomes closest to *segundos* (*seconds*). Similarly, *paint* initially has *tintado* (*tinted*) as the closest Spanish word, and then *pintura* (*paint*).

4.2.2 Word similarity

We perform experiments on both monolingual and cross-lingual word similarity. In monolingual similarity, models are tested in their ability to determine the similarity between two words in the same language, whereas in cross-lingual similarity the words belong to different languages. While in the monolingual setting the main objective is to test the quality of the monolingual subsets of the bilin-

---

[6] The results on this task are lower than those reported in Artetxe et al. (2017). This is due to the different corpora and embedding algorithms used to train the monolingual embeddings. In particular, they use corpora including Wikipedia, which is comparable across languages.

Table 2: Monolingual word similarity results. Pearson (r) and Spearman (ρ) correlation.

gual vector space, the cross-lingual setting constitutes a straightforward benchmark to test the quality of bilingual embeddings.

Experimental setting For monolingual word similarity we use the English SimLex-999 (Hill et al., 2015), and the language-specific versions of SemEval-17[7] (Camacho-Collados et al., 2017), WordSim-353[8] (Finkelstein et al., 2002), and RG-65 (Rubenstein and Goodenough, 1965). The corresponding cross-lingual datasets from SemEval-18, WordSim-353 and RG-65 were considered for the cross-lingual word similarity evaluation[9]. Cosine similarity is again used as comparison measure.

Results Tables 2 and 3 show the monolingual[10] and cross-lingual word similarity results[11], respectively. For both the monolingual and cross-lingual settings, we can notice that our models generally outperform the corresponding baselines. Moreover, in cases where no improvement is obtained, the differences tend to be minimal, with the exception of RG-65, but this is a very small test set for which larger variations can thus be expected. In contrast, there are a few cases where substantial gains were obtained by using our model. This is most notable for English WordSim and SimLex in the monolingual setting.

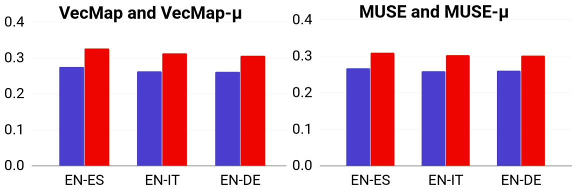

Figure 1: Comparative average similarity between `VecMap` and `MUSE` (blue) and our proposed model (red) on the SemEval cross-lingual similarity datasets.

Analysis In order to further understand the movements of the space with respect to the original `VecMap` and `MUSE` spaces, Figure 1 displays the average similarity values on the SemEval cross-lingual datasets (the largest among all benchmarks) of each model. As expected, the figure clearly shows how our model consistently brings the words from both languages closer on all language pairs. Furthermore, this movement is performed smoothly across all pairs, i.e., our model does not make large changes to specific words but rather small changes overall. This can be verified by inspecting the standard deviation of the difference in similarity after applying our transformation. These standard deviation scores range from 0.031 (English-Spanish for `VecMap`) to 0.039 (English-Italian for `MUSE`), which are relatively small given that the cosine similarity scale ranges from -1 to 1.

As a complement of this analysis we show some qualitative results which give us further insights on the transformations of the vector space after our average approximation. In particular, we analyze the reasons behind the higher quality displayed by our bilingual embeddings in monolingual settings. While `VecMap` and `MUSE` do not transform the initial monolingual spaces, our model transforms both spaces simultaneously. In this analysis we focus on the source language of our experiments (i.e., English). We found interesting patterns which are learned by our model and

---

[7] The original datasets of SemEval-17 contained also multiwords, but for consistency we use the version containing single words only.

[8] WordSim datasets consist of the similarity re-scoring for several languages of Leviant and Reichart (2015), downloaded from `http://leviants.com/ira.leviant/MultilingualVSMdata.html`

[9] The WordSim-353 and RG-65 cross-lingual datasets (Camacho-Collados et al., 2015) were downloaded at `http://lcl.uniroma1.it/similarity-datasets/`

[10] The English results correspond to the averaged performance of the English fragments of English-Spanish, English-Italian and English-German cross-lingual embeddings.

[11] The results of the original `VecMap` in cross-lingual similarity are comparable or better to those reported in Artetxe et al. (2017) on the three datasets used in their evaluation.

Table 3: Cross-lingual word similarity results. Pearson (r) and Spearman (ρ) correlation.

help understand these monolingual gains. For example, a recurring pattern is that words in English which are translated to the same word, or to semantically close words, in the target language end up closer together after our transformation. For example, in the case of English-Spanish the following pairs were among the pairs whose similarity increased the most by applying our transformation: *cellphone-telephone*, *movie-film*, *book-manuscript* or *rhythm-cadence*, which are either translated to the same word in Spanish (i.e., *teléfono* and *película* in the first two cases) or are already very close in the Spanish space. More generally, we found that word pairs which move together the most tend to be semantically very similar and belong to the same domain, e.g., *car-bicycle*, *opera-cinema*, or *snow-ice*.

4.2.3 Cross-lingual hypernym discovery

Modeling hypernymy is a crucial task in NLP, with direct applications in diverse areas such as semantic search (Hoffart et al., 2014; Roller and Erk, 2016), question answering (Prager et al., 2008; Yahya et al., 2013) or textual entailment (Geffet and Dagan, 2005). Hypernyms, in addition, are the backbone of lexical ontologies (Yu et al., 2015), which are in turn useful for organizing, navigating and retrieving online content (Bordea et al., 2016). Thus, we propose to evaluate the contribution of cross-lingual embeddings towards the task of hypernym discovery, i.e., given an input word (e.g., *cat*), retrieve or discover its most likely (set of) valid hypernyms (e.g., *animal*, *mammal*, *feline*, and so on). Intuitively, by leveraging a bilingual vector space condensing the semantics of two languages, one of them being English, the need for large amounts of training data in the target language may be reduced.

Experimental setting We follow Espinosa-Anke et al. (2016) and learn a (cross-lingual) linear transformation matrix between the hyponym and hypernym spaces, which is afterwards used to predict the most likely (set of) hypernyms, given an unseen hyponym. Training and evaluation data come from the SemEval 2018 Shared Task on Hypernym Discovery (Camacho-Collados et al., 2018). Note that current state-of-the-art systems aimed at modeling hypernymy (Shwartz et al., 2016; Bernier-Colborne and Barriere, 2018) combine large amounts of annotated data along with language-specific rules and cue phrases such as Hearst Patterns (Hearst, 1992), both of which are generally scarcely (if at all) available for languages other than English. Therefore, we report experiments with training data only from English (11,779 hyponym-hypernym pairs), and "enriched" models informed with relatively few training pairs (500, 1k and 2k) from the target languages. Evaluation is conducted with the same metrics as in the original SemEval task, i.e., Mean Reciprocal Rank (MRR), Mean Average Precision (MAP) and Precision at 5 (P@5). These measures explain a model's behavior from complementary prisms, namely how often at least one valid hypernym was highly ranked (MRR), and in cases where there is more than one correct hypernym, to what extent they were all correctly retrieved (MAP and P@5). Finally, as in the previous experiments, we report comparative results between our proposed models and the two competing baselines (`VecMap` and `MUSE`). As an additional informative baseline, we include the highest scoring unsupervised system at the SemEval task for both Spanish and Italian (`BestUns`), which is based on the distributional models described in Shwartz et al. (2017).

Results The results listed in Table 4 indicate several trends.[12] First and foremost, in terms of

---

[12] Note that this task is harder than hypernymy detection (Upadhyay et al., 2018). Hypernymy detection is framed as a binary classification task, while in hypernym discovery hypernyms have to be retrieved from the whole vocabulary.

Train data	Model	Spanish			Italian		
		MAP	MRR	P@5	MAP	MRR	P@5

Table 4: Results on the hypernym discovery task.

model-wise comparisons, we observe that our proposed alterations of both `VecMap` and `MUSE` improve their quality in a consistent manner, across most metrics and data configurations. In Italian our proposed model shows an improvement across all configurations. However, in Spanish `VecMap` emerges as a highly competitive baseline, with our model only showing an improved performance when training data in this language abounds (in this specific case there is an increase from 17.2 to 19.5 points in the MRR metric). This suggests that the fact that the monolingual spaces are closer in our model is clearly beneficial when hybrid training data is given as input, opening up avenues for future work on weakly-supervised learning. Concerning the other baseline, `MUSE`, the contribution of our proposed model is consistent for both languages, again becoming more apparent in the Italian split and in a fully cross-lingual setting, where the improvement in MRR is almost 3 points (from 10.6 to 13.3). Finally, it is noteworthy that even in the setting where no training data from the target language is leveraged, all the systems based on cross-lingual embeddings outperform the best unsupervised baseline, which is a very encouraging result with regards to solving tasks for languages on which training data is not easily accessible or not directly available.

Analysis A manual exploration of the results obtained in cross-lingual hypernym discovery reveals a systematic pattern when comparing, for example, `VecMap` and our model. It was shown in Table 4 that the performance of our model gradually increased alongside the size of the training data in the target language until surpassing `VecMap` in the most informed configuration (i.e., EN+2k). Specifically, our model seems to show a higher presence of generic words in the output hypernyms, which may be explained by these being closer in the space. In fact, out of 1000 candidate hyponyms, our model correctly finds *person* 143 times, as compared to the 111 of `VecMap`, and this systematically occurs with generic types such as *citizen* or *transport*. Let us mention, however, that the considered baselines perform remarkably well in some cases. For example, the English-only `VecMap` configuration (EN), unlike ours, correctly discovered the following hypernyms for *Francesc Macià* (a Spanish politician and soldier): *politician*, *ruler*, *leader* and *person*. These were missing from the prediction of our model in all configurations until the most informed one (EN+2k).

5 Conclusions and Future Work

We have shown how to refine bilingual word embeddings by applying a simple transformation which moves cross-lingual synonyms closer towards their average representation. Before applying this strategy, we start by aligning the monolingual embeddings of the two languages of interest. For this initial alignment, we have considered two state-of-the-art methods from the literature, namely `VecMap` (Artetxe et al., 2017) and `MUSE` (Conneau et al., 2018), which also served as our baselines. Our approach is motivated by the fact that these alignment methods do not change the structure of the individual monolingual spaces. However, the internal structure of embeddings is, at least to some extent, language-specific, and is moreover affected by biases of the corpus from which they are trained, meaning that after the initial alignment significant gaps remain between the representations of cross-lingual synonyms. We tested our approach on a wide array of datasets from different tasks (i.e., bilingual dictionary induction, word similarity and cross-lingual hypernym discovery) with state-of-the-art results.

This paper opens up several promising avenues for future work. First, even though both languages are currently being treated symmetrically, the initial monolingual embedding of one of the languages may be more reliable than that of the other. In such cases, it may be of interest to replace the vectors $\vec{\mu}_{w,w'}$ by a weighted average of the monolingual word vectors. Second, while we have only considered bilingual scenarios in this paper, our approach can naturally be applied to scenarios involving more languages. In this case, we would first choose a single target language, and obtain alignments between all the other languages and this target language. To apply our model, we can then simply learn mappings to predict averaged word vectors across all languages. Finally, it would also be interesting to use the obtained embeddings in downstream applications such as language identification or cross-lingual sentiment analysis, and extend our analysis to other languages, with a particular focus on morphologically-rich languages (after seeing our success with Finnish), for which the bilingual induction task has proved more challenging for standard cross-lingual embedding models (Søgaard et al., 2018).

WikiAtomicEdits: A Multilingual Corpus of Wikipedia Edits for Modeling Language and Discourse

Manaal Faruqui* **Ellie Pavlick*** **Ian Tenney** **Dipanjan Das**
Google AI Language

Abstract

We release a corpus of 43 million *atomic edits* across 8 languages. These edits are mined from Wikipedia edit history and consist of instances in which a human editor has inserted a single contiguous phrase into, or deleted a single contiguous phrase from, an existing sentence. We use the collected data to show that the language generated during editing differs from the language that we observe in standard corpora, and that models trained on edits encode different aspects of semantics and discourse than models trained on raw, unstructured text. We release the full corpus as a resource to aid ongoing research in semantics, discourse, and representation learning.

1 Introduction

Written language often undergoes several rounds of revision as human authors determine exactly what information they want their words to convey. On Wikipedia, this process is carried out collectively by a large community at a rate of nearly two revisions per second (Yang et al., 2017). While Wikipedia's revision history contains arbitrarily complex edits, our corpus and analysis focuses on *atomic insertion edits*: instances in which an editor has inserted a single, contiguous span of text into an existing complete sentence (Table 1). This restriction allows us to make several assumptions which we believe make the data an especially powerful source of signal. Namely, we can assume that 1) some information was not communicated by the original sentence, 2) that information *should* have been communicated (according to a human editor), and 3) that information *is* communicated by the inserted phrase. Thus, we believe that a large data set of such edits is inherently valuable for researchers modeling inference and discourse and that the data can yield insights about representation at both the phrase and the sentence level.

Adding new relevant information

Table 1: Example atomic insertions (in bold) from the corpus and the types of semantic and discourse phenomena that such edits capture.

We mine Wikipedia edit history to create a corpus of 43 million atomic insertion and deletion edits covering 8 languages. We argue that the corpus contains distinct semantic signals not present in raw text. We thus focus our experiments on answering the following questions:

1. How is language that is inserted during editing different from general Wikipedia text?
2. What can we learn about language by observing the editing process that we cannot readily learn by observing only the final edited text?

Specifically, the contributions of this paper are:

- A new corpus (WikiAtomicEdits) of 26M atomic insertions and 17M atomic deletions covering 8 languages (§3 and §4): `http://goo.gl/language/wiki-atomic-edits`.
- Linguistic analysis showing that inserted language differs measurably from the language observed in general Wikipedia text (§5).

---

*Both authors contributed equally.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 305–315
Brussels, Belgium, October 31 - November 4, 2018.

- Language modeling experiments showing that models trained on WikiAtomicEdits encode different aspects of semantics and discourse than models trained on raw, unstructured text (§6).

2 Theoretical Motivation

We borrow the idea of an *atomic edit* from prior work in natural language inference, specifically natural logic (Lakoff, 1970; Van Benthem, 1986). MacCartney (2009) defines an atomic edit e applied to a natural language expression s as the insertion, deletion, or substitution of a sub-expression p such that both the original expression s and the resulting expression $e(s)$ are well-formed semantic constituents. E.g. s = *"She died from an illness"*, p = *"in 1949"*, and $e(s)$ = *"She died in 1949 from an illness"*. This formulation is desirable because it exposes a relationship between the surface form and the semantics of natural language while remaining agnostic about the underlying semantic representation. That is, the difference in "meaning" between s and $e(s)$ is exactly the "meaning" of p (in context), regardless of how that meaning is represented.

We adopt this philosophy in creating our corpus. We focus our analysis specifically on atomic insertion edits. We make the assumption that editors on Wikipedia are attempting to communicate true information[1] and to do so effectively. Insertion edits are thus particularly interesting because the underlying generation process admits the following assumptions:

1. The original sentence s does not effectively communicate some piece of information.
2. A reasonable reader of s would like/expect this information to be communicated.
3. This information is communicated by the inserted phrase p (in the context of $e(s)$).

We therefore believe that the supervision provided by insertion edits can improve our understanding of semantics, discourse, and composition, and that the data released will be valuable for research in these areas. The goal of our experiments is to establish that the signal provided in these edits is distinct from what one could easily obtain given currently available text corpora.

Language	Ins	Del	Total
German	3.3	1.9	5.2
English	13.7	9.3	23.0
Spanish	1.4	0.9	2.3
French	2.0	2.0	4.0
Italian	1.0	0.6	1.6
Japanese	2.2	1.3	3.5
Russian	1.4	0.9	2.3
Chinese	0.7	0.4	1.1
Total	25.7	17.2	42.9

Table 2: The number of instances (in millions) of atomic insertions/deletions for each language.

3 WikiAtomicEdits: Corpus Creation

3.1 Extracting Edits

Wikipedia edits can be accessed through Wikipedia dumps. The edits are stored as diffs on the entire Wikipedia page, meaning some processing is required to reconstruct the changes that were made at the sentence level. We use historical snapshots of each Wikipedia document and compare against subsequent snapshots to extract sentence-level edits. We strip the HTML tags and Wikipedia markup of the page and then run a sentence splitter (Gillick, 2009) to obtain a list of sentences for each snapshot. Rather than run a full, quadratic-time (Myers, 1986) sequence alignment to compare the two lists of sentences, which is infeasible for long articles, we propose an efficient precision-oriented approximation.

Given n sentences in one snapshot ("base") and m sentences in a subsequent one ("edited"), we assume that most edits are local and restrict our attention to a fixed-size window. For each sentence s_i in the base snapshot, we compute pairwise BLEU scores (Papineni et al., 2002) between s_i and the sentences $\{t_j\}_{j=i-k}^{i+k}$ ($k = 5$) in the edited snapshot. We consider the sentence with the highest BLEU score in this window as a candidate. If the sentences are not identical and the difference consists of an insertion or deletion of a single contiguous phrase[2], we add this example to the corpus. For each article, we run this algorithm over the most recent 100,000 snapshots as of February 2018. We extract edits for 8 languages. Statistics are shown in Table 2.

---

[1] This is true for the majority of edits, although about 13% of edits are "spam" (§4.3).

[2] We use the Python 2.7 `difflib` library to compute a minimal diff at the byte level.

3.2 Insertions vs. Deletions

We use the algorithm described above to extract both atomic insertions and atomic deletions. However, we chose to omit the deletions from our linguistic (§5) and language modeling (§6) analyses for two reasons. First, our intuition is that spans which are deleted by an editor are more likely to be "bad" phrases (e.g. spam, false information, or grammatical errors introduced by a previous editor). To confirm this, we manually inspected 100 of each type of edit. We found that indeed deletions contained a higher proportion of spam text and malformed English (16/100) than did insertions (7/100). Second, while insertions permit a clean set of assumptions about the relationship between the original sentence and the edited sentence (§2), it is more difficult to make generalizations about deletions. Specifically, it is difficult to say whether the original sentence *should not* communicate the information in the deleted phrase (i.e. the phrase contains false, irrelevant, or otherwise erroneous information) or rather the original sentence/surrounding context *already communicates* the information in the deleted phrase (i.e. the deleted phrase is redundant). As such, deletions are a noisier target for analysis. Nonetheless, we recognize that the deletions provide a related and likely useful signal. We thus include deletions in our corpus but leave their deeper linguistic analysis for future work.

4 Corpus Quality & Reproducibility

4.1 Annotation

Given the data collected as above, we now investigate whether the extracted edits are sufficiently clean to be useful for computational language analysis and modeling. To do this, we focus our attention specifically on the English, Spanish, and German subcorpora, as these are languages for which we could find a sufficient number of native speakers to perform the necessary annotation for our analysis. Thus, the discussion and results in this section may not be representative of the other languages in the corpus.

We are interested specifically in two questions. First, we want to measure the overall corpus quality: how many of the inserted phrases represent meaningful edits and how many are simply noise (e.g. from editor or preprocessing error)? Second, we want to understand, at least in part, the reproducibility of the corpus: could we expect a different group of human editors to produce the same edits as those observed?

	en	es	de
No Error	78%	55%	85%
Possible Error	13%	30%	9%
Clear Error	9%	15%	6%

Table 3: Corpus quality for three languages for which we were able to collect annotations. "No Error"/"Clear Error" means annotators agreed unanimously that the edit was/was not an error; "Possible Error" means annotations were mixed.

To address these questions, we collect annotations in a semi-generative manner. Each annotator is shown a sentence s and a phrase p to be inserted, and is asked to insert p into s in order to form a new sentence $e(s)$. If s is not a complete and well-formed sentence, or if there is no location at which p can be inserted such that $e(s)$ would be a complete and well-formed sentence, annotators are instructed to mark the edit as an error. We use the "error" labels in order to study corpus quality (§4.2) and use the annotators' insertion location to estimate reproducibility (§4.3).

We collect labels for 5,000 English edits, and 1,000 each for Spanish and German edits using a crowd-sourcing platform. We collect 5-way annotations for English and 3-way annotations for Spanish and German. Our choices of languages and the differing levels of redundancy were due to availability of annotators. We will release these 7,000 edits and their annotations with the corpus.

4.2 Corpus Quality

To measure corpus quality, we compute the proportion of edits marked as errors by our annotators. Table 3 shows our results. For English, in 78% of cases our annotators agreed unanimously that p could be inserted meaningfully into s (55% for Spanish; 85% for German). These numbers reassure us that, while there is some noise, the majority of the corpus represents legitimate edits with meaningful signal. For more discussion of the errors refer to Supplementary Material.

4.3 Agreement and Ambiguity

We next explore the extent to which the edits in the corpus are reproducible. In an ideal world, we would like to answer the question: given the same original sentences, would a different group of human editors produce the same edits? Answering this directly would require annotators with domain expertise and is infeasible in practice. However, we can use our crowdsourced annotation to answer a restricted variant of this question: given a sentence s and an insertable phrase p, do humans agree on where p belongs in s? We can measure agreement in this setting straightforwardly using exact match, and can interpret human performance as that of a "perfect" language model. I.e. we can interpret disagreement as evidence that reproducing the particular edit is dependent on exogenous information not available in the language of s alone (e.g. knowledge of the underlying facts being discussed, or of the author's individual style).

Based on our annotation experiment, we find that individual annotators agree with the original editor 66% of the time for English, 72% for Spanish, and 85% for German.[3] More interesting than how often humans disagree on this task, however, is *why* they disagree. To better understand this, we take a sample of 100 English sentences in which at least one human annotator disagreed with the original editor and no annotator marked the edit as an error. We then manually inspect the sample and record whether or not the annotators' choices of different insertion points give rise to sentences with different semantic meaning or simply to sentences with different discourse structure.

In particular, we consider three categories for the observed disagreements: 1) the sentences are **meaning equivalent** from a truth-conditional perspective, 2) the sentences contain **significant differences in meaning** from a truth-conditional perspective, or 3) the sentences contain **minor differences or ambiguities** in meaning (but would likely be considered equivalent from the point of view of most readers). We also include an error category, for when the disagreement stems from a single annotator making an erroneous choice. Examples of each category are given in Table 4. Note that the assessment of the truth conditions of the sentence and their equivalence is based on our judgment, and many of these judgments are subjective. We will release our annotations for this analysis with the corpus, to enable reproducibility and refinement in future research.

Table 5 shows our results. We found 49% to be meaning equivalent (i.e. the edit's location effected discourse structure only), and 22% to have significant differences in meaning (i.e. the edit's location fundamentally changed the meaning of the sentence). An additional 13% exhibited minor differences or ambiguities in meaning, and in the remaining 16% of cases, the disagreement appeared to be due to annotator error.

5 Corpus Linguistic Analysis

We now turn our attention to exploring the language in the corpus itself. In this section and in §6, our focus is on the questions put forth in the introduction: 1) how does the language that is inserted during editing differ from language that is observed in general? and 2) what can we learn about language by observing the editing process that we cannot readily learn by observing only raw text? Here, we explore these questions from a corpus linguistics perspective. The analysis in this section is based predominantly on the 14M insertion edits from the English subcorpus (Table 2).

5.1 Manual Categorization of Insertions

We first characterize the types of insertions in terms of the function they serve. Manually inspecting the edits, we identify four high-level categories. Note that we do not intend these categories to be formal or exhaustive, but rather to be illustrative of the types of semantic and discourse phenomena in the corpus: i.e. to give sense of the balance between semantic, pragmatic, and grammatical edits in the corpus. The categories we identify are as follows:

1. **Extension**: the explicit addition of new information that the author of the original sentence did *not* intend to communicate.[4]
2. **Refinement**: the addition of information that the author of the original sentence either intended to communicate or assumed the reader would already know. This category includes hedges, non-restrictive modifiers, and other clarifications or scoping-down of claims.
3. **Fluency / Discourse**: grammatical fixes, as well as the insertion of discourse connectives (*"thus"*), presuppositions (*"also"*), and editorializations (*"very"*).

---

[3] We consider cases which the annotator marks as "error" to be a disagreement with the original editor.

[4] Whether or not the author "intended" to communicate something is based on our judgment. Since this annotation is intended to be exploratory, we allow a degree of informality.

Meaning Equivalent
Paul Wheelahan**, the son of a mounted policeman,** was born in Bombala, South Wales...
Paul Wheelahan was born in Bombala, South Wales**, the son of a mounted policeman,**...
Minor Difference / Ambiguity
She moved to Australia **in 1964** and attended the University of New South Wales...

Significant Difference in Meaning
...he and Bart have to share a raft with Ned Flanders and **his youngest son,** Todd Flanders.
...he and **his youngest son,** Bart have to share a raft with Ned Flanders and Todd Flanders.

Table 4: Examples of sentences falling into three disagreement categories, defined in terms of the truth conditions of the edited sentence. See text for a more detailed explanation.

Meaning Equivalent	49
Significant Differences in Meaning	22
Minor Differences/Ambiguities	13
Annotator Error	16

Table 5: Analysis of 100 sentences for which at least one annotator disagreed with the gold label and no annotator marked as an error.

4. **Referring Expressions** (RE): changes in the name of an entity that do not change the underlying referent, such as adding a first name (*"Andrew"*) or a title (*"Dr."*). RE edits could fall within our definition of "refinement", but because they are especially prevalent we annotate them as a separate category.

We also define an **Error** category for spam, vandalism, and other "mistake" edits.

We manually categorize 100 randomly-sampled edits. The breakdown is shown in Table 6. In our sample, the majority (43%) were extensions, and the second most frequent where refinements (24%). No single category dominates and all are well-represented, suggesting that a variety of phenomena can be studied using this corpus.

5.2 Comparing Insertions to Raw Text

Understanding the high-level functions of edits, as above, provides some insight into the type of linguistic signals contained in the data. However, we are particularly interested in whether the language used for these functions is noticeably different from general Wikipedia text. That is: it is not obvious that the language humans use to e.g. extend or refine an existing claim should necessarily be different, in aggregate, from the language used to formulate these claims in general. We thus explore whether this is the case.

We first compare the distribution of parts of speech observed for the inserted phrases to the distribution of parts of speech that we observe in Wikipedia overall–i.e. in the sentences appearing in the final, published version of Wikipedia, not only the edit history. In order to compare the relative frequencies in a straightforward way, we look only at edits in which a single word was inserted.[5] Figure 1 shows our results for English, Spanish, and German. We see, for example, that in English, adjectives and adverbs combined make up nearly 30% of all inserted words, three and a half times higher than the frequency of adjectives/adverbs observed in the general Wikipedia corpus, and that proper nouns are inserted at a higher rate than would be suggested given their base frequency.

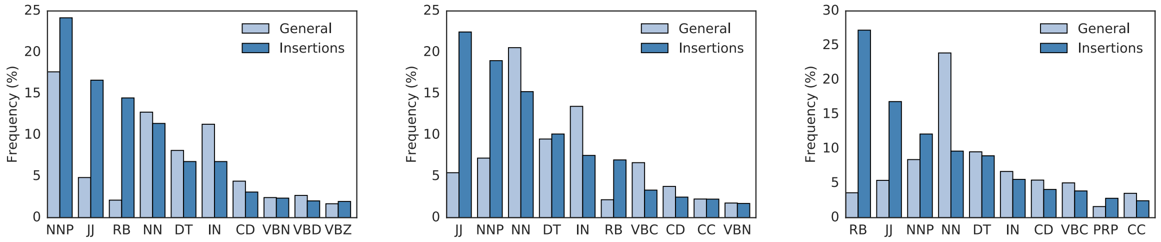
Looking more carefully, we see that the nature of the edits for each part of speech are qualitatively different as well. To explore this further, we look at which words appear at substantially higher rate as insertions than they do in the general Wikipedia corpus. We compute this as follows: for a word w with part of speech pos, we compute the number of times w occurs as an insertion per thousand insertions of any word of type pos, and compare this to the rate of occurrence of w per thousand occurrences of any word of type pos within the general Wikipedia corpus. Table 7 shows our results for English (Spanish and German are given in the Supplementary Material). In particular, we see that many words which are inserted at a significantly higher-than-baseline rate reflect "refinement"-type edits. Many of these are words which the original author may have commu-

---

[5] In our corpus 30% of inserted phrases are a single word, and 70% are less than five words. We compared frequencies for longer POS sequences as well, but it did not yield particular insight over looking at single POS tags.

Category	Freq.	Example
Extend	43%	The population was 39,000 in 2004**, measured at 29,413 at the 2011 Census**.
Refine	24%	. . . began an investigation into Savile 's **apparent** history of abuse. . .
RE	11%	**Andrew** Sugerman has been involved in the production of motion pictures. . .
Fluency	9%	Philippine coconut jam**, meanwhile,** is made from coconut cream. . .
Error	13%	The team **are well - known as a loser team in the past 5 years.The team** is. . .

Table 6: High-level categories into which we manually characterize edits, to understand the variety of phenomena captured by the corpus. Frequencies are based on our annotation of a sample of 100 edits.



(a) English (b) Spanish (c) German

Figure 1: Most frequent POS tags for English, Spanish, and German single-word insertions. Dark blue bars show the relative frequency among inserted phrases and light blue bars show the relative frequency among phrases observed in Wikipedia in general.

nicated implicitly but the editor chose to state explicitly, such as whether or not a person is a *"current"*/*"former"* public figure[6] or is *"famous"*. On the other hand, words which are inserted at a significantly lower-than-baseline rate are those which would be unlikely to be omitted by the original author. For example, if an event is famously the *"first"* or the *"only"* one of its kind, it is highly unlikely for the original author describing that event not to use these words explicitly.

6 Language Modeling Analysis

We next explore the corpus from a language modeling perspective. Again, we are interested in understanding how the signal captured by the editing process is distinct from that captured by the final edited text alone, and in characterizing the types of signals we can learn from modeling the insertions directly. We investigate this through two tasks: first, given a sentence s and insertable phrase p, predict the index i at which p should appear in s (§6.1), and second, given a sentence s and an index i, generate candidate phrases that would be appropriate to insert into s at i (§6.2).

	NNP	JJ	RB
Over	City 16:2 Sir 7:1 US 7:1 John 6:3 Roman 4:1	former 34:6 current 11:2 famous 9:2 professional 10:3 fictional 5:1	also 187:91 currently 40:7 very 24:11 then 45:33 allegedly 10:1
Under	New 1:5 United 2:5 I 2:4 9 de 2:4 School 1:3	first 9:29 only 2:20 other 12:26 total 2:13 such 3:13	not 35:96 first 9:68 all 1:35 only 22:47 about 4:29

Table 7: Words that appear as insertions at significantly higher rates (top row) and significantly lower rates (bottom row) than their rate of occurance in Wikipedia in general. We compute "rate" as simply the observed occurrence of the given word per thousand occurrences of any word with the given POS. Table shows each word followed by (rate as insertion):(rate in general)

6.1 Predicting Insertion Locations

Task. This task–given a phrase p and a sentence s, choose the best index i in s at which to insert p–is identical to the task we asked humans to perform in §4. We consider two simple models for performing this task: a basic language model and a discriminative model trained on the insertion data. We report performance as overall accuracy. We analyze whether a model which is trained to

---

[6] We note that the addition of *"former"* is likely tied to changes in the real world (Wijaya et al., 2015).

model insertions directly captures something different than a general language model in terms of the types of errors each model makes.

Models. We evaluate two models. First, we evaluate a standard language modeling baseline (**General LM**), in which we simply insert the phrase p at every possible point in s and chose the index which yields the lowest perplexity. We use the LSTM language model from Jozefowicz et al. (2016), which obtained SOTA results on language modeling on the one billion words benchmark for English (Chelba et al., 2013). We train this language model for each language on an average of $\sim$ 500 million tokens from Wikipedia. Second, we evaluate a discriminative model specifically trained on the insertion data (**Discriminative Model**). This model represents the base sentence using a sentence encoder that produces a context-dependent representation of every word index in the sentence, and then at test time, compares the learned representation of each index with the representation of the phrase p to be inserted. We use a 256-dimensional 2-layer biLSTM encoder, initialized with FastText 300-dimensional word vectors (Mikolov et al., 2018; Grave et al., 2018).[7] We hold out 50K and 10K insertion edits for each language as development and test sets, and use the remaining edits (insertions and deletions) as training data. This provides us with at least 1 million examples for training in each language (cf. Table 2). See Supplementary Material for additional details.

Results. Table 8 shows the accuracy of each model for each language. We see that the discriminitve model trained on insertions directly performs better than the general LM by at least 1% absolute accuracy on every language, and by 3.8% absolute on average. It is worth emphasizing that this performance improvement is despite the fact that the general LM was trained with, on average, four times the number of tokens[8] and is a much larger model–the general LM has $\sim$ 2 billion parameters (Jozefowicz et al., 2016) compared to $\sim$ 1 million for the discriminative model.

	General LM	Discr. Model
German	68.1	72.9
English	58.7	68.4
Spanish	67.0	70.1
French	69.9	73.4
Italian	69.0	72.9
Japanese	73.0	74.2
Russian	72.9	74.3
Chinese	65.5	68.9
Average	68.0	71.8

Table 8: Insertion accuracy on the test set.

More interesting than raw performance is the difference in the types of errors that the models make. For each model, we take a random sample of 50 examples on which the model made a correct prediction and 50 examples on which the model made an incorrect prediction. We annotate these 200 examples[9] according to the edit type classification discussed in §5.1. Table 9 shows the results. We find a significant difference[10] ($p < 0.01$) between the types of edits on which the General LM makes correct predictions and the types on which it makes incorrect predictions. Specifically, the General LM appears to be especially good at predicting location for fluency/discourse edits, and especially poor at predicting the location of refinement edits. In contrast, we do not see any significant bias in the errors made by the discriminative model compared to its correct predictions ($p = 0.23$). We interpret this as evidence that the insertion data captures some semantic signal that is not readily gleaned from raw text corpora.

6.2 Predicting Insertion Phrases

Task. In a final set of experiments, we explore a generative version of the language modeling task: given a sentence s and an specified index i, generate a phrase p which would be appropriate to insert into s at i. We are interested in what such a model can learn about the nature of how sentences are extended: what type of information would be relevant from a semantic perspective, and natural from a discourse perspective to insert at a given point? We train two models for this task, one trained on the training split of the WikiAtomicEdits corpus, and one baseline trained on a comparable set of phrasal insertions not derived from human edits. We evaluate on the same 10K held-out insertion

---

[7] `https://fasttext.cc/docs/en/crawl-vectors.html`

[8] The number of tokens in the WikiAtomicEdits is computed as the the total number of words in the edited sentence $e(s)$ after the insertion. Refer to Supplementary Material for more detailed statistics on the size of the dataset.

[9] To avoid bias, the 200 examples are shuffled and the annotator does not know which group (correct/incorrect, or which model) each example belongs to.

[10] We use the chi-squared test provided by scipy.stats.

	Base Freq.	General LM		Discr. Model	
		✓	✗	✓	✗
Extend	25	21	19	25	21
Refine	14	7	18	13	14
RE	6	7	9	4	9
Fluency	5	15	4	8	6

Table 9: Relationship between model accuracy and insertion type, based on a sample of 50 correct (✓) and 50 incorrect (✗) predictions from each model. Base frequency is shown for reference and is based on our analysis from §5.1. The General LM shows a bias in accuracy by insertion type. This bias is not observed for the discriminative model.

edits as in §6.1, and measure performance using both a strict "exact match" as well as a softer similarity metric.

Model. We use an standard sequence-to-sequence model (Sutskever et al., 2014), modifying the input with a special token denoting the insertion point. For example, given the input [*" Angel " is a song recorded by <ins> pop music duo Eurythmics .*], the model would be trained to produce the target phrase [*the British*]. We use a two-layer bidirectional encoder using the same 300-dimensional FastText embeddings as in §6.1, and a sequence decoder with attention (Bahdanau et al., 2015) using a learned wordpiece model (Schuster and Nakajima, 2012) with a vocabulary of 16,000.

Experimental Design. We train one version of this model on the same set of 23M English examples as the discriminative insertion model from §6.1; we refer to the model trained on this data as **Edits**. For comparison, we train an identical model on a set of simulated insertions which we create by sampling sentences from Wikipedia and removing contiguous spans of tokens, which we then treat as the insertion phrases. To ensure that this data is reasonably comparable to the WikiAtomicEdits data, we parse the sampled sentences (Andor et al., 2016) and only remove a span if it represents a full subtree of the dependency parse and is not the subject of the sentence.[11] We generate 23M such "psuedo-edits" for training, the same size as the WikiAtomicEdits training set. We refer to the model trained on this data as **General**.

Results. We look at the top 10 phrases proposed by each model, as decoded by beam search. In addition to reporting standard LM perplexity, we compute two measures of performance, which are intended to provide an intuitive picture of how well each model captures the nature of the information that is introduced by the human editors. Specifically, we compute **Exact Match** as the proportion of sentences for which the model produced the gold phrase (i.e. the phrase inserted by the human editor) somewhere among the top 10 phrases. We also compute **Similarity@1** as the mean cosine similarity of each top-ranked phrase and respective gold phrase over the test set. We use the sum of the Glove embeddings (Pennington et al., 2014) of each word in the phrase as a simple approximation of the phrase vector.

Table 11 shows the results. We see that, compared to the model trained on General Wikipedia, the model trained on WikiAtomicEdits generates edits which are more similar to the human insertions, according to all of our metrics. Table 10 provides a few qualitative examples of how the phrases generated by the Edits model differ from those generated by the General model. Specifically, we see that the Edits model proposes phrases which better capture the discourse function of the human edit: e.g. providing context for/elaboration on a previously-stated fact. We note that this does not mean that training on Edits is inherently "better" than on General text, but rather that the supervision encoded by the WikiAtomicEdits corpus encodes aspects of language that are distinct from those easily learned from existing resources.

7 Related Work

Wikipedia Edits. Wikipedia edit history has been used as a source of supervision for a variety of NLP tasks, including sentence compression and simplification (Yamangil and Nelken, 2008; Yatskar et al., 2010), paraphrasing (Max and Wisniewski, 2010), entailment (Zanzotto and Pennacchiotti, 2010; Cabrio et al., 2012), and writing assistance (Zesch, 2012; Cahill et al., 2013; Grundkiewicz and Junczys-Dowmunt, 2014). User edits from Wikipedia and elsewhere have also been analyzed extensively for insight into the editing process and the types of edits made (Daxenberger and Gurevych, 2012, 2013; Yang et al., 2017)

---

[11] Not all of the inserted phrases in WikiAtomicEdits are well-formed constituents. However, generating psuedo-edits using this heuristic provided a cleaner, more realistic comparison than using fully-random spans.

and to better understand argumentation (Tan and Lee, 2014). Particular attention has been given to spam edits (Adler et al., 2011) and editor quality (Leskovec et al., 2010). Our work differs in that WikiAtomicEdits is much larger than currently available corpora, both by number of languages and by size of individual languages. In addition, our focus on atomic edits should facilitate more controlled studies of semantics and discourse.

Sentence Representation and Generation. We view the WikiAtomicEdits corpus as being especially valuable for ongoing work in sentence representation and generation, which requires models of what “good” sentences look like and how they are constructed. Recent work has attempted to model sentence generation by re-writing existing sentences, either using crowdsourced edit examples (Narayan et al., 2017) or unsupervised heuristics (Guu et al., 2018); in contrast, we provide a large corpus of natural, human-produced edits.

Also related is recent work in sentence representation learning from raw text (Kiros et al., 2015; Peters et al., 2018), bitext (McCann et al., 2017), and other supervised tasks including NLI (Conneau et al., 2017). Especially related is work on learning representations from weakly-labelled discourse relations (Nie et al., 2017; Jernite et al., 2017), as the WikiAtomicEdits corpus captures similar types of discourse signal.

Description of Data Release

Our full corpus is available for download at `http://goo.gl/language/wiki-atomic-edits`. The data contains 26M atomic insertions and 17M atomic deletions covering 8 languages. All sentences (both the original sentence s, and the edited sentence $e(s)$) have been POS-tagged and dependency parsed (Andor et al., 2016) as well as scored using a SOTA LM (Jozefowicz et al., 2016). We also release the 5K 5-way human insertion annotations for English, and 1K 3-way annotations each for Spanish and German, as described in §4.

8 Conclusion

We have introduced the WikiAtomicEdits corpus, derived from Wikipedia’s edit history, which contains 43M examples of atomic insertions and deletions in 8 languages. We have shown that the language in this corpus is meaningfully different from the language we observe in general, and that models trained on this corpus encode different aspects of semantics and discourse than models trained on raw text. These results suggest that the corpus will be valuable to ongoing research in semantics, discourse, and representation learning.

Abstract

A key challenge in cross-lingual NLP is developing general language-independent architectures that are equally applicable to any language. However, this ambition is largely hampered by the variation in structural and semantic properties, i.e. the typological profiles of the world's languages. In this work, we analyse the implications of this variation on the language modeling (LM) task. We present a large-scale study of state-of-the art *n-gram based* and *neural* language models on 50 typologically diverse languages covering a wide variety of morphological systems. Operating in the *full vocabulary LM setup* focused on *word-level prediction*, we demonstrate that a coarse typology of morphological systems is predictive of absolute LM performance. Moreover, *fine-grained typological features* such as exponence, flexivity, fusion, and inflectional synthesis are borne out to be responsible for the proliferation of low-frequency phenomena which are organically difficult to model by statistical architectures, or for the meaning ambiguity of character n-grams. Our study strongly suggests that these features have to be taken into consideration during the construction of next-level language-agnostic LM architectures, capable of handling morphologically complex languages such as Tamil or Korean.

1 Introduction

Deep learning has allowed NLP algorithms to dispose of manually-crafted features, and to virtually achieve language independence. However, their performance still varies noticeably across languages due to different underlying data distributions (Bender, 2013; O'Horan et al., 2016). Linguistic typology, the systematic comparison of the world's languages, holds promise to explain these idiosyncrasies and interpret statistical models in terms of variation in language structures (Ponti et al., 2017).

In order to evaluate how cross-lingual structural variation hinders the design of effective general-purpose algorithms, we propose the task of language modeling (LM) as a testbed. In particular, we opt for a full-vocabulary setup where no word encountered at training time is treated as an unknown symbol, in order to **a)** ensure a fair comparison across languages with different word frequency rates and **b)** avoid setting an arbitrary threshold on vocabulary size (Cotterell et al., 2018).

Although there has recently been a tendency towards expanding test language samples, the datasets considered in previous works (Botha and Blunsom, 2014; Vania and Lopez, 2017; Kawakami et al., 2017; Cotterell et al., 2018) are not entirely adequate yet to represent the typological variation and to ground cross-lingual generalisations empirically. Hence, we test several LM architectures (including n-gram, neural, and character-aware models) on a novel and wider set of 50 languages sampled according to stratification principles.

Through this large-scale multilingual analysis, we shed new light on the current limitations of standard LM models and offer support to further developments in multilingual NLP. In particular, we demonstrate that the previous fixed-vocabulary assumption in fact ignores the limitations of language modeling for morphologically rich languages. Moreover, we find a strong correlation across the board between LM model performances and the type of morphological system adopted in each language.

To motivate this correlation we show how fine-grained typological properties interact with the frequency distribution (Zipf, 1949) by regulating word boundaries and the proliferation of word forms; and 2) with the mapping between morphemes (here intended as character n-grams) and meaning, by possibly blurring it.

The paper is organised as follows. After provid-

Brussels, Belgium, October 31 - November 4, 2018.

ing a short overview of multilingual LM and its possible setups (§2), we describe the cross-lingual variation in morphological systems and propose a novel typologically diverse dataset for LM in §3. We outline the data in §4 and benchmarked language models in §5. Finally, we discuss the results in light of linguistic typology in §6.

2 Multilingual Language Modeling

A language model computes a probability distribution over sequences of word tokens, and is typically trained to maximise the likelihood of word input sequences. The LM objective is expressed as:

$$P(w_1, ...w_n) = \prod_i P(w_i|w_1, ...w_{i-1}) \qquad (1)$$

w_i is a word token with the index i in the sequence. LM is considered a central task in NLP and language understanding, with applications in speech recognition (Mikolov et al., 2010), text summarisation (Filippova et al., 2015; Rush et al., 2015), and information retrieval (Ponte and Croft, 1998; Zamani and Croft, 2016). The importance of language modeling has been accentuated even more in representation learning recently, where it is used as a novel form of unsupervised pre-training (and an alternative to static word embeddings) for the benefit of a variety of NLP applications (Peters et al., 2018; Howard and Ruder, 2018).

Related Work: Datasets and Evaluation. Language modeling is predominantly tested on English and other Western European languages. Standard English LM benchmarks are the Penn Treebank (PTB) (Marcus et al., 1993) and the 1 Billion Word Benchmark (BWB) (Chelba et al., 2013). Datasets extracted from BBC News (Greene and Cunningham, 2006) and IMDB Movie Reviews (Maas et al., 2011) are also used for LM evaluation in English (Wang and Cho, 2016; Miyamoto and Cho, 2016; Press and Wolf, 2017).

For multilingual LM evaluation, Botha and Blunsom (2014) extract datasets for Czech, French, Spanish, German, and Russian from the 2013 Workshop on Statistical Machine Translation (WMT) data (Bojar et al., 2013). Kim et al. (2016) reuse these datasets and add Arabic. Ling et al. (2015) evaluate on English, Portuguese, Catalan, German and Turkish datasets extracted from Wikipedia. Kawakami et al. (2017) evaluate on 7 European languages using Wikipedia data, including Finnish.

To the best of our knowledge, the largest datasets used in previous work are from (Müller et al., 2012; Cotterell et al., 2018) and amount to 21 languages from the Europarl data (Koehn, 2005). Despite the large coverage of languages, these sets are still restricted only to the languages of the European Union. On the other hand, the most typologically diverse dataset thus far was released by Vania and Lopez (2017). It includes 10 languages representing some morphological systems.

This short survey of related work demonstrates a clear tendency towards extending LM evaluation to other languages, abandoning English-centric assumptions, and focusing on language-agnostic LM architectures. However, a comprehensive evaluation set that systematically covers a wide and balanced spectrum of typologically diverse languages is still missing. The novel dataset we discuss in this paper aims at bridging this gap (see §4).

Fixed vs. Full Vocabulary Setup. A majority of language models rely on the fixed-vocabulary assumption: they use a special symbol <UNK> that represents all words not present in the fixed vocabulary V, which are termed out-of-vocabulary (OOV). Selecting the set V typically slips under the radar, and can be seen as "something of a black art" despite its enormous impact on final LM performance (Cotterell et al., 2018).[1] Standard LM setups either fix the vocabulary V to the top n most frequent words, typically with $n = 10,000$ or $n = 5,000$ (Mikolov et al., 2010; Ling et al., 2015; Vania and Lopez, 2017; Lee et al., 2017, *inter alia*), or include in V only words with a frequency below a certain threshold (typically 2 or 5) (Heafield et al., 2013).

The rationale behind fixing the set V is **a)** to make the language model more robust to handling OOVs and to effectively bypass the problem of unreliable word estimates for low-frequency and unseen words (by ignoring them), and **b)** to enable direct comparisons of absolute perplexity scores across different models. However, this posits a critical challenge as cross-linguistic evaluation becomes uneven. In fact, we witness a larger proportion of vocabulary words replaced by <UNK> in morphologically rich languages because of their higher OOV rates (see Table 3). What is more, while the fixed-vocabulary assumption artificially

---

[1] For instance, Vania and Lopez (2017) report perplexity scores of ≈20 for Finnish when V is fixed to the $5k$ most frequent words. The same model in the full-vocabulary setup obtains perplexity scores of ≈2,000.

FI	*Kreikkalaiset sijoittivat geometrian synnyn muinaiseen Egyptiin , jossa sitä tarvittiin maanmittaukseen .*
FI (MIN-5)	*<UNK> <UNK> <UNK> synnyn <UNK> Egyptiin , jossa sitä tarvittiin <UNK> .*
FI (10K)	*<UNK> <UNK> <UNK> <UNK> <UNK> <UNK> , jossa sitä <UNK> <UNK> .*
KO	그 뒤 한시 백일장에서 장원하여 신동으로 알려졌다. 그러나 그의 집은 지독하게 가난했다 .
KO (MIN-5)	그 뒤 <UNK> <UNK> <UNK> <UNK> 알려졌다 . 그러나 그의 집은 <UNK> <UNK> .
KO (10K)	그 뒤 <UNK> <UNK> <UNK> <UNK> 알려졌다 . 그러나 그의 <UNK> <UNK> <UNK> .

Table 1: Examples from Finnish and Korean LM datasets after applying the standard fixed-vocabulary assumption. MIN=5: only words with corpus frequency above 5 are retained in the final fixed vocabulary V; 10K: V comprises the $10k$ most frequent words.

Type	Fusion	Exponence	Flexivity	Synthesis
Isolating	low	1:1	1:1	low
Fusional	mid	many:1	1:many	mid
Introflexive	high	many:1	1:many	mid
Agglutinative	mid	1:1	1:1	high

Table 2: Traditional morphological types described in terms of selected features from WALS.

improves the perplexity measure, it actually makes the models less useful, especially in morphologically rich languages, as exemplified in Table 1.

Our goal is to get a clear picture on how different typological features and the corresponding corpus frequency distributions affect LM performance, without the influence of the unrealistic fixed-vocabulary assumption. Therefore, we work in the *full-vocabulary LM setup* (Adams et al., 2017; Grave et al., 2017). This means that we explicitly decide to retain also infrequent words in the modeled data: V contains all words occurring at least once in the training set, only unseen words from test data are treated as OOVs. We believe that this setup leads to an evaluation that pinpoints the crucial limitations of standard LM architectures.[2]

Why Not Open Vocabulary Setup? Recent neural LM architectures have also focused on handling large vocabularies and unseen words using character-aware modeling (Luong and Manning, 2016; Jozefowicz et al., 2016; Kawakami et al., 2017, *inter alia*). This setup is commonly referred to as the *open-vocabulary* setup. However, two distinct approaches with crucial modeling differences are referred to by the same term in the literature. **a)** *Word-level generation* constructs word vectors for arbitrary words from constituent subword-level components, but word-level prediction is still evaluated based on the fixed-vocabulary assumption. **b)** *Character-level generation* predicts characters instead of words.

Given that character-level prediction and word-level prediction operate on entirely different sets of symbols, their performance is hardly comparable. Still, Jozefowicz et al. (2016) report that, in a hybrid setup which evaluates character-level prediction based on word-level perplexity with the fixed-vocabulary assumption, current state-of-the-art word-level prediction models (i.e., the ones we discuss in §5) still significantly outperform such hybrid character-level prediction approaches. Therefore, we operate in the full-vocabulary setup.

3 Typology of Morphological Systems

Aiming for a comprehensive multilingual LM evaluation in this study, we survey all possible types of morphological systems (Haspelmath and Sims, 2013), which possibly lead to different performances. Traditionally, languages have been grouped into the four main categories: *isolating*, *fusional*, *introflexive* and *agglutinative*, based on their position along a spectrum measuring the preference on breaking up concepts in many words (on one extreme) or rather compose them into single words (on the other extreme).

The mono-dimensionality of this spectrum has recently been challenged as languages exhibit a multitude of morphological features that do not covary across languages (Plank, 2017; Ponti et al., 2018). The typological database WALS (Dryer and Haspelmath, 2013) documents several of them that are relevant for LM: *inflectional synthesis*, *fusion*, *exponence*, and *flexivity*. Note that the prototypes of traditional categories can be approximated in terms of these features, as shown in Table 2, although more combinations are possible.

Languages specify different subsets of grammatical categories (such as tense for verbs, or num-

---

[2] For instance, as discussed later in §3 and validated empirically in §6, the vocabularies of morphologically rich languages are inherently larger: it is simply more difficult to learn and make LM predictions in such languages.

ber for nouns), and for each category different values are available in each language: for instance, Finnish has less tense values (it lacks a future), whereas Slovene has more number values (including a dual) compared to English. The feature **inflectional synthesis** for verbs (Bickel and Nichols, 2013) measures how many categories appear on the maximally inflected verb per language. More available categories enlarge the vocabulary (and consequently the OOV rate) with forms instantiating all possible combinations of their values.

Another crucial aspect is how the available grammatical categories are expressed, which can be described by fusion, exponence, and flexivity. **Fusion** measures the degree of connectedness between a grammatical marker to another word. The marker can be (from lower to higher fusion) a separate word, a clitic, an affix, or can affect the form of the root itself (e.g. an umlaut or a tone).

Exponence measures the number of categories (e.g., tense, number) a single morpheme tends to convey. Exponence is separative if one grammatical category is conveyed by one morpheme (1:1), and cumulative if multiple categories are grouped into one morpheme (many:1).

Flexivity indicates the possibility that the value of a grammatical category be mapped into different morphological forms (1:many). In other terms, lemmas belonging to the same part-of-speech are divided into inflectional classes (such as declension classes for nouns or conjugation classes for verbs), each characterised by a different paradigm, that is, a different set of value-to-form mappings.

The three last features are illustrated by the examples Ex. (2)-Ex. (5), all uttering the sentence "*I will guard the doors and I will not open (them)*".[3]

(2) *tôi* *sẽ* *bảo* *vệ* *cửa* *và* *tôi* *sẽ*
I FUT guard door and I FUT
không *mở*
NEG open (Vietnamese)

(3) *kapı-lar-ı* *koruy-acağ-ım* *ve*
door-PL-ACC guard-FUT-1SG and
aç-may-acağ-ım
open-NEG-FUT-1SG (Turkish)

(4) *sorvegli-erò* *le* *port-e* *e* *non*
guard-FUT.1SG DEF door-PL and NEG
apr-irò
open-FUT.1SG (Italian)

(5) *'e-šmor* *'al* *ha-d'lat-ót* *v'-lo*
1SG-guard.FUT on DEF-door-PL and-NEG
'e-ftach *otán*
1SG-wait.FUT them (Hebrew)

In particular, consider how tense and person are expressed on verbs. Vietnamese in Ex. (2) puts two particles *tôi* and *sẽ* before the verb, which are distinct (separate exponence), autonomous from the root (no fusion), and fixed (absence of flexivity). Turkish in Ex. (3) attaches suffixes: *-acak-* for tense and *-ım* for person. These are distinct (separate exponence), joined to the roots (concatenative fusion), and (phonologically determined variants of) the same morpheme (1:1 flexivity). Italian in Ex. (4) uses affixes *-erò* and *-irò*: they are concatenated to the root with respect to fusion, convey both tense and person (cumulative exponence), and are dissimilar (presence of flexivity). Finally, in Ex. (5) for Hebrew the consonant pattern of the verb *š-m-r* is interdigitated by the vowel *-o-* for tense, and preceded by a prefix *'e-* for person. The first phenomenon alters the root itself (introflexive fusion), is distinct from the second (separate exponence), and changes its realisation based on the verb's lemma (presence of flexivity).

The above evidence strongly motivates us, as well as recent previous work (Vania and Lopez, 2017; Kawakami et al., 2017; Cotterell et al., 2018), to approach LM with models that are aware of the inner structure of their input words, and to benchmark these modeling choices on a typologically diverse range of languages, as shown in §4.

4 Data

Selection of Languages. Our selection of test languages is guided by the following goals: **a)** we have to ensure the coverage of typological properties from §3, and **b)** we want to analyse a large set of languages which extends and surpasses other work in the LM literature (see §2).

Since cross-lingual NLP aims at modeling *extant* languages rather than *possible* languages (including, e.g., extinct ones), creating a balanced sample is challenging. In fact, attested languages, intended as a random variable, are extremely sparse and not independent-and-identically-distributed (Cotterell and Eisner, 2017). First, available and reliable data exist only for a fraction of the world's languages. Second, these data are biased because their features may not stem from the underlying distribution, i.e., from what is naturally possible/frequent, but rather

---

[3] All morphological glosses follow the Leipzig glossing rules, listed at `https://www.eva.mpg.de/lingua/resources/glossing-rules.php`

can be inherited by genealogical relatedness or borrowed by areal proximity (Bakker, 2010). To mitigate these biases, theoretical works resorted to stratification approaches, where each subgroup of related languages is sampled independently. maximizing their diversity (Dryer, 1989, *inter alia*). We perform our selection in the same spirit.

We start from the Polyglot Wikipedia (PW) project (Al-Rfou et al., 2013) which provides cleaned and tokenised Wikipedia data in 40 languages. However, the majority of the PW languages are similar from the perspective of genealogy (26/40 are Indo-European), geography (28/40 are Western European), and typology (26/40 are fusional). Consequently, the PW set is not a representative sample of the world's languages.

To amend this limitation, we source additional languages with the data coming from the same domain, Wikipedia, considering candidates in descending order of corpus size cleaned and preprocessed by the Polyglot tokeniser (Al-Rfou et al., 2013). Since fusional languages are already represented in the PW, we add new languages from other morphological types: isolating (*Min Nan, Burmese, Khmer*), agglutinative (*Basque, Georgian, Kannada, Tamil, Mongolian, Javanese*), and introflexive languages (*Amharic*).

Partition. We construct datasets for all 50 languages by extracting the first 40K sentences for each language, and split them into train (34K), validation (3K), and test (3K). This choice has been motivated by the following observations: **a)** we require similarly-sized datasets from the same domain for all languages; **b)** the size of the datasets has to be similar to the standard English PTB dataset (Marcus et al., 1993) which has been utilised to guide LM development in English for more than 20 years. The final list of 50 languages along with their language codes (ISO 639-1), morphological type (i.e., isolating, fusional, introflexive, agglutinative), and corpus statistics is provided in Table 3.

5 Models and Experimental Setup

Benchmarked Language Models. The availability of LM evaluation sets in a large number of diverse languages, as described in §4, gives an opportunity to conduct a full-fledged multilingual analysis of representative LM architectures for word-level prediction. First, we evaluate a state-of-the-art model from the *n-gram* family of models (Goodman, 2001) from the KenLM package.[4] It is based on 5-grams with extended Kneser-Ney smoothing (Kneser and Ney, 1995; Heafield et al., 2013). We refer to this model as **KN5**.

Modern LM architectures are almost exclusively based on recurrent neural networks (RNNs), and especially on Long-Short-Term Memory networks (LSTMs). (Mikolov et al., 2010; Sundermeyer et al., 2015; Chen et al., 2016, *inter alia*). They map a sequence of input words to embedding vectors using a look-up matrix and then perform word-level prediction by passing the vectors to the **LSTM**.

Finally, we also evaluate a character-aware variant of the neural LSTM LM architecture. We use the **Char-CNN-LSTM** model (Kim et al., 2016) due to its public availability and strong performance in several languages. In this model, each character is embedded and passed through a convolutional neural network with max-over-time pooling (LeCun et al., 1989), followed by a highway network transformation (Srivastava et al., 2015) to build word representations from their constituent characters. By resorting to character-level information, the model is able to provide better parameter estimates for lower-frequency words, which is particularly important for morphologically rich languages. The CNN-based word representations are then processed in a sequence by a regular LSTM network to obtain word-level predictions.

Evaluation Setup. We report *perplexity* scores (Jurafsky and Martin, 2017, chapter 4.2.1) using the *full* vocabulary for each respective LM dataset. This means that we explicitly decide to retain also infrequent words in the data and analyse the difficulty of modeling such words in morphologically rich languages (see §2 for the discussion).

In the full-vocabulary setup, the set V comprises all words occurring at least once in the training set. Unseen test words are mapped to *one* <UNK> vector, sampled from the the space of trained word vectors relying on a normal distribution and the same fixed random seed for all models. On the other hand, KN5 by design has a slightly different way of handling unseen test words: they are regarded as outliers and assigned low-probability estimates.

Training Setup and Parameters. For LSTM and Char-CNN-LSTM language models, we reproduce the standard LM setup of Zaremba et al. (2015) and parameter choices of Kim et al. (2016).

---

[4] `https://github.com/kpu/kenlm`

Batch size is 20 and a sequence length is 35, where one step corresponds to one word token. The maximum word length is chosen dynamically based on the longest word in the corpus. The corpus is processed continuously; the RNN hidden states reset at the beginning of each epoch. Parameters are optimised with SGD, and the gradient is averaged over the batch size and sequence length. We then scale the averaged gradient by the sequence length (=35) and clip to 5.0 for more stable training. The learning rate is 1.0, decayed by 0.5 after each epoch if the validation perplexity does not improve. All models are trained for 15 epochs, which is typically sufficient for model convergence. Finally, KN5 is trained relying on the suggested parameters from the KenLM package.

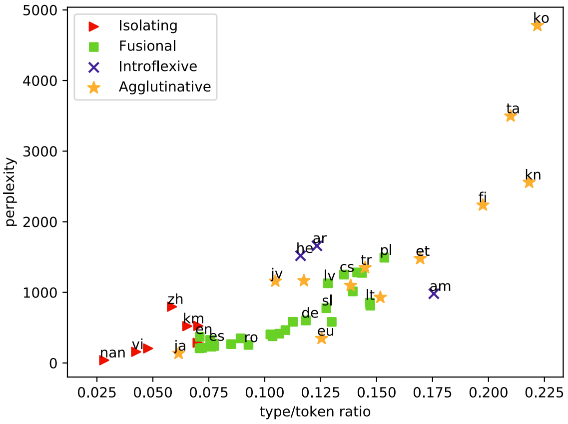

Figure 1: Perplexity scores with the Char-CNN-LSTM language model (Kim et al., 2016) on PTB-sized language modeling data in 50 languages as a function of type-to-token ratios in training data.

6 Results and Discussion

In this section, we present our main empirical findings on the connection between LM performance and corpus statistics emerging from different typological profiles (see §3). Before proceeding, we stress that the absolute perplexity scores across different languages are not directly comparable, but their values provide evidence on the difficulty and limitations of language modeling in each language, considering the fact that all language models were trained on similarly-sized datasets. The results for all three benchmarked language models on all 50 languages are summarised in Table 3.

Comparison of Language Models. A quick inspection of the results from Table 3 reveals that the Char-CNN-LSTM model is the best-performing model overall. We report the best results with that model for 48/50 languages and across all traditional morphological types. Gains over the simpler recurrent LM architecture (i.e., the LSTM model) are present for all 50/50 languages. In short, this means that character-level information on the input side of neural architectures, in addition to leading to fewer parameters, is universally beneficial for the final performance of word-level prediction, as also suggested by Kim et al. (2016) on a much smaller set of languages. By relying on character-level knowledge, Char-CNN-LSTM model provides better estimates for lower-frequency words.

Moreover, the results show that KN5 is a competitive baseline for several languages (e.g., Kannada, Thai, Amharic). This further highlights the importance of testing models on a typologically diverse set of languages: despite the clear superiority of neural LM architectures such as Char-CNN-LSTM in a large number of languages, the results and the marked outliers still suggest that there is currently no “one-size-fits-all” model.

In general, large perplexity scores for certain languages (e.g., agglutinative languages such as Finnish, Korean, Tamil, or introflexive languages), especially when compared to performance on English on a similarly-sized dataset, clearly point at the limitations of all the “language-agnostic” LM architectures. As suggested by Jozefowicz et al. (2016), LM performance in English can be boosted by simply collecting more data and working with large vocabularies (e.g., reducing the number of relevant OOVs). However, this solution is certainly not applicable to a majority of the world’s languages (Bird, 2011; Gandhe et al., 2014; Adams et al., 2017), see later in §6: *Further Discussion.*

Frequency Analysis and Traditional Morphological Types. We now analyse all languages in our collection according to word-level frequency properties also listed in Table 3 for all 50 languages. We report: 1) the vocabulary size (i.e., the total number of vocabulary words in each training dataset); 2) the total number of test words not occurring in the corresponding training data; 3) the total number of tokens in both training and test data; and finally 4) type-to-token ratios (TTR) in training data. We also plot absolute perplexity scores of Char-CNN-LSTM (Kim et al., 2016), the best-performing model overall (see §6), in relation to TTR ratios in Figure 1.

Table 3: Test perplexities for 50 languages (ISO 639-1 codes sorted alphabetically) in the full-vocabulary prediction LM setup; **Left**: Basic statistics of LM evaluation data (see §4 and §5). **Right**: Results with all three language models in our comparison. Best absolute perplexity scores for each language are in bold, but note that the absolute scores in the KN5 column are not directly comparable to the scores obtained with neural models due to a different handling of OOVs at test time (see §5).

In isolating and some fusional languages (e.g., Vietnamese, Thai, English) the TTR tends to be small: we have a comparatively low number of infrequent words. Agglutinative languages such as Finnish, Estonian, and Korean are on the other side of the spectrum. Introflexive and fusional languages, typically over-represented in prior work (see the discussion in §3), are found in the middle.

This emerges clearly in Figure 1, grouping isolating languages to the left side of the x-axis, followed by fusional languages (Germanic and Romance first to the left, and then Balto-Slavic to the right), and placing agglutinative languages towards the far right. Crucially, TTR is an excellent predictor of LM performance. To measure the correlation between this corpus statistics variable and absolute LM performance, we compute their Pearson's r correlation. We find a strong positive correlation, with a value of $r = 0.83$ and significance $p < 0.001$.

We do observe a strong link between each language's morphological type, and the corresponding perplexity score. A transition in terms of the spectrum of morphological systems (see §3) can be traced again on the y-axis of Figure 1, roughly following the reported LM performance: from isolating, over fusional and introflexive to agglutinative languages. In fact, a correlation exists also between traditional morphological types and LM performance. We assessed its strength with the one-way ANOVA statistical test, obtaining a value of $\eta^2 = 0.37$ and a significance of $p < 0.001$.

Finally, it should be noted that the choice of TTP over other corpus statistics such as vocabulary size is motivated by the fact that the corpora are comparable, and not parallel. Because of this, the variation of V may stem from the contents rather than the intrinsic linguistic properties. As a counter-check, the correlation between V and LM performance is in fact milder, with $r = 0.64$. Yet, notwithstanding the stronger correlation, TTP is unable to explain the results entirely. Only through finer-grained typological features it becomes possible to justify several outliers, as shown in the next subsection.

Fine-Grained Typological Analysis. Among the relevant typological features (see §3 and Table 2), fusion and inflectional synthesis have the largest impact on word-level predictions. In fact, the former determines the word boundaries, whereas the latter regulates the amount of possible morpheme combinations. Consider their effect on the frequency distribution of words, expressed as follows (Zipf, 1949):

$$f = \frac{\frac{1}{k^s}}{\sum_{n=1}^{V} \frac{1}{n^s}} \qquad (6)$$

f is the frequency, k the rank, and $s \geq 0$ the exponent characteristic of the distribution. If high, both typological features enlarge V and s, assigning less probability mass to each word.

Low fusion means a preference for separate words (as in isolating languages such as Vietnamese and Chinese), leading to a smaller vocabulary with less (but more frequent) words. This property, additionally boosted by low inflectional synthesis, facilitates statistical language modeling in isolating languages. Vice versa, high fusion results in preference for concatenation of morphemes or introflection, and consequently sparser vocabularies. Yet, this distinction cannot justify the figures by itself, as it equates agglutinative languages and traditional fusional languages. Here, inflectional synthesis is also at play. Through the statistical test of one-way ANOVA, we found a weak effect of $\eta^2 = 0.09$ for fusion and a medium effect of $\eta^2 = 0.21$ for inflection synthesis.

On the other hand, the fine-grained typological features of exponence and flexivity play a role in the ambiguity of the mapping between morphemes and meanings or grammatical functions. This turns out to be especially relevant for character-aware models. The intuition is that if the mapping is straightforward, injecting character information is more advantageous. To validate this claim, we evaluate the ANOVA between exponence of nouns and verbs and the difference in perplexity between LSTM and Char-CNN-LSTM.[5] We report a weak, although existent, correlation with value $\eta^2 = 0.07$ and $\eta^2 = 0.04$, respectively.

Further Discussion. Importantly, our large-scale multilingual LM study strongly indicates that due to diverse typological profiles, certain languages and language groups are inherently more complex to language-model when relying on established statistical models, even when such models are constructed as widely applicable and (arguably) language-agnostic. This finding supports preliminary results from prior work (Botha and Blunsom, 2014; Adams et al., 2017; Cotterell et al., 2018), and is also backed by insights from linguistic theory on variance of language complexity in general and variance of morphological complexity in specific (McWhorter, 2001; Evans and Levinson, 2009). More broadly and along the same line, earlier research in statistical machine translation (SMT) has also shown that typological factors such as the amount of reordering, the morphological complexity, as well as genealogical relatedness of languages are crucial in predicting success in SMT (Birch et al., 2008; Paul et al., 2009; Daiber, 2018).

Our results indicate that the artificial fixed-

---

[5] Unfortunately no values are available in WALS for the feature of flexivity besides a limited domain.

vocabulary assumption from prior work produces overly optimistic perplexity scores, and its limitation is even more pronounced in morphologically rich languages, which inherently contain a large number of infrequent words due to their productive morphological systems. The typical solution to collect more data (Jozefowicz et al., 2016; Kawakami et al., 2017) mitigates this effect to a certain extent, but stills suffers from the Zipfian hypothesis (1949), and it cannot be guaranteed for resource-poor languages where obtaining sufficient monolingual data is also a challenge (Adams et al., 2017).

Therefore, another solution is to resort to other sources of information which are not purely contextual/distributional. For instance, a promising line of current and future research is to (learn to) exploit subword-level patterns captured in an unsupervised manner (Pinter et al., 2017; Herbelot and Baroni, 2017) or integrate existing morphological generation and inflection tools and regularities (Cotterell et al., 2015; Vulić et al., 2017; Bergmanis et al., 2017) into language models to reduce data sparsity, and improve language modeling for morphologically rich languages. For instance, a recent enhancement of the Char-CNN-LSTM language model that enforces similarity between parameters of morphologically related words leads to large perplexity gains across a large number of languages, with the most prominent gains reported for morphologically complex languages (Gerz et al., 2018).

Given the recent success and improved performance with LM-based pre-training methodology (Peters et al., 2018; Howard and Ruder, 2018) across a wide variety of syntactic and semantic NLP tasks in English, improving language models for other languages might have far-reaching consequences for multilingual NLP in general. Typological information coded in typological databases (Ponti et al., 2018) offer invaluable support to language modeling (e.g., knowledge on word ordering, morphological regularities), but such typologically-informed LM architectures are still non-existent.

7 Conclusion

In this paper, we have run a large-scale study on Language Modeling (LM) across several architectures and a collection of 50 typologically diverse languages. We have demonstrated that typological properties of languages, such as their morphological systems, have an enormous impact on the performance of allegedly "language-agnostic" models. We have found that the corpus statistics most predictive of LM performance is type-to-token ratio (TTR), as demonstrated by their strong Pearson's correlation. In turn, the value of TTR is motivated by fine-grained typological features that define the type of morphological system within a language. In fact, such features affect the word boundaries and the number of morphemes per word, affecting the word frequency distribution for each language.

We have also observed that injecting character information into word representations is always beneficial because this mitigates the above-mentioned sparsity issues. However, the extent of the gain in perplexity partly depends on some typological properties that regulate the ambiguity of the mapping between morphemes (here modeled as character n-grams) and their meaning.

We hope that NLP/LM practitioners will find the datasets for 50 languages put forth in this work along with benchmarked LMs useful for future developments in (language-agnostic as well as typologically-informed) multilingual language modeling. This study calls for next-generation solutions that will additionally leverage typological knowledge for improved language modeling. Code and data are available at: `http://people.ds.cam.ac.uk/dsg40/lmmrl.html`.

A Fast, Compact, Accurate Model for Language Identification of Codemixed Text

Abstract

We address fine-grained multilingual language identification: providing a language code for every token in a sentence, including codemixed text containing multiple languages. Such text is prevalent online, in documents, social media, and message boards. We show that a feed-forward network with a simple globally constrained decoder can accurately and rapidly label both codemixed and monolingual text in 100 languages and 100 language pairs. This model outperforms previously published multilingual approaches in terms of both accuracy and speed, yielding an 800x speed-up and a 19.5% averaged absolute gain on three codemixed datasets. It furthermore outperforms several benchmark systems on monolingual language identification.

1 Introduction

Codemixed text is common in user-generated content, such as web articles, tweets, and message boards, but most current language ID models ignore it. Codemixing involves language switches within and across constituents, as seen in these English-Spanish and English-Hindi examples.

(1) dame [$_{NP}$ ese book that you told me about]
Give me this book that you told me about.

(2) [$_{NP}$ aapki profile photo] [$_{VP}$ pyari hai]
Your profile photo is lovely.

Codemixing is the norm in many communities, e.g. speakers of both Hindi and English. As much as 17% of Indian Facebook posts (Bali et al., 2014) and 3.5% of all tweets (Rijhwani et al., 2017) are codemixed. This paper addresses fine-grained (token-level) language ID, which is needed for many multilingual downstream tasks, including syntactic analysis (Bhat et al., 2018), machine translation and dialog systems. Consider this example, which seeks a Spanish translation for the English word *squirrel*:

(3) como se llama un squirrel en español
What do you call a squirrel in Spanish?

Per-token language labels are needed; a system cannot handle the whole input while assuming it is entirely English or Spanish.

Fine-grained language ID presents new challenges beyond sentence- or document-level language ID. Document-level labels are often available in metadata, but token-level labels are not. Obtaining token-level labels for hundreds of languages is infeasible: candidate codemixed examples must be identified and multilingual speakers are required to annotate them. Furthermore, language ID models typically use character- and word-level statistics as signals, but shorter inputs have greater ambiguity and less context for predictions. Moreover, codemixing is common in informal contexts that often have non-standard words, misspellings, transliteration, and abbreviations (Baldwin et al., 2013). Consider (4), a French-Arabic utterance that has undergone transliteration, abbreviation and diacritic removal.

(4) cv bien hmd w enti
ça va bien **al**h**a**md**ullilah** w**a** enti
ça va bien الحمد اللّه وانت
It's going well, thank God, and you?

Language ID models must be fine-grained and robust to surface variations to handle such cases.

We introduce **CMX**, a fast, accurate language ID model for **C**ode**M**i**X**ed text that tackles these challenges. CMX first outputs a language distribution for every token independently with efficient feed-forward classifiers. Then, a decoder chooses labels using both the token predictions and global constraints over the entire sentence. This decoder

Brussels, Belgium, October 31 - November 4, 2018.

produces high-quality predictions on monolingual texts as well as codemixed inputs. We furthermore show how selective, grouped dropout enables a blend of character and word-level features in a single model without the latter overwhelming the former. This dropout method is especially important for CMX's robustness on informal texts.

We also create synthetic training data to compensate for the lack of token-level annotations. Based on linguistic patterns observed in real-world codemixed texts, we generate two million codemixed examples in 100 languages. In addition, we construct and evaluate on a new codemixed corpus of token-level language ID labels for 25k codemixed sentences (330k tokens). This corpus contains examples derived from user-generated posts that contain English mixed with Spanish, Hindi or Indonesian.

Language ID of monolingual text has been extensively studied (Hughes et al., 2006; Baldwin and Lui, 2010; Lui and Baldwin, 2012; King and Abney, 2013), but language ID for codemixed text has received much less attention. Some prior work has focused on identifying larger language spans in longer documents (Lui et al., 2014; Jurgens et al., 2017) or estimating proportions of multiple languages in a text (Lui et al., 2014; Kocmi and Bojar, 2017). Others have focused on token-level language ID; some work is constrained to predicting word-level labels from a single language pair (Nguyen and Doğruöz, 2013; Solorio et al., 2014; Molina et al., 2016a; Sristy et al., 2017), while others permit a handful of languages (Das and Gambäck, 2014; Sristy et al., 2017; Rijhwani et al., 2017). In contrast, CMX supports 100 languages. Unlike most previous work–with Rijhwani et al. 2017 a notable exception–we do not assume a particular language pair at inference time. Instead, we only assume a large fixed set of language pairs as a general constraint for all inputs.

We define and evaluate CMX and show that it strongly outperforms state-of-the-art language ID models on three codemixed test sets covering ten languages, and a monolingual test set including 56 languages. It obtains a 19.5% absolute gain on codemixed data and a 1.1% absolute gain (24% error reduction) on the monolingual corpus. Our analysis reveals that the gains are even more pronounced on shorter text, where the language ID task naturally becomes more difficult. In terms of runtime speed, CMX is roughly 800x faster than existing token-level models when tested on the same machine. Finally, we demonstrate a resource-constrained but competitive variant of CMX that reduces memory usage from 30M to 0.9M.

2 Data

We create synthetic codemixed training examples to address the expense and consequent paucity of token-level language ID labels. We also annotate real-world codemixed texts to measure performance of our models, understand code-mixing patterns and measure the impact of having such examples as training data.

Synthetic data generation from monolingual text. For training models that support hundreds of languages, it is simply infeasible to obtain manual token-level annotations to cover every codemixing scenario (Rijhwani et al., 2017). However, it is often easy to obtain sentence-level language labels for monolingual texts. This allows projection of sentence-level labels to each token, but a model trained only on such examples will lack codemixed contexts and thus rarely switch within a sentence. To address this, we create synthetic training examples that mix languages within the same sequence.

To this end, we first collect a monolingual corpus of 100 languages from two public resources: the W2C corpus[1] and the Corpus Crawler project.[2] Then we generate a total of two million synthetic codemixed examples for all languages.

In generating each training example, we first sample a pair of languages uniformly.[3] We sample from a set of 100 language pairs, mainly including the combination of English and a non-English language. The full set is listed in the supplemental material. Then we choose uniformly between generating an *intra-mix* or *inter-mix* example, which are two of the most prominent types of codemixing in the real world (Barman et al., 2014; Das and Gambäck, 2014).[4] An *intra-mix* sentence like (1) starts with one language and switches to another language, while an *inter-mix* sentence like (2) has

[2] `https://github.com/googlei18n/corpuscrawler`

[3] Both our collected codemixed data and Barman et al. (2014) indicate that more than 95% of codemixed instances are bilingual.

[4] The two types of codemixing have roughly equal proportions in our labeled corpus.

	en/es	en/hi	en/id
Number of tokens	98k	140k	94k
Number of sentences	9.5k	9.9k	5.3k

Table 1: Statistics of our YouTube and Google+ dataset, GY-Mix.

Test Set	Languages
Twitter-Mix	en, es
Web-Mix6	cs, en, eu, hu, hr, sk
GY-Mix	en, es, hi, id
KB-Mono56	56 languages

Table 2: The languages of each testing corpora in our experiments. The first three sets primarily include codemixed texts while the last one (KB-Mono56) is monolingual.

an overall single language with words from a second language in the middle. To generate an example, we uniformly draw phrases from our monolingual corpus for the chosen target languages, and then concatenate or mix phrases randomly. The shorter phrase in *inter-mix* examples contains one or two tokens, and the maximum length of each example is eight tokens.

Manual annotations on real-world codemixed text. We obtain candidates by sampling codemixed public posts from Google+[5] and video comments from YouTube,[6] limited to three language pairs with frequent code switching: English-Spanish, English-Hindi[7] and English-Indonesian. All texts are tokenized and lowercased by a simple rule-based model before annotation. Both the candidate selection and the annotation procedures are done by linguists proficient in both languages. The final annotated corpus contains 24.7k sentences with 334k tokens; 30% are monolingual, 67% are bilingual and 3% have more than two languages. Finally, we create an 80/10/10 split (based on tokens) for training, development and testing, respectively. Table 1 gives the token and sentence counts per language. In the rest of the paper, we refer to this dataset as GY-Mix.

Evaluation datasets. We evaluate on four datasets, three codemixed and one monolingual. For a fair comparison, we report accuracies on subsets of these test sets that include languages supported by all tested models. Examples with Hindi words written in Latin script are also removed because the benchmark systems we compare to do not support it.

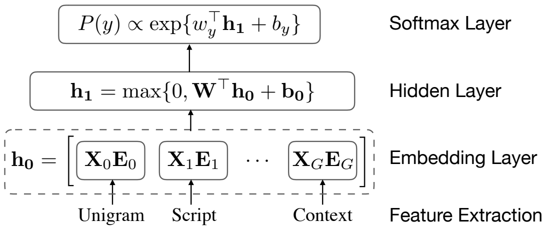

Figure 1: Basic feed-forward network unit for scoring each token in the input and predicting possible languages. Multiple features are embedded, concatenated, and fed into a hidden layer with ReLU activation.

- **Twitter-Mix**: Codemixed data from the EMNLP 2016 shared task (Molina et al., 2016b).
- **Web-Mix6**: Codemixed data crawled from multilingual web pages (King and Abney, 2013), using a subset of six languages.
- **GY-Mix**: The test set of our token-level codemixed data (en-es, en-hi, and en-id).
- **KB-Mono56:** Monolingual test set of Kocmi and Bojar (2017), using a subset of 56 languages.

Table 2 summarizes the final language setting of each test set used in our experiments.

3 Identifying Language Spans in Codemixed Text

CMX uses two stages to assign language codes to every token in a sentence. First, it predicts a distribution over labels for each token independently with a feed-forward network that uses character and token features from a local context window. Then, it finds the best assignment of token labels for an entire sentence using greedy search, subject to a set of global constraints. Compared to sequence models like CRFs or RNNs, this two-stage strategy has several major advantages for fine-grained language ID: (1) it does not require annotated codemixed text over hundreds of languages and their mixed pairings, (2) learning independent classifiers followed by greedy decoding

[7] Hindi texts found in both Devanagari and Latin scripts.

Features	Window	D	V
Character n-gram	+/- 1	16	1000-5000
Script	0	8	27
Lexicon	+/- 1	16	100

Table 3: Feature spaces of CMX. The window column indicates that CMX uses character n-gram and lexicon features extracted from the previous and following tokens as well as the current one.

is significantly faster than structured training (especially considering the large label set inherent in language ID), and (3) it is far easier to implement.

3.1 Token Model

Simple feed-forward networks have achieved near state-of-the-art performance in a wide range of NLP tasks (Botha et al., 2017; Weiss et al., 2015). CMX follows this strategy, with embedding, hidden, and softmax layers as shown in Figure 1. The inputs to the network are grouped feature matrices, e.g. character, script and lexicon features. Each group g's features are represented by a sparse matrix $\mathbf{X}_g \in \mathbb{R}^{F_g \times V_g}$, where F_g is the number of feature templates and V_g is the vocabulary size of the feature group. The network maps sparse features to dense embedding vectors and concatenates them to form the embedding layer:

$$\mathbf{h}_0 = vec[\mathbf{X}_g \mathbf{E}_g | \forall g] \quad (1)$$

where $\mathbf{E}_g \in \mathbb{R}^{V_g \times D_g}$ is a learned embedding matrix per group. The final size of the embedding layer $|\mathbf{h}_0| = \sum_g F_g D_g$ is the sum of all embedded feature sizes. CMX uses both discrete and continuous features. We use a single hidden layer with size 256 and apply a rectified linear unit (ReLU) over hidden layer outputs. A final softmax layer outputs probabilities for each language. The network is trained per-token with cross-entropy loss.

We explain the extraction process of each feature type below. Table 3 summarizes the three types of features and their sizes used in CMX. Character and lexicon features are extracted for the previous and following tokens as well as the current token to provide additional context.

Character n-gram features We apply character n-gram features with $n = [1, 4]$. RNNs or CNNs would provide more flexible character feature representations, but our initial experiments did not show significant gains over simpler n-gram features. We use a distinct feature group for each n. The model averages the embeddings according to the fractions of each n-gram string in the input token. For example, if the token is *banana*, then one of the extracted trigrams is *ana* and the corresponding fraction is 2/6. Note that there are six trigrams in total due to an additional boundary symbol at both ends of the token.

Following Botha et al. (2017), we use feature hashing to control the size V and avoid storing a big string-to-id map in memory during runtime. The feature id of an n-gram string x is given by $\mathcal{H}(x) \bmod V_g$ (Ganchev and Dredze, 2008), where $\mathcal{H}$ is a well-behaved hash function. We set $V = 1000, 1000, 5000, 5000$ for $n = 1, 2, 3, 4$ respectively; these values yield good performance and are far smaller than the number of n-gram types.

Script features Some text scripts are strongly correlated with specific languages. For example, Hiragana is only used in Japanese and Hangul is only used in Korean. Each character is assigned one of the 27 types of scripts based on its unicode value. The final feature vector contains the normalized counts of all character scripts observed in the input token.

Lexicon features This feature group is backed by a large lexicon table which holds a language distribution for each token observed in the monolingual training data. For example, the word *mango* occurs 48% of the time in English documents and 18% in Spanish ones. The table contains about 6.2 million entries. We also construct an additional prefix table of language distributions for 6-gram character prefixes. If the input token matches an entry in the lexicon table (or failing that, the prefix table), our model extracts the following three groups of features.

- *Language distribution.* The language distribution itself is included as the feature vector.
- *Active languages.* As above, but feature values are set to 1 for all non-zero probabilities. For example, the word *mango* has feature value 1 on both English and Spanish.
- *Singletons.* If the token is associated with only one language, return a one-hot vector whose only non-zero value is the position indicating that language.

The size of all lexicon feature vectors is equal to the number of supported languages.

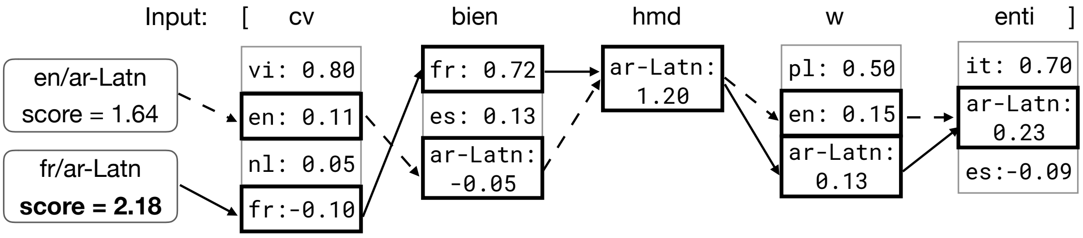

Figure 2: Example of our decoding algorithm with global constraints for example (4) for two allowed language pairs, en/ar-Latn and fr/ar-Latn.

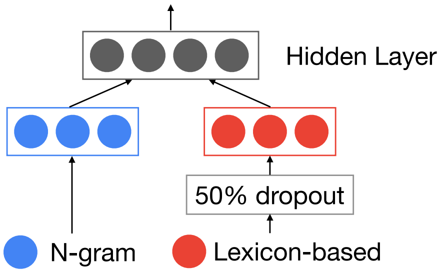

Figure 3: Our selective feature dropout method. The model randomly sets the lexicon feature vectors to zero with 50% probability while n-gram features are always used.

3.2 Selective Feature Dropout

Preliminary experiments showed poor performance, especially on informal texts, when all three types of features are simply merged. Consider the following example outputs on misspelled word *Ennnglish*, for which no lexicon features fire.

Input: *Ennnglish*

With Lexicon Features	*W/o Lexicon Features*
• $p(sv) = 0.27$	• $p(en) = 0.74$
• $p(da) = 0.24$	• $p(nl) = 0.10$
• $p(nl) = 0.18$	• $p(fy) = 0.06$
• …	• …

Without dropout, the model with lexicon features does not make effective use of the token's character n-grams and makes a catastrophically wrong prediction. The core problem is that lexicon features are both prevalent and highly predictive for language ID; during training, this dampens the updating of weights of n-gram features and thus diminishes their overall utility.

To address this issue and make CMX more robust to noisy inputs, we selectively apply a grouped feature dropout strategy that stochastically down-weights lexicon features during training. Figure 3 illustrates the idea: for each input, after feature extraction, the vector of lexicon features is randomly set to zero. This way, the model must rely entirely on n-gram features for this particular input. Note that our feature dropout is different from standard dropout in at least two ways: (1) dropout happens to entire feature groups rather than on individual neurons, (2) we selectively apply dropout only on a subset of features. After tuning the dropout rate on development data (Figure 5) we choose a dropout rate of 50%. Section 4.3 explains the tuning procedure.

3.3 Decoding with Global Constraints

Given a trained model, the goal of decoding is to find the sequence of per-token languages that maximizes the overall score. The simple, greedy strategy of picking the top prediction for each token over-predicts too many languages in a single sentence. For example, on average the greedy method predicts more than 1.7 languages per sentence on monolingual inputs. Because the token classier uses a window including only the previous, current, and next token, it has a quite limited view on the entire sequence.

Motivated by this observation, we add the following **global constraint** in decoding: only monolingual outputs or codemixed outputs from a fixed set of language pairs are permitted. We choose a set of 100 language pairs, primarily including the combination of English and a non-English language. The full set is listed in the supplemental material.

Finally, we introduce a straightforward variant of greedy decoding that finds the optimal language assignment in the presence of these global constraints. We independently find the best assignment under each allowed language combination (monolingual or language pair) and return the one with the highest score.

Figure 2 shows paths for example (4) with two allowed language pairs: en/ar-Latn and

DATASET	Twitter-Mix	Web-Mix6	GY-Mix				Average
LANGUAGES	es/en	6 Langs	es/en	hi/en	hi/hi-Latn/en	id/en	
LanideNN	71.3	52.1	65.7	79.6	–	22.9	58.3
EquiLID	87.9	63.5	71.0	81.9	–	64.9	73.9
CMX-small	88.8	91.0	89.9	98.2	85.0	86.7	90.9
CMX	**92.4**	**93.2**	**91.8**	**98.4**	**87.4**	**91.1**	**93.4**

Table 4: **Codemixed Texts:** Token-level accuracy (%) of different approaches on codemixed texts. "CMX-small" corresponds to our small model without lexicon features and vocabulary tables. The *hi/hi-Latn/en* column shows the accuracy on texts in English, Latin Hindi and Devanagari Hindi; the baseline models do not support identification of text in Hindi in Latin script. *Average* shows averaged accuracy on all sets except *hi/hi-Latn/en*. Boldface numbers indicate the best accuracy for each testing set.

fr/ar-Latn.[8] The two paths in dashed and solid lines indicate the best assignment for each language pair respectively. Because scoring is independent across tokens, each subtask is computed in $O(N)$ time. The total decoding time is $O(N|\mathcal{L}|)$ where $\mathcal{L}$ is the constraint set, and the global optimality of this algorithm is guaranteed because the assignment found in each subtask is optimal.

4 Experiments

4.1 Training Setup

We train CMX on the concatenation of three datasets: (a) GY-Mix's training portion, (b) synthetic codemixed data and (c) a monolingual corpus that covers 100 languages. Every token in the training set spawns a training instance. Our training set consists of 38M tokens in total, which is on the same magnitude as the sizes of training data reported in previous work (Jurgens et al., 2017; Joulin et al., 2016).

We use mini-batched averaged stochastic gradient descent (ASGD) (Bottou, 2010) with momentum (Hinton, 2012) and exponentially decaying learning rates to learn the parameters of the network. We fix the mini-batch size to 256 and the momentum rate to 0.9. We tune the initial learning rate and the decay step using development data.

4.2 Main Results

Codemixed Texts Table 4 lists our main results on the codemixed datasets. We primarily compare our approach against two benchmark systems: EquiLID (Jurgens et al., 2017) and LanideNN (Kocmi and Bojar, 2017). Both achieved state-of-the-art performance on several monolingual and codemixed language ID datasets. LanideNN makes a prediction for every character, so we convert its outputs to per-token predictions by a voting method over characters in each word. For both benchmarks, we use the public pre-trained model provided by the authors. The EquiLID model uses 53M parameters, LanideNN uses 3M, and CMX only uses 0.28M parameters.[9]

Across all datasets, CMX consistently outperforms both benchmark systems by a large margin. On average, our full model (CMX) is 19.5% more accurate than EquiLID (93.4% vs. 73.9%); the gain is even larger compared to LanideNN. Note that none of the models are trained on the Twitter-Mix or the Web-Mix6 dataset, so these two datasets provide an evaluation on the out-domain performance of each approach. In this setting CMX also yields significant improvement in accuracy, e.g. a 4.5% (absolute) gain over EquiLID on the Twitter-Mix dataset.

An Even Smaller Model We further compare between CMX and a variant we call CMX-small, which has no access to lexicon resources or lexicon features. This smaller variant has only 237k parameters and reduces the memory footprint from 30M to 0.9M during runtime, while the (average) loss on accuracy is only 2.5%. This comparison demonstrates that our approach is also an excellent fit for resource-constrained environments, such as on mobile phones.

Monolingual Texts In addition to EquiLID and LanideNN, we further compare CMX against

---

[8] Scores are sorted. Some languages omitted for illustration purposes.

[9] We explain how we compute the number of parameters of our model in the supplemental material.

MODEL	Sent Acc.	Char/Sec
CODEMIXING MODELS		
LanideNN	94.6	0.17k
EquiLID	95.1	0.25k
CMX-small	94.6	265.5k
CMX	**96.6**	206.1k
MONOLINGUAL MODELS		
Langid.py	92.8	183.8k
fastText-small	92.5	2,671.1k
fastText-full	94.4	2,428.3k
CLD2	95.5	4,355.0k

Table 5: **Monolingual Texts:** Sentence-level accuracy (%) on KB-Mono56. Monolingual models make per-sentence predictions only.

Langid.py (Lui and Baldwin, 2012), CLD2[10] and fastText (Joulin et al., 2016, 2017)—all are popular off-the-shelf tools for monolingual language ID. Sentence-level predictions for EquiLID and LanideNN models are obtained by simple voting. Table 5 summarizes sentence-level accuracy of different approaches on the KB-Mono56 test set. CMX achieves the best sentence-level accuracy over all monolingual and codemixing benchmark systems. The resource-constrained CMX-small also performs strongly, obtaining 94.6% accuracy on this test set.

Our approach also maintains high performance on very short texts, which is especially important for many language identification contexts such as user-generated content. This is demonstrated in Figure 4, which plots the cumulative accuracy curve on KB-Mono56 over sentence length (as measured by the number of non-whitespace characters). For example, points at x=50 show the averaged accuracies over sentences with no more than 50 characters. We compare CMX against the best performing monolingual and codemixing benchmark systems. The relative gain is more prominent on shorter sentences than on longer ones. For example, the improvement is 4.6% on short sentences ($\leq$30 characters), while the gain on segments $\leq$150 characters is 1.9%. Similar patterns are seen with respect to other systems.

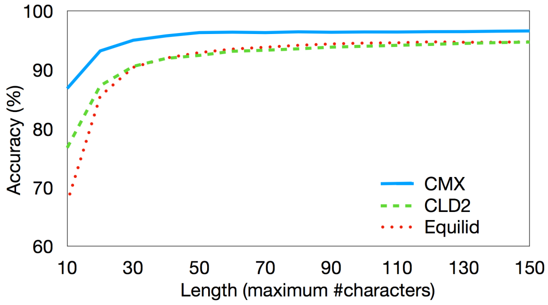

Figure 4: Sentence-level accuracy (y-axis) on KB-Mono56 as a function of the maximum number of non-whitespace characters in a sentence (x-axis). For example, the point at $x = 50$ denotes the accuracy on all the sentences with $\leq$ 50 characters.

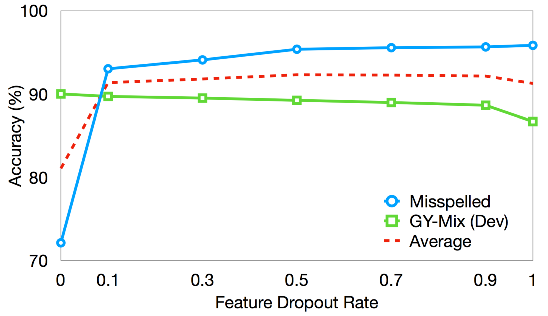

Figure 5: Accuracy on development sets with various feature dropout rate values p.

Inference Speed Table 5 also shows the inference speed of each method in characters per second, tested on a machine with a 3.5GHz Intel Xeon processor and 32GB RAM. CMX (written in C++) is far faster than other fine-grained systems, e.g. it has an 800x speed-up over EquiLID. It is not surprising that monolingual models are faster than CMX, which makes a prediction for every token rather than once for the entire sequence. Of course, monolingual models do not support language ID on codemixed inputs, and furthermore CMX performs the best even on monolingual texts.

4.3 Analysis

Feature Dropout Rate To analyze how the feature dropout rate impacts the model performance, we create a set of *synthetically misspelled* tokens by random duplication or replacement of one or two characters. In addition, we ensure that every token has at least one language-unique character, so a model with character n-gram features should be able to easily identify the language of this token. Figure 5 shows the tuning results for dropout values on misspelled tokens and the GY-Mix development set. Without feature dropout (p=0.0), our model only gets 72.1% on misspelled tokens,

---

TRAINING DATA	Twitter-Mix	Web-Mix6	GY-Mix (Test)	KB-Mono56
All Training Corpora	92.4	93.2	93.6	95.1
w/o GY-Mix (Train)	88.5	92.9	89.3	95.0
w/o Synthetic	92.1	88.8	92.5	95.1

Table 6: Token-level accuracy of our full model with different training sets, removing either GY-Mix annotations or synthetic codemixed corpus at a time.

METHOD	GY-Mix	KB-Mono56	#Lang/Sent
Independent	87.8	91.9	1.78
Switching Penalty	89.4	93.1	1.58
Bilingually Constrained	93.6	95.1	1.27
Gold	-	-	1.15

Table 7: Token-level accuracy of different decoding methods on GY-Mix and KB-Mono56, as well as the averaged number of predicted languages in each sentence.

indicating that n-gram features are not properly trained. The proposed feature dropout method effectively addresses this issue, improving the accuracy to 95.3% with $p \geq 0.5$. We choose $p = 0.5$ (Figure 3) because it gives the best trade-off on the two tuning sets. The curves in Figure 5 also show that model performance is robust across a wide range of dropout rates between the two extremes, so the strategy is effective, but is not highly sensitive and does not require careful tuning.

Impact of Decoding Algorithm Table 7 shows a comparison over different decoding strategies, including (a) *independent* greedy prediction for each token, (b) adding a *switching penalty* and decoding with Viterbi, (c) and our *bilingually constrained* decoding. For the second method, we add a fixed transition matrix that gives a penalty score $\log p$ for every code switch in a sentence. We choose $p = 0.5$, which gives the best overall results on the development set. Our approach outperforms *switching penalty* by more than 2% on both GY-Mix and KB-Mono56. To analyze the reason behind this difference we show the average number of languages in each sentence in Table 7. Both baseline approaches on average predict more than 1.5 languages per sentence while the oracle number based on gold labels is only 1.15. Our global bilingual constraints effectively address this over-prediction issue, reducing the average number of predicted languages to 1.27. We also measure the running time of all methods. The decoding speed of our method is 206k char/sec (Table 5), while the *independent* method is 220k char/sec. Our decoding with global constraints thus only increases the running time by a factor of 1.07.

Codemixed Training Datasets Our training data consists of two codemixed corpora: manual annotations on real-world data (GY-Mix) and a synthetic corpus. To analyze their contribution, we remove each corpus in turn from the training set and report the results in Table 6. Adding the GY-Mix training set mainly improves accuracy on GY-Mix test and Twitter-Mix, while the gains from the synthetic data are greatest on Web-Mix6. This shows that synthetic data helps CMX generalize to a broader range of languages since GY-Mix has language overlap only with Twitter-Mix, not Web-Mix6. The two examples below further demonstrate the benefit of synthetic examples:

With Synthetic Data

- [Translate $]_{\text{en}}$ [**maçã** $]_{\text{pt}}$ [to English $]_{\text{en}}$
- [Translate $]_{\text{en}}$ [**Apfel** $]_{\text{de}}$ [to English $]_{\text{en}}$

Without Synthetic Data

- [Translate **maçã** to $]_{\text{pt}}$ [English $]_{\text{en}}$
- [Translate **Apfel** to English $]_{\text{en}}$

Both examples are likely potential queries "Translate *apple* to English" with *apple* replaced by its translation in German(de) or Portuguese(pt). The underlying language pairings never appear in GY-Mix. CMX with synthetic training data is able to correctly identify the single token inter-mixed in a sentence, while the model trained without synthetic data fails on both cases.

Contribution of Features CMX has three types of features: character n-gram, script, and lexicon features. n-gram features play a crucial role as back-off from lexicon features. Consider informal Latin script inputs, like *hellooooo*, for which no lexicon features fire. Foregoing n-gram features results in abysmal performance (<20%) on this type of input because script features alone are inadequate. The main impact of script features is to avoid embarrassing mistakes on inputs that can be easily identified from their scripts. Finally, note that removing lexicon features corresponds to the CMX-small model. On monolingual inputs (Table 5), the lexicon features in CMX provide a 2.0% absolute improvement in accuracy.

5 Conclusions

CMX is a fast and compact model for fine-grained language identification. It outperforms related models on codemixed and monolingual texts, which we show on several datasets covering text in a variety of languages and gathered from diverse sources. Furthermore, it is particularly robust to the idiosyncrasies of short informal text.

Acknowledgments

We thank Emily Pitler, Slav Petrov, John Alex, Daniel Andor, Kellie Webster, Vera Axelrod, Kuzman Ganchev, Jan Botha, and Manaal Faruqui for helpful discussions during this work, and our anonymous reviewers for their thoughtful comments and suggestions. We also thank Elixabete Gomez, Héctor Alcalde, Knot Pipatsrisawat, and their stellar team of linguists who helped us to annotate and curate much of our data.

Abstract

Sentiment expression in microblog posts can be affected by user's personal character, opinion bias, political stance and so on. Most of existing personalized microblog sentiment classification methods suffer from the insufficiency of discriminative tweets for personalization learning. We observed that microblog users have consistent individuality and opinion bias in different languages. Based on this observation, in this paper we propose a novel user-attention-based Convolutional Neural Network (CNN) model with adversarial cross-lingual learning framework. The user attention mechanism is leveraged in CNN model to capture user's language-specific individuality from the posts. Then the attention-based CNN model is incorporated into a novel adversarial cross-lingual learning framework, in which with the help of user properties as bridge between languages, we can extract the language-specific features and language-independent features to enrich the user post representation so as to alleviate the data insufficiency problem. Results on English and Chinese microblog datasets confirm that our method outperforms state-of-the-art baseline algorithms with large margins.

1 Introduction

The past decade has witnessed an exploding interest in microblog sentiment classification from both academic and commercial communities due to its inherent challenges and wide applications (Liu, 2012; Jawa and Hasija, 2015). However, most existing algorithms largely ignore latent personal distinctions among microblog users (Wu et al., 2015; Sun et al., 2015; Yu et al., 2015). In fact, the sentiment expression in posts can be affected by user's language habit, personal character, opinion bias and so on, and even the same sentence can deliver quite different sentiment polarities depending on user's underlying context.

Table 1 illustrates a simple case where two users are talking about house price. In the first two example posts, we can see that the **Seller**, as a real estate agent, is excited about the growth of the price, while as a consumer, the **Buyer** feels sad for the situation. Without knowing the users' background, it would be difficult for the traditional methods to detect the sentiment polarities of posts 1 and 2.

In recent years, personalized sentiment classification considering user's individuality has emerged as one of the prevailing research topics in the field. Song et al. (2015b, 2016) utilized a latent factor model to capture personal sentiment variations of microblog users. Zhao et al. (2017) exploited the social relation information to facilitate user representation learning. In rating prediction research, Tang et al. (2015) embedded user and product level information into a neural network model. Chen et al. (2016a) further improved the model by incorporating global user and product information as attentions into a hierarchical LSTM model. These studies have achieved promising results on personalized sentiment classification. However, most of them suffer from the insufficiency of discriminative posts for personalization learning.

We observed that the microblog users have consistent individuality and opinion bias in different languages on different platforms. Posts 3 and 4 in Table 1 are posted by the same couple of **Seller** and **Buyer** in Chinese on Sina Weibo[1]. Both of them expressed their own stance or opinion across the two platforms as consistently as what each has said in English on Twitter, indicating the stable underlying individuality of each user. Jointly analyzing microblog posts in different languages can help us enrich the user features and ex-

ID	Source	Post	Label
1	Twitter	**Seller**: The house prices are getting higher and higher!	(positive)
2	Twitter	**Buyer**: The house prices are getting higher and higher!	(negative)
3	Weibo	**Seller**: 房价一直在提高，我们会有不错的效益。 (*The house prices have been rising and we will have good benefits.*)	(positive)
4	Weibo	**Buyer**: 过高的房价已经超出了我的承受范围。 (*High house prices have exceeded my tolerance.*)	(negative)

Table 1: A toy example of microblogs of the same users in English and Chinese. Note that posts 3 and 4 are brand new and not the translation of posts 1 and 2.

tract more precise personalized view and opinion bias. Furthermore, the microblog posts on Twitter and Weibo share many similarities in social and textual styles regardless of different languages used. By cross-lingual learning from the same (or similar) users' posts, we can extract the common language-independent features to enhance the representations for both monolingual and cross-lingual sentiment classification. We hypothesize that general cross-lingual sentiment words such as adjectives have similar effect on the sentiment of sentences in different languages, which can be considered generally independent of language. It is thus meaningful to leverage the individuality features to bridge the language gap and exploit the global language-independent sentiment knowledge learned to help alleviate data insufficiency for personalized sentiment classification.

Convolutional neural networks (CNN) are effective in short text analysis thanks to the n-grams of text that contain rich and accurate information for capturing user's attention. Besides, adversarial multi-task learning provides us with a feasible method to bridge the semantics of posts of different languages by utilizing the correlation between the two related language-specific tasks. In this paper, we propose a user-attention-based CNN model with adversarial multi-task learning (dubbed as ACNN-AMT). Firstly, we incorporate user attention into CNN model to capture user's language-specific individuality from the posts. Secondly, we propose an adversarial multi-task learning framework to co-train cross-lingual sentiment features with the help of user's consistent individuality. The main contributions of our paper are three-fold:

- We propose a novel user attention mechanism over n-gram semantics of short posts to capture the language-specific individuality and opinion bias of users for personalized sentiment classification.
- We incorporate the user-attention-based CNN model into a novel adversarial cross-lingual multi-task learning framework. With the help of consistency of user individuality as bridge across two languages, we learn language-specific features and language-independent features to enrich the user post representation, and alleviate the problem of insufficiency of personal data.
- We conduct comprehensive experiments on real-world Sina Weibo datasets and Twitter datasets to confirm the effectiveness of our proposed model. The experimental results demonstrate that our model consistently outperforms strong baseline methods by a large margin. Our datasets have been made publicly available[2].

2 Related Work

Recently, personalized sentiment classification has attracted lots of attention in research community. Song et al. (2015b) proposed a personalized sentiment classification method based on latent factor model to capture personal sentiment variations. Tang et al. (2015) was first to incorporate user and product information into a neural network model for personalized rating prediction of products. Wu and Huang (2016) proposed a personalized microbolg sentiment classification framework via multi-task learning to capture the personal properties and take advantage of common sentiment knowledge shared among all users. Chen et al. (2016a) adopted a hierarchical neural network to incorporate global user and product information into the sentiment model via attention mechanism. Zhao et al. (2017) exploited both the

---

[2] `https://github.com/githubfordata/data`

semantics of posts and the social relations among users for microblog sentiment classification with recurrent random-walk network model. Although these methods have achieved reasonable results, they are limited by insufficient personalized data that the learning of personal sentiment features and user representations has to rely on.

Generative adversarial network (Goodfellow et al., 2014) has been successfully applied to Natural Language Processing, especially domain and language adaptation, including measuring and matching different feature space distribution between source and target. Ganin and Lempitsky (2015) presented an adversarial approach to domain adaptation for transferring knowledge from source domain to target domains. Chen et al. (2016b) proposed an adversarial deep averaging network to transfer sentiment knowledge from labeled source language to low-resource target language where only unlabeled data exists. Liu et al. (2017) tried an adversarial multi-task learning framework for text classification, intending to refrain the shared and private latent feature spaces from interfering each other. These methods only took multi-domain or multi-language setting into account, aiming to address the problem caused by low-resource languages or specific domains, but they ignored the important factors of users across different domains or languages, which is a very important factor in sentiment analysis.

Unlike the previous studies, we incorporate cross-lingual sentiment consistency and personalized user sentiment model from the viewpoint of multi-task learning for alleviating the insufficiency of personal data and improving the performance of personalization in sentiment analysis.

3 Attention-based Personalization Model

In CNN, we can use attention mechanism to predict the importance probability of each component with respect to attention query (Bahdanau et al., 2014). Given a post, the user usually focuses on its specific portions depending on one's individuality or interest. The user attention can be incorporated into CNN model to learn appropriate user-specific features and capture crucial components that the user cares about.

Given a data example (x, u, y) in a monolingual dataset, the post content x is denoted as:

$$x = w_1 \oplus w_2 \oplus \cdots \oplus w_i \oplus \cdots \oplus w_n \qquad (1)$$

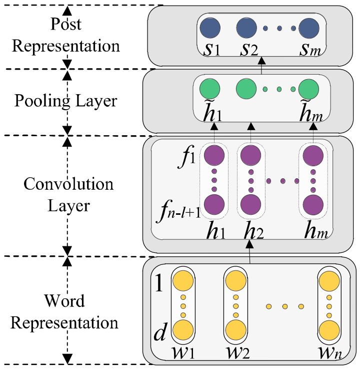

Figure 1: Convolutional Neural Network for post representation.

where n is number of words contained in x, $\oplus$ is the concatenation operator, each word w_i is mapped to its d-dimensional embedding representation $w_i \in \mathbb{R}^d$, the user of the post is represented by a continuous vector of o dimensions $u \in \mathbb{R}^o$ which is initialized as zero-valued vector, and y is the sentiment label of x. Given all training examples, our goal is to learn appropriate text and user representations for classifying sentiment class of different users' new posts.

3.1 CNN-based Text Representation

We use CNN (Kim, 2014; Kalchbrenner et al., 2014) for learning the semantic representation s of input post x, which is shown in Figure 1. The semantic representations of n-grams with sliding window are mapped to fixed and lower dimension via the convolutional filters. Let l be the width of convolutional filter, W and b be the parameters and bias of linear mapping, which is shared among all layers in a filter. Each sliding window with fixed-length window size of l starting from the k-th word is denoted as $\Omega_k = w_k \oplus w_{k+1} \oplus \cdots \oplus w_{k+l-1}$, where $\Omega_k \in \mathbb{R}^{d\times l}$. The convolutional layer output $f_k \in \mathbb{R}^m$ of the window Ω_k is calculated by applying the linear mapping below, following a convolution operation:

$$f_k = W \cdot \Omega_k + b \qquad (2)$$

where $W \in \mathbb{R}^{m\times d}$, $b \in \mathbb{R}^m$, and m is the output length of each linear mapping. With the convolution operation, $n - l + 1$ features in total, i.e., one for each window, are obtained and denoted as $\mathbf{f} = [f_1, f_2, \cdots, f_{n-l+1}]^\top$ For each column vector h_j for $j = 1, \ldots, m$ in $\mathbf{f}$, a scalar $\tilde{h}_j$ is calculated as the representation of h_j. By concatenating all scalars, the output vector of a post representation

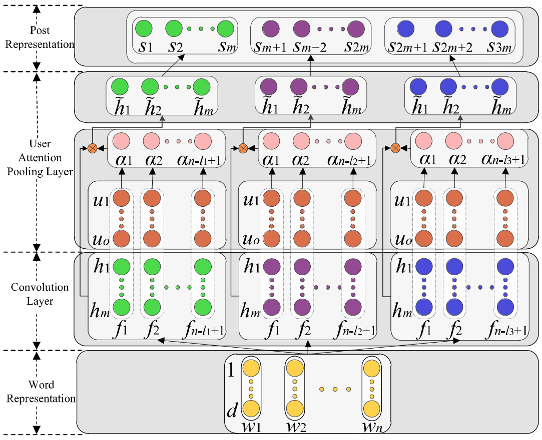

Figure 2: Our user-attention-based CNN model (ACNN) for post representation. The convolution windows (in convolution layer) in green, purple and blue color correspond to three sizes of n-grams used, i.e., l_1, l_2, and l_3, respectively.

$s = [s_1, s_2, \ldots, s_m]$ with fixed length of m is generated. Note that s can be generated from $\tilde{h}$ with the similar linear mapping as Eq. 2, but for simplicity we treat it the same as $\tilde{h}$ in our experiment.

3.2 Incorporating User Attention

The model incorporating user attention mechanism is shown in Figure 2.

The users information are distinguished by user id, and each user u is embedded as vector $u \in \mathbb{R}^o$ for capturing their opinion bias and individuality. All the users embedding will be regarded as attention query parts in user attention mechanism, and the model gives all input windows different attention weights according to the individuality of post users for semantic representation. We treat user embeddings as model parameters, which can be updated with the optimization algorithm in training process (see Section 4).

Formally, the final post representation $s = \tilde{h}$ is a weighted sum of all sliding windows of convolution layer:

$$\tilde{h} = \sum_{k=1}^{n-l+1} \alpha_k f_k \tag{3}$$

where α_k measures the importance of the k-th n-gram (i.e., window) for current user. The attention weight α_k of each window's hidden state can be defined as:

$$\alpha_k = \frac{\exp(\sigma(f_k, u))}{\sum_{j=1}^{n-l+1} \exp(\sigma(f_j, u))} \tag{4}$$

where σ is a scoring function which scores the importance of each n-gram by taking into account both post and user representations.

For each input window, the attention score is calculated for getting the attentive degree of input to current user attention query by combining them together linearly. The scoring function σ is defined as:

$$\sigma(f_k, u) = v \cdot \tanh\left(W_f \cdot f_k + W_u \cdot u + b\right) \tag{5}$$

where $W_f \in \mathbb{R}^{m \times m}$ is a weight matrix for hidden states of input windows of a post, $W_u \in \mathbb{R}^{m \times o}$ is weight matrix for the user of the current post, and $v \in \mathbb{R}^m$ is the weight vector, which is randomly initialized, for getting a score number for the function. v is needed since a matrix $\mathbb{R}^{m \times 1}$ is obtained by $\tanh(\cdot)$, and for getting a scalar, we need a matrix $\mathbb{R}^{1 \times m}$ for matrix multiplication.

To make our model more accurate, we apply three kinds of convolutional filters to capture the semantics of n-grams corresponding to three levels of granularities, i.e., we let $l \in \{l_1, l_2, l_3\}$ corresponding to unigram, bi-gram and tri-gram, respectively, and we concatenate the representations $\tilde{h}$ of these n-grams of these three granularities as the representation of each post. Similar as (Tang et al., 2015), for modeling user-sentiment consistencies, we also concatenate the representation of users and that of posts as the final semantic representation. Note that for the current post, the user embedding is the same among three different granularities, but the model parameters W_f and W_u among the three granularities are different because the convolutional representation of post f_k is dependent on specific granularity of n-grams used.

4 Adversarial Learning for Personalized Sentiment Classification

Multi-task learning can utilize the correlation among different tasks to learn related knowledge for better performance (Evgeniou and Pontil, 2004). The posts of each user are often insufficient for personalized sentiment analysis with a monolingual dataset. By exploiting posts of both Chinese and English in multi-task learning, we can enrich the original monolingual posts of each user to alleviate the data insufficiency problem. Inspired by the adversarial network that can build the mapping between generative distribution and target distribution (Goodfellow et al., 2014),

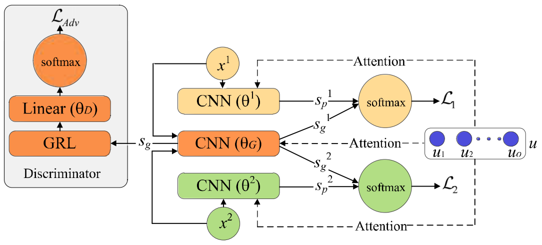

Figure 3: The ACNN-AMT model for sentiment classification. The left hand side is the language discriminator of the adversarial network; the CNNs in the middle are the feature generators of language-specific sentiment classification tasks; and the right hand side are the decision functions of the corresponding sentiment classifiers. Both sentiment classification tasks share the same user representation where the bridge is established via user's consistent individuality across languages. The adversarial learning is realized by gradient reversal layer (GRL).

we conjecture that the sentiment knowledge between two different languages can be mapped to the same feature space to further improve the effect of multi-task learning with a feature generator and a language category discriminator. Formally, given a data sample (x^t, u^t, y^t) from the posts of the t-th language (i.e., task), we aim to predict the sentiment class of the posts with our adversarial cross-lingual multi-task learning method.

4.1 Adversarial Multi-task Learning

Intuitively, a user may post on different microblogging platforms in different languages, but the individuality and opinion bias embedded in the posts of different languages are supposed to be consistent. By regarding user's individuality as bridge between languages, we adopt multi-task learning to utilize the correlation of user's individuality across Chinese and English platforms for learning better user representation.

As shown in Figure 3, we illustrate our user attention based CNN model with adversarial multi-task learning (ACNN-AMT). All tasks share a same collection of users embedding u via the attention mechanism as a cross-lingual bridge. Each task is a sentiment classification model, which is decomposed into two components, i.e., a global ACNN model trained with posts from all languages for extracting common sentiment features (the orange-color CNN model), a language-specific ACNN model which is trained with posts from a specific language (the yellow- or green-color CNN model) for generating language-specific features, and a softmax classifier for predicting sentiment classification. Therefore, this multi-task model is both a sentiment classifier and meanwhile a generator for producing post representations at global and language-specific levels. Both tasks share the same global ACNN model.

For any input post x^t of the t-th task[3], we can compute its global representation s_g^t and task-specific representation s_p^t with the ACNN model. The final features s^t of post x^t are concatenation of the features from the specific and global space and user embedding. Formally, we define s_g^t, s_p^t and s^t as follows:

$$\begin{aligned} s_g^t &= \text{ACNN}(x^t, u^t, \theta_G) \\ s_p^t &= \text{ACNN}(x^t, u^t, \theta^t) \\ s^t &= s_g^t \oplus s_p^t \oplus u^t \end{aligned} \tag{6}$$

where θ_G contain parameters of the global task-independent model (which acts as the generator in the adversarial network), and θ^t contain the model parameters of the t-th task, and u^t is the user embedding of the t-th task which is constant across different tasks.

Because Chinese and English have different lexical and linguistic structures, the global sentiment classifier could learn little knowledge from English for Chinese sentiment classification, and vice versa. Nevertheless, if we could learn sentiment features independent of language category, the global sentiment classifier will be well trained by posts of both languages. To get such language-independent features, we introduce adversarial training into the global model. We formulate the global model as a generator and the language classification model as a discriminator using Generative Adversarial Network (GAN) (Goodfellow et al., 2014). During training, the generator is trying to generate language-independent sentiment features that would confuse the discriminator as to these features' language category, so that the discriminator is forced to struggle to become a strong classifier for correctly predicting the language category of the generated representation, until both the generator and discriminator cannot improve any more. The language discriminative model D parameterized by θ_D and θ_G is defined as follows:

$$\hat{y}(\theta_D, \theta_G) = \text{softmax}(\tanh(W_D s^g(\theta_G) + b_D)) \tag{7}$$

---

[3] For simplicity, we consider a two-task case here, i.e., $t = \{1, 2\}$. But our model is generic which can easily consider more tasks.

where $\hat{y}(\cdot)$ is the predicted language category, θ_D contain parameters $W_D \in \mathbb{R}^{T\times 3m}$ which are the weights (T is number of language categories) and $b_D \in \mathbb{R}^{T\times 3m}$ which are the bias terms, and $s^g(\theta_G) \in \mathbb{R}^{3m}$ is the language-independent sentiment features extracted by global ACNN model parameterized by θ_G.

Finally, we get the adversarial loss by cross-entropy error between gold language distribution and our predicted language distribution:

$$\mathcal{L}_{Adv} = \sum_{t=1}^{T}\sum_{i=1}^{N^t} y_i^t \log(\hat{y}_i^t) \tag{8}$$

where y_i^t denotes the ground-truth language label indicating that the i-th post comes from the t-th task (or language), $\hat{y}_i^t$ is the predicted language of the post, and N^t is the number of posts in the t-th task. We use the gradient reversal layer (GRL) (Ganin and Lempitsky, 2015) to perform the adversarial learning. The objective of GRL is to optimize θ_G and θ_D via the min-max steps as $\min_{\theta_G}\max_{\theta_D}\mathcal{L}_{Adv}$. After the adversarial training, we can obtain stronger language category discriminator and language-independent sentiment features.

4.2 Sentiment Classification

For the t-th task, the predicted post sentiment distribution is defined as follows:

$$\hat{z}^t = \mathrm{softmax}(\tanh(W^t s^t + b^t)) \tag{9}$$

where $W^t \in \mathbb{R}^{C\times(6m+o)}$ are the weights and $b^t \in \mathbb{R}^{(6m+o)}$ are the biases. For each sentiment category, cross-entropy error between gold sentiment distribution and our predicted sentiment distribution is defined as sentiment loss:

$$\mathcal{L}^t = -\sum_{c=1}^{C}\sum_{i=1}^{N_c^t} z_{c,i}^t \log(\hat{z}_{c,i}^t) \tag{10}$$

where $z_{c,i}^t$ denotes the ground-truth label indicating sentiment of the i-th post of the t-th task, $\hat{z}_{c,i}^t$ is the predicted sentiment label of the post, C is the number of sentiment classes, and N_c^t is the number of posts of class c in the t-th task.

Similar to (Liu et al., 2017), we add a squared Frobenius norm term to the loss function:

$$\mathcal{L}_{Frobenius} = \sum_{t=1}^{T}\|{G^t}^{\top}P^t\|_F^2 \tag{11}$$

where $\|\cdot\|_F^2$ is the squared Frobenius norm, G^t and P^t are matrics whose rows are s_g^t and s_p^t of each input sentence, respectively.

The final loss function of our model can be written as:

$$\mathcal{L} = \beta\mathcal{L}^1 + \lambda\mathcal{L}^2 + \gamma\mathcal{L}_{Adv} + \delta\mathcal{L}_{Frobenius} \tag{12}$$

where $\mathcal{L}^1$ and $\mathcal{L}^2$ are the loss functions of sentiment classification models of the two languages, and the hyper parameters β, λ, γ and δ are the weights of their corresponding losses.

To minimize the overall loss function $\mathcal{L}$, we use Adadelta (Zeiler, 2012) to update the model parameters. In particular, we employ Adadelta to update θ_D to maximize the adversarial loss term $\mathcal{L}_{Adv}$, and update other parameters to minimize the overall loss function $\mathcal{L}$.

5 Experiment

5.1 Experimental Setting

Our experiments are conducted on two real-world microblog sentiment datasets. The first dataset was crawled using our built-in-house crawler from Sina Weibo, which contain only Chinese posts. Weibo users have their personal profile, and their homepage links to Twitter may also appear in it. We extracted the Twitter homepage links for crawling our Twitter dataset via Twitter API, and the dataset contain only English posts. We labeled the posts with sentiment polarity based on frequently used emoticons as emoticons which are given by users were commonly regarded as appropriate personal sentiment labels (Song et al., 2015a,b; Wu and Huang, 2016).

The statistics of the two datasets are summarized in Table 2 and 3, where 96 bilingual users were found appearing in both datasets. In the experiment, we used all users, i.e., 755 from Twitter, and 379 from Weibo, assuming that similar users can be embedded into similar user representation space. The bilingual users will especially bring strong effects on personalization learning because the posts of bilingual users can be better represented with consistent individuality than those of monolingual users.

For each user's posts in different languages, we split them into training, development and testing sets by user volumes under the ratio of 7:2:1 randomly, and used Stanford CoreNLP (Manning et al., 2014) for word segmentation of Chinese and English posts. For evaluation, we use precision,

Dataset	classes	users	posts	positive	negative	posts/user	vocabulary	words/post
Twitter	2	755	41,210	28,782	12,428	54.58	27,211	10.70
Weibo	2	379	40,081	25,367	14,714	105.75	25,702	15.74

Table 2: Statistics of Weibo and Twitter datasets.

Dataset	users	posts	positive	negative	posts/user	vocabulary	words/post
Twitter	96	6,942	4,879	2,063	72.31	10,181	9.84
Weibo		13,563	7,448	6,115	141.28	14,031	15.19

Table 3: Statistics of Weibo and Twitter data of bilingual users.

recall and F-score to measure the classification results with 10-fold cross validation, and take average over ten folds for obtaining the values of the three evaluation metrics.

For Chinese posts, we trained our Word2Vec model (Mikolov et al., 2013) on our crawled 30M Weibo corpus. For English posts, we used the 200d GloVe vectors (Pennington et al., 2014) as word embeddings. We set the dimensionality of user embedding to 100.

The other model parameters were initialized by randomly sampling from uniform distribution in $[-0.1, 0.1]$. We set the mini-batch size to 32. Besides, we employed dropout technique (Srivastava et al., 2014) and the dropout rate was set to 0.5. We tuned the hyper-parameters on the development sets, and empirically set β to 0.8, λ to 1, γ to 0.1, and δ to 0.01. The width of three convolutional filter was fixed to 1, 2, and 3, corresponding to unigram, bi-gram and tri-gram, respectively.

5.2 Baselines

We compared our model with several strong baseline methods for microblog sentiment classification:

SVM + Wordvec: It averages the embeddings of all words in a post, which are regarded as features of a SVM classifer using LibSVM library (Chang and Lin, 2011).

LSTM: It uses traditional LSTM model for sentiment classification.

CNN: It uses CNN model (Kim, 2014) for sentiment classification.

NSC + UPA: It uses user and product attention mechanism over word-level and sentence-level semantics based on LSTM (Chen et al., 2016a). The original method focused on modeling product review texts. Because microblog posts contain users but no particular products information, we implemented the method with word-level modeling and user attention for fair comparison.

UPNN: It uses vector space model for modeling user preferences and product qualities, which is integrated with word-level representation and post-level representation (Tang et al., 2015). Original UPNN models user preference and product characteristic. We modified it to only model user preferences as a baseline method for comparison.

ASP-MTL: It uses LSTM model with adversarial multi-task learning to extract the domain-invariant features for cross-domain text classification (Liu et al., 2017). We regard domain category as language category for cross-lingual sentiment classification.

5.3 Result Comparisons

Table 4 shows the comparison of results among different models. We separate results into two groups which are monolingual results and cross-lingual results respectively.

In the first group, the SVM with averaging word embedding performs poorly because SVM cannot capture semantic information as well as deep neural networks. The CNN model performs better than LSTM, because LSTM model is easier to overfit. The NSC with UPA yields better results than LSTM, and UPNN yields better results than CNN, because they exploit the impact of user information. Our ACNN model archives the best performance by exploiting user information on top of the semantics of n-grams.

In the second group, the ASP-MTL performs better than LSTM, because global sentiment classifier is well trained by language-independent sentiment features with adversarial training. Our ACNN-AMT model significantly outperforms all the other baseline methods, confirming the importance of both user information and global

language-independent sentiment features.

5.4 Effect of Attention Mechanism and Multi-task Learning

Table 5 shows the effect of user attention in combination with pure CNN and multi-task CNN (CNN-MT) models. We can observe that: 1) The ACNN model and ACNN-MT model yield better sentiment classification results compared with CNN model and CNN-MT model without attention. It demonstrates that our user attention mechanism can capture crucial components for each user. 2) The CNN-MT model improves slightly compared with CNN model, and the reason is that there are substantial differences between Chinese and English languages, curbing from extracting global common sentiment features. The ACNN-MT model yields much better results than ACNN model, confirming that multi-task learning with user to bridge the gap between two languages can help generate more accurate user representation. We can also see that the ACNN-MT model improves more obviously on Weibo dataset. This is because larger proportion of Weibo posts than that of Twitter posts share users cross-lingually.

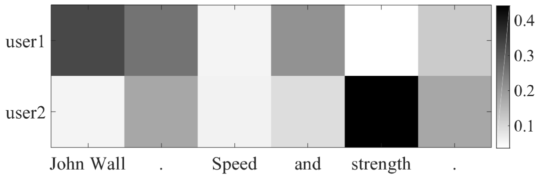

Figure 4: Visualization of attentions over unigram of Twitter. The darker color means higher attention weight.

In Figure 4 and Figure 5, we visualize the attention weights over n-grams to justify the effectiveness of our ACNN model. In Figure 4, we choose a tweet posted by user1 with content “John Wall. Speed and strength”. The user1 is a fan of “John Wall”, and the user2 has never talked about him. For the word “John Wall”[4], user1 has the largest attention weight, but user2 almost pays no attention, demonstrating that our ACNN model can capture crucial components for each user.

In Figure 5, we visualize the weights of a Chinese post posted by user1 with content “奇才 后卫 约翰沃尔 在 美国 国家队 表演赛 一显身手” (“The Wizards’s guard John Wall displayed his skills in the exhibition match of US national team”). As shown in this post, user1’s pursuit of John Wall is unchanged in Chinese, indicating that analyzing texts jointly could help extract more precise individuality of a user. For unigram, user1 does not have the largest attention weight for word “ 约翰沃尔” (“John Wall”). Nonetheless, for bi-grams and tri-grams, user1 has the largest attention weights on “后卫 约翰沃尔” (“guard John Wall”) and “奇才 后卫 约翰沃尔” (“Wizards guard John Wall”), respectively, and the reason is that n-grams contain more abundant and accurate semantic information that is crucial for each user to compose appropriate post representation.

5.5 Effect of Adversarial Mechanism

Table 6 shows the effect of adversarial mechanism. Chen et al. (2016b) has proved the important role of bilingual word embeddings in cross-lingual classification with adversarial learning. We train our bilingual word embeddings with MUSE (Conneau et al., 2017) so that semantically similar words in different languages are drawn closely in the embedding space. When the model is trying to classify Twitter posts, we transform Chi-

nese word embeddings into English word embeddings for alignment, and vice versa. By comparing models with adversarial mechanism (i.e., CNN-AMTL, ACNN-AMTL) and models without adversarial mechanism (i.e., CNN-MTL, ACNN-MTL), the former yield better results, suggesting that the adversarial learning could help generate language-independent sentiment features, and improve the effect of sentiment classification.

6 Conclusion

In this paper, we proposed an ACNN model for capturing user's individuality on microblogs, and an ACNN-AMT model for alleviating the data insufficiency problem in personalized sentiment classification. By exploiting the user information, our ACNN model could put emphasis on the key portions of posts that reflect users' individuality. By utilizing the consistent individuality and opinion bias of microblog users across different languages, our ACNN-AMT model could extract the language-specific features and language-independent features to enrich the user-specific post representation. Experimental results on English and Chinese microblog datasets confirm the clear advantage of our method over state-of-the-art baseline algorithms.

Abstract

Multilingual knowledge graphs (KGs) such as DBpedia and YAGO contain structured knowledge of entities in several distinct languages, and they are useful resources for cross-lingual AI and NLP applications. Cross-lingual KG alignment is the task of matching entities with their counterparts in different languages, which is an important way to enrich the cross-lingual links in multilingual KGs. In this paper, we propose a novel approach for cross-lingual KG alignment via graph convolutional networks (GCNs). Given a set of pre-aligned entities, our approach trains GCNs to embed entities of each language into a unified vector space. Entity alignments are discovered based on the distances between entities in the embedding space. Embeddings can be learned from both the structural and attribute information of entities, and the results of structure embedding and attribute embedding are combined to get accurate alignments. In the experiments on aligning real multilingual KGs, our approach gets the best performance compared with other embedding-based KG alignment approaches.

1 Introduction

Knowledge graphs (KGs) represent human knowledge in the machine-readable format, are becoming the important basis of many applications in the areas of artificial intelligence and natural language processing. Multilingual KGs such as DBpedia (Bizer et al., 2009), YAGO (Suchanek et al., 2008; Rebele et al., 2016), and BabelNet (Navigli and Ponzetto, 2012) are especially valuable if cross-lingual applications are to be built. Besides the knowledge encoded in each distinct language, multilingual KGs also contain rich cross-lingual links that match the equivalent entities in different languages. The cross-lingual links play an important role to bridge the language gap in a multilingual KG; however, not all the equivalent entities are connected by cross-lingual links in most multilingual KGs. Therefore, increasingly more research work studies the problem of cross-lingual KG alignment, aiming to match entities in different languages in a multilingual KG automatically.

Traditional cross-lingual KG alignment approaches either rely on machine translation technique or defining various language-independent features to discover cross-lingual links. Most recently, several embedding-based approaches have been proposed for cross-lingual KG alignment, including MTransE (Chen et al., 2017) and JAPE (Sun et al., 2017). Given two KGs and a set of pre-aligned entities of them, embedding-based approaches project entities into low-dimensional vector spaces; entities are matched based on the computations on their vector representations. Following very similar ideas as above, JE (Hao et al., 2016) and ITransE (Zhu et al., 2017) are embedding-based approaches for matching entities between heterogeneous KGs, and they can also work for the problem of cross-lingual KG alignment. The above embedding-based approaches can achieve promising performance without machine translation or feature engineering.

However, we find that the above approaches all try to jointly model the cross-lingual knowledge and the monolingual knowledge in one unified optimization problem. The loss of two kinds of knowledge has to be carefully balanced during the optimization. For example, JE, MTransE, and ITransE all use hyper-parameters to weight the loss of entity alignments in the loss functions of their models; JAPE uses the pre-aligned entities to combine two KGs as one, and adds weight to the scores of negative samples in its loss function. In the above approaches, entities' embeddings have to encode both the structural information in KGs and the equivalent relations of entities. Further-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 349–357
Brussels, Belgium, October 31 - November 4, 2018.

more, the attributes of entities (e.g., the age of a people, the population of a country) have not been fully utilized in the existing models. MTransE and ITransE cannot use attributional information in KGs; although JAPE includes the attribute types in the model, the attribute values of entities are ignored. We believe that considering the attribute values can further improve the results of KG alignment.

Having the above observations, we propose a new embedding-based KG alignment approach which directly models the equivalent relations between entities by using graph convolutional networks (GCNs). GCN is a kind of convolutional network which directly operates on graph-structured data; it generates node-level embeddings by encoding information about the nodes' neighborhoods. The adjacencies of two equivalent entities in KGs usually contain other equivalent entities, so we choose GCNs to generate neighborhood-aware embeddings of entities, which are used to discover entity alignments. Our approach can also provide a simple and effective way to include entities' attribute values in the alignment model. More specifically, our approach has the following advantages:

- Our approach uses the entity relations in each KG to build the network structure of GCNs, and it only considers the equivalent relations between entities in model training. Our approach has small model complexity and can achieve encouraging alignment results.
- Our approach only needs pre-aligned entities as training data, and it does not require any pre-aligned relations or attributes between KGs.
- Entity relations and entity attributes are effectively combined in our approach to improve the alignment results.

In the experiments on aligning real multilingual KGs, our approach gets the best performance compared with the baseline methods.

The rest of this paper is organized as follows, Section 2 reviews some related work, Section 3 introduces some background knowledge, Section 4 describes our proposed approach, Section 5 presents the evaluation results, Section 6 is the conclusion and future work.

2 Related Work

2.1 KG Embedding

In the past few years, much work has been done on the problem of KG embedding. KG embedding models embed entities and relations in a KG into a low-dimensional vector space while preserving the original knowledge. The embeddings are usually learned by minimizing a global loss function of all the entities and relations in a KG, which can be further used for relation prediction, information extraction, and some other tasks. TransE is a representative KG embedding approach (Bordes et al., 2013), which projects both entities and relations into the same vector space; if a triple (h, r, t) holds, TransE wants that $\boldsymbol{h} + \boldsymbol{r} \approx \boldsymbol{t}$. The embeddings are learned by minimizing a margin-based ranking criterion over the training set. TransE model is simple but powerful, and it gets promising results on link prediction and triple classification problems. To further improve TransE, several enhanced models based on it have been proposed, including TransR (Lin et al., 2015), TransH (Wang et al., 2014) and TransD (Ji et al., 2015) etc. By introducing new representations of relational translation, later approaches achieve better performance at the cost of increasing model complexity. There are many other KG embedding approaches, recent surveys (Wang et al., 2017; Nickel et al., 2016) give detailed introduction and comparison.

2.2 Embedding-based KG Alignment

Here we introduce the KG Alignment approaches most related to ours, and discuss the main differences between our approach and them.

JE (Hao et al., 2016) jointly learns the embeddings of multiple KGs in a uniform vector space to align entities in KGs. JE uses a set of seed entity alignments to connect two KGs, and then learns the embeddings by using a modified TransE model, which adds a loss of entity alignments in its global loss function.

MTransE (Chen et al., 2017) encodes entities and relations of each KG in a separated embedding space by using TransE; it also provides transitions for each embedding vector to its cross-lingual counterparts in other spaces. The loss function of MTransE is the weighted sum of two component models' loss (i.e., knowledge model and alignment model). To train the alignment model, MTransE needs a set of aligned triples of two KGs.

JAPE (Sun et al., 2017) combines structure embedding and attribute embedding to match entities in different KGs. Structure embedding follows the TransE model, which learns vector representations of entities in the overlay graph of two KGs. Attribute embedding follows the Skip-gram model, which aims to capture the correlations of attributes. To get desirable results, JAPE needs the relations and attributes of two KGs to be aligned in advance.

ITransE (Zhu et al., 2017) is a joint knowledge embedding approach for multiple KGs, which is also suitable for the cross-lingual KG alignment problem. ITransE first learns both entity and relation embeddings following TransE; then it learns to map knowledge embeddings of different KGs into a joint space according to a set of seed entity alignments. ITransE performs iterative entity alignment by using the newly discovered entity alignments to update joint embeddings of entities. ITransE requires all relations being shared among KGs.

The above approaches follow the similar framework to match entities in different KGs. They all rely on TransE model to learn entity embeddings, and then define some kinds of transformation between embeddings of aligned entities. Compared with these approaches, our approach uses an entirely different framework; it uses GCNs to embed entities in a unified vector space, where aligned entities are expected to be as close as possible. Our approach only focuses on matching entities in two KGs, and it does not learn embeddings of relations. MTransE, JAPE, and ITransE all require relations being aligned or shared in KGs; our approach does not need this kind of prior knowledge.

3 Problem Formulation

KGs represent knowledge about real-world entities as triples. Here we consider two kinds of triples in KGs: relational triples, and attributional triples. Relational triples represents relations between entities, and it has the form $\langle entity_1, relation, entity_2 \rangle$. Attributional triples describe attributes of entities, and it has the form $\langle entity, attribute, value \rangle$. For example in the data of YAGO, *graduatedFrom* is a relation, and (*Albert_Einstein, graduatedFrom, ETH_Zurich*) is a relational triple; *diedOnDate* is an attribute, and (*Albert_Einstein, diedOnDate, 1955*) is an attributional triple. Both relational and attributional triples describe important information about entities, we will take both of them into account in the task of cross-lingual KG alignment.

Formally, we represent a KG as $G = (E, R, A, T_R, T_A)$, where E, R, A are sets of entities, relations and attributes, respectively; $T_R \subset E \times R \times E$ is the set of relational triples, $T_A \subset E \times A \times V$ is the set of attributional triples, where V is the set of attribute values.

Let $G_1 = (E_1, R_1, A_1, T_1^R, T_1^A)$ and $G_2 = (E_2, R_2, A_2, T_2^R, T_2^A)$ be two KGs in different languages, and $S = \{(e_{i_1}, e_{i_2}) | e_{i_1} \in E_1, e_{i_2} \in E_2\}_{i=1}^m$ be a set of pre-aligned entity pairs between G_1 and G_2. We define the task of cross-lingual KG alignment as finding new entity alignments based on the existing ones. In multilingual KGs such as DBpedia and YAGO, the cross-lingual links in them can be used to build the sets of pre-aligned entity pairs. The already known entity alignments are used as seeds or training data in the process of KG alignment.

4 The Proposed Approach

The framework of our proposed approach is shown in Figure 1. Given two KGs G_1 and G_2 in different languages, and a set of known aligned entity pairs $S = \{(e_{i_1}, e_{i_2})\}_{i=1}^m$ between them, our approach automatically find new entity alignments based on GCN-based entity embeddings. The basic idea of our approach is to use GCNs to embed entities from different languages into a unified vector space, where equivalent entities are expected to be as close as possible. Entity alignments are predicted by applying a pre-defined distance function to entities' GCN-representations.

4.1 GCN-based Entity Embedding

GCNs (Bruna et al., 2014; Henaff et al., 2015; Defferrard et al., 2016; Kipf and Welling, 2017) are a type of neural network that directly operates on graph data. GCNs allow end-to-end learning of prediction pipelines whose inputs are graphs of arbitrary size and shape. The inputs of a GCN are feature vectors of nodes and the structure of the graph; the goal of a GCN is to learn a function of features on the input graph and produces a node-level output. GCNs can encode information about the neighborhood of a node as a real-valued vector, which was usually used for classification or regression. When solving the problem of KG alignment, we assume that (1) equivalent entities tend

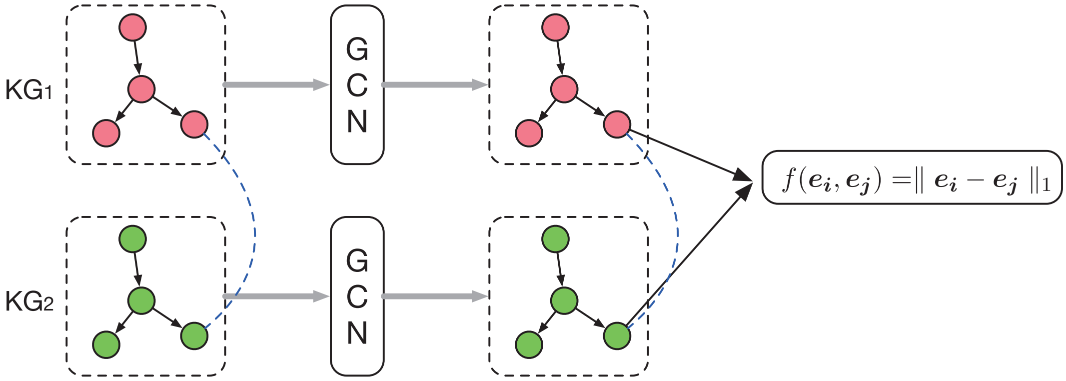

Figure 1: Framework of our approach (dashed blue lines connects equivalent entities in two KGs)

to have similar attributes, and (2) equivalent entities are usually neighbored by some other equivalent entities. GCNs can combine the attribute information and the structure information together, therefore our approach uses GCNs to project entities into low-dimensional vector space, where equivalent entities are close to each other.

A GCN-model consists of multiple stacked GCN layers. The input to the l-th layer of the GCN model is a vertex feature matrix, $H^{(l)} \in \mathbb{R}^{n \times d^{(l)}}$, where n is the number of vertices and $d^{(l)}$ is the number of features in the l-th layer. The output of the l-th layer is a new feature matrix $H^{(l+1)}$ by the following convolutional computation:

$$H^{(l+1)} = \sigma\left(\hat{D}^{-\frac{1}{2}}\hat{A}\hat{D}^{-\frac{1}{2}}H^{(l)}W^{(l)}\right) \qquad (1)$$

where σ is an activation function; A is a $n \times n$ connectivity matrix that represents the structure information of the graph; $\hat{A} = A + I$, and I is the identity matrix; $\hat{D}$ is the diagonal node degree matrix of $\hat{A}$; $W^{(l)} \in \mathbb{R}^{d^{(l)} \times d^{(l+1)}}$ is the weight matrix of the l-th layer in the GCN, $d^{(l+1)}$ is the dimensionality of new vertex features.

Structure and Attribute Embedding. In our approach, GCNs are used to embed entities of two KGs in a unified vector space. To utilize both structure and attribute information of entities, our approach assigns two feature vectors to each entity in GCN layers, structure feature vector h_s and attribute feature vector h_a. In the input layer, $h_s^{(0)}$ is randomly initialized and updated during the training process; $h_a^{(0)}$ is the attribute vectors of entities and it is fixed during the model training. Let H_s and H_a be the structure and attribute feature matrices of all the entities, we redefine the convolutional computation as:

$$\begin{aligned} &[H_s^{(l+1)}; H_a^{(l+1)}] \\ &= \sigma\left(\hat{D}^{-\frac{1}{2}}\hat{A}\hat{D}^{-\frac{1}{2}}[H_s^{(l)}W_s^{(l)}; H_a^{(l)}W_a^{(l)}]\right) \end{aligned} \qquad (2)$$

where $W_s^{(l)}$ and $W_a^{(l)}$ are the weight matrices for structure features and attribute features in the l-th layer, respectively; [;] denotes the concatenation of two matrices. The activation function σ is chosen as $ReLU(\cdot) = max(0, \cdot)$.

Model Configuration. More specifically, our approach uses two 2-layer GCNs, and each GCN processes one KG to generate embeddings of its entities. As defined in Section 3, we denote two KGs as $G_1 = (E_1, R_1, A_1, T_1^R, T_1^A)$ and $G_2 = (E_2, R_2, A_2, T_2^R, T_2^A)$; and let their corresponding GCN models be denoted as GCN_1 and GCN_2. As for the structure feature vectors of entities, we set the dimensionality of feature vectors to d_s in all the layers of GCN_1 and GCN_2; and two GCN models share the weight matrices $W_s^{(1)}$ and $W_s^{(2)}$ for the structure features in two layers. As for the attribute vectors of entities, we set the dimensionality of output feature vectors to d_a. Because two KGs may have different number of attributes (i.e. $|A_1| \neq |A_2|$), the dimensionalities of the input attribute feature vectors in two GCN models are different. The first layer of each GCN model transforms the input attribute feature vectors into vectors of size d_a; and two GCN-models generate attribute embeddings of the same dimensionality. Table 1 outlines the parameters of two GCNs in our approach. The final outputs of two GCNs are $(d_s + d_a)$-dimensional embeddings of entities, which are further used to discover entity alignments.

Parameter	GCN_1	GCN_2
Initial Structure Feature Matrices	$H_{s1}^{(0)} \in \mathbb{R}^{\lvert E_1\rvert \times d_s}$	$H_{s2}^{(0)} \in \mathbb{R}^{\lvert E_2\rvert \times d_s}$

Weight Matrix for Attribute Features in Layer 1	$W_{a1}^{(1)} \in \mathbb{R}^{\lvert A_1\rvert \times d_a}$	$W_{a2}^{(1)} \in \mathbb{R}^{\lvert A_2\rvert \times d_a}$
Weight Matrix for Attribute Features in Layer 2	$W_a^{(2)} \in \mathbb{R}^{d_a \times d_a}$	
Output Attribute Embeddings	$H_{a1}^{(2)} \in \mathbb{R}^{\lvert E_1\rvert \times d_a}$	$H_{a2}^{(2)} \in \mathbb{R}^{\lvert E_2\rvert \times d_a}$

Table 1: Parameters of two GCNs

Computation of Connectivity Matrix. In a GCN model, the connectivity matrix A defines the neighborhoods of entities in the convolutional computation. For an undirected graph, the adjacency matrix can be directly used as A_s. But KGs are relational multi-graphs, entities are connected by typed relations. Therefore, we design a particular method for computing A of a KG; we let $a_{ij} \in A$ indicate to what extent the information of alignments propagates from the i-th entity to the j-th entity. The probability of two entities being equivalent differs greatly considering they connect to aligned entities by different relations (e.g., *hasParent* vs. *hasFriend*). Therefore, we compute two measures, which are called functionality and inverse functionality, for each relation:

$$fun(r) = \frac{\#Head\_Entities\_of\_r}{\#Triples\_of\_r} \tag{3}$$

$$ifun(r) = \frac{\#Tail\_Entities\_of\_r}{\#Triples\_of\_r} \tag{4}$$

where $\#Triples\_of\_r$ is the number of triples of relation r; $\#Head\_Entities\_of\_r$ and $\#Tail\_Entities\_of\_r$ are the numbers of head entities and tail entities of r, respectively. To measure the influence of the i-th entity over the j-the entity, we set $a_{ij} \in A$ as:

$$a_{ij} = \sum_{\langle e_i,r,e_j\rangle \in G} ifun(r) + \sum_{\langle e_j,r,e_i\rangle \in G} fun(r) \tag{5}$$

4.2 Alignment prediction

Entity alignments are predicted based on the distances between entities from two KGs in the GCN-representation space. For entities e_i in G_1 and v_j in G_2, we compute the following distance measure between them:

$$\begin{aligned} D(e_i, v_j) = &\beta \frac{f(\boldsymbol{h_s}(e_i), \boldsymbol{h_s}(v_j)}{d_s} \\ &+ (1-\beta)\frac{f(\boldsymbol{h_a}(e_i), \boldsymbol{h_a}(v_j))}{d_a} \end{aligned} \tag{6}$$

where $f(\boldsymbol{x}, \boldsymbol{y}) = \| \boldsymbol{x} - \boldsymbol{y} \|_1$, $\boldsymbol{h_s}(\cdot)$ and $\boldsymbol{h_a}(\cdot)$ denote the structure embedding and attribute embedding of an entity, respectively; d_s and d_a are dimensionalities of structure embeddings and attribute embeddings; β is a hyper-parameter that balances the importance of two kinds of embeddings.

The distance is expected to be small for equivalent entities and large for non-equivalent ones. For a specific entity e_i in G_1, our approach computes the distances between e_i and all the entities in G_2, and returns a list of ranked entities as candidate alignments. The alignment can be also performed from G_2 to G_1. In the experiments, we report the results of both directions of KG alignment.

4.3 Model Training

To enable GCNs to embed equivalent entities as close as possible in the vector space, we use a set of known entity alignments S as training data to train GCN models. The model training is performed by minimizing the following margin-based ranking loss functions:

$$\begin{aligned} L_s = \sum_{(e,v)\in S} \sum_{(e',v')\in S'_{(e,v)}} &[f(\boldsymbol{h_s}(e), \boldsymbol{h_s}(v)) + \gamma_s \\ &- f(\boldsymbol{h_s}(e'), \boldsymbol{h_s}(v')]_+ \end{aligned} \tag{7}$$

$$
\begin{aligned}
L_a = \sum_{(e,v)\in S} \sum_{(e',v')\in S'_{(e,v)}} & [f(\boldsymbol{h_a}(e), \boldsymbol{h_a}(v)) + \gamma_a \\
& - f(\boldsymbol{h_a}(e'), \boldsymbol{h_a}(v'))]_+
\end{aligned}
\tag{8}
$$

where $[x]_+ = \max\{0, x\}$, $S'_{(e,v)}$ denotes the set of negative entity alignments constructed by corrupting (e, v), i.e. replacing e or v with a randomly chosen entity in G_1 or G_2; $\gamma_s, \gamma_a > 0$ are margin hyper-parameters separating positive and negative entity alignments. L_s and L_a are loss functions for structure embedding and attribute embedding, respectively; they are independent of each other and hence are optimized separately. We adopt stochastic gradient descent (SGD) to minimize the above loss functions.

5 Experiment

5.1 Datasets

We use the DBP15K datasets in the experiments, which were built by Sun et al. (2017). The datasets were generated from DBpedia, a large-scale multilingual KG containing rich inter-language links between different language versions. Subsets of Chinese, English, Japanese and French versions of DBpedia are selected following certain rules. Table 2 outlines the detail information of the datasets. Each dataset contains data two KGs in different languages and 15 thousand inter-language links connecting equivalent entities in two KGs. In the experiments, the known equivalent entity pairs are used for model training and testing.

5.2 Experiment Settings

In the experiments, we compared our approach with JE, MTransE and JAPE. We also build JAPE′, a variant of JAPE which does not use pre-aligned relations and attributes. Because the approach ITransE performs iterative alignment and it requires two KGs sharing the same relations, we do not include it in the comparison. The inter-language links in each dataset are used as the gold standards of entity alignments. For all the compared approaches, we use 30% of inter-language links for training and 70% of them for testing; the split of training and testing are the same for all approaches. We use $Hits@k$ as the evaluation measure to assess the performance of all the approaches. $Hits@k$ measures the proportion of correctly aligned entities ranked in the top k candidates. For the parameters of our approach, we set $d_s = 1,000$, $d_a = 100$; the margin $\gamma_s = \gamma_a = 3$ in the loss function, and β in the distance measure is empercally set to 0.9.

5.3 Results

Table 3 shows the results of all the compared approaches on DBP15K datasets. We report $Hits@1$, $Hits@10$ and $Hits@50$ of approaches on each dataset. Because we use the same datasets as in (Sun et al., 2017), the results of JE, MTransE, and JAPE are obtained from (Sun et al., 2017). For JAPE and JAPE′, each of them has three variants: Structure Embedding without negative triples (SE w/o neg.), Structure Embedding (SE), Structure and attribute joint embedding (SE+AE). We use GCN(SE) and GCN(SE+AE) to denote two variants of our approach: one only uses relational triples to perform structure embedding, and the other uses both relational and attributional triples to perform structure and attribute embedding.

GCN(SE) vs. GCN(SE+AE)

We first compare the results of GCN(SE) and GCN(SE+AE) to see whether the attributional information is helpful in the KG alignment task. According to the results, adding attributes in our approach do lead to slightly better results. The improvements range from 1% to 10%, which are very similar to the improvements of JAPE(SE) over JAPE(SE+AE). It shows that the KG alignment mainly relays on the structural information in KGs, but the attributional information is still useful. Our approach uses the same framework for embedding structure and attribute information, the combination of two kinds of embeddings works effectively.

GCN(SE+AE) vs. Baselines

On the dataset of DBP15K$_{ZH-EN}$, JAPE(SE+AE) performs best and gets five best $Hits@k$ values; our approach GCN(SE+AE) gets the best $Hits@1$ in the alignment direction of ZH→EN. The results of GCN(SE+AE) and JAPE gets very close results regarding $Hits@1$ and $Hits@10$ in the direction of ZH→EN. In the alignment direction of EN→ZH, JAPE(SE+AE) outperforms GCN(SE+AE) by about 2-3%. But it should be noticed that JAPE uses additional aligned relations and attributes as its inputs,

Datasets		Entities	Relations	Attributes	Rel. triples	Attr. triples

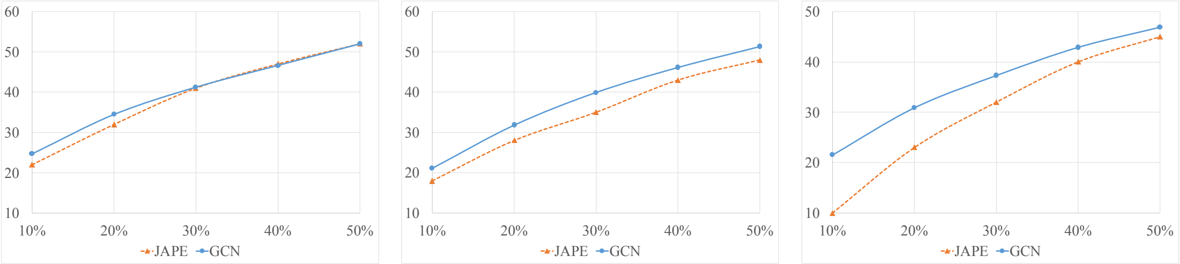
Table 3: Results comparison of cross-lingual KG alignment (* marks the results obtained from (Sun et al., 2017))

while our approach does not use these kinds of prior knowledge. If compared with JAPE′, GCN(SE+AE) performs better than it regrading $Hits@1$ and $Hits@10$. While compared with



(a) ZH-EN (b) JA-EN (c) FR-EN

Figure 2: GCN and JAPE using different sizes of training data (horizontal coordinates: proportions of pre-aligned entities used in training data; vertical coordinates: $Hits@1$)

JE and MTransE, GCN(SE+AE) outperform them by more than 10% in most cases. On the datasets of DBP15K$_{JA-EN}$ and DBP15K$_{FR-EN}$, GCN(SE+AE) outperforms all the compared approaches regarding all the $Hits@k$ measures. Even compared with JAPE which uses extra relation and attribute alignments, GCN(SE+AE) still gets better results than it.

Comparing with all the baselines, both GCN(SE) and GCN(SE+AE) outperform JE and MTransE significantly. Among all the baselines, JAPE is the strongest one; it might due to its ability of using both relational and attributional triples, and the extra alignments of relations and attributes that it consumes. Our approach achieves better results than JAPE on two datasets; Although JAPE performs better than our approach, the differences between their results are small. If there are no existing relation and attribute alignments between two KGs, our approach will have distinct advantage over JAPE.

GCN vs. JAPE using different sizes of training data

To investigate how the size of training set affects the results of our approach, we further compare our approach with JAPE by using different number of pre-aligned entities as training data. For JAPE, the pre-aligned entities are used as seeds to make their vectors overlapped. In our approach, all the pre-aligned entities are used to train GCN models. Intuitively, the more pre-aligned entities used, the better results should be obtained by both GCN and JAPE.

Here we use different proportions of pre-aligned entities as training data, which ranges 10% to 50% with step 10%; all the rest of pre-aligned entities are used for testing. Figure 2 shows the $Hits@1$ of two approaches in three datasets. It shows that both approaches perform better as the size of training data increases. And our approach always outperforms JAPE except using 40% pre-aligned entities as training data in Figure 2(a). Especially in the tasks of aligning Japanese to English and French to English, our approach has a distinct advantage over JAPE.

6 Conclusion and Future Work

This paper presents a new embedding-based KG alignment approach which discovers entity alignments based on the entity embeddings learned by GCNs. Our approach can make use of both the relational and the attributional triples in KGs to discover the entity alignments. We evaluate our method on the data of real multilingual KGs, and the results show the advantages of our approach over the compared baselines.

In the future work, we will explore more advanced GCN models for KG alignment task, such as Relational GCNs (Schlichtkrull et al., 2017) and Graph Attention Networks (GATs) (Velickovic et al., 2017). Furthermore, how to iteratively discover new entity alignments in the framework of our approach is another interesting direction that we will study in the future.

Abstract

Sememes are defined as the minimum semantic units of human languages. As important knowledge sources, sememe-based linguistic knowledge bases have been widely used in many NLP tasks. However, most languages still do not have sememe-based linguistic knowledge bases. Thus we present a task of cross-lingual lexical sememe prediction, aiming to automatically predict sememes for words in other languages. We propose a novel framework to model correlations between sememes and multi-lingual words in low-dimensional semantic space for sememe prediction. Experimental results on real-world datasets show that our proposed model achieves consistent and significant improvements as compared to baseline methods in cross-lingual sememe prediction. The codes and data of this paper are available at `https://github.com/thunlp/CL-SP`.

1 Introduction

Words are regarded as the smallest meaningful unit of speech or writing that can stand by themselves in human languages, but not the smallest indivisible semantic unit of meaning. That is, the meaning of a word can be represented as a set of semantic components. For example, "*Man = human + male + adult*" and "*Boy = human + male + child*". In linguistics, the minimum semantic unit of meaning is named sememe (Bloomfield, 1926). Some people believe that semantic meanings of concepts such as words can be composed of a limited closed set of sememes. And sememes can help us comprehend human languages better.

Unfortunately, the lexical sememes of words are not explicit in most human languages. Hence, people construct sememe-based linguistic knowledge bases (KBs) via manually annotating every words with a pre-defined closed set of sememes. HowNet (Dong and Dong, 2003) is one of the most well-known sememe-based linguistic KBs. Different from WordNet (Miller, 1995) which focuses on the relations between senses, it annotates each word with one or more relevant sememes. As illustrated in Fig. 1, the word *apple* has two senses including *apple (fruit)* and *apple (brand)* in HowNet. The sense *apple (fruit)* has one sememe *fruit*, and the sense *apple (brand)* has five sememes including *computer*, *PatternValue*, *able*, *bring* and *SpecificBrand*. There exist about 2,000 sememes and over 100 thousand labeled Chinese and English words in HowNet. HowNet has been widely used in various NLP applications such as word similarity computation (Liu and Li, 2002), word sense disambiguation (Zhang et al., 2005), question classification (Sun et al., 2007) and sentiment classification (Dang and Zhang, 2010).

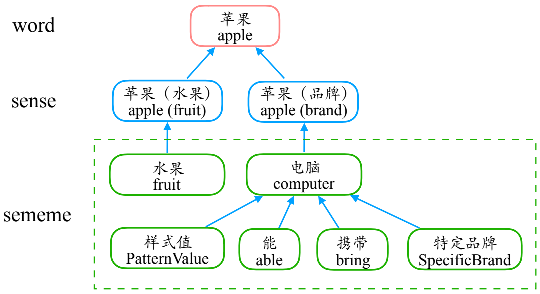

Figure 1: An example of HowNet.

However, most languages do not have such sememe-based linguistic KBs, which prevents us understanding and utilizing human languages to a greater extent. Therefore, it is important to build sememe-based linguistic KBs for various languages. Manual construction for sememe-based linguistic KBs requires efforts of many linguistic experts, which is time-consuming and

labor-intensive. For example, the construction of HowNet has cost lots of Chinese linguistic experts more than 10 years.

To address the issue of the high labor cost of manual annotation, we propose a new task, cross-lingual lexical sememe prediction (CLSP) which aims to automatically predict lexical sememes for words in other languages. CLSP aims to assist in the annotation of linguistic experts. There are two critical challenges for CLSP: (1) There is not a consistent one-to-one match between words in different languages. For example, English word "beautiful" can refer to Chinese words of either "美丽" or "漂亮". Hence, we cannot simply translate HowNet into another language. And how to recognize the semantic meaning of a word in other languages becomes a critical problem. (2) Since there is a gap between the semantic meanings of words and sememes, we need to build semantic representations for words and sememes to capture the semantic relatedness between them.

To tackle these challenges, in this paper, we propose a novel model for CLSP, which aims to transfer sememe-based linguistic KBs from source language to target language. Our model contains three modules including (1) monolingual word embedding learning which is intended for learning semantic representations of words for source and target languages respectively; (2) cross-lingual word embedding alignment which aims to bridge the gap between the semantic representations of words in two languages; (3) sememe-based word embedding learning whose objective is to incorporate sememe information into word representations. For simplicity, we do not consider the hierarchy information in HowNet in this paper.

In experiments, we take Chinese as source language and English as target language to show the effectiveness of our model. Experimental results show that our proposed model could effectively predict lexical sememes for words with different frequencies in other languages. Our model also has consistent improvements on two auxiliary experiments including bilingual lexicon induction and monolingual word similarity computation by jointly learning the representations of sememes, words in source and target languages.

2 Related Work

Since HowNet was published (Dong and Dong, 2003), it has attracted wide attention of researchers. Most of related works focus on applying HowNet to specific NLP tasks (Liu and Li, 2002; Zhang et al., 2005; Sun et al., 2007; Dang and Zhang, 2010; Fu et al., 2013; Niu et al., 2017; Zeng et al., 2018; Gu et al., 2018). To the best of our knowledge, only Xie et al. (2017) and Jin et al. (2018) conduct studies of augmenting HowNet by recommending sememes for new words. However, both of the two works are aimed to recommend sememes for monolingual words and not applicable to cross-lingual circumstance. Accordingly, our work is the first effort to automatically perform cross-lingual sememe prediction to enrich sememe-based linguistic KBs.

Our novel model adopts the method of word representation learning (WRL). Recent years have witnessed great advances in WRL. Models like Skip-gram, CBOW (Mikolov et al., 2013a) and GloVe (Pennington et al., 2014) are immensely popular and achieve remarkable performance in many NLP tasks. However, most WRL methods learn distributional information of words from large corpora while the valuable information contained in semantic lexicons are disregarded. Therefore, some works try to inject semantic information of KBs into WRL (Faruqui et al., 2015; Liu et al., 2015; Mrkšic et al., 2016; Bollegala et al., 2016). Nevertheless, these works are all applied to word-based KBs such as WordNet, few works pay attention to how to incorporate the knowledge from sememe-based linguistic KBs.

There also have been plenty of studies working on cross-lingual WRL (Upadhyay et al., 2016; Ruder, 2017). Most of them require parallel corpora (Zou et al., 2013; AP et al., 2014; Hermann and Blunsom, 2014; Kočiskỳ et al., 2014; Gouws et al., 2015; Luong et al., 2015; Coulmance et al., 2015). Some of them adopt unsupervised or weakly supervised methods (Mikolov et al., 2013b; Vulić and Moens, 2015; Conneau et al., 2017; Artetxe et al., 2017). There are also some works using a seed lexicon as the cross-lingual signal (Dinu et al., 2014; Faruqui and Dyer, 2014; Lazaridou et al., 2015; Shi et al., 2015; Lu et al., 2015; Gouws et al., 2015; Wick et al., 2016; Ammar et al., 2016; Duong et al., 2016; Vulić and Korhonen, 2016).

In terms of our cross-lingual sememe prediction task, parallel data-based bilingual WRL methods are unsuitable because most language pairs have no large parallel corpora. Besides, unsupervised methods are not appropriate either as they are generally hard to learn high-quality bilingual word embeddings. Therefore, we choose the seed lexicon method in our model, and further introduce matching mechanism that is inspired by Zhang et al. (2017) to enhance its performance.

3 Methodology

In this section, we introduce our novel model for CLSP. Here we define the language with sememe annotations as source language and the language without sememe annotations as target language. The main idea of our model is to learn word embeddings of source and target languages jointly in a unified semantic space, and then predict sememes for words in target language according to the words with similar semantic meanings in source language.

Our method consists of three parts: monolingual word representation learning, cross-lingual word embedding alignment and sememe-based word representation learning. Hence, we define the objective function of our method corresponding to the three parts:

$$\mathcal{L} = \mathcal{L}_{mono} + \mathcal{L}_{cross} + \mathcal{L}_{sememe}. \quad (1)$$

Here, the monolingual term $\mathcal{L}_{mono}$ is designed for learning monolingual word embeddings from non-parallel corpora for source and target languages respectively. The cross-lingual term $\mathcal{L}_{cross}$ aims to align cross-lingual word embeddings in a unified semantic space. And $\mathcal{L}_{sememe}$ can draw sememe information into word representation learning and conduce to better word embeddings for sememe prediction. In the following subsections, we introduce the three parts in detail.

3.1 Monolingual Word Representation

Monolingual word representation is responsible for explaining regularities in monolingual corpora of source and target languages. Since the two corpora are non-parallel, $\mathcal{L}_{mono}$ comprises two monolingual sub-models that are independent of each other:

$$\mathcal{L}_{mono} = \mathcal{L}^S_{mono} + \mathcal{L}^T_{mono}, \quad (2)$$

where the superscripts S and T denote source and target languages respectively.

As a common practice, we choose the well established Skip-gram model to obtain monolingual word embeddings. Skip-gram model is aimed at maximizing the predictive probability of context words conditioned on the centered word. Formally, taking the source side for example, given a training word sequence $\{w^S_1, \cdots, w^S_n\}$, Skip-gram model intends to minimize:

$$\mathcal{L}^S_{mono} = -\sum_{c=K+1}^{n-K} \sum_{-K \le k \le K, k \ne 0} \log P(w^S_{c+k} | w^S_c), \quad (3)$$

where K is the size of the sliding window. $P(w^S_{c+k}|w^S_c)$ stands for the predictive probability of one of the context words conditioned on the centered word w^S_c, formalized by the following softmax function:

$$P(w^S_{c+k}|w^S_c) = \frac{\exp(\mathbf{w}^S_{c+k} \cdot \mathbf{w}^S_c)}{\sum_{w^S_s \in V^S} \exp(\mathbf{w}^S_s \cdot \mathbf{w}^S_c)}, \quad (4)$$

in which V^s indicates the word vocabulary of source language. $\mathcal{L}^T_{mono}$ can be formulated similarly.

3.2 Cross-lingual Word Embedding Alignment

Cross-lingual word embedding alignment aims to build a unified semantic space for the words in source and target languages. Inspired by Zhang et al. (2017), we align the cross-lingual word embeddings with signals of a seed lexicon and self-matching.

Formally, $\mathcal{L}_{cross}$ is composed of two terms including alignment by seed lexicon $\mathcal{L}_{seed}$ and alignment by matching $\mathcal{L}_{match}$:

$$\mathcal{L}_{cross} = \lambda_s \mathcal{L}_{seed} + \lambda_m \mathcal{L}_{match}, \quad (5)$$

where λ_s and λ_m are hyperparameters for controlling relative weightings of the two terms.

Alignment by Seed Lexicon

The seed lexicon term $\mathcal{L}_{seed}$ encourages word embeddings of translation pairs in a seed lexicon $\mathcal{D}$ to be close, which can be achieved via a L_2 regularizer:

$$\mathcal{L}_{seed} = \sum_{\langle w^S_s, w^T_t \rangle \in \mathcal{D}} \|\mathbf{w}^S_s - \mathbf{w}^T_t\|^2, \quad (6)$$

in which w^S_s and w^T_t indicate the words in source and target languages in the seed lexicon respectively.

Alignment by Matching Mechanism

As for the matching process, it is founded on an assumption that each target word should be matched to a single source word or a special empty word, and vice versa. The goal of the matching process is to find the matched source (target) word for each target (source) word and maximize the matching probabilities for all the matched word pairs. The loss of this part can be formulated as:

$$\mathcal{L}_{match} = \mathcal{L}_{match}^{T2S} + \mathcal{L}_{match}^{S2T}, \tag{7}$$

where $\mathcal{L}_{match}^{T2S}$ is the term for target-to-source matching and $\mathcal{L}_{match}^{S2T}$ is the term for source-to-target matching.

Next, we give a detailed explanation of target-to-source matching, and the source-to-target matching is defined in the same way. We first introduce a latent variable $m_t \in \{0, 1, \cdots, |V^S|\}$ $(t = 1, 2, \cdots, |V^T|)$ for each target word w_t^T, where $|V^S|$ and $|V^T|$ indicate the vocabulary size of source and target languages respectively. Here, m_t specifies the index of the source word that w_t^T matches with, and $m_t = 0$ signifies the empty word is matched. Then we have $\mathbf{m} = \{m_1, m_2, \cdots, m_{|V^T|}\}$, and can formalize the target-to-source matching term:

$$\begin{aligned} \mathcal{L}_{match}^{T2S} &= -\log P(\mathcal{C}^T|\mathcal{C}^S) \\ &= -\log \sum_{\mathbf{m}} P(\mathcal{C}^T, \mathbf{m}|\mathcal{C}^S), \end{aligned} \tag{8}$$

where $\mathcal{C}^T$ and $\mathcal{C}^S$ denote the target and source corpus respectively. Here, we simply assume that the matching processes of target words are independent of each other. Therefore, we have:

$$\begin{aligned} P(\mathcal{C}^T, \mathbf{m}|\mathcal{C}^S) &= \prod_{w^T \in \mathcal{C}^T} P(w^T, \mathbf{m}|\mathcal{C}^S) \\ &= \prod_{t=1}^{|V^T|} P(w_t^T | w_{m_t}^S)^{c(w_t^T)}, \end{aligned} \tag{9}$$

where $w_{m_t}^S$ is the source word that w_t^T matches with, and $c(w_t^T)$ is the number of times w_t^T occurs in the target corpus.

3.3 Sememe-based Word Representation

Sememe-based word representation is intended for improving word embeddings for sememe prediction by introducing the information of sememe-based linguistic KBs of source language. In this section, we present two methods of sememe-based word representation.

Word Relation-based Approach

A simple and intuitive method is to let words with similar sememe annotations tend to have similar word embeddings, which we name word relation-based approach. To begin with, we construct a synonym list from sememe-based linguistic KBs of source language, where we regard words sharing a certain number of sememes as synonyms. Next, we force synonyms to have closer word embeddings.

Formally, we let $\mathbf{w}_i^S$ be original word embedding of w_i^S and $\hat{\mathbf{w}}_i^S$ be its adjusted word embedding. And let $\text{Syn}(w_i^S)$ denote the synonym set of word w_i^S. Then the loss function is:

$$\begin{aligned} \mathcal{L}_{sememe} = \sum_{w_i^S \in V^S} \Big[& \alpha_i \|\mathbf{w}_i^S - \hat{\mathbf{w}}_i^S\|^2 + \\ & \sum_{w_j^S \in \text{Syn}(w_i^S)} \beta_{ij} \|\hat{\mathbf{w}}_i^S - \hat{\mathbf{w}}_j^S\|^2 \Big], \end{aligned} \tag{10}$$

where α and β control the relative strengths of the two terms. It should be noted that the idea of forcing similar words to have close word embeddings is similar to the state-of-the-art retrofitting approach (Faruqui et al., 2015). However, retrofitting approach cannot be applied here because sememe-based linguistic KBs such as HowNet cannot directly provide its needed synonym list.

Sememe Embedding-based Approach

Simple and effective as the word relation-based approach is, it cannot make full use of the information of sememe-based linguistic KBs because it disregards the complicated relations between sememes and words as well as relations between different sememes. To address this limitation, we propose sememe embedding-based approach, which learns both sememe and word embeddings jointly.

In this approach, we represent sememes with distributed vectors as well and place them into the same semantic space as words. Similar to SPSE (Xie et al., 2017), which learns sememe embeddings by decomposing word-sememe matrix and sememe-sememe matrix, our method utilizes sememe embeddings as regularizers to learn better word embeddings. Different from SPSE, we do not use pre-trained word embeddings. Instead, we learn word embeddings and sememe embeddings simultaneously.

More specifically, from HowNet we can extract a source-side word-sememe matrix M^S with $M^S_{sj} = 1$ indicating word w^S_s is annotated with sememe x_j, otherwise $M^S_{sj} = 0$. Hence by factorizing M^S, we can define the loss function as:

$$\mathcal{L}_{sememe} = \sum_{w^S_s \in V^S, x_j \in X} (\mathbf{w}^S_s \cdot \mathbf{x}_j + b_s + b'_j - M^S_{sj})^2, \tag{11}$$

where b_s and b'_j are the biases of w^S_s and x_j, and X denotes sememe set.

In this approach, we obtain word and sememe embeddings in a unified semantic space. The sememe embeddings bear all the information about the relationships between words and sememes, and they inject the information into word embeddings. Therefore, the word embeddings are expected to be more suitable for sememe prediction.

3.4 Training and Prediction

Training

When training monolingual word embeddings, we use negative sampling following Mikolov et al. (2013a). In the optimization of sememe part, we adopt the iterative updating method following Faruqui et al. (2015) for word relation-based approach and stochastic gradient descent (SGD) for sememe embedding-based approach. As for the optimization of the seed lexicon term of cross-lingual part, we also apply SGD.

Nevertheless, due to the existence of the latent variable, optimization of the matching process in cross-lingual part poses a challenge. We settle on Viterbi EM algorithm to address the problem. Next, we still take the target-to-source side as an example and give a detailed description of the training process using Viterbi EM algorithm.

Viterbi EM algorithm alternates between a Viterbi E step and a subsequent M step. The Viterbi E step aims to find the most probable matched word pairs given the current parameters. Considering the independence, we can seek the match for each word individually:

$$\hat{m}_t = \mathop{\arg\max}_{s \in \{0,1,\cdots,|V^S|\}} P(w^T_t | w^S_s). \tag{12}$$

As for the parametrization of the matching probability, there are various choices. For computational simplicity, we select cosine similarity:

$$P(w^T_t | w^S_s) = \begin{cases} \epsilon & \text{if } s = 0, \\ cos(\mathbf{w}^T_t, \mathbf{w}^S_s) & \text{otherwise,} \end{cases} \tag{13}$$

where ϵ is a hyperparameter indicating the probability of matching the empty word. Therefore, the Viterbi E step computes matching by:

$$\tilde{m}_t = \mathop{\arg\max}_{s \in \{1,\cdots,|V^S|\}} cos(\mathbf{w}^T_t, \mathbf{w}^S_s), \tag{14}$$

$$\hat{m}_t = \begin{cases} \tilde{m}_t & \text{if } cos(\mathbf{w}^T_t, \mathbf{w}^S_{\tilde{m}_t}) > \epsilon, \\ 0 & \text{otherwise.} \end{cases} \tag{15}$$

From this, we can see that ϵ serves as a threshold to keep out unreliable matched pairs.

The Viterbi M step performs maximization as if the latent variable has been observed in the Viterbi E step. Thus, we can treat the matched pairs as correct translations, and use a L_2 regularizer as well. Consequently, the M step computes:

$$(\hat{\mathbf{w}}^S, \hat{\mathbf{w}}^T) = \mathop{\arg\max}_{\mathbf{w}^S, \mathbf{w}^T} \mathcal{M}(\mathbf{w}^S, \mathbf{w}^T), \tag{16}$$

where $\mathcal{M}(\mathbf{w}^S, \mathbf{w}^T)$ is defined as:

$$\mathcal{M}(\mathbf{w}^S, \mathbf{w}^T) = -\sum_{t=1}^{|V^T|} \mathbb{I}[\tilde{m}_t \neq 0] \frac{c(w^T_t)}{|\mathcal{C}^T|} \|\mathbf{w}^T_t - \mathbf{w}^S_{\tilde{m}_t}\|^2. \tag{17}$$

Prediction

Since we assume that words with similar sememe annotations are similar and similar words should have similar sememes, which resembles collaborative filtering in personalized recommendation, we can recommend sememes for target words according to their most similar source words.

Formally, we define the score function $P(x_j | w^T_t)$ of sememes x_j given a target word w^T_t as:

$$P(x_j | w^T_t) = \sum_{w^S_s \in V^S} cos(\mathbf{w}^S_s, \mathbf{w}^T_t) \cdot M^S_{sj} \cdot c^{r_s}, \tag{18}$$

where r_s is the descending rank of word similarity $cos(\mathbf{w}^S_s, \mathbf{w}^T_t)$ for the source word w^S_s, and $c \in (0, 1)$ is a hyperparameter. Thus, c^{r_s} is a declined confidence factor which can eliminate the noise from irrelevant source words and concentrate on the most similar source words when predicting sememes for target words.

4 Experiments

In this section, we first introduce the dataset used in the experiments and then describe the experimental settings of both baseline method and our model. Next, we present the experimental results of different methods on the task of cross-lingual lexical sememe prediction. And then we conduct detailed analysis and exhaustive case studies. Following this, we investigate the effect of word frequency on cross-lingual sememe prediction results. Finally, we perform further quantitative analysis through two sub-tasks including bilingual lexicon induction and word similarity computation.

4.1 Dataset

We use sememe annotations in HowNet for sememe prediction. HowNet annotates sememes for $118,346$ Chinese words and $104,025$ English words. The number of sememes in total is $1,983$. Since some sememes only appear few times in HowNet, which are expected to be unimportant, we filter out those low-frequency sememes. Specifically, the frequency threshold is 5, and the final number of distinct sememes used in our experiments is $1,400$.

In our experiments, Chinese is source language and English is target language. To learn Chinese and English monolingual word embeddings, we extract about 2.0G text from Sogou-T[1] and Wikipedia[2] respectively. And we use THULAC[3] (Li and Sun, 2009) for Chinese word segmentation.

As for seed lexicon, we build it in a similar way to Zhang et al. (2017). First, we employ Google Translation API[4] to translate the source side (Chinese) vocabulary. Then the translations in the target language (English) are queried again in the reverse direction to translate back to the source language (Chinese). And we only keep the translation pairs whose back translated words match with the original source words.

In the task of bilingual lexicon induction, we opt for Chinese-English Translation Lexicon Version 3.0[5] to be the gold standard. In the task of word similarity computation, we choose WordSim-240 and WordSim-297 (Jin and Wu, 2012) datasets for Chinese, and WordSim-353 (Finkelstein et al., 2002) and SimLex-999 (Hill et al., 2015) datasets for English to evaluate the performance of our model. These datasets contain word pairs as well as human-assigned similarity scores. The word vectors are evaluated by ranking the word pairs according to their cosine similarities, and measuring Spearman's rank correlation coefficient with the human ratings.

4.2 Experimental Settings

We empirically set the dimension of word and sememe embeddings to 200. And the embeddings are all randomly initialized. In monolingual word embedding learning, we follow the optimal parameter settings in Mikolov et al. (2013a). We set the window size K to 5, down-sampling rate for high-frequency words to 10^{-5}, learning rate to 0.025 and the number of negative samples to 5. In cross-lingual word embedding alignment, the seed lexicon term weight λ_s is 0.01, and the matching term weight λ_m is $1,000$. In sememe-based word representation, the number of shared sememes for synonyms in the word relation-based approach is 2. In the training of matching process, we set ϵ to 0.5 empirically. When predicting sememes for words in target language, we only consider 100 most similar source words for each target word and the attenuation parameter c is 0.8. The testing set for cross-lingual lexical sememe prediction contains $2,000$ randomly selected English words from the vocabulary.

4.3 Cross-lingual Lexical Sememe Prediction

We evaluate our model by recommending sememes for English words. In HowNet, many words have multiple sememes, so that sememe prediction can be regarded as a multi-label classification task. We use mean average precision (MAP) and F_1 score to evaluate the sememe prediction results.

We compare our model that incorporates sememe information with word relation-based approach (named CLSP-WR) and our model which jointly trains word and sememe embeddings (named CLSP-SE) with a baseline method BiLex (Zhang et al., 2017), a bilingual WRL model without incorporation of sememe information. For BiLex, we use its trained bilingual word embeddings to predict sememes for the words in target language with our sememe prediction approach.

Table 1 exhibits the evaluation results of cross-lingual lexical sememe prediction with different

Method	Seed Lexicon	Sememe Prediction	
		MAP	F_1 Score
BiLex	1000	27.57	16.08
	2000	33.79	22.33
	4000	35.78	25.74
	6000	38.29	28.71
CLSP-WR	1000	28.12	18.55
	2000	33.78	23.64
	4000	38.30	27.74
	6000	41.23	30.64
CLSP-SE	1000	31.78	18.22
	2000	37.70	24.31
	4000	40.77	29.33
	6000	**43.16**	**32.49**

Table 1: Evaluation results of cross-lingual lexical sememe prediction with different seed lexicon sizes.

seed lexicon sizes in {1000, 2000, 4000, 6000[6]}. From the table, we can clearly see that:

(1) Our two models perform much better compared with BiLex in all the seed lexicon size settings. It indicates that incorporating sememe information into word embeddings can effectively improve the performance of predicting sememes for target words. The reason is that both of our models make words with similar sememe annotations have similar embeddings, and as a result, we can recommend better sememes for target words according to its related source words.

(2) CLSP-SE model achieves better results than CLSP-WR model. The reason is that by representing sememes in a latent semantic space, CLSP-SE model can further capture the relatedness between sememes as well as the relatedness between words and sememes, which is helpful for modeling the representations of those words with similar sememes.

4.4 Case Study

In case study, we conduct qualitative analysis to explain the effectiveness of our models with detailed cases. We show two examples of cross-lingual word sememe prediction, in which we predict sememes for *handcuffs* and *canoeist*. Fig. 2 shows the embeddings of five closest Chinese and English words to *handcuffs* and *canoeist*, and the vector of each word is projected down to two dimensions using t-SNE (Maaten and Hinton, 2008).

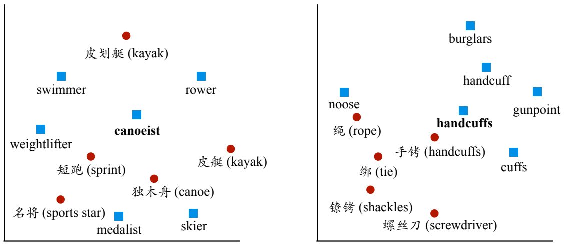

Figure 2: Two examples of nearest English and Chinese words.

Table 2 lists top-5 sememes we predict for the two words and the sememes annotated for each word in HowNet are in boldface. In the table, we also exhibit the annotated sememes of the five closest Chinese words.

In the first example, our model finds the best translated word for *handcuffs* in Chinese 手铐 "handcuffs", whose sememe annotations are exactly the same as those of *handcuffs*. In addition, the second closest Chinese word 镣铐 "shackles" is a synonym for 手铐 "handcuffs" and also has the same sememe annotations. Therefore, our model predicts all the correct sememes successfully. From the prediction results of this example, we notice that our model can accurately predict general sememes like 用具 "tool" and 人 "human", which are supposed to be difficult to predict.

In the second example, accurate Chinese translated counterpart for *canoeist* does not exist, but our model still hits all the three annotated sememes in the top-5 predicted sememes. By observing the most similar Chinese words, we can find that although these words do not have the same meaning as *canoeist*, they are related to *canoeist* in different aspects. For example, 短跑 "sprint" and *canoeist* are both in the sports domain so that they share the sememes 锻炼 "exercise" and 体育 "sport". 名将 "sports star" has the meaning of sports star and it can provide the sememe 人 "human" in sememe prediction. Furthermore, it is noteworthy that our model predicts 船 "ship" due to the nearest Chinese words 独木舟 "canoe" and 皮艇 "kayak", whereas 船 "ship" is not annotated for *canoeist* in HowNet. It is obvious that 船 "ship" is an appropriate sememe for *canoeist*. Since HowNet is manually annotated by experts, misannotated words always exist inevitably, which in some cases underestimates our models.

---

[6] The largest seed lexicon size is 6000 because that is the maximum number of translation word pairs that we can obtain from the bilingual corpora.

Type	Words	Sememes
English Word	handcuffs	**用具 “tool”**, **警 “police”**, **扣住 “detain”**, **人 “human”**, **有罪 “guilty”**
5 Nearest Chinese Words	手铐 “handcuffs”	**有罪 “guilty”**, **警 “police”**, **人 “human”**, **扣住 “detain”**, **用具 “tool”**
	镣铐 “shackles”	**有罪 “guilty”**, **警 “police”**, **人 “human”**, **扣住 “detain”**, **用具 “tool”**
	绑 “tie”	包扎 “wrap”
	螺丝刀 “screwdriver”	**用具 “tool”**, 放松 “loosen”, 勒紧 “tighten”
	绳 “rope”	线 “linear”, 材料 “material”, 拴连 “fasten”
English Word	canoeist	**锻炼 “exercise”**, **人 “human”**, **体育 “sport”**, 事情 “fact”, 船 “ship”
5 Nearest Chinese Words	短跑 “sprint”	事情 “fact” **锻炼 “exercise”** **体育 “sport”**
	独木舟 “canoe”	船 “ship”
	皮艇 “kayak”	船 “ship”
	名将 “sports star”	著名 “famous”, **人 “human”**, 官 “official”, 军 “military”
	皮划艇 “kayak”	事情 “fact”, **锻炼 “exercise”**, **体育 “sport”**

Table 2: Two examples of cross-lingual lexical sememe prediction.

4.5 Effect of Word Frequency

To explore how frequencies of target words affect cross-lingual sememe prediction results, we split the testing set into four subsets according to word frequency and then calculate the sememe prediction MAP and F_1 score for each subset. The results are shown in Table 3.

Method	Word Frequency	Sememe Prediction	
		MAP	F_1 Score
BiLex	<200	30.35	21.83
	200 - 500	34.83	25.95
	501 - 2500	40.21	28.62
	>2500	47.56	35.80
CLSP-WR	<200	34.73	24.41
	200 - 500	39.50	29.49
	501 - 2500	43.92	33.87
	>2500	47.33	34.99
CLSP-SE	<200	36.54	27.49
	200 - 500	41.46	30.09
	501 - 2500	45.35	35.01
	>2500	**49.34**	**37.16**

Table 3: Evaluation results of cross-lingual lexical sememe prediction with different word frequencies. The number of words in each frequency range is 497, 458, 522 and 523 respectively.

From the table we can see that: (1) The more frequently a target word appears in the corpus, the better its predicted sememes are. It is because high-frequency words normally have better word embeddings, which are crucial to sememe prediction. (2) Our models evidently perform better than BiLex in different word frequencies, especially in low frequency. It indicates that by considering external information of HowNet, our models are more robust and can competently handle sparse scenarios.

4.6 Further Quantitative Analysis

In this section, we conduct two typical auxiliary experiments to further analyze the superiority of our models quantitatively.

Bilingual Lexicon Induction

Our models learn bilingual word embeddings in one unified semantic space. Here we use translation top-1 and top-5 average precision (P@1 and P@5) to evaluate bilingual lexicon induction performance of our models and BiLex. The seed lexicon size also varies in {1000, 2000, 4000, 6000}.

Method	Seed Lexicon	Lexicon Induction	
		P@1	P@5
BiLex	1000	6.48	10.78
	2000	10.84	15.84
	4000	19.48	23.96
	6000	25.89	29.59
CLSP-WR	1000	6.89	11.28
	2000	11.96	18.08
	4000	19.50	25.78
	6000	25.83	31.03
CLSP-SE	1000	6.60	11.04
	2000	11.90	18.62
	4000	19.26	25.11
	6000	**26.91**	**32.17**

Table 4: Bilingual lexicon induction performance with different seed lexicon sizes.

The results are shown in Table 4. From this table, we observe that our models, especially CLSP-SE model, enhance the performance of word translation compared to BiLex no matter how large the seed lexicon is. It indicates that our models can bind bilingual word embeddings better.

Word Similarity Computation

We also evaluate the task of monolingual word similarity computation on WordSim-240 (WS-240) and WordSim-297 (WS-297) datasets for Chinese, and WordSim-353 (WS-353) and SimLex-999 (SL-999) datasets for English.

Method	Chinese (source)		English (target)	
	WS-240	WS-297	WS-353	SL-999
BiLex	60.36	62.17	60.46	27.22
CLSP-WR	61.27	65.25	60.46	27.22
CLSP-SE	60.84	65.62	62.47	28.79

Table 5: Performance on monolingual word similarity computation with seed lexicon size 6000.

Table 5 shows the results of monolingual word similarity computation on four datasets. From the table, we find that: (1) Our models perform better than BiLex on both Chinese word similarity datasets. It signifies incorporating sememe information helps learn better monolingual embeddings; (2) CLSP-WR model does not enhance English word similarity results but CLSP-SE model does. It is because CLSP-WR model only post-processes Chinese word embeddings and keeps English word embeddings unchanged while CLSP-SE model undertakes bilingual alignment and sememe information incorporation together, which makes English word embeddings improve with Chinese word embeddings.

5 Conclusion and Future Work

In this paper, we introduce a new task of cross-lingual sememe prediction. This task is very important because the construction of sememe-based linguistic knowledge bases in various languages is beneficial to better understanding these languages. We propose a simple and effective model for this task, including monolingual word representation learning, cross-lingual word representation alignment and sememe-based word representation learning. Experimental results on real-world datasets show that our model achieves consistent and significant improvements compared to baseline method in cross-lingual sememe prediction.

In the future, we will explore the following research directions: (1) In this paper, for simplification, we ignore the rich hierarchy information in HowNet and also ignore the fact that a word may have multiple senses. We will extend our models to consider the structure information of sememe and multiple senses of words; (2) In fact, our framework for cross-lingual lexical sememe prediction can be transferred to other cross-lingual tasks. We will explore the effectiveness of our model in these tasks such as cross-lingual information retrieval.

Abstract

For languages with no annotated resources, unsupervised transfer of natural language processing models such as named-entity recognition (NER) from resource-rich languages would be an appealing capability. However, differences in words and word order across languages make it a challenging problem. To improve mapping of lexical items across languages, we propose a method that finds translations based on bilingual word embeddings. To improve robustness to word order differences, we propose to use self-attention, which allows for a degree of flexibility with respect to word order. We demonstrate that these methods achieve state-of-the-art or competitive NER performance on commonly tested languages under a cross-lingual setting, with much lower resource requirements than past approaches. We also evaluate the challenges of applying these methods to Uyghur, a low-resource language.[1]

1 Introduction

Named entity recognition (NER), the task of detecting and classifying named entities from text into a few predefined categories such as people, locations or organizations, has seen the state-of-the-art greatly advanced by the introduction of neural architectures (Collobert et al., 2011; Huang et al., 2015; Chiu and Nichols, 2016; Lample et al., 2016; Yang et al., 2016; Ma and Hovy, 2016; Peters et al., 2017; Liu et al., 2018; Peters et al., 2018). However, the success of these methods is highly dependent on a reasonably large amount of annotated training data, and thus it remains a challenge to apply these models to languages with limited amounts of labeled data. Cross-lingual NER attempts to address this challenge by transferring knowledge from a high-resource source language with abundant entity labels to a low-resource target language with few or no labels. Specifically, in this paper we attempt to tackle the extreme scenario of *unsupervised transfer*, where no labeled data is available in the target language. Within this paradigm, there are two major challenges to tackle: how to effectively perform lexical mapping between the languages, and how to address word order differences.

To cope with the first challenge of lexical mapping, a number of methods use parallel corpora to project annotations between languages through word alignment (Ehrmann et al., 2011; Kim et al., 2012; Wang and Manning, 2014; Ni et al., 2017). Since parallel corpora may not be always available, Mayhew et al. (2017) proposed a "cheap translation" approach that uses a bilingual dictionary to perform word-level translation. The above approaches provide a reasonable proxy for the actual labeled training data, largely because the words that participate in entities can be translated relatively reliably given extensive parallel dictionaries or corpora (e.g., with 1 million word pairs or sentences). Additionally, as a side benefit of having explicitly translated words, models can directly exploit features extracted from the surface forms (e.g. through character-level neural feature extractors), which has proven essential for high accuracy in the monolingual scenario (Ma and Hovy, 2016). However, these methods are largely predicated on the availability of large-scale parallel resources, and thus, their applicability to low-resource languages is limited.

In contrast, it is also possible to learn lexical mappings through bilingual word embeddings (BWE). These bilingual embeddings can be obtained by using a small dictionary to project two sets of embeddings into a consistent space (Mikolov et al., 2013a; Faruqui and Dyer,

Brussels, Belgium, October 31 - November 4, 2018.

2014; Artetxe et al., 2016; Smith et al., 2017), or even in an entirely unsupervised manner using adversarial training or identical character strings (Zhang et al., 2017; Artetxe et al., 2017; Lample et al., 2018). Many approaches in the past have leveraged the shared embedding space for cross-lingual applications (Guo et al., 2015; Ammar et al., 2016b; Zhang et al., 2016; Fang and Cohn, 2017), including NER (Bharadwaj et al., 2016; Ni et al., 2017). The minimal dependency on parallel resources makes the embedding-based method much more suitable for low-resource languages. However, since different languages have different linguistic properties, it is hard, if not impossible, to align the two embedding spaces perfectly (see Figure 1). Meanwhile, because surface forms are not available, character-level features cannot be used, resulting in reduced tagging accuracy (as demonstrated in our experiments).

To address the above issues, we propose a new lexical mapping approach that combines the advantages of both discrete dictionary-based methods and continuous embedding-based methods. Specifically, we first project embeddings of different languages into the shared BWE space, then learn discrete word translations by looking for nearest neighbors in this projected space, and finally train a model on the translated data. This allows our method to inherit the benefits of both embedding-based and dictionary-based methods: its resource requirements are low as in the former, but it suffers less from misalignment of the embedding spaces and has access to character-level information like the latter.

Turning to differences in word ordering, to our knowledge there are no methods that explicitly deal with this problem in unsupervised cross-lingual transfer for NER. Our second contribution is a method to alleviate this issue by incorporating an order-invariant self-attention mechanism (Vaswani et al., 2017; Lin et al., 2017) into our neural architecture. Self-attention allows re-ordering of information within a particular encoded sequence, which makes it possible to account for word order differences between the source and the target languages.

In our experiments, we start with models trained in English as the source language on the CoNLL 2002 and 2003 datasets and transfer them into Spanish, Dutch, and German as the target languages. Our approach obtains new state-of-the-art cross-lingual results in Spanish and Dutch, and competitive results in German, even without a dictionary, completely removing the need for resources such as Wikipedia and parallel corpora. Next, we transfer English using the same approach into Uyghur, a truly low-resource language. With significantly fewer cross-lingual resources, our approach can still perform competitively with previous best results.

2 Approach

We establish our problem setting (§2.1), then present our methods in detail (§2.2), and provide some additional motivation (§2.3).

2.1 Problem Setting

NER takes a sentence as the input and outputs a sequence of labels corresponding to the named entity categories of the words in the sentence, such as location, organization, person, or none. In standard supervised NER, we are provided with a labeled corpus of sentences in the target language along with tags indicating which spans correspond to entities of each type.

As noted in the introduction, we study the problem of unsupervised cross-lingual NER: given labeled training data only in a separate source language, we aim to learn a model that is able to perform NER in the target language. This transfer can be performed using a variety of resources, including parallel corpora (Täckström et al., 2012; Ni et al., 2017), Wikipedia (Nothman et al., 2013), and large dictionaries (Ni et al., 2017; Mayhew et al., 2017). In this work, we limit ourselves to a setting where we have the following resources, making us comparable to other methods such as Mayhew et al. (2017) and Ni et al. (2017):

- Labeled training data in the source language.
- Monolingual corpora in both source and target languages.
- A dictionary, either a small pre-existing one, or one induced by unsupervised methods.

2.2 Method

Our method follows the process below:

1. Train separate word embeddings using monolingual corpora using standard embedding training methods (§2.2.1).
2. Project word embeddings in the two languages into a shared embedding space by optimizing

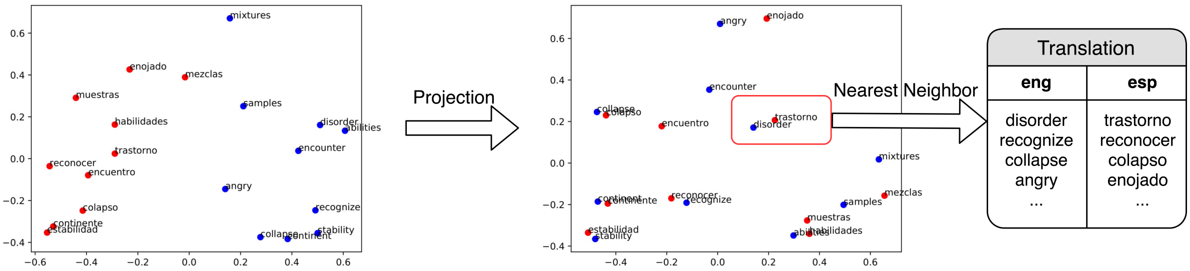

Figure 1: Example of the result of our approach on Spanish-English words not included in the dictionary (embeddings are reduced to 2 dimensions for visual clarity). We first project word embeddings into a shared space, and then use the nearest neighbors for word translation. Notice that the word pairs are not perfectly aligned in the shared embedding space, but after word translation we obtain correct alignments.

the word embedding alignment using the given dictionary (§2.2.2).

3. For each word in the source language training data, translate it by finding its nearest neighbor in the shared embedding space (§2.2.3).
4. Train an NER model using the translated words along with the named entity tags from the English corpus (§2.2.4).

We consider each in detail.

2.2.1 Learning Monolingual Embeddings

Given text in the source and target language, we first independently learn word embedding matrices X and Y in the source and target languages respectively. These embeddings can be learned on monolingual text in both languages with any of the myriad of word embedding methods (Mikolov et al., 2013b; Pennington et al., 2014; Bojanowski et al., 2017).

2.2.2 Learning Bilingual Embeddings

Next, we learn a cross-lingual projection of X and Y into a shared space. Assume we are given a dictionary $\{x_i, y_i\}_{i=1}^{D}$, where x_i and y_i denote the embeddings of a word pair. Let $X_D = [x_1, x_2, \cdots, x_D]^\top$ and $Y_D = [y_1, y_2, \cdots, y_D]^\top$ denote two embedding matrices consisting of word pairs from the dictionary.

Following previous work (Zhang et al., 2016; Artetxe et al., 2016; Smith et al., 2017), we optimize the following objective:

$$\min_{W} \sum_{i=1}^{d} \|Wx_i - y_i\|^2 \;\; \text{s.t.} \;\; WW^\top = I,$$

where W is a square parameter matrix. This objective can be further simplified as

$$\max_{W} \text{Tr}(X_D W Y_D^\top) \;\; \text{s.t.} \;\; WW^\top = I.$$

Here, the transformation matrix W is constrained to be orthogonal so that the dot product similarity of words is invariant with respect to the transformation both within and across languages.

To optimize the above objective (the Procrustes problem), we decompose the matrix $Y_D^\top X_D$ using singular value decomposition. Let the results be $Y_D^\top X_D = U \sum V^\top$, then $W = UV^\top$ gives the exact solution. We define the similarity matrix between X and Y to be $S = YWX^\top = YU(XV)^\top$, where each column contains the cosine similarity between source word x_i and all target words y_i. We can then define $X' = XV$ and $Y' = YU$, which are X and Y transformed into a shared embedding space.

To refine the alignment in this shared space further, we iteratively perform a self-learning refinement step k [2] times by:

1. Using the aligned embeddings to generate a new dictionary that consists of mutual nearest neighbors obtained using the same metric as introduced below.
2. Solving the Procrustes problem based on the newly generated dictionary to get a new set of bilingual embeddings.

The bilingual embeddings at the end of the kth step, X'_k and Y'_k, will be used to perform translation.

2.2.3 Learning Word Translations

To learn actual word translations, we next proceed to perform nearest-neighbor search in the

---

[2] We use $k = 3$ in this paper.

common space. Instead of using a common distance metric such as cosine similarity, we adopt the cross-domain similarity local scaling (CSLS) metric (Lampple et al., 2018), which is designed to address the hubness problem common to the shared embedding space (Dinu and Baroni, 2014). Specifically,

$$\text{CSLS}(x_i, y_j) = 2\cos(x_i, y_j) - r_T(x_i) - r_S(y_j)$$

where $r_T(x_i) = \frac{1}{K}\sum_{y_t \in N_T(x_i)} \cos(x_i, y_t)$ denotes the mean cosine similarity between x_i and its K neighbors y_t. Using this metric, we find translations for each source word s by selecting target word $\hat{t_s}$ where $\hat{t_s} = \arg\max_t \text{CSLS}(x_s, y_t)$.

2.2.4 Training the NER Model

Finally, we translate the entire English NER training data into the target language by taking English sentences $S = s_1, s_2, ..., s_n$ and translating them into target sentences $\hat{T} = \hat{t_1}, \hat{t_2}, ..., \hat{t_n}$. The label of each English word is copied to be the label of the target word. We can then train an NER model directly using the translated data. Notably, because the model has access to the surface forms of the target sentences, it can use the character sequences of the target language as part of its input.

During learning, all word embeddings are normalized to lie on the unit ball, allowing every training pair an equal contribution to the objective and improving word translation accuracy (Artetxe et al., 2016). When training the NER model, however, we do not normalize the word embeddings, because preliminary experiments showed the original unnormalized embeddings gave superior results. We suspect this is due to frequency information conveyed by vector length, an important signal for NER. (Named entities appear less frequently in the monolingual corpus.)

2.3 Discussion

Figure 1 shows an example of the embeddings and translations learned with our approach trained on Spanish and English data from the experiments (see §4 for more details). As shown in the figure, there is usually a noticeable difference between the word embeddings of a word pair in different languages, which is inevitable because different languages have distinct traits and different monolingual data, and as a result it is intrinsically hard to learn a perfect alignment. This indicates that models trained directly on data using the source embeddings may not generalize well to the slightly different embeddings of the target language.

Instead of directly modeling the shared embedding space (Guo et al., 2015; Zhang et al., 2016; Fang and Cohn, 2017; Ni et al., 2017), we leverage the shared embedding space for word translation. As shown in Figure 1, unaligned word pairs can still be translated correctly with our method, as the embeddings are still closer to the correct translations than the closest incorrect one.

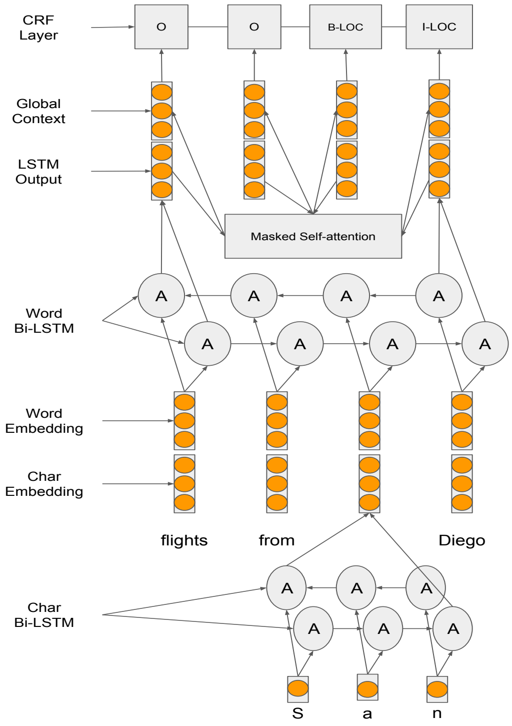

Figure 2: Self-attentive Bi-LSTM-CRF Model

3 NER Model Architecture

We describe the model we use to perform NER. We will first describe the basic hierarchical neural CRF tagging model (Lample et al., 2016; Ma and Hovy, 2016; Yang et al., 2016), and introduce the self-attention mechanism that we propose to deal with divergence of word order.

3.1 Hierarchical Neural CRF

The hierarchical CRF model consists of three components: a character-level neural network, either an RNN or a CNN, that allows the model to capture subword information, such as morphological variations and capitalization patterns; a word-level neural network, usually an RNN, that consumes word representations and produces context sensitive hidden representations for each word; and a linear-chain CRF layer that models the dependency between labels and performs inference.

In this paper, we closely follow the architecture proposed by Lample et al. (2016), and use bidirectional LSTMs for both the character level and word level neural networks. Specifically, given an input sequence of words $(w_1, w_2, ..., w_n)$, and each word's corresponding character sequence, the model first produces a representation for each word, x_i, by concatenating its character representation with its word embedding. Subsequently, the word representations of the input sequence $(x_1, x_2, \cdots, x_n)$ are fed into a word level Bi-LSTM, which models the contextual dependency within each sentence and outputs a sequence of context sensitive hidden representations $(h_1, h_2, \cdots, h_n)$. A CRF layer is then applied on top of the word level LSTM and takes in as its input the sequence of hidden representations $(h_1, h_2, \cdots, h_n)$, and defines the joint distribution of all possible output label sequences. The Viterbi algorithm is used during decoding.

3.2 Self-Attention

The training-time inputs to our model are in essence corrupted sentences from the target language (e.g., Spanish), which have a different order from natural target sentences. We propose to alleviate this problem by adding a self-attention layer (Vaswani et al., 2017) on top of the word-level Bi-LSTM. Self-attention provides each word with a context feature vector based on *all* the words of a sentence. As the context vectors are obtained irrespective of the words' positions in a sentence, at test time, the model is more likely to see vectors similar to those seen at training time, which we posit introduces a level of flexibility with respect to the word order, and thus may allow for better generalization.

Let $H = [h_1, h_2, \cdots, h_n]^\top$ be a sequence of word-level hidden representations. We apply a single layer MLP on H to obtain the queries Q and keys $K = \tanh(HW + b)$, where $W \in \mathbb{R}^{d \times d}$ is a parameter matrix and $b \in \mathbb{R}^d$ is a bias term, with d being the hidden state size. The output of attention layer is defined as:

$$\begin{aligned} H^a &= \text{softmax}(QK^\top) \odot (E - I)H \\ &= [h_1^a, h_2^a, ..., h_3^a]^\top \end{aligned}$$

where I is an identity matrix and E is an all-one matrix. The term $(E - I)$ serves as an attention mask that prevents the weights from centering on the word itself, as we would like to provide each word with sentence level context. The outputs from the self-attention layer are then concatenated with the original hidden representations to form the final inputs to the CRF layer, which are $([h_1, h_1^a], [h_2, h_2^a], ..., [h_3, h_3^a])$.

4 Experiments

To examine the effectiveness of both of our proposed methods, we conduct four sets of experiments. First, we evaluate our model both with and without provided dictionaries on a benchmark NER dataset and compare with previous state-of-the-art results. Second, we compare our methods against a recently proposed dictionary-based translation baseline (Mayhew et al., 2017) by directly applying our model on their translated data.[3] Subsequently, we conduct an ablation study to further understand our proposed methods. Lastly, we apply our methods to a truly low-resource language, Uyghur.

4.1 Experimental Settings

We evaluate our proposed methods on the benchmark CoNLL 2002 and 2003 NER datasets (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003), which contain 4 European languages, English, German, Dutch and Spanish. For all experiments, we use English as the source language and translate its training data into the target language. We train a model on the translated data, and test it on the target language. For each experiment, we run our models 5 times using different seeds and report the mean and standard deviation, as suggested by Reimers and Gurevych (2017).

Word Embeddings For all languages, we use two different embedding methods, fastText (Bojanowski et al., 2017) and GloVe (Pennington et al., 2014), to perform word-embedding based translations and train the NER model, respectively. For fastText, we use the publicly available embeddings trained on Wikipedia for all languages. For GloVe, we use the publicly available embeddings pre-trained on Gigaword and Wikipedia for English. For Spanish, German and Dutch, we use Spanish Gigaword and Wikipedia, German WMT News Crawl data and Wikipedia, and Dutch

---

[3] We thank the authors of Mayhew et al. (2017) for sharing their data.

Wikipedia, respectively, to train the GloVe word embeddings. We use a vocabulary size of 100,000 for both embedding methods.

Dictionary We consider three different settings to obtain the seed dictionary, including two methods that do not use parallel resources:

1. Use identical character strings shared between the two vocabularies as the seed dictionary.
2. Lample et al. (2018)'s method of using adversarial learning to induce a mapping that aligns the two embedding spaces, and the mutual nearest neighbors in the shared space will be used as a dictionary. The learning procedure is formulated as a two player game, where a discriminator is trained to distinguish words from the two embedding spaces, and a linear mapping is trained to align the two embedding spaces and thus fool the discriminator.
3. Use a provided dictionary. In our experiments, we use the ones provided by Lample et al. (2018),[4] each of which contain 5,000 source words and about 10,000 entries.

Translation We follow the general procedure described in Section 2, and replace each word from the English training data with its corresponding word in the target language. For out-of-vocabulary (OOV) words, we simply keep them as-is. We capitalize the resulting sentences following the pattern of the original English words. Note that for German, simply following the English capitalization pattern does not work, because all nouns in German are capitalized. To handle this problem, we count the number of times each word is capitalized in Wikipedia, and capitalize the word if the probability is greater than 0.6.

Network Parameters For our experiments, we set the character embedding size to be 25, character level LSTM hidden size to be 50, and word level LSTM hidden size to be 200. For OOV words, we initialize an unknown embedding by uniformly sampling from range $[-\sqrt{\frac{3}{\text{emb}}}, +\sqrt{\frac{3}{\text{emb}}}]$, where emb is the size of embedding, 100 in our case. We replace each number with 0 when used as input to the character level Bi-LSTM.

Network Training We use SGD with momentum to train the NER model for 30 epochs, and select the best model on the target language development set. We choose the initial learning rate to be $\eta_0 = 0.015$, and update it using a learning decay mechanism after each epoch, $\eta_t = \frac{\eta_0}{1+\rho t}$, where t is the number of completed epoch and $\rho = 0.05$ is the decay rate. We use a batch size of 10 and evaluate the model per 150 batches within each epoch. We apply dropout on the inputs to the word-level Bi-LSTM, the outputs of the word-level Bi-LSTM, and the outputs of the self-attention layer to prevent overfitting. The self-attention dropout rate is set to 0.5 when using our translated data, and 0.2 when using cheap-translation data. We use 0.5 for all other dropouts. The word embeddings are not fine-tuned during training.

4.2 Results

Table 1 presents our results on transferring from English to three other languages, alongside results from previous studies. Here "BWET" (bilingual word embedding translation) denotes using the hierarchical neural CRF model trained on data translated from English. As can be seen from the table, our methods outperform previous state-of-the-art results on Spanish and Dutch by a large margin and perform competitively on German even without using any parallel resources. We achieve similar results using different seed dictionaries, and produce the best results when adding the self-attention mechanism to our model.

Despite the good performance on Spanish and Dutch, our model does not outperform the previous best result on German, and we speculate that there are a few reasons. First, German has rich morphology and contains many compound words, making the word embeddings less reliable. Our supervised result on German indicates the same problem, as it is about 8 F_1 points worse than Spanish and Dutch. Second, these difficulties become more pronounced in the cross-lingual setting, leading to a noisier embedding space alignment, which lowers the quality of BWE-based translation. We believe that this is a problem with all methods using word embeddings. In such cases, more resource-intensive methods may be necessary.

4.2.1 Comparison with Dictionary-Based Translation

Table 1 also presents results of a comparison between our proposed BWE translation method and the "cheap translation" baseline of (Mayhew et al., 2017). The size of the dictionaries used by both

Table 1: NER F_1 scores. *Approaches that use more resources than ours ("Wikipedia" means Wikipedia is used not as a monolingual corpus, but to provide external knowledge). †Approaches that use multiple languages for transfer. "Only Eng. data" is the model used in Mayhew et al. (2017) trained on their data translated from English without using Wikipedia and other languages. The "data from Mayhew et al. (2017)" is the same data translated from only English they used. "Id.c." indicates using identical character strings between the two languages as the seed dictionary. "Adv." indicates using adversarial training and mutual nearest neighbors to induce a seed dictionary. Our supervised results are obtained using models trained on annotated corpus from CoNLL.

approaches are given in the right-most column. Using our model on their translated data from English outperforms the baseline scores produced by their models over all languages, a testament to the strength of our neural CRF baseline. The results produced by our model on their data indicate that our approach is effective, as we manage to outperform their approaches on all three languages using much smaller dictionaries and even without dictionaries. Also, we see that self-attention is effective when applied on their data, which also does not carry the correct word order.

4.2.2 Why Does Translation Work Better?

In this section, we study the effects of different ways of using bilingual word embeddings and the resulting induced translations. As we pointed out previously, finding translations has two advantages: (1) the model can be trained on the exact points from the target embedding space, and (2) the model has access to the target language's original character sequences. Here, we conduct ablation studies over these two variables. Specifically, we consider the following three variants.[5]

- **Common space** This is the most common setting for using bilingual word embeddings, and has recently been applied in NER (Ni et al., 2017). In short, the source and target word embeddings are cast into a common space, namely $X' = XV$ and $Y' = YU$, and the model is trained with the source side embedding and the source character sequence, and directly applied on the target side.

- **Replace** In this setting, we replace each original word embedding x_i with its nearest neighbor y_i in the common space but do not perform translation. This way, the model will be trained with target word embeddings and source-side character sequences.

- **Translation** This is our proposed approach, where the model is trained on both exact points in the target space and target language character sequences.

The three variants are compared in Table 2. The "common space" variant performs the worst by a large margin, confirming our hypothesis that discrepancy between the two embedding spaces harms the model's ability to generalize. From the comparison between the "replace" and "translation," we observe that having access to the target language's character sequence helps performance, especially for German, perhaps due in part to its capitalization patterns, which differ from English. In this case, we have to lower-case all the words for character inputs in order to prevent the model from overfitting the English capitalization pattern.

---

[5] In this study, we use GloVe for learning bilingual embeddings and word translations instead of fastText.

Model	Spanish	Dutch	German
Common space	65.40 ± 1.22	66.15 ± 1.62	43.73 ± 0.94
Replace	68.21 ± 1.22	69.37 ± 1.33	48.59 ± 1.21
Translation	**69.21** ± 0.95	**69.39** ± 1.21	**53.94** ± 0.66

4.3 Case Study: Uyghur

In this section, we directly apply our approach to Uyghur, a truly low-resource language with very limited monolingual and parallel resources. We test our model on 199 annotated evaluation documents from the DARPA LORELEI program (the "unsequestered set") and compare with previously reported results in the cross-lingual setting by Mayhew et al. (2017). Similar to our previous experiments, we transfer from English, use fastText embeddings trained on Common Crawl and Wikipedia[6] and a provided dictionary to perform translation, and use GloVe trained on a monolingual corpus that has 30 million tokens to perform NER. Results are presented in Table 3.

Our method performs competitively, considering that we use a much smaller dictionary than Mayhew et al. (2017) and no knowledge from Wikipedia in Uyghur. Our best results come from a combined approach: using word embeddings to translate words that are not covered by Mayhew et al. (2017)'s dictionary (last line of Table 3). Note that for the CoNLL languages, Mayhew et al. (2017) used Wikipedia for the Wikifier features (Tsai et al., 2016), while for Uyghur they used it for translating named entities, which is crucial for low-resource languages when some named entities are not covered by the dictionary or the translation is not reliable. We suspect that the unreliable translation of named entities is the major reason why our method alone performs worse but performs better when combined with their data that has access to higher quality translations of named entities.

The table omits results using adversarial learning and identical character strings, as both failed (F_1 scores around 10). We attribute these failures to the low quality of Uyghur word embeddings and the fact that the two languages are distant. Also, Uyghur is mainly written in Arabic script, making the identical character method inappropriate. Overall, this reveals a practical challenge for multilingual embedding methods, where the underlying distributions of the text in the two languages are divergent.

5 Related Work

Cross-Lingual Learning Cross-lingual learning approaches can be loosely classified into two categories: annotation projection and language-independent transfer.

Annotation projection methods create training data by using parallel corpora to project annotations from the source to the target language. Such approaches have been applied to many tasks under the cross-lingual setting, such as POS tagging (Yarowsky et al., 2001; Das and Petrov, 2011; Täckström et al., 2013; Fang and Cohn, 2016), mention detection (Zitouni and Florian, 2008) and parsing (Hwa et al., 2005; McDonald et al., 2011).

Language independent transfer-based approaches build models using language independent and delexicalized features. For instance,

---

[6] `https://github.com/facebookresearch/fastText/blob/master/docs/crawl-vectors.md`

Zirikly and Hagiwara (2015) transfers word cluster and gazetteer features through the use of comparable copora. Tsai et al. (2016) links words to Wikipedia entries and uses the entry category as features to train language independent NER models. Recently, Ni et al. (2017) propose to project word embeddings into a common space as language independent features. These approaches utilize such features by training a model on the source language and directly applying it to the target language.

Another way of performing language independent transfer resorts to multi-task learning, where a model is trained jointly across different languages by sharing parameters to allow for knowledge transfer (Ammar et al., 2016a; Yang et al., 2017; Cotterell and Duh, 2017; Lin et al., 2018). However, such approaches usually require some amounts of training data in the target language for bootstrapping, which is different from our unsupervised approach that requires no labeled resources in the target language.

Bilingual Word Embeddings There have been two general paradigms in obtaining bilingual word vectors besides using dictionaries: through parallel corpora and through joint training. Approaches based on parallel corpora usually learn bilingual word embeddings that can produce similar representations for aligned sentences (Hermann and Blunsom, 2014; Chandar et al., 2014). Jointly-trained models combine the common monolingual training objective with a cross-lingual training objective that often comes from parallel corpus (Zou et al., 2013; Gouws et al., 2015). Recently, unsupervised approaches also have been used to align two sets of word embeddings by learning a mapping through adversarial learning or self-learning (Zhang et al., 2017; Artetxe et al., 2017; Lample et al., 2018).

6 Conclusion

In this paper, we propose two methods to tackle the cross-lingual NER problem under the unsupervised transfer setting. To address the challenge of lexical mapping, we find translations of words in a shared embedding space built from a seed lexicon. To alleviate word order divergence across languages, we add a self-attention mechanism to our neural architecture. With these methods combined, we are able to achieve state-of-the-art or competitive results on commonly tested languages under a cross-lingual setting, with lower resource requirements than past approaches. We also evaluate the challenges of applying these methods to an extremely low-resource language, Uyghur.

Abstract

Beam search is a widely used approximate search strategy for neural network decoders, and it generally outperforms simple greedy decoding on tasks like machine translation. However, this improvement comes at substantial computational cost. In this paper, we propose a flexible new method that allows us to reap nearly the full benefits of beam search with nearly no additional computational cost. The method revolves around a small neural network *actor* that is trained to observe and manipulate the hidden state of a previously-trained decoder. To train this actor network, we introduce the use of a pseudo-parallel corpus built using the output of beam search on a base model, ranked by a target quality metric like BLEU. Our method is inspired by earlier work on this problem, but requires no reinforcement learning, and can be trained reliably on a range of models. Experiments on three parallel corpora and three architectures show that the method yields substantial improvements in translation quality and speed over each base system.

1 Introduction

Neural network sequence decoders yield state-of-the-art results for many text generation tasks, including machine translation (Bahdanau et al., 2015; Luong et al., 2015; Gehring et al., 2017; Vaswani et al., 2017; Dehghani et al., 2018), text summarization (Rush et al., 2015; Ranzato et al., 2015; See et al., 2017; Paulus et al., 2017) and image captioning (Vinyals et al., 2015; Xu et al., 2015). These decoders generate tokens from left to right, at each step giving a distribution over possible next tokens, conditioned on both the input and all the tokens generated so far. However, since the space of all possible output sequences is infinite and grows exponentially with sequence length, heuristic search methods such as greedy decoding or beam search (Graves, 2012; Boulanger-Lewandowski et al., 2013) must be used at decoding time to select high-probability output sequences. Unlike greedy decoding, which selects the token of the highest probability at each step, beam search expands all possible next tokens at each step, and maintains the k most likely prefixes, where k is the beam size. Greedy decoding is very fast—requiring only a single run of the underlying decoder—while beam search requires an equivalent of k such runs, as well as substantial additional overhead for data management. However, beam search often leads to substantial improvement over greedy decoding. For example, Ranzato et al. (2015) report that beam search (with $k = 10$) gives a 2.2 BLEU improvement in translation and a 3.5 ROUGE-2 improvement in summarization over greedy decoding.

Various approaches have been explored recently to improve beam search by improving the method by which candidate sequences are scored (Li et al., 2016; Shu and Nakayama, 2017), the termination criterion (Huang et al., 2017), or the search function itself (Li et al., 2017). In contrast, Gu et al. (2017) have tried to directly improve greedy decoding to decode for an arbitrary decoding objective. They add a small *actor* network to the decoder and train it with a version of policy gradient to optimize sequence objectives like BLEU. However, they report that they are seriously limited by the instability of this approach to training.

In this paper, we propose a procedure to modify a trained decoder to allow it to generate text greedily with the level of quality (according to metrics like BLEU) that would otherwise require the relatively expensive use of beam search. To do so, we follow Cho (2016) and Gu et al. (2017) in our use of an *actor* network which manipulates the decoder's hidden state, but introduce a stable and effective procedure to train this actor. In our

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 380–390
Brussels, Belgium, October 31 - November 4, 2018.

training procedure, the actor is trained with ordinary backpropagation on a model-specific artificial parallel corpus. This corpus is generated by running the un-augmented model on the training set with large-beam beam search, and selecting outputs from the resulting k-best list which score highly on our target metric.

Our method can be trained quickly and reliably, is effective, and can be straightforwardly employed with a variety of decoders. We demonstrate this for neural machine translation on three state-of-the-art architectures: RNN-based (Luong et al., 2015), ConvS2S (Gehring et al., 2017) and Transformer (Vaswani et al., 2017), and three corpora: IWSLT16 German-English,[1] WMT15 Finnish-English[2] and WMT14 German-English.[3]

2 Background

2.1 Neural Machine Translation

In sequence-to-sequence learning, we are given a set of source–target sentence pairs and tasked with learning to generate each target sentence (as a sequence of words or word-parts) from its source sentence. We first use an encoding model such as a recurrent neural network to transform a source sequence into an encoded representation, then generates the target sequence using a neural decoder.

Given a source sentence $\mathbf{x} = \{x_1, ..., x_{T_s}\}$, a neural machine translation system models the distribution over possible output sentences $\mathbf{y} = \{y_1, ..., y_T\}$ as:

$$P(\mathbf{y}|\mathbf{x}; \boldsymbol{\theta}) = \prod_{t=1}^{T} P(y_t|y_{<t}, \mathbf{x}; \boldsymbol{\theta}), \qquad (1)$$

where $\boldsymbol{\theta}$ is the set of model parameters.

Given a parallel corpus $D_{x,y}$ of source–target sentence pairs, the neural machine translation model can be trained by maximizing the log-likelihood:

$$\hat{\boldsymbol{\theta}} = \underset{\boldsymbol{\theta}}{\operatorname{argmax}} \left\{ \sum_{\langle \mathbf{x},\mathbf{y} \rangle \in D_{x,y}} \log P(\mathbf{y}|\mathbf{x}; \boldsymbol{\theta}) \right\}. \qquad (2)$$

2.2 Decoding

Given estimated model parameters $\hat{\boldsymbol{\theta}}$, the decision rule for finding the translation with the highest probability for a source sentence $\mathbf{x}$ is given by

$$\hat{\mathbf{y}} = \underset{\mathbf{y}}{\operatorname{argmax}} \left\{ P(\mathbf{y}|\mathbf{x}; \hat{\boldsymbol{\theta}}) \right\}. \qquad (3)$$

However, since such exact inference requires the intractable enumeration of large and potentially infinite set of candidate sequences, we resort to approximate decoding algorithms such as greedy decoding, beam search, noisy parallel decoding (NPAD; Cho, 2016), or trainable greedy decoding (Gu et al., 2017).

Greedy Decoding In this algorithm, we generate a single sequence from left to right, by choosing the token that is most likely at each step. The output $\hat{\mathbf{y}} = \{\hat{y}_1, ..., \hat{y}_T\}$ can be represented as

$$\hat{y}_t = \underset{y}{\operatorname{argmax}} \left\{ P(y|\hat{y}_{<t}, \mathbf{x}; \hat{\boldsymbol{\theta}}) \right\}. \qquad (4)$$

Despite its low computational complexity of $O(|V| \times T)$, the translations selected by this method may be far from optimal under the overall distribution given by the model.

Beam Search Beam search decodes from left to right, and maintains $k > 1$ hypotheses at each step. At each step t, beam search considers all possible next tokens conditioned on the current hypotheses, and picks the k with the overall highest scores $\prod_{t'=1}^{t} P(y_{t'}|y_{<t'}, \mathbf{x}; \hat{\boldsymbol{\theta}})$. When all the hypotheses are complete (they end in an end-of-the-sentence symbol or reach a predetermined length limit), it returns the hypothesis with the highest likelihood. Tuning to find a roughly optimal beam size k can yield improvements in performance with sizes as high as 30 (Koehn and Knowles, 2017; Britz et al., 2017). However, the complexity of beam search grows linearly in beam size, with high constant terms, making it undesirable in some applications where latency is important, such as in on-device real-time translation.

NPAD Noisy parallel approximate decoding (NPAD; Cho, 2016) is a parallel decoding algorithm that can be used to improve greedy decoding or beam search. The main idea is that a better translation with a higher probability may be found by injecting unstructured random noise into the hidden state of the decoder network. Positive results with NPAD suggest that small manipulations to the decoder hidden state can correspond to substantial but still reasonable changes to the output sequence.

Figure 1: A single step of a generic actor interacting with a decoder of each of three types. The dashed arrows denote an optional recurrent connection in the actor network.

Trainable Greedy Decoding Approximate decoding algorithms generally approximate the maximum-a-posteriori inference described in Equation 3. This is not necessarily the optimal basis on which to generate text, since (i) the conditional log-probability assigned by a trained NMT model does not necessarily correspond well to translation quality (Tu et al., 2017), and (ii) different application scenarios may demand different decoding objectives (Gu et al., 2017). To solve this, Gu et al. (2017) extend NPAD by replacing the unstructured noise with a small feedforward actor neural network. This network is trained using a variant of policy gradient reinforcement learning to optimize for a target quality metric like BLEU under greedy decoding, and is then used to guide greedy decoding at test time by modifying the decoder's hidden states. Despite showing gains over the equivalent actorless model, their attempt to directly optimize the quality metric makes training unstable, and makes the model nearly impossible to optimize fully. This paper offers a stable and effective alternative approach to training such an actor, and further develops the architecture of the actor network.

3 Methods

We propose a method for training a small actor neural network, following the trainable greedy decoding approach of Gu et al. (2017). This actor takes as input the current decoder state $\mathbf{h}_t$, an attentional context vector $\mathbf{e}_t$ for the source sentence, and optionally the previous hidden state $\mathbf{s}_{t-1}$ of the actor, and produces a vector-valued action $\mathbf{a}_t$ which is used to update the decoder hidden state. The actor function can take on a variety of forms, and we explore four: a feedforward network with one hidden layer (*ff*), feedforward network with two hidden layers (*ff2*), a GRU recurrent network (*rnn*; Cho et al., 2014), and gated feedforward network (*gate*).

The feedforward *ff* actor function is computed as

$$\begin{aligned} \mathbf{z}_t &= \sigma([\mathbf{h}_t, \mathbf{e}_t]W^i + \mathbf{b}^i), \\ \mathbf{a}_t &= \tanh(\mathbf{z}_t W^o + \mathbf{b}^o), \end{aligned} \tag{5}$$

the *ff2* actor is computed as

$$\begin{aligned} \mathbf{z}_t^1 &= \sigma([\mathbf{h}_t, \mathbf{e}_t]W^i + \mathbf{b}^i), \\ \mathbf{z}_t^2 &= \sigma(\mathbf{z}_t^1 W^z + \mathbf{b}^z), \\ \mathbf{a}_t &= \tanh(\mathbf{z}_t^2 W^o + \mathbf{b}^o), \end{aligned} \tag{6}$$

the *rnn* actor is computed as

$$\begin{aligned} \mathbf{z}_t &= \sigma([\mathbf{h}_t, \mathbf{e}_t]U^z + \mathbf{s}_{t-1}W^z), \\ \mathbf{r}_t &= \sigma([\mathbf{h}_t, \mathbf{e}_t]U^r + \mathbf{s}_{t-1}W^r), \\ \tilde{\mathbf{s}}_t &= \tanh\left([\mathbf{h}_t, \mathbf{e}_t]U^h + (\mathbf{s}_{t-1} \circ \mathbf{r}_t)W^h\right), \\ \mathbf{s}_t &= (1 - \mathbf{z}_t) \circ \tilde{\mathbf{s}}_t + \mathbf{z}_t \circ \mathbf{s}_{t-1}, \\ \mathbf{a}_t &= \mathbf{s}_t U, \end{aligned} \tag{7}$$

and the *gate* actor is computed as

$$\begin{aligned}\mathbf{z}_t &= \sigma([\mathbf{h}_t, \mathbf{e}_t]U^z),\\ \mathbf{a}_t &= \mathbf{z}_t \circ \tanh([\mathbf{h}_t, \mathbf{e}_t]U).\end{aligned} \tag{8}$$

Once the action $\mathbf{a}_t$ has been computed, the hidden state $\mathbf{h}_t$ is simply replaced with the updated state $\tilde{\mathbf{h}}_t$:

$$\tilde{\mathbf{h}}_t = f(\mathbf{h}_t, \mathbf{e}_t) + \mathbf{a}_t. \tag{9}$$

Figure 1 shows a single step of the actor interacting with the underlying neural decoder of each of the three NMT architectures we use: the RNN-based model of Luong et al. (2015), ConvS2S (Gehring et al., 2017), and Transformer (Vaswani et al., 2017). We add the actor at the decoder layer immediately after the computation of the attentional context vector. For the RNN-based NMT, we add the actor network only to the last decoder layer, the only place attention is used. Here, it takes as input the hidden state of the last decoder layer $\mathbf{h}_t^L$ and the source context vector $\mathbf{e}_t$, and outputs the action $\mathbf{a}_t$, which is added back to the attention vector $\tilde{\mathbf{h}}_t^L$. For ConvS2S and Transformer, we add an actor network to each decoder layer. This actor is added to the sublayer which performs multi-head or multi-step attention over the output of the encoder stack. It takes as input the decoder state $\mathbf{h}_t^l$ and the source context vector $\mathbf{e}_t^l$, and outputs an action $\mathbf{a}_t^l$ which is added back to get $\tilde{\mathbf{h}}_t^l$.

Training To overcome the severe instability reported by Gu et al. (2017), we introduce the use of a *pseudo-parallel corpus* generated from the underlying NMT model (Gao and He, 2013; Auli and Gao, 2014; Kim and Rush, 2016; Chen et al., 2017; Freitag et al., 2017; Zhang et al., 2017) for actor training. This corpus includes pairs that both (i) have a high model likelihood, so that we can coerce the model to generate them without much additional training or many new parameters and, (ii) represent high-quality translations, measured according to a target metric like BLEU. We do this by generating sentences from the original unaugmented model with large-beam beam search and selecting the best sentence from the resulting k-best list according to the decoding objective.

More specifically, let $\langle \mathbf{x}, \mathbf{y} \rangle$ be a sentence pair in the training data and $\mathcal{Z} = \{\mathbf{z}^1, ..., \mathbf{z}^k\}$ be the k-best list from beam search on the pretrained NMT model, where k is the beam size. We define the objective score of the translation $\mathbf{z}$ w.r.t. the gold-standard translation $\mathbf{y}$ according to a target metric such as BLEU (Papineni et al., 2002), NIST (Doddington, 2002), negative TER (Snover et al., 2006), or METEOR (Lavie and Denkowski, 2009) as $O(\mathbf{z}, \mathbf{y})$. Then we choose the sentence $\tilde{\mathbf{z}}$ that has the highest score to become our new target sentence:

$$\tilde{\mathbf{z}} = \underset{\mathbf{z}=\mathbf{z}^1,..,\mathbf{z}^k}{\operatorname{argmax}} O(\mathbf{z}, \mathbf{y}). \tag{10}$$

Once we obtain the pseudo-corpus $D_{x,z} = \{\langle \mathbf{x_i}, \tilde{\mathbf{z}}_i \rangle\}_{i=1}^n$, we keep the underlying model fixed and train the actor by maximizing the log-likelihood of the actor parameters with these pairs:

$$\hat{\boldsymbol{\theta}}_a = \underset{\boldsymbol{\theta}_a}{\operatorname{argmax}} \left\{ \sum_{\langle \mathbf{x}, \mathbf{z} \rangle \in D_{x,z}} \log P(\mathbf{z} | \mathbf{x}; \hat{\boldsymbol{\theta}}, \boldsymbol{\theta}_a) \right\} \tag{11}$$

In this way, the actor network is trained to manipulate the neural decoder's hidden state at decoding time to induce it to produce better-scoring outputs under greedy or small-beam decoding.

4 Experiments

4.1 Setting

We evaluate our approach on IWSLT16 German-English, WMT15 Finnish-English, and WMT14 De-En translation in both directions with three strong translation model architectures.

For IWSLT16, we use *tst2013* and *tst2014* for validation and testing, respectively. For WMT15, we use *newstest2013* and *newstest2015* for validation and testing, respectively. For WMT14, we use *newstest2013* and *newstest2014* for validation and testing, respectively. All the data are tokenized and segmented into subword symbols using byte-pair encoding (BPE; Sennrich et al., 2016) to restrict the size of the vocabulary. Our primary evaluations use tokenized and cased BLEU. For METEOR and TER evaluations, we use multeval[4] with tokenized and case-insensitive scoring. All the underlying models are trained from scratch, except for ConvS2S WMT14 English-German translation, for which we use the trained model (as well as training data) provided by Gehring et al. (2017).[5]

Table 2: Generation quality (BLEU↑) using the proposed trainable greedy decoder without and with beam search ($k = 4$). Results without beam search (*tg*) are also appeared in Table 1.

RNN We use OpenNMT-py (Klein et al., 2017)[6] to implement our model. It is composed of an encoder with two-layer bidirectional RNN, and a decoder with another two-layer RNN. We refer to OpenNMT's default setting (*rnn_size* = 500, *word_vec_size* = 500) and the setting in Artetxe et al. (2018) (*rnn_size* = 600, *word_vec_size* = 300), and choose similar hyper-parameters: *rnn_size* = 500, *word_vec_size* = 300 for IWSLT16 and *rnn_size* = 600, *word_vec_size* = 500 for WMT. We use the input-feeding decoder and global attention with the general alignment function (Luong et al., 2015).

ConvS2S We implement our model based on fairseq-py.[7] We follow the settings in *fconv_iwslt_de_en* and *fconv_wmt_en_de* for IWSLT16 and WMT, respectively.

Transformer We implement our model based on the code from Gu et al. (2018).[8] We follow their hyperparameter settings for all experiments.

In the results below, we focus on the *gate* actor and pseudo-parallel corpora constructed by choosing the sentence with the best BLEU score from the k-best list produced by beam search with $k = 35$. Experiments motivating these choices are shown later in this section.

4.2 Results and Analysis

The results (Table 1) show that the use of the actor makes it practical to replace beam search with greedy decoding in most cases: We lose little or no performance, and doing so yields an increase in decoding efficiency, even accounting for the small overhead added by the actor. Among the three architectures, ConvS2S—the one with the most and largest layers—performs best. We conjecture that this gives the decoder more flexibility with which to guide decoding. In cases where model throughput is less important, our method can also be combined with beam search at test time to yield results somewhat better than either could achieve alone. Table 2 shows the result when combining our method with beam search.

Table 3: Translation examples from the WMT14 De-En test set with Transformer. We show translations generated by the underlying transformer using greedy decoding, beam search with $k = 4$, and beam search with $k = 35$ and the oracle BLEU scorer ($\star$). We also show the translations using our trainable greedy decoder both without and with beam search. Phrases of interest are underlined.

	IWSLT16 De-En				WMT14 De-En			
	ref	greedy	k35*	tg	ref	greedy	k35*	tg
Base Model	20.4	65.3	61.5	64.2	23.5	65.2	63.8	65.1
+Trainable Greedy Decoder	19.1	70.4	65.3	75.1	18.9	76.0	72.6	82.8

Table 4: Word-level likelihood (%) averaged by sentence for the IWSLT16 and WMT14 De-En test sets with Transformer. Each row represents the model used to evaluate word-level likelihood, and each column represents a different source of translations, including the reference (ref), greedy decoding on the base model (greedy), beam search with $k = 35$ on the base model and the BLEU scorer (k35*), and trainable greedy decoder (tg).

Examples Table 3 shows a few selected translations from the WMT14 German-English test set. In manual inspection of these examples and others, we find that the actor encourages models to recover missing tokens, optimize word order, and correct prepositions.

Likelihood We also compare word-level likelihood for different decoding results assigned by the base model and the actor-augmented model. For a sentence pair $\langle \mathbf{x}, \mathbf{y} \rangle$, word-level likelihood is defined as

$$P_w = \frac{1}{T} \sum_{t=1}^{T} P(y_t | y_{<t}, \mathbf{x}; \boldsymbol{\theta}). \qquad (12)$$

Table 4 shows the word-level likelihood averaged over the test set for IWSLT16 and WMT14 German to English translation with Transformer. Our trainable greedy decoder learns a much more peaked distribution and assigns a much higher probability mass to its greedy decoding result than the base model. When evaluated under the base model, the translations from trainable greedy decoding have smaller likelihood than the translations from greedy decoding using the base model for both datasets. This indicates that the trainable greedy decoder is able to find a sequence that is not highly scored by the underlying model, but that corresponds to a high value of the target metric.

Magnitude of Action Vector We also record the L_2 norm of the action, decoder hidden state, and attentional source context vectors on the validation set. Figure 2 shows these values over the course of training on the IWSLT16 De-En validation set with Transformer. The norm of the action starts

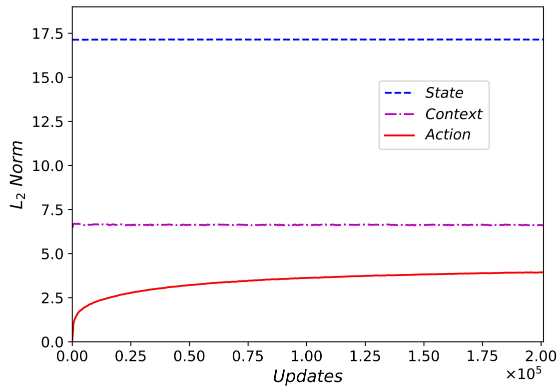

Figure 2: The norms of the three activation vectors on the IWSLT16 De-En validation set with Transformer. *Action*, *Context* and *State* represent the norm of the action, attentional source context vector and decoder hidden state, respectively.

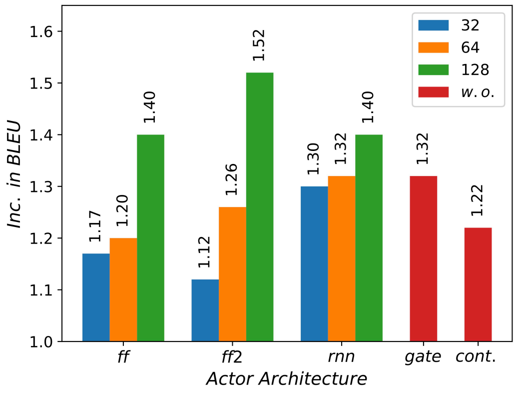

Figure 3: The effect of the actor architecture and hidden state size on trainable greedy decoding results over the IWSLT16 De-En validation set with Transformer (BLEU↑), shown with a baseline (*cont.*) in which the underlying model, rather than the actor, is trained on the pseudo-parallel corpus. The Y-axis starts from 1.0. *w.o.* indicates an actor with no hidden layer. 0.0 corresponds to 33.04 BLEU.

small, increases rapidly early in training, and converges to a value well below that of the decoder hidden state. This suggests that the action adjusts the decoders hidden state only slightly, rather than overwriting it.

4.3 Effects of Model Settings

Actor Architecture Figure 3 shows the trainable greedy decoding result on IWSLT16 De-En validation set with different actor architectures. We observe that our approach is stable across different actor architectures and is relatively insensitive to the hyperparameters of the actor. For the same type of actor, the performance increases gradually with the hidden layer size. The use of a recurrent connection within the actor does not meaningfully improve performance, possibly since all actors can use the recurrent connections of the underlying decoder. Since the gate actor contains no additional hyperparameters and was observed to learn quickly and reliably, we use it in all other experiments.

Here, we also explore a simple alternative to the use of the actor: creating a pseudo-parallel corpus with each model, and then training each model, unmodified and entirety, directly on this new corpus. This experiment (*cont.* in Figure 3) yields results that are comparable to, but not better than, the results seen with the actors. However, this comes with substantially greater computational complexity at training time, and, if the same trained model is to be optimized for multiple target metrics, greater storage costs as well.

Beam Size Figure 4a shows the effect of the beam size used to generate the pseudo-parallel corpus on the IWSLT16 De-En validation set with Transformer. Trainable greedy decoding improves over greedy decoding even when we set $k = 1$, namely, running *greedy* decoding on the unaugmented model to construct the new training corpus. With increased beam size k, the BLEU score consistently increases, but we observe diminishing returns beyond roughly $k = 35$, and we use that value elsewhere.

Training Corpus Construction There are a variety of ways one might use the output of beam search to construct a pseudo-parallel corpus: We could use the single highest-scoring output (by BLEU, or our target metric) for each input (*top1*), use all 35 beam search outputs (*full*), use all those outputs that score higher than the threshold, namely the base model's greedy decoding output (*thd*), or combine the *top1* results with the gold-standard translations (*comb.*). We show the effect of training corpus construction in Figure 4b. *para* denotes the baseline approach of training the actor with the original parallel corpus used to train the underlying NMT model. Among the four novel approaches, *full* obtains the worst performance, since the beam search outputs contain translations that are far from the gold-standard translation. We choose the best performing *top1* strategy.

	Obj.	BLEU↑	MTR↑	TER↓
Greedy	-	27.15	29.0	54.4
Beam4	-	28.74	29.9	51.9
	sBLEU	28.36	29.7	52.0
	sMTR	28.36	29.6	51.8
	-sTER	28.05	29.6	51.4

Table 5: Results when trained with different decoding objectives on IWSLT16 De-En translation using Transformer. MTR denotes METEOR. We report greedy decoding and beam search ($k = 4$) results using the original model, and results with trainable greedy decoding (lower half).

Decoding Objectives As our approach is capable of using an arbitrary decoding objective, we investigate the effect of different objectives on BLEU, METEOR (MTR) and TER scores with Transformer for IWSLT16 De-En translation. Table 5 shows the final result on the test set. When trained with one objective, our model yields relatively good performance on that objective. For example, negative sentence-level TER (i.e., -sTER) leads to -3.0 TER improvement over greedy decoding and -0.5 TER improvement over beam search. However, since these objectives are all well correlated with each other, training with different objectives do not differ dramatically.

5 Related Work

Data Distillation Our work is directly inspired by work on knowledge distillation, which uses a similar pseudo-parallel corpus strategy, but aims at training a compact model to approximate the function learned by a larger model or an ensemble of models (Hinton et al., 2015). Kim and Rush (2016) introduce knowledge distillation in the context of NMT, and show that a smaller student network can be trained to achieve similar performance to a teacher model by learning from pseudo-corpus generated by the teacher model. Zhang et al. (2017) propose a new strategy to generate a pseudo-corpus, namely, fast sequence-interpolation based on the greedy output of the teacher model and the parallel corpus. Freitag et al. (2017) extend knowledge distillation on an ensemble and oracle BLEU teacher model. However, all these approaches require the expensive procedure of retraining the full student network.

Pseudo-Parallel Corpora in Statistical MT Pseudo-parallel corpora generated from beam search have been previously used in statistical machine translation (SMT) (Chiang, 2012; Gao and He, 2013; Auli and Gao, 2014; Dakwale and Monz, 2016). Gao and He (2013) integrate a recurrent neural network language model as an additional feature into a trained phrase-based SMT system and train it by maximizing the expected BLEU on k-best list from the underlying model. Our work revisits a similar idea in the context trainable greedy decoding for neural MT.

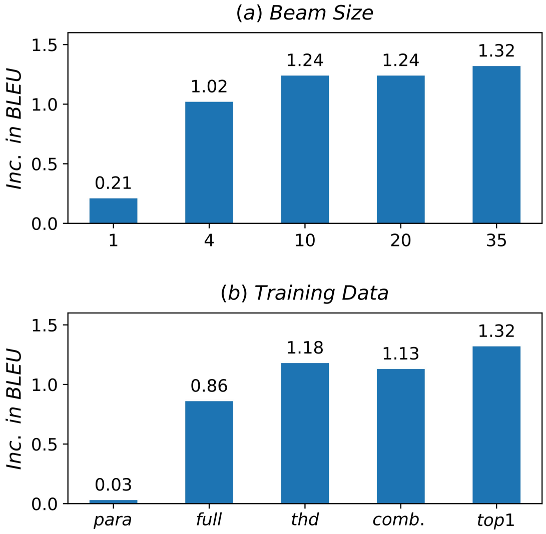

Figure 4: (a) The effect of beam size on the IWSLT16 De-En validation with Transformer and (b) the effect of the training corpus composition in the same setting. *para*: parallel corpus; *full*: all 35 beam search outputs; *thd*: beam search outputs that score higher than the base model's greedy decoding output; *top1*: beam search output with the highest bleu score; *comb.*: *top1+para*. 0.0 corresponds to 33.04 BLEU.

Decoding for Multiple Objectives Several works have proposed to incorporate different decoding objectives into training. Ranzato et al. (2015) and Bahdanau et al. (2016) use reinforcement learning to achieve this goal. Shen et al. (2016) and Norouzi et al. (2016) train the model by defining an objective-dependent loss function. Wiseman and Rush (2016) propose a learning algorithm tailored for beam search. Unlike these works that optimize the entire model, Li et al. (2017) introduce an additional network that predicts an arbitrary decoding objective given a source sentence and a prefix of translation. This prediction is used as an auxiliary score in beam search. All of these methods focus primarily on improving beam search results, rather than those with greedy decoding.

6 Conclusion

This paper introduces a novel method, based on an automatically-generated pseudo-parallel corpus, for training an actor-augmented decoder to optimize for greedy decoding. Experiments on three models and three datasets show that the training strategy makes it possible to substantially improve the performance of an arbitrary neural sequence decoder on any reasonable translation metric in either greedy or beam-search decoding, all with only a few trained parameters and minimal additional training time.

As our model is agnostic to both the model architecture and the target metric, we see the exploration of more diverse and ambitious model–target metric pairs as a clear avenue for future work.

Abstract

One of the weaknesses of Neural Machine Translation (NMT) is in handling low-frequency and ambiguous words, which we refer as troublesome words. To address this problem, we propose a novel memory-enhanced NMT method. First, we investigate different strategies to define and detect the troublesome words. Then, a contextual memory is constructed to memorize which target words should be produced in what situations. Finally, we design a hybrid model to dynamically access the contextual memory so as to correctly translate the troublesome words. The extensive experiments on Chinese-to-English and English-to-German translation tasks demonstrate that our method significantly outperforms the strong baseline models in translation quality, especially in handling troublesome words.

1 Introduction

Neural machine translation (NMT) based on the encoder-decoder architecture becomes the new state-of-the-art due to distributed representation and end-to-end learning (Cho et al., 2014; Bahdanau et al., 2015; Junczys-Dowmunt et al., 2016; Gehring et al., 2017; Vaswani et al., 2017).

However, the current NMT is a global model that maximizes the performance on the overall data and has problems in handling low-frequency words and ambiguous words[1], we refer these words as troublesome words and define them in Section 3.1.

Some previous work attempt to tackle the translation problem of low-frequency words. Sennrich et al. (2016) propose to decompose the words into subwords which are used as translation units so that the low-frequency words can be represented by frequent subword sequences. Arthur et al. (2016) and Feng et al. (2017) try to incorporate a translation lexicon into NMT in order to obtain the correct translation of low-frequency words. However, the former method still faces the low-frequency problem of subwords. And the latter one has a drawback that they use lexicons without considering specific contexts. Fig. 1 shows an example, in which "aerkate" is an infrequent word and the baseline NMT incorrectly translates it into a pronoun "he". Incorporation of bilingual lexicon rectifies the mistake but wrongly converts "chengzhang" into an incorrect target word "growth" since an entry "(chengzhang, growth)" in the bilingual lexicon is somewhat wrongly used without taking the contexts into account. Furthermore, these two kinds of methods mainly focus on low-frequency words that are just a part of the troublesome words.

In this paper, we categorize the words (including infrequent words and ambiguous words) which are difficult to translate as troublesome words and propose a novel memory-augmented framework to

Source: 阿尔卡特 宣称 去年 第四 季 销售 成长 近 百分之三十

Pinyin: **aerkate** cheng qunian disi ji xiaoshou **chengzhang** jin baifenzhisanshi

Reference: **alcatel** says sales in fourth quarter last year **grew** nearly 30 %

NMT: **he** said sales **grew** nearly 30 percent in fourth quarter of last year

NMT+LexiconTable: **alcatel** said sales **growth** nearly 30 percent in fourth quarter of last year

Figure 1: The NMT model produces a wrong translation for the low-frequency word "aerkat". While introducing an external lexicon table without contextual information, the model incorrectly translates the ambiguous word "chengzhang" into "growth".

---

[1] In this work, we consider a source word is ambiguous if it has multiple translations with high entropy of probability distribution.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 391–400
Brussels, Belgium, October 31 - November 4, 2018.

address them. Our method first investigates different strategies to define the troublesome words. Then, these words and their contexts in the training data are memorized with a contextual memory which is finally accessed dynamically during decoding to solve the translation problem of the troublesome words.

Specifically, we first decode all the source sentences of the bilingual training data with baseline NMT and define the troublesome source words according to the distance between the predicted words and the gold words. The troublesome words associated with their hidden contextual representations are stored in a memory which memorizes the correct translation and the corresponding contextual information. During decoding, we activate the contextual memory when we encounter the troublesome words and employ the contextual similarity between the test sentence and the memory to determine appropriate target words. We test our methods on Chinese-to-English and English-to-German translation tasks. The experimental results demonstrate that the translation performance can be significantly improved and a large portion of troublesome words can be correctly translated. The contributions are listed as follows:

1) We are the first to define and handle the troublesome words in neural machine translation.

2) We propose to memorize not only the bilingual lexicons but also their contexts with a contextual memory.

3) We design a dynamic approach to correctly translate the troublesome words by combining the contextual memory and the NMT model.

2 Neural Machine Translation

NMT contains an encoder and a decoder. The encoder transforms a source sentence $X = \{x_1, x_2, ..., x_{Tx}\}$ into a set of context vectors $C = (h_1^m, h_2^m, ..., h_{Tx}^m)$ by using m stacked Long Short Term Memory (LSTM) layers (Hochreiter and Schmidhuber, 1997) . h_j^m is the hidden state of the top layer in encoder. The bottom layer of encoder is a bi-direction LSTM layer to collect the context from the left side and right side.

The decoder generates one target word at a time by computing $p_i^N(y_i|y_{<i}, C)$ as follows:

$$p_i^N(y_i|y_{<i}, C) = softmax(W_{y_i}\widetilde{z}_i + b_s) \quad (1)$$

where $\widetilde{z}_i$ is the attention output:

$$\widetilde{z}_i = tanh(W_z[z_i^m; c_i]) \quad (2)$$

c_i can be calculated as follows:

$$c_i = \sum_{j=1}^{Tx} a_{ij} h_i^m \quad (3)$$

where $a_{i,j}$ is the attention weight:

$$a_{i,j} = \frac{h_j^m z_i^m}{\sum_j h_j^m z_i^m} \quad (4)$$

where z_i^m is the hidden state of the top layer in decoder. More detailed introduction can be found in (Luong et al., 2015).

Notation. In this paper, we denote the whole source vocabulary by $V_S = \{s_m\}_{m=1}^{|V_S|}$ and target vocabulary by $V_T = \{t_n\}_{n=1}^{|V_T|}$, where s_m is the source word and t_n is the target word. We denote a source sentence by X and a target sentence by Y. Each source word in X is denoted by x_j. Each target word in Y is denoted by y_i. Accordingly, a target word can be denoted not only by t_n, but also by y_i. This does not contradict. t_n means this target word is the n^{th} word in vocabulary V_T, and y_i means this target word is the i^{th} word in sentence Y. Similarly, we denote a source word by s_m and x_j.

3 Method Description

Our method contains three parts: 1) definition and detection of the troublesome words (Section 3.1); 2) contextual memory construction (Section 3.2); and 3) hybrid approach combining contextual memory and baseline NMT model (Section 3.3).

3.1 Troublesome Word Definition

Generally speaking, troublesome words are those that are difficult to translate for the baseline NMT system $BNMT$. Fig. 2 shows the main process to detect the troublesome words. Given each training sentence pair (X, Y), $BNMT$ decodes the source sentence X and outputs the predicted probability of each gold target word $p_i^N(y_i)$. We call y_i an **exception** if $p_i^N(y_i)$ satisfies the predefined **exception criteria** introduced below. The source word x_j is an exception (a candidate troublesome word) if (x_j, y_i) is an entry in the word alignment A[2]. Suppose x_j appears N times in the training data and there are M exceptions among all its aligned

---

[2] The word alignments A is extracted using the fast-align tool (Dyer et al., 2013) on the bilingual training data with both source-to-target and target-to-source directions.

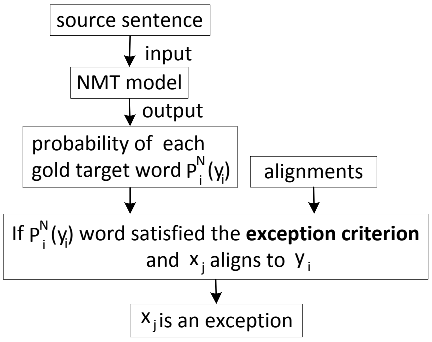

Figure 2: The main process to detect an exception.

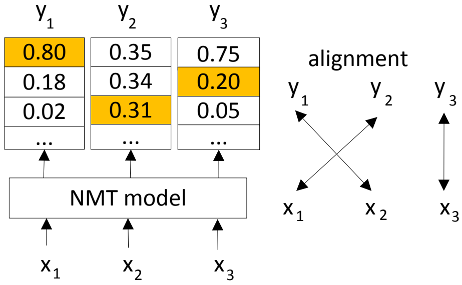

Figure 3: A toy example to show the process: if $p_i^N(y_i)$ (left) satisfies the predefined exception criteria and x_j aligns to y_i, then x_j is an exception.

gold target words. Then, the **exception rate** $r(x_j)$ will be M/N.

Definition: x_j is a **troublesome word** if $r(x_j) > \epsilon$ in which ϵ is a predefined threshold.

Exception Criteria. As discussed before, we need an exception criterion to measure whether a gold target word is an exception or not. In this paper, we investigate three exception criteria. Here, we introduce each of them through a toy example shown in Fig. 3, in which the source sentence is $X = \{x_1, x_2, x_3\}$ and the gold target sentence is $Y = \{y_1, y_2, y_3\}$. The left shows the probability distribution of all target vocabulary $p_i^N(V_T)$ at each decoding step i, where the probability of the gold target word is highlighted in yellow. The right shows the word alignments between X and Y.

1) Absolute Criterion. A gold target word y_i is an exception if its predicted probability $p_i^N(y_i)$ is lower than a predefined threshold, namely $p_i^N(y_i) < p_0$. In Fig. 3, $p_i^N(y_i)$ at each decoding step is respectively 0.8, 0.31 and 0.2. If we set $p_0 = 0.5$, $p_2^N(y_2)$ and $p_3^N(y_3)$ are lower than threshold p_0. x_1 and x_3 are both exceptions according to the alignments.

2) Gap Criterion. For this criterion, we utilize the predicted probability gap between the gold target word and the top one. Specifically, the gap can be calculated by:

$$g(y_i) = max(p_i^N(V_T)) - p_i^N(y_i) \qquad (5)$$

where $max(p_i^N(V_T))$ is the top one in the probability distribution at the i^{th} decoding step. y_i is an exception if $g(y_i) > g_0$. In Fig. 3, the largest predicted probabilities at each decoding step $max(p_i^N(V_T))$ are respectively 0.8, 0.35 and 0.75. Thus, the gap is 0.0, 0.04 and 0.55. If $g_0 = 0.1$, x_3 is an exception since $g(y_3) > g_0$ and x_3 aligns to y_3.

3) Ranking Criterion. This criterion is based on the ranking of $p_i^N(y_i)$ in $p_i^N(V_T)$ (denoted by $rank(y_i)$). If $rank(y_i) > rank_0$, then y_i is an exception. In Fig. 3, the ranking of each gold target word is 1, 3 and 2. If we set $rank_0 = 2$, then $rank(y_2) = 3 > rank_0$ and x_1 is an exception due to the alignment between x_1 and y_2.

Using the above exception criteria and the definition of troublesome words, we can detect all the source-side troublesome words in the bilingual training data.

3.2 Contextual Memory Construction

For a troublesome word, we now introduce how to build a contextual memory $\mathbb{M}$ to store its translation knowledge. Specifically, the contextual memory contains five elements:

$$\{s_m, t_n, c(s_m, t_n), p^L(s_m, t_n), r(s_m)\} \qquad (6)$$

each of them is described as follows:

- s_m is a troublesome source word.
- t_n is a gold target word for s_m.
- $c(s_m, t_n)$ is the context of lexicon pair (s_m, t_n). Here, we use the hidden states of encoder h_j to represent the context, since it contains the information from left ($\overrightarrow{h_j}$) and right ($\overleftarrow{h_j}$). Note that when we traverse the training data and memorize the contexts of all troublesome words, there must be many cases in which the same pair (s_m, t_n) appears in different contexts. In order to reduce the memory size and fuse different contexts of a same lexicon pair, we merge these memories by averaging the contexts. Assume there are K different contexts for (s_m, t_n), and they

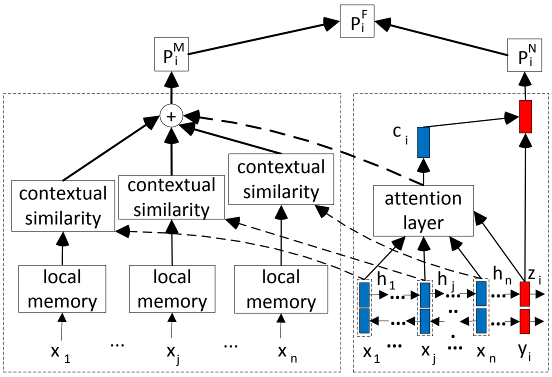

Figure 4: The architecture of contextual memory-augmented NMT.

are denoted by $h_k(s_m, t_n)$. The average context of (s_m, t_n) can be calculated by:

$$c(s_m, t_n) = \frac{\sum_{k=1}^{K} h_k(s_m, t_n)}{K} \quad (7)$$

Note that the context here is defined on the source side.

- $p^L(s_m, t_n)$ is the lexicon translation probability. It is the average of source-to-target and target-to-source probabilities calculated through maximum likelihood estimation on word alignments.
- $r(s_m)$ is the exception rate of s_m introduced in Section 3.1 and it can indicate the translation difficulty of a source word. We will use $r(s_m)$ to determine the dynamic weights of contextual memories in Section 4.

Noise Reduction. As we know, the training data and word alignments are not perfect and may introduce noise to the contextual memory. To reduce the noise, we employ two strategies.

1) To improve the quality of the alignments A, we derive the alignment results from source-to-target and target-to-source, respectively. We only save the alignments which exist in both directions.

2) We eliminate the lexicon pairs whose translation probabilities are too small. For a lexicon pair (s_m, t_n), if its lexicon translation probability is smaller than 0.01, we treat this lexicon pair as a noisy sample and eliminate it from our memory.

3.3 Integrating Contextual Memory into NMT

In this section, we integrate the contextual memory into NMT to handle troublesome words. The overall framework is depicted in Fig. 4 and the integration process can be divided into four steps:

Step 1. Given a test sentence X, the first step is to find the troublesome words in X and collect corresponding **local memories** from the **global contextual memory** $\mathbb{M}$. For each source word x_j, we retrieve from $\mathbb{M}$ if it is a troublesome word and obtain the local memory as follows:

$$\{x_j, t_n, c(x_j, t_n), p^L(x_j, t_n), r(x_j)\} \quad (8)$$

Step 2. The next step is to measure the contextual similarity between the context in the test sentence X and the context in $\mathbb{M}$. For the troublesome word $x_j \in X$, we still use the encoder hidden state h_j to represent the context in X. The corresponding context in $\mathbb{M}$ is $c(x_j, t_n)$ in Eq. (8). Here, we use a feed-forward network to measure this similarity[3]:

$$d_j(t_n) = \\ sigmoid(v_d^T * tanh(W_h * h_j + W_c * c(x_j, t_n))) \quad (9)$$

where v_d, W_h and W_c are learnable parameters. The sigmoid function guarantees the similarity score is in the range $(0, 1)$. This similarity $d_j(t_n)$ will determine whether or not to adopt the target translation word t_n in $\mathbb{M}$.

Step 3. The next task is calculating the probability $p_i^M(t_n)$ of t_n at each decoding step i. $p_i^M(t_n)$ is the probability predicted by the contextual memory $\mathbb{M}$ and is calculated by:

$$p_i^M(t_n) = \sum_{j}^{Tx} a_{i,j} * d_j(t_n) * p^L(x_j, t_n) \quad (10)$$

where $a_{i,j}$ is the attention weight, $d_j(t_n)$ is the context similarity in Eq. (9), and $p^L(x_j, t_n)$ is the lexicon translation probability.

Step 4. The final task is to combine the memory predicted probability (p_i^M in Eq. (10)) and the NMT predicted one (p_i^N in Eq. (1)). Here, we propose a dynamic strategy to balance these two probabilities:

$$p_i^F(t_n) = \lambda_i * p_i^M(t_n) + (1 - \lambda_i) * p_i^N(t_n) \quad (11)$$

where $p_i^F(t_n)$ is the final probability of the target word t_n, λ_i is the dynamic weight to adjust

---

[3] In our preliminary experiment, we also try cosine distance to measure this similarity, while the performance of cosine distance is lower than the current feed-forward network method.

the contribution from the memory and NMT. Here we explain the reason why we apply the dynamic manner. Recall that for each source troublesome word s_m, we calculate its exception rate (similar to error rate). If a troublesome word has a lower exception rate, indicating that this source word is easier to be translated for the neural model. In this case, p_i^N is more reliable. Thus we design the dynamic weight λ_i according to the exception rate $r(x_j)$:

$$\begin{aligned} \lambda_i &= sigmoid(\beta_\gamma * \gamma_i) \\ \gamma_i &= \sum_{j}^{Tx} a_{i,j} * r(x_j) \end{aligned} \tag{12}$$

where β_γ is a learnable parameter. From Eq. (12), the dynamic weight λ_i is determined by both of the attention weight $a_{i,j}$, and the exception rate $r(x_j)$.

Training the parameters. As discussed above, our method contains some parameters (v_d, W_h, W_c and β_γ) to be learned. We denote the parameters introduced by our method by θ^M and the parameters in NMT by θ^N. To make it efficient, given the aligned training data $D = \{X^{(d)}, Y^{(d)}\}_{d=1}^{|D|}$, we keep θ^N unchanged and optimize θ^M by maximizing the following objective function.

$$L(\theta^M) = \frac{1}{|D|} \sum_{d=1}^{|D|} \sum_{i}^{T_y} log\ p_i^F(y_i^{(d)}; \theta^M) \tag{13}$$

where p_i^F can be calculated by Eq. (11).

4 Experimental Settings

We test the proposed methods on Chinese-to-English (CH-EN) and English-to-German (EN-DE) translation. In CH-EN translation, we use LDC corpus which includes 2.1M sentence pairs for training. NIST 2003 dataset is used for validation. NIST04-06 and 08 datasets are used for testing. In EN-DE translation, we use WMT 2014 EN-DE dataset, which includes 4.5M sentence pairs for training. 2012-2013 datasets are used for validation and 2014 dataset is used for testing.

We use the Zoph_RNN toolkit[4] to implement all described methods. In all experiments, the encoder and decoder include two stacked LSTM layers. The word embedding dimension and the size of hidden layers are both set to 1,000. The mini-batch size is set to 128. We discard the training sentence pairs whose length exceeds 100. We run a total of 20 iterations for all translation tasks. We test all methods based on two granularities: words and sub-words. For word granularity, we limit the vocabulary to 30K (CH-EN) and 50K (EN-DE) for both the source and target languages. For sub-word granularity, we use the BPE method (Sennrich et al., 2016) to merge 30K (CH-EN) and 32K (EN-DE) steps. The beam size is set to 12. We use case-insensitive 4-gram BLEU (Papineni et al., 2002) for translation quality evaluation.

We compare our method with other relevant methods as follows:

1) **Baseline**: It is the baseline NMT system with global attention (Luong et al., 2015; Zoph and Knight, 2016; Jean et al., 2015).

2) **Arthur**: It is the state-of-the-art method which incorporates discrete translation lexicons into NMT (Arthur et al., 2016). We implement Arthur et al. (2016)'s method in two different ways. In the first way, we fix the **Baseline** unchanged, and utilize Arthur et al. (2016)'s method in the test phase. We denote this system by **Arthur(test)**. In second way, we allow **Baseline** to be retrained by Arthur et al. (2016)'s method, and denote the system by **Arthur(train+test)**. We replicate the Arthurs work using the bias method with the hyper parameter being set to 0.001 as reported in their paper.

3) **X+MEM**: It is our proposed memory augment method for any neural model **X**, in which we define the troublesome word by using the gap criterion with threshold $g_0 = 0.1$. We set threshold $\epsilon = 0.05$, which is fine-tuned in validation set. It means if the exception rate of a source word exceeds 0.05, we treat this word as a troublesome word.

5 Results on CH-EN Translation

5.1 Our methods vs. Baseline

Table 1 reports the main translation results of CH-EN translation. We first compare **Baseline+MEM** with **Baseline**. As shown in row 1 and row 5 in Table 1, **Baseline+MEM** can improve over **Baseline** on all test datasets, and the average improvement is 1.37 BLEU points. The results show that our method could significantly outperform the baseline model.

---

#	Model	03	04	05	06	08	Avg.	△
1	Baseline	41.01	42.94	40.31	40.57	30.96	39.16	-
2	Arthur(test)	41.34	43.31	40.79	40.84	31.11	39.48	-
3	Arthur(train+test)	41.88	43.75	41.16	41.63	31.47	39.98	-
4	Baseline(sub-word)	43.93	44.74	42.46	43.01	32.53	41.33	-
5	Baseline+MEM	$42.74^{\dagger}$	$43.94^{\dagger}$	$42.15^{\dagger}$	$41.94^{\dagger}$	$31.86^{\dagger}$	40.53	+1.37
6	Arthur(train+test)+MEM	$43.04^{\dagger}$	44.65^{*}	$42.19^{\dagger}$	$42.59^{\dagger}$	32.05^{*}	40.90	+0.92
7	Baseline(sub-word)+MEM	$44.98^{\dagger}$	$45.51^{\dagger}$	$43.93^{\dagger}$	$43.95^{\dagger}$	$33.33^{\dagger}$	42.34	+1.01

Table 1: The main results of CH-EN translation. △ shows the BLEU points improvement of system "X+MEM" than system X. "*" indicates that system "X+MEM" is statistically significant better ($p < 0.05$) than system X and "†" indicates $p < 0.01$.

Model	#Pairs	Size	Time	BLEU
Baseline	-	-	0.406	39.16
Arthur(test)	938K	58M	0.429	39.48
Tword	125K	7.4M	0.423	39.77
+Context	125K	893M	0.508	40.19
+Dynamic	125K	893M	0.511	40.53
All+Context	938K	6.4G	1.829	40.23

Table 2: The effects of lexicon pairs only containing troublesome words (Tword), context and dynamic weights. Column **#Pairs** shows the number of lexicon pairs. Column **Time** shows the average decoding time (seconds) of per sentence.

Source: 阿尔卡特 宣称 去年 第四 季 销售 成长 近 百分之三十

Pinyin: aerkate cheng qunian disi ji xiaoshou chengzhang jin baifenzhisanshi

Reference: alcatel says sales in fourth quarter last year grew nearly 30 %

Baseline: he said sales grew nearly 30 percent in fourth quarter of last year

Arthur: alcatel says sales growth nearly 30 percent in fourth quarter of last year

Baseline+MEM: alcatel says sales grew nearly 30 percent in fourth quarter of last year

Figure 5: An example to show that considering context could produce a better translation result. In the example, **Arthur(test)** translates *chengzhang* into a wrong target word *growth*, while **Baseline+MEM** could overcome this mistake with the help of the context modeling.

5.2 Results on Sub-words

We also test the proposed method when the translation unit is sub-word. The baseline and our method using sub-word as translation unit are respectively denoted by **Baseline(sub-word)** and **Baseline(sub-word)+MEM**. The results are shown in row 4 and row 7. From the results, **Baseline(sub-word)+MEM** outperforms **Baseline(sub-word)** by 1.01 BLEU points, indicating that adopting sub-words as translation units still faces the problem of troublesome tokens, and our method could alleviate this problem.

5.3 Our Method vs. Method Using Translation Lexicon

We also compare our method with Arthur et al. (2016)'s method which incorporates a translation lexicon into NMT. Here, the comparison is conducted in two ways based on whether the baseline neural model is fixed or retrained.

Fixed Baseline. Comparing **Arthur(test)** (row 2 in Table 1) and **Baseline+MEM** (row 5 in Table 1), we can see that our proposed method can surpass **Arthur(test)** with 1.05 BLEU points. As there are three differences between our methods and **Arthur(test)**, we take the following experiments to evaluate the effect of each difference.

The first difference is that our memory only stores the lexicon pairs for troublesome words, while **Arthur(test)** utilizes all the available lexicon pairs. We implement another system which is similar to **Arthur(test)**, except that we only utilize the troublesome lexicon pairs. We denote the system by **Tword**. The results are reported in Table 2. From the results, we can find that **Tword** obtains better translation results than **Arthur(test)** while using much fewer lexicon pairs (125K vs. 938K).

The second difference is that we take the context into consideration. When we add the context on the basis of **Tword** (denoted by **+Context**), it further improves the baseline system by 1.03 BLEU points, indicating the importance of the context. Fig.5 shows the mentioned example in Section 1, in which **Arthur(test)** translates *chengzhang* into a wrong target word *growth*, while **Baseline+MEM** could overcome this mistake with the help of the context modeling.

We also implement another system, in which we build the contextual memory for all source words.

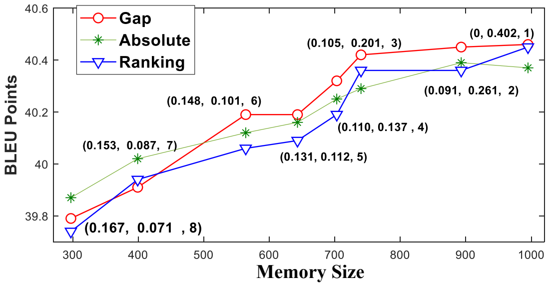

Figure 6: The comparison of different criteria. The gap criterion outperforms others with the increase of the memory size.

We denote the system by **All+Context** and the results are reported in Table 2. As shown in Table 2, **All+Context** surpasses **Arthur(test)** with 0.75 BLEU points while at the cost of 6.4G memory footprint and 1.829s time consuming. However, if we only build the contextual memory for the troublesome words, comparing to **All+Context**, there is only a slighter BLEU points decline (40.19 vs. 40.23) while sharply reduces memory size to 893M and decoding time to 0.511s, showing that our strategy of only building the contextual memory for troublesome words is effective.

The final difference is that we employ the dynamic strategy to balance between NMT and the contextual memory. When we employ this dynamic strategy (denoted by **+Dynamic**), the improvement can further reach 1.37 BLEU points.

Retrained Baseline. In the second comparison, we allow the baseline model to be retrained by Arthur's method (**Arthur(train+test)**). We then implement our method using **Arthur(train+test)** as baseline (denoted by **Arthur(train+test)+MEM**). Comparing the results of these two methods in Table 1 (line 3 and 6), our method is still effective on the retrained model. The average gains are 0.92 BLEU points.

5.4 Effects of Different Exception Criteria

In our method, we investigate three exception criteria to define the troublesome words. The following experiment is conducted to compare their performances. For fairness, the comparison of the three criteria is conducted under the same number of contextual memory, which can be achieved by adjusting the respective thresholds (p_0, g_0 and $rank_0$). The results are reported in Fig. 6, in which the x axis represents the size of contextual memory, the y axis denotes BLEU score, and the numbers in the bracket from left to right are the respective thresholds of **gap**, **absolute** and **ranking**. As shown in Fig. 6, all the three criteria can improve the translation quality. When the memory size is relatively small, absolute criterion performs best. With the size increases, the gap criterion achieves a higher performance than others.

Type	Baseline	Baseline+MEM
Low+Amb	38.15	39.75
Low	38.56	40.03
Amb	39.86	40.67
Others	40.49	40.76

Table 3: The BLEU score on different kinds of sentences. **Low** denotes low frequency words, **Amb** denotes ambiguous words. **Low+Amb** denotes the low frequency and ambiguous words.

Type	Tword	Error	Rectify	Deterio
Total	374	153	70 (45.8%)	11
Low+Amb	77	30	16 (53.3%)	3
Low	144	59	30 (50.8%)	4
Amb	117	48	20 (41.7%)	4
Others	36	16	4 (25%)	0

Table 4: The manual analysis on the word level. Column **Tword** shows the number of troublesome words in sentence. Column **Error** shows the number of errors made by **Baseline** when translates the troublesome words. The number (ratio) of rectification caused by our method is reported in column **Rectify**. Column **Deterio** shows the number of deterioration (the original translation is correct, while our method produces the incorrect translation) caused by our method.

Note that our current criteria only consider one single factor. The combination of different criteria may be more beneficial, and we leave this as our future work.

5.5 Results on Low-Frequency Words and Ambiguous Words

We further analyze our method on specific troublesome words, such as low-frequency words and ambiguous words. Here, we use the following definition in our analysis.

Low-frequency words: The words whose frequency is lower than 100.

Ambiguous words: Assume a word s_m contains K candidate translations with a probability p_k^L. If the entropy of probability distribution $-\sum_{k=1}^{K} p_k^L log p_k^L > E_0$ ($E_0 = 1.5$ in this paper), we treat this word as an ambiguous word.

Therefore, the sentences containing troublesome words can be divided into four different parts: 1) sentences which contain both low-frequency and ambiguous words (**Low+Amb**,

Model	Rectify	Deterio
Arthur(test)	51	17
Baseline+MEM	70	11

Table 5: The numbers of rectification (**Rectify**) and deterioration (**Deterio**) caused by different models.

986 sentences), 2) sentences which contain low-frequency words but no ambiguous words (**Low**, 1427 sentences). 3) sentences which contain ambiguous words while do not contain low-frequency words (**Amb**, 1301 sentences). 4) Other sentences (**Others**, 832 sentences). The results are reported in Table 3. From this table, we observe that our proposed method improves the translation quality on all kinds of sentences. **Low+Amb** performs best (**Low** the second), indicating that our method is most effective in dealing with low-frequency words. The improvement on **Amb** is 0.81 BLEU points, showing that our method can also well handle the ambiguous words.

We also conduct a manual analysis to figure out how many troublesome words could be rectified by our method. We randomly select 200 testing sentences, and count the following three numbers: 1) the number of troublesome words in the sentence (**Tword**), 2) the number of mistakes produced by **Baseline** (**Error**), 3) the number (ratio) of rectification using our method (**Rectify**). 4) The number of deterioration caused by our method (**Deterio**). The statistics are reported in Table 4. From the results, we can get similar conclusions that our method is most effective on low-frequency and ambiguous words with the rectification rate 50.8% and 41.7% respectively.

We can notice that the proposed method also produces 11 deterioration cases (**Deterio**) when rectifying the troublesome words. As a comparison, we also count the total rectification and deterioration numbers of **Arthur(test)**. The results are reported in Table 5. These results show that our method could rectify more words (51 vs. 70) with less deterioration (17 vs. 11) than **Arthur(test)**.

6 Results on EN-DE Translation

We also test our method on EN-DE translation and the results are reported in Table 6. We can see that our method is still effective on EN-DE translation. Specifically, when the translation unit is word, the proposed method improves the baseline by 1.13 BLEU points. The improvement is 0.76 BLEU points when the translation unit is sub-word.

Model	Unit	EN-DE	
		dev	test
Baseline	word	20.28	21.04
Baseline+MEM	word	$21.34^{\dagger}$	$22.17^{\dagger}$
Baseline	sub-word	22.10	22.85
Baseline+MEM	sub-word	$23.05^{\dagger}$	23.61^{*}

Table 6: The results on EN-DE translation. "*" indicates that it is statistically significantly better ($p < 0.05$) than system X and "†" indicates $p < 0.01$.

7 Related Work

The related work can be divided into three categories and we describe each of them as follows:

Neural Turing Machine for NMT. Our idea is first inspired by the Neural Turing Machine (NTM) (Graves et al., 2014, 2016) and memory network (Weston et al., 2014). (Wang et al., 2017a) used special NTM memory to extend the decoder in the attention-based NMT. In their method, the memory is used to provide temporary information from source to assist the decoding process. In contrast, our work uses memory to store contextual knowledge in the training data.

Smaller translation granularity. Our work is also inspired by the other studies to deal with the low-frequency and ambiguous words (Vickrey et al., 2005; Zhai et al., 2013; Rios et al., 2017; Carpuat and Wu, 2007; Li et al., 2016). Among them, the most relevant is the work that decomposes the low-frequency words into smaller granularities, e.g, hybrid word-character model (Luong and Manning, 2016), sub-word model (Sennrich et al., 2016) or word piece model (Wu et al., 2016). These methods mainly focus on low-frequency words that are just a subset of the troublesome words. Furthermore, our experimental results show that even using a smaller translation unit, the NMT model still faces the problem of troublesome tokens and our method could alleviate this problem.

Combining SMT and NMT. Our ideas are also inspired by the work which combines SMT and NMT. Earlier studies were mostly based on the SMT framework, and have been deeply discussed by the review paper in Zhang and Zong (2015). Later, the researchers transfer to NMT framework, e.g. (Wang et al., 2017b; Zhang and Zong, 2016; Zhou et al., 2017; Tu et al., 2016; Mi et al., 2016; He et al., 2016; Dahlmann et al., 2017; Wang et al., 2017c,d; Gu et al., 2018; Zhao et al., 2018). The most relevant studies are Arthur et al. (2016) and

Feng et al. (2017). They incorporate the lexicon pairs into NMT to improve the translation quality. There are three differences between our method and theirs. First, we only utilize the lexicon pairs for the troublesome words, rather than using all lexicon pairs. Second, we take contextual information into consideration for memory construction. Third, we design a dynamic strategy to balance the memory and NMT. The experiments show the superiority of our proposed methods.

8 Conclusions

To address troublesome words in NMT, we have proposed a novel memory-enhanced framework. We first define and detect the troublesome words, then construct a contextual memory to store the translation knowledge and finally access the contextual memory dynamically to correctly translate the troublesome words. The extensive experiments on Chinese-to-English and English-to-German translation tasks demonstrate that our method significantly outperforms the strong baseline models in translation quality, especially in handling the troublesome words.

Abstract

The addition of syntax-aware decoding in Neural Machine Translation (NMT) systems requires an effective tree-structured neural network, a syntax-aware attention model and a language generation model that is sensitive to sentence structure. We exploit a top-down tree-structured model called DRNN (Doubly-Recurrent Neural Networks) first proposed by Alvarez-Melis and Jaakola (2017) to create an NMT model called Seq2DRNN that combines a sequential encoder with tree-structured decoding augmented with a syntax-aware attention model. Unlike previous approaches to syntax-based NMT which use dependency parsing models our method uses constituency parsing which we argue provides useful information for translation. In addition, we use the syntactic structure of the sentence to add new connections to the tree-structured decoder neural network (Seq2DRNN+SynC). We compare our NMT model with sequential and state of the art syntax-based NMT models and show that our model produces more fluent translations with better reordering. Since our model is capable of doing translation and constituency parsing at the same time we also compare our parsing accuracy against other neural parsing models.

1 Introduction

Neural machine translation (NMT) models were initially proposed as extensions of sequential neural language models (Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2015) or convolutions over n-grams in the decoder (Kalchbrenner and Blunsom, 2013). Early methods for discriminative training of machine translation models showed that the loss functions for translation were not sensitive to the production of certain important words such as verbs, without which the output sentence might be uninterpretable by humans. A good solution was to penalise such bad outputs using tree structures which get very low scores if important words like verbs are missing (Chiang, 2005; Zollmann and Venugopal, 2006; Galley et al., 2006). To this end, there has been a push to incorporate some syntax into NMT models: Sennrich and Haddow (2016) incorporate POS tags and dependency information from the source side of a translation pair in NMT models. Stahlberg et al. (2016) use source language syntax to guide the decoder of an NMT system to follow hierarchical structures (Hiero) rules (Chiang, 2005). Eriguchi et al. (2016) and Bastings et al. (2017) use tree-structured encoders to exploit source language syntax. Aharoni and Goldberg (2017) take the approach of serialising the parse trees to use in a sequential decoder. Eriguchi et al. (2017) propose an NMT+RNNG model, which explores the possibilities of using dependency syntax trees from the target language using StackLSTMs (Dyer et al., 2015, 2016) to aid a sequential decoder. These approaches showed promising improvements in translation quality but all the models in previous work, even the model in Eriguchi et al. (2017) which uses RNNG, are bottom-up tree structured decoders.

In contrast, we use a top-down tree-structured model called DRNN (Doubly-Recurrent Neural Networks) first proposed by Alvarez-Melis and Jaakkola (2017) to model structural syntactic information for NMT. We call our novel NMT model Seq2DRNN, using DRNNs as a tree-structured decoder combined with a sequential encoder and a novel syntax-aware attention model.

All the previous work in syntax-aware NMT mentioned above has focused on dependency parsing as the syntactic model. In contrast, we wish to pursue phrase structure (aka constituency) based syntax-based NMT. We provide some analysis that shows that constituency information can help recover information in NMT decoding.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 401–413
Brussels, Belgium, October 31 - November 4, 2018.

We perform extensive experiments comparing our model against other state-of-the-art sequence to sequence and syntax-aware NMT models and show that our model can improve translation quality and reordering quality. The model performs translation and constituency parsing simultaneously so we also compare our parsing accuracy to other neural parsing models.

2 Model Description

In this paper, source sentence will be written as $\mathbf{f} = x_1, x_2, ..., x_n$, target sentence as $\mathbf{e} = y_1, y_2, ..., y_m$ where y_j is a word. Additionally, p_k represents a non-terminal symbol (constituent, phrase) in the target sentence constituency tree. $[\mathbf{v}; \mathbf{u}]$ stands for concatenation of vectors $\mathbf{v}$ and $\mathbf{u}$. $\mathbf{W}(x)$ is the word embedding of word x.

The design of our NMT system follows the encoder-decoder model (also known as a sequence to sequence model) proposed by Cho et al. (2014) and Sutskever et al. (2014). Our system uses a standard bidirectional gated RNN (BiLSTM or bidirectional Long Short-Term Memory) (Huang et al., 2015) as the encoder and our proposed tree-structured RNN as the decoder.

2.1 Sequence to Sequence NMT (Seq2Seq)

Neural machine translation models generally consist of an encoder, a decoder and an attention model (Luong et al., 2015; Cho et al., 2015). The encoder is used to produce hidden representations of the source sentence, which is fed into the decoder along with the attention information to produce the translation output sequence.

A common approach is to use bidirectional LSTMs as encoder, produce forward hidden states $\overrightarrow{\mathbf{h}}_i$ and backward hidden states $\overleftarrow{\mathbf{h}}_i$, and the final representation $\mathbf{h}_i^{\text{enc}}$ is the concatenation of both:

$$\begin{aligned}\overrightarrow{\mathbf{h}}_i &= \overrightarrow{\text{RNN}}_{\text{enc}}(\overrightarrow{\mathbf{h}}_{i-1}, \mathbf{W}_x(x_i)) \\ \overleftarrow{\mathbf{h}}_i &= \overleftarrow{\text{RNN}}_{\text{enc}}(\overleftarrow{\mathbf{h}}_{i+1}, \mathbf{W}_x(x_i)) \\ \mathbf{h}_i^{\text{enc}} &= [\overrightarrow{\mathbf{h}}_i; \overleftarrow{\mathbf{h}}_i]\end{aligned} \tag{1}$$

The decoder takes the output of the encoder and generates a sequence in target language. The attention mechanism provides additional context vectors $\mathbf{c}_j$ which is a weighted average contribution of each $\mathbf{h}_i$ source side encoding.

$$\begin{aligned}\mathbf{h}_j^{\text{dec}} &= \text{RNN}_{\text{dec}}(\mathbf{h}_{j-1}^{\text{dec}}, [\mathbf{o}_{j-1}; \mathbf{c}_j]) \\ \mathbf{o}_j &= \text{softmax}(\mathbf{U}\mathbf{h}_j^{\text{dec}} + \mathbf{b})\end{aligned} \tag{2}$$

Here, $\mathbf{U}$ is the readout matrix and $\mathbf{b}$ is the bias vector. $\mathbf{o}_j$ is the output word embedding.

2.2 NMT with a Tree-Structured Decoder (Seq2DRNN)

The output translation from a translation system should convey the same meaning as the input. This includes the correct word choices but also the right information structure. Sentence structure can be viewed as starting with an action or state (described via verbs or other predicates) and the entities or propositions involved in that activity or state (usually described via arguments to verbs). Thus certain words in the output translation, like verbs, are crucial to the understanding of the target language sentence but only provide marginal value in n-gram matching evaluations like the BLEU score. Tree representations, produced via dependency parsing and constituency parsing, are useful because they are sensitive to this information structure. Our tree-structured decoder uses a neural network to generate trees (described in §2.2.1), which is incorporated into an NMT model (our novel encoder-decoder model is in §2.2.2) which translates and produces a parse tree. Our new Syntactic Connection method (SynC) is described in §2.2.4 which is combined with the Seq2DRNN model (Seq2DRNN+SynC) and the attention mechanism (§2.2.3).

2.2.1 Doubly-Recurrent Neural Network

The Doubly-Recurrent Neural Network model (Alvarez-Melis and Jaakkola, 2017) takes a vector representation as input and generates a tree. Alvarez-Melis and Jaakkola (2017) show that the DRNN model can effectively reconstruct trees but they do not use DRNNs within a full-scale NMT system. We also use DRNNs for phrase-structure (aka constituency) tree structures rather than dependency trees as in previous work. DRNN decoding proceeds top-down; the generation of nodes at depth d depend solely on the state of nodes at depth $< d$. Unlike previous work in tree-structured decoding for NMT by Dyer et al. (2016) and Eriguchi et al. (2017), the output sentence generation is not done in sequence, where the target word y_j is generated after all $y_{<j}$ are generated. DRNN first predicts the structure of the sentence and then expands each component to predict words. When generating y_j, information regarding the structure of words from 1 to $j - 1$ and $j + 1$ to m can be used to aid prediction of y_j.

A DRNN consists of two recurrent neural network units, which separately process ancestral and fraternal information about nodes in the tree. Assuming a node is v, its immediate parent node is $P(v)$ and its closest sibling on the left side (appears in the target language sequence just before v) is $S(v)$. The label of node v is $\mathbf{z}_v$. Then the ancestral hidden representation $\mathbf{h}^a$ and fraternal representation $\mathbf{h}^f$ of a node are calculated with Equation 3.

$$\begin{aligned} \mathbf{h}_v^a &= \text{RNN}_{\text{dec}}^a(\mathbf{h}_{P(v)}^a, \mathbf{z}_{P(v)}) \\ \mathbf{h}_v^f &= \text{RNN}_{\text{dec}}^f(\mathbf{h}_{S(v)}^f, \mathbf{z}_{S(v)}) \end{aligned} \tag{3}$$

$\mathbf{h}_v^a$ and $\mathbf{h}_v^f$ are then combined to produce the hidden state of node v for prediction (predictive hidden state $\mathbf{h}_v$, Equation 4), which is used to predict the labels of node v.

$$\mathbf{h}_v = \tanh(\mathbf{U}^f \mathbf{h}_v^f + \mathbf{U}^a \mathbf{h}_v^a) \tag{4}$$

During the label prediction, DRNN first makes topological decisions: whether (i) the current node is a leaf node (node with no children, α_v); then (ii) whether the current node has siblings on its right-hand side (γ_v). Both predictions are done using sigmoid activations:

$$\begin{aligned} o_v^a &= \sigma(\mathbf{u}^a \mathbf{h}_v) \\ \alpha_v &= 1 \text{ if } o_v^a \text{ is activated.} \end{aligned} \tag{5}$$

$$\begin{aligned} o_v^f &= \sigma(\mathbf{u}^f \mathbf{h}_v) \\ \gamma_v &= 1 \text{ if } o_v^f \text{ is activated.} \end{aligned} \tag{6}$$

Then, label representation $\mathbf{o}_v$ is predicted using α_v and γ_v, and the predictive hidden state $\mathbf{h}_v$:

$$\mathbf{o}_v = \text{softmax}(\mathbf{U}_o \mathbf{h}_v + \alpha_v \mathbf{u}_a + \gamma_v \mathbf{u}_f) \tag{7}$$

At inference time each node at the same depth is expanded independently, therefore the whole process can be parallelised. This parallelism advantage is not observed in any of the sequential decoders that generate output sequence strictly from left to right nor from right to left (§4 has more discussion).

2.2.2 Parsing and Translating with DRNN

A DRNN is capable of producing a tree structure with labels given an input vector representation. If we train the DRNN to produce parse trees from the output of an encoder RNN, this system will be able to translate and parse at the same time. (Alvarez-Melis and Jaakkola, 2017) in their paper provided a proof-of-concept NMT experiment using dependency trees. Instead of an single RNN unit to process fraternal information they had multiple for modelling the fraternal information on syntactic tree structure because dependency parse trees differentiate between left and right children. The model itself also disregards the sequentiality of natural language, and lack attention mechanisms to make it work in exchange for a strict top-bottom decoding procedure.

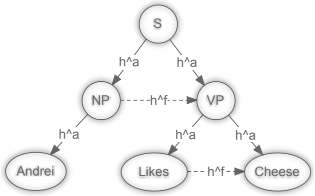

Figure 1: Seq2DRNN on Constituency Tree

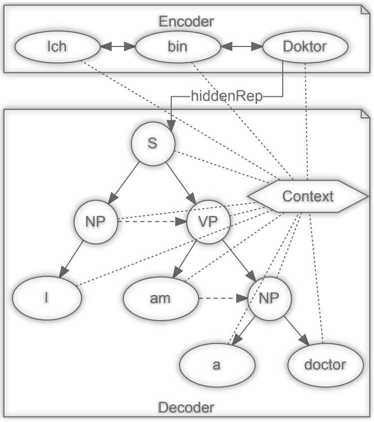

Figure 2: Seq2DRNN Encoder-Decoder

We use constituency parse trees to represent sentences in the target language (Figure 1) because constituency or phrase-structure trees are more amenable to top-down derivation compared to dependency trees. It is also easier to model for DRNN, and presumably more capable at handling unknown words which is common in NMT systems with limited vocabulary size.

Each node on the tree represents either a terminal symbol (a word) or a non-terminal symbol (a clause or phrase type). The sub-tree dominated by a non-terminal node is the clause or phrase identified with this non-terminal node label.

A conventional bidirectional RNN (BiLSTM) encoder (Cho et al., 2014; Sutskever et al., 2014) is used to produce hidden states for the decoder (see Figure 2).

We use breadth-first search to implement the Seq2DRNN decoder. Two queues are used here: *current* queue which is the queue containing all of the nodes on the currently being processed depth, and *next* queue with nodes on the next depth (Algorithm 1 has all the details).

The decoding process starts from top to bottom, from root to its children, then to its grandchildren, and so on until the leaf nodes which are the output words.

In our implementation, sentence clauses (S nodes) are generated as the children of the root node to generalise over sentence types and in case there are multiple sentences in a single translation pair.

Initially, the *current* queue will only have one entry: the root node, which is initialised with the hidden representation of the source sentence.

Each node in the *current* queue is expanded in the following manner: first generate all of its siblings and add them to the *current* queue, and if any node happens to be non-terminal, generate its first child and add it to the *next* queue. After the *current* queue is empty, make *next* the new *current* queue and start working on nodes at the next depth.

For training, we use back-propagation through trees using the approach in Goller and Küchler (1996). In the forward pass, the source sentence is encoded into a hidden representation and fed into the decoder. The decoder generates the tree, predicts the labels of every node from root to leaves. Then in the backward pass, gradients are calculated and used to update the parameters. The loss calculation includes losses in topological predictions: o_v^a and o_v^f (Equations 5 and 6) and label predictions: $\mathbf{o}_v$ (Equation 7).

$$\begin{aligned}\mathrm{Loss(e)} = &\sum_v \mathrm{Loss}^{\mathrm{label}}(\mathbf{o}_v, \hat{\mathbf{o}_v})+\\ &\alpha \sum_v \mathrm{Loss}^{\mathrm{topo}}(o_v^a, \hat{o_v^a})+\\ &\alpha \sum_v \mathrm{Loss}^{\mathrm{topo}}(o_v^f, \hat{o_v^f})\end{aligned} \tag{8}$$

Here α is a hyper-parameter.

2.2.3 Attention Mechanism

Attention mechanisms usually work by adding an additional context vector during label prediction. We use a variation of an existing attention mechanism proposed by Luong et al. (2015). In our attention model, we produce a context vector $\mathbf{c}_v$ for every node v by looking at all hidden states produced by the encoder $\mathbf{h}_i^{\mathrm{enc}}$, then calculating the weights and adding up the weighted hidden states.

$$\mathrm{weight}_{v,i} = \mathbf{V}_a \tanh(\mathbf{W}_a \mathbf{h}_v + \mathbf{U}_a \mathbf{h}_i^{\mathrm{enc}}) \in \mathbb{R} \tag{9}$$

$$\mathbf{c}_v = \sum_{i=1}^{n} \hat{\mathrm{weight}}_{v,i} \mathbf{h}_i^{\mathrm{enc}} \tag{10}$$

After the calculation in Equation 9, the weights are normalised with a softmax function before being used to calculate the context vector. The attention module allows the generation of labels to pay more attention to specific token representations of words in the input sentence.

Algorithm 1 Seq2DRNN Decoder

```
procedure DECODE(hiddenRep)
    currentQueue ← Node from hiddenRep
    nextQueue ← empty
loop:
    if currentQueue is not empty then
        node ← currentQueue.pop()
        Generate labels of node
        if node has siblings then
            currentQueue ← sibling(node)
        if node has children then
            nextQueue ← child(node)
        goto loop
    ▷ all nodes at current depth are generated
    ▷ move on to the next depth
    if nextQueue is not empty then
        currentQueue ← nextQueue
        nextQueue ← empty
        goto loop.
    ▷ both queues should be empty now
```

2.2.4 SynC: Syntactic Connections for Language Generation (Seq2DRNN+SynC)

A conventional Seq2Seq model uses an RNN language model (Cho et al., 2014; Sutskever et al., 2014) conditioned on the input representation produced by the encoder to generate the output one word at a time (Equation 11). The prediction of a word y_j is directly conditioned on previously generated words where $\mathbf{c}_j$ is the context vector.

$$\mathrm{P}(\mathbf{e}) = \prod_j \mathrm{P}(y_j | y_{<j}, \mathbf{c}_j) \tag{11}$$

The problem with this word-level language model is that it treats a sentence as a plain sequence of symbols regardless of its syntactic construction. Sentences may contain multiple subordinate clauses and their boundaries are not well-modelled by sequential language models.

We propose a new method to connect the hidden units in the Seq2DRNN decoder that pays attention to contextual tree relationships. The prediction of the representation of a word or a constituent z_j (if a constituent then p_j, if a word then y_j) is defined as follows:

$$\begin{aligned}&\mathrm{P}(z_j \mid y_{<j}, \mathbf{c}_j) =\\ &\quad \mathrm{P}(z_j \mid y_{<j}, y_k(\forall k, z_j \in p_k \vee\\ &\quad \mathrm{precedes}(y_k, z_j)) \mid \mathbf{c}_j)\end{aligned} \tag{12}$$

The generation of the representation of a word/constituent z_j, which is part of the clause

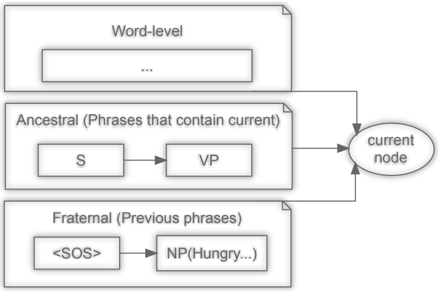

Figure 3: SynC example: the three types of information explicitly modelled when generating the current node/word *likes* in *Andrei when starving likes cheese*.

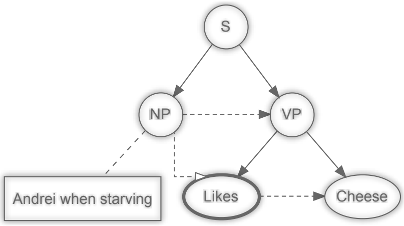

Figure 4: SynC in action; when generating the word *likes* in *Andrei when starving likes cheese*, the prediction will be made knowing that the preceding clause is a noun phrase.

that contain it ($z_j \in p_k$), with clauses before which ($\text{precedes}(p_k, z_j)$), is conditioned on the following information: i) Word-level: previously generated words $y_{<j}$; ii) Ancestral Clause: the clauses that contain the current word p_k, i.e. ($\forall k z_j \in p_k$); iii) Fraternal Clause: the clauses that precede the current clause p_k, i.e. ($\forall k\, \text{precedes}(p_k, z_j)$).

In practice, the generation of a node looks at the following representations:

1. Word-level: an RNN unit that produces the representation of previous words as a sequence $y_{<j}$;
2. Ancestral: treating the ancestors of the current node as a sequence (from root to the immediate parent), the representation of that sequence: $p_k(\forall k, z_j \in p_k)$;
3. Fraternal: treating the previous siblings of the current node as well as the previous siblings of its parent node and so on as a sequence, the representation of that sequence: $p_k(\forall k, \text{precedes}(p_k, z_j))$.

SynC creates connections in the tree-structured decoder that pays attention to the structural context of generation of each terminal or non-terminal symbol in the phrase structure tree. For example in English, it is common for verb phrases to follow a noun phrase. But that noun phrase could itself be a subordinate clause with its own verb phrases. In this case, our goal is to explicitly model the fact that the previous phrase is a noun phrase instead of just the entire sequence of words.

SynC can be easily incorporated in the proposed Seq2DRNN model (Seq2DRNN+SynC). In addition to the fraternal RNN unit that focuses on preceding sibling nodes, and the ancestral DRNN unit that focus on parent nodes, a node would also look at its parent's previous sibling state (the hidden vector representation of preceding clauses from the very beginning of the sentence). When a non-terminal symbol is expanded into a sub-tree, it's first child will not have a previous sibling to provide fraternal information ($S(v) = \text{Null}$, as in Equ 3). In this case, SynC establishes connection between its first child and its parent's fraternal information provider for such fraternal RNN state ($S(v) = S(P(v))$).

$$\mathbf{h}_v^f = \begin{cases} S(v) \neq \text{Null}, & \text{RNN}_{\text{dec}}^f(\mathbf{h}_{S(v)}^f, \mathbf{z}_{S(v)}) \\ S(v) = \text{Null}, & S(v) := S(P(v)), \\ & \text{RNN}_{\text{dec}}^f(\mathbf{h}_{S(v)}^f, \mathbf{z}_{S(v)}) \end{cases} \tag{13}$$

An example is shown in Figure 4. In this case, a word-level language model will regard *starving* as the previous word, which is less helpful for the prediction of a verb phrase *likes cheese*.

3 Experiments

3.1 Model Training

Experiments in this paper utilise constituency trees on the target side, these trees are obtained by using the Stanford Lexical Parser (Klein and Manning, 2003a) which we chose for its speed and accuracy prior to training.

This procedure of pre-parsing data is not required at test time, our NMT system would take a sentence as input and produces the translation in target language along with its constituency tree as output.

We use the German-English dataset from IWSLT2017 [1] for our experiments, and tst2010-2015 as the test set (Table 1).

To compare with other decoders that utilise target-side syntactic information, we also evaluate on three more datasets from News Commentary v8 using newstest2016 as testset (Table 2).

We replace all rarely occurring words with

3.2 Modelling details

The implementation of all models in this paper is done using DyNet (Neubig et al., 2017a) with Autobatching (Neubig et al., 2017b). We use Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) as RNN units. Each LSTM unit has 2 layers, with input and hidden dimension of 256. We use a minibatches of 64 samples. We use early stopping mechanism for all experiments and Adam optimiser (Kingma and Ba, 2015) as trainer.

Note that this configuration is significantly smaller in both dimension and batch size than those presented in IWSLT2017 due to hardware limitations. All experiments are carried out on a single GTX 1080 Ti GPU with 11GB of VRAM.

3.3 Results

Table 3 and Table 4 has the BLEU (Papineni et al., 2002) and RIBES (Isozaki et al., 2010) scores. In our IWSLT2017 tests, both Seq2DRNN and Seq2DRNN+SynC produce better results than the Seq2Seq baseline model in terms of BLEU scores, while Seq2DRNN+SynC also produces better RIBES scores indicating better reordering of phrases in the output. The Seq2DRNN+SynC model performs better than the Seq2DRNN model. Both Seq2Seq and Seq2DRNN+SynC are able to produce results with lower perplexities than the baseline Seq2Seq model on the test data.

In our News Commentary v8 tests, the same relative performance from Seq2DRNN(SynC) can be observed. The Seq2DRNN+SynC model is also able to out-perform the Str2Tree model proposed by Aharoni and Goldberg (2017) and NMT+RNNG by Eriguchi et al. (2017) in most cases. Note that Eriguchi et al. (2017) used dependency information instead of constituency information as presented in our work and Aharoni and Goldberg (2017)'s work.

Table 5 shows an example translation from all of the models we use in our experiments. Seq2Seq is able to translate with the correct vocabulary, but the sentences are often syntactically awkward. As the sentence length increases the syntactic fluency of Seq2Seq gets worse. Seq2DRNN is able to produce more syntactically fluent sentences since each lowest sub-clause contains typically ≤ 5 words. Seq2DRNN+SynC produces the best results in this example: produces more syntactically fluent sentences, chooses the right words in the right place more frequently.

We also took several examples from our IWSLT17 experiment and blank out certain nouns by replacing them with unknown tokens (Table 6). Note that in our training set, most sentences do not have unknown tokens, and those that do only have at most 1. Our assumptions of the observed patterns in this case are: i) the proposed models are more capable at handling unknown tokens; ii) while Seq2DRNN is more capable at retaining the structure of the sentence, it cannot rely on a wider context to predict certain common phrases with noises in the source sentence; iii) the proposed Seq2DRNN+SynC model is more capable at handling unknown words both in the sense of being better at retaining sentence structure and handling noisy input.

3.4 Attention Module

We visualise the attention weights of our Seq2DRNN+SynC model. Attention §2.2.3 computes a context vector for each node in the tree (a weighted sum of the source side vector representations). For the translation pair in Figure 2, we show the attention weight of each pair of word and node (Equation 9) in Figure 5.

The addition of syntax nodes in the output enables the attention model to be used more effectively and is also valuable for visual inspection of syntactic nodes in the output mapping to the input.

Dataset	DE-EN		CS-EN		RU-EN	
	BLEU	RIBES	BLEU	RIBES	BLEU	RIBES
Seq2Seq	16.61	73.8	11.22	69.6	12.03	69.6
Str2Tree	16.13	—	11.65	—	11.94	—
NMT+RNNG	16.41	75.0	12.06	**70.4**	12.46	71.0
Seq2DRNN	16.90	75.1	11.84	67.3	12.04	69.7
Seq2DRNN+SynC	**17.21**	**75.8**	**12.11**	70.3	**12.96**	**71.1**

Table 4: News Commentary v8 Experiment results. Seq2Seq and NMT+RNNG results are taken from Eriguchi et al. (2017), Str2Tree (string-to-linearised-tree) results (no RIBES scores) come from Aharoni and Goldberg (2017) All numbers reported here are of non-ensemble models.

Source	wir wiederholten diese übung mit denselben studenten. was glauben sie passiert nun? nun verstanden sie den vorteil des prototyping. so wurde aus demselben, schlechten team eines unter den besten. sie produzierten die höchste konstruktion in der geringsten zeit.
Literal	we repeated this exercise with the same students. now what do you believe happened? now they understand the value of prototyping. so the same terrible team became one of the very best. they produced the tallest construction in the shortest time.
Gold	we did the exercise again with the same students. what do you think happened then? so now they understand the value of prototyping. so the same team went from being the very worst to being among the very best. they produced the tallest structures in the least amount of time.
Seq2Seq	we repeated this with the same students. what happened you think differently? now, you know, the advantage of the design of the cycle. so, the same one of the team of the team among the best. it produced songs in the slightest building.
Seq2DRNN	well repeat these queries with the same students. what do you think of this? now it understood the advantage of the interests. that's been made of the same thing of one thing. they produced the highest construction of the best time at the best time.
Seq2DRNN+SynC	we repeated this practice with the same students. what do you think happened? now, they understood the value of prototyping. it was being made of the same thing of one of the best ones. they produced the highest construction in the best time.

Table 5: Translation Sample. *Gold* is the reference, and *Literal* is produced by a bilingual German-English speaker.

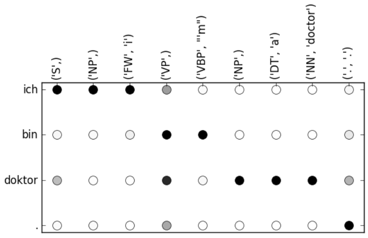

Figure 5: Attention Module in Seq2DRNN+SynC. "ich" means "I", "bin" is "am", "doktor"'s literal translation is "doctor". Darker colour means higher weight (relevance score) as calculated in Equation 9. The values of each column sum up to 1. The attention weights in this example perfectly align with the appropriate clauses. Additional example is provided in the appendix.

3.5 Parsing Quality

To evaluate the parsing quality, we follow the approach by Vinyals et al. (2015) and train a DRNN(SynC) model to produce English to English(Tree) translation. We use the same data and experiment settings that Vinyals et al. (2015) used: the Wall Street Journal Penn Treebank English corpus with golden constituency structure, 256 for input/hidden dimension and 3 layers of RNN. We evaluate on section 23 of the aforementioned WSJ data using EVALB[2]. The results are presented in Table 7.

Although falling short behind more specifically designed models like the RNNG by Dyer et al. (2016), our model is able to produce better results than the LSTM+AD model proposed by Vinyals et al. (2015), which is more comparable to ours since they are also using an NMT model to do constituency parsing. Since our work is more focusing on the translation aspect, optimising and designing a dedicated parser is slightly off-topic here. Nevertheless, it is worth noting that in 50.89% of the cases, Seq2DRNN+SynC was able to produce output that perfectly matches the reference. The same number for sentences with less than 40 words is 52.16%, while the F-measure increases to 90.5. This shows Seq2DRNN(SynC) when doing parsing can produce outputs of similar quality when handling longer sentences.

We also do evaluation on our translation results from the IWSLT dataset. Since translation results do not come with reference parse trees, we parse the output of our decoder using the same parser we used in our other experiments: the Stanford Parser. Constituency parsing evaluation is done using Precision/Recall/F1-scores on the output constituent spans (unlabelled) and spans and labels (labelled). The results are presented in Table 8 and Table 9. The parser we use gets F1 score of 87.04 on Penn Treebank English constituency

Table 6: Unknown noun experiment samples. Substituted and correct nouns are marked in **Bold**, while incorrect elements are marked in underline. Examples shown are: no UNK; 1 UNK; 2 UNKs; 3 UNKs. When there are no unknown tokens, all three compared models are able to produce reasonably good if not identical translations. When there is only one UNK token, Seq2DRNN often does not use the context to predict an appropriate word or phrase. In contrast, both the Seq2Seq and Seq2DRNN+SynC were able to correctly predict that *die gute UNK ist* could be translated to *the good news is*. When there are 2 UNK tokens in the source sentence, Seq2Seq produces more incorrect predictions, Seq2DRNN makes some mistakes, while Seq2DRNN+SynC is able to get the most parts correct. Finally, when we replace 3 nouns, all models fail to some degree while Seq2Seq's output is the worst.

parsing (Klein and Manning, 2003b).

The presence of SynC in the decoder influences parse tree construction: the Seq2DRNN+SynC F1 score is comparable but lower than Seq2DRNN.

4 Related Work

Recent research shows that modelling syntax is useful for various neural NLP tasks. Dyer et al. (2015, 2016); Vinyals et al. (2015); Luong et al. (2016) have works on language modelling and parsing, Tai et al. (2015) on semantic analysis, and Zhang et al. (2016) on sentence completion, etc.

Eriguchi et al. (2017) showed that NMT model can benefit from neural syntactical parsing models. Choe and Charniak (2016) showed that a neural parsing problem shares similarity to neural language modelling problem, which forms a building block of an NMT system. We can then make the assumption that structural syntactic information utilised in neural parsing models should be able to aid NMT, which is shown to be true here.

Zhang et al. (2016) proposed TreeLSTM which is another structured neural decoder. TreeLSTM is not only structurally more complicated but also uses external classifiers. Dong and Lapata (2016) also proposed a sequence-to-tree (Seq2Tree) model for question answering. Both of these models are not designed for NMT and lack a language model. While operate from top-to-bottom like Seq2DRNN(+SynC), TreeLSTM and Seq2Tree produce components that lack sequential continuity which we have shown to be non-negligible for language generation.

Aharoni and Goldberg (2017), Wu et al. (2017), and Eriguchi et al. (2017) experimented with NMT models that utilise target side structural syntax. Aharoni and Goldberg (2017) treated constituency trees as sequential strings (linearised-tree) and trained a Seq2Seq model to produce such sequences. Wu et al. (2017) proposed SD-NMT, which models dependency syntax trees by adding a shift-reduce neural parser to a standard RNN decoder. Eriguchi et al. (2017) in addition to Wu et al. (2017)'s work, proposed NMT+RNNG which uses a modified RNNG generator (Dyer et al., 2016) to process dependency instead of constituency information as originally proposed by Dyer et al. (2016), making it consequently a StackLSTM sequential decoder with additional RNN units so it is still a bottom-up tree-structured decoder rather than a top-down decoder like ours. Nevertheless, all of these research showed that target side syntax could improve NMT systems. We believe these models could also be augmented with SynC connections (with NMT+RNNG one has to instead use constituency information).

5 Conclusions

We propose an NMT model that utilises target side constituency syntax with a strictly top-down tree-structured decoder using Doubly-Recurrent Neural Networks (DRNN) incorporated into an encoder-decoder NMT model. We propose a new way of modelling language generation by establishing additional clause-based syntactic connections called SynC. Our experiments show that our proposed models can outperform a strong sequence to sequence NMT baseline and several rival models and do parsing competitively.

In the future we hope to incorporate source side syntax into the model. We plan to explore the applications of SynC in NMT with more structured attention mechanisms, and potentially a hybrid phrase-based NMT systems with SynC, in which the model can benefit from SynC to be more extensible when handling larger lexicons.

Abstract

Task-oriented dialog systems are becoming pervasive, and many companies heavily rely on them to complement human agents for customer service in call centers. With globalization, the need for providing cross-lingual customer support becomes more urgent than ever. However, cross-lingual support poses great challenges—it requires a large amount of additional annotated data from native speakers. In order to bypass the expensive human annotation and achieve the first step towards the ultimate goal of building a universal dialog system, we set out to build a cross-lingual state tracking framework. Specifically, we assume that there exists a source language with dialog belief tracking annotations while the target languages have no annotated dialog data of any form. Then, we pre-train a state tracker for the source language as a teacher, which is able to exploit easy-to-access parallel data. We then distill and transfer its own knowledge to the student state tracker in target languages. We specifically discuss two types of common parallel resources: bilingual corpus and bilingual dictionary, and design different transfer learning strategies accordingly. Experimentally, we successfully use English state tracker as the teacher to transfer its knowledge to both Italian and German trackers and achieve promising results.

1 Introduction

Over the past few years, we have witnessed the burgeoning of real-world applications of dialog systems, with many academic, industrial, and startup efforts racing to lead the widely-believed next-generation human-machine interfaces. As a result, numerous task-oriented dialog systems such as virtual assistants and customer conversation services were developed (Wen et al., 2015; Rojas-Barahona et al., 2017; Bordes and Weston, 2017; Williams et al., 2017; Li et al., 2017), with Google Duplexbeing the most recent example.

With the rapid process of globalization, more countries have observed growing populations of immigrants, and more companies have moved forward to develop their overseas business sectors. To provide better customer service and bring down the cost of labor at call centers, the development of universal dialog systems has become a practical issue. A straightforward strategy is to separately collect training data and train dialog systems for each language. However, it is not only tedious but also expensive. Two settings naturally arise for more efficient usage of the training data: (1) Multi-lingual setting: we annotate data for multiple languages and train a single model, with possible innovations on joint training. (2) Cross-lingual setting: we annotate data and train a model for only one (popular) language, and transfer the learned knowledge to other languages. Here we are interested in the second case, and the important research question we ask is: *How can we build cross-lingual dialog systems that can support less popular, low- or even zero-resource languages*?

As an initial step towards cross-lingual dialog systems, we focus on the cornerstone of dialog systems – *dialog state tracking* (DST), or *belief tracking*, a key component for understanding user inputs and updating *belief state*, i.e., a system's internal representation of the state of conversation (Young et al., 2010). Based on the perceived belief state, the dialog manager can decide which action to take, and what verbal response to generate (Precup and Teh, 2017; Bordes and Weston, 2017).

DST models require a considerable amount of annotated data for training (Henderson et al., 2014b; Mrksic et al., 2015, 2017). For a common dialog shown in Figure 1, a typical data acquisition process (Rojas-Barahona et al., 2017) not only requires two human users to converse for multiple

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 414–424
Brussels, Belgium, October 31 - November 4, 2018.

turns but also requires annotators to identify user's intention in each turn. Such two-step annotation is very expensive, especially for rare languages.

We study the novel problem of *cross-lingual DST*, where one leverages the annotated data of a source language to train DST for a target language with *zero* annotated data (Figure 1); no conversation dialog or dialog state annotation is available for the target language. In order to deal with this zero-resource challenging scenario, we first decouple the state-of-the-art neural belief tracker framework (Mrksic et al., 2017) into sub-modules, namely *utterance encoder*, *context gate*, and *slot-value decoder*. By introducing a teacher-student framework, we are able to transfer knowledge across languages module by module, following the divide-and-conquer philosophy. Requiring no target-side dialog data, our method relies on other easy-to-access parallel resources to understand the connection between languages. Depending on the popularity and availability of target language resources, we study two kinds of parallel data: bilingual corpus and bilingual dictionary, and we respectively design two transfer learning strategies.

We use the popular *Wizard-of-Oz* (Rojas-Barahona et al., 2017) dataset as our DST benchmark to evaluate the effectiveness of our cross-lingual transfer learning. We specify English as the source (primary) language and two different European languages (German and Italian) as our zero-annotation target languages. Compared with an array of alternative transfer learning strategies, our cross-lingual DST models consistently achieve promising results in both scenarios for both zero-annotation languages. To ensure reproducibility, we release our code, training data and parallel resources in the github[1]. Our main contributions are three-fold:

- Towards building cross-lingual dialog systems, we are the first to study the cross-lingual dialog state tracking problem.
- We systematically study different scenarios for this problem based on the availability of parallel data and propose novel transfer learning methods to tackle the problem.
- We empirically demonstrate the efficacy of the proposed methods, showing that our methods can accurately track dialog states for languages with zero annotated data.

2 Related Work

2.1 Dialog State Tracking

Broadly speaking, the dialog belief tracking algorithms can be divided into three families: 1) hand-crafted rules 2) generative models, and 3) maximum-entropy model (Metallinou et al., 2013). Later on, many deep learning based discriminative models have surged to replace the traditional strategies (Henderson et al., 2014a; Mrksic et al., 2017; Williams et al., 2016) and achieved state-of-the-art results on various datasets. Though the discriminative models are reported to achieve fairly high accuracy, their applications are heavily restricted by the domain, ontology, and language. Recently, a pointer network based algorithm (Xu and Hu, 2018) and another multi-domain algorithm (Rastogi et al., 2017) have been proposed to break the ontology and domain boundary. Besides, (Mrkšić et al., 2017) has proposed an algorithm to train a unified framework to deal with multiple languages with annotated datasets. In contrast, our paper focuses on breaking the language boundary and transfer DST knowledge from one language into other zero-annotation languages.

2.2 Cross-Lingual Transfer Learning

Cross-lingual transfer learning has been a very popular topic during the years, which can be seen as a transductive process. In such process, the input domains of the source and target are different (Pan and Yang, 2010) since each language has its own distinct lexicon. By discovering the underlying connections between the source and target domain, we could design transfer algorithms for different tasks. Recently, algorithms have been successfully designed for POS tagging (Zhang et al., 2016; Kim et al., 2017), NER (Pan et al., 2017; Ni et al., 2017) as well as image captioning (Miyazaki and Shimizu, 2016). These methods first aim at discovering the relatedness between two languages and separate language-common modules from language-specific modules, then resort to external resources to transfer the knowledge across the language boundary. Our method addresses the transfer learning using a teacher-student framework and proposes to use the teacher to gradually guide the student to make more proper decisions.

Figure 2: Cross-lingual DST structure, the ontology and database between multiple languages are shared.

The dialog states are defined as a set of search constraints (i.e. informable slots or goals) that the user specified through the dialog and a set of attribute questions regarding the search results (i.e. requestable slots or requests). The objective of dialog state tracking (DST) is to predict and track the user intention (i.e., the values of the aforementioned slots) at each time step based on the current user utterance and the entire dialog history. As shown in Figure 2, for each slot, the DST computes an output distribution of the candidate values using three inputs: (i) *system response* a_t, which is the sentence generated by the system, (ii) *utterance* u_t, which is the sentence from the user, and (iii) *previous state*, which denotes the selected slot-value pairs. We define the ontology of the dialog system to be the set of all the possible words the dialog slot and value can take. In this paper, we are interested in learning a cross-lingual DST. Specifically, we assume that the DST for the *source* language has access to a human-annotated training dataset D while the DSTs for the *target* languages do not have access to annotated data in other languages except for testing data. We here mainly consider two different types of parallel resources to assist the transfer learning:

(1) Bilingual Corpus, where abundant bilingual corpora exist between the source and the target languages. This is often the case for common language pairs like German, Italian, and French, etc.

(2) Bilingual Dictionary, where public bilingual dictionaries exist between the source and the target languages, but large-scaled parallel corpus are harder to obtain. This can be the case for rarer languages like Finnish, Bulgarian, etc.

Furthermore, we assume that all the languages share a common multi-lingual database, whose column/row names and entry values are stored via multiple languages (see the database in Figure 1). That is, the ontology of dialog among different languages is known with a one-to-one mapping between them (e.g., greek=griechisch=greco, food=essen=cibo). Based on that, we could construct a mapping function M to associate the ontology terms from different languages with pre-designed language-agnostic concepts: for example, $M(foods) = M(Essen) = M(Cibo) =$ FOOD. We illustrate our problem definition in Figure 2.

4 Decoupled Neural Belief Tracker

We design our cross-lingual DST on top of the state-of-the-art Neural Belief Tracker (NBT) (Mrksic et al., 2017), which demonstrates many advantages (no hand-crafted lexicons, no linguistic knowledge required, etc). These nice properties are essential for our cross-lingual DST design because we are pursuing a general and simple framework regardless of the language properties. In short, NBT consists of a neural network that computes the matching score for every candidate slot-value pair (c_s, c_v) based on the following three inputs: (i) the system dialog acts $a_t = (t_q, t_s, t_v)$,[2] (ii) the user utterance u_t, and (iii) the candidate slot-value pair. And it identifies the user intents by evaluating the scores for all the slot-value pairs (see Figure 3). With a slight abuse of notation, we still use $c_s, c_v, t_s, t_v, t_q \in \mathbb{R}^H$ to denote the vector representations of themselves, where H is the embedding dimension. We will use pre-trained embedding vectors in our cross-lingual NBT, just like the original NBT and they will be fixed during training. To enable cross-lingual transfer learning, we first re-interpret the architecture of the original NBT by decomposing it into three components:

Utterance Encoding The first component is an utterance encoder, which maps the utterance $u_t = \{w_1, w_2, \cdots, w_N\}$ of a particular language into a semantic representation vector $r(u_t) \in \mathbb{R}^H$, where $w_i \in \mathbb{R}^H$ is the word vector for the i-th token and N is the length of the utterance. Note that the dimension of the semantic vector $r(u_t)$ is the same as that of the word vector. We implement the encoder using the same convolutional neural network (CNN) as the original NBT, with a slight modification of adding a top batch normalization layer. We will explain this change in section 5.

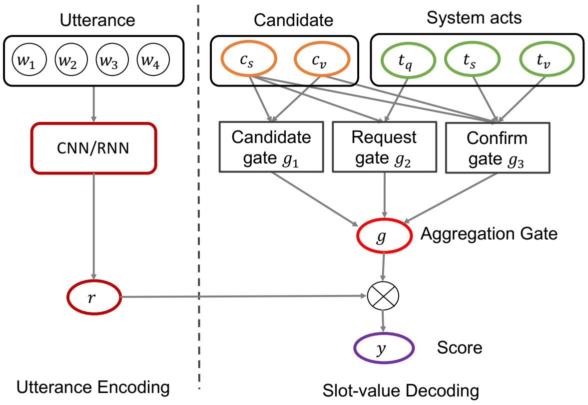

Figure 3: Our implementation of baseline NBT, slightly modified from (Mrksic et al., 2017).

Context Gate The second part is the context gate, which takes the system acts $a_t = (t_q, t_s, t_v)$ and the candidate slot-value pair (c_s, c_v) as its inputs and filter out the desired information from the encoded utterance. The context gate g is a sum of three separate gates:

$$g(c_s, c_v, a_t) = g_1 + g_2 + g_3 \tag{1}$$

where the individual gates are defined as:

$$\begin{aligned} g_1 &= \sigma(W_c^s(c_s + c_v) + b_c^s) \\ g_2 &= (c_s \cdot W_t^q t_q) \odot [1, \cdots, 1]^H \\ g_3 &= (c_s \cdot W_t^s t_s)(c_v \cdot W_t^v t_v) \odot [1, \cdots, 1]^H \end{aligned} \tag{2}$$

where $W_c^s, W_t^q, W_t^s, W_t^v \in \mathbb{R}^{H \times H}$ are the weight matrices, and $\odot$ and $\cdot$ denote the Hadamard product and the inner product, respectively. The three gates $g_1 \in \mathbb{R}^H, g_2 \in \mathbb{R}^H, g_3 \in \mathbb{R}^H$ model the relevance between the candidate slot and value, the system request and the system confirms, respectively. The transformation matrices W_t^q, W_t^s, W_t^v are added to the original NBT to increase the model flexibility of the gates.

Slot-Value Decoding The final component is a slot-value decoder, which predicts the score y of a given slot-value pair using the filtered information from the utterance representation r as:

$$y(c_s, c_v, u_t, a_t) = W_y^T [r(u_t) \odot g(c_s, c_v, a_t)] \tag{3}$$

where $W_y \in \mathbb{R}^{H \times 1}$ is the weight vector. The above expression computes the score for the slot-value pair based on the information from the current turn. We combine it with the information from previous turns to get the final score:

$$\begin{aligned} \hat{y}(c_v | u_t, a_t, c_s) =& \lambda y(c_s, c_v, u_t, a_t) + \\ & (1 - \lambda) \hat{y}(c_s, c_v, u_{t-1}, a_{t-1}) \end{aligned} \tag{4}$$

here λ is a combination weight. For each given slot c_s, NBT selects the single highest value for informable slots and selects all values above a certain threshold for request slots. Here we replace the multi-layer perceptron in the orginal NBT by a linear output layer (to be explained in section 5).

5 Cross-lingual Neural Belief Tracker

In this section, we develop a cross-lingual Neural Belief Tracker (XL-NBT) that distills knowledge from one NBT to another using a teacher-student framework. We assume the ontology mapping M is known a priori (see Figure 3). XL-NBT uses language-specific utterance encoder and context gate for each input language while sharing a common (language-agnostic) slot-value decoder across different languages (see Figure 3).

---

[2] t_q represents the system request, t_s, t_v represents the system confirmation. If the system wants to request some information from the user by asking "what's your favorite area?", then NBT sets t_q="AREA". If the system wants to confirm some information from a user by asking "should I try Persian restaurants in the north?" then NBT sets t_s, t_v="area, north".

The key idea is to optimize the language-specific components of the student network (NBT of the target language) so that their outputs are language-agnostic. This is achieved by making these outputs close to that of the teacher network (NBT of the source language), as we detail below.

5.1 Teacher-Student Framework

We are given a well-trained NBT for a source language e, and we want to learn an NBT for a target language f without any annotated training data. Therefore, we cannot learn the target-side NBT from standard supervised learning. Instead, we use a teacher-student framework to distill the knowledge from the source-side NBT (teacher network) into the target-side NBT (student network) (see Figure 4). Let $x_e \triangleq (c_s^e, c_v^e, u_t^e, a_t^e)$ be the input to the teacher network and let $x_f \triangleq (c_s^f, c_v^f, u_t^f, a_t^f)$ be the associated input to the student network. The standard teacher-student framework trains the student network by minimizing

$$\hat{J}_1 = \sum_{x_e, x_f} ||y(c_s^e, c_v^e, u_t^e, a_t^e) - y(c_s^f, c_v^f, u_t^f, a_t^f)||^2 \qquad (5)$$

where $y(c_s^e, c_v^e, u_t^e, a_t^e)$ and $y(c_s^f, c_v^f, u_t^f, a_t^f)$ denote the scores by the teacher and the student networks, respectively, and the slot-value pairs satisfy $M(c_v^f) = M(c_v^e)$ and $M(c_s^f) = M(c_s^e)$. However, the target-side inputs $(c_s^f, c_v^f, u_t^f, a_t^f)$ parallel to $(c_s^e, c_v^e, u_t^e, a_t^e)$ are usually not available in cross-lingual DST, and, even worse, the target-side utterance u_t^e is not available. We may have to generate synthetic input data for the student network or leverage external data sources. It is relatively easy to use the mapping $M(\cdot)$ to generate $(c_s^f, c_v^f, a_t^f))$ (i.e., the inputs of the target-side context gate) from the (c_s^e, c_v^e, a_t^e). But it is more challenging to obtain the parallel utterance data u_t^f from u_t^e). Therefore, we have to leverage external bilingual data sources to alleviate the problem. However, the external bilingual data are usually not in the same domain as the utterance, and hence they are not aligned with the slot-value pair and system acts (i.e., (c_s^e, c_v^e, a_t^e) or (c_s^f, c_v^f, a_t^f)). For this reason, we cannot perform the knowledge transfer by minimizing the cost (5). Instead, we need to develop a new cost function where the utterance is not required to be aligned with the slot-value pair and the system acts. To this end, let $g^e = g_e(c_s^e, c_v^e, a_t^e)$ and $g^f = g_f(c_s^f, c_v^f, a_t^f)$. And we substitute (3) into (5) and get:

$$\begin{aligned}
\hat{J}_1 &\leq ||W_y||^2 \sum_{c_v^f, c_v^e} ||r_e \odot g^e - r_f \odot g^f||^2 \\
&= ||W_y||^2 \sum_{c_v^f, c_v^e} ||g^e \odot (r_e - r_f) + r_f \odot (g^e - g^f)||^2 \\
&\leq ||W_y||^2 \sum_{c_v^f, c_v^e} ||g^e||^2 ||r_e - r_f||^2 + ||r_f||^2 ||g^e - g^f||^2
\end{aligned}$$

where $r_e = r_e(u_t^e)$ and $r_f = r_f(u_t^f)$. As we mentioned earlier, the weight W_y in the slot-value decoder is shared between the student and the teacher networks and will not be updated. The teacher-student optimization only adjusts the weights related to the language-specific parts in Figure 3 (i.e., utterance encoding and context gating). Therefore, the shared weight $||W_y||$ is seen as a constant. Furthermore, $\sum_{c_v^f, c_v^e} ||g^e||^2$ can be seen as a constant since the teacher gate is fixed. Since we use batch normalization layer to normalize the encoder output (described in Figure 3), $||r_f(u_t^f)||^2$ can also be treated as a constant C_2. Therefore, we formally write the upper bound of $\hat{J}_1$ as our surrogate cost function J:

$$J = C_1 ||r_e(u_t^e) - r_f(u_t^f)||^2 + C_2 \sum_{c_v^f, c_v^e} ||g^e - g^f||^2 \qquad (6)$$

The surrogate cost has successfully decoupled utterance encoder with context gate, and we use J_r and J_g to measure the encoder matching cost and the gate matching cost, respectively.

$$\begin{aligned}
J_r &= ||r_e(u_t^e) - r_f(u_t^f)||^2 \\
J_g &= \sum_{c_v^f, c_v^e} ||g^e - g^f||^2
\end{aligned} \qquad (7)$$

The encoder cost J_r is optimized to distill the knowledge from the teacher encoder to student encoder while gate cost J_g is optimized to distill the knowledge from teacher gate to student gate. This objective function successfully *decouples* the optimization of encoder and gate, thus we are able to optimize J_r and J_g separately from different data sources. Recall that we can easily simulate the target-side system acts, slot-value pairs (c_s^f, c_v^f, a^f) by using the ontology mapping M. Therefore, optimizing J_g is relatively easy. Formally, we write the gate matching cost as follows:

$$J_g = \sum_{\substack{a_t^e, c_s^e, c_v^e \\ a_t^f, c_s^f, c_v^f}} ||g_e(c_s^e, c_v^e, a_t^e) - g_f(c_s^f, c_v^f, a_t^f)||^2 \qquad (8)$$

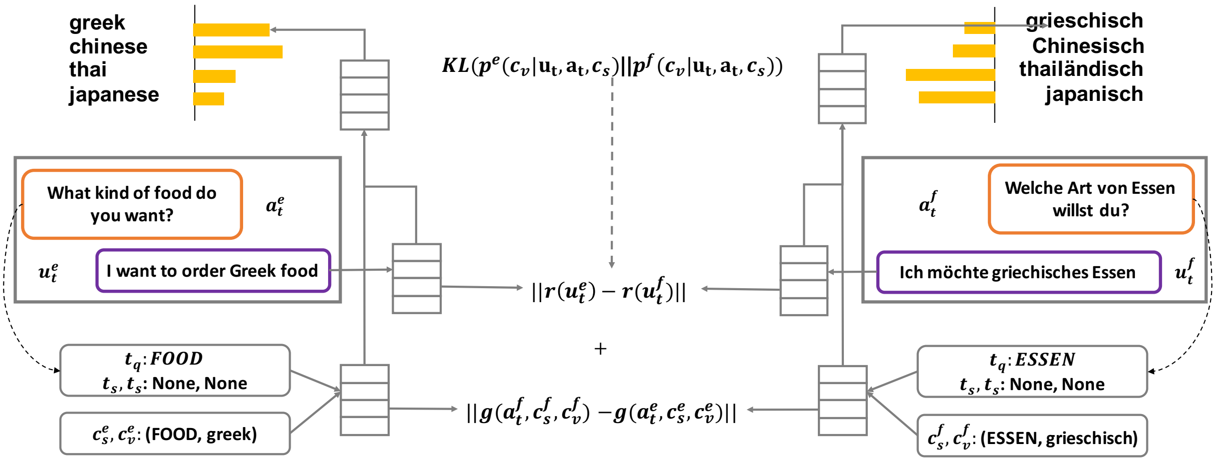

Figure 4: Teacher-Student Framework for cross-lingual transfer learning. The dotted line denotes the imaginary utterances, which expresses the same intention as the source side.

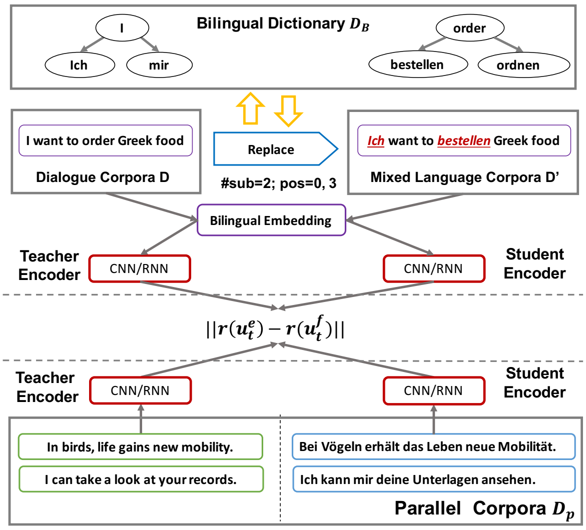

Figure 5: XL-NBT-C and XL-NBT-D for two scenarios

However, exact optimization of J_r is difficult and we have to approximate it using external parallel data. We consider two kinds of external resources (bilingual corpus and bilingual dictionary) in the sections 5.2-5.3 (see Figure 5 for the main idea).

5.2 Bilingual Corpus (XL-NBT-C)

In our first scenario, we assume there exists a parallel corpus D_p consisting of sentence pairs from the source language and the target language. In this case, the cost function (6) is approximated by

$$J = \mathop{\mathbb{E}}_{(m_e, m_f) \in D_p} ||r_e(m_e) - r_f(m_f)||^2 + \alpha J_g \qquad (9)$$

where α is the balancing factor and J_g is defined in (6). The cost function (9) is minimized by stochastic gradient descent. At test time, we switch the encoder to receive target language inputs.

5.3 Bilingual Dictionary (XL-NBT-D)

In the second scenario, we assume there exists no parallel corpus but a bilingual dictionary D_B that defines the correspondence between source words and target words (a one-to-many mapping $\{w : M_D(w)\}$). Likewise, it is infeasible to optimize the exact encoder cost J_r due to the lack of target-side utterances. We propose a word replacement strategy (to be described later) to generate synthetic parallel sentence $\hat{u}_t^f$ of "mixed" language. Then, we use the generated target parallel sentences to approximate the cost (6) by

$$J_r = \mathop{\mathbb{E}}_{u_t \in D} ||r_e(u_t^e) - r_f(\hat{u}_t^f)||^2 + \alpha J_g \qquad (10)$$

where α is the balancing factor. For word replacement, we first decide the number of words N_w to be replaced, then we draw N_w positions randomly from the source utterance and substitute the corresponding word w_i with their target word synonym from $M_D(w)$ based on the context as follows:

$$\begin{aligned} jp(N_w = i) &= \frac{\exp(-i/\tau)}{\sum_{i' < N} \exp(-i'/\tau)} \\ p(\hat{w}) &= \frac{\hat{w} \cdot h_{\hat{w}}}{\sum_{w' \in M(w_i)} w' \cdot h_{\hat{w}}} \end{aligned} \qquad (11)$$

where $h_{\hat{w}} = \sum_{k=-2:k\neq 0}^{2} w_{i+k}$ represents the context vector and N denotes the utterance length. The context similarity of context and the target-side synonym can better help us in choosing the most appropriate candidate from the list. In our following experiments, we adjust the temperature of τ to control the aggressiveness of replacement.

6 Experiments

6.1 Dataset

The Wizard of Oz (WOZ) (Rojas-Barahona et al., 2017) dataset is used for training and evaluation, which consists of user conversations with task-oriented dialog systems designed to help users find suitable restaurants around Cambridge, UK. The corpus contains three informable (i.e. goal-tracking) slots: FOOD, AREA, and PRICE. The users can specify values for these slots in order to find which best meet their criteria. Once the system suggests a restaurant, the users can ask about the values of up to eight requestable slots (PHONE NUMBER, ADDRESS, etc.). Multilingual WOZ 2.0 (Mrksic et al., 2017) has expanded this dataset to include more dialogs and more languages. The train, valid and test datasets for three different languages (English, German, Italian) are available online[3]. We use the English as source language where 600 dialogs are used for training, 200 for validation and 400 for testing. We use the German and Italian as the target language to transfer our knowledge from English DST system. In the experiments, we do not have access to any training or validation dataset for German and Italian, and we only have access to their testing dataset which is composed of 400 dialogs.

For external resource, we use the IWSLT2014 Ted Talk parallel corpus (Mauro et al., 2012) from the official website[4] for bilingual corpus scenario. In the IWSLT2014 parallel corpus, we only keep the sentences between 4 and 40 words and decrease the sentence pairs to around 150K. We use Panlex (Kamholz et al., 2014) as our data source and crawl translations for all the words appearing in the dialog datasets to build our bilingual dictionary. We specifically investigate two kinds of pre-trained embedding, and we use Glove (Pennington et al., 2014) as the monolingual embedding and MUSE (Conneau et al., 2017) as the bilingual embedding to see their impacts on the DST performance.

We split the raw DST corpus into turn-level examples. During training, we use the ground truth previous state V_{t-1} as inputs. At test time, we use the model searched states as the previous state to continue tracking intention until the end of the dialog. When the dialog terminates, we use two evaluation metrics introduced in Henderson et al. (2014a) to evaluate the DST performance: (1) *Goals*: the proportion of dialog turns where all the users search goal constraints were correctly identified. (2) *Requests*: similarly, the proportion of dialog turns where users requests for information were identified correctly. Our implementation is based on the NBT[5], the details of our system setting are described in the appendix.

6.2 Results

Here we highlight the baselines we use to compare with our cross-lingual algorithm as follows:
(1) Supervised: this baseline algorithm assumes the existence of annotated dialog belief tracking datasets, and it determines the upper bound of the DST model.
(2) w/o Transfer: this algorithm trains an English NBT, and then directly feeds target language into the embedding level as inputs during test time to evaluate the performance.
(3) Ontology-match: this algorithm directly uses exact string matching against the utterance to discover the perceived slot-value pairs, it directly assigns a high score to the appearing candidates.
(4) Translation-based: this system pre-trains a translator on the external bilingual corpus and then translates the English dialog and ontology into target language as "annotated" data, which is used to train the NBT in the target language domain (more details about the implementation, performance and examples are listed in the appendix).
(5) Word-By-Word (WBW): this system transforms the English dialog corpus into target language word by word using the bilingual dictionary, which is used to train the NBT in target side.
We demonstrate the results for our proposed algorithms and other competing algorithms in Table 2, from which we can easily conclude that that (i) our Decoupled NBT does not affect the performance, and (ii) our cross-lingual NBT framework is able to achieve significantly better accuracy for both languages in both parallel-resource scenarios.

Compare with Translator/WBW. With bilingual corpus, XL-NBT-C with pre-trained bilingual embedding can significantly outperform our Translator baseline (Klein et al., 2017). This is intuitive because the translation model requires

	XL-NBT-D (mono)	0.14	0.15	0.23	0.22	-	-
	XL-NBT-D (bilingual)	**0.51**	**0.56**	**0.73**	**0.63**	-	-

Table 2: Experimental results for cross-lingual NBT and other baseline algorithms. All results are averaged over 5 runs. Here we use "mono" to refer to the experiments with pre-trained monolingual embedding, "bilingual" to refer to the experiments with pre-trained bilingual embedding.

both source-side encoding and target-side word-by-word decoding, while our XL-NBT only needs a bilingual source-encoding to align two vector space, which averts the compounded decoding errors. With the bilingual dictionary, the word-by-word translator is very weak and leading to many broken target sentences, which poses challenges for DST training. In comparison, our XL-NBT-D can control the replacement by adjusting its temperature to maintain the stability of utterance representation. Furthermore, for both cases, our teacher-student framework can make use of the knowledge learned in source-side NBT to assist its decision making, while translator-based methods learn from scratch.

Bilingual Corpus vs. Bilingual Dictionary. From the table, we can easily observe that bilingual corpus is obviously a more informative parallel resource to perform cross-lingual transfer learning. The accuracy of XL-NBT-D is lower than XL-NBT-C. We conjecture that our replacement strategy to generate "mixed" language utterance can sometimes break the semantic coherence and cause additional noises during the transfer process, which remarkably degrades the DST performance.

Monolingual vs. Bilingual embedding. From the table, we can observe that the bilingual embedding and monolingual embedding does not make much difference in supervised training. However, the gap in the bilingual corpus case is quite obvious. Monolingual embedding even causes the transfer to fail in a bilingual dictionary case. We conjecture that the bilingual word embedding already contain many alignment information between two languages, which largely eases the training of encoder matching objective.

German vs. Italian As can be seen, the transfer learning results for Italian are remarkably higher than German, especially for the "Goal" accuracy. We conjecture that it is due to German declension, which can produce many word forms. The very diverse word forms present great challenges for DST to understand its intention behind. Especially for the bilingual dictionary, German tends to have much longer replacement candidate lists than Italian, which introduces more noises to the replacement procedure.

Error Analysis Here we showcase the most frequent error types in subsection 6.1. From our observation, these three types of errors distribute evenly in the test dialogs. The error mainly comes from the unaligned utterance space, which leads to failure in understanding the intention of human utterance in the target language. This can lead the system to fail in modifying the dialog state or maintaining the previous dialog states.

6.3 Discussion

Here we want to further highlight the comparison between our transfer learning algorithm with the MT-based approach. Though our approach outperforms the standard Translator trained on IWSLT-2014, it does not necessarily claim that our transfer algorithm outperforms any translation methods on any parallel corpus. In our further ablation studies, we found that using Google Translator [6] can actually achieve a better score than our transfer algorithm, which is understandable considering the complexity of Google Translator and the much larger parallel corpus it leverages. By leveraging more close-to-domain corpus and comprehensive entity recognition/replacement strategy, the translator model is able to achieve a higher score. Apparently, we need to trade off the efficiency for the accuracy. For DST problem, it is an overkill to introduce a more complex translation algorithm, what we pursue is a simple yet efficient algorithm to achieve promising scores. It is also worth mentioning that our XL-NBT algorithm only takes several hours to achieve the reported score, while the translator model takes much more time and memory to train depending on the complexity. Thus, the simplicity and efficiency makes our model a better fit for rare-language and limited-budget scenarios.

6.4 Ablation Test

Here we investigate the effect‘ of hyper-parameter α, τ on the evaluation results. The α is used to balance the optimization of encoder constraint and gate constraint, where larger α means more optimization on gate constraint. The temperature τ is used to control the aggressiveness of the replacement XL-NBT-D, where smaller τ means more source words are replaced by target synonyms. From the table Table 3, we can observe that the experimental results are not very sensitive to α, a dramatic change of α will not harm the final results too much, we simply choose $\alpha = 1$ as the hyper-parameter. In contrast, the system is more sensitive to temperature. Too conservative replacement will lead to weak transfer, while too aggressive replacement will destroy the utterance representation. Therefore, we choose the a moderate temperature of $\tau = 0.1$ throughout our experiments. We also draw the learning curve (Precision vs. Iteration) in the Appendix for both XL-NBT-C and XL-NBT-D. The learning curves show that our algorithm is stable and converges quickly, and the reported results are highly reproducible.

α ablation (τ fixed to 0.1)			**τ ablation (α fixed to 1)**		
value	Goal	Request	value	Goal	Request
α=0	0.13	0.00	τ=0	0.14	0.08
α=0.1	0.46	0.54	τ=0.03	0.43	0.50
α=1	**0.51**	**0.56**	τ=0.1	**0.51**	**0.56**
α=5	0.46	0.54	τ=0.3	0.47	0.51
α=10	0.46	0.52	τ=1	0.44	0.52
α=100	0.44	0.50	τ=10	0.33	0.32

Table 3: Ablation test for hyper-parameter α and τ on English-to-German XL-NBT-D.

7 Conclusion

In our paper, we propose a novel teacher-student framework to perform cross-lingual transfer learning for DST. The key idea of our model is to decouple the current DST neural network into two separate modules and transfer them separately. We believe our method can be further extended into a general purpose multi-lingual transfer framework to resolve other NLP matching or classification problems.

8 Acknowledgement

We are gratefully supported by a Tencent AI Lab Rhino-Bird Gift Fund. We are also very thankful for the public belief tracking code and multi-lingual state-tracking datasets released by Nikola Mrksic from the University of Cambridge.

Abstract

We propose a simple modification to existing neural machine translation (NMT) models that enables using a single *universal* model to translate between multiple languages while allowing for language specific parameterization, and that can also be used for *domain adaptation*. Our approach requires no changes to the model architecture of a standard NMT system, but instead introduces a new component, the *contextual parameter generator* (CPG), that generates the parameters of the system (e.g., weights in a neural network). This parameter generator accepts source and target language embeddings as input, and generates the parameters for the encoder and the decoder, respectively. The rest of the model remains unchanged and is shared across all languages. We show how this simple modification enables the system to use monolingual data for training and also perform *zero-shot* translation. We further show it is able to surpass state-of-the-art performance for both the IWSLT-15 and IWSLT-17 datasets and that the learned language embeddings are able to uncover interesting relationships between languages.

1 Introduction

Neural Machine Translation (NMT) directly models the mapping of a source language to a target language without any need for training or tuning any component of the system separately. This has led to a rapid progress in NMT and its successful adoption in many large-scale settings (Wu et al., 2016; Crego et al., 2016). The encoder-decoder abstraction makes it conceptually feasible to build a system that maps any source sentence in any language to a vector representation, and then decodes this representation into any target language. Thus, various approaches have been proposed to extend this abstraction for multilingual MT (Luong et al., 2016; Dong et al., 2015; Johnson et al., 2017; Ha et al., 2016; Firat et al., 2016a).

Prior work in multilingual NMT can be broadly categorized into two paradigms. The first, *universal NMT* (Johnson et al., 2017; Ha et al., 2016), uses a single model for all languages. Universal NMT lacks any language-specific parameterization, which is an oversimplification and detrimental when we have very different languages and limited training data. As verified by our experiments, the method of Johnson et al. (2017) suffers from high sample complexity and thus underperforms in limited data settings. The universal model proposed by Ha et al. (2016) requires a new coding scheme for the input sentences, which results in large vocabulary sizes that are difficult to scale. The second paradigm, *per-language encoder-decoder* (Luong et al., 2016; Firat et al., 2016a), uses separate encoders and decoders for each language. This does not allow for sharing of information across languages, which can result in overparameterization and can be detrimental when the languages are similar.

In this paper, we strike a balance between these two approaches, proposing a model that has the ability to learn parameters separately for each language, but also share information between similar languages. We propose using a new *contextual parameter generator* (CPG) which (a) generalizes all of these methods, and (b) mitigates the aforementioned issues of *universal* and *per-language encoder-decoder* systems. It learns language embeddings as a context for translation and uses them to generate the parameters of a shared translation model for all language pairs. Thus, it provides these models the ability to learn parameters separately for each language, but also share information between similar languages. The parameter generator is general and allows any existing NMT model to be enhanced in this way.[1] In addition, it has the following desirable features:

1. **Simple:** Similar to Johnson et al. (2017) and Ha et al. (2016), and in contrast with Luong et al. (2016) and Firat et al. (2016a), it can

---

[1] In fact, it could likely be applied in other scenarios, such as domain adaptation, as well.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 425–435
Brussels, Belgium, October 31 - November 4, 2018.

be applied to most existing NMT systems with some minor modification, and it is able to accommodate attention layers seamlessly.

2. **Multilingual:** Enables multilingual translation using the same single model as before.
3. **Semi-supervised:** Can use monolingual data.
4. **Scalable:** Reduces the number of parameters by employing extensive, yet controllable, sharing across languages, thus mitigating the need for large amounts of data, as in Johnson et al. (2017). It also allows for the decoupling of languages, avoiding the need for a large shared vocabulary, as in Ha et al. (2016).
5. **Adaptable:** Can adapt to support new languages, without requiring complete retraining.
6. **State-of-the-art:** Achieves better performance than pairwise NMT models and Johnson et al. (2017). In fact, our approach can surpass state-of-the-art performance.

We first introduce a modular framework that can be used to define and describe most existing NMT systems. Then, in Section 3, we introduce our main contribution, the *contextual parameter generator* (CPG), in terms of that framework. We also argue that the proposed approach takes us a step closer to a common universal interlingua.

2 Background

We first define the multi-lingual NMT setting and then introduce a modular framework that can be used to define and describe most existing NMT systems. This will help us distill previous contributions and introduce ours.

Setting. We assume that we have a set of source languages S and a set of target languages T. The total number of languages is $L = |S \cup T|$. We also assume we have a set of $C \leq |S| \times |T|$ pairwise parallel corpora, $\{P_1, \dots, P_C\}$, each of which contains a set of sentence pairs for a single source-target language combination. The goal of multilingual NMT is to build a model that, when trained using the provided parallel corpora, can learn to translate well between any pair of languages in $S \times T$. The majority of related work only considers pairwise NMT, where $|S| = |T| = 1$.

2.1 NMT Modules

Most NMT systems can be decomposed to the following modules (also visualized in Figure 1).

Preprocessing Pipeline. The data preprocessing pipeline handles tokenization, cleaning, normalizing the text data and building a *vocabulary*, i.e. a two-way mapping from preprocessed sentences to sequences of word indices that will be used for the translation. A commonly used proposal for defining the vocabulary is the byte-pair encoding (BPE) algorithm which generates subword unit vocabularies (Sennrich et al., 2016b). This eliminates the notion of out-of-vocabulary words, often resulting in increased translation quality.

Encoder/Decoder. The *encoder* takes in indexed source language sentences, and produces an intermediate representation that can later be used by a *decoder* to generate sentences in a target language. Generally, we can think of the encoder as a function, $\mathbf{f}^{(enc)}$, parameterized by $\theta^{(enc)}$. Similarly, we can think of the decoder as another function, $\mathbf{f}^{(dec)}$, parameterized by $\theta^{(dec)}$. The goal of learning to translate can then be defined as finding the values for $\theta^{(enc)}$ and $\theta^{(dec)}$ that result in the best translations. A large amount of previous work proposes novel designs for the encoder/decoder module. For example, using attention over the input sequence while decoding (Bahdanau et al., 2015; Luong et al., 2015) provides significant gains in translation performance.[2]

Parameter Generator. All modules defined so far have previously been used when describing NMT systems and are thus easy to conceptualize. However, in previous work, most models are trained for a given language pair, and it is not trivial to extend them to work for multiple pairs of languages. We introduce here the concept of the *parameter generator*, which makes it easy to define and describe multilingual NMT systems. This module is responsible for generating $\theta^{(enc)}$ and $\theta^{(dec)}$ for any given source and target language. Different parameter generators result in different numbers of learnable parameters and can thus be used to share information across different languages. Next, we describe related work, in terms of the parameter generator for NMT:

- **Pairwise:** In the simple and commonly used pairwise NMT setting (Wu et al., 2016; Crego et al., 2016), the parameter generator would generate separate parameters, $\theta^{(enc)}$ and $\theta^{(dec)}$, for each pair of source-target languages. This re-

---

[2] Note that depending on the vocabulary that is used and on whether it is one shared vocabulary across all languages, or one vocabulary per language, the output projection layer of the decoder (which produces probabilities over words) may be language dependent, or common across all languages. In our experiments, we used separate vocabularies and thus this layer was language-dependent.

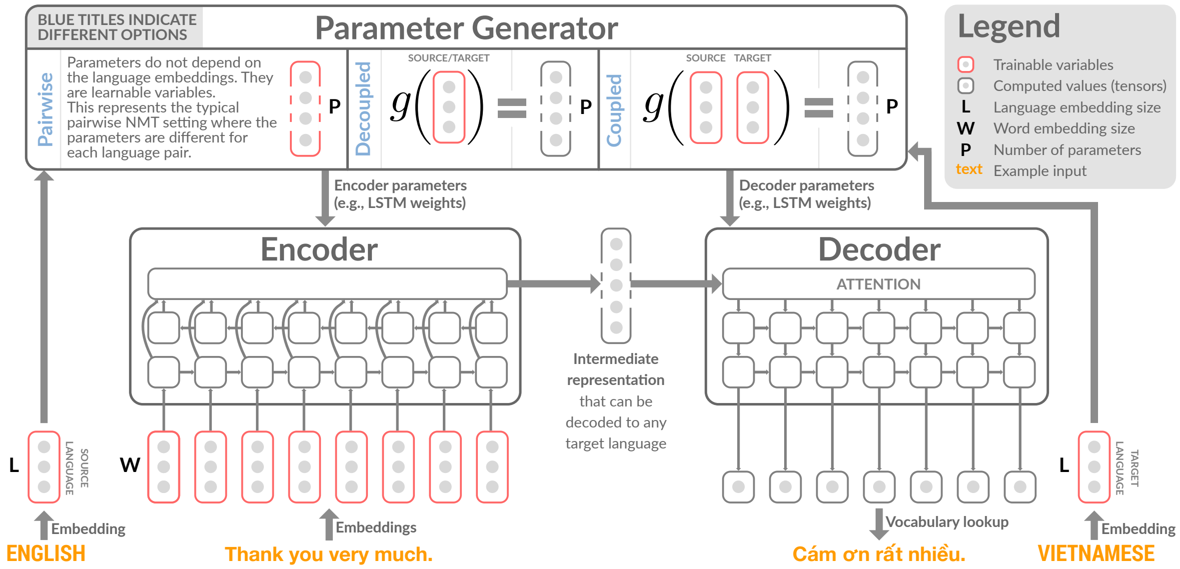

Figure 1: Overview of an NMT system, under our modular framework. Our main contribution lies in the parameter generator module (i.e., coupled or decoupled — each of the boxes with blue titles is a separate option). Note that g denotes a parameter generator network. In our experiments, we consider linear forms for this network. However, our contribution does not depend on the choices made regarding the rest of the modules; we could still use our parameter generator with different architectures for the encoder and the decoder, as well as using different kinds of vocabularies.

sults in no parameter sharing across languages, and thus $\mathcal{O}(ST)$ parameters.

- **Per-Language:** In the case of Dong et al. (2015), Luong et al. (2016) and Firat et al. (2016a), the parameter generator would generate separate encoder parameters, $\theta^{(enc)}$, for each source language, and separate decoder parameters, $\theta^{(dec)}$, for each target language. This leads to a reduction in the number of learnable parameters for multilingual NMT, from $\mathcal{O}(ST)$ to $\mathcal{O}(S+T)$. On one hand, Dong et al. (2015) train multiple models as a one-to-many multilingual NMT system that translates from one source language to multiple target languages. On the other hand, Luong et al. (2016) and Firat et al. (2016a) perform many-to-many translation. Luong et al. (2016), however, only report results for a single language pair and do not attempt multilingual translation. Firat et al. (2016a) propose an attention mechanism that is shared across all language pairs. We generalize the idea of multi-way multilingual NMT with the parameter generator network, described later.
- **Universal:** In the case of Ha et al. (2016) and Johnson et al. (2017), the authors propose using a single common set of encoder-decoder parameters for all language pairs. While Ha et al. (2016) embed words in a common semantic space across languages, Johnson et al. (2017) learn language embeddings that are in the same space as the word embeddings. Here, the parameter generator would provide the same parameters $\theta^{(enc)}$ and $\theta^{(dec)}$ for all language pairs. It would also create and keep track of learnable variables representing language embeddings that are prepended to the encoder input sequence. As we observed in our experiments, this system fails to perform well when the training data is limited. Finally, we believe that embedding languages in the same space as words is not intuitive; in our approach, languages are embedded in a separate space.

In contrast to all these related systems, we provide a simple, efficient, yet effective alternative – a parameter generator for multilingual NMT, that enables semi-supervised and zero-shot learning. We also learn language embeddings, similar to Johnson et al. (2017), but in our case they are separate from the word embeddings and are treated as a *context* for the translation, in a sense that will become clear in the next section. This notion of *context* is used to define parameter sharing across various encoders and decoders, and, as we discuss in our conclusion, is even applicable beyond NMT.

3 Proposed Method

We propose a new way to share information across different languages and to control the amount of sharing, through the parameter generator module. More specifically, we propose *contextual parameter generators*.

Contextual Parameter Generator. Let us denote the source language for a given sentence pair by ℓ_s and the target language by ℓ_t. Then, when using the contextual parameter generator, the parameters of the encoder are defined as $\theta^{(enc)} \triangleq g^{(enc)}(\mathbf{l_s})$, for some function $g^{(enc)}$, where $\mathbf{l_s}$ denotes a language embedding for the source language ℓ_s. Similarly, the parameters of the decoder are defined as $\theta^{(dec)} \triangleq g^{(dec)}(\mathbf{l_t})$ for some function $g^{(dec)}$, where $\mathbf{l_t}$ denotes a language embedding for the target language ℓ_t. Our generic formulation does not impose any constraints on the functional form of $g^{(enc)}$ and $g^{(dec)}$. In this case, we can think of the source language, ℓ_s, as a context for the encoder. The parameters of the encoder depend on its context, but its architecture is common across all contexts. We can make a similar argument for the decoder, and that is where the name of this parameter generator comes from. We can even go a step further and have a parameter generator that defines $\theta^{(enc)} \triangleq g^{(enc)}(\mathbf{l_s}, \mathbf{l_t})$ and $\theta^{(dec)} \triangleq g^{(dec)}(\mathbf{l_s}, \mathbf{l_t})$, thus coupling the encoding and decoding stages for a given language pair. In our experiments we stick to the previous, *decoupled*, form, because unlike Johnson et al. (2017), it has the potential to lead to an *interlingua*.
